A large number of the polysaccharides occurring in nature are known to contain uronic acid residues as an integral part of their molecular structure. The carboxyl group in such instances usually does not occur in the free state but rather is combined as a salt with metallic ions such as calcium, magnesium, and the like or as an ester with methyl alcohol. In general, the uronic acid possesses the glucose, mannose or galactose configuration and it has been considered to play an important role in the mechanism of plant synthesis. In a few instances polysaccharides have been reported to contain small percentages of ether type methoxyl and this grouping appears to be associated invariably with the uronic acid component. The observation is particularly interesting since it records the natural synthesis of an aliphatic ether linkage as contrasted with the usual aromatic, ester and acetal types. Unfortunately, however, the presence of this particular grouping[2] has been indicated hitherto only by analyses and no definite crystalline compounds or derivatives have been prepared to prove the actual existence of the group or to establish its exact location in any given polysaccharide.

The presence of ether methoxyl in mesquite gum was reported first by Anderson and co-workers[3a,b,c,d] who traced the group to the uronic acid component and, largely by a process of elimination, suggested the three position thereof as the most likely point of attachment. It has now been shown[4] that the uronic acid residues occupy terminal positions in the mesquite gum macromolecule and the present study was designed to locate definitely the position of the methyl ether linkage.

The well known reaction of polysaccharides with anhydrous acidic methyl alcohol solutions results in simultaneous esterification of the uronides and formation of the corresponding methyl glycosides and uronosides. In such reactions, whereas a single methyl group is substituted in the saccharides, two such groups are introduced into the uronic acid component. One of these is uronosidic or acetal in character while the second is of the ester type. In the present instance these two methyl groups together with the aliphatic ether group originally present furnish a trimethyl substituted uronic acid fission product which can be separated readily from the glycosidic fragments. Accordingly, mesquite gum which had been partially hydrolyzed to remove the labile arabinose fraction[5] was treated with methanolic hydrogen chloride and the resulting sirup extracted with anhydrous acetone. The extract was concentrated and then diluted with anhydrous ether to precipitate residual methyl galactoside. Evaporation of the mixed solvent and fractional

---

[1] Presented in part at the Fall Meeting of the Technical Association of the Pulp and Paper Industry, Appleton, Wisconsin, September 3–5, 1947.

[2] It should be noted that the aliphatic methyl ether grouping has been found in the carbohydrate component of certain cardiac glycosides, notably, cymarose and digitalose. A review of these compounds is given by Elderfield, "Recent Advances in Carbohydrate Chemistry," Vol. I, Academic Press, Inc., New York, N. Y., 1945, p. 147.

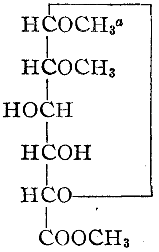
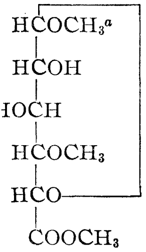
vacuum distillation of the sirup furnished the methyl ester of monomethyl-methyl-glucuronoside.

The ether type methoxyl group of this compound must obviously be located at either the second, third or fourth carbon atom since the uronoside ester contains the normal pyranose ring structure.[4] A decision as to the correct position was provided by the selective action of periodic acid which reacts in stoichiometric proportion with the compound. Since such reaction necessitates vicinal hydroxyl groups in the reacting substance, the presence of an ether grouping at the third carbon atom is untenable and the uronoside ester must be represented either by Formula I or Formula II.

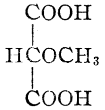
I



II



Ia

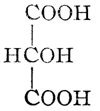


$$\begin{array}{c}\mathrm{COOH}\\ |\\ \mathrm{HCOCH_3}\\ |\\ \mathrm{COOH}\end{array}$$

IIa

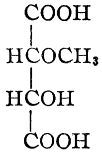
$$\begin{array}{c}\mathrm{COOH}\\ |\\ \mathrm{COOH}\end{array}$$

Ib



$$\begin{array}{c}\mathrm{COOH}\\ |\\ \mathrm{HCOH}\\ |\\ \mathrm{COOH}\end{array}$$

IIb



$$\begin{array}{c}\mathrm{COOH}\\ |\\ \mathrm{HCOCH_3}\\ |\\ \mathrm{HCOH}\\ |\\ \mathrm{COOH}\end{array}$$

[a] The alpha form is represented although both alpha and beta forms are present in the uronoside ester sirup.

In the first example (I) treatment of the compound with periodic acid followed by bromine oxidation, acetal hydrolysis and re-oxidation according to the splendid methods of Jackson and Hudson[6] should provide eventually methoxymalonic acid (Ia) and hydroxymalonic acid (Ib), both of which are optically inactive. On the other hand, a similar treatment of the compound represented by Formula II should furnish oxalic acid (IIa) and a methoxy-*meso*-tartaric acid (IIb), the latter being optically active.

With these possibilities in mind the compound in quesion was subjected to a series of reactions employing one molecular equivalent of periodic acid and followed by oxidation with bromine in the presence of strontium carbonate. The product was isolated as both a crystalline and an amorphous strontium salt with identical analyses but different optical activity. Further reaction of this compound after quantitative removal of strontium as sulfate involved hydrolysis of the acetal grouping and bromine oxidation of the aldehyde thus formed. The resulting reaction product now contained two dibasic organic acids which were separated and identified. One of these was found to be oxalic acid and identified as the dimethyl ester. The second acid proved to be an optically active methoxy-*meso*-tartaric acid which was also isolated as the dimethyl ester and from which a crystalline diamide was prepared. Complete methylation of this ester furnished crystalline dimethoxy-*i*-dimethyl-succinate which was identified further as the crystalline diamide.

The above experiments seem to provide convincing proof that the methyl ester of monomethyl-glucuronoside isolated from mesquite gum possesses the structure represented by Formula II. The methyl ether linkage in this particular polysaccharide is thus located at the fourth carbon atom of the uronic acid component and its synthesis by natural agencies seems well established. It is interesting to note also that the position of ether linkage is characteristically that involved in the glycosidic linkage of glucose in the polysaccharides. This property is, of course, shared to some extent with the terminal hydroxyl grouping, while the remaining groups appear to be inactive.

Experimental Part

Preparation of Monomethyl-methyl-glucuronoside Methyl Ester from Mesquite Gum.—Two hundred grams of crude mesquite gum was dissolved in one liter of distilled water and filtered to remove extraneous material. The solution was then made 0.15 *N* with sulfuric acid and heated at 92° on a water-bath for thirty-six hours.[5] The hydrolyzate was dialyzed against water for two days to remove acid, arabinose, etc., filtered and concentrated at 50° to a thin sirup by evaporation. The concentrate, diluted with an equal volume of methyl alcohol, was added slowly to rapidly stirred anhydrous methanol. The flocculent precipitate was settled, filtered, washed with fresh alcohol and ether, and finally dried at 40° under reduced pressure; yield 78 g.

The above product was suspended in 500 cc. of methanol containing 7% anhydrous hydrogen chloride and heated under reflux for eighteen hours. The polysaccharide under these conditions dissolves rapidly with frequent swirling during the first half hour. The concentration of hydrogen chloride decreased steadily during the heating period and residual acidity was finally removed with silver carbonate. After filtering off silver salts the solution was evaporated to a sirup, taken up in 100 cc. of fresh acetone and 400 cc. of anhydrous ether added slowly with swirling. After a few hours the clear solution was siphoned off and the residue re-extracted using one-third quantities of the same solvents. The combined extracts were evaporated to a sirup which was distilled, b. p. 130° (0.2 mm.), under high vacuum; yield 15.2 g.; specific rotation +95° (25°, *c* 10, water).

Anal. Calcd. for $C_9H_{16}O_7$: OCH_3, 39.4. Found: OCH_3, 39.3.

Treatment of a sample, 1.0 g., with methyl alcoholic ammonia in the usual manner furnished an amide, recrystallized from methanol–acetone, m. p. 218°.

Anal. Calcd. for $C_8H_{15}O_6N$: OCH_3, 28.0; N, 6.34. Found: OCH_3, 27.8; N, 6.3.

Preparation of the Strontium Salt of Oxidized Monomethyl-methyl-glucuronoside Methyl Ester.—The above ester, 16.7 g., was dissolved in 300 cc. of water, treated with norite and filtered. To the filtrate was added one molecular equivalent plus 5% excess of periodic acid dissolved in 200-cc. of water. The solution was allowed to stand at room temperature for sixteen hours when an excess of strontium carbonate was carefully added with stirring. The precipitate of strontium salts was then re-

---

(6) Jackson and Hudson, This Journal, **59**, 994 (1937).

moved and washed with 100 cc. of water. The filtrate, 600 cc., was added in 200-cc. portions to three flasks each containing 5 cc. of bromine dissolved in 500 cc. of water and 50 g. of strontium carbonate. After eighteen hours in the dark, with occasional swirling especially during the first two hours, excess bromine was removed by aeration. Silver carbonate was added to remove bromine ion and after filtering, silver ion was removed as sulfide. The colorless, combined filtrates were distilled at 30° under reduced pressure to a thin sirup which was diluted with two volumes of 95% ethanol. The crystalline strontium salt of the acid separated overnight and was removed, washed with cold 65% ethanol, ethanol and ether, and dried; yield 13.3 g.; specific rotation −24° (25°, *c* 5, water).

Anal. Calcd. for $C_9H_{12}O_9Sr$: OCH_3, 26.5; Sr, 24.9. Found: OCH_3, 25.4; Sr, 24.0.

The filtrates upon evaporation to dryness gave a residue which did not crystallize but gave the same analysis as above: yield, 7.8 g.; specific rotation +13° (25°, *c* 5, water).

The former compound, which has not yet been recrystallized in pure form, is thought to be derived from the alpha form of the uronoside, with the latter representing a mixture of the alpha and beta modifications.

Proof of Structure of the Strontium Salt of Oxidized Monomethyl-methyl-glucuronoside Methyl Ester.—Ten grams of either the crystalline or amorphous forms of the strontium salt was dissolved in 100 cc. of water and treated with the exact quantity of sulfuric acid dissolved in 100 cc. of ethanol to precipitate the strontium as sulfate. After several hours the precipitate was filtered off, washed with 50% ethanol and concentrated under reduced pressure (40–45° bath) to about 30 cc. The thin sirup was then diluted with ethanol, filtered free from residual strontium salt and re-evaporated. The sirup was diluted to 100 cc. with water and heated for two hours on a boiling water-bath to hydrolyze the acetal group. The hydrolyzate was then added to 500 cc. of distilled water containing 5 cc. of dissolved bromine. After forty-five hours in the dark excess bromine was removed by aeration and silver carbonate added to free the solution from bromine ion. Silver was then removed as sulfide and the clear solution evaporated to a thin sirup under reduced pressure. The sirup was extracted with ethanol, concentrated and re-extracted with ether to separate inorganic material. Excess solvent was then removed and the residue methylated by Purdie's method using methyl iodide and silver oxide. After complete methylation the silver residues were extracted with petroleum ether and upon removal of solvent the sirup was distilled fractionally under reduced pressure.

Fraction I, b. p. 62° (11 mm.), crystallized spontaneously and after recrystallization from light petroleum furnished dimethyl oxalate; m. p. 54°[7]; yield 2.4 g.

Anal. Calcd. for $C_4H_6O_4$: OCH_3, 52.5. Found: OCH_3, 52.1.

Fraction II, b. p. 78° (0.2 mm.), distilled as a colorless optically inactive liquid which crystallized completely upon standing, m. p. 68°[8] from ether; yield 4.6 g.

Anal. Calcd. for $C_8H_{14}O_6$: OCH_3, 60.2. Found: OCH_3, 60.2.

Treatment of a sample, 1.0 g., with methyl alcoholic ammonia in the usual manner furnished a crystalline compound upon removal of solvent. Recrystallization from methyl alcohol gave dimethoxy-*i*-succinic acid diamide; m. p. 256°.[9]

Anal. Calcd. for $C_6H_{12}O_4N_2$: OCH_3, 35.2. Found: OCH_3, 35.2.

Obviously, Fraction II must have been formed from a four-carbon dibasic acid in the above Purdie methylation. Accordingly, in a separate experiment a similar ether extract containing 4.0 g. dissolved material was treated with an excess of diazomethane in order to form the methyl esters of the dissolved organic acids. After removal of excess reactant and solvent the sirup was distilled under high vacuum. An optically active fraction was collected and redistilled, b. p. 87° (0.2 mm.); yield 2.2 g.; specific rotation +49° (25°, *c* 5, methanol).

Anal. Calcd. for $C_7H_{12}O_6$: OCH_3, 48.4. Found: OCH_3, 47.7.

Treatment of a sample, 0.5 g., with methyl alcoholic ammonia in the usual manner furnished the diamide of 3-hydroxy-2-methoxy-D-erythrosuccinic acid, recrystallized from acetone–methyl alcohol, m. p. 156°.

A similiar reaction using methyl alcoholic methylamine furnished 3-hydroxy-2-methoxy-D-erythrosuccinobismethyl amide; recrystallized from ethyl acetate, m. p. 135°[10]; specific rotation −10.5° (25°, *c*, 5, water).

Complete methylation of the ester by the Purdie method gave dimethoxy-*i*-dimethyl succinate which was identified as the above described diamide, m. p. 256°.[6]

Summary

1. The uronic acid component of mesquite gum has been isolated as the monomethyl-methyl-glucuronoside methyl ester.

2. The structure of this compound is shown to be that derived from 4-methoxy-D-glucuronic acid.

3. The methyl ester grouping in mesquite gum is located at the fourth carbon atom of the glucuronic acid component.

Preparation of Some Substituted β-Phenylisovaleric Acids

BY JOSEPH CORSE[1] AND EWALD ROHRMANN

β-Phenylisovaleric acid was prepared by Hoffman[2] by the haloform oxidation of 4-methyl-4-phenyl-2-pentanone, a substance readily prepared by the reaction of benzene and mesityl oxide with aluminum chloride as catalyst. The acid has also been prepared by the carbonation of neophylmagnesium chloride.[3]

We have carried out the synthesis of a number of substituted β-phenylisovaleric acids which were desired in connection with some antibiotic studies. These were prepared either from the corresponding substituted ketones by haloform oxidation or from the parent unsubstituted β-phenylisovaleric acid.

A number of substituted benzenes were subjected to reaction with mesityl oxide and aluminum chloride. The reaction was found to proceed well with benzene and with fluoro-, chloro- and bromobenzenes. We were unable to effect reaction with anisole and mesitylene, while complex mixtures resulted with toluene, *o*-xylene and tetralin. Eijkman[4] noted a similar failure of toluene to add to β,β-dimethylacrylic acid, in contrast to the behavior of benzene. Reaction of thiophene with mesityl oxide could not be satisfactorily effected with either aluminum chloride or stannic chloride.

Both Eijkman[4] and Hoffman[2] reported the preparation of the nitro derivative of β-phenylisovaleric acid by direct nitration of the acid. We have reduced this nitro acid catalytically to β-(*p*-aminophenyl)-isovaleric acid, which was diazotized and treated in the usual ways to give the *p*-arsono, *p*-arsenoso, *p*-bromo and *p*-hydroxy substituted phenylisovaleric acids. The bromo acid prepared by the Sandmeyer reaction from the amine was identical with that derived from 4-methyl-4-*p*-bromophenyl-2-pentanone and sodium hypochlorite. This indicates that the nitration of phenylisovaleric acid occurs largely in the para position, as one might expect.

β-(*p*-Iodophenyl)-isovaleric acid was made by the direct iodination of β-phenylisovaleric acid.[5]

We wish to thank Mr. W. L. Brown and Mr. H. L. Hunter of these Laboratories for the analyses.

Experimental

4-(*p*-Halophenyl)-4-methyl-2-pentanones.[2]—These were prepared by the aluminum chloride catalyst condensation of the *p*-halobenzene and mesityl oxide in carbon disulfide solution, essentially as described by Hoffman[2] for benzene. The organic layer was separated, dried and distilled *in vacuo*.

4-*p*-Fluorophenyl-4-methyl-2-pentanone.—B. p. 66° (0.1 mm.); $n^{28}\mathrm{D}$ 1.4911; yield, 38.0 g. (70%).

Anal. Calcd. for $C_{12}H_{15}OF$: C, 74.19; H, 7.78. Found: C, 74.33; H, 8.03.

4-*p*-Chlorophenyl-4-methyl-2-pentanone.—B. p. 169–171° (16 mm.); $n^{24.5}\mathrm{D}$ 1.5228; yield, 102.5 g. (95%).

Anal. Calcd. for $C_{12}H_{15}OCl$: C, 68.40; H, 7.17. Found: C, 68.35; H, 7.58.

4-*p*-Bromophenyl-4-methyl-2-pentanone.—B. p. 128–130° (0.6 mm.); $n^{28}\mathrm{D}$ 1.5392; yield, 52 g. (41%).

Anal. Calcd. for $C_{12}H_{15}OBr$: C, 56.48; H, 5.92. Found: C, 56.38; H, 5.85.

Haloform Oxidation of 4(*p*-Halophenyl)-4-methyl-2-pentanones.—The haloform reactions were run with sodium hypochlorite according to the directions of Newman and Holmes[6] to yield the corresponding β-substituted phenylisovaleric acids. The yields varied from 51 to 74% of theoretical.

β-(*p*-Fluorophenyl)-isovaleric acid.—M. p. 60–62°.

Anal. Calcd. for $C_{11}H_{13}O_2F$: C, 67.23; H, 6.67. Found: C, 66.76; H, 6.45.

β-(*p*-Chlorophenyl)-isovaleric acid.—M. p. 65–67°.

Anal. Calcd. for $C_{11}H_{13}O_2Cl$: C, 62.11; H, 6.16. Found: C, 62.24; H, 5.68.

β-(*p*-Bromophenyl)-isovaleric acid.—M. p. 60–61°.

Anal. Calcd. for $C_{11}H_{13}O_2Br$: C, 51.38; H, 5.09. Found: C, 51.66; H, 4.77.

β-(*p*-Iodophenyl)-isovaleric acid.—This acid was prepared by the method of Plati, *et al.* (*cf.* ref. 5(b)). The crude acid was purified by conversion to the ethyl ester which was fractionally distilled. That portion boiling at 145–146° (0.9 mm.) proved to be the desired ester; yield, 34.6 g. (53%), $n^{28}\mathrm{D}$ 1.5501.

Anal. Calcd. for $C_{13}H_{17}O_2I$: C, 46.99; H, 5.16. Found: C, 46.51; H, 4.80.

The acid was prepared by saponification with potassium hydroxide; m. p. 76–78°.

Anal. Calcd. for $C_{11}H_{13}O_2I$: C, 43.43; H, 4.31. Found: C, 43.32; H, 4.49.

β-(*p*-Nitrophenyl)-isovaleric Acid.—One hundred and forty grams of β-phenylisovaleric acid was added with stirring, over a period of one hour, to 250 ml. of fuming nitric acid cooled to −30° in a Dry Ice-bath. The temperature was then allowed to rise during another hour to +5°, and stirring was maintained an additional two hours at 0 to 5°. The solution was poured onto cracked ice and the product was collected on a filter and washed well with water. The product was recrystallized from alcohol–benzene; m. p. 172–175°.

Anal. Calcd. for $C_{11}H_{13}O_4N$: N, 6.28. Found: N, 6.63.

β-(*p*-Aminophenyl)-isovaleric acid.—Catalytic reduction of the above nitro acid in methanol solution on the Adams machine, using Raney nickel catalyst or platinum oxide at 3 atmospheres pressure, gave the *p*-amino substituted acid in almost quantitative yield. After being twice recrystallized from methanol–ether the melting point was 135°.

Anal. Calcd. for $C_{11}H_{15}O_2N$: N, 7.24. Found: N, 7.31.

β-(*p*-Arsonophenyl)-isovaleric acid.—This acid was prepared from β-(*p*-aminophenyl)-isovaleric acid by the diazonium salt replacement reaction with arsenic trioxide. The crude acid was purified by recrystallization from hot water; yield, 56 g. (75%).

Anal. Calcd. for $C_{11}H_{15}O_5As$: As, 24.85. Found: As, 24.38, 24.35.

β-(*p*-Arsenosophenyl)-isovaleric acid.—Forty grams of the above arsono acid was dissolved in a solution of 100 ml. of concentrated hydrochloric acid and 100 ml. of water. A small crystal of potassium iodide was added, and sulfur dioxide was passed through the solution for four and one-half hours. The solid which formed was collected and dissolved in sodium bicarbonate solution. Careful acidification with 10% hydrochloric acid precipitated the acid, which was collected and washed several times with cold water; yield, 9.2 g. The material was hygroscopic and analyzed for the hydrate.

Anal. Calcd. for $C_{11}H_{15}O_4As$: As, 26.14. Found: As, 26.83, 26.81.

β-(*p*-Hydroxyphenyl)-isovaleric Acid.—This acid was prepared from β-(*p*-aminophenyl)-isovaleric acid by the diazonium salt replacement reaction. Purification was best done by esterifying the crude acid with ethanol and sulfuric acid and taking advantage of the alkali solubility of the ester. Subsequent saponification and recrystallization of the acid from ethanol–ether–petroleum ether gave a white crystalline product melting at 146–148°.

Anal. Calcd. for $C_{11}H_{14}O_3$: C, 68.02; H, 7.26. Found: C, 68.04; H, 7.08.

Summary

The Friedel–Crafts addition of three halogenated benzenes to mesityl oxide to give 4-methyl-4-halogen substituted phenyl-2-pentanones is described.

A number of β-(*p*-substituted phenyl)-isovaleric acids are described.

INDIANAPOLIS, INDIANA RECEIVED JULY 21, 1947

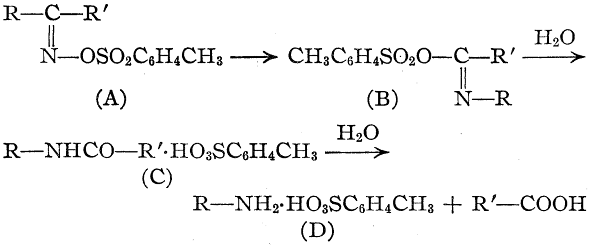
Studies on Furan Compounds. I. Conversion of 2-Acetofuran to Hexen-2-dion-4,5-acetal-1 and Pyrocatechol

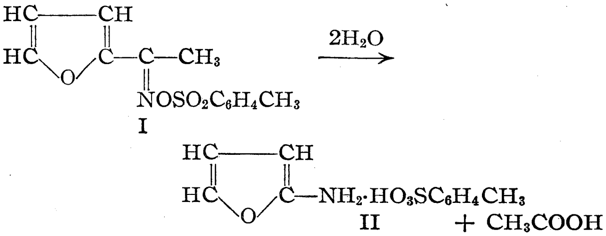
BY L. VARGHA, J. RAMONCZAI AND P. BITE

Several workers have already tried to synthesize 2-aminofuran. However, hydrolysis experiments on furan-2-ethylurethan[1] and on 2-benzyl- and 2-propionylaminofuran[2] have only resulted in the formation of ammonia and tar-like products, probably because 2-aminofuran decomposes very rapidly. We have thought that a milder procedure, such as the reaction discovered by Neber and v. Friedolfsheim[3] on the *p*-toluenesulfonyl derivatives of certain aromatic ketoximes (A) might lead to the desired goal. According to this process a compound like (A) when shaken with ethanol at room temperature, undergoes first a Beckmann rearrangement, then the intermediate (B) suffers hydrolytic cleavage (C) under the influence of traces of water with the eventual formation of an amine (D).[3,4]



$$\underset{(A)}{R{-}\underset{\overset{\|}{N}{-}OSO_2C_6H_4CH_3}{C}{-}R'} \longrightarrow \underset{(B)}{CH_3C_6H_4SO_2O{-}\underset{\overset{\|}{N}{-}R}{C}{-}R'} \xrightarrow{H_2O} \underset{(C)}{R{-}NHCO{-}R'\cdot HO_3SC_6H_4CH_3} \xrightarrow{H_2O} \underset{(D)}{R{-}NH_2\cdot HO_3SC_6H_4CH_3 + R'{-}COOH}$$

However, on shaking *p*-toluenesulfonyl 2-acetofuran oxime (I) with ethanol, not the expected toluenesulfonic acidic salt of 2-aminofuran (II) was obtained. Rather, we isolated, in addition to ammonium *p*-toluenesulfonate, a yellowish-green, strongly reducing liquid, which was free of nitrogen. Although very sensitive to heat, the liquid can be distilled *in vacuo* at constant temperature without being decomposed. The analysis and determination of molecular weight gave the elementary formula $C_{10}H_{16}O_4$ (III). Methanol, instead of ethanol, gave rise to a very similar substance with the formula $C_8H_{12}O_4$ (IV). These substances were found to represent *cis*-hexen-2-dion-4,5-diethylacetal-1 (III), and -dimethylacetal-1 (IV), respectively, as the end-products of the over-all reaction



$$CH_3COCOCH{=}CHCH(OR)_2$$
$$\text{III, } R = {-}C_2H_5$$
$$\text{IV, } R = {-}CH_3$$
$$CH_3COCOCH_2CH_2CH(OR)_2$$
$$\text{V, } R = {-}C_2H_5$$
$$\text{VI, } R = {-}CH_3$$

$$\underset{(I)}{C_6H_6O{-}NOSO_2C_6H_4CH_3} + H_2O + 2ROH = CH_3C_6H_4SO_3(NH_4) + \text{III or IV}$$

Proof of the structures of III and IV rests on the following experimental facts.

With maleic anhydride no adduct originated[5] from III; therefore, the latter could not possess the furan nucleus. On catalytic hydrogenation

---

[1] Leimbach, *J. prakt. Chem.*, [2], **65**, 20 (1902).

[2] Singleton and Edwards, THIS JOURNAL, **60**, 540 (1938).

[3] Neber and v. Friedolfsheim, *Ann.*, **449**, 109 (1926).

[4] Neber and Huh, *ibid.*, **515**, 292 (1935).

[5] Alder and Schmidt, *Ber.*, **76**, 18 (1943).

in the presence of palladium catalyst III and IV took up only one mole of hydrogen giving rise to two liquids with the elementary formulas of $C_{10}H_{18}O_4$ (V) and $C_8H_{14}O_4$ (VI), respectively, whereas a furan compound would have required two moles of hydrogen at least. These experiments, therefore, indicated that the furan ring opened up during the reaction of I with alcohol, and that the substances (III, IV) so formed must be regarded as unsaturated aliphatic compounds.

In spite of the strong reduction shown toward ammoniacal silver nitrate or cold Fehling solution, substances III to VI could not contain free aldehyde groups because they gave positive test with fuchsin–sulfurous acid solution only after acid-catalyzed hydrolysis. Since the latter operation, beside one mole of acetic acid, yielded ethyl or methyl alcohol, it was concluded that each compound from III to VI contained an acetal grouping, which accounted for two atoms of oxygen in the empirical formulas. This conclusion was confirmed by the reactions of III and IV with aqueous hydroxylamine hydrochloride which gave rise to an identical oxime with the formula $C_6H_6O_2({=}NOH)$. The fact that the latter substance was a true oxime was proved by benzoylation which produced the expected benzoyl ester, $C_6H_6O_2({=}NOCOC_6H_5)$.

The remaining two oxygen atoms in III and IV were assumed to belong to two carbonyl groups, for no active hydrogen could be found in equivalent quantity according to Zerewitinow's method. The presence of one of these carbonyl groups could be demonstrated experimentally by the reaction of either III or IV with phenylhydrazine which led, under loss of two moles of alcohol, to an identical bisphenylhydrazone, $C_6H_6O({=}NNHC_6H_5)_2$. The presence of the second carbonyl group could not be demonstrated in this reaction, because the substance suffered decomposition on prolonged heating with the carbonyl reagent.

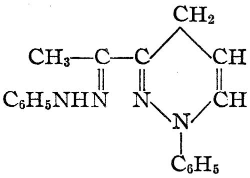
Final evidence of the correctness of structures III and IV was derived from the results of the oxidative degradations of these compounds. Thus it was found that, on treatment with ozone, compound IV gave rise to glyoxal which was isolated in form of its phenylosazone. This experiment proved that compound IV was essentially an unsaturated aldehyde, which contained its double bond between carbon atoms 2 and 3. Since oxidation of IV by potassium permanganate led to the formation of acetic acid and oxalic acid, the presence of an CH_3CO— group in the molecule was indicated. This conclusion was in accord with the result of the acid-catalyzed hydrolysis of IV, which, instead of giving the expected unsaturated diketo-aldehyde, $CH_3COCOCH{=}CHCHO$, decomposed with formation of acetic acid and methyl alcohol. The correctness of structural formulas III to VI was also confirmed by other degradation reactions. Hollemann[6] and Böeseken[7] have shown that the oxidation of 1,2-diketones by hydrogen peroxide results in the corresponding acids, according to the reaction

$$R{-}COCO{-}R' + H_2O_2 = R{-}COOH + R'{-}COOH$$

By the application of this reaction in glacial acetic acid to IV, we obtained maleic acid, in consequence of the simultaneous hydrolysis of the acetal grouping and further oxidation of the free aldehyde to the acid

$$CH_3COCOCH{=}CH{-}CH(OCH_3)_2 \longrightarrow$$
$$2CH_3OH + CH_3COOH +$$
$$[HOOC{-}CH{=}CH{-}CHO] \longrightarrow$$
$$HOOC{-}CH{=}CH{-}COOH$$

These results confirmed not only the correctness of the established structural formulas for III to VI, but they also proved, because of the formation of maleic acid, the *cis*-configuration of III and IV, which could exist in two geometrical isomeric forms. The oxidation of the saturated compound VI by silver oxide in aqueous solution resulted in succinic acid, in accordance with the result obtained on the corresponding unsaturated compounds III and IV. The 1,4-relationship between the acetal group and one of the two carbonyl groups in compounds III to VI follows from the behavior of the saturated diketo-acetal VI toward phenylhydrazine. It is known from the literature[8] that 1,4-dicarbonyl compounds usually give rise to pyridazine derivatives. Accordingly, we have obtained from V or VI, on treatment with phenylhydrazine, a light-yellowish, crystalline powder which, on the basis of analysis, represents the phenylhydrazone of the 1-phenyl-3-acetodihydropyridazine (VII).



VII

In the course of our further work, we wished to study the free aldehydes, corresponding with the acetals III to VI. However, the unsaturated diketo-aldehyde, $CH_3COCOCH{=}CHCHO$, could not be produced by hydrolysis of III or IV, because, as already mentioned, the carbon-chain between the adjacent carbonyl groups split up with formation of acetic acid, even in cold aqueous solution. We attribute this easy cleavage of the carbon to carbon linkage in the dicarbonyl grouping to a loosening effect of the double bond which occupies an α,β-position.

The hydrolysis of the saturated acetals V and VI also led to a surprising result; because instead of the expected diketo-aldehyde (VIII), $CH_3COCOCH_2CH_2CHO$, there was produced pyrocatechol. The formation of the latter, however, can easily be explained through the trienol form (IX)

VIII

IX

Since pyrocatechol and its derivatives are very common in nature, it is perhaps of interest to point out a possible way by which they can eventually be formed from carbohydrates through furan derivatives.

At present no definitive explanation can be offered as to the mechanism of the conversion of I into III or IV. It is very probable that the reaction does not proceed according to Neber's formulas through 2-aminofuran, because by such a process the formation of a six-membered carbon-chain cannot be explained. On the other hand, it is known that the furan ring may open up even under mild experimental conditions as illustrated by the formation of levulinic aldehyde dimethylacetal[9] from 2-methylfuran in methyl alcoholic hydrogen chloride solution.

Experimental

2-Acetofuranoxime.—A solution of 2-acetofuran[10] (40 g.), hydroxylamine hydrochloride (30 g.) and anhydrous sodium acetate[11] (40 g.) in 200 cc. of ethyl alcohol was refluxed for five hours. The hot solution was filtered from the precipitated sodium chloride, the filtrate concentrated *in vacuo*, and ice water was added to the residue. The substance first separated as an oil but soon became crystalline on stirring. It was recrystallized from methyl alcohol; yield, 90%, m. p. 104°.

***p*-Toluenesulfonyl 2-Acetofuranoxime** (I).—Fifty grams of powdered *p*-toluenesulfonyl chloride was added gradually to a solution of 2-acetofuran oxime (30 g.) in 140 cc. of pyridine at −10° with stirring. After standing at 0° for two hours the reaction mixture was poured into ice water. The crystalline precipitate was filtered, washed with water, dried *in vacuo* and recrystallized from benzene by addition of petroleum ether; yield, almost quantitative, m. p. 80° with decomposition. The colorless needles were soluble in ether, benzene and acetone, sparingly soluble in alcohol, practically insoluble in water and petroleum ether.

Anal. Calcd. for $C_{13}H_{13}O_4NS$: C, 55.90; H, 4.69. Found: C, 55.95; H, 4.61.

Hexen-2-dion-4,5-diethylacetal-1 (III).—A solution of fifty grams of the *p*-toluenesulfonyl ester (I) in 250 cc. of 95% ethyl alcohol was shaken for five days at room temperature on the machine. Then the ammonium *p*-toluenesulfonate precipitate was filtered off, the filtrate was concentrated *in vacuo* at 30–35° bath-temperature to a small volume, to which 250 cc. of ether was added. After removal by filtration of a small quantity of the ammonium salt, the ether solution was stirred with a little water, dried with anhydrous sodium sulfate and the solvent distilled off first under atmospheric pressure, finally *in vacuo*. The remaining liquid distilled at 75–90° (3 mm.). The bath temperature must not rise above 130° because the resinous residue on overheating decomposes with explosion-like violence. On rectification most of the substance distilled at 65–68° (1 mm.); yield, 80%. The acetal had a yellowish-green color, it was readily soluble in water and in the common organic solvents. It reduced Fehling solution and ammoniacal silver nitrate solution in the cold. Its freshly prepared aqueous solution was neutral to litmus and did not react with Schiff reagent. On standing, the solution became acidic because of decomposition with the production of acetic acid.

Anal. Calcd. for $C_{10}H_{16}O_4$: C, 59.96; H, 8.06; mol wt., 200.2. Found: C, 59.64; H, 8.25; mol. wt., 198, by freezing point depression in benzene.

For the attempted preparation of an adduct from III with maleic anhydride an ether solution of the equivalent quantities of the components was kept for two days in the ice-chest. After distillation of the solvent the starting materials were recovered unchanged almost quantitatively.

Hexen-2-dion-4,5-dimethylacetal-1 (IV).—The preparation of the dimethylacetal was carried out in the same manner as that of the diethylacetal (III), but methanol was applied instead of ethanol. The resulting yellowish-green liquid showed the same chemical behavior as III; yield, 80–90%, b. p. 80.5–81.5° (3 mm.).

Anal. Calcd. for $C_8H_{12}O_4$: C, 55.78; H, 7.03; mol. wt., 172.2. Found: C, 55.93; H, 7.11; mol. wt., 171.6, by freezing point depression in benzene.

Hexan-dion-4,5-diethylacetal-1 (V).—A 20.2-g. quantity of hexen-2-dion-4,5-diethylacetal-1 (III) in 100 cc. of ethyl alcohol was hydrogenated in the presence of 3 g. of palladium–charcoal (10% Pd) at room temperature and at atmospheric pressure. The substance took up 1 mole of hydrogen during a few hours, then the rate of the reaction decreased. At this point the hydrogenation was interrupted, the filtered solution evaporated *in vacuo*, and the remaining liquid distilled at 73–75° (3 mm.); yield, 80%. The almost colorless substance reduced ammoniacal silver nitrate solution in the cold; it was readily soluble in water and in the common organic solvents. According to Zerewitinow's method the substance contained about 0.3 atom of active hydrogen.

Anal. Calcd. for $C_{10}H_{18}O_4$: C, 59.41; H, 8.91; mol. wt., 202.2. Found: C, 59.45; H, 9.19; mol. wt., 200.5, by freezing point depression in benzene.

Hexandion-4,5-dimethylacetal (VI).—This substance was prepared from the unsaturated dimethylacetal (IV) as V from III, b. p. 78–82° (2 mm.). Both of the saturated acetals V and VI showed very similar properties. According to Zerewitinow's method the substance contained about 0.2 atom of active hydrogen.

Anal. Calcd. for $C_8H_{14}O_4$: C, 55.14; H, 8.10. Found: C, 54.64; H, 8.21.

Hydrolysis of the Hexen-2-dion-4,5-diemthylacetal-1 (IV).—A solution of 5 g. of the acetal in 50 cc. of 2% sulfuric acid was refluxed for thirty minutes. The solution first became yellow, then brown and finally some resinous product precipitated. The filtered solution was evaporated *in vacuo*, the distillate exactly neutralized with 0.1 *N* sodium hydroxide solution, and then about two-thirds of its volume was distilled. In this distillate the presence of methyl alcohol could be demonstrated by Denigès' reaction. The residue was evaporated to dryness and mixed with a saturated silver nitrate solution. The crystalline precipitate was filtered off, washed with a little cold water and dried *in vacuo;* it proved to be silver acetate.

Anal. Calcd. for $C_2H_3O_2Ag$: Ag, 64.64. Found: Ag, 64.18.

Hexen-2-dion-4,5-aldoxime and its Benzoyl Derivative.—To 0.5 g. of either unsaturated acetal III or IV in 10 cc. of water there was added a concentrated aqueous solution of 0.5 g. of hydroxylamine hydrochloride. The oxime soon precipitated in needles which were recrystallized from hot water; m. p. 236° with decomposition. It was soluble in alkalies, sparingly soluble in cold water and alcohol, and almost insoluble in the other usual solvents. Its aqueous solution showed a red coloration with ferric chloride.

Anal. Calcd. for $C_6H_7O_3N$: C, 51.03; H, 4.96; N, 9.92. Found: C, 51.26; H, 5.18; N, 9.99.

[10] Sandolin, *ibid.*, **33**, 492, 1176 (1900); Torrey and Zanetti, *Chem. Zentr.*, **82**, I, 81 (1911).

[11] Sandolin (ref. 10) applied sodium carbonate instead of sodium acetate, and the yield was only 50%.

For benzoylation 0.1 g. of the oxime, dissolved in 15 cc. of 2 *N* sodium hydroxide solution, was shaken with 0.5 g. of benzoyl chloride for fifteen minutes. The ester was filtered, washed with water and recrystallized from alcohol; colorless needles, m. p. 168°.

Anal. Calcd. for $C_{13}H_{11}O_4N$: N, 5.71. Found: N, 5.77.

bis-Phenylhydrazone of Hexen-2-dion-4,5-al-1.—One gram of the acetal III or IV, dissolved in 30 cc. of water, was mixed with a solution of 3 g. of phenylhydrazine hydrochloride in 15 cc. of water. The bis-phenylhydrazone precipitated as an oil which soon changed into crystals. It was filtered, washed with water, and recrystallized from alcohol with activated carbon; orange-red crystals, m. p. 209° with decomposition.

Anal. Calcd. for $C_{18}H_{18}ON_4$: C, 70.55; H, 5.92; N, 18.29. Found: C, 70.48; H, 5.94; N, 18.19.

Oxidation of Hexen-2-dion-4,5-dimethylacetal-1 (IV): (a) **Oxidation by Ozone.**—Into a solution of the acetal (6 g.) in anhydrous chloroform (30 cc.) 1.1 mole of ozone was introduced. Then the solvent was distilled off *in vacuo* and the oily residue was boiled with 60 cc. of water under reflux until clear solution was obtained (two hours). Addition of phenylhydrazine in acetic acid solution caused the precipitation of glyoxal-bisphenylhydrazone which was recrystallized from alcohol; m. p. and mixed m. p. with an authentic sample, 169°.

(b) **Oxidation with Potassium Permanganate.**—To 6.8 g. of IV in 50 cc. of water which was made slightly alkaline by addition of a few drops of potassium hydroxide solution, there was added at 5 to 10° 28 g. of potassium permanganate in 500 cc. of water, in small portion during twelve hours with stirring. After completed oxidation the solution, filtered from the precipitated manganese dioxide, was concentrated *in vacuo* to 100 cc., then acidified with dilute sulfuric acid to congo paper, and distilled. About 70 cc. of the distillate, after neutralization with 0.1 *N* alkali, was evaporated to dryness on the steam-bath. For decomposition of the sodium formate which formed part of the residue, the latter was treated with concentrated sulfuric acid, then diluted with water and the solution was distilled. From this distillate the acetic acid, produced by the oxidation, was isolated in form of its silver salt.

Anal. Calcd. for $C_2H_3O_2Ag$: Ag, 64.64. Found: Ag, 64.12.

From the residue of the first distillation, by addition of an acetic acid solution of phenylhydrazine, the phenylhydrazine salt of oxalic acid was obtained in colorless plates; m. p. and mixed m. p. with an authentic sample, 182°.

(c) **Oxidation with Hydrogen Peroxide.**—One g. of IV in 10 cc. of glacial acetic acid was refluxed with 10 cc. of a 15% hydrogen peroxide solution for four hours. The colorless substance, obtained after evaporation of the solution *in vacuo* and recrystallization of the solid residue from water, was identified as maleic acid; m. p. and mixed m. p. with an authentic sample, 132°.

Oxidation of Hexandion-4,5-dimethylacetal-1 (VI) with Silver Oxide.—Four grams of the saturated acetal (VI) in 100 cc. of water was refluxed for one hour with 4 g. of freshly prepared silver oxide. The hot, filtered solution was then saturated with hydrogen sulfide, filtered from the precipitated silver sulfide and evaporated to dryness on the steam-bath. The solid residue was recrystallized from absolute alcohol. The colorless substance proved to be succinic acid; m. p. and mixed m. p. with an authentic sample, 183°.

1-Phenyl-3-acetodihydropyridazine Phenylhydrazone (VII).—About 0.5 g. of the saturated acetal V or VI was heated on the steam-bath for ten minutes with 1 g. of phenylhydrazine in 5 cc. of glacial acetic acid. After the precipitate was filtered and washed with water and alcohol, it had the appearance of a pale-yellow crystalline powder, which was practically insoluble in water and the other usual solvents. The substance did not melt up to 280°.

Anal. Calcd. for $C_{18}H_{18}N$: C, 74.41; H, 6.24; N, 19.34. Found: C, 74.51; H, 6.44; N, 19.12.

Formation of Pyrocatechol on Hydrolysis of Hexandion-4,5-dimethylacetal-1 (VI).—A solution of the acetal (2.5 g.) in 2% sulfuric acid (60 cc.) was refluxed for one hour. After cooling the faintly brown solution was saturated with sodium bicarbonate and extracted with ether. The ether extract was dried with anhydrous sodium sulfate, evaporated, and the residue distilled *in vacuo;* b. p. 111–112° (3 mm.). The distillate crystallized from ligroin in colorless plates which showed all the characteristic properties of pyrocatechol; m. p. and mixed m. p. with authentic sample, 104°. The aqueous solution of the substance gave an emerald-green coloration with ferric chloride.

Anal. Calcd. for $C_6H_6O_2$: C, 65.45; H, 5.45. Found: C, 65.78; H, 5.59.

Summary

On shaking *p*-toluenesulfonyl 2-acetofuranoxime (I) with ethanol or methanol, not the expected 2-aminofuran was formed, but unsaturated aliphatic compounds, represented by the formulas $C_{10}H_{16}O_4$ (III) and $C_8H_{12}O_4$ (IV), respectively. The constitution and configuration of these substances were determined by various methods which definitely established their identities as being *cis*-hexen-2-dion-4,5-diethylacetal-1 and -dimethylacetal-1, respectively.

The corresponding aldehydes could not be produced because the carbon-chain between the carbonyl groups 4 and 5 split up with formation of acetic acid, even in cold aqueous solution.

The hydrolysis of the saturated acetals also led to a surprising result; because instead of the expected hexandion-4,5-al-1, there was obtained pyrocatechol.

It is suggested that natural pyrocatechol derivatives might be formed in a similar manner from carbohydrates through furan derivatives.

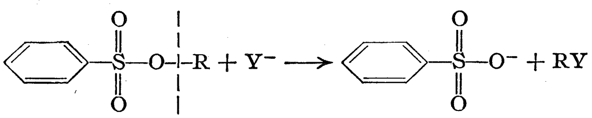
A Kinetic Study of Alkylation by Ethyl Arylsulfonates

BY MARCUS S. MORGAN AND LEONARD H. CRETCHER

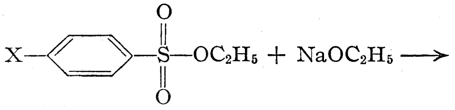
Alkyl esters of aromatic sulfonic acids function as strong alkylating agents[1] toward various types of organic compounds, this reaction occurring by alkyl-oxygen fission[2] according to the general scheme

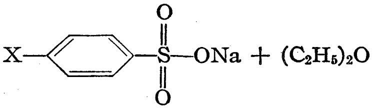


where R = alkyl group; Y^- = a nucleophilic reagent, *e. g.*, EtO^-, PhO^-, RS^-, I^-, etc.

Although various types of substituted benzenesulfonates are known and might conceivably be used, the vast majority of experimental alkylations have been carried out with the alkyl *p*-toluenesulfonates. Whereas the effect of nuclear substituents on the reactions of alkyl benzoates has been investigated extensively,[3] no such study has been made of the effect of nuclear substituents on the reactivity of alkyl esters of arylsulfonates. To do so seemed of considerable theoretical as well as potentially practical interest.[4] Such studies as have been made deal primarily with the hydrolysis of these compounds. It has been noted that with increasing nuclear halogen substitution, the ester is more readily saponified by alcohol.[5,6] The rate of the solvolytic reaction of ethyl toluenesulfonate and the rates of displacement of toluenesulfonate ion by chloride, bromide, iodide and hydroxyl ions has been studied kinetically.[7] Demeny's study[8] of the effect of a substituent in the aromatic nucleus upon the rate at which an alkyl sulfonate *hydrolyzes* demonstrated that a nitro group has a powerful accelerating influence while a *para* methyl reduces the reaction rate.

In this paper we present the results of a study of the influence of the *para* substituent on the reactivity of ethyl benzenesulfonate with sodium ethoxide in absolute ethanol solution.





where X = CH_3O, CH_3, H, Br and NO_2

The progress of this irreversible reaction was followed by titration of the unreacted sodium ethoxide at suitable time intervals with 0.05 *N* hydrochloric acid. Apparently the strong nucleophilic character of the ethoxide ion causes this reaction to take place readily at moderate temperature without observable side-effects. All of the rate constants reported in this study are based on an approximately equal initial concentration (0.05 molar) of each of the reactants. By trial, it was found that 35° was a suitable temperature at which to measure the relative reaction rates over a major part of the reaction. The measurements were repeated at a 10° interval to permit an approximate calculation of the energies of activation. The particular group of substituents selected represents a wide range of electronic character, varying from the electron-repulsion of the methoxy group to the electron attraction of the nitro-group, as exhibited in the benzene series.

p-Methoxybenzenesulfonyl chloride was prepared in 66% yield by the direct chlorosulfonation of anisole. High yields of the ethyl esters were obtained by reacting the corresponding sulfonyl chloride with an equimolar quantity of sodium ethoxide in alcohol or alcohol–ether solution under mild conditions.

Experimental

Aryl Sulfonyl Chlorides.—*p*-Toluenesulfonyl chloride, benzenesulfonyl chloride, *p*-bromobenzenesulfonyl chloride and *p*-nitrobenzenesulfonyl chloride were purchased from the Eastman Kodak Company.

***p*-Methoxybenzenesulfonyl Chloride.**—The literature on the preparation of this compound was very incomplete and in one case quite erroneous. This substance apparently was first synthesized by Moody[9] by sulfonation of anisole followed by treating the salt with phosphorus pentachloride. Although Huntress and Carten[10] prepared a small quantity of the compound by the action of chlorosulfonic acid on anisole, they did not isolate it, but immediately converted it into the sulfonamide in 53% yield. Gebauer-Fülnegg and Meissner[11] in a study of the action of chlorosulfonic acid on anisole made the statement, "An anisole monosulfonyl chloride could not be prepared in spite of extensive variations in reaction conditions."

Anisole (40 g., 0.37 mole) was dissolved in 150 ml. of chloroform and the solution cooled in an ice–salt-bath to −8°. Chlorosulfonic acid (86.2 g., 2 equiv., 0.74 mole) was added dropwise, as rapidly as possible while maintaining the internal temperature at 0°. Addition time was twenty minutes. The ice-bath was removed and the temperature allowed to approach room temperature during thirty minutes with continuous stirring. The solution

was poured onto chopped ice and the mixture transferred to a separatory funnel with an additional 200 ml. of chloroform. The chloroform extract was washed with three small portions of ice-water, dried with anhydrous sodium sulfate, filtered and redried with Drierite. On evaporating the chloroform solution under reduced pressure there remained a pale yellow liquid which crystallized on cooling and scratching. Yield was 54.7 g. (72%) of crude sulfonyl chloride. The product may be purified by recrystallization from boiling hexane (10 volumes) to give colorless crystals, m. p., 40–42° in 52% yield.

It was found that purification may be accomplished more efficiently by vacuum distillation. *p*-Methoxybenzenesulfonyl chloride boiled at 103–105° at 0.25 mm. (bath temp., 120–135°) to give a colorless distillate in 66% yield. The product had a m. p. of 41–42°, which is in agreement with values recorded in the literature.[12]

Anal.[13] Calcd. for $C_7H_7ClO_3S$: Cl, 17.16; S, 15.52. Found: Cl, 16.89; S, 15.38.

Ethyl Arylsulfonates—General Procedure.—The sulfonyl chloride (0.1 mole) was dissolved in 100 ml. of absolute ethanol in a 250-ml. three-necked flask fitted with a mercury-sealed stirrer, reflux condenser, dropping funnel and thermometer. In those cases where the sulfonyl chloride is not very soluble in ethanol (*e. g.*, *p*-nitro- and *p*-bromobenzenesulfonyl chloride) 75 ml. of ether was used. The flask was surrounded by a cold water-bath to maintain an internal temperature of 20°. A solution of 0.1 mole of sodium ethoxide in 100 ml. of ethanol (prepared by dissolving sodium in ethanol and standardizing the solution against standard hydrochloric acid) was added dropwise with continuous stirring. The reaction time varied somewhat with the reactivity of the sulfonyl chloride but was generally run until a test portion (10 drops) was no longer alkaline to phenolphthalein. The *p*-methoxy compound required forty-five minutes whereas the *p*-nitro was run for 145 minutes.

The suspension was poured into 300 to 500 cc. of water (sufficient to dissolve the precipitated sodium chloride) and the mixture thoroughly extracted with 200 ml. of chloroform. (Where ether was used as a solvent, the reaction mixture was first evaporated at reduced pressure to remove all of the ether.) The aqueous layer was extracted with two additional portions (100 ml.) of chloroform and the combined extract washed successively with 50 ml. of water, 150 ml. of saturated sodium bicarbonate and two 60-ml. portions of water.

The chloroform solution was dried over anhydrous sodium sulfate, filtered, and evaporated to dryness at reduced pressure. With the exception of the *p*-nitro ester, the crude esters thus obtained were all purified by fractional vacuum distillation, the intermediate constant-boiling fraction being retained for kinetic study.

Ethyl *p*-Nitrobenzenesulfonate.—The crude, pale-yellow ester obtained in 81% yield (m. p., 91–91.5°) was recrystallized from absolute ether to give practically colorless crystals; m. p. 92–92.5°, in 70% yield. Demeny[8] reported m. p. as 92°.

Anal. Calcd. for $C_8H_9NO_5S$: N, 6.06; S, 13.87. Found: N, 6.01; S, 13.88.

Ethyl *p*-Methoxybenzenesulfonate.—The pure ester was obtained as a colorless liquid in 83% yield after fractional vacuum distillation, b. p., 137–139° at 0.3 mm. (bath temp., 164–169°), n^{20}_D 1.5230.

Anal. Calcd. for $C_9H_{12}O_4S$: C, 49.98; H, 5.60; S, 14.83. Found: C, 49.84; H, 5.53; S, 14.88.

This compound was recently reported by Carr and Brown[12b] who prepared it in a different manner.

Ethyl *p*-Bromobenzenesulfonate.—The pure ester (obtained in 74% yield) distilled at 111–113° at 0.15 mm. (bath temp., 132–135°), f. p., 39.0–39.1°. Krafft and Roos[14] reported the m. p. as 39.5°.

Ethyl *p*-Toluenesulfonate.—The pure ester distilled at 108–109° at 0.35 mm.; bath temp., 121–123°. The freezing point was 32.2° which is in agreement with the value reported by McCleary and Hammett,[7] m. p., 32.2–32.3°.

Ethyl Benzenesulfonate.—Although this ester can be prepared by the general procedure given above, it was prepared by the pyridine method[15] which is useful for esters which cannot be made from the sodium alkoxide. Benzenesulfonyl chloride (Eastman Kodak Co. 32, 36 g., 0.2 mole) was dissolved in 100 ml. of dry pyridine and the solution cooled to −8°. Absolute ethanol (11.7 ml., 0.2 mole) was now added from a pipet and the temperature kept between −8 and −5°. Crystallization of pyridine hydrochloride commenced after several minutes and the mixture was kept at −5° for a total of twenty-two minutes. Sulfuric acid (250 ml. of 5 *N*, pre-cooled to 3°) was now added rapidly, with cooling, thereby liberating a colorless oil which settled to the bottom of the flask. The oil was extracted with chloroform and this solution was treated in the described manner. The pure ester (obtained in 75% yield) distilled at 96–98° at 0.3 mm. (bath temp., 109–113°), n^{20}_D 1.5092.

Kinetic Technique.—The apparatus consisted essentially of a thermostatically controlled (±0.04°) water-bath fitted with clamps to hold a series (usually 7) of stoppered test-tubes and several 100-ml. volumetric flasks. Since it was not deemed desirable to mix a standardized solution of the ethyl arylsulfonate in ethanol with a standard solution of sodium ethoxide in ethanol (both solutions equilibrated to constant temperature) because of possible ester alcoholysis prior to mixing, a weighed amount of the ester (0.005 mole) in a small, thin glass vial (11 × 40 mm.) was added directly to an ethanol solution of sodium ethoxide already equilibrated to temperature. This was done in the following manner. The reaction vessel was a 100-ml. volumetric flask calibrated to correct for the thermal expansion of ethanol at the specific reaction temperature plus the volume-displacement of the glass vial. A solution of sodium ethoxide in ethanol, as close to 0.1 molar as expedient, was prepared in a 100-ml. volumetric flask and standardized against 0.05 *N* hydrochloric acid. A 50-ml. aliquot (0.005 mole) was then added to the calibrated flask and sufficient ethanol added to bring the volume to a point such that the addition of the ester-containing vial (after temperature equilibration) would bring the final volume close to the calibration mark. The final volume adjustment was thus made immediately after the addition of ester. The flask containing the ethoxide solution (representing about 99+% of the mass) could thus be accurately adjusted to the reaction temperature and the vial containing the ester only approximately adjusted in a separate tube. In all cases except the *p*-nitro, dissolution of the liquid ester was sufficiently rapid so that zero time was essentially that of the moment of mixing. The solid nitro-ester, which has the lowest alcohol solubility, was finely powdered; zero time being taken as of one-half time of solution. Owing to the graphic method of determining the rate, this factor had no bearing on the determination of the value of *k*.

As soon as the ester was completely dissolved, the homogeneous solution was aliquoted in seven, 10-ml. portions to the equilibrated, stoppered test-tubes. This was necessitated by the low alcohol-solubility and consequent crystallization of the sodium salts of the arylsulfonic acids. The pipet used in making these transfers was also calibrated for the thermal expansion of ethanol. At suitable time intervals, an aliquot-containing tube was removed from the water-bath and plunged into a Dry Ice–acetone mixture to stop the reaction. The cold mixture was then carefully diluted with 100 ml. of carbon dioxide-free water and titrated with 0.05 *N* hydrochloric acid using phenolphthalein as the indicator. Each run thus gave seven points with which to plot a graph.

Rate Calculations.—Since we were dealing with a nucleophilic displacement we postulated second-order kinetics and determined the rate constant, k, from the simplified equation for second-order reactions in which initial concentrations of reactants are equal; $k_2 = x/ta(a - x)$, where a = initial concentration of sodium ethoxide in moles/liter and x = moles per liter which have reacted in time t. The reported values of k (expressed in min.$^{-1}$ moles^{-1} liter) were determined graphically by plotting the function $x/(a - x)$ against t which resulted in a straight line with a slope equal to ak. This value was checked by plotting $1/(a - x)$ against t, the slope of the resulting line being directly equal to k. The excellent straight line relationship which we observed in every case, the graphs having been plotted over a major part of the course of each reaction, substantiated our assumption of second-order kinetics.

In Table I, we present a typical experimental record for the determination of the value of k in a specific reaction. The figures of column 5 and the inverse of the figures in column 3 were plotted against t to give a value of $k_2 = 0.235$. By using the equation[16] $k(t_2 - t_1)a = [x_2/(a - x_2) - x_1/(a - x_1)]$ or $\Delta(x/a - x)$ (column 6), the interval values of k_2 (column 7) may be obtained.

TABLE I

REACTION OF ETHYL BENZENESULFONATE WITH SODIUM ETHOXIDE AT 45°

Concn. of ester = 0.0489 molar
Concn. of ethoxide = 0.0504 molar

Time, min.	Acid titer*	$a - x$ m./l.	x m./l.	$x/(a - x)$	$\Delta[x/(a - x)]$	k_2

180	3.17	.0158	.0330	2.085	.361	.246

* = ml. of 0.05 N hydrochloric acid used in titration of aliquot.

Since the rate constant for each ester was determined at two temperatures only, the energy of activation, E, was evaluated from the integrated expression[17]

$$E = \frac{2.303RT_2T_1}{(T_2 - T_1)} \log \frac{k_2}{k_1}$$

Results and Discussion

The rate constants, obtained at two temperatures, for the reaction of *para*-substituted ethyl benzenesulfonates with sodium ethoxide in ethanol solution are given in Table II. The substituents are listed in ascending order of ester reactivity which is also the order of relative electron-recession from the seat of the reaction, *i. e.*, the alkyl–oxygen bond in the ester.

TABLE II

Substituent X	Rate constant t, °C.	k_2	Relative reactivity at 35°	Energy of activation cal.	log PZ
p-CH_3O	35	0.0321	0.42	21,670	12.12
	45	.0977			
p-CH_3	35	.0484	.63	20,820	11.69
	45	.141			
p-H	35	.0769	1.00	21,750	12.56
	45	.235			
p-Br	35	.172	2.24	22,240	13.25
	45	.539			
p-NO_2	35	.901	11.8	24,040	15.25
	25	.241			

A comparison of the relative reactivity of these esters at 35° indicates a twenty-eight fold variation in the relative velocity constants, indicating the desirability of investigating the alkylating efficacy of arylsulfonic esters other than those of p-toluenesulfonic acid.

Due largely to the work of Hammett,[18] linear relationships have been found to apply between

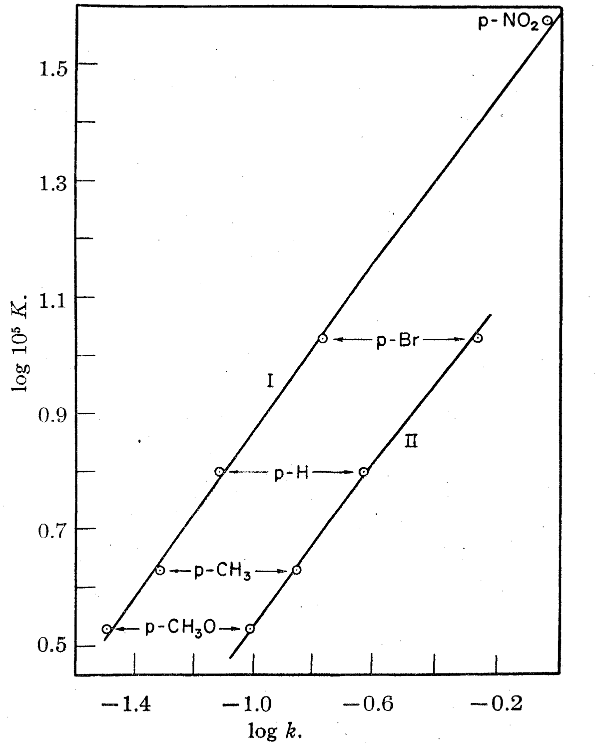

Fig. 1.—Relationship of log 10^5 K and log k, where K = dissociation constant of substituted benzoic acid; k = rate constant for reaction of substituted ethyl benzenesulfonate with sodium ethoxide in ethanol at (I) 35° and at (II) 45°.

[17] Moelwyn-Hughes, "Kinetics of Reactions in Solution," Oxford University Press, Oxford, 1933, p. 30.

[18] Hammett, "Physical Organic Chemistry," McGraw-Hill Book Co., New York. N. Y., 1940, p. 184.

the rate and the equilibrium constants of practically all side chain reactions of benzene derivatives substituted in the *meta* or *para* positions. In accordance with this relationship we have plotted in Fig. 1, as ordinates the logarithms of the dissociation constants of several substituted benzoic acids[19] and as abscissas the logarithms of the rate constants (Table II, column 3) for the reaction of similarly substituted ethyl benzenesulfonates with ethoxide ion. In view of the satisfactory linear relationship resulting, the present example can be added to the list of reactions tabulated by Hammett.

Since in the Arrhenius equation, $k = PZe^{-E/RT}$, the collision frequency Z varies but little from one reaction to another, it is apparent that the influence of a polar substituent on the velocity constant may be due to an effect on the energy of activation, E, or on the probability factor P, or both. For most reactions of nuclear substituted benzene derivatives it is commonly observed that the influence of substituents is almost entirely upon changes in E.[20] In several instances, however, it has been observed that substituents cause appreciable changes in the PZ term of the equation, *e. g.*, the acid hydrolysis of ethyl benzoates,[21] the alcoholysis of benzyl chlorides,[22] and the hydrolysis of arylsulfuric acids.[23] In the present investigation, since E has been estimated from values of k obtained at only two reaction temperatures, it probably is not to be considered accurate to more than ±1000 calories. From the results given in Table II it may be seen that although there is a slight trend to E, the individual values are grouped about the average of 22,100 calories almost within limits of the estimated experimental error.

Following Branch and Nixon,[22] the logarithm of the probability factors in the Arrhenius equation have been calculated from the relationship $\log PZ = \log k_{35} + E/2.3RT$ and are included in Table II. The values of $\log PZ$ listed are in the general region of those usually associated with reactions between ions and neutral molecules and belong to the class characterized by Moelwyn-Hughes as "normal" reactions. In view of the near-constancy of E, and the definite trend to the values of $\log PZ$, it would appear that we have here an additional example of a case in which the effect of polar substituents is mainly on the PZ term of the Arrhenius equation. It may be noted from Table II that although the effect of a *para*-methoxy substituent on the velocity constant is in accord with its electron-repulsive character, its effect on E and $\log PZ$ is anomalous.

Acknowledgment.—The authors wish to express appreciation to Dr. Warner W. Carlson of these laboratories for helpful discussion in the preparation of this manuscript.

Summary

Details have been worked out for the synthesis of *p*-methoxybenzenesulfonyl chloride by direct chlorosulfonation of anisole. The preparation and purification of five substituted ethyl benzenesulfonates are described.

The effect of a nuclear substituent on the alkylating efficacy of alkyl benzenesulfonates has been investigated by a study of the relative reaction rates of these esters with sodium ethoxide in ethanol. This reaction followed second-order kinetics.

The value of the rate-constants increased in the order *p*-CH_3O < *p*-CH_3 < *p*-H < *p*-Br < *p*-NO_2, which is in agreement with the electronic influence exhibited by these groups on the dissociation constants of substituted benzoic acids. Good quantitative accord was also observed with Hammett's relationship for the effect of structure on reactivity.

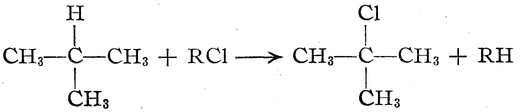
Condensation of Saturated Hydrocarbons with Haloöefins. II. The Reaction of Isobutane with *cis*- and *trans*-Dichloroethylene

BY LOUIS SCHMERLING

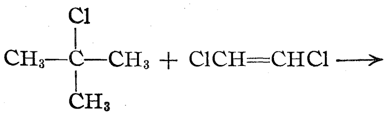
It was shown previously[1] that the condensation of isobutane with allyl chloride and vinyl chloride in the presence of aluminum chloride at −10° apparently proceeds via the conversion of the isoparaffin to *t*-butyl chloride which then adds to the chloroölefin to yield, respectively, 1,2-dichloro-4,4-dimethylpentane and 1,1-dichloro-3,3-dimethylbutane. The greater part of the former reacts with isobutane, producing 1-chloro-3,4-dimethylpentane as the major product. On the other hand, the 1,1-dichloro-3,3-dimethylbutane undergoes little conversion to monochloride and is, therefore, isolated as the principal chlorine-containing product.

The condensation of isobutane with a dichloroolefin, namely, 1,2-dichloroethylene, has now been investigated. It was found that the chief product is 1,1,2-trichloro-3,3-dimethylbutane, the same trichlorohexane which is obtained by the addition of *t*-butyl chloride to the dichloroethylene.[2] The intermediate conversion of the isobutane to *t*-butyl chloride is again indicated. Furthermore, since no dichlorohexane was isolated, it may be concluded that the trichloride is quite stable toward further reaction with the isobutane; that portion which does react is eventually reduced to paraffin (*i. e.*, all three chlorine atoms are successively replaced by hydrogen) by means of the hydrogen–chlorine exchange reaction with isobutane.[3] The trichloride is relatively unreactive because two of the chlorine atoms are attached to a primary carbon atom and the third to a secondary carbon atom which is in a neopentyl group. The intermediate di- and mono-chlorohexanes are comparatively unstable because tertiary carbon atoms are formed during the hydrogen–chlorine exchange; for example, the trichloride is probably converted to 1,1-dichloro-2,3-dimethylbutane which then isomerizes to reactive 1,2-dichloro-2,3-dimethylbutane.

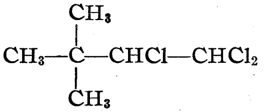
The mechanism of the condensation may be written as



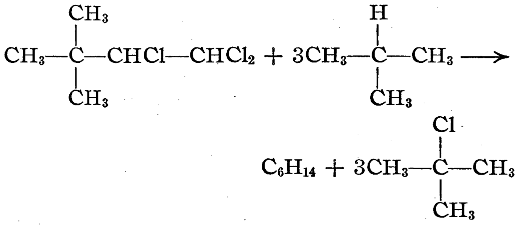
$$CH_3-\underset{CH_3}{\overset{H}{C}}-CH_3 + RCl \longrightarrow CH_3-\underset{CH_3}{\overset{Cl}{C}}-CH_3 + RH \quad (1)$$



$$CH_3-\underset{CH_3}{\overset{Cl}{C}}-CH_3 + ClCH{=}CHCl \longrightarrow$$



$$CH_3-\underset{CH_3}{\overset{CH_3}{C}}-CHCl-CHCl_2 \quad (2)$$



$$CH_3-\underset{CH_3}{\overset{CH_3}{C}}-CHCl-CHCl_2 + 3CH_3-\underset{CH_3}{\overset{H}{C}}-CH_3 \longrightarrow$$

$$C_6H_{14} + 3CH_3-\underset{CH_3}{\overset{Cl}{C}}-CH_3 \quad (3)$$

t-Butyl chloride formed as in equation 3 (actually the sum of three successive reactions) reacts with dichloroethylene as in equation 2. Since the reaction of equation 1 is a chain initiating step only, the nature of RCl (which might be dichloroethylene, trichloroethane, complex of catalyst with dichloroethylene, etc.) is unimportant. It is apparent that the highest possible yield of trichlorohexane is two-thirds of a mole per mole of dichloroethylene.

There is a very marked difference in reactivity between the *cis* and *trans* isomers of 1,2-dichloroethylene. The trichloride was obtained in 35% yield[4] by the reaction of isobutane with the *cis* compound at room temperature and in less than 5% yield by reaction with the *trans* isomer under the same conditions. A similar difference was found[2] for the condensation of the two isomers with isopropyl chloride or *t*-butyl chloride. Steric effects are presumably involved.

The structure of the trichloride was proved by converting it to a chlorohexene by reaction with zinc and alcohol; that the chlorohexene was 1-chloro-3,3-dimethyl-1-butene was shown by the facts that it yielded trimethylacetic acid on oxidation and that it was identical with the product obtained by the dehydrochlorination of 1,1-dichloro-3,3-dimethylbutane (obtained by the condensation of *t*-butyl chloride with vinyl chloride[5]).

It seems worth while at this time to discuss further[6] the significance which the reaction of isobutane with chloroölefins bears on the mechanism of the alkylation of isoparaffins with olefins. Gorin, Kuhn and Miles[7] have recently proposed an alkylation mechanism which is similar to those of Caesar and Francis[8] and of McAllister, Anderson,

Ballard and Ross[9] in that all three postulate that the isoparaffin undergoes carbon to carbon cleavage to yield two alkyl fragments (isopropyl and methyl in the case of isobutane). By assuming that the fragments (behaving as if positively and negatively charged) add to a complex formed between catalyst and olefin and by setting up rules governing the structure of the complex, Gorin, *et al.*, make it possible for this type of mechanism to explain why some isomers are formed and others are not. They state "The assumption that carbon–carbon fission occurs in the isobutane molecule . . . was recently rejected by Schmerling[6] in a criticism of the alkylation mechanisms proposed by these investigators [Caesar and Francis,[8] and McAllister, *et al.*[9]]. In the opinion of the writers, however, such a rupture of the isobutane molecule is scarcely less likely, *a priori*, than the similar α–β shift of a methyl group embodied in the mechanism of Schmerling or required, for that matter, to account for isomerization of alkanes. There seems to be little to choose between the two proposals on the basis of information now available."

Even without entering into a discussion of the vast literature on intramolecular rearrangements which involve shifting of methyl groups,[10] it is possible to furnish information which permits making a choice between the two proposals. This information consists in the results obtained in the condensation of isobutane with chloroölefins (*i. e.*, with olefins which have been "tagged"). The Gorin, *et al.*, mechanism can explain the formation of 1-chloro-3,4-dimethylbutane by the reaction of isobutane with allyl chloride; on the other hand, it cannot explain the formation of 1,2-dichloro-4,4-dimethylpentane as by-product of this reaction. Furthermore, it does not account for the principal chlorinated product of the reaction of isobutane with vinyl chloride (namely, 1,1-dichloro-3,3-dimethylbutane) or with 1,2-dichloroethylene (namely, 1,1,2-trichloro-3,5-dimethylbutane). In contrast to this, the mechanism proposed by the present writer for the alkylation of isoparaffins with olefins readily explains the formation of these polychloroalkanes; indeed, they are the inherent products of the second step of the mechanism (*cf.* equation 2). As has already been indicated, these compounds are comparatively unreactive and more or less of each will therefore be isolated as such. The analogous product of the alkylation of an isoparaffin with an olefin is an alkyl chloride (or other alkyl ester if catalyst other than aluminum chloride is used) which is usually not isolated because it readily undergoes the third step of the mechanism (*cf.* equation 3).

Experimental[11]

Procedure.—The dichloroethylene, isobutane and aluminum chloride were weighed into a glass liner (cooled in a bath at −78°) for an Ipatieff-type rotating autoclave of 850-cc. capacity. The liner was sealed into the autoclave which was then rotated at room temperature for four hours, after which it was allowed to stand overnight. The gaseous products were discharged through a soda lime tower to absorb hydrogen chloride and thence into a trap immersed in Dry Ice–acetone. The liquid product in the liner was decanted from the catalyst layer, washed, dried and distilled.

Reaction of *cis*-Dichloroethylene with Isobutane.—The reaction of 50 g. (0.52 mole) of *cis*-dichloroethylene (prepared by the isomerization[12] of *trans*-dichloroethylene) and 122 g. (2.1 mole) of isobutane in the presence of 10 g. of aluminum chloride yielded 11 g. (0.30 mole) of hydrogen chloride, 28 g. of red-brown, fluid catalyst layer, and a liquid product, distillation of which yielded 13 g. of product, b. p. 39–100°, $n^{20}\text{D}$ 1.3680–1.3842; 9 g., b. p. 100–106°, $n^{20}\text{D}$ 1.4056–1.4508; 23.5 g. (0.12 mole, 35% yield) of trichlorohexane, b. p. 196–200°, m. p. −16 to −17°, $n^{20}\text{D}$ 1.4755; and residue, 2.5.g.

Similar results were obtained in the presence of added hydrogen chloride. The reaction of 60 g. (0.62 mole) of *cis*-dichloroethylene and 125 g. (2.2 mole) of isobutane in the presence of 10 g. of aluminum chloride and 12 g. of anhydrous hydrogen chloride yielded 18 g. of liquid product, b. p. 45–190°; 28 g. (0.15 mole, 36% yield) of the trichlorohexane, b. p. 68–70° (6 mm.) or 198–200°

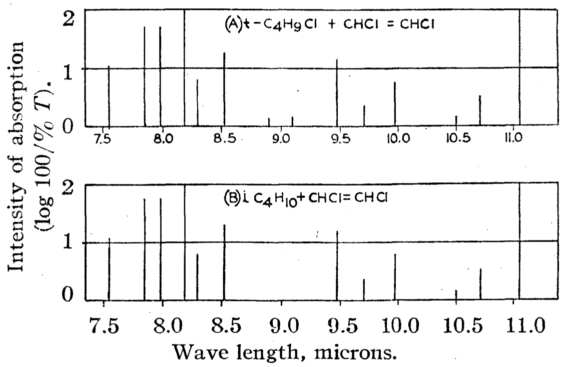

Fig. 1.—The infrared absorption spectra of the trichlorohexane formed by the reaction of *cis*-dichloroethylene with (A) *t*-butyl chloride and (B) isobutane.

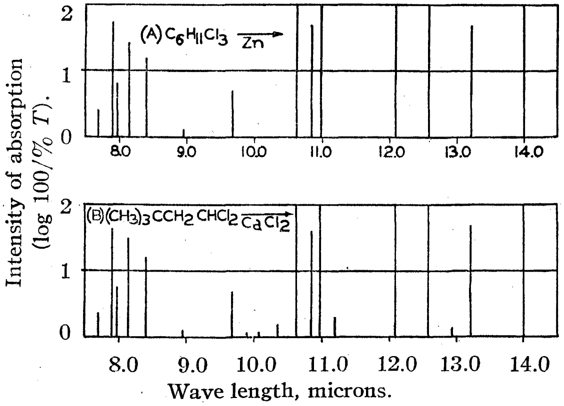

Fig. 2.—The infrared absorption spectra of the chlorohexene obtained by the reaction of (A) the trichlorohexane with zinc and (B) 1,1-dichloro-3,3-dimethylbutane over calcium chloride.

(9) S. H. McAllister, J. Anderson, S. A. Ballard and W. E. Ross, *J. Org. Chem.*, **6**, 647 (1941).

(10) That the postulated migrations of methyl groups do occur when the particular alkylation intermediates are converted to paraffins was proved experimentally.[6]

(11) Microanalyses by Dr. T. S. Ma, University of Chicago.

(12) G. Chavanne, *C. A.*, **7**, 1180 (1913); **9**, 2898 (1915).

(760 mm.), m. p. −13 to −12°, $n^{20}D$ 1.4760; d^{20}_4 1.2078; and residue, 2.5 g. The catalyst was converted to 30 g. of red-brown viscous liquid; 14 g. of hydrogen chloride was recovered.

Anal. Calcd. for $C_6H_{11}Cl_3$: C, 38.00; H, 5.85; Cl, 56.15. Found: C, 38.10; H, 5.71; Cl, 56.42.

The presence of *t*-butyl chloride in the lower-boiling liquid (b. p. 45–60°) was proved by adding about 0.1 g. of aluminum chloride to a solution of 1 cc. of the liquid in 1 cc. of benzene. Hydrogen chloride was evolved and the catalyst was converted to a clear yellow liquid. The upper layer was decanted and the excess benzene was permitted to evaporate spontaneously (overnight). Crystals of *p*-di-*t*-butylbenzene (m. p. 76°) were deposited.

The trichlorohexane (m. p. −13 to −12°) was shown to be substantially the same as the product (m. p. −14 to −13°) obtained by the addition of *t*-butyl chloride to *cis*-dichloroethylene[2] in the presence of aluminum chloride. A mixture of the two products melted at −13.5 to −13°. Comparison of the infrared spectra[13] (see Fig. 1) confirmed their identity.

Reaction of *trans*-Dichloroethylene with Isobutane.—Comparatively little reaction occurred when a mixture of 30 g. of *trans*-dichloroethylene (purchased from Eimer and Amend), 55 g. of isobutane and 6 g. of aluminum chloride was rotated in the autoclave at room temperature. The liquid product consisted chiefly of unreacted dichloroethylene; about 6 g. of intermediate material and 2 g. of trichlorohexane fraction (b. p. 190–200°) were obtained.

Reaction of 1,1,2-Trichloro-3,3-dimethylbutane with Zinc.—A solution of 30 g. of the trichlorohexane in 100 g. of *n*-propyl alcohol was refluxed over 10 g. of zinc dust for sixteen hours. The product was distilled until addition of water to the distillate no longer yielded an appreciable amount of water-insoluble material. There was obtained 15.5 g. of reaction product, $n^{20}D$ 1.4272. Redistillation yielded 14 g. (75% yield) of chlorohexene (b. p. 102–103°; $n^{20}D$ 1.4260; d^{20}_4 0.8815; *MR* calcd., 34.26; *MR* obs. 34.42) and 1.5 g. of residue ($n^{20}D$ 1.4320).

Anal. Calcd. for $C_6H_{11}Cl$: C, 60.74; H, 9.35; Cl, 29.91. Found: C, 60.54; H, 8.85; Cl, 30.34.

The infrared spectrum[13] of the chlorohexene was compared with that of product (b. p. 102–104°, $n^{20}D$ 1.4262) obtained by the dehydrochlorination of 1,1-dichloro-3,3-dimethylbutane[5] over calcium chloride at 450°. The materials were found to be substantially the same (see Fig. 2).

Oxidation of 1-Chloro-3,3-dimethyl-1-butene.—A mixture of 6.5 g. of the chlorohexene and a solution of 16 g. of potassium permanganate in 500 cc. of water was stirred at ice-bath temperature for eight hours and then at 2–10° for an additional eight hours. All of the permanganate reacted. The product was filtered and the filtrate was evaporated to 30 cc. and acidified with dilute sulfuric acid. Steam distillation of the acidified solution yielded 3 cc. of organic material which was taken up in ether. Removal of the ether yielded 2.5 g. of trimethylacetic acid, b. p. 161–162°, m. p. 30–31°, characterized as the *p*-bromophenacyl ester, m. p. 76°.

Acknowledgment.—The continued interest of Professor V. N. Ipatieff is gratefully acknowledged.

Summary

A trichloride, 1,1,2-trichloro-3,3-dimethylbutane, is the principal product of the reaction of isobutane with 1,2-dichloroethylene in the presence of aluminum chloride at room temperature. It is obtained in 35% yield when *cis*-dichloroethylene is used, and in less than 5% yield when *trans*-dichloroethylene is used.

The probable mechanism of the reaction is presented.

It is shown that the reaction serves as a means of evaluating recently proposed mechanisms for the alkylation of isoparaffins with olefins.

RIVERSIDE, ILLINOIS RECEIVED MAY 28, 1947

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

Sulfur as a Promoter for a Nickel Catalyst in Dehydrogenation

BY HOMER ADKINS, DOROTHY S. RAE,[1] JAMES W. DAVIS,[2] GLENN F. HAGER[3] AND KATHRYN HOYLE[1]

The method of aromatizing a hydroaromatic compound by oxidizing it with benzene has given excellent results.[4] However, uniformly good yields were not obtained in attempting to duplicate results and extend the method. For example, in testing catalysts in the conversion of dicyclohexyl to diphenyl, *i.e.*

$$C_6H_{11}C_6H_{11} + 2C_6H_5 \xrightarrow[350°]{Ni} C_6H_5C_6H_5 + 2C_6H_{12}$$

the yield of diphenyl after reaction for two hours varied from 1 to 90%.

The variability in yields was found to depend upon the quality of the benzene used. Fractionation of a sample of benzene which gave good results showed that the lower boiling fractions were better than the higher boiling ones. A number of false leads were followed which, however, led to the discovery that the addition of 25 mg. of tetramethyl tin or of carbon tetrachloride to 20 ml. of benzene and 2 g. of catalyst improved the yield of diphenyl so that the conversion was approximately 80%. The fruitful observation was made that the more thoroughly the benzene was purified from thiophene the poorer were the yields of diphenyl obtained. It was then found that the addition of a suitable amount of thiophene to pure benzene gave excellent yields of diphenyl. For example, the per cent. conversions of dicyclohexyl to diphenyl were with varying amounts of thiophene

as follows: 0 mg., 1%; 1 mg., 32%; 2 mg., 61%; 3 mg., 79%; 5 mg., 79%; 20 mg., 89% and 40 mg., 4%. These results were with 5 g. of dicyclohexyl in 20 ml. of thiophene-free benzene and 2 g. of reduced nickel chromite catalyst for two hours at 350° in a 270 ml. (void) steel reaction vessel. When the amount of catalyst was reduced to 1 g. the optimum amount of thiophene was 10 mg., the conversion being the same as with 20 mg. of thiophene and 2 g. of catalyst. The use of larger ratios than 10 mg. of thiophene per gram of catalyst gave lower conversions of dicyclohexyl. Thiophene-free benzene was obtained by boiling commercial benzene with Raney nickel and distilling.

Diphenyl sulfide was found to be even more satisfactory than thiophene as a promoter for the nickel catalyst. Some of the data are summarized in Table I. It may be noted that the ratio of diphenyl sulfide to catalyst for the optimum results is about twice as large as for thiophene, as might be expected from the sulfur content of the two compounds.

[a] The "% solid" indicates the amount of diphenyl actually isolated. The "% conversion" given in this table and earlier is based upon refraction indices of the liquid product which may have also contained phenylcyclohexane as well as dicyclohexyl.

The effect of the addition of various amounts of thiophene, in promoting the formation of 4,5-benzohydrindene from 1-methyl-1,2-cyclopentanodecalin was also determined.[5] The reaction was carried out at 350° for eight hours on 4 g. of the hydroaromatic compound in 20 ml. of pure benzene with 2 g. of catalyst. The optimum ratio of thiophene to catalyst was found to be approximately 10 mg. per gram of catalyst just as in the aromatization of dicyclohexyl. The yields of 4,5-benzohydrindene varied from 5 to 27 to 39 to 44 to 33 to 20 to 15 as the thiophene was increased from 0 to 5 to 10 to 20 to 30 to 40 to 50 mg. for 2 g. of catalyst.

The catalyst used in the dehydrogenations described above was prepared by the reduction of "nickel chromite" as previously described.[4] The amount of nickel in the catalyst before reduction is from 25 to 30%. The lower value corresponds to the analysis for $NiCr_2O_4$, *i.e.*, nickel chromite. After reduction all catalysts analyzed contained about 11% nickel in the metallic state.[6] Thus it may be calculated that the optimum ratio is of the order to 1 part of sulfur to about 30 parts of reduced nickel. It appears that the catalyst is deactivated if the ratio of sulfur to reduced nickel is as much as 1 to 20.

The addition of thiophene to a Raney nickel catalyst did not render it active for the dehydrogenation of dicyclohexyl in the process. Neither thiophene nor diphenyl sulfide had any effect either in promoting or poisoning the activity of platinum or palladium catalysts for the aromatization of dicyclohexyl. The addition of small amounts of sulfur or of nickel sulfide to the nickel catalyst increased the formation of diphenyl from dicyclohexyl in benzene solution, but the effect was not nearly so marked as with thiophene or diphenyl sulfide. Carbon bisulfide did not promote the activity of the nickel catalyst.

Summary

Thiophene-free benzene is not effective with a nickel catalyst at 350° in the oxidation (dehydrogenation) of dicyclohexyl to diphenyl. However, benzene containing thiophene or diphenyl sulfide in a suitable proportion to the weight of catalyst present brings about an almost quantitative conversion of dicyclohexyl to diphenyl.

MADISON, WISCONSIN RECEIVED AUGUST 25, 1947

Preparation of Aldehydes from Alkenes by the Addition of Carbon Monoxide and Hydrogen with Cobalt Carbonyls as Intermediates

BY HOMER ADKINS AND GEORGE KRSEK

A U. S. patent issued to Otto Roelen[1] discloses a most interesting and rather surprising reaction, *i.e.*

$$RCH{=}CH_2 + CO + H_2 \xrightarrow[125\text{–}200\text{ atm.}]{90\text{–}200^\circ} RCH_2CH_2CHO$$

In the examples given in the patent the reaction is applied to ethylene, to oil of turpentine and to a lubricating oil. The catalysts specified contained cobalt, thorium oxide, kieselguhr and sometimes copper. The liquid product from ethylene was reported as made up of "40% propionaldehyde, 20% diethyl ketone and 40% higher boiling aldehydes and ketones or other oxygenated products." The results of inquiries made in Germany in 1945–1946 indicated the practicality of this so called "oxo process," particularly for the preparation of primary alcohols from alkenes through the reduction of the aldehydes first formed.

Apart from the merits of the process for commercial utilization, the Roelen reaction is obviously of considerable potential value in organic syntheses. We were interested in working out the best conditions for carrying out the reaction in standard steel equipment in the laboratory, and in ascertaining the yields of aldehyde from various unsaturated compounds. There are limitations to the reaction as, for example, two aldehydes might be obtained by the addition of carbon monoxide and hydrogen to an alkene $RCH{=}CH_2$, *i.e.*, RCH_2CH_2CHO and $RCH(CH_3)CHO$ as well as ketones where two molecules of the alkene and one of carbon monoxide reacted. Other reactions which may occur under the conditions used are the reduction of the alkene or the reduction or condensation of the carbonyl compounds.

In view of the well-known variation in the reactivity of alkenes, depending upon their structure, it seemed improbable that all compounds containing a carbon to carbon double bond would add carbon monoxide and hydrogen. However, it has been possible to produce aldehydes in the indicated yield from unsaturated compounds having as diverse structures as pentene-2 (75%), styrene (30%), methyl undecylenate (75%), ethyl crotonate (36%), diethyl fumarate (51%), allyl alcohol (18%) and allyl acetate (70%).

The range of conditions specified in the Roelen patent are, as might be expected, rather wide. However, after a considerable number of experiments, conditions were found under which the reaction has proceeded well with several unsaturated compounds. For example, 25 g. of commercial pentene-2 in 60 ml. of ether, with 0.6 g. of a reduced cobalt on kieselguhr catalyst, was placed in a steel reaction vessel having a 270-ml. void. The vessel was charged with carbon monoxide to a pressure of 2400 p.s.i. and hydrogen was added until the total pressure was 3600 p.s.i. The bomb was then shaken and heated to 150° when the pressure was 4300 p.s.i. During three hours the pressure dropped to 2200 p.s.i. The pressure drop was 96% of that required for the absorption of one mole of carbon monoxide and one mole of hydrogen per mole of pentene. The bomb was allowed to cool to room temperature, opened and the catalyst separated by centrifugation. The ether was removed by distillation and the product distilled under reduced pressure. The yield of aldehydes amounted to 75% of the theoretical. The boiling range of the product indicated that the aldehydes were those which would be produced by the alternate possible adducts of pentene-2, *i.e.*, $CH_3CH_2CH_2CH(CH_3)CHO$ and $CH_3CH_2CH(C_2H_5)CHO$.

Another representative synthesis was with 21.5 g. of methyl undecylenate in 80 ml. of ether under the same condition of temperature, pressure and catalyst as given for pentene-2. There was an incubation period of about twenty minutes after the reaction mixture reached 150°. However, 100% of the theoretical amount of carbon monoxide and hydrogen was then taken up within 140 minutes. Methyl 11-aldehydo-undecanoate was obtained in yield of 75% of the theoretical by distillation under reduced pressure.

While carrying out experiments of the type described above we began to suspect that we were not primarily concerned with a reaction in heterogenous catalysis where the reaction occurs at the surface of a solid, as in catalytic hydrogenation. The reaction mixture in successful syntheses was always colored, whereas in the failures it was colorless. In order to test the hypothesis that the catalyst was soluble in ether, the reactions were carried out in two stages. In the first stage an ether soluble cobalt compound, dicobalt octacarbonyl, was prepared by reaction of cobalt and carbon monoxide. The ether solution so obtained was used as the catalyst for the reaction of an alkene with carbon monoxide and hydrogen. The reaction, in the presence of the preformed dicobalt octacarbonyl, proceeded to completion within a few minutes at a temperature 25° lower than was necessary where a soluble cobalt compound was not used.

It appears that the synthesis may be considered to involve at least four reactions which may be outlined as

---

[1] Otto Roelen, U. S. Patent 2,327,066 (1943). The patent was vested in the Alien Property Custodian.

$$2Co + 8CO \xrightleftharpoons[150^\circ]{} [Co(CO)_4]_2 \qquad (1)$$

$$[Co(CO)_4]_2 \xrightleftharpoons[125^\circ]{H_2} 2Co(CO)_3COH \qquad (2)$$

$$4Co(CO)_3COH + 4CH_2{=}CH_2 \xrightarrow[125^\circ]{H_2} 4CH_3CH_2CHO + [Co(CO)_3]_4 \qquad (3)$$

$$[Co(CO)_3]_4 + 4CO \xrightleftharpoons[125^\circ]{} 2[Co(CO)_4]_2 \qquad (4)$$

In the first stage metallic cobalt is converted to dicobalt octacarbonyl (as in 1), a reaction which requires a higher temperature than the subsequent steps and even so goes more slowly. Dicobalt octacarbonyl is then reduced to cobalt tetracarbonyl hydride as indicated in (2). We suggest that a hydride is the reagent effective in the synthesis as shown in 3. The tetracobalt dodecacarbonyl $[Co(CO)_3]_4$, postulated as formed in 3, would be converted to dicobaltoctacarbonyl $[Co(CO)_4]_2$ by reaction with carbon monoxide as indicated in 4. The transformations involved are perhaps more clearly seen if the brackets in the formulas, indicating polymeric forms, are disregarded. The chemistry of the cobalt carbonyls, except that suggested in reaction 3, is covered in recent publications.[2,3]

The direct preparation of dicobalt octacarbonyl[4] from cobalt and carbon monoxide was carried out as follows: Raney cobalt (4 to 8 g.) was placed with 145 ml. of ether under carbon monoxide at 3200 p.s.i. and heated with shaking for five or six hours at 150°, after which the reaction vessel was allowed to cool. The pressure during the period of heating dropped from 4900 to 4300 p.s.i. and then to 2200 p.s.i. when the bomb was cooled to room temperature. The insoluble portion of the reaction mixture was removed by centrifugation. The dark reddish brown clear solution of 160 ml., including ether used in the transfers, contained 8.9 g. of dicobalt octacarbonyl. This compound was found to be soluble in ether to the extent of approximately 7.5 g. per 100 ml. of solution. The Raney cobalt has been specified above but the metal obtained by reduction of the Harshaw cobalt on kieselguhr catalyst, "Co-100 powder," has also been used.

Our practice has been to place the ether solution of dicobalt octacarbonyl as obtained from the reaction of cobalt and carbon monoxide in a 250 ml. Pyrex centrifuge bottle held in a wire guard, such as is used in hydrogenation at 2 or 3 atm. pressure. The bottle was provided with a rubber stopper held in place by a clamp. One leg of an inverted glass U tube extended through the stopper to the bottom of the flask. The other leg of the tube carried a stopcock. The container was kept in a refrigerator until a quantity of the catalyst solution was needed. The bottle was then allowed to warm up to room temperature or a little higher. Sufficient pressure was thus developed in the bottle so that the ether solution would flow through the U tube into a graduate when the stopcock was opened. The pressure developed over the solution at 30° was less than 0.5 atmosphere and was largely due to the vapor pressure of the ether.

The synthesis was carried out by placing 50 g. of allyl acetate, 40 ml. of the ether solution containing 2.2 g. of dicobalt octacarbonyl and 40 ml. of ether in a steel reaction vessel. Carbon monoxide was introduced to a pressure of 3200 p.s.i. and hydrogen added to a pressure of 4800 p.s.i. The pressure dropped to 4250 p.s.i. when the mixture was shaken and then rose to a maximum of 5050 p.s.i. when it was heated up to 115°. The bomb was then heated more slowly so that the temperature did not exceed 125°, by which time the pressure had already fallen to 4000 p.s.i. Within less than nine minutes the pressure had fallen to 3100 p.s.i. and the reaction was considered complete. The pressure in the bomb, when it had cooled to room temperature, was 2000 p.s.i. The drop in pressure during the reaction corresponded to the absorption of approximately 1 mole of each gas per mole of allyl acetate. When the product was worked up in the usual way γ-acetoxybutyraldehyde was obtained in 69% yield.

Hazards

The use of carbon monoxide under pressure with the highly poisonous cobalt carbonyls is not without danger. The ill effect of breathing carbon monoxide is sufficiently well known so that a warning is perhaps not necessary. According to Gilmont and Blanchard[2] "the odor of cobalt tetracarbonyl hydride is so intolerable that the danger from inhaling it is much less than from nickel tetracarbonyl. However, it is probably equally poisonous, and the same precautions should be taken as with nickel tetracarbonyl." The hydride decomposes even at room temperature, so that it will disappear rapidly from reaction mixtures held at atmospheric pressure, with the formation of dicobalt octacarbonyl. Fortunately this latter compound has a low vapor pressure and so may be handled with much less hazard than nickel tetracarbonyl. The dicobalt octacarbonyl also decomposes slowly in an open vessel to give carbon monoxide at room temperature. However, in an ether solution in a closed Pyrex bottle there is no development of pressure or appreciable decomposition at room temperature.

---

(3) Hieber, Schulten and Marin, *Z. anorg. allgem. Chem.*, **240**, 261–272 (1939).

(4) Apparently the preferred procedure for preparing dicobalt octacarbonyl has been that described by Gilmont and Blanchard.[2] Their procedure involves a series of reactions from cobalt nitrate to a potassium cobaltocyanide, to a potassium salt of cobalt tetracarbonyl hydride, to the hydride and then to the desired product. The process seems rather long and laborious, and while the weight of product is not stated it is apparently of the order of 2 g. The availability of steel reaction vessels and carbon monoxide under pressure makes the preparation of dicobalt octacarbonyl an easy and simple process.

First class steel equipment in good condition and in the hands of a competent operator are essential if accidents are to be avoided. There should be no leaks of any kind in the equipment. All transfers of material and washing of the reaction vessel should be carried out in a hood with rapid ventilation. The residual gas from the reaction vessel, which contains carbon monoxide and probably volatile cobalt compounds, should be burned in a Bunsen burner or slowly vented in the hood. The exit gas from all distillations or filtrations should be taken care of by large quantities of running water. Residues after distillation should be similarly disposed of, *all* operations being carried out under a hood.

It is said that the presence of traces of volatile cobalt or nickel compounds in the air may be detected by the color of the flame of a burner. The U. S. Bureau of Standards has developed a tube with a filler which we have found useful in detecting carbon monoxide in air. In some laboratories canaries are used as detectors for carbon monoxide.

Pressures higher than necessary probably were used. This was done so that a quantity of carbon monoxide and hydrogen, sufficient to react with the desired quantity of alkene, could be placed in the bomb. The ratio of carbon monoxide to hydrogen was probably higher than necessary. Incidentally it may be noted that successful hydrogenations, with nickel or copper chromium oxide, usually cannot be carried out for some time after a bomb has been used with carbon monoxide.

Experimental Details

Cobalt Catalysts.—The cobalt on kieselguhr catalyst was "Co-100 powder" as supplied by the Harshaw Chemical Co. of Cleveland, Ohio. According to the supplier the "Co-100 powder" would give 50% of its weight of cobalt when reduced. In our experience the reduced catalyst contained 12 to 15% metallic cobalt after treatment with hydrogen at 425° for four hours. Raney cobalt was made from the Raney 40% cobalt–60% aluminum alloy, by the procedure used for preparing Raney nickel.[5]

Isolation and Characterization of Products.—The products (27 g.) from pentene-2 (25 g.) distilled at 40–50° (12 mm.) A titration by the hydroxylamine method[6] with methyl orange as the indicator, showed that the aldehyde content, calculated for $C_5H_{13}CHO$, was 88%. Fractional distillation gave a fraction, b.p. 28–29° (10 mm.), $n^{25}\text{D}$ 1.4009, which was 95% aldehyde. The 2,4-dinitrophenylhydrazones melted over the range 90–120°. The boiling points of the two aldehydes[7,8] which would be produced from pentene-2 are too close together to make their separation feasible.

Styrene (18 g.) reacted as did the other unsaturated compounds giving a product (9.3 g.) boiling 78–120° (10 mm.) which analyzed[6] for 80% aldehyde. After fractionation hydrotropaldehyde, b.p. 76–77° (0.08 mm.), $n^{25}\text{D}$ 1.5148, was obtained 95% pure.[9] It gave a semicarbazone,[10] m.p. 153–154°.

Diethyl fumarate (17.2 g.) reacted with carbon monoxide and hydrogen as did methyl undecenylate. The product (14.3 g.) distilled at 85-120° (1 mm.) and was 70% pure by titration.[6] After fractionation the diethyl α-formyl-succinate[11] had a b.p. 104–105° (0.04 mm.), $n^{25}\text{D}$ 1.4486, and was 95% pure. It gave a semicarbazone, m.p. 124–125°, and a *p*-nitrophenylhydrazone, m.p. 100–101°.

The product (18 g.) from methyl undecylenate (21.5 g.) distilled at 125–150° at less than 1 mm. pressure, was 90% methyl 11-aldehydo-undecanoate according to hydroxylamine titration.[6] After fractionation the aldehyde, b.p. 144–147° (0.1 mm.), $n^{25}\text{D}$ 1.4432, was 97% pure.[12] The 2,4-dinitrophenylhydrazone had the m.p. 69–70°. Oxidation with air at 60° followed by saponification to dodecanedioic acid $(CH_2)_{10}(CO_2H)_2$, m.p. 122–124°, showed the aldehyde to be methyl 11-aldehydo-undecanoate,[13] $CHO(CH_2)_{10}CO_2CH_3$.

Allyl alcohol (29 g.) in ether reacted with carbon monoxide and hydrogen in the presence of 2.2 g. of dicobalt octacarbonyl, as has been described for allyl acetate. The product (16 g.) distilled at 80–100° (28 mm.) and was found to be 55% pure. After fractionation γ-hydroxybutyraldehyde, 96% pure, b.p. 98–99° (35 mm.), $n^{25}\text{D}$ 1.4384, gave a 2,4-dinitrophenyl-hydrazone, m.p. 178–179°. The aldehyde was oxidized with air at 60° and lactonized to give an 80% yield of butyrolactone,[14] b.p. 90–91° (25 mm.), $n^{25}\text{D}$ 1.4345, having a saponification equivalent of 85.

The product (46 g.) from the reaction as described above of allyl acetate (50 g.) distilled at 60–90° (10 mm.) and was 92% pure by titration. After fractionation the γ-acetoxybutyraldehyde, b.p. 59–60° (1 mm.), $n^{25}\text{D}$ 1.4245, was 94% pure and gave a 2,4-dinitrophenylhydrazone, m.p. 180–181°. The aldehyde was oxidized with air at 60° in 97% yield to give γ-acetoxybutyric acid, b.p. 112–113° (1 mm.), $n^{25}\text{D}$ 1.4343, which was by titration 99% pure. The acid was hydrolyzed and lactonized to butyrolactone. *Anal.* Calcd. for γ-acetoxybutyraldehyde $C_6H_{10}O_3$: C, 55.4; H, 7.8, Found: C, 55.4; H, 8.0. *Anal.* Calcd. for γ-acetoxybutyric acid $C_6H_{10}O_4$: C, 49.3; H, 6.7. Found: C, 49.3; H, 7.1.

Ethyl crotonate (29 g.) in ether reacted with carbon monoxide and hydrogen in the presence of dicobalt octacarbonyl (2.2 g.) as described for allyl acetate. The product (19.1 g.), b.p. 96–100° (35 mm.), was 96% pure by titration. The ethyl β-formylbutyrate distilled at 58–59° (0.01 mm.), had $n^{25}\text{D}$ 1.4236 and gave a 2,4-dinitrophenylhydrazone, m.p. 87–88°.

Anal. Calcd. for $C_7H_{11}O_3$: C, 58.3; H, 8.4. Found: C, 58.5; H, 8.5.

Summary

Several aldehydes, *i.e.*, hexaldehydes, hydratropaldehyde, diethyl α-formylsuccinate, methyl 11-aldehydoundecanoate, γ-hydroxybutyraldehyde, γ-acetoxybutyraldehyde and ethyl β-formylbutyrate, have been prepared in an average yield of 50% by the addition of carbon monoxide and hydrogen to the alkene linkage in pentene-2, styrene, diethyl fumarate, methyl undecylenate, allyl alcohol, allyl acetate or ethyl crotonate.[15]

The first step in the catalysis of the reaction appears to be the formation of an ether-soluble cobalt compound, dicobalt octacarbonyl. While the conversion of the alkene to the aldehyde may be brought about at 150° in the presence of cobalt

[15] Succindialdehyde-1,1-diacetate and γ-carbethoxypropionaldehyde were prepared in 74–75% yields from 50 g. of allylidene diacetate and of ethyl acrylate, respectively, with 0.6 g. of dicobalt octacarbonyl as a catalyst in benzene at 125° and 1200 to 4000 p. s. i. (Added in proof, January 5, 1948.)

on a support, it appears advantageous to use preformed dicobalt octacarbonyl in ether or other solvent for the catalysis of the synthetic reaction. The dicobalt octacarbonyl is readily made at 150° by the direct reaction of cobalt and carbon monoxide, and may be kept in ether for use as needed as a catalyst. The addition of carbon monoxide and hydrogen to an alkene goes very rapidly at 125° or lower in the presence of dicobalt octacarbonyl. The reactions may be carried out at 100 to 300 atm. pressure in the steel reaction vessels ordinarily used for hydrogenation.

The poisonous properties of carbon monoxide and of the cobalt carbonyls suggest that considerable care be exercised in carrying out the syntheses of aldehydes for alkenes by the method outlined.

Some Quinoline Derivatives of 2-Amino-*p*-cymene[1]

BY ALVIN SAWYER WHEELER AND JOSEPH NISBET LECONTE

Introduction

This paper records a study of several methyl homologs of 5-isopropylquinoline. The 8-methyl derivative was prepared by the method of Cohn and Gustavson,[2] and the 2,4,8-trimethyl compound was obtained by cyclizing, according to Bulow and Issler,[3] the compound I obtained by condensing 2-amino-*p*-cymene with acetylacetone.

The 8-methyl derivative and the 2,8-dimethyl compound of Phillips and Goss[4] on reduction with sodium and absolute ethanol yielded py-tetrahydroquinolines.

Experimental

Temperatures are in °C., uncorrected.

5-Isopropyl-8-methylquinoline.—2-Amino-*p*-cymene (59.6 g.), 2-nitro-*p*-cymene (35.8 g.), 80% acetic acid (60 cc.), 95% sulfuric acid (54 cc.) and glycerol (100 g.) were treated in the manner of Cohn and Gustavson[2] to yield 20 g. (27%) of the quinoline which is a pale yellow oil with the characteristic quinoline-like odor; b. p. 175° (35 mm.); $d^{26.2}_{4}$ 1.0287; n^{27}_{D} 1.5798. *Anal.* Calcd. for $C_{13}H_{15}N$: N, 7.56. Found: N, 7.43. Chloroplatinate, m. p. 212° (shrinks at 160°). *Anal.* Calcd. for $C_{13}H_{17}NCl_6Pt$: Pt, 24.82. Found: Pt, 24.90. Picrate, m. p. 166–168°. *Anal.* Calcd. for $C_{19}H_{18}N_4O_7$: N, 13.52. Found: N, 13.44.

Reduction of this quinoline with sodium and absolute ethanol yielded py-tetrahydro-5-isopropyl-8-methylquinoline, b. p. 165–167° (27 mm.). *Anal.* Calcd. for $C_{13}H_{19}N$: N, 7.40. Found: N, 7.39. Chloroplatinate, m. p. 198°. *Anal.* Calcd. for $C_{13}H_{21}NCl_6Pt$: Pt, 24.22. Found: Pt, 24.37.

2,8-Dimethyl-5-isopropylquinoline was prepared in the manner formerly employed by Phillips and Goss.[4] Chloroplatinate, m. p. 226° (shrinks 212°). *Anal.* Calcd. for $C_{14}H_{19}NCl_6Pt$: Pt, 23.62. Found: Pt, 23.80. Picrate, m. p. 142°. *Anal.* Calcd. for $C_{20}H_{20}N_4O_7$: N, 14.52. Found: N, 14.60.

Reduction of this quinoline with sodium and absolute ethanol yielded py-tetrahydro-2,8-dimethyl-5-isopropylquinoline, m. p. 65°. *Anal.* Calcd. for $C_{14}H_{21}N$: N, 6.89. Found: N, 6.78. Chloroplatinate, m. p. 202° (shrinks 199°). *Anal.* Calcd. for $C_{14}H_{23}NCl_6Pt$: Pt, 23.39. Found: Pt, 23.80.

Compound I.—A mixture of 2-amino-*p*-cymene (15.05 g.) and acetylacetone (10 g.) was refluxed on a steam-bath for three hours, during which water appeared in the mixture and the mixture became dark red in color. Distillation of the mixture under reduced pressure yielded 11.8 g. of a pale yellow oil, b. p. 184–185° (22 mm.), $d^{27.5}$ 0.9827, insoluble in water, easily soluble in alcohol and ether, blood-red color with ferric chloride, and no reaction with the Hinsberg reagent. *Anal.* Calcd. for $C_{15}H_{21}ON$: N, 6.06. Found: N, 5.89. Chloroplatinate, m. p. 177°. *Anal.* Calcd. for $C_{15}H_{23}ONCl_6Pt$: Pt, 21.93. Found: Pt, 22.04.

2,4,8-Trimethyl-5-isopropylquinoline.—Ninety-five per cent. sulfuric acid (60 cc.) was cooled to 0° and 19.5 g. of compound I was cautiously added. The mixture was allowed to stand ten minutes, heated on a steam-bath for one hour, poured into a mixture of ice (100 g.) and water (60 cc.), made basic with ammonium hydroxide, saturated with sodium chloride and extracted with ether. Distillation of the dried ether solution under reduced pressure yielded 5 g. of a pale yellow oil, b. p. 170–178° (22 mm.) (boiling mostly at 177–178°). *Anal.* Calcd. for $C_{15}H_{19}N$: N, 6.57. Found: N, 6.70. Chloroplatinate, m. p. 213–216°. *Anal.* Calcd. for $C_{15}H_{21}NCl_6Pt$: Pt, 22.85. Found: Pt, 22.89. Picrate, m. p. 181–183°. *Anal.* Calcd. for $C_{21}H_{22}N_4O_7$: N, 12.67. Found: N, 12.58.

Summary

1. Some methyl homologs of 5-isopropylquinoline have been prepared.

2. 8-Methyl and 2,8-dimethyl-5-isopropylquinolines were reduced to their corresponding py-tetrahydroquinolines.

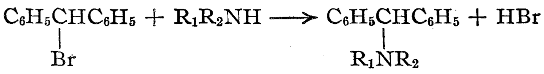
N-Substituted Benzohydrylamines

BY NORMAN H. CROMWELL AND W. E. FITZGIBBON

Numerous investigators[1] have reported the preparation of benzohydrylamines.

Sommelet[1a] found that when such compounds are prepared by condensing benzohydryl bromide with various amines the medium should not be a reactive one such as an alcohol because it is possible for the benzohydryl ether to form instead of the desired benzohydryl amine, especially at elevated temperatures.

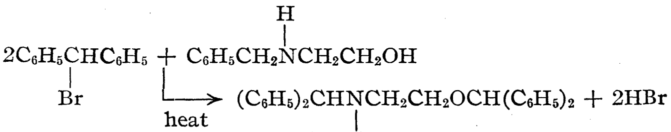
N-Methyl-*p*-methoxybenzylamine, N-methylethanolamine and N-benzylethanolamine each was condensed with benzohydryl bromide in benzene solution using essentially the conditions reported previously[1j] to give good yields of the desired N-substituted benzohydryl amines, (I), (II) and (III). The latter two compounds were isolated as their hydrochlorides.



$$C_6H_5\underset{\underset{Br}{|}}{C}HC_6H_5 + R_1R_2NH \longrightarrow C_6H_5\underset{\underset{R_1NR_2}{|}}{C}HC_6H_5 + HBr$$

(I), $R_1 = CH_3$; $R_2 = p\text{-}CH_3OC_6H_4$
(II), $R_1 = CH_3$; $R_2 = CH_2CH_2OH$
(III), $R_1 = C_6H_5CH_2$; $R_2 = CH_2CH_2OH$

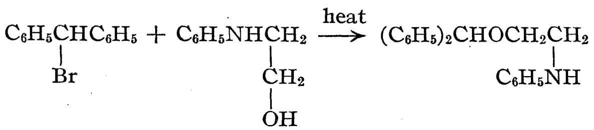
In one experiment N-benzylethanolamine was heated with benzohydryl bromide to the boiling point of the toluene solution. From this reaction mixture only the amino ether (IV) was isolated, resulting from reaction of the bromide with both the amino group and the hydroxyl group of the N-benzylethanolamine.



$$2C_6H_5\underset{\underset{Br}{|}}{C}HC_6H_5 + C_6H_5CH_2\overset{\overset{H}{|}}{N}CH_2CH_2OH \xrightarrow{\text{heat}} (C_6H_5)_2CH\underset{\underset{C_6H_5CH_2}{|}}{N}CH_2CH_2OCH(C_6H_5)_2 + 2HBr$$

(IV)

N-Phenylethanolamine proved to be too nonreactive to condense with benzohydryl bromide under the usual conditions. Moreover, at elevated temperatures the reaction proceeded in such a manner as to give the amino ether (V), resulting from reaction of the benzohydryl bromide with only the hydroxyl group of the N-phenylethanolamine.

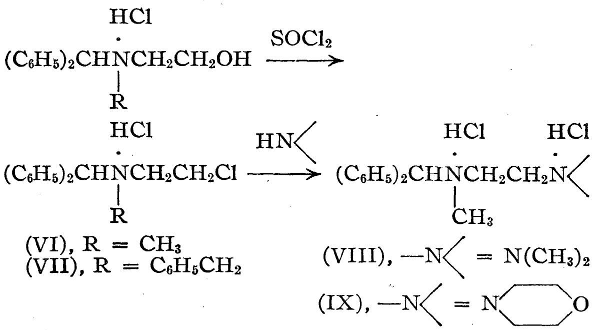


$$C_6H_5\underset{\underset{Br}{|}}{C}HC_6H_5 + C_6H_5NH\underset{\underset{\underset{OH}{|}}{CH_2}}{\underset{|}{C}}H_2 \xrightarrow{\text{heat}} (C_6H_5)_2CHOCH_2\underset{\underset{C_6H_5NH}{|}}{C}H_2$$

(V)

When this condensation was attempted in aqueous alcohol in the presence of potassium carbonate the benzohydryl bromide was slowly converted to benzohydrol. Using absolute alcohol and anhydrous potassium carbonate at reflux temperature for four hours, the benzohydryl bromide apparently reacted only with the ethyl alcohol to give benzohydryl ethyl ether. When (V) was treated with thionyl chloride only the hydrochloride of (V) resulted, indicating the absence of the alcohol group.

The low reactivity of the amino group in N-phenylethanolamine with the benzohydryl bromide would seem to be the result of the reduced electron density at the nitrogen, combined with the steric difficulties involved in the approach of the benzohydryl group toward this nitrogen that is attached to both a phenyl and an ethanol group.



$$(C_6H_5)_2CH\underset{\underset{R}{|}}{\overset{\overset{HCl}{\cdot}}{N}}CH_2CH_2OH \xrightarrow{SOCl_2} (C_6H_5)_2CH\underset{\underset{R}{|}}{\overset{\overset{HCl}{\cdot}}{N}}CH_2CH_2Cl \xrightarrow{HN\langle} (C_6H_5)_2CH\underset{\underset{CH_3}{|}}{\overset{\overset{HCl}{\cdot}}{N}}CH_2CH_2\overset{\overset{HCl}{\cdot}}{N}\langle$$

(VI), $R = CH_3$
(VII), $R = C_6H_5CH_2$
(VIII), $-N\langle = N(CH_3)_2$
(IX), $-N\langle = N\qquad O$

The hydrochlorides of the N-benzohydrylethanolamines (II) and (III) were each readily converted to the β-chloroethylamine hydrochlorides (VI) and (VII) by reaction with thionyl chloride in chloroform solution.

The β-chloroethylamine hydrochloride (VI) was condensed with dimethylamine and with morpholine, respectively, to give the substituted ethylenediamines (VIII) and (IX), isolated as their dihydrochlorides.

The various N-substituted benzohydrylamines resulting from this investigation have been submitted for pharmacological screen testing, the results of which will be reported elsewhere.

Experimental

Benzohydryl Bromide.—The benzohydryl bromide used in these condensations was prepared from benzohydrol in 90% yields by the method given by Courtot,[2] and purified

to a colorless crystalline product by vacuum distillation, b. p. 176–180° (17 mm.).

N-Methyl-N-(*p*-methoxylbenzyl)-benzohydrylamine (I).—This compound was prepared by the method given previously[1j] for the preparation of N-benzohydrylmorpholine, by condensing benzohydryl bromide with N-methyl-*p*-methoxybenzylamine[3] (see Table I).

N-Benzohydrylethanolamine Hydrochlorides (II) and (III).—Pure benzohydryl bromide (24.7 g., 0.10 mole) was mixed with 14.8 g. (0.21 mole) of N-methylethanolamine[4] and with 31.7 g. (0.21 mole) of N-benzylethanolamine,[5] respectively, in 30 ml. of dry benzene. After standing for twelve hours at room temperature the solutions were diluted with 300 ml. of dry ether to complete the precipitation of the by-product hydrobromides of the starting ethanol amines. The ether–benzene solutions of the products were decanted from the oily by-product and washed with ten 10-ml. portions of water and dried for twelve hours over anhydrous calcium sulfate.

The hydrochlorides (II) and (III) were precipitated by passing dry hydrogen chloride gas into the solutions. These crude products were recrystallized twice from mixtures of absolute alcohol and dry ether to give colorless granular products, (II) and (III).

N-Benzohydryl-N-benzyl-β-aminoethyl Benzohydryl Ether, (IV).—Pure benzohydryl bromide (16.05 g., 0.065 mole) was mixed with 20.8 g. (0.137 mole) of N-benzylethanolamine in 16 ml. of toluene and refluxed for one hour. After standing at room temperature for twelve hours 100 ml. of dry ether was added to complete the precipitation of the by-product hydrobromide. The ether–toluene layer was decanted from the oily hydrobromide and washed with water. Evaporation of the solvent left an oil which was dissolved in alcohol. Addition of water to this solution and cooling caused an oily solid to form (3.6 g.). Recrystallization of this product first from boiling absolute alcohol and then from boiling petroleum ether (b. p. 60–70°) gave a colorless granular product (IV).

N-Phenyl-β-aminoethyl Benzohydryl Ether, (V).—When 10 g. of benzohydryl bromide was mixed with 11.1 g. (2.1 equiv.) of N-phenylethanolamine in 25 ml. of dry benzene and refluxed for two hours no precipitate of an amine hydrobromide appeared. The benzene was removed by distillation and the residual dark oil heated on an oil-bath for two hours at 130–140°. Dry ether and benzene were added to the cooled, dark mass to cause precipitation of a grey powder which was removed by filtration (10.8 g. as compared with the expected theoretical weight of 8.9 g. of N-phenylethanolamine hydrobromide). The filtrate was washed with water, dried and evaporated to leave a brown oil. Crystallization from benzene and petroleum ether followed by recrystallization from alcohol and water gave a colorless, flaky product (V).

When a sample of (V) was treated with thionyl chloride according to the procedure given below for the preparation of β-chloroethylamines only the hydrochloride of (V) resulted, identical with a sample prepared by treating (V) with dry hydrogen chloride gas in dry ether. When a sample of (V) was treated with a solution of nitrous acid in an alcohol–water mixture a pale yellow oil precipitated which could not be crystallized, but which gave the Liebermann test[6] for a nitrosamine.

N-Benzohydryl-β-chloroethylamine Hydrochlorides (VI) and (VII).—Cold solutions of the N-benzohydrylethanolamines (II) and (III) (0.10 mole) in 100 ml. of chloroform were treated dropwise over a period of one-half hour with an ice-cold solution of 0.20 mole of thionyl chloride in 15 ml. of chloroform. The solutions were allowed to come to room temperature and then refluxed for two hours. The solvent and excess thionyl chloride were removed under reduced pressure on a steam-bath. The resulting white powders were recrystallized three times from absolute alcohol and ether to give colorless granular products (VI) and (VII).

N-Benzohydryl-N-methyl-β-dimethylaminoethylamine Dihydrochloride, (VIII).—Anhydrous dimethylamine (5.41 g., 0.12 mole) was added to a solution of 8.9 g. (0.030 mole) of (VI) in 100 ml. of absolute alcohol at room temperature and allowed to stand in a tightly stoppered flask for ninety-six hours. The solution was refluxed for an hour and the solvent removed by distillation. The solid residue was extracted with four 20-ml. portions of ether but this extract left no residue on evaporation.

The ether-insoluble residue was mixed with 10 ml. of 6 *N* sodium hydroxide and the resulting oil extracted with

ether. The ether extract was washed with four 10-ml. portions of 6 *N* sodium hydroxide. The ether solution was dried and evaporated to leave a yellow oil which was dissolved in 15 ml. of absolute alcohol and treated with dry hydrogen chloride gas. Addition of dry ether precipitated a colorless solid which was recrystallized from absolute alcohol and dry ether to give (VIII).

N-Benzohydryl-N-methyl-β-morpholinoethylamine Dihydrochloride (IX).—A solution of 7.0 g. (0.08 mole) of morpholine and 7.41 g. (0.025 mole) of (VI) in 25 ml. of 70% ethyl alcohol was placed in a closed flask and allowed to stand at room temperature for twenty-four hours. The solvent was removed by distillation from a steam-bath under reduced pressure. The residue was extracted with dry ether and the ether solution washed with water, dried and evaporated to leave a colorless oil that could not be crystallized from petroleum ether or alcohol–water mixtures. The oily product was dissolved in 30 ml. of absolute alcohol and dry hydrogen chloride gas added. After addition of 200 ml. of dry ether a colorless crystalline precipitate formed which was recrystallized from absolute alcohol and dry ether to give (IX).

Summary

1. The synthesis of certain N-benzohydrylethanolamines by reaction of benzohydryl bromide with ethanolamines of the type $RNHCH_2CH_2OH$ has been studied. When R was methyl or benzyl the desired N-benzohydrylethanolamines were obtained, but when R was phenyl only ether formation resulted.

2. The N-benzohydrylethanolamines were converted to N-benzohydryl-β-chloroethylamines, one of which was condensed with dimethylamine and morpholine, respectively, to give substituted ethylenediamines.

LINCOLN, NEBRASKA RECEIVED SEPTEMBER 12, 1947

Isomeric Unsaturated Esters. II. The Dehydration of Ethyl 3-Hydroxy-2-ethyl-3-methylbutanoate

BY RALPH C. HUSTON, GORDON L. GOERNER AND HANS H. GYÖRGY

In a previous communication[1] the dehydration of ethyl 3-hydroxy-2,3-dimethylbutanoate was shown to yield a mixture of α,β and β,γ unsaturated esters which were readily separated because of their large difference in boiling points. The β,γ unsaturated ester, contrary to the report in the literature, was found to possess the lower boiling point. It appeared that other unsaturated esters might be recorded erroneously.

Blaise and Maire[2] dehydrated ethyl 3-hydroxy-2-ethyl-3-methylbutanoate (I) and obtained an unsaturated ester boiling at 167°. To this they assigned formula III. They also obtained a small quantity of an ester boiling at 175°.

$$\underset{\text{I}}{(CH_3)_2C(OH)CH(C_2H_5)COOC_2H_5} \longrightarrow$$

$$\underset{\text{II}}{CH_2{=}C(CH_3)CH(C_2H_5)COOC_2H_5}, \text{ and}$$

$$\underset{\text{III}}{(CH_3)_2C{=}C(C_2H_5)COOC_2H_5}$$

This was assumed to be an isomer of the low boiling ester. Hydrolysis of the ester boiling at 167° yielded an acid distilling at 100° (10 mm.). If esters II and III are analogous to those obtained by Huston and Goerner,[1] ester II should boil at 167° and ester III at the higher temperature. Further evidence that Blaise and Maire had probably assigned the incorrect formula to their low boiling ester was found in the fact that Crossley and LeSueur[3] report a boiling point of 175–180° (748 mm.) for a mixture of ester III and ethyl 2-(1-methylethyl)-2-butenoate obtained by dehydrobromination of ethyl 2-bromo-2-ethyl-3-methylbutanoate by diethylaniline.

Ester I was prepared from propanone and ethyl 2-bromobutanoate by the Reformatsky reaction. It proved to be more stable than expected. An attempt to dehydrate it with dry hydrogen chloride[4] was unsuccessful. Phosphorus pentoxide[2,5] in benzene gave the unsaturated esters in good yield. Esters II and III could be separated readily in approximately equal quantities by fractionation under diminished pressure.

The proof of structure consisted of hydroxylating the esters to the glycols[6] IV and VI and splitting these into aldehydes and ketones by means of "ceric perchlorate"[1,7] or by thermal decomposition. The low boiling ester gave glycol IV. This was split into methanal (which is oxidized to carbon dioxide and water) and ethyl 3-keto-2-ethylbutanoate (V). The solution containing compound V gave 2-pentanone upon alkaline hydrolysis. The high boiling ester gave glycol VI. On distillation this decomposed into propanone and 2-ketobutanoic acid.

VI

$$CH_3-\underset{OH}{\overset{CH_3}{C}}-\underset{OH}{\overset{C_2H_5}{C}}-COOC_2H_5 \xrightarrow{\Delta} CH_3COCH_3 + C_2H_5COCOOH$$

The ketones were identified through the 2,4-dinitrophenylhydrazones. Catalytic hydrogenation of both unsaturated esters yielded ethyl 2-ethyl-3-methylbutanoate.[8] Here again[1] the reduction of the β,γ ester was found to proceed much more easily than the reduction of the α,β isomer.

Hydrolysis of the esters yielded the corresponding unsaturated acids. The acid obtained from the high boiling ester III appears to be identical with the β,β-dimethyl-α-ethylacrylic acid of Kon, Smith and Thorpe[9] which melted at 49.5°. The acid obtained from the low boiling ester appears to be identical with the acid obtained by Blaise and Maire.[2]

Experimental

All melting points and micro boiling points are corrected.

Ethyl 3-Hydroxy-2-ethyl-3-methylbutanoate (I) was prepared by the Reformatsky reaction, using 1.5 moles of propanone per mole of ethyl 2-bromobutanoate and excess zinc, as suggested by Perkin and Thorpe.[10] The propanone was dried over anhydrous potassium carbonate and the benzene over sodium. Ethyl 2-bromobutanoate was prepared by the bromination of butanoic acid[11] followed by its subsequent esterification.[12] Ten-mesh zinc was cleaned and dried by the method of Fieser and Johnson.[13]

A solution of 15 g. of acetone and 15 g. of ethyl 2-bromobutanoate in 75 ml. of benzene was added to 245 g. (3.75 moles) of zinc. The reaction was initiated by the addition of a small crystal of iodine and slight heating. When vigorous reflux had begun, a solution of the rest of the reactants was added at a rate rapid enough to maintain reflux. Using 585 g. (3 moles) of ethyl 2-bromobutanoate and 261 g. (4.5 moles) of propanone in 750 ml. of benzene, a reaction time of one hour was required with a maximum reaction temperature of 75°.

After refluxing for one and one-half hours the reaction mixture was cooled and poured into 1800 ml. of cold 10% (volume) sulfuric acid. After forty-five minutes the clear benzene layer was removed and the acid layer washed with benzene. The combined benzene extracts were washed with 250 ml. of 5% (volume) sulfuric acid, 250 ml. of 10% (weight) sodium carbonate, and 400 ml. of water. These were then dried over anhydrous sodium sulfate.

Separation of I was attained by the removal of the benzene under reduced pressure and the fractionation of the ester through a 60-cm. Fenske-type column packed with 3/32-inch glass helices. (This column was used for all subsequent fractionations.) The yield of ethyl 3-hydroxy-2-ethyl-3-methylbutanoate was 163 g. (31%) distilling at 76 to 77° (3 mm.), $n^{20}{}_D$ 1.4310, $d^{20}{}_4$ 0.9668, γ_{20} 27.8 (du Noüy, cor.[14]).

Dehydration of Ethyl 3-Hydroxy-2-ethyl-3-methylbutanoate.—One hundred seventy-four grams (1 mole) of ester I was refluxed for two hours with 177 g. of phosphorus pentoxide in three volumes (555 ml.) of benzene.[2,5] The supernatant liquid was decanted and fractionated under reduced pressure. The yield of ethyl 2-ethyl-3-methyl-3-butenoate (II) boiling at 57° (13 mm.) was 49 g., (31%, based on hydroxy ester); micro b.p. 167° (741 mm.), $n^{20}{}_D$ 1.4250, $d^{20}{}_4$ 0.9005, γ_{20} 20.61 (drop-weight, cor.[15]).

Anal. Calcd. for $C_9H_{16}O_2$: C, 69.19; H, 10.32. Found: C, 69.25; H, 10.30.

Fifty-one grams (33%, based on hydroxy ester) of III was obtained boiling at 67° (13 mm.); micro b.p. 180° (741 mm.), $n^{20}{}_D$ 1.4430, $d^{20}{}_4$ 0.9492, γ_{20} 24.05 (drop-weight, cor.[15]).

Anal. Calcd. for $C_9H_{16}O_2$: C, 69.19; H, 10.32. Found: C, 69.27; H, 10.25.

The total yield of the unsaturated esters was 20%, based on the bromo ester. By dehydrating the crude reaction mixture without isolating the hydroxy ester, a yield of 25% was obtained.

Reduction of the Unsaturated Esters.—One-tenth mole of the ester, 150 ml. of ethanol, 0.1 g. of the platinic oxide catalyst,[16] and 50 lb. of hydrogen pressure were used. The low boiling ester (II) was completely reduced in thirty minutes. In the case of the high-boiling ester (III), four hours were necessary for complete reduction. Ethyl 2-ethyl-3-methylbutanoate, micro b.p. 167° (744 mm.), was recovered upon fractionation,[8] $n^{20}{}_D$ 1.4100; $d^{20}{}_4$ 0.8686; γ_{20} 22.30 (drop-weight, cor.[15]).

Degradation of Ethyl 2-Ethyl-3-methyl-3-butenoate (II).—Seven and eight-tenths grams (0.05 mole) of the ester was dissolved in a 7% solution of hydrogen peroxide (0.05 mole) in 2-methyl-2-propanol. Two milliliters of osmium tetroxide solution was added according to the procedure of Milas and Sussman.[6] After fifteen minutes the 2-methyl-2-propanol was removed under reduced pressure and the glycol treated with "ceric perchlorate."[1,7] When the "ceric perchlorate" no longer gave a red color, the solution was made alkaline with potassium hydroxide and was refluxed for four hours. Air was bubbled through the warmed reaction mixture and then into a 5% solution of 2,4-dinitrophenylhydrazine in 20% perchloric acid. The precipitate obtained was crystallized twice from ethanol, m.p. 142–144°. A mixed melting point with a known sample of 2-pentanone-2,4-dinitrophenylhydrazone (m.p. 143–144°) gave no depression.

Degradation of Ethyl 2-Ethyl-3-methyl-2-butenoate (III).—The glycol of this ester was synthesized as described above. It proved to be thermally unstable, yielding propanone and 2-ketobutanoic acid. On distillation from a Claisen flask at 15 mm. pressure, the 2-ketobutanoic acid was collected as distillate. The 2,4-dinitrophenylhydrazone of propanone was recovered by placing a trap containing a 5% solution of 2,4-dinitrophenylhydrazine in 20% perchloric acid in the vacuum line. The formation of propanal by decarboxylation of the keto acid caused some difficulty in the isolation of the propanone-2,4-dinitrophenylhydrazone.

The 2,4-dinitrophenylhydrazone of the propanone obtained by the degradation melted at 124–126°; a mixed melting point with an authentic sample of propanone-2,4-dinitrophenylhydrazone (m.p. 126°) gave no depression.

The 2,4-dinitrophenylhydrazone of the 2-ketobutanoic acid melted at 139–141°. The method described by Tschelinzeff and Schmidt[17] was used for the preparation of 2-ketobutanoic acid. Its 2,4-dinitrophenylhydrazone was prepared in perchloric acid solution and melted at 139–141°. A mixed melting point with the above degradation product gave no depression. No melting point is recorded in the literature for this derivative. *Anal.* Calcd. for $C_{10}H_{10}N_4O_6$: N, 19.86. Found: N, 19.65.

Hydrolysis of the Unsaturated Esters.—Both esters proved difficult to hydrolyze. Hydrolysis was carried out

by refluxing in alcoholic potassium hydroxide solution and subsequently neutralizing with hydrochloric acid.

Ethyl 2-ethyl-3-methyl-3-butenoate (II) yielded an acid, b.p. 85° at 4 mm.; $n^{20}D$ 1.4400; neutralization equivalent calcd. 128, found 130. This acid was isolated with difficulty due to the general tendency of β,γ-unsaturated acids to rearrange to the conjugated α,β-acids in the presence of base.[18] Hydrolysis of (III) yielded a white solid which, on recrystallization from water–ethanol, gave plates melting at 47–48°; b.p. 85° (2 mm.); micro b.p. 218° (741 mm.) with decomposition; neutralization equivalent calcd. 128, found 129.

Summary

Ethyl 3-hydroxy-2-ethyl-3-methylbutanoate has been dehydrated to ethyl 2-ethyl-3-methyl-2-butenoate and ethyl 2-ethyl-3-methyl-3-butenoate. These have been isolated and their physical constants determined.

The structure of these unsaturated esters has been assigned on the basis of the ketones to which they have been degraded.

These unsaturated esters have been hydrolyzed and the corresponding acids isolated.

Some Derivatives of 2-Acylthiophenes[1]

BY E. CAMPAIGNE AND JAMES LOREN DIEDRICH[2]

Several acylthiophenes ranging in side-chain length from two to eighteen carbon atoms[3] have been prepared, usually by some modification of the procedure described by Johnson and May[4] for the preparation of 2-acetylthiophene. The capric acid derivative was prepared by Schleicher,[5] but the homologous 2-hexanoyl, 2-octanoyl, and 2-nonanoylthiophenes have not been synthesized previously.[5a]

The acylthiophenes provide convenient intermediates for the preparation of the corresponding alcohols and alkylthiophenes. The thienyl ketones were readily reduced to the corresponding secondary alcohols by using aluminum isopropoxide in isopropyl alcohol as described by Mowry, Renoll and Huber[6] for 2-acetylthiophene; however, the yields were somewhat lower with the higher molecular weight ketones. The alkylthiophenes were prepared from the ketones by a slight modification of the Clemmensen method described by Fieser and Kennelly.[7]

In addition to the ketones, alcohols and alkylthiophenes, the characteristics of which are summarized in Table I, the oximes, semicarbazones and 2,4-dinitrophenylhydrazones of the ketones, and the 5-chloromercuri derivatives of the alkylthiophenes were prepared and characterized.

An attempt was made to prepare suitable urethans or esters of the secondary alcohols as solid derivatives but the hydroxy group is relatively inactive, apparently due to hindrance of the α-carbon in 2-substituted thiophenes,[8] and no derivatives were isolated.

Experimental

Acylthiophenes.—The procedure used for the ketone preparations was essentially that of Johnson and May[4] for the preparation of acetylthiophene. The thiophene, obtained from the Socony–Vacuum Oil Company, was distilled through a column and the fraction boiling from 82–84° was collected and stored in brown bottles until used. In each acylation freshly distilled stannic chloride was employed. The best yields of the ketones were obtained under the following conditions: 0.5 mole of thiophene and 0.5 mole of the required acid chloride were dissolved in 500 ml. of benzene in a 3-necked flask equipped with a mechanical stirrer, thermometer and dropping funnel, and the mixture was cooled to 0° with stirring. Stannic chloride (0.5 mole) was then added dropwise over a period of one and one-half hours, maintaining the temperature at 0°. When all of the stannic chloride had been added, the cooling bath was removed and stirring was continued for one hour longer. Dilute hydrochloric acid was then added and the benzene layer was separated, washed and dried. The ketone was isolated and purified by distillation.

2-Alkylthiophenes.—The preparation of 2-octylthiophene is typical. A mixture of 125 g. of amalgamated zinc, 225 ml. of 1:1 hydrochloric acid and 26.2 g. (0.125 mole) of 2-octanoylthiophene was allowed to stand in a water-bath at 22° for three and one-half days. To complete the reaction the mixture was refluxed gently for twenty minutes. It was then cooled, extracted several times with ether and the combined ether extracts dried. The ether was removed and the residue distilled at reduced pressure. The yield of colorless oil, b.p. 106–108° at 1 mm., was 13.5 g. (55%).

1-(2-Thienyl)-alkanols.—The preparation of 1-(2-thienyl)-nonanol is typical. In a 125-ml. three-necked flask equipped with stirrer, distilling column and nitrogen-inlet tube was mixed 5.6 g. (0.025 mole) of 2-nonanoylthiophene and three times the calculated quantity of pure freshly distilled aluminum isopropoxide (5 g., 0.025 mole) in 30 ml. of dry isopropyl alcohol. The mixture was heated under an atmosphere of nitrogen to 100–110°, and acetone and isopropyl alcohol were allowed to distill from the mixture. When 12–13 ml. of distillate had been collected an additional 10 ml. of dry isopropyl alcohol was

The Distribution of Nitrogen in the Oxidation Products of Coals and Selected Nitrogen Compounds[1]

BY C. R. KINNEY, J. W. ECKERD, PAULINE REXFORD AND H. B. CHARMBURY

The chemical nature of the nitrogen occurring in coals is little understood, although it is agreed that its source is the proteins of the plants, animals, and microörganisms that inhabited the coal-swamps. In a peat, as much as 78.5% of the nitrogen can be extracted by dilute acid[2] but the percentage of the nitrogen extracted from coals rapidly falls with increasing rank; lignite, 21.8%; bituminous coal, 5.4%; anthracite, 2.6%. The nitrogen compounds which are extracted are largely amino acids among which present-day acids have been identified. The decrease in extractability of nitrogen compounds from the higher rank fuels indicates that the proteins or the amino acids present in the original starting material have undergone condensation reactions, possibly of the type suggested by Maillard.[3]

A knowledge of the chemical nature of the nitrogen in coal might be of particular value in the coking industry because of the possibility of making changes in the yields of nitrogen products and it might also be of importance in the hydrogenation of coal because of the amines which may be obtained. When coal is coked, 50% or more of the nitrogen remains in the coke,[4,5] about 15–20% is evolved as ammonia and 25–30% as free nitrogen. The formation of a variety of nitrogen-containing products strongly suggests that more than one nitrogen structure occurs in coal.

On the hydrogenolysis of coal[6] a considerable part of the nitrogen is evolved as ammonia. At moderate temperatures, less than 500°, the maxi-

[4] In the older literature low nitrogen analyses of cokes were reported because the ordinary Kjeldahl procedure failed to obtain all of the nitrogen from cokes and to obtain a material balance the difference was often ascribed to a larger yield of gaseous nitrogen.

[5] Lowry, Landan and Naugle, *Trans. A. I. M. E.*, **149**, 297–330 (1942), have published average percentages of nitrogen distributed among the carbonization products of a number of coals. Using these data it can be calculated that the average per cent. of the nitrogen remaining in 1000°-coke is 56.6%.

mum amount of ammonia appears to be about 30–35%. The remainder of the nitrogen is converted to nitrogen containing oils, which are probably amines. This also suggests that coals contain more than one kind of nitrogen structure. On the other hand Fisher and Eisner[7] have shown that the rate of removal of nitrogen during hydrogenolysis of coal is constant although quite slow, at least over the temperature range of 385–415° and up to twelve hours time. This may be due to the presence of only one form of nitrogen in coal but it seems more reasonable to assume that the constant rate of nitrogen removal is dependent upon another reaction which is relatively slow.

In view of these differences in the behavior of nitrogen in coals, an investigation of the distribution of the nitrogen in the products of the oxidation of coals and of a variety of pure organic compounds has been made. As the oxidizing reagent for this purpose, alkaline permanganate was selected.

Experimental

Oxidation Procedure.—Oxidations were carried out in iron kettles of 3 liters capacity, equipped with condensers of one meter length and with an opening for admitting air. Samples of 3 g. were used with 60 g. of potassium permanganate and 50 g. of potassium hydroxide dissolved in a liter of water. The mixture was refluxed and any ammonia that was formed was carried out by a slow stream of air entering the kettle, passing out through the condenser and into a beaker containing standard acid. A plug of glass wool was inserted in the top of the condenser to prevent any spray from being carried into the acid. The oxidation was continued until only traces of ammonia (less than 0.01% nitrogen) were obtained in an eight hour period of refluxing. The residue was then tested quantitatively for nitrate ion.

The Determination of Ammonia.—The ammonia formed during the oxidation was trapped in 400-ml. tall-form beakers containing 25 ml. of 0.1 *N* sulfuric acid diluted to 200 ml. With most of the samples used several days of refluxing were required to complete the liberation of ammonia and in these cases a fresh lot of acid was used daily. The amount of ammonia was determined by back titration with 0.1 *N* base using methyl red indicator. When the ammonia titration fell below 0.01% nitrogen in the sample on two successive days, the liberation of ammonia was considered to be complete.

Since ammonia might be oxidized by alkaline permanganate, test runs were made with samples of ammonium chloride. The per cent. nitrogen obtained was 26.22 and 26.32% which compared with the theory of 26.17% shows that ammonia is not readily oxidized by alkaline permanganate.

The Determination of Nitrate Nitrogen.—After the ammonia had been completely removed, the excess permanganate was destroyed with formic acid. The manganese dioxide was filtered out and washed thoroughly. The filtrate and washings were returned to the kettle together with 50 g. of potassium hydroxide and 20 g. of Devarda alloy. The condenser and air inlet were arranged as before to collect the ammonia formed by the reduction of the nitrate ion. When all of the alloy had reacted, the ammonia was distilled out and titrated in the usual manner.

The results of these determinations, calculated as per cent. of nitrogen in the sample, are arranged in Tables I and II.

Discussion

Table I gives the data obtained from the various coals and cokes oxidized. The total quantity of nitrogen recovered during the oxidation approached that obtained by the Kjeldahl procedure. The difference between the two results varied between −0.36 and ±0.07% nitrogen in the sample. Similar differences between the theory and the total recovered nitrogen from the pure compounds (Table II) were observed and it seems likely that certain nitrogen structures are not quantitatively partitioned into ammonia and nitrate. Possibly, in these cases, a part of the nitrogen is converted into free nitrogen since it escapes detection.

Also in Table I are compared the percentages of nitrogen converted to ammonia and nitrate ion and the relative percentages of ammonia and nitrate based on the total of these products. It will be observed that about two-thirds of the nitrogen is liberated as ammonia from the coal samples,

[a] Glass apparatus used. [b] Flask destroyed by the alkali at this point.

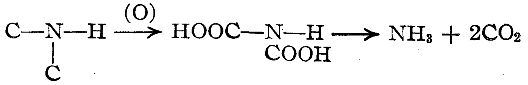
with the exception of the low-volatile anthracite, and about one-third as nitrate. With the low-volatile anthracite and the coke samples, a larger yield of nitrate was obtained and less ammonia.

These results most closely approximate the yields of ammonia and nitrate ion obtained from β-naphthylamine (Table II). The secondary amine structure in diethanolamine, carbazole and diphenylamine also appears to be a possibility, particularly if other structures are present to offset the somewhat low yield of ammonia. The imino grouping in *p*-benzalaminophenol and benzalaniline gave more widely separated results, but apparently this structure is also a possibility depending upon the character of other groups in combination with it.

The results obtained with the plant proteins, edestin and wheat gluten, suggest that, while proteins are not present in coal, the basic nitrogen structures in the proteins have not been greatly altered by the process of coalification. Because of the almost quantitative yields of ammonia from glycine and nicotinic acid, structures such as these would be expected to be present in coal in relatively small quantities. For the same reason the nitro group which is oxidized in high yield to nitrate would not be expected in coal.

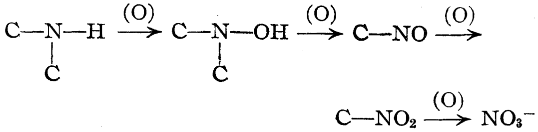
The mechanism of the oxidation of nitrogen-containing carbon compounds with the liberation of nitrogen as ammonia seems most likely to be the result of reaction (1) while the oxidation of nitrogen to nitrate ion may be accounted for by reaction (2).

(1)



$$\underset{\textstyle C}{C{-}\underset{|}{N}{-}H} \xrightarrow{(O)} HOOC{-}\underset{COOH}{N}{-}H \longrightarrow NH_3 + 2CO_2$$

(2)



$$\underset{\textstyle C}{C{-}\underset{|}{N}{-}H} \xrightarrow{(O)} \underset{\textstyle C}{C{-}\underset{|}{N}{-}OH} \xrightarrow{(O)} C{-}NO \xrightarrow{(O)} C{-}NO_2 \xrightarrow{(O)} NO_3^-$$

From the results in Table II it would appear that the two reactions are competitive, but that in those compounds in which a higher oxidation potential is required to oxidize the carbon radical a greater proportion of the nitrogen is oxidized to nitrate.[8]

While alkaline permanganate does not differentiate sharply between all of the various nitrogen structures, the surprising constancy of the quantities of ammonia and nitrate obtained from the various ranks of coal, considering the wide variations in yields from pure compounds, indicate that coals of different rank and from different localities contain the same kind of nitrogen linkages, that these similar nitrogen structures were produced in all coals by means of similar chemical reactions acting on similar proteins which were present in the peats from which the coals were made and that on oxidation these structures gave about the same yields of ammonia and nitrate ion. These condensed structures, formed during coalification, may possibly be aromatic amino or imino derivatives related to those in Table II, although an essentially carbon structure in which the carbon atoms are interspersed with nitrogen atoms appears likely for the cokes and possibly to a limited extent in anthracites and the fusain and opaque attritus of the lower rank coals as well. Such a structure would be, so far as the nitrogen is concerned, that of a tertiary amine. This conclusion is suggested by the higher yield of nitrate ion obtained from cokes and low volatile anthracite.

Summary

The oxidation of coals with alkaline permanganate liberates the nitrogen in two forms, ammonia and nitrate ion. A comparison of the relative amounts with similar data obtained from pure nitrogen compounds has been made.

State College, Pennsylvania

Received August 1, 1947

Pyrolysis of Methane Flowing Through a Porcelain Tube in the Region 1000°[1]

BY ALVIN S. GORDON[2]

The reaction between methane and steam at temperatures between 1000 and 1100° has been investigated,[3] using a porcelain reaction vessel in a flowing system. It was found that steam does not attack methane directly, but rather the carbon or highly carbonaceous material which results from the decomposition of methane. It seemed worth while to investigate the decomposition of methane at the same temperature and pressure conditions and in the absence of steam. Kassel[4] made an exhaustive study of methane decomposition in the range between 700 and 800° and sub-atmospheric pressure, using a static system of quartz. He also used a sillimanite vessel and did not report appreciable difference in decomposition rate. Kassel found that the first portion of the reaction was first order and homogeneous, with hydrogen depressing the rate. There was an induction period of indeterminate origin. Wheeler and Wood[5] used a static system and found that quartz chips gave an initial decomposition-rate increase at 700° and sub-atmospheric pressure. In a flowing system, increase in quartz surface had no effect. The same authors reported in another paper[6] that, in a flowing system up to 1050°, no appreciable difference in rate of decomposition was observed with quartz and porcelain tubes. Holliday and Excell[7] found that hydrogen was somewhat soluble in quartz, the solubility increasing with temperature. They also reported that hydrogen slowed the velocity of decomposition of methane.

Apparatus, Materials and Procedure

The essential parts of the apparatus have previously been described[8]: a platinum-rhodium furnace 24″ long surrounded a McDaniel porcelain combustion tube, 1″ o. d. × 3/4″ i. d. × 30″ long, the porcelain tubing extending beyond the furnace about 3 inches at each end. A 2-mm. Pyrex capillary was sealed to the small-diameter end and a 29/42 Pyrex ground-glass joint to the other. Two closely fitting porcelain tubes, faced with porcelain discs at the ends, were inserted into the combustion tube; the space between these inserts determined the volume of the reaction cell. The temperature was measured by two platinum–platinum-rhodium thermocouples, one cemented at each end of the reaction cell to the outer porcelain surface.

Purification of methane from a cylinder involved removal of ethane and higher hydrocarbons by passage through an activated charcoal trap at Dry-Ice temperature and of hydrogen, through a cupric oxide tube at about 300°. This gas was dried and passed through a flowmeter into the furnace. From the furnace the gases were led into a collection bottle filled with nearly saturated sodium chloride solution, constructed so that the gases discharged at atmospheric pressure. The rate of displacement of the salt solution was measured to determine the exit velocity of the gases.

During the investigation it was noted that the products of decomposition which covered the surface slowed down the reaction; after run 257 these products were burned off with oxygen after every few experiments. The rate was reproducible within 5–10% by this method; *e. g.*, runs 318 and 319 are reproduced to about 8%.

The gas analyses for each experiment were made by a mass spectrometer (under the supervision of Dr. R. A. Friedel). Most of the analyses were done in duplicate; percentages of hydrocarbons present in tenths of a per cent. could be reproduced within ten per cent., whereas methane could be reproduced within one-tenth per cent. Nitrogen reproducibility was quite erratic. These analyses were used to determine the methane percentage decomposed on an original volume basis. To obtain this value, hydrocarbon products with a molecular weight higher than benzene were calculated as carbon. Since naphthalene, anthracene, phenanthrene and pyrene were identified by their ultraviolet spectra, this assumption introduced an error. Benzene was present in very small percentage, so that these products, presumably formed from benzene, will probably be present in small percentage. From the percentages of hydrocarbons in the exit gas, the percentage of methane decomposed on an original volume basis was calculated.

Benton's[9] equation for reaction in a flowing system with change in volume was used in treating these data. It is assumed, in deriving this equation, that the diffusion was small compared to the linear velocity. For small percentage of decomposition, even a large diffusion effect will not give a large error in using the above equation.

The rate of decomposition was assumed to be first order, and the specific rate constant was calculated from the equation

$$k = \frac{V_o}{V_b}\left(g \ln \frac{1}{1 - F} - (g - 1)\, F\right)$$

[a] $\bar{t}$ = average time of contact of methane in reaction cell. [b] "k" = first-order constant (sec.$^{-1}$).

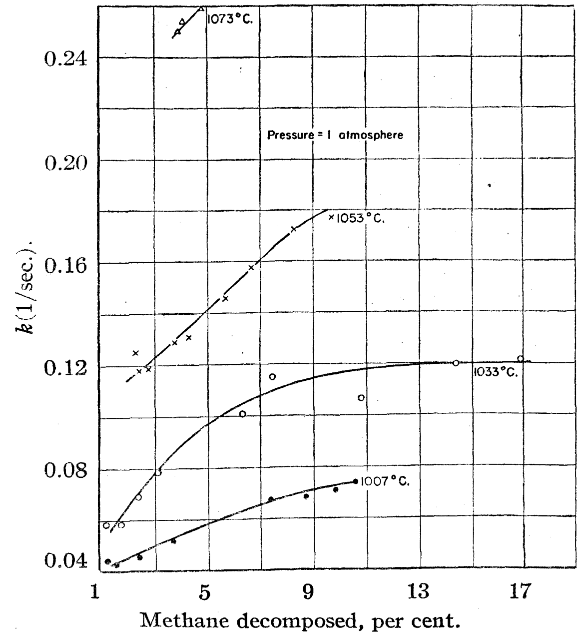

Fig. 1.—First-order constants against percentage of methane decomposed at various temperatures.

where

k = first-order specific rate constant (1/second)
V_0 = velocity (cc./second) of the gases entering the reaction cell
V_b = volume of the reaction cell (cc.)
$g = \dfrac{\text{gaseous moles formed from methane decomposed}}{\text{moles methane decomposed}}$
F = fraction of methane decomposed

Results and Discussion

Effect of Product Gases on the Pyrolysis

Referring to the data in Table I, which have been plotted in Fig. 1, it may be seen that the first-order constant always tended to increase with increasing decomposition of methane at each of the temperatures studied. It may be shown[9a] that increase of first-order constants with time indicates a less-than-first-order reaction or an autocatalytic reaction. To test the latter hypothesis, small percentages of the product gases were added to the methane entering the reaction vessel. When 0.72%

(9a) If k_T is the true constant and k_1 is the first-order constant

$$-\frac{d(CH_4)}{dt} = k_1(CH_4) = k_T(CH_4)^T$$

$$k_T = k_1\ (CH_4)^{1-T}$$

since k_1 increases with time, T must be less than 1 so that $(CH_4)^{1-T}$ will decrease correspondingly with time in order to keep k_T constant.

[a] $\bar{t}$ = average time of contact of methane in the reaction cell. [b] "*k*" = first-order constant (sec.$^{-1}$).

of acetylene was in the entering gas, as the results in Table II show, 2 to 2.5 times as much methane decomposed in the same time as when no acetylene was present, even after as much as 8.5% of methane had been decomposed. With the smallest contact time (0.16 second) only 0.29% of acetylene appears in the exit gas when 0.72% of acetylene was in the in-gas, and the temperature was 1007°. After a short time in the reaction cell, even though the percentage of acetylene was quite small, it had a large catalytic effect on the decomposition rate of methane. Because the percentage of ethylene in the exit gas in the study with acetylene in the in-gas was increased somewhat over the percentage observed for pure methane, the decomposition was studied with about 1% of ethylene in the in-gas. As may be seen in Table II, the ethylene in the exit gas was never less than 0.85%. For about the same contact time, the percentages of methane decomposed were in the same range, whether acetylene or ethylene was added to the in-gas. If the shorter of the comparable contact times was examined, it was seen that, with acetylene in the in-gas (average of runs 265 and 266), 0.52% of ethylene and 0.25% of acetylene appeared in the exit gas; when the contact time was 0.281 second, 3.28% of methane was decomposed. On the other hand, with ethylene in the in-gas (average of runs 303 and 309), 0.86% of ethylene and 0.30% of acetylene were in the exit gas when the contact time was 0.291 second; 3.33% of methane was decomposed in these experiments. These data showed that increasing the percentage of ethylene has little, if any, effect on the rate of decomposition. For longer contact times, comparisons between ethylene and acetylene in the in-gas were not possible because the percentages of ethylene and acetylene in the exit gas were so nearly the same.

It may be noted that the percentage of acetylene in the exit gas increased with increasing percentage of methane decomposed; since acetylene was a catalyst for the decomposition of methane, the reaction was autocatalytic.

It was of some interest to examine the possible reactions of acetylene as a catalyst in this reaction. If the primary products of methane pyrolysis were methyl radicals and hydrogen atoms, these atoms of hydrogen probably formed hydrogen molecules by reaction with methane molecules before any appreciable reverse reaction with methyl radicals occurred. On the other hand, the primary products may have been methylene radicals and hydrogen molecules, as suggested by Kassel,[4] so that the reverse reaction would be with hydrogen molecules. For both mechanisms, the concentration of hydrogen molecules would determine the reverse-reaction velocity. In the early stages of the reaction, acetylene could react with hydrogen, preventing the reverse reaction to reform methane, and a percentage of methane equal to the acetylene percentage could be decomposed, which is not enough to account for the large observed effect. If acetylene should react with the free radicals, not enough methane would be decomposed to account for the large observed effect. It was thought possible that acetylene attacked methane directly, yielding ethylene and a methylene radical. The methylene reacted with methane to form ethane, which decomposed to ethylene and then acetylene, setting up a chain reaction. Another possibility was that only one hydrogen atom was removed from the methane by acetylene, forming a C_2H_3 and CH_3 radical, the C_2H_3 reacting with another methane molecule to form ethylene and a second CH_3 radical. The above mechanism required the percentage of ethylene to be increased over the normal percentage in the exit gas. This increase of ethylene percentage was noted.

Kassel[4] studied the effect of the addition of hydrogen on the velocity of decomposition at 760° in a static system and found that 10% or more of hydrogen greatly retarded the reaction. The effect of hydrogen was studied in the present investigation at 1007° by adding 2.01% hydrogen to the reactant gas. As seen in Table II, there was a 20 to 30% increase in reaction rate over that of the untreated gas when between 1.64 to 3.09% of methane was decomposed. More ethylene and acetylene appeared in the exit gas for the same percentage of methane decomposed in these experiments than when there was no hydrogen in the reactant gas. Thus there was a greater catalysis of the decomposition.

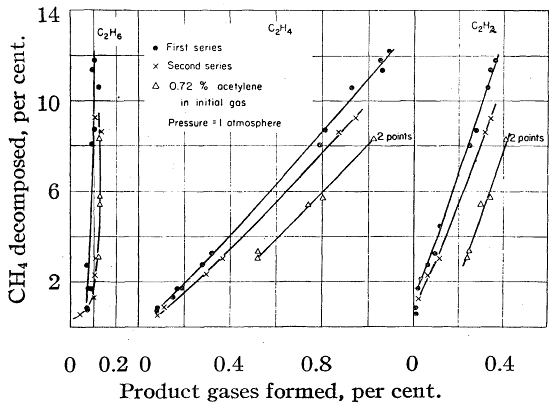

Fig. 2.—Gases formed from methane decomposed at 1007°.

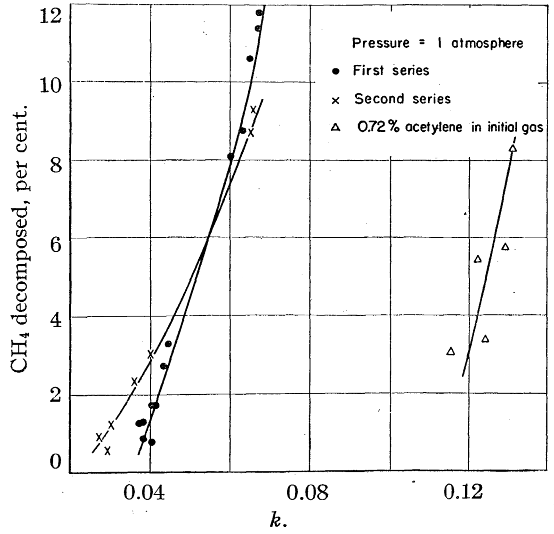

Fig. 3.—The first-order constants at various percentages of methane decomposed at 1007°.

It was hard to account for the difference in the effect of hydrogen in Kassel's paper and the present work, because the experimental conditions were different. The increase in acetylene catalysis when hydrogen was in the entering gas could more than compensate for a hydrogen retardation effect.

Effect of Surface on the Pyrolysis

If a series of runs with successively greater decomposition of methane at 1007° was followed, without any cleansing of the reaction vessel, by a similar series of successively greater decomposition, the first-order constants were smaller in the second series for the same percentage of methane decomposed. At the same time, the percentages of ethylene and acetylene were greater in the second series. These data are plotted in Figs. 2 and 3. Since the catalytic effect of acetylene was greater in the second series, the higher reaction constants must be viewed as the larger effect of surface, the surface being partly poisoned in the second series by decomposition products. Results obtained when the porcelain tube was cleansed with oxygen, *e. g.*, runs 318–321, Table II, show that the velocity of methane decomposition was greatest in this case. To compare the effect of surface and product gases at an equally active surface, the surface was cleansed with oxygen after every few runs.

The effect of increased surface : volume ratio was studied by inserting three porcelain tubes $^3/_8$-inch o. d. by 2 inches length by $^1/_{32}$-inch wall thickness (to get a large surface increase with small volume decrease) into the reaction cell. The results of experiments at 1007 and 1033° are reported in Table III. Results of experiments without any additional surface are included for comparison. It was seen that, at comparable times of contact, between two and three times as much methane was decomposed in the same time when the extra surface was present as in the normal decomposition of methane. From the results in Table III, it was seen that the concentration of ethylene or acetylene or both (since the concentration of one always influences the other) was relatively increased by increases $S : V$ ratio at very low concentrations of these gases, and relatively decreased with increased $S : V$ ratio when a small concentration of ethylene and acetylene had been built up. Thus the surface catalyzes the decomposition of ethylene and acetylene.

The effect of surface was not quantitative be-

[a] $\bar{t}$ = average time of contact of methane in reaction cell. [b] $S:V$ = surface:volume ratio in reaction cell.

cause, in the effort to make the porcelain wall thickness as small as possible to get a large increase in area with a small increase in volume, a much more porous structure results than is present in the porcelain of the reaction cell. Thus these reported values err on the high side for the effect of macro-measured surface.

The effect of surface probably was quite high, and there was therefore a large but indeterminate effect of the large $S:V$ ratio (67.5) in the annular entrance and exit spaces, since the temperature varies; the effects compared at constant contact time are not affected by this correction.

The results of increased $S:V$ ratio on the rate of decomposition of methane containing 0.72% of acetylene, keeping contact time as near constant as possible, may be compared in Tables II and III. They show that the larger $S:V$ ratio increases the decomposition velocity, the effect decreasing with increasing contact time. The acetylene content of the exit gases built up faster with time for the smaller $S:V$ ratio; its effect counterbalanced the $S:V$ ratio effect, and the difference in per cent. of methane decomposed between the larger and smaller $S:V$ ratios became smaller.

At the shortest contact time studied, the acetylene in the exit gas was about the same for the two different $S:V$ ratios. Since the acetylene in the in-gas was also the same, it seemed reasonable to assume that the acetylene contents were not too different at any point in the reaction vessel. The effect of acetylene alone, $S:V$ ratio alone, and the two acting simultaneously was obtained by subtracting the normal methane decomposed at the same contact time from the value of methane decomposed when one or both of the above effects were present in addition. Using the average values of the duplicate experiments reported in Tables II and III, the following resulted:

Methane Decomposed, Per cent.

Acetylene + $S:V$	Acetylene	$S:V$
4.94	3.28	3.82

subtracting the average of the normal methane decomposition (1.45) from each of these values

3.49	1.83	2.37

Adding the effect of acetylene and $S:V$ and comparing with acetylene plus $S:V$, it was seen that the sum of the separate values was 0.71 per cent. *greater* than the effect of the two combined. This was evidence for no interaction of surface and acetylene, which pointed to a homogeneous catalysis by acetylene. For the longer contact times the above procedure could not be employed because the acetylene percentage in exit gases was quite different for the two $S:V$ ratios.

The products of reaction besides those mentioned include propene, methyleneacetylene, benzene, naphthalene, pyrene and anthracene. There

was always less than 0.01% of propane, or butadiene, contrary to the experience of Hague and Wheeler,[10] who found butadiene in the products from the decomposition of methane in a flowing system at 950° in quartz, from which they concluded that benzene was formed with butadiene as an intermediate. The results in this research indicated no stable 4-carbon intermediate. If the naphthalene is formed from benzene, it is presumably made in a two-step reaction with acetylene or ethylene, or both.

Propene and methylacetylene were observed as products in the decomposition of methane. These compounds could form by the reaction of free methylene radicals and ethylene to give propene, which dehydrogenates to methylacetylene, or alternatively acetylene could react with methylene to give methylacetylene. The question of whether methylene, methyl or both are the primary radicals of methane decomposition has not been definitely answered. Barrow, Pearson and Purcell[11] reviewed the question and concluded that both may be present. Eltenton[12] used a mass spectrometer to detect the free radicals from methane decomposition and reported that only methyl radicals were detected.

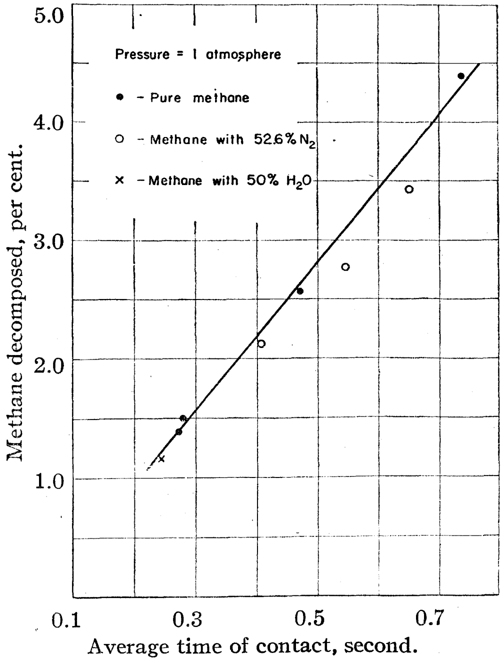

Fig. 4.—Percentage of methane decomposed *vs.* average time of contact at 1007° and $s/v = 2.47$.

Three tubes of quartz were added to the reaction cell with quartz surface:volume of reaction cell = 10.24. At 1007°, there was only an increase from 1.45% of methane decomposed, with no extra surface, to 1.97% of methane decomposed for the added quartz surface at about the same average time of contact. Part of the above increase may be explained by the increased time spent in the entrance and exit annular spacing, since the volume of these tubes necessitated about a 30% decrease in velocity through the reaction cell to keep the contact time stationary. Thus quartz surface had a minor effect on the reaction velocity.

The effect of porcelain surface when 30% of methane was decomposed was investigated at 1033°. For the same contact time, the decomposition of methane when the $S:V$ ratio = 6.94 was *less* than the decomposition of methane when the $S:V$ ratio = 2.47. Thus, surface had a large effect on the decomposition velocity only in the early stages of the decomposition, and this may account for the small effect of porcelain over quartz surface previously reported.

The average time of contact here was over four seconds. About 1% of carbon monoxide was found in the exit gas, owing to the slow reaction between methyl or some intermediate and porcelain. A similar result with much larger carbon monoxide was reported previously by Bone and Coward.[13]

The result of percentages of the methane decomposed in passage through the furnace, with

pure methane and with methane diluted about 1:1 with nitrogen and with steam, were shown in Table IV and plotted in Fig. 4. A straight line was drawn through the four points for pure methane decomposition; the three points with nitrogen fell reasonably close to this line and the two almost identical points with steam fell on the line. Since the first-order "constants" for pure methane over this range of contact times increased some 36%, these plotted results were quite interesting because they indicated a first-order decomposition. It may be noted in Table IV that the percentages of acetylene in the exit gas for the same percentage of methane decomposed were not very different for these various cases. One possible way the observed results may be explained was by assuming that, in the rate of decomposition of methane, the effect of surface and of acetylene depended on the concentration of methane to the first power; the acetylene and surface may be to any power. Kassel[4] has already shown the homogeneous decomposition to be first order at somewhat lower temperatures.

Acknowledgments.—I should especially like to thank Dr. R. A. Friedel and his group, including Mr. A. G. Sharkey, Jr., Mr. C. R. Humbert, Mrs. G. Bloom, and Miss H. R. Borgman, for their kindness in analyzing the off-gas from each run with the mass spectrometer. I should like to express my appreciation to Dr. Helmut Pichler for illuminating discussions of the results, and to Dr. H. H. Storch, chief of the synthetic liquid fuels research program, for his encouragement during this research. Mrs. Norma Golumbic read the manuscript critically and made many valuable suggestions.

Summary

The decomposition of methane has been studied in a porcelain tube at temperatures between 1007 and 1075°. The following observations were made:

1. Within this range the first-order reaction constants increased with increasing decomposition.
2. There was a catalytic effect of acetylene, probably homogeneous, which accounts for (1), since the percentage of acetylene increased with increasing percentage of decomposition.
3. There was probably no effect of ethylene on the decomposition of methane.
4. There was a large catalytic effect of surface in the early stages of the reaction which disappeared by the time 30% of the methane was decomposed.
5. No induction period was found.
6. In the early stages of the decomposition, 50% nitrogen or steam in the entering gas resulted in about the same percentage of decomposition of the methane for equal contact time.

The Effect of Activator Concentration on the Infrared-Sensitive Phosphor, Strontium Sulfide–Samarium, Europium[1]

BY KENNETH F. STRIPP AND ROLAND WARD

The recognition by Urbach[2] that the double activator principle permits long storage of energy in infrared-sensitive phosphors at room temperatures led to the development of his Standard VI phosphor. This material was originally prepared by heating a mixture containing approximately 70% strontium sulfide, 25% strontium sulfate and 5% calcium fluoride to which samarium and europium salts had been added. It has been shown[3] that the strontium sulfate and calcium fluoride constitute the flux for this phosphor and that the sulfate may cause some oxidation to occur.

In attempts to simplify the composition of these phosphors, it was found that satisfactory fluxing could be obtained with strontium chloride. The only complication which this flux may cause is the introduction of chloride ions. The lattice constants from pure strontium sulfide and from strontium sulfide fluxed with strontium chloride were the same within experimental error, indicating a very limited solubility of the chloride in the sulfide. The luminescent characteristics of phosphors prepared in this way appeared to be much more consistent than those obtained by the Lenard procedure so that it was thought worthwhile to undertake a more critical determination of the optimum concentrations of the activators.

Experimental

(a) The Preparation and Measurement of Samples.—Pure strontium sulfate obtained by precipitation from purified strontium nitrate solution[4] was reduced to the sulfide by heating in silica glass boats to constant weight in a stream of dry hydrogen or hydrogen sulfide. The products were white powders which showed neither fluorescence nor phosphorescence on exposure to ultraviolet radiation.

Strontium chloride solution was purified by a procedure

---

similar to that described for strontium nitrate.[4] The strontium chloride hexahydrate was crystallized from this solution and dried at 200° to give the anhydrous salt. The most satisfactory weight proportion of base and flux for our purpose was found to be 100 strontium sulfide to 12 strontium chloride. The samples were prepared as previously described for the selenide phosphor.[4] When the fired samples were split open it was observed that a thin layer at the surface which had been exposed during the fluxing operation was noticeably different in optical properties from the fracture surface. This was shown later to be due to oxidation at the surface of the sample which might be attributable to the effect of traces of moisture adsorbed on the sample during its preparation, or to oxygen in the nitrogen stream. Since neither of these factors could conveniently be brought under strict control it was decided to split the fired sample and measure the brightness of the fracture surface. With some practice it is possible to obtain reasonably plane fracture surfaces and in most cases both halves of the sample were measured. Preliminary experiments indicated that after heating for one and one-half hours at 1050° very little change occurred in the brightness of the fracture surfaces and that during this period the variable outer layer did not penetrate deeply into the sample.

The apparatus used to measure the brightness of the phosphors under constant I. R. stimulation is shown in Fig. 1. The stimulating light source (L) is a 6 volt, 3 c. p. lamp run from a 6-volt constant voltage transformer. The light passes through a ground glass (G) and through a Corning 2540 infrared filter (F) to be reflected by a mirror (M) to the surface of the phosphor sample (P). The light emitted by the phosphor is measured by the phototube multiplier (T). A calibrating light (a 6 volt, 3 c. p. tungsten lamp) was run off the same transformer as the stimulating light (L). It was placed directly above the aperture for the phosphor in a box in which a small pinhole covered with opalescent glass permitted the light to fall on the phototube multiplier. To take a calibrating reading the phosphor was replaced by a piece of ground glass which was illuminated by the light from the pinhole. To make sure that readings on different samples were strictly relative, this was done at the beginning and end of every set of readings. It was fairly easy to obtain brightness measurements on duplicate samples which agreed within 5%. Two minutes of exposure to the filtered light of a 60-watt tungsten lamp at a distance of 8 inches was the standard excitation given all phosphor samples. The filters were Corning Aklo and Blue-Green each about 5 mm. thick. The phosphorescence was measured up to five minutes after excitation at which time the phosphor was stimulated by infrared. The increment in emission was taken as the Brightness. At five minutes after excitation the phosphorescence (Background) of most samples was usually less than 10% of the Brightness except for those with low samarium concentrations in which it rose as high as 40%. The Brightness is given in galvanometer divisions.

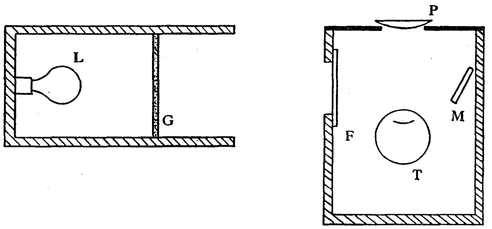

Fig. 1.—Apparatus for measuring the brightness of infrared-sensitive phosphors under constant infrared stimulation.

(b) The Effect of Addition of Oxide upon the Brightness of the SrS(Sm,Eu) Phosphor.—The first experiments were carried out using lithium fluoride as flux. Samples of composition 100SrS + xSrO(0.017 Eu, 0.02 Sm)9 LiF were prepared as described above. The numbers refer to parts by weight. The amount of strontium oxide (x) consciously added to the mixture ranged from 0 to 10. The stimulated brightness of these samples as a function of added oxide is shown in curve 1, Fig. 2. It can be seen that maximum brightness is reached at 3% added oxide and the further increase in oxide concentration leads to a decline in brightness. This is similar to the results reported for the strontium selenide phosphor.[4]

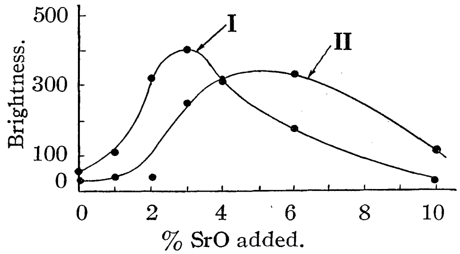

Fig. 2.—The effect of addition of oxide upon brightness: I, SrS(0.2 Sm, 0.017 Eu) 9 LiF, X SrO; II, 90 SrS:10 CaS(0.02 Sm, 0.017 Eu) 9 LiF, XSrO.

When similar experiments were tried using strontium chloride as flux, it was found that in general the addition of 1% strontium oxide led to a decrease in brightness and that with 2% oxide the brightness was reduced to a very low value. By using smaller increments of added oxide, however, a measurable maximum in brightness was usually obtained.

Several typical brightness *vs.* oxide plots are shown in

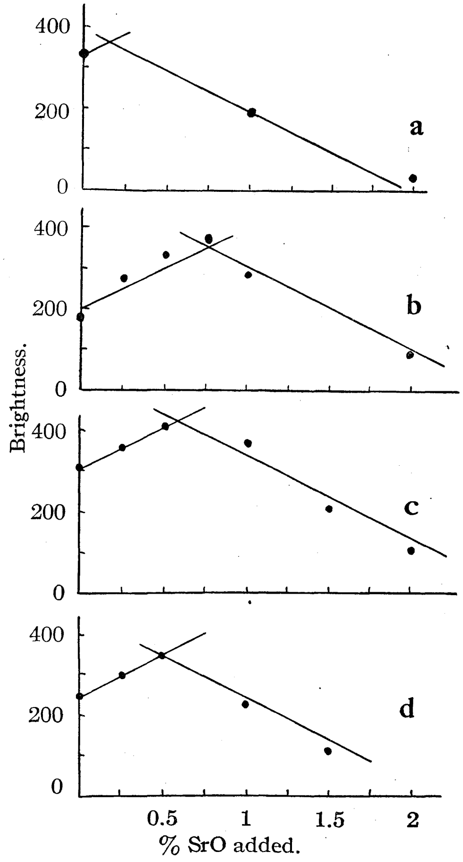

Fig. 3.—The effect of addition of oxide upon brightness: 100 SrS(0.02 Sm, 0.017 Eu) 12 $SrCl_2$, XSrO.

Fig. 3. The strontium sulfide represented in Fig. 3(a) is the same as that used with the lithium fluoride flux (Fig. 2). It was prepared by reduction of strontium sulfate with hydrogen. Fig. 3(b) represents another batch of strontium sulfide prepared by the same procedure while Fig. 3(c) was obtained by use of a sample of strontium sulfide prepared by heating the sulfate in hydrogen sulfide. Straight lines with the same slopes have been drawn rather arbitrarily through the experimental points. The point of intersection of these lines lies within 10 Brightness units of 380, which is about the maximum value obtained with lithium fluoride.

It appeared reasonable to suppose that the relative position of the maxima is indicative of the relative amount of oxide in different samples of strontium sulfide. Thus, Fig. 3(a) represents a sulfide which contains about 0.75% more oxide than represented by Fib. 3(b).

Many attempts were made to prepare a sample of strontium sulfide completely free from oxide. One of these involves the reaction between anhydrous strontium chloride and dry hydrogen sulfide. Under suitable conditions this reaction can be carried essentially to completion and the only impurity which should be present is strontium chloride. The oxide–brightness curve for strontium sulfide prepared in this way is shown in Fig. 3(d). It differs very little from the others.

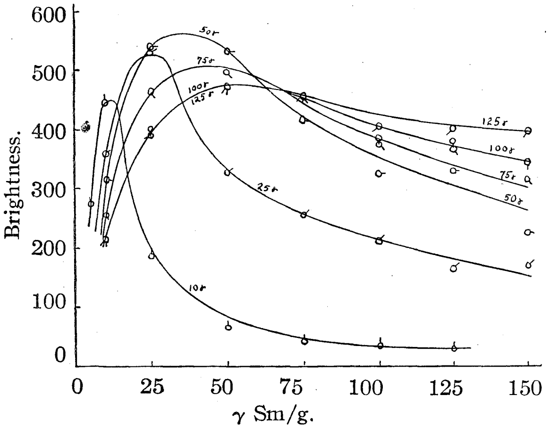

Fig. 4.—Variation of brightness with samarium concentration, SrS(XSm, Eu) 12% SrCl$_2$: ό, 10γEu; σ', 25γEu; o-, 50γ Eu; ɑ, 75γEu; ♀, 100γEu; ρ, 125γEu.

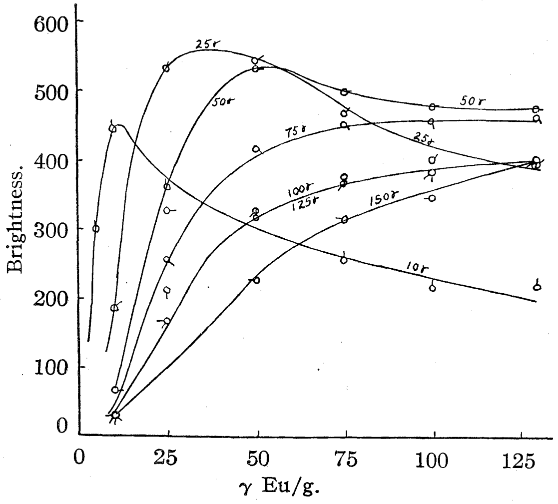

Fig. 5.—Variation of brightness with europium concentration, SrS(Sm, XEu) 12% SrCl$_2$: ό, 10γSm; σ', 25γ Sm; o-, 50γSm; ɑ, 75γSm; ♀, 100γSm; ρ, 125γSm; -o, 150γSm.

A mixture of 90 parts of strontium sulfide to 10 parts calcium sulfide was tested in this way using lithium fluoride as flux. The results shown in Curve II, Fig. 2, indicate that much more oxide can be tolerated in this mixture. The maximum brightness is obtained with 5 to 6% oxide. With 0 to 2% oxide, phosphors of very low stimulability are formed. The lower value for the maximum brightness is probably to be attributed to the shift in emission color toward the red caused by the introduction of calcium.

(c) **The Effect of Varying Concentrations of Samarium and Europium upon the Brightness of the Strontium Sulfide Phosphor using Strontium Chloride as the Flux.**—Strontium chloride was chosen as the flux for this investigation. Strontium sulfide was prepared by reduction of the sulfate with hydrogen. Several batches were intimately mixed to give a sufficient quantity so that the entire investigation could be carried out with the same base material. No addition of oxide was made to the material to be used in the activator concentration experiments. A sample of the sulfide, however, was found to give a maximum in brightness upon the addition of about $^1/_3$ per cent. oxide.

Samples of composition 100SrS(xSm,0.001Eu)12SrCl$_2$ were prepared where x varied from 0 to 125 γ per g. of strontium sulfide. The brightness under infrared stimulation of these samples was plotted as a function of the samarium concentration. This gave a curve which may be called a constant europium profile. Similar series of constant europium samples were prepared with 25, 50, 75, 100 and 125 γ of europium per gram of strontium sulfide. The results are shown in Fig. 4. Constant samarium profiles were also determined for the concentrations 10, 25, 50, 75, 100, 125 and 150 γ of samarium per gram of strontium sulfide.

From Fig. 4 we see that at 10 γ europium concentration the addition of samarium causes a very rapid rise in infrared sensitivity to a maximum value at about 10 γ samarium. Further addition of samarium causes a rapid decline in sensitivity. At progressively higher europium concentrations the maxima become broader and the sensitivity does not fall off so rapidly at higher samarium concentrations. There is also a shift in the position of the maxima toward higher samarium concentrations as the europium concentration increases. The brightness represented by the peaks of the profiles passes through a maximum in the 50 γ europium profile but appears to level off at the 100 γ europium profile.

In Fig. 5 which gives the constant samarium profiles it is shown that similar shifts in the maxima are obtained.

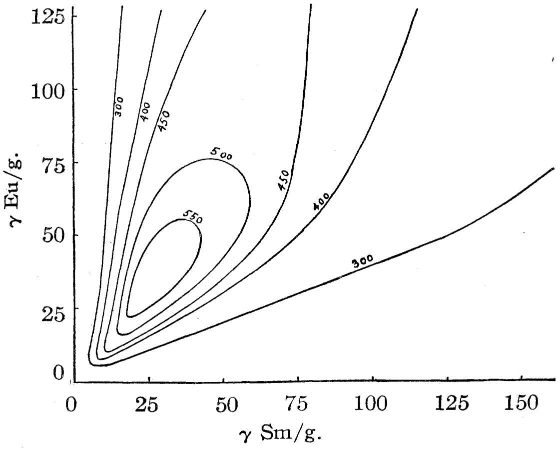

Fig. 6.—Brightness as a function of samarium and europium concentration: SrS(XSm, YEu)12% SrCl$_2$.

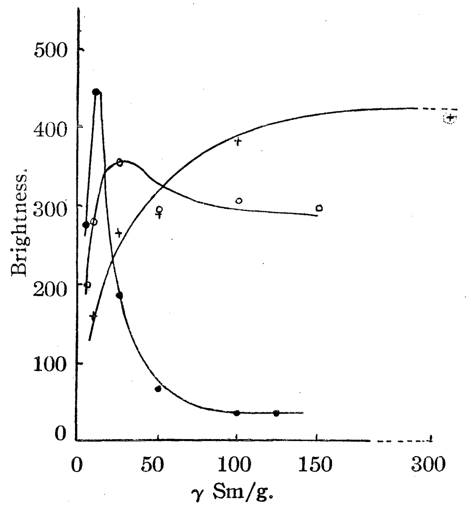

Fig. 7.—The influence of oxide upon the brightness of phosphors with varying samarium concentration, SrS-(XSm, 10Eu) 12% $SrCl_2$: ●, no SrO added; ○, 0.5%; +, 1%.

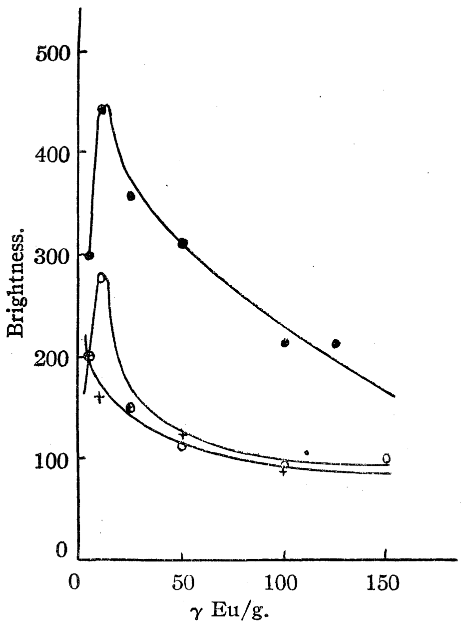

Fig. 9.—The influence of oxide upon the brightness of phosphors with varying europium concentration, SrS-(10Sm, XEu) 12% $SrCl_2$: ●, no SrO added; ○, 0.5%; +, 1%.

At the higher samarium concentrations no maxima were observed within the limits of europium concentrations used.

From Figs. 4 and 5 a contour plot was made of the brightness as a function of the samarium and europium concentrations. This is shown in Fig. 6 which indicates that at low concentrations of activators the optimum ratio of europium to samarium concentrations is about unity. Above 15 parts per million, however, this ratio increases and the brightest phosphors are those in which the europium concentration falls between 22 and 55 γ and the samarium concentration between 17 and 42 γ. If we were to assume that all of the activators entered the base material lattice and were uniformly distributed, the linear separation of activator ions in the maximum brightness region would be about 15 to 18 cation–cation distances. This must represent the minimum separation of the activator ions. The distribution coefficients of the activators between the flux and the strontium sulfide, however, are not at present known and an investigation of this problem is now being made. The increase of the europium to samarium ratio above unity at higher activator concentrations may be in

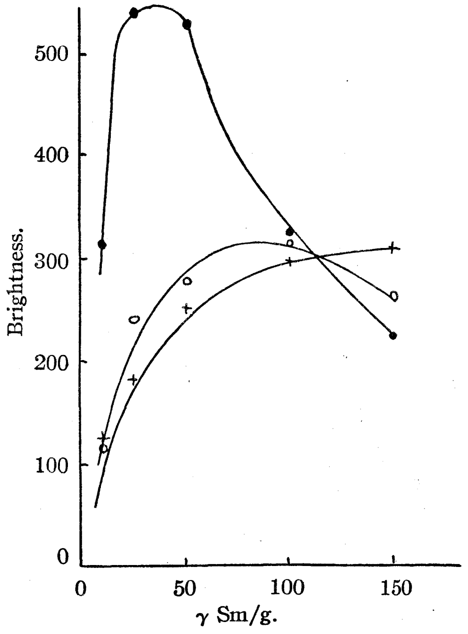

Fig. 8.—The influence of oxide upon the brightness of phosphors with varying samarium concentration, SrS-(XSm, 50Eu) 12% $SrCl_2$: ●, no SrO added; ○, 0.5%; +, 1%.

part due to a difference in distribution coefficients of the two activators.

It should be noted that the measurement of brightness made here is the stimulated emission of the fully excited phosphor after the normal phosphorescence (or background) has decreased to a negligible value. The phosphors with low activator concentration showed a time lag in stimulation. The maximum brightness in these cases was recorded.

From the work of Urbach[2] it would seem likely that the samarium ion (auxiliary activator) provides the trapping states which lead to long storage of energy while the europium ion (the dominant activator) supplies the excited electrons. The stimulation involves the transfer of the trapped electrons to the conduction band whence they may return to the dominant activator ion with the emission of light or may return to a trap without the emission of visible radiation. From this model we would expect an increase in brightness with increasing samarium concentration up to the point at which the re-trapping of excited electrons predominates. This point appears to be reached at 40 to 50 γ of samarium or at a minimum lattice separation of 36 cation distances.

The effect of increasing the europium concentration beyond that required for maximum brightness is not so pronounced. With low samarium concentrations, however, it causes a definite decrease in brightness. This also would be predicted from the mechanism suggested above. Upon excitation of the phosphor the electrons from the europium are transferred to the conduction band. They may subsequently be trapped by the samarium or return to the europium, the latter giving rise to phosphorescence. Qualitatively, it would seem reasonable to suppose that fewer electrons would be trapped by the samarium when europium concentration is relatively high.

(d) **The Effect of Addition of Oxide to Samples with Varying Samarium and Europium Concentrations.**—Three series of samples containing 10 γ of europium per gram of strontium sulfide were prepared with zero, one-half and one per cent. added oxide. In each series the samarium concentration ranged from 5 to over 100 γ. The stimulated brightness of these series as a function of samarium concentration is shown in Fig. 7. The results for a similar set of samples containing 50 γ of europium are presented in Fig. 8. These data show that at low samarium concentrations the addition of oxide causes a marked decrease in brightness while the reverse is true at higher samarium concentrations. The maximum in brightness, shown by the series containing no added oxide, is not so well marked in the series containing 0.5% oxide and does not appear when 1% oxide is added.

The influence of oxide additions upon the constant samarium profiles was also determined at 10 and 50 γ of samarium. The results given in Figs. 9 and 10 show that the addition of oxide causes increase in brightness only at low concentrations of europium with 50 γ of samarium. At high europium concentrations the addition of oxide causes a lowering of the brightness.

It should be noted that the most sensitive phosphor was produced without the addition of oxide. The effect of oxide in general appears to be most noticeable at high samarium and low europium concentrations.

An interesting observation was made by the comparison of the brightness values of the fracture surfaces of a series of constant europium phosphors to which 0.5% oxide had been added with the brightness values of the outside surfaces of a similar series to which no oxide had been added. The curves are shown in Fig. 11. The close correspondence between the 0.5% oxide series and the outside surfaces of the phosphors to which no oxide was added is a strong indication that the change occurring at the surface of the samples in heating is the introduction of a small amount of oxide.

(e) **The Effect of Oxide upon the Phosphorescence of Strontium Sulfide Activated with Europium.**—The light emission from the singly activated phosphor 100SrS-(xEu)12SrCl$_2$ was measured as a function of europium concentration. The results shown in Fig. 12 indicate that there is a maximum at about 10 γ/g. of europium.

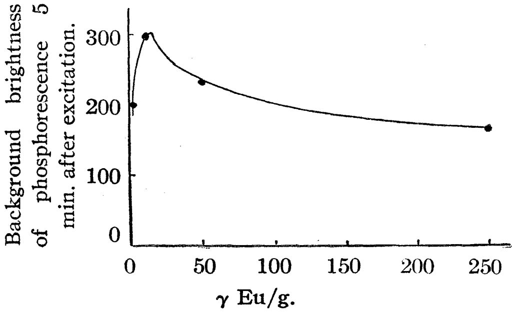

Fig. 12.—Phosphorescence of 100 SrS(Eu) 12SrCl$_2$ as a function of europium concentration.

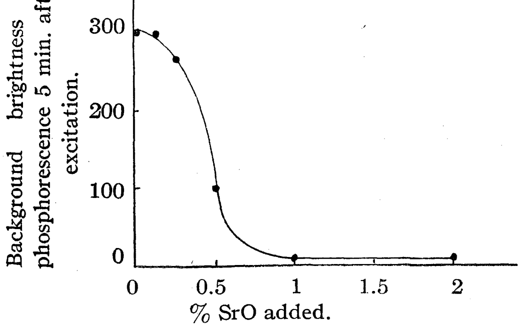

Fig. 13.—Phosphorescence of 100SrS(0.001Eu)12SrCl$_2$, XSrO as a function of oxide concentration.

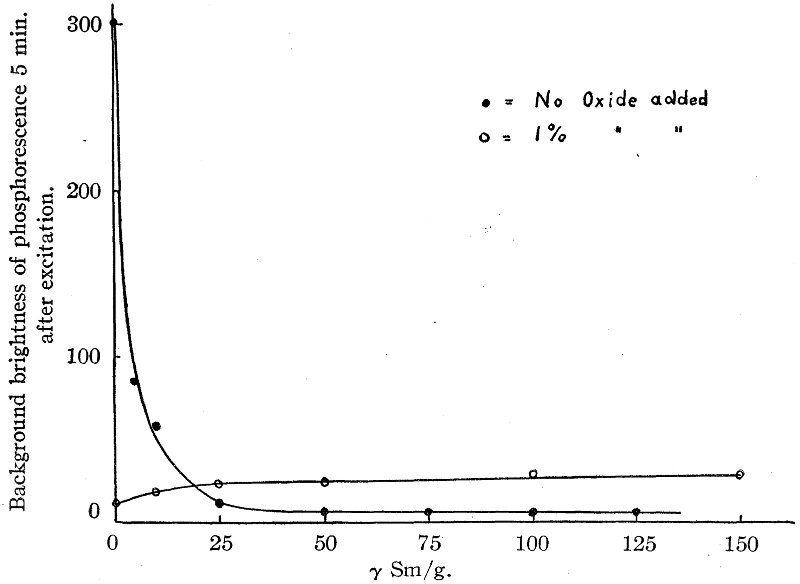

Fig. 14.—The phosphorescence of 100 SrS(0.001Eu, XSm) with and without the addition of oxide.

The phosphorescence was measured at one minute intervals after the phosphor had been fully excited. The data given represent the brightness at five minutes. From these results it would appear that the number of electrons which remain in the excited state is decreased by the addition of europium beyond 10 γ.

Samples of composition $100SrS(0.001Eu)12SrCl_2,xSrO$ where x varied from 0 to 2 were prepared and the phosphorescence measured as described above. The results, given in Fig. 13, show that the phosphorescence is lowered by a factor of one-third upon the addition of 0.5% strontium oxide and becomes practically zero at 1%.

The effect of the addition of samarium upon the phosphorescence of the europium phosphors $100SrS(xSm,0.001Eu)12SrCl_2$ and $100SrS(xSm,0.001Eu)12SrCl_2 \cdot 1SrO$ is shown in Fig. 14.

Unfortunately we have no theoretical interpretation of the peculiar influence of oxide upon the luminescent characteristics of the strontium sulfide phosphors. The measurement of brightness under infrared stimulation is obviously rather superficial. More fundamental information should be forthcoming from the measurement of light sum, quantum efficiency, photoconductivity, etc. Some preliminary investigations of these have been made.

The facts presented here, however, show clearly that impurities other than heavy metals may have profound effects on the behavior of these phosphors and that great care must be exercised in the preparation of samples.

Acknowledgments.—The authors wish to thank R. T. Ellickson and W. L. Parker for the construction of apparatus used in measuring the brightness of the phosphors.

Summary

A method is described by which reproducible measurements of the brightness of infrared sensitive phosphors can be made. The strontium sulfide–samarium, europium phosphor fluxed with lithium fluoride and with strontium chloride was shown to be affected by the addition of small quantities of strontium oxide. The presence of lithium fluoride or of calcium ions increases the tolerance of the phosphor toward oxide.

The dependence of the brightness of the phosphor upon the concentrations of samarium and europium, using strontium chloride as flux, was determined. It was shown that, at activator concentrations from 0 to 15 (γ) parts per million, the brightest phosphors are obtained with about equal concentrations of the two activators. At higher activator concentrations an excess of europium seems to be best. The brightest phosphors contain between 22 and 55 γ of europium and 17 and 42 γ of samarium per gram of strontium sulfide.

The Preparation of Optically Active Hydrocarbons by the Wurtz Reaction

BY R. L. LETSINGER

Of the attempts to prepare optically active hydrocarbons by the Wurtz reaction with secondary halides,[1,2] the only successful cases which have been reported are (a) the preparation of (+)2,3-diphenylbutane by the reaction of sodium with (−)1-chloro-1-phenylethane[3] and (b) the preparation of (−)3-methylnonane by the condensation of ethylsodium with (−)2-bromoöctane.[2] Even in these cases the yields were so low and the products so extensively racemized that the reactions are of little synthetic interest.

In the present paper it is shown that benzylsodium condenses with optically active 2-bromoöctane and 2-bromobutane to give good yields of the corresponding hydrocarbons and, furthermore, that in the reaction with 2-bromobutane a major portion of the optical activity is retained and an inversion of configuration probably occurs.

Hydrocarbon Preparation.—Data on the hydrocarbon syntheses are presented in Tables I and II. For comparative purposes, the reaction

[a] Calculated on the basis of the 2-bromoalkane.

of an alkylsodium compound, butylsodium, is also included. The complete racemization observed in the butylsodium reaction and the extensive racemization reported for ethylsodium[2] suggest that a practical preparation of optically active hydrocarbons by this procedure may be limited to the use of organosodium compounds which do not appreciably exceed benzylsodium in activity. This point will be investigated further.

Extent of Racemization.—In order to determine the extent of racemization in the condensation step, it is necessary to know the maximum rotation for both the hydrocarbon formed and the alkyl bromide employed. An estimation of these rotations for optically active 1-phenyl-2-methylbutane and 2-bromobutane follows. The remaining discussion is limited to a consideration of the 1-phenyl-2-methylbutane synthesis since an independent value for the rotation of 1-phenyl-2-methyloctane is not available.

A sample of 1-phenyl-2-methylbutane which was prepared by the reaction of phenylsodium with optically active 2-methyl-1-bromobutane ($[\alpha]^{25}D + 3.84°$) had a rotation $[\alpha]^{25}D + 10.73°$. On the basis of Braun's value[4] for the maximum rotation of 2-methyl-1-bromobutane, the bromide employed in this reaction contained 95% optically active amyl bromide and 5% inactive material. The inactive material may have been either isoamyl bromide or *t*-amyl bromide. In order to estimate the amount of amylbenzene which would form from the impurity, therefore, the reactions of these two bromides with phenylsodium were investigated. Isoamyl bromide gave approximately one and a half times as great a yield of amylbenzene as did the active amyl bromide, whereas *t*-amyl bromide yielded no isolatable coupling product with phenylsodium. Therefore, since the 1-phenyl-2-methylbutane sample may have contained from zero to 7.5% of an inactive isomer (depending upon the relative amounts of isoamyl and *t*-amyl bromide which had been present), the maximum rotation for the pure hydrocarbon should lie between $[\alpha]^{25}D + 10.7°$ and 11.6°[5,6]

The rotation of optically pure 2-bromobutane is not known. Different methods for preparing the bromide lead to different degrees of racemization.[7] The best case observed in this Laboratory was the conversion of 2-butanol, $[\alpha]^{25}D + 7.25°$, to 2-bromobutane with a rotation $[\alpha]^{25}D - 13.66°$. From this information and the maximum rotation of 2-butanol,[8] it is apparent that the rotation of a pure enantiomorph of 2-bromobutane would be at least $[\alpha]^{25}D$ 26.1°.

The extent of racemization in the reaction of benzylsodium with (+)2-bromobutane, which can be calculated from these rotations (11.6° for the hydrocarbon and 26.1° for the bromide) and the data in Tables I and II, is 26%. Since the values for the maximum rotations are only limiting values, however, the actual racemization is probably considerably less.

---

[4] Braun, *J. Research Natl. Bur. Standards*, **18**, 315 (1937).

(5) These limits correspond to $[M]^{25}D$ +15.8° and 17.1°. Therefore, the approximate value, $[M]^{25}D \pm 9.5°$, set by Levene and Rothen, *J. Org. Chem.*, **1**, 85 (1936), was too low.

(6) These rotations are based on the assumption that no racemization occurred during the Wurtz step. This assumption is valid since the reaction is not at the asymmetric carbon atom, and Whitmore and Olewine, THIS JOURNAL, **60**, 2570 (1938), reported a series of reactions which involved conversion of optically active amyl alcohol to the Grignard, and back to the alcohol, with less than 10% racemization.

Configuration.—(+)1-Phenyl-2-methylbutane corresponds to (−)2-methyl-1-butanol,[9] and (+)2-bromobutane corresponds to (+)2-butanol.[10] The determination of the configurational change in the benzylsodium condensation, therefore, depends upon a knowledge of the relationship of 2-methyl-1-butanol and 2-butanol. Unfortunately, this relationship has not been unequivocally established; however, a considerable body of evidence[7a,11] indicates that (−)2-methyl-1-butanol corresponds to (+)2-butanol. On this basis, the reaction of benzylsodium with 2-bromobutane (reaction 2) took place with an inversion of configuration.

A survey of related reactions revealed at least six other cases for which it is possible to relate the configuration of the reactant to (+)2-butanol and that of the product to (−)2-methyl-1-butanol. These reactions include the condensations of secondary bromides with methylmagnesium bromide,[12] ethylsodium,[2] and sodium malonic ester[7b,12] and the reactions of (+)*s*-butyl-*p*-toluenesulfonate[7a] with potassium cyanide and phenylmagnesium bromide. It is interesting that all of these reactions, and the benzylsodium condensation, are found to take place in the same stereochemical sense,[13] *i. e.*, either all take place with inversion or none of them do.

It has been demonstrated that a Walden inversion occurs in the reaction of sodium malonic ester with cyclopentene oxide.[14] Since this reaction probably takes place in the same manner as the condensation of sodium malonic ester with a secondary bromide,[14] this fact supports the view that all the reactions previously listed are accompanied by an inversion of configuration.

Experimental

2-Bromobutane.—Eastman Kodak Company white label 2-butanol was partially resolved by means of the brucine salt of the acid phthalate ester.[15] Physical constants for the optically active alcohols were: (−)2-butanol, b.p. 99–100°, $[\alpha]^{25}\mathrm{D}$ − 3.82°, d^{25}_4 0.806, $n^{25}\mathrm{D}$ 1.3931; (+)2-butanol, b.p. 99–100°, $[\alpha]^{25}\mathrm{D}$ + 7.25°, d^{25}_4 0.807, $n^{25}\mathrm{D}$ 1.3931.

The bromides were prepared by passing dry hydrogen bromide into solutions made up of equal parts of the alcohol and petroleum ether (b.p. 30–60°) at a temperature of 5–10°. The resulting mixtures were allowed to warm up slowly overnight, refluxed for four hours the following day, and worked up as described by Levene[7b]; yield, 50–59%. The bromide from (−)2-butanol boiled at 89–91°, $[\alpha]^{25}\mathrm{D}$ + 6.84°, d^{25}_4 1.256, $n^{26}\mathrm{D}$ 1.4330; that from (+)2-butanol boiled at 90–91°, $[\alpha]^{25}\mathrm{D}$ − 13.66°, d^{25}_4 1.254.

2-Bromoöctane.—Eastman Kodak Co. 2-octanol was resolved by the method of Ingersoll,[15] and converted to the bromide with phosphorus tribromide according to Hsueh and Marvel[16]; b.p. of (+)2-bromoöctane 76° (15 mm.), $[\alpha]^{25}\mathrm{D}$ + 28.8°, d^{24}_4 1.102, $n^{25}\mathrm{D}$ 1.4481; b.p. of (−)2-bromoöctane, 84° (22-mm.), $[\alpha]^{25}\mathrm{D}$ − 32.5°, d^{25}_4 1.101.

Amyl Bromides.—Optically active 2-methyl-1-butanol, obtained by fractionation of fusel oil, had the following constants:[17] $[\alpha]^{25}\mathrm{D}$ −5.74°, d^{25}_4 0.8186, $n^{25}\mathrm{D}$ 1.4077. It was converted to the bromide by the same procedure employed for the butyl bromides; b.p. of (+)2-methyl-1-bromobutane 120–120.5°, $[\alpha]^{25}\mathrm{D}$ + 3.84°, d^{25}_4 1.214, $n^{25}\mathrm{D}$ 1.4412.

Eastman Kodak Co. isoamyl bromide was used after distillation, b.p. 119–120°. *t*-Amyl bromide was prepared from Sharples refined *t*-amyl alcohol and hydrogen bromide at 0°; b.p. 44–45° (90 mm.).

Organosodium Reagents.—The preparation of the organosodium reagents and the condensation reactions were carried out in creased flasks with high speed stirring (5000 r.p.m.) in a nitrogen atmosphere. Petroleum ether (b.p. 30–60°) was used as solvent. Butylsodium, amylsodium[18a] and phenylsodium[18b] were prepared from the corresponding chlorides by the method of Morton and co-workers. Benzylsodium was prepared by the metalation of toluene[19]; amylsodium was used to metalate the toluene in the reaction in which 1-phenyl-2-methyloctane was prepared, and butylsodium was used as metalating agent in the preparation of 1-phenyl-2-methylbutane.

Condensations with 2-Bromoalkanes.—For the hydrocarbon synthesis the 2-bromoalkane, dissolved in an equal volume of petroleum ether (b.p. 30–60°), was added dropwise (fifteen-minute period) to the rapidly stirred suspension of organosodium reagent at a temperature of 20°. The resulting mixture was stirred for another hour, allowed to stand overnight and forced from the flask with nitrogen pressure onto Dry Ice the following morning. After the Dry Ice had disappeared, water was added (cautiously at first); the hydrocarbon layer was then separated by conventional methods and distilled at reduced pressure. Tests for unreacted halide were negative in all cases. Data on the quantities of reagents used in these experiments are given in Table I; data on the products are given in Table II.

Anal. (−)1-phenyl-2-methylbutane (Ex.2). Calcd. for $C_{11}H_{16}$: C, 89.12; H, 10.88. Found: C, 88.99; H, 10.78. (−)1-phenyl-2-methyloctane (Ex.4). Calcd. for $C_{15}H_{24}$: C, 88.16; H, 11.84. Found: C, 88.01; H, 12.17.

Condensations with 2-Methyl-1-bromobutane.—Two reactions with phenylsodium were carried out. In the first case, (a), the major product was 3,6-dimethyloctane; in the second case, (b), the desired 1-phenyl-2-methylbutane was obtained in moderate yield. In both reactions the amyl bromide was added to the phenylsodium at 0° over a fifteen-minute period. After an hour of stirring at 0° and then another hour at 20–25° the mixture was forced with nitrogen pressure into a centrifuge bottle. Solid matter was separated by centrifugation, then recentrifuged with fresh petroleum ether. The combined hydrocarbon portions were distilled through a 6″ Vigreux column, and the solid phenylsodium was converted to sodium benzoate with Dry Ice. In both cases benzoic acid was isolated, and tests for halogen in the hydrocarbon portion were negative.

---

(9) (+)1-Phenyl-2-methylbutane has the same configuration as (−)2-methyl-1-butanol since there was no possibility for inversion in the reactions of hydrogen bromide with (−)2-methyl-1-butanol and of phenylsodium with (+)2-methyl-1-bromobutane. See also Levene, *J. Biol. Chem.*, **110**, 323 (1935).

(16) Hsueh and Marvel, THIS JOURNAL, **50**, 855 (1928).

(17) For reported values for these constants see Whitmore and Olewine, *ibid.*, **60**, 2569 (1938); Braun, note 4.

(18) (a) Morton, Paterson, Donovan and Little, *ibid.*, **68**, 93 (1946); (b) Morton and Letsinger, *ibid.*, **69**, 172 (1947).

(19) Morton, Little and Strong, *ibid.*, **65**, 1339 (1943).

(a) The reaction was carried out in a 500-cc. flask with 11.5 g. (0.50 m.) sodium, 25.5 cc. (0.25 m.) chlorobenzene and 15.1 g. (0.1 m.) active amyl bromide. Distillation of the hydrocarbon layer gave 3.8 g. material boiling at 65–75° (30 mm.) and only 0.2 g. boiling from 75–90° (30 mm.). Redistillation of the first fraction yielded 3.3 g. hydrocarbon, b.p. 65–70° (28 mm.), $[\alpha]^{25}\text{D} + 18.7$, d^{25}_4 0.731, $n^{25}\text{D}$ 1.4166. Literature values for 3,6-dimethyloctane: $[\alpha]^{27}\text{D} + 16.85$,[20] d^{27}_4 0.7269,[20] d^{15}_4 0.7402,[21] $n^{20}\text{D}$ 1.4145.[21]

Only a trace of 1-phenyl-2-methylbutane was obtained from this reaction. The principal product, apparently 3,6-dimethyloctane, was probably produced by a Wurtz reaction of the active amyl bromide with metallic sodium. To reduce the amount of sodium present during the condensation, therefore, excess chlorobenzene was employed in preparing the phenylsodium, and the effectiveness of the agitation was increased by carrying the reaction out in a smaller flask.

(b) A 250-cc. creased flask was employed with 5.75 g. (0.25 mole) of sodium, 15.5 cc. (0.152 mole) of chlorobenzene and 9.8 g. (0.065 mole) of amyl bromide.

The following fractions were obtained from the first distillation.

Fraction	B. p., °C. (30 mm.)	Wt., g.
1	60–75	1.4
2	75–94	0.2
3	94–103	3.8
4	Residue	1.2

Fraction 3 was redistilled twice to give 2.6 g. (27%) of 1-phenyl-2-methylbutane: b.p. 94° (28 mm.), $[\alpha]^{25}\text{D} + 10.73°$, d^{25}_4 0.854, n^{25}_4 1.4862; literature values:[22] d^{25}_4 0.8584, d^{25}_4 0.855; $n^{25}\text{D}$ 1.4873, $n^{25}\text{D}$ 1.4849, etc.

Anal. Calcd. for $C_{11}H_{16}$: C, 89.12; H, 10.88. Found: C, 89.29, 89.34; H, 11.00, 11.11.

From redistillation of fraction 1, 0.8 g. hydrocarbon (3,6-dimethyloctane) was obtained, b.p. 65–70° (28 mm.), $n^{25}\text{D}$ 1.4171. (Compare values with those listed under experiment (a) for 3,6-dimethyloctane.)

Anal. Calcd. for $C_{10}H_{22}$: C, 84.43; H, 15.57. Found: C, 84.60; H, 15.66.

Condensations with Isoamyl Bromide and *t*-Amyl Bromide.—The procedure and quantities of reagents were the same as employed in the previous reaction (condensation of active amyl bromide and phenylsodium, b).

Distillation of the hydrocarbons from the isoamyl bromide reaction gave the fractions:

Fraction	B. p., °C. (31 mm.)	Wt., g.
1	42–85	0.7
2	85–98	0.2
3	98–107	4.5
4	residue	3.0

Isoamylbenzene (4.1 g. 43%) was obtained by distillation of fraction 3: b.p. 94–96° (28 mm.), $n^{24}\text{D}$ 1.4839, d^{25}_4 0.854.

No *t*-amylbenzene was isolated from the reaction of phenylsodium with *t*-amyl bromide. After the removal of petroleum ether from the hydrocarbon layer biphenyl (2.2 g.) crystallized out, and on distillation no hydrocarbon forerun was obtained before the biphenyl started passing over.

Diacetamido Derivatives of 1-Phenyl-2-methylbutane.—These derivatives were prepared by the method of Ipatieff and Schmerling.[23] The derivative of (+)1-phenyl-2-methylbutane (from (+)2-methyl-1-bromobutane) melted at 201–202° (taken with an Anschütz thermometer immersed in the sulfuric acid-bath); that of the less active (−)1-phenyl-2-methylbutane (from (+)2-bromobutane) melted at 198–199°. The mixed m.p. was 198–199°. Ipatieff and Schmerling report 198–199° cor. as the m.p. of the *d,l*-diacetamido derivative of 1-phenyl-2-methylbutane.

Acknowledgment.—The author is very grateful to Professor Robert L. Burwell, who kindly supplied the sample of optically active 2-methyl-1-butanol which was used in this work. The analyses were performed by Margaret M. Ledyard and Patricia Craig. Ruth Peterson assisted in the resolution of 2-butanol.

Summary

(−)1-Phenyl-2-methylbutane and (+)1-phenyl-2-methyloctane were prepared in good yields by the reaction of benzylsodium with (+)2-bromobutane and (+)2-bromoöctane, respectively.

(+)1-Phenyl-2-methylbutane was prepared by the condensation of phenylsodium with (+)2-methyl-1-bromobutane.

The extent of racemization in the reaction of benzylsodium and 2-bromobutane was estimated and the stereochemical relationships were discussed.

Ionization Constants of Some Substituted 8-Hydroxyquinolines

BY JOHN P. PHILLIPS[1] AND LYNNE L. MERRITT, JR.

In the course of other work still in progress, values for the acidic and basic ionization constants of some methyl substituted 8-hydroxyquinolines and their sulfonic acid derivatives were needed. The optical method of Stenstrom and Goldsmith[2] was used to determine these constants.

Experimental

The methyl substituted 8-hydroxyquinolines and 8-methoxyquinaldine were prepared by modification of the Skraup reaction. 8-Hydroxyquinaldine, m.p. 73–73.5°, was made by the Doebner–v. Miller method[3]; 2,4-dimethyl-8-hydroxyquinoline, m.p. 64–64.5°, was prepared according to Bauer and Engler from *o*-aminophenol plus a mixture of paraldehyde and acetone saturated with dry hydrogen chloride[4]; 8-hydroxylepidine, m.p. 140–141°, and 3,4-dimethyl-8-hydroxyquinoline, m.p. 123–124°, were obtained by the analogous reactions of *o*-aminophenol with methylal plus acetone saturated with hydrogen chloride gas and with methylal plus methyl ethyl ketone saturated with hydrogen chloride gas, respectively; 8-methoxyquinaldine, m.p. 123°, was made from *o*-anisidine and crotonaldehyde by the type of procedure used by Campbell and Schaffner to make 4-methylquinolines.[5]

8-Methoxyquinoline,[6] m.p. 45.5–46°, was made from 8-hydroxyquinoline, m.p. 75°, by methylation with dimethyl sulfate.

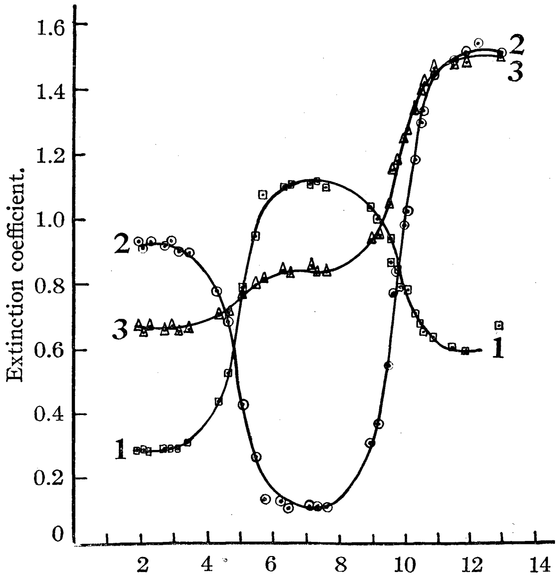

Fig. 1.—8-Hydroxyquinoline, 0.008% in aqueous solution: 1, at 280 mμ; 2, at 330 mμ; 3, at 355 mμ.

The sulfonic acid derivatives of these compounds were formed by direct sulfonation with fuming sulfuric acid at 0–10°.[7]

All compounds were recrystallized until the melting points agreed with those in the literature or, in the case of those compounds whose melting points are not recorded in the literature, until a constant melting point was obtained. The sulfonic acid derivatives melt above 300° and therefore their melting points were not accurately determined.

The ultraviolet absorption spectra of accurately prepared 0.008% aqueous solutions of these compounds (excepting 3,4-dimethyl-8-hydroxyquinoline which had to be run in 0.004% solution owing to its low solubility) at varying *p*H values were measured with a Beckman Model DU Quartz Spectrophotometer using 1.0-cm. cells and slit widths from 1.2 to 0.2 mm. as required. The *p*H was adjusted by additions of dilute sodium hydroxide or hydrochloric acid and was determined with a Beckman *p*H meter that had been standardized against a potassium acid phthalate buffer of *p*H 4.01 and also against five known sodium carbonate–hydrochloric acid buffers in the range of *p*H 10.17–11.36. *p*H above 11.36 was calculated approximately by adding known amounts of a standard sodium hydroxide solution.

From thirty to forty solutions of *p*H between 2 and 13 were measured for each compound, and extinction values at two different wave lengths (280 mμ and 355 mμ in most cases) were used in the calculations. A typical plot of extinction against *p*H at three wave length values for 8-hydroxyquinoline is shown in Fig. 1.

Results

The phenolic ionization constants were obtained by a graphical determination of the *p*H at which the extinction was halfway between its values in alkaline and in neutral solution. (The average values at two wave lengths were used; in no case did the *pKa* determined at one wave length differ by more than about 0.1 unit from the *pKa* at the other wave length.) According to Stenstrom and Goldsmith,[2] at the mid-point *p*H = *pKa*. By analogy, the graphical determination of the *p*OH at which the extinction was halfway between its neutral and acid values gave *pKb*.

For 8-methoxyquinoline and 8-methoxyquinaldine, the extinctions in neutral and basic solutions were the same since no acid ionization could occur.

The experimental results are listed in Table I and the constants *Ka* and *Kb* are given in Table II. By *Ka* is meant the dissociation constant for the phenolic group alone.

Discussion

The relative basicities of these compounds agree very well with what would be predicted from the electron-releasing tendencies of methyl groups substituted *o*, *m*, and *p* to the basic nitrogen; methyl groups in *ortho* or *para* position increase the basicity and decrease the acidity of the substituted

8-hydroxyquinoline; *meta* substitution exerts a relatively slight influence.

TABLE I

pKa AND *pKb* OF 8-HYDROXYQUINOLINE DERIVATIVES

Compound	Wave length mμ	*pKa*	*pKb*
8-Hydroxyquinoline	280	9.70	9.08
	330	9.70	9.10
	355	9.72	9.08
8-Hydroxylepidine	280	10.08	8.50
	330	9.90	..
	355	10.00	8.38
3,4-Dimethyl-8-hydroxyquinoline	280	10.10	8.20
	355	10.00	8.20
8-Hydroxyquinaldine	280	...	8.43
	330	10.33	8.48
	355	10.28	8.45
2,4-Dimethyl-8-hydroxyquinoline	330	10.60	7.77
	355	10.60	7.83
8-Methoxyquinoline	305	...	8.99
8-Methoxyquinaldine	350	...	8.30
8-Hydroxyquinoline-5-sulfonic acid	280	8.85	9.98
	355	8.87	9.87
8-Hydroxyquinaldine-5?-sulfonic acid	290	9.30	9.20
	355	9.30	9.20
8-Hydroxylepidine-7?-sulfonic acid	300	10.00	9.21
	340	10.01	9.24
2,4-Dimethyl-8-hydroxyquinoline-7?-sulfonic acid	340	10.17	8.80
	350	10.10	8.80

TABLE II

ACIDIC AND BASIC IONIZATION CONSTANTS OF 8-HYDROXYQUINOLINE DERIVATIVES

Substance	$Ka \times 10^{+10}$	$Kb \times 10^{+10}$
8-Hydroxyquinoline	1.95	8.32
8-Hydroxylepidine	1.00	36.4
3,4-Dimethyl-8-hydroxyquinoline	0.892	63.1
8-Hydroxyquinaldine	.490	35.5
2,4-Dimethyl-8-hydroxyquinoline	.252	159
8-Methoxyquinoline	....	10.2
8-Methoxyquinaldine	....	50.1
8-Hydroxyquinoline-5-sulfonic acid	13.8	1.20
8-Hydroxyquinaldine-5?-sulfonic acid	5.01	6.30
8-Hydroxylepidine-7?-sulfonic acid	0.976	6.04
2,4-Dimethyl-8-hydroxyquinoline-7?-sulfonic acid	.725	15.9

The fact that the basic dissociation constants of 8-methoxyquinoline and 8-methoxyquinaldine are only slightly larger than those of the corresponding 8-hydroxy compounds suggests that the hydroxyl group in the latter does not have much influence on the basic dissociation, and hence that the 8-hydroxyquinolines are not ampholytes.

It appears probable from its physical and spectral resemblance to 8-hydroxyquinoline-5-sulfonic acid that the sulfonation product of 8-hydroxyquinaldine has the sulfonic acid group in the 5 position. Owing to the physical differences between these two compounds and the sulfonation products of 8-hydroxylepidine and 2,4-dimethyl-8-hydroxyquinoline and also to the marked discrepancy in their phenolic ionization constants, it is likely that the latter compounds sulfonate in the 7-position rather than the 5-position.

Previous measurements of *Ka* for 8-hydroxyquinoline have been made by Fox[8] and by Stone and Friedman.[9] By hydrolysis measurements Fox obtained 0.368×10^{-10} and by solubility and spectroscopic measurements Stone and Friedman obtain the values 0.420×10^{-10} and 0.428×10^{-10}. Our measurements are not in too good agreement with these values, but we feel that the checks obtained by using different wave lengths for measurement and the care in determining *p*H at a large number of values justify this report. Furthermore the ionic strength was not considered in either case. Feldman and Powell[10] by colorimetric means obtain 80×10^{-10} and 0.8×10^{-10}, respectively, for *Ka* and *Kb* for 8-hydroxyquinoline-5-sulfonic acid. These values from visual comparisons are not as precise as spectrophotometric measurements but are of the same order of magnitude as our results.

Summary

The phenolic and basic ionization constants of some methyl substituted 8-hydroxyquinolines and their sulfonic acid derivatives have been determined spectrophotometrically, and have been found to be in good agreement with predictions based on the electron-releasing tendencies of methyl groups.

NOTES

Comparison of Nickel Catalysts in the Hydrogenation of β-Naphthol

By Homer Adkins and George Krsek

The partial hydrogenation of β-naphthol over nickel catalysts may give predominantly either the alcohol, 1,2,3,4-tetrahydro-2-naphthol or the phenol, 5,6,7,8-tetrahydro-2-naphthol. In this Laboratory Musser[1] obtained the alcohol in a 55% yield, while Schultz[2] prepared the phenol in 70% yield. Stork[3] obtained the phenol in 55% or the alcohol in 66% yield depending upon the alkalinity of the reaction mixture. With copper–chromium oxide as the catalyst the alcohol is produced to the exclusion of the phenol.[1]

Musser used Raney nickel (W-1) prepared by the Covert process.[4] Schultz and Stork used Raney nickel (W-2), prepared by the Mozingo procedure,[5] under a pressure of about 200 atmospheres. Schultz completed the reaction in less than thirty minutes at 120° while Stork did the hydrogenation in two to three hours at 85°. Musser used a lower pressure of about 100 atmospheres and somewhat more drastic conditions, *i. e.*, six hours at 140°, in forcing the hydrogenation to completion so that decalols and decalin were also produced.

It seemed worth while to test different nickel catalysts for activity in the hydrogenation of β-naphthol. There is recorded in Table I the temperature and time required for the addition of two moles of hydrogen per mole of β-naphthol over various catalysts and the yields of the alcohol and the phenol obtained. The hydrogenations were on 36 g. of β-naphthol in 50 ml. of ethanol with 1 g. of catalyst at 3600 to 4000 p. s. i. The results given are the average of two runs. The catalysts could not be compared at the same temperature because the activity of a Raney nickel catalyst is so dependent upon the procedure followed in preparing it from the nickel aluminum alloy. The catalyst W-4 gave a more rapid hydrogenation at 65° than did the W-1 catalyst at 140°. The data show that in the order of increasing activity the Raney nickel catalysts are: W-1 as prepared by the Covert process; commercial Raney nickel catalyst as supplied by the Gilman Paint and Varnish Co., Chattanooga, Tenn.; W-2 as prepared by the Mozingo procedures; and W-4 as prepared by the Pavlic procedure.[6] The W-6 Raney nickel, described in a paper submitted for publication, is even more active than W-4. Catalysts W-1 and W-2 were somewhat more active if the procedure for washing the catalyst described in the Pavlic process was used.

Table I

Comparison of Raney Nickel Catalysts in Hydrogenation of β-Naphthol

Catalyst	Temp., °C.	Time, minutes	Yield, % Alcohol	Yield, % Phenol
Commercial	90	260	7	86
Commercial	120	25	11	75
W-1[f]	140	160	8	83
W-1	140	240	9	72
W-2	65	245	6	81
W-2	90	180	6	84
W-2	140	15	7	82
W-4	65	120	9	87
U. O. P.	130	30	21	65
W-1[a]	140	240	48	31
W-4[b]	65	90	65	19
W-4[c]	65	90	23	61
W-4[d]	65	90	22	59
U. O. P.[e]	130	30	68	8
W-6[g]	65	30	18	73

[a] 0.02 g. sodium hydroxide. [b] 0.24 g. sodium hydroxide. [c] 0.02 g. sodium hydroxide. [d] 0.6 ml. triethylamine. [e] 0.24 g. sodium hydroxide. [f] Washed by Pavlic method. [g] test by Harry Billica with a Raney nickel W-6 catalyst described in a forthcoming paper.

All of the catalysts referred to above except W-6 gave 6 to 11% yields of the alcohol and yields of the order of 80% of the phenol. The addition of small amounts of sodium hydroxide or of triethylamine to the hydrogenation mixture changed the proportion of the products so that with the W-4 catalyst, for example, the yield of alcohol was increased almost eight-fold with a corresponding decrease in the yield of the phenol. In no case did the addition of sodium hydroxide, in the quantities used, decrease the rate of hydrogenation.

The nickel on kieselguhr catalyst sold by the Universal Oil Products Co. was also tested for the hydrogenation of β-naphthol. It was similar in rate of reaction to the commercial Raney nickel but gave a higher yield of alcohol and a lower yield of the phenol than did any of the Raney nickel catalysts. The U.O.P. catalyst, for a similar rate of hydrogenation, must be used at a temperature 50 or 60° higher than that required by a Raney nickel catalyst prepared by the preferred procedure. The addition of a small amount of sodium hydroxide to the U.O.P. catalyst had the same effect in shifting the course of the hydrogenation to the production of the alcohol as with Raney nickel catalysts.

On the Fortification of Edible Fat with Vitamin A

By U. P. Basu and S. K. Sen Gupta

For making up the deficiency of vitamin A edible fat is fortified with some vitamin preparation; but on storage the preparation often loses its vitamin A potency, mainly due to oxidation. The addition of a suitable anti-oxidant retards this oxidation. Baxter and Robeson[1] have further shown that vitamin A in the form of its ester (vitamin A acetate) is less susceptible to oxidation. Accordingly, it has been of interest to see how an edible fat in which vitamin A acetate had been incorporated would behave on aeration in presence of some suitable anti-oxidant.

Cow's "ghee" (butter clarified by boiling) was fortified in one case with a vitamin A concentrate made by saponification containing 0.2 million I.U. per gram and in another with a crystalline vitamin A acetate, in presence of 0.05% ethyl gallate (*cf.* Lea,[2] and Bose and Banerjee[3]) and the initial potencies of vitamin A in both the preparations were measured in terms of Carr–Price blue value. Air free from moisture and carbon dioxide was passed through both the preparations under identical conditions at 40°. The relative fall in C.-P. blue values in the two preparations was noted from time to time and the results are being recorded in the table.

Table I

Loss of Vitamin A Potency on Aeration

Period of aeration, hours	Carr-Price value in preparations With concentrate	With acetate
0	19.2	17.4
20	18.2	17.2
60	15.3	17.0
100	9.8	17.0
150	6.4	16.0
200	3.2	15.3
250	nil	12.8

The preliminary investigations indicate that vitamin A acetate may preferentially be used in fortifying an edible fat. Details of the work will be published elsewhere.

Influence of Temperature on the Production of Glycerol during Alcoholic Fermentation

By M. C. Brockmann[1] and T. J. B. Stier

A small amount of glycerol is always produced during alcoholic fermentation. The intermediary processes leading to this formation of glycerol are included in the current theory for the mechanism of alcoholic fermentation (see Meyerhof).[2] This scheme, however, does not provide an insight into the way in which substrate is diverted into the series of reactions leading to glycerol formation. Inasmuch as the immediate origin of glycerol involves the hydrolysis of glycerol-1-phosphate, it follows that the phosphatase activity of yeast can be assumed to play a part in its production. While certain special conditions are known to enhance glycerol formation, the influence of common environmental factors—such as temperature, oxygen tension and concentration of ammonium salts—on the production of glycerol during alcoholic fermentation remains unsettled. This paper deals with the production of glycerol in the course of fermentations maintained at 30 and 37 or 40°. As a means of throwing further light on differences in glycerol formation at these temperatures, observations were made on the phosphatase activity of yeast recovered from fermentations maintained at different temperatures.

Experimental

Yeast Strain.—All experiments were performed with a distillery strain of *Saccharomyces cerevisiae.*

Medium.—The medium contained 10 g. of glucose, 0.7 g. of dehydrated yeast extract (Difco) and 0.5 g. of potassium dihydrogen phosphate per 100 ml. This medium was autoclaved at 120° for ten minutes.

Preparation of Inoculum and Management of Fermentation.—In the development of inoculum, yeast was transferred through the following steps at twenty-four-hour intervals: (A) from the stock slant to 10 ml. of medium; (B) 1 ml. from (A) to each of two tubes containing 10 ml. of medium apiece; (C) the contents of each tube from (B) were added to 150 ml. of medium in a centrifuge bottle. All cultures were incubated at 30°. At the time of inoculation, yeast was centrifuged from the cultures prepared in step (C), washed twice with potassium dihydrogen phosphate solution (0.5 g. per 100 ml.) and transferred to 1300 ml. of medium. After a thorough mixing, 600-ml. portions of the inoculated medium were transferred to 2 sterile, 1-liter Florence flasks which were plugged with cotton and suspended in water-baths maintained at 30, 37 or 40°. Both flasks were continuously agitated.

Analytical Operations.—Immediately after inoculation and at intervals throughout the twelve–fourteen hour observation period samples were withdrawn for evaluation of glucose and glycerol concentrations. Glycerol concentration was determined by the procedure of Amerine and Dietrich.[3] Because the yeast extract present in the medium contributes to the observed glycerol concentration, the apparent glycerol concentration of the medium immediately after inoculation was subtracted from the observed concentration of subsequent samples. This difference was recorded as "glycerol formed." At the end of the indicated observation period yeast cells were centrifuged from the culture, washed with water, and dried for forty hours in a vacuum desiccator over activated alumina. A known weight of dried cells was assayed for phosphatase activity at *p*H 4.1 using disodium glycerol phosphate (Eastman Kodak Co. #644) as substrate.

Results

In Fig. 1 glycerol formation during fermentation at 30, 37 and 40° is identified as a function of

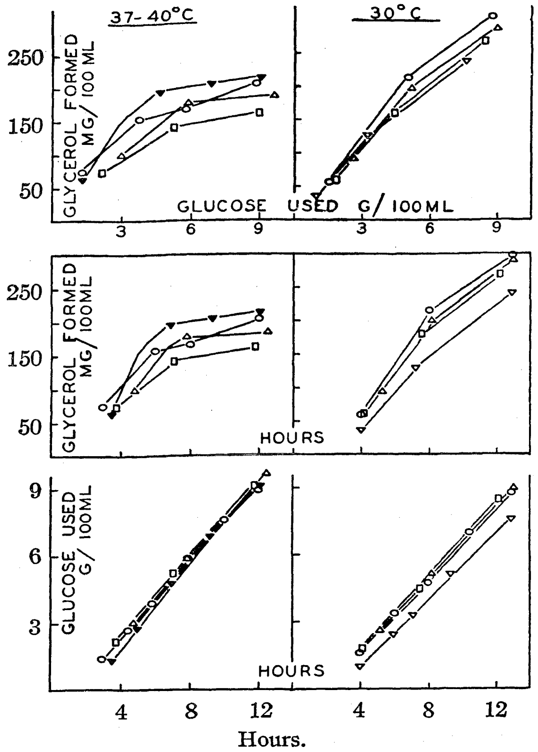

Fig. 1.—Glycerol formation and glucose utilization during four representative experiments conducted at 30° and 37 or 40° (closed triangle represents observations at 37°).

time as well as of the glucose metabolized. With fermentations maintained at 30°, the yield of glycerol after 40 to 50% of the initial sugar has been metabolized is from 3.7 to 4.2 g. per 100 g. of glucose utilized. Later, when 80 to 90% of the sugar has been metabolized, the glycerol yield is between 3.0 and 3.5 g. per 100 g. of sugar used. This represents a slight but consistent decrease in the yield of glycerol during the latter half of fermentation.

In fermentations held at 37 or 40° glycerol formation with respect to sugar utilization follows about the same pattern as at 30°, up to the point of the metabolism of 25 to 30% of the sugar initially present. When approximately half of the sugar has been metabolized, the yield of glycerol in fermentations held at 37 or 40° is 2.7 to 3.2 g per 100 g. of sugar used—a range definitely lower than that observed at a corresponding point of the fermentations maintained at 30°. By the time 85 to 90% of the sugar has been metabolized, the yield of glycerol in fermentations held at 37 to 40° amounts to only 1.8 to 2.3 g. per 100 g. of glucose utilized. Of the glycerol produced during the entire observation period, more than three-fourths was formed by the time one-half of the ultimate sugar utilization was attained.

As is evident from the glucose-used time relationships shown in Fig. 1, the rate of glucose utilization in the 30° fermentations was only slightly less than in those held at 40°. This, however, is an incomplete picture, because in fermentations held at 40°, the cell populations were only 40 to 50% of those observed at like periods in fermentations maintained at 30°. Thus, on a per cell basis, the rate of glucose utilization at 40° was always more than twice the rate at 30°.

From the observations summarized in Fig. 1, it is apparent, particularly in the fermentations conducted at 40°, that the production of glycerol was not constant throughout the observation period, although the rate of glucose utilization during the same period was nearly constant. It follows, therefore, that glycerol production must be controlled by some enzyme system not involved directly in the over-all utilization of substrate. These specifications appear to be met by the cell phosphatases capable of promoting the hydrolysis of glycerol-1-phosphate. To test this concept, yeast cells were recovered from fermentations at the end of a twelve–fourteen hour holding period and assayed for phosphatase activity. Representative results from essays are shown in Table I.

TABLE I

PHOSPHATASE ACTIVITY OF YEAST AND FERMENTATION MEDIUM AFTER TWELVE–FOURTEEN HOURS OF FERMENTATION AT DIFFERENT TEMPERATURES

Phosphatase activity[a]			
30° fermentation		37 or 40° fermentation	
For 5 mg. dry yeast	For 1 ml. medium	For 5 mg. dry yeast	For 1 ml. medium
155	205	60[b]	55
122	239	25	32
110	136	52	73
100	148	30	29

[a] Micrograms of phosphorus liberated from disodium glycerol phosphate by either 5 mg. of dry yeast or yeast present in 1 ml. of fermentation medium during ninety minutes at 30°. [b] 37°.

While the results shown in Table I indicate a considerable variation in the phosphatase activity observed in yeast cultures of comparable history, there can be little question that yeast held at 37 or 40° has far less phosphatase activity than yeast maintained at 30° over corresponding periods of time. Because the procedure employed for the assay of cell phosphatase activity is not specific for those enzymes which hydrolyze *l*-glycerol-1-phosphate to glycerol, it cannot be stated conclusively that the reduction in the amount of glycerol formed in fermentations maintained at 37 or 40° is related to a deterioration of cell phosphatase activity. However, if glycerol formation parallels the combined activities of the cell phosphatases capable of hydrolyzing the isomers of glycerol phosphate, this relationship suggests that the phosphatase activity of yeast is a significant factor in the control of glycerol formation during normal alcoholic fermentation.

A Simplified Synthesis of α-Phenylcinnamic Acid and α-Phenyl-*p*-nitrocinnamic Acid[1]

BY ROBERT E. BUCKLES AND EUGENE A. HAUSMAN

Benzaldehyde or *p*-nitrobenzaldehyde can be condensed with phenylacetic acid in the presence of tertiary amines with about the same yields as the Perkin reaction.[2] The advantage of this synthesis is that it does not require the anhydrous sodium salt, nor is it carried out at the high temperature of the Perkin reaction. The method is an application of one used by Bakunin and Peccerillo[3] for the synthesis of α-phenyl-*o*-nitrocinnamic acid.

A comparison of triethylamine, tri-*n*-propylamine and tri-*n*-butylamine as catalysts in the preparation of α-phenyl-*p*-nitrocinnamic acid was made. The yields in three identical experiments except for catalyst were: triethylamine, 52%; tripropylamine, 56%; tributylamine, 33%.

When the reactions were carried out with *p*-nitrophenylacetic acid in place of phenylacetic acid a successful condensation was obtained only with benzaldehyde.

Experimental

α-Phenylcinnamic Acid.[1]—Twelve cc. of benzaldehyde, 11 g. of phenylacetic acid, 23 cc. of acetic anhydride and 8 cc. of tripropylamine[4] were heated together on a steam-bath for ten hours. The reaction mixture was then poured into a dilute (10%) hydrochloric acid solution. The solid which precipitated was dissolved in benzene (125 cc.). This solution was extracted three times with 100-cc. portions of 5% sodium hydroxide. The aqueous solution was acidified with hydrochloric acid to precipitate the crude product. Two recrystallizations from a mixture of equal volumes of benzene and ligroin yielded 9.0 g. (50%) of phenylcinnamic acid, m. p. 172°.

α-Phenyl-*p*-nitrocinnamic Acid.[5]—A mixture of 3.0 g. of *p*-nitrobenzaldehyde,[6] 2.7 g. of phenylacetic acid, 5.7 cc. of acetic anhydride and 2.8 cc. of triethylamine was heated on a steam-bath for four hours. The resulting solution was made basic with sodium carbonate solution and then filtered while warm. The filtrate was acidified with hydrochloric acid. The precipitate was removed by filtration and recrystallized from ethyl alcohol. A yield of 3.6 g. (66%) of product, m. p. 208°, was obtained. A second recrystallization gave a 3.3 g. (61%) of α-phenyl-*p*-nitrocinnamic acid of m. p. 213°.

Smaller amounts were used in similar experiments to determine the relative merits of triethylamine, tripropylamine[4] and tributylamine[4] as catalysts.

When 3.6 g. of *p*-nitrophenylacetic acid (Eastman Kodak Co.) was used instead of phenylacetic acid in the above procedure, a negligible precipitate was obtained on acidification.

α-*p*-Nitrophenylcinnamic Acid.[7]—A mixture of 3.0 cc. of benzaldehyde, 3.6 g. of *p*-nitrophenylacetic acid, 5.7 cc. of acetic anhydride and 2.8 cc. of triethylamine was heated for ten hours. The red solution was poured into a 10% hydrochloric acid solution. The resinous mass obtained in this manner was extracted with ether. The yellow crystals not soluble in ether were recrystallized from ethyl alcohol. A yield of 0.7 g. (13%) of α-*p*-nitrophenylcinnamic acid, m. p. 224° was obtained.

Chlorination of Thiophenes with Sulfuryl Chloride

BY E. CAMPAIGNE AND WILLIAM M. LESUER

In an attempted preparation of 3-thenyl chloride from 3-methylthiophene it was found that sulfuryl chloride did not react with alkyl thiophenes as it does with alkyl benzenes. Kharasch and Brown[1] reported a high yield of benzyl or benzal chloride, depending on the mole ratio of reactants, on treatment of toluene with sulfuryl chloride in the presence of small amounts of benzoyl peroxide. No nuclear substitution occurred. The reactive thiophene nucleus yielded only nuclear substitution products in high yield on chlorination of 2- and 3-methylthiophene by this procedure. Thiophene was also readily chlorinated by this method. The chlorinations were effected in similarly high yields in the absence of the peroxide catalyst. The chlorination of thiophene has been reported previously using sulfuryl chloride in the presence of aluminum chloride.[2]

Experimental

Chlorination of 3-Methylthiophene.—To a solution of 98 g. (1.0 mole) of 3-methylthiophene was added 140 g. (1.03 mole) of sulfuryl chloride. Spontaneous refluxing commenced during the addition and continued throughout the addition, about one-half hour being required. The solution was then heated to reflux for one additional hour. Fractionation of the product yielded 104 g. (79%) of 2-chloro-3-methylthiophene, b. p. 153–155° (754 mm.). Vacuum distillation yielded a product with an odor of chlorotoluene, b. p. 154–155° (742 mm.), 54° (19 mm.); $n^{20}{}_D$ 1.5408, $d^{25}{}_4$ 1.2281. The physical constants are in accordance with those previously reported.[3]

Chlorination of Thiophene and 2-Methylthiophene.—These compounds were chlorinated by the same procedure as described above. The yield of 2-methyl-5(?)-chlorothiophene from 2-methylthiophene was 77% theory, b p. 154–155° (742 mm.), 55° (19 mm.); $n^{20}{}_D$ 1.5372, $d^{25}{}_4$ 1.2147. This is the same compound obtained by Opolski[4] on direct chlorination of 2-methylthiophene.

Three moles of thiophene on treatment with three moles of sulfuryl chloride yielded on distillation 0.8 mole of unchanged thiophene, 1.3 moles of 2-chlorothiophene (43%), and 0.3 mole of 2,5-dichlorothiophene (10%). Higher chlorination products were not identified.

2-Chlorothiophene.—B. p. 127–129° (742 mm.), 56° (56 mm.); $n^{20}{}_D$ 1.5490, $d^{26}{}_4$ 1.2923.

2,5-Dichlorothiophene.—B. p. 160–162° (742 mm.), 64.5° (25 mm.); $n^{20}{}_D$ 1.5627, $d^{27}{}_4$ 1.4486.

The physical constants for the mono- and dichlorothiophenes are in agreement with those previously reported.[5]

Acknowledgment.—The authors wish to thank Dr. George A. Harrington and Dr. Darwin E.

Some N-Basically Substituted Derivatives of *o*-Nitroaniline

BY ALFRED BURGER AND JAMES M. FREDERICKSEN

Some syntheses designed by us to lead to 9-(dialkylaminoalkyl)-isoalloxazine derivatives as potential metabolite antagonists to natural flavines were interrupted by the war four years ago, and the appearance of several recent articles based on similar thoughts[1,2,3,4] made resumption of this work inadvisable. We wish to report the syntheses and properties of some of the intermediates prepared in these studies.

TABLE I

Deriv. of chlorobenzene	Amine	Product	Yield, %	M. p., °C.	B. p., °C. (mm.)	Formula	% Composition

[g] Dipicrate m. p. 112–113°. [h] Red crystals from ligroin. [i] The insoluble orange solid was washed with ether and sublimed at 1 mm. [j] Dipicrate m. p. 210–212° (dec.); $C_{24}H_{23}N_9O_{17}$: % N calcd., 17.76; found, 17.56. [k] Red crystals from dilute ethanol. [l] Red oil. [m] O-Acetyl derivative prepared with acetic anhydride in pyridine at 100°, *cf.* Karrer and Naef, *Helv. Chim. Acta*, **19**, 1029 (1936), yellow crystals m. p. 64–65° from ethanol.

Experimental

Alkylaminonitrobenzenes.—Approximately equivalent amounts of 2-nitrochlorobenzene or its 5-methoxy derivative and the amine were refluxed for several hours in two equivalents of dry pyridine, 0.5 mole of the 2-nitrochlorobenzene and 0.01 to 0.05 mole of the 5-methoxy derivative being taken. Four to five hours of reaction time was used for runs of one-twentieth mole or less; eight hours for those of one-half mole. In some cases, unreacted chloronitroanisole was then removed by steam distillation. The residue was extracted with several portions of ether, and the reaction product obtained by evaporation of the solvent. Data as to the percentage composition and the physical properties of the substances prepared from the derivatives of chlorobenzene are given in Table I.

2-(2-Morpholinoethyl)-aminoaniline.—When a solution of 7.5 g. of 2-(2-morpholinoethyl)-aminonitrobenzene in 150 cc. of hot 50% ethanol was treated with a freshly prepared solution of 20.7 g. of sodium hydrosulfite dihydrate in 100 cc. of hot water, the red color soon changed to green. After brief boiling, the mixture was acidified with 80 cc. of 10% hydrochloric acid, the solution was cleared with norite, and evaporated to dryness under reduced pressure. The residue was washed with ether, and then decomposed with a cold 20% sodium hydroxide solution under ether. The aniline derivative was extracted into ether and worked up, yielding 5.3 g. (80%) of a red oil. Its *tripicrate* crystallized from ethanol, m. p. 201–203° (dec.).

Anal. Calcd. for $C_{30}H_{28}N_{12}O_{22}$: N, 18.50. Found: 18.33, 18.75.

1,4-bis-(2-Nitro-ethylaminophenyl)-piperazine.—A mixture of 3.0 g. of *o*-(β-chloroethyl)-aminonitrobenzene, 2.8 g. of piperazine and 0.05 g. of sodium iodide reacted exothermically, and was then refluxed for six hours. It was poured into water, the small amount of precipitated solid was filtered from much red oil, and washed with water. The oil from the filtrate was treated with alcohol and deposited another crop of the same orange crystals. Recrystallization from ethanol raised the melting point to 140–141°. The yield was 0.9 g.

Anal. Calcd. for $C_{20}H_{26}N_6O_4$: N, 20.28. Found: N, 20.27.

Preparation of 2- and 4-Benzylpyridine

BY KENNETH E. CROOK

Several investigators have reported the preparation of 2- and 4-benzylpyridines by heating a mixture of benzyl chloride, pyridine and a copper catalyst.[1]

Reported yields of the mixed benzylpyridines are 40 to 50%. The isomers have usually been separated as the picrates. Yields of the pure isomers are seldom given. The article of von Braun and Pinkernelle[1b] reporting a 50% yield of the 2-isomer, is not explicit as to whether this yield is based on the starting material or on the mixture of isomers.

Need for rather large quantities of 2- and 4-benzylpyridine prompted a search for conditions giving better yields. It was found possible to obtain 75% yields of a mixture of 2- and 4-benzylpyridines, 90% of which was separated into the two isomers by fractional distillation.

Experimental

Solvent.—By using pyridine hydrochloride as a solvent, the yields of the mixed benzylpyridines were nearly double and the violence of the initial exothermal reaction between benzyl chloride and pyridine was greatly reduced. At the conclusion of the rearrangement, the pyridine hydrochloride was recovered by distillation and used for succeeding runs without purification or replenishment.

Catalyst.—Copper metal (or cuprous chloride into which the copper is assumed to be converted) has been used as the catalyst for the rearrangement of the pyridinium salt. Copper (or cuprous chloride) has been reported to cause the conversion of benzyl chloride into dibenzyl and products of unknown composition.[2] This reaction may account for most of the tarry material produced when a mixture of copper, benzyl chloride and pyridine is heated. If benzylpyridinium chloride (no catalyst) is distilled, the vapors which pass over at about 190° (liquid temperature) consist of a mixture of benzyl chloride and pyridine. Rearrangement of benzylpyridinium chloride (catalyst present) is negligible at 190°. By dissolving the catalyst in the hot pyridine–pyridine hydrochloride mixture *prior* to the addition of benzyl chloride, the amount of tar formation is negligible. Copper, equivalent quantities of copper and cupric chloride, or cupric chloride alone, may be used.

Procedure

The procedure employed was a modification of that originally used by Tschitschibabin[1a] as modified by LaForge[1a] and by Crook and McElvain.[1c] The procedure finally adopted is given in some detail since it was found to be advantageous to modify most of the steps in previously recorded procedures.

Four moles (462 g.) of pyridine hydrochloride was distilled into a one-liter flask and allowed to solidify while the flask lay on its side. This flask was fitted with a Claisen adapter carrying a dropping funnel and a water reflux condenser bearing a tube containing calcium chloride, 5 g. of anhydrous cupric chloride and 80 cc. (1 mole) of pyridine were added, and the flask heated until all the pyridine hydrochloride had melted and the cupric chloride dissolved. Heating was discontinued and 115 cc. (1 mole) of benzyl chloride (b. p. 90–91° at 40 mm.) was added during ten–fifteen minutes while the flask was shaken continuously. The mixture was then refluxed gently for twelve hours. The pyridine hydrochloride was distilled off through a 45-cm. Vigreux column at 90 mm. pressure. Distillation was stopped when the vapor temperature reached 195°. This pyridine hydrochloride was used without purification for the next run. There was a slight gain in quantity of pyridine hydrochloride with succeeding runs.

The black residue was cooled, 200 cc. of water and 15 cc. of hydrochloric acid (sp. gr. 1.2) added, and the mixture warmed until it appeared homogeneous. The brown to black liquid was made basic with ammonium hydroxide, 100 cc. of a 1–1 mixture of benzene and ligroin added and the organic layer washed with 100-cc. portions of 1–10 ammonium hydroxide until the aqueous layer ceased to acquire a blue color (2–4 times), then washed once with water.

The organic layer was dried by placing it, together with stock potassium hydroxide, in a separatory funnel and withdrawing the aqueous layer periodically until no more formed.

After removing the solvent at atmospheric pressure, the residue was distilled through a 45-cm. Vigreux column and gave 123.5–128.5 g. of a mixture of 2- and 4-benzylpyridines boiling at 175–190° (40 mm.) and a higher boiling residue of 16–20 g.

By using 0, 1 and 2 moles of pyridine hydrochloride as the solvent, the quantities of benzylpyridines and of higher boiling material were 60 and 56 g., 88 and 30 g., and 103 and 28 g., respectively. Decreasing the time of heating to six hours gave erratic results. Other modifications which did not increase yields were: heating for twenty-four hours, heating in a carbon dioxide atmosphere, stirring, continuous addition of cupric chloride during the heating period, and the use of equivalent amounts of copper and cupric chloride as the catalyst.

The isomers were separated by fractional distillation through a 1.2 × 115-cm. column packed with 0.32-cm. glass helices. In order to minimize losses of the less abundant 4-isomer, as much as possible of the 2-isomer was removed at 276.5–277° and two intermediate fractions of 277–280.5 and 280.5–289° were collected. The residue in the still was then set aside while the intermediate fractions were put through the column a second time. All material boiling at 289° and above was then returned to the still and the fraction boiling at 289–289.5° collected as 4-benzylpyridine. From 1 kg. lots, 640–680 g. of 2-benzylpyridine (b. p. 276.5–277° cor. (730 mm.)) and 245–255 g. of 4-benzylpyridine (b. p. 289–289.5° cor. (730 mm.)) were obtained.

As an indication of purity the 2- and 4-isomer gave picrates which melted without purification at 139.5–140° and 138.5–139°, respectively. Reported melting points of the picrates of the 2- and 4-isomer are 140° and 136–138°.[1a]

Brominations with Pyridine Hydrobromide Perbromide

BY CARL DJERASSI AND CAESAR R. SCHOLZ

In connection with another problem, we had occasion to investigate the action of pyridine hydrobromide perbromide on some steroid ketones. Although pyridine and quinoline hydrobromide perbromides have been used occasionally as brominating agents, particularly with phenols and for the addition of bromine to double bonds,[1] no examples of the bromination of ketones with these reagents seem to have been recorded.

---

[1] *Cf.* Rosenmund, Kuhnhenn and Lesch, *Ber.*, **56**, 1262, 2042 (1923).

Pyridine hydrobromide perbromide[2] is a crystalline and stable salt, which is quite useful for brominations of ketones on a micro or semimicro scale, since it can be weighed very accurately in small quantities in contrast to bromine. Representative examples of monobromination and dibromination of steroid ketones are given in the experimental section. The reactions were carried out by warming equimolar quantities of the salt and ketone in glacial acetic acid or ethanol and the yields were comparable to those obtained by using bromine.

Aliphatic and alicyclic ketones, such as acetone or cyclohexanone, also readily decolorize the reagent, and details of the small scale bromination of an amino ketone are given in the experimental section. It is very likely that this reagent could be used in most brominations which are successful with bromine, with particular application to small scale experiments.

Attempts to employ pyridine perbromide,[3] a reagent which should bind any hydrogen bromide liberated, proved disappointing.

Experimental

Pyridine Hydrobromide Perbromide ($C_5H_5N\cdot HBr\cdot Br_2$).—The reagent was prepared in 85% yield by adding one mole of bromine to one mole of pyridine in 48% hydrobromic acid solution and recrystallizing the product from acetic acid; red prismatic crystals, m. p. 134° (dec.) with previous softening; lit.,[2] m. p. 132–134°. We are indebted to Dr. A. C. Shabica of our development department for a supply of this salt.

Monobromination of 3-Ketosteroids

Allo Series.—To a warm solution (40–60°) of 38 mg. of cholestanone in 1 cc. of glacial acetic acid was added 31 mg. of pyridine hydrobromide perbromide. Hydrogen bromide was evolved, the solution turned colorless and crystals of 2-bromocholestanone appeared within one minute. On cooling and filtering the crystals, 37 mg. (81%) of 2-bromocholestanone of m. p. 168–169°, $[\alpha]^{23}\mathrm{D}$ +38.1° (chloroform) was obtained, which gave no depression in melting point on admixture with an authentic sample.[4] By the same procedure, but using methyl 3-keto*allo*etiocholanate, there was obtained 75% of the corresponding 2-bromo derivative[5] of m. p. 184–188°. Glacial acetic acid could be replaced by ethanol or a mixture of ethanol and chloroform as solvent for the bromination.

Normal Series.—A mixture of 110 mg. of methyl 3-keto-12-acetoxycholanate and 75 mg. of the hydrobromide perbromide was warmed to *ca.* 40° for one minute in 5 cc. of glacial acetic acid and diluted with a few drops of water to yield 80 mg. (61%) of the 4-bromo derivative of m. p. 165–167°, $[\alpha]^{23}\mathrm{D}$ +91.5° (chloroform), identical (rotation and mixed m. p.) with an authentic sample prepared by the method of Burckhardt and Reichstein.[6] Similarly, coprostanone gave the 4-bromo compound[4] of m. p. 104–107°, $[\alpha]^{23}\mathrm{D}$ +40.5° (chloroform).

Monobromination of a 12-Ketosteroid.—A mixture of 195 mg. of methyl 3(α)-acetoxy-12-ketoetiocholanate and 155 mg. of pyridine hydrobromide perbromide in 1.2 cc. of glacial acetic acid was warmed until complete solution resulted, allowed to stand at room temperature for two and one-half hours and diluted with ether. The ether solution was washed well with water, evaporated to dryness and the residue was saponified and rearranged as described by Gallagher.[7] The crude yield of 3(α),12-dihydroxy-11-ketoetiocholanic acid of m. p. 248–257° was 130 mg. (74%); one recrystallization from ethanol gave colorless prisms of the acid melting at 274–278° (uncor.), with foaming at 282°. This material gave no depression in m. p. when mixed with an authentic sample (kindly furnished by Dr. H. B. MacPhillamy of our laboratories).

Dibromination of Cholestanone.—Treatment of 380 mg. of cholestanone with 640 mg. of the reagent in the usual manner gave after ten minutes 390 mg. (73%) of 2,4-dibromocholestanone[8] of m. p. 193–194° (dec.)

Bromination of an Aminoketone.—A solution of 65 mg. of 4-piperidino-2-butanone in 1 cc. of acetic acid containing 41% of hydrogen bromide was warmed with 135 mg. of pyridine hydrobromide perbromide for *ca.* thirty seconds until all the reagent had dissolved. Excess isopropyl ether was added which precipitated a pale yellow oil, which in turn was washed several times by decantation with isopropyl ether and crystallized from isopropyl alcohol. The yield of colorless, long needles of **1-bromo-4-piperidino-2-butanone hydrobromide** of m. p. 157–158° (dec.) was 77 mg. (55%). The product gave no depression in m. p. on admixture with a colorless sample prepared by the method of Land and co-workers[9] who reported a 44% yield of brown material of m. p. 157–158°.

Brominations with Pyridine Perbromide ($C_5H_5N\cdot Br_2$).—Pyridine perbromide (m. p. 62–63.5°) was prepared freshly for each reaction by the method of Williams,[3] since it decomposed within a few hours. The bromination of cholestanone and coprostanone was carried out in acetic acid as described above for the hydrobromide perbromide and required three to five days for completion. Warming caused polymerization of the reagent,[10] but exposure to ultraviolet light shortened the reaction time to about twenty-four hours. No hydrogen bromide was evolved, but for substances sensitive to hydrogen bromide, N-bromosuccinimide[11] should be preferred, since the latter reagent is stable and reaction is complete after a few minutes.

The Stobbe Condensation with Sodium Hydride

BY GUIDO H. DAUB AND WILLIAM S. JOHNSON

In previous communications[1] it was shown that in the Stobbe condensation of a ketone with succinic ester, the use of potassium *t*-butoxide as the catalyst generally gave higher yields and purer products during shorter reaction periods than were obtained by the classical procedure with sodium ethoxide. Since sodium hydride has been employed with considerable success in place of alkoxides in certain ester condensations,[2] it seemed worth while to investigate its possible

use in the Stobbe condensation. The preliminary results of our study were so promising that we are announcing them herewith. The new procedure appears to afford some advantage over the *t*-butoxide method in that it is considerably simplified, while the yields with two representative ketones, acetophenone and benzophenone, are at least as good. In a future communication we expect to report on a more extensive study of this new modification as well as on the mechanism of the condensation.

Experimental[3]

Stobbe Condensation with Acetophenone.—A mixture of 6.00 g. (0.05 mole) of the ketone, 26.13 g. (0.15 mole) of diethyl succinate and 2.4 g. (0.1 mole) of sodium hydride[4] was stirred for three and three-quarters hours at room temperature, care being taken to exclude all moisture from reagents and apparatus. The rate of evolution of hydrogen which was very slow at first gradually increased until after two hours it became quite rapid, slackening off toward the end of the reaction period. After three hours, 10 ml. of anhydrous benzene was added to facilitate stirring. The mixture was acidified with acetic acid, and extracted with ether. The ether solution was extracted with 5% sodium bicarbonate solution which on acidification gave 11.59 g. (93.5% yield) of pale yellow semi-solid acid undoubtedly consisting of a mixture of isomeric half-esters of Stobbe condensation product (neut. equiv., calcd., 248; found, 261). Crystallization from petroleum ether (b. p. 60–68°) rendered about one-third of the material crystalline; m. p. 111–112° after recrystallization from benzene–petrolum ether. This is probably identical with the half-ester of γ-methyl-γ-phenylisoitaconic acid, described by Stobbe[5] as melting at 110–112°. Saponification of the 112° half-ester with barium hydroxide afforded the crystalline dibasic acid, m. p. 180–182° with dec. (reported,[5] 178–179° and 183–185° with dec.).

Extraction of the ether solution, remaining after removal of the bicarbonate-soluble fraction, with 5% potassium hydroxide solution gave 1.23 g. of crude diethyl 1,4-diketocyclohexane-2,5-dicarboxylate, m. p. 117–123.5°, arising from the self-condensation of diethyl succinate. Recrystallization from alcohol raised the melting point to 126–127.5°, undepressed on admixture with an authentic specimen. This product gave a deep cherry-red color with alcoholic ferric chloride solution.

With Benzophenone.—When 9.11 g. (0.05 mole) of benzophenone and 26.13 g. (0.15 mole) of diethyl succinate were treated with 2.4 g. (0.1 mole) of sodium hydride as described above, no appreciable reaction took place even at steam-bath temperature. The addition of 10 drops of ethanol, however, initiated the reaction which proceeded readily at room temperature. The rate of hydrogen evolution increased as the reaction progressed until the sodium hydride was consumed (about eight hours). After about five hours 25 ml. of dry ether was added to facilitate the stirring of the mixture, which had become quite thick. The bicarbonate-soluble material, isolated as described above, amounted to 15.05 g. (a 97% yield) of almost colorless crystals, m. p. 124.5–125.5°, undepressed on admixture with an authentic specimen of β-carbethoxy-γ,γ-diphenylvinylacetic acid (m. p. 125–126°).[1c]

The 1,4-diketocyclohexane-2,5-dicarboxylate isolated by extraction with potassium hydroxide amounted to 1.58 g., m. p. 119–123.5°.

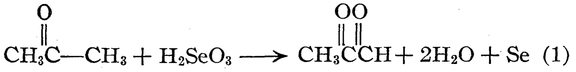
Kinetics of the Oxidation of Acetone by Selenious Acid

BY FREDERICK R. DUKE

The discovery of intermediates in appreciable concentration during the glycol-splitting type of specific oxidation[1] prompted this investigation of the selenious acid–acetone reaction. The stoichiometry is represented by the equation[2]



$$CH_3\overset{\overset{\displaystyle O}{\|}}{C}—CH_3 + H_2SeO_3 \longrightarrow CH_3\overset{\overset{\displaystyle O}{\|}}{C}\overset{\overset{\displaystyle O}{\|}}{C}H + 2H_2O + Se \quad (1)$$

The reaction was studied extensively by Mel'nikov and Rokitskaya.[3] They found that the common alkyl esters of selenious acid decomposed at high temperatures to yield the corresponding aldehyde or ketone and selenium, and from this concluded that the oxidation of aldehydes and ketones proceeded through the enol ester intermediate. Data on the ease of oxidation of a series of aldehydes and ketones was used by these investigators to arrange the compounds in order of ease of enolization.

In the present investigation, the effects of high hydrogen ion and acetone concentrations on the rate of the reaction were studied in an attempt to demonstrate kinetically the presence of an intermediate. The data obtained clearly show that no appreciable amount of intermediate accumulates; however, certain conclusions may be drawn from the results and these are presented below.

Experimental

C. P. reagents were used. The specific gravity of the acetone was 0.7890 (25°/4°), fixing the water content at less than 1.5%.[4] Fifty-ml. volumetric flasks were used as reaction vessels; in Experiments I the appropriate amount of 5 *M* perchloric acid, 5 *M* sodium perchlorate, pure water and acetone and 2.0 ml. of 0.1 *M* selenious acid were pipetted into the flasks; then the latter were filled to the mark with *t*-butanol. After fifteen minutes in the constant temperature bath, sampling was begun with a 5-ml. pipet. The samples were quenched in acidified 5% KI solution, and the iodine titrated with 0.01 *N* thiosulfate. *t*-Butanol was used to maintain the reaction mixture at approximately constant dielectric as the acetone concentration was varied; the alcohol possesses the additional desirable property of low reactivity in esterification and aldol formation.

Experiments II were run in the same manner as Experiments I, except that the reacting mixture was prepared from 2 *M* acetone and 2 *M* perchloric acid. The acetone concentration was kept sufficiently low that the solutions in all cases may be considered truly aqueous. Sodium perchlorate was added where necessary to maintain constant ionic strength.

Experiments III were identical with the low-temperature runs of Experiment I except that the water concentration was varied and the acetone kept constant.

The constant temperature-bath was water maintained to ±0.1°.

Results.—In each of the experiments, the concentrations of reactants were chosen such that

essentially only the selenious acid concentration changed. Plots of log $[H_2SeO_3]$ *vs.* time yielded straight lines, the slopes being the first order (in oxidant) pseudoconstants.

The results of Experiments I are listed in Table I. It is evident that the reaction is first-order in acetone over a wide range of concentration. Experiments II (Table II) run at relatively low acetone concentrations and in aqueous solution to ensure incontrovertible meaning for $[H^+]$, demonstrate that equation I holds over a wide range of acidity

$$-d[H_2SeO_3]/dt = k\,[\text{acetone}][H_2SeO_3][H^+] \quad \text{(I)}$$

No acidities lower than 0.04 *N* were studied because at higher *p*H values the loss of selenious acid from solution would invalidate the assumption that $[H^+]$ remains constant throughout a given run.

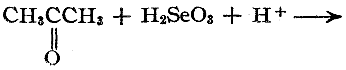
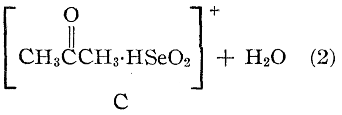
33.3	.63	21.0

Experiments III indicate that an increase in the concentration of water results in a lowered reaction rate. These results are discussed below.

Discussion.—Since the stoichiometry of reaction (1), contrary to the kinetics data, requires no hydrogen ion, the logical conclusion is that an intermediate, C, is formed



$$CH_3\underset{\underset{O}{\|}}{C}CH_3 + H_2SeO_3 + H^+ \longrightarrow$$



$$\underset{C}{\left[CH_3\overset{\overset{O}{\|}}{C}CH_3{\cdot}HSeO_2\right]^+} + H_2O \quad (2)$$

(C, as written, is not intended to include an implication of structure.) Reaction (2) presents two alternative possibilities: that the rate of formation of C is the measurable reaction, equation I correctly designating the kinetics; or that reaction (2) is an equilibrium reaction with $K = [C][H_2O]/[\text{acetone}][H_2SeO_3][H^+]$. In the latter case, the correct kinetics expression is $-d[H_2SeO_3]/dt = kK[\text{acetone}][H_2SeO_3][H^+]/[H_2O]$, since the data demonstrate that no detectable concentration of C is present. The variation in rate with water concentration (Table III) is in the right direction for this equation but is as reasonably explained by changes in activities of reactants with change of solvent. Thus, although no definite conclusion may be reached concerning these possibilities, it seems likely that equation I correctly expresses the kinetics. On this basis, the activation energy for reaction (2) may be calculated to be 18 kcal. per mole.

The Nature of the Intermediate.—One possible structure for C, postulated by Mel'nikov and Rokitskaya[2] is the enol ester. However, Olivier and Berge[5] have shown that for acids similar to selenious, the rate of esterification is not proportional to $[H^+]$. In addition, the oxidation proceeds at a negligible rate in alkaline solution (experiment not reported) under conditions favoring both enolization and esterification. Further, Michaelis and Landmann[6] have demonstrated that diethyl selenite is easily decomposed by pure water, a characteristic of esters whose rates of formation and hydrolysis are relatively independent of acidity.

Consideration of a second structure is dictated by the reaction under similar conditions of sulfurous acid, the closest analog of selenious acid. The preponderance of evidence[7] indicates that acetone and sulfurous acid react to yield an α-hydroxysulfonic acid, the analog being an α-hydroxyselenonic acid. Since, however, no compounds of the type $RSeO_3H$ have ever been prepared directly from selenious acid in spite of repeated attempts to do so,[8] and since the reaction rate of sulfurous acid with carbonyl compounds is inverse to $[H^+]$,[9] it does not seem that the selenonic acid structure deserves further consideration.

The demonstrated basicity of acetone toward selenium dioxide[10] is the basis for a third possibil-

ity =  where the acetone has displaced a hydroxyl ion from the selenium. In favor of this structure, one may cite the complete agreement with the kinetic evidence; but also, the subsequent disproportionation of the intermediate to pyruvaldehyde and selenium is most reasonable. The coördination of the acetone through its oxygen necessarily results in a redistribution of charge within the acetone molecule which would result in enhanced reactivity of the α-hydrogens; and it is not unlikely that the bond distances and angles in the complex are such that the selenium oxygens are placed in a favorable steric position for reaction with α-carbon.

KEDZIE CHEMICAL LABORATORY
MICHIGAN STATE COLLEGE
EAST LANSING, MICHIGAN

Iodometric Analysis of *o*-Nitrobenzeneseleninic Acid

BY OLAV FOSS

o-Nitrobenzeneseleninic acid has been found to react with thiosulfuric acid as follows

$$o\text{-}O_2NC_6H_4Se(O)OH + 3S_2O_3^{--} + 3H^+ = o\text{-}O_2NC_6H_4SeS_2O_3^- + S_4O_6^{--} + 2H_2O$$

The reaction is rapid and quantitative. The reaction product, *o*-nitrobenzeneselenenyl thiosulfate, has previously been isolated as a potassium salt by the reaction of *o*-nitrobenzeneselenenyl bromide with potassium thiosulfate,[1] and is also formed in reactions of various *o*-nitrobenzeneselenenyl sulfur compounds with thiosulfate.[1] It forms yellowish green, stable solutions. In neutral and acid solutions it is indifferent to iodine and does not interfere with iodine–thiosulfate titrations carried out in the same solutions. Hence the above reaction may be utilized for the iodometric analysis of *o*-nitrobenzeneseleninic acid, excess of thiosulfate being back-titrated with iodine. The following procedure may be employed.

To 12–20 mg. of *o*-nitrobenzeneseleninic acid dissolved in 25 ml. of water are added 5 ml. of 0.1 *N* sulfuric acid and then 20–30 ml. of 0.01 *N* sodium thiosulfate (5 ml. excess). After standing for two to three minutes at room temperature, starch is added, and the excess of thiosulfate is back-titrated with 0.01 *N* iodine.

Notice may be made to the analogous method of Norris and Fay[2] for the iodometric analysis of selenious acid, by means of the change

$$SeO_2 + 4S_2O_3^{--} + 4H^+ = Se(S_2O_3)_2^{--} + S_4O_6^{--} + 2H_2O$$

Experimental

The *o*-nitrobenzeneseleninic acid employed was prepared from the trichloride by hydrolysis,[3] and recrystallized from water until colorless.

0.1589 g. of the acid was dissolved to 250 ml. in water in a volumetric flask. Twenty-five ml. was pipetted out and 5 ml. 0.1 *N* sulfuric acid and then 25 ml. 0.01 *N* sodium thiosulfate (consuming 24.79 ml. of 0.01078 *N* iodine) were added. The time of standing was 2, 2, 5, 5, 8, 8 minutes. Amounts of 0.01078 *N* iodine then consumed: 5.95, 5.92, 5.92, 5.93, 5.92, 5.93 ml., respectively. Average: 5.93 ml., which gives 0.1585 g. of *o*-nitrobenzeneseleninic acid, *i.e.*, 99.7%.

Indifference of *o*-nitrobenzeneselenenyl thiosulfate to iodine. To 25 ml. of 0.01 *N* sodium thiosulfate were added 5 ml. 10% acetic acid, 5 ml. of starch solution, and (a) 20 ml. of water, (b) 20 ml. of 0.01 *M* potassium *o*-nitrobenzeneselenenyl thiosulfate. The solutions were then titrated with 0.01 *N* iodine. Amounts consumed: (a) 24.49, 24.50 ml. (b) 24.50, 24.50, 24.49 ml.

Mixed Crystal Formation in Linear Copolyesters

BY C. S. FULLER

Slagle and Ott[1] showed that solidified mixes of normal aliphatic acids frequently exhibit a single X-ray spacing along the direction of the molecule axes in the mixed crystal. The purpose of this note is to point out that an analogous behavior occurs in copolymers in which the constituents are ethylene glycol dibasic acid residues of different chain lengths and, presumably, are randomly distributed along the long chain molecules.

A copolyester capable of being cold drawn into strong fibers was prepared by treating equal molar quantities of pure 10-, 11- and 12-membered aliphatic dicarboxylic acids with ethylene glycol. The X-ray fiber diagram of the copolymer (Fig. 1 (a)) is similar to that exhibited by many simple linear polyesters.[2] A mixed crystal is therefore indicated.

The average fiber period for the copolyester measures 17.83 Å. This value was obtained from the three strongest layer-line reflections (17.78, 18.00, 17.70). The fiber periods of the constituent ethylene polyesters prepared from the individual pure dibasic acids according to the same procedure are as follows ·

Ethylene decane 1-10 polyester	16.86 Å.
Ethylene undecane 1-11 polyester	36.32 (18.16 Å.)
Ethylene dodecane 1-12 polyester	19.40 Å.

The odd number of chain atoms in the 1-11 polyester causes a doubling of the fiber period. In addition, as the fiber pattern of Fig. 1b shows, the polar layers are perpendicular to the fiber axis unlike the even polyesters in which these planes are inclined to the axis.[3] It is noteworthy that (insofar as we can speak of polar layers in the copolymer) the pattern of the copolyester exhibits

layer-line reflections corresponding to *inclined* polar layers.

The fiber period of 17.83 Å. observed for the copolyester is somewhat lower than the value (18.03) obtained by averaging the three repeating lengths of the pure polyesters (19.40, 18.16, 16.84). However, it seems unlikely that an accuracy of greater than ±0.15 Å. can be expected in these measurements. Consequently, for the purposes of the present work the observed fiber period of the copolyester may be considered to be the same as the average of the lengths of the units which have been put into the copolymer.

The presence of pyramidal rather than meridian reflections in the copolyester indicates a preponderance of the staggered over the horizontal type of packing of the polar groups of adjacent chains. This might be anticipated from the fact that there are two "even" type units in the chain molecules to every one of the "odd" type. Strong meridian reflections must occur at the Bragg spacings corresponding to the approximate C–C component distance (1.25) along the fiber axis, but this is only observable with electron rays.[4]

We conclude from these results that a fiber pattern showing discrete reflections can be obtained from random copolymers composed of units which are able to crystallize together such as those comprising chain hydrocarbon spacers and small side polar groups. When equal numbers of units are present, the fiber period observed under such circumstances is given by the averages of those of the units present, but it bears no real relation to the structure present. There is evidence, however, that the longitudinal adjustment of adjacent chains is not random but is determined by the dipole interactions in such a way as to provide a minimum free energy for the entire structure. Recently Bunn and Peiser[5] reported a similar instance to that described here for a copolymer consisting of ethylene and hydroxyl substituted ethylene units. Bunn gives no information however about the kind of polar packing exhibited, so a full comparison with the results here reported is not possible.

Experimental

The polyesters were prepared by passing dry hydrogen through mixtures of the reactants at 200° until the degree of condensation was sufficient to allow fibers to be cold-drawn from solidified filaments. The dibasic acids all melted sharply and agreed with literature values for the respective compounds. The sebacic acid (m. p. 133°) was distilled from the commercial product. The 11- and 12-member acids (m. p.'s 110 and 124°) were prepared from 11-hydroxyundecylic acid and ω-bromoundecylic acid, respectively. From ultimate analysis the 11 member acid was estimated to be 97% pure. The ethylene glycol was redistilled from the C. P. laboratory product. About 5% excess of the equivalent amount of glycol needed for reaction was added and the mixture pre-condensed at about 120° until most of the water was removed. The condensation was then continued at 200° in bubbling hydrogen until the cold-drawing stage was reached.

The X-ray diagrams were taken on individual uniaxially oriented specimens. Filtered copper radiation was employed. Sodium chloride was dusted on the specimens as a reference standard. The fiber periods were calculated from the best reflections on several photographs. Five photographs were used to obtain the fiber period of the 14-membered polyester (16.84), four for the 15-

Some Halogenated Naphthoxyacetic Acids[1]—A Confirmation

BY C. ROBERT GEISER AND HOKE S. GREENE

The preparation of 2,4-dichloro-1-naphthoxyacetic acid, 1,6-dibromo-2-naphthoxyacetic acid, 4-chloro-1-naphthoxyacetic acid, and 2,4-dibromo-1-naphthoxyacetic acid reported by Haskelberg[2] has been independently confirmed by us using similar methods. Templeman and Sexton[3] had previously reported the melting point of 2,4-dichloro-1-naphthoxyacetic acid as 135° but we have found it to be 178° in agreement with Haskelberg.[2]

The aforementioned compounds showed selectivity as weed killers in 0.1% solution as a triethanolamine salt. However, at that concentration they were not as effective as 2,4-dichlorophenoxyacetic acid.

Separation of Tropic and Atropic Acids by Partition Chromatography

BY SIDNEY GOTTLIEB

In the course of a study on the hydrolysis of alkaloids of the atropine group, it became necessary to separate tropic from atropic acids in a large number of hydrolysates. Although the solubility characteristics of these two acids permit their separation from one another by several steps involving fractional crystallization, a much more rapid and convenient method was developed using partition chromatography.

This technique, originally developed by Martin and Synge,[1] consists essentially of passing one of a pair of immiscible solvents over a film of the other, the latter solvent being adsorbed onto an inert lattice. The substances dissolved in the mobile solvent will then partition themselves between the two phases according to their partition coefficients in such a way as to form distinct bands. Since tropic and atropic acids differ significantly in their partition coefficients between water and chloroform, this pair of solvents was used, with precipitated silicic acid as the supporting lattice. An acid–base indicator in the form of an azo dye was incorporated into the aqueous phase and, as the acids moved down the column, their positions were clearly indicated by dark blue bands against a red background.

In several parallel determinations, the identity of the first fraction to come through the column was established as atropic acid by evaporating the solvent and recrystallizing the residue once from hot water, which yielded monoclinic prisms, m. p. 106.0–106.5° (cor.). That the material comprising the upper band was tropic acid was proved by evaporating the solvent and recrystallizing the residue twice from boiling benzene to yield needes, m. p. 116.0–117.0° (cor.).

Experimental

A typical column was prepared by intimately mixing 10 cc. of a 0.1% aqueous solution of 3,6-disulfo-β-naphthaleneazo-N-phenyl-α-naphthylamine[2] with 20 g. of dry precipitated silicic acid. In this investigation Eimer and Amend C. P. silicic acid, batch #403320, was used. The mixing was done with a mortar and pestle until the mixture had uniformly taken on the red color of the dye, and no lumpiness remained. A slurry of this preparation was made with 50 cc. of chloroform and the slurry poured into a glass tube having a diameter of 24 mm., constricted and plugged with cotton at one end. When enough chloroform had run through the column so that the suspension acted like a stiff gel on shaking, a mixture of 5 mg. each of tropic and atropic acids dissolved in 3 cc. of chloroform was pipetted into the column. After this solution had just passed the top of the column, 5 cc. of chloroform was added to wash any acid remaining on the sides of the column into the narrow band. Then 50 cc. of chloroform was run through the column to separate and develop the bands. The atropic acid, being more soluble in chloroform, moved rapidly down in a sharp band, usually being completely washed out by 40 cc. of chloroform. The upper band, containing the slower-moving tropic acid, which had moved about one-fourth of the way down the column, was then washed through with a mixture of 10% butyl alcohol in chloroform. Titration of the residues with $N/50$ sodium hydroxide indicated essentially quantitative recovery and separation of the two acids.

The Existence of Beta Cristobalite at Room Temperature

BY ALEXANDER GRENALL

Due to some unexplained circumstance, overheating of pelleted clay catalyst occurred in the regenerator kiln of a catalytic cracking unit to such a degree that some of the pellets were fused and glassy in appearance. On breaking open these pellets it was found that while the surfaces were glassy, the centers were not.

Independent X-ray diffraction examinations were made of the surface and center material. A complete analysis of the diffraction data from Debye–Scherrer photographs revealed, in addition to other phases, the presence of β-cristobalite in the glassy surface of the pellets and the existence of α-cristobalite in the centers. The identity of these substances was established by comparison of the data from this work with that for β- and α-cristobalite given by the A.S.T.M. index,[1] excellent agreement in line position and relative intensities being shown.

Sosman,[2] in his authoritative treatise on silica, states that the inversion of the high temperature form, β-cristobalite, to the low temperature form, α-cristobalite, is rapid and occurs promptly as soon as the inversion temperature range of 200 to 275° is reached. In order to substantiate our identification of the β-cristobalite pattern for the overheated catalyst, a literature search was made and two other reported instances in which β-cristobalite had been identified in room temperature samples were found: in opals[3,4] and in glassy matrices containing silica.[4] In the latter publication this phenomenon was attributed to the prevention of inversion by the glassy matrix in which the crystals of β-cristobalite existed. Sosman[2,5] has denied the possibility of maintaining the beta structure by quenching but[5] has kept open the possibility that in a glass this might occur and asked for further study.

Our results are of interest because the cristobalite in the glassy surface of the fused clay catalyst pellets was shown to be the beta form while in the non-glassy interior, complete inversion to the alpha form had taken place. This provides an excellent confirmation of Greig's[4] contentions that the high-low inversion of cristobalite may be restrained and the high temperature form, β-cristobalite, may exist indefinitely at room temperature when the crystals of cristobalite are formed in a glassy medium. At the same time the results on the non-glassy centers are in agreement with Sosman's contention that the transformation to the alpha form cannot be delayed by quenching, if now this statement is qualified to apply to the changes occurring in a non-enclosing solid medium. As demonstrated by Greig,[4] when adhesion between enclosing medium and cristobalite crystal is broken, then inversion to the low temperature form takes place readily. Furthermore, from his results, it appears that once the α form has been developed, cristobalite may be taken up and down through the high-low inversion point with rapid transformation into the phase expected in complete accord with Sosman's statement.

It may be of significance to researchers in the field of ceramics to note that the diffraction patterns of both α- and β-cristobalite showed practically the same extent of line broadening. From the information that line broadening is present, it is possible to fix an upper limit to the crystal size of the cristobalites at 10^{-5} cm. Since the lines are only moderately broadened by comparison with sharp diffraction lines of the other phases present it is estimated that the crystal size lies between 5×10^{-6} and 10^{-5} cm.

Crystallization of Triacetin

BY BERNARD HANCOCK, DONALD M. SYLVESTER AND SYLVAN E. FORMAN

Triacetin has been reported to form a glass at −78 and at −60°.[1] We have observed triacetin to crystallize at +3.2°.

A tank car of impure triacetin which had been shipped a long distance in cold weather was received with the contents partly solidified. Some of this slush was kept overnight in a refrigerator at +5°, but the solids had melted before morning.

The melt would not crystallize when cooled with dry ice or with an ice and salt mixture, but a portion diluted with an equal volume of absolute ethyl alcohol was crystallized readily by cooling to about −10 or −15°. Several such portions were crystallized on that day and some crystals were preserved in an ice and salt mixture.

On subsequent occasions, crystallizations of triacetin samples were induced by seeding. However, no crystals could be obtained without this aid.

A sample of triacetin was distilled at 130.5° (7 mm.). It had $n^{26}\mathrm{D}$ 1.4288 and gave saponification equivalents of 72.42 and 72.35 (theory 72.70). Five small portions were cooled to about −15° and the first one was seeded with triacetin. This tube was used to seed the second tube, the second to seed the third, and so forth. This procedure was carried out to prevent impurities from being transferred by the seed crystals. Finally about 10 ml. of pure triacetin in a shielded tube was cooled to about −15° and seeded from the fifth tube. The temperature rose to +3.2° (cor.) where it remained until all of the solid melted.

The triacetin was converted into glycerol and ethyl acetate with ethyl alcohol and a trace of sulfuric acid. The glycerol was vacuum steam distilled. It was 98.5% glycerol by acetylation and 1.3% water by Karl Fischer titration; $n^{25}\mathrm{D}$ 1.4698.

The ethyl acetate was purified by extraction with water followed by rectification. It distilled at 77° and was 99.3% pure by saponification.

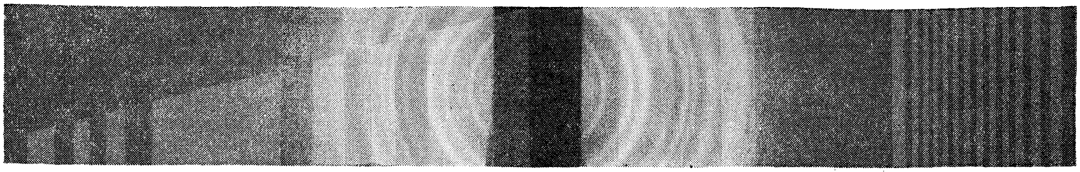

Fig. 1a.—Schardinger α-dextrin nitrate.

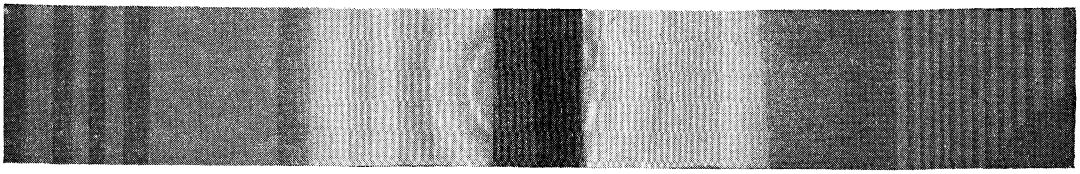

Fig. 1b.—Schardinger β-dextrin nitrate.

seven glucose residues. During the course of recent molecular weight determinations of completely nitrated starches and dextrins by means of the Barger isopiestic method[2] we decided to check the Barger technique on nitric esters of the crystalline Schardinger dextrins, compounds previously described only once.[3]

We were able to nitrate without difficulty the Schardinger α and β-dextrins, employing nitrogen pentoxide in chloroform in the presence of sodium fluoride according to a method previously described.[4]

Proof of the crystalline character of these Schardinger dextrin nitric esters is attested by the photographs (Fig. 1) of their X-ray powder patterns.[5]

The derivation $c \rightarrow 0$ of number average molecular weights, determined by the Barger method,[2] is shown graphically in Fig. 2. Values of *ca.* 1,700 for the α-dextrin nitrate and 2,000 for the β-nitrate were obtained. The observed nitrogen contents were 13.61 and 13.52%, respectively.[6] From these nitrogen values the calculated molecular weights are1, 728 and 2,009, respectively, assuming six and seven glucose residues. Complete nitration of Schardinger dextrins should yield 14.14% N. The observed degree of nitration is lower than anticipated from previous experience with starches and dextrins under similar conditions,[4] and is attributed tentatively to steric hindrance in a ring structure.

Intrinsic viscosities, $[\eta] = \lim_{c \to 0} \eta_{sp}/c$, were determined in ethyl acetate solution. The $[\eta]$ of the α-dextrin nitrate was 0.048, of the β-dextrin nitrate 0.080.

The Schardinger dextrin nitrates failed to exhibit a sharp melting point. The α-dextrin nitrate began to decompose slowly at 167–168°, the β-nitrate at 184–186°.

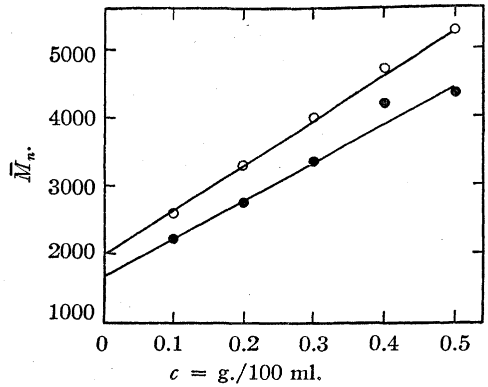

Fig. 2.—Schardinger dextrin nitrates; derivation of $\bar{M}_{nc \rightarrow 0}$ in ethyl acetate: ●, α; ○, β-dextrin.

Experimental

Preparation of Schardinger Dextrin Nitrates.—A chloroform solution of 250 ml. containing 47.3 g. of nitrogen pentoxide was cooled to −15°. Ten grams of sodium fluoride was added and the dispersion mechanically agitated during the slow addition of 10 g. of dried crystalline Schardinger dextrin.[7] The temperature was allowed to rise slowly to 8° during a reaction period of one hour. The nitrated dextrin, admixed with sodium fluoride, was removed by filtration, purified and stabilized according to the procedure elsewhere described.[4]

Molecular Weight and Intrinsic Viscosity Determinations.—These were determined according to procedures elsewhere described.[2]

X-Ray Diffraction Patterns.[5]—These (Fig. 1) were obtained with a cylindrical camera of approximately 10 cm. radius using filtered copper radiation.

Acknowledgment.—The authors wish to express their appreciation to Dr. C. S. Hudson for the Schardinger dextrins and for helpful suggestions, also to Dr. G. C. Nutting and F. R. Senti for the X-ray diffraction photographs.

Synthesis of Ketones from Aliphatic Nitriles and Phenylmagnesium Bromide

BY CHARLES R. HAUSER, WILBERT J. HUMPHLETT AND MARTIN J. WEISS

Shriner and Turner[1] have shown that, in the synthesis of acetophenone from acetonitrile and phenylmagnesium bromide, the best result is obtained with a 300% excess of the Grignard reagent. Accordingly these workers employed this large excess of the reagent in corresponding reactions with higher homologs of acetonitrile. Apparently on this basis the statement has been made in texts[2] that, with the higher aliphatic nitriles, as well as acetonitrile, the large excess of the Grignard reagent is necessary for satisfactory yields of ketones. However, Bary[3] had reported previously that a 90% yield of butyrophenone is obtained from butyronitrile with a 50% excess of phenylmagnesium bromide.

In the present investigation, high yields of ketones have been obtained from propionitrile and higher homologs through *n*-capronitrile with only a 10% excess of phenylmagnesium bromide. These results, and also the corresponding cases reported by Shriner and Turner,[1] are given in Table I. With the three higher nitriles, our results appear even slightly better than those from the large excess of the Grignard reagent.

It should be pointed out that, with ethylmagnesium bromide and propionitrile, we have obtained only a 23% yield of diethyl ketone (b. p. 101–105°) using a 10% excess of the reagent. Earlier workers[4] have similarly reported only fair yields of ketones with this aliphatic Grignard reagent and propionitrile or butyronitrile.

[d] Layraud [*Bull. soc. chim.*, (3) **35**, 223 (1906)] gives 1.5152 at 19°. [e] Ref. 1.

Procedure.—In a 1-liter three-necked round-bottomed flask equipped through ground-glass joints with a mercury-sealed stirrer, dropping funnel, and a reflux condenser (having a drying tube) was placed 300 ml. of an ether solution containing 0.275 mole of phenylmagnesium bromide. To the stirred refluxing solution was added, during fifteen to twenty minutes, 0.250 mole of the nitrile in 125 ml. of dry ether. The stirring and refluxing was continued for one to six hours[5]; during the first hour a precipitate formed. The cooled mixture was decomposed with ice and acid and the ether removed on the steam-bath under an ether still. After heating for an hour longer to ensure hydrolysis of the ketimine, the ketone was extracted with four 150-ml. portions of ether. The solvent was distilled from the dried combined ether solutions and the residue distilled through a 15 cm. Vigreux column.

Some Azeotropes of Alkylacetylenes and Ethyl Alcohol[1]

BY G. F. HENNION AND J. J. GROEBNER

Azeotropic distillation is a well-known means for the separation and purification of various hydrocarbons and data are available for many hydrocarbon-carrier systems. Particular attention has been given to the azeotropes of paraffins, naphthenes, olefins, diolefins and aromatics. Since there is no information on constant boiling mixtures of higher acetylenes, we have investigated four acetylene–ethyl alcohol binaries. The data are given in Table I. When the boiling points of the azeotropes are plotted against their compositions a smooth curve is obtained, similar to, but appreciably above, the one for paraffins.[2]

The lowering of the hydrocarbon boiling point achieved by azeotropic distillation is greatest for paraffins and least for aromatics; the other hydrocarbons are intermediate and usually in the order cited above.[3] When the data for the acetylenes are compared with those of the other hydrocarbons it appears that the acetylenes fall between the aromatics and the others. Thus the

acetylene–alcohol mixtures boil slightly higher than those of the other classes of aliphatic hydrocarbons. This may prove to be significant should the problem of separating acetylenes from hydrocarbon mixtures ever present itself.

Analysis of the constant boiling acetylene–alcohol mixtures was accomplished both by refractive index and density. A sufficient number of mixtures was prepared in each case to establish both isotherms. All distillations were done at atmospheric pressure when the barometer read 745 ± 5 mm.

The acetylenes form ternary alcohol–water heteroazeotropes also. These were not analyzed although some of the data for them were recorded (Table II).

TABLE II

TERNARY HETEROAZEOTROPES OF ALKYLACETYLENES WITH ETHYL ALCOHOL AND WATER

Acetylene	Constant b. p., °C.	Vol. % lower layer[a]	Upper layer $n^{25}D$	Upper layer d^{25}	Lower layer $n^{25}D$	Lower layer d^{25}
n-Butyl	59.9	5.6	1.3921	0.7202	1.3598	0.8597
Diethyl	64.4	14.8	1.4025	.7290	1.3674	.8539
Isoamyl	69.0	17.4	1.3955	.7371	1.3672	.9519
n-Amyl	71.0	28.6	1.3970	.7436	1.3680	.8329

[a] These values are approximate and were measured at 25°.

Experimental

The acetylenes were prepared in the usual way from the alkyl bromides and sodium acetylide in liquid ammonia.[4] Absolute ethyl alcohol (Commercial Solvents Corp.) was redried with magnesium ethoxide immediately before use; d^{25} 0.7852, $n^{25}D$ 1.3594.

A carefully purified sample of each acetylene was mixed with an excess of amount of absolute alcohol and slowly distilled through a helix packed column having an efficiency of 15 plates as determined with an ethylene bromide–benzene mixture. The distillate was collected in fractions and those of nearly the same boiling point, density and refractive index were combined and redistilled. The process was repeated until successive fractions of the distillate showed practically the same composition, not altered by redistillation.

The ternary mixtures were obtained in substantially the same way, except that water was added to the still charge and the column was provided with a special head to prevent premature phase separation. The material which distilled at constant temperature was collected separately but was not redistilled since analysis was not intended.

Relative Association of Hydrogen and Deuterium Fluorides in the Liquid State

BY JOEL H. HILDEBRAND AND ALLEN GEE

Claussen and Hildebrand[1] found that the vapor pressure of deuterium fluoride is greater than that of hydrogen fluoride, the ratio, P_{DF}/P_{HF} varying from 1.150 at 240° K. to 1.049 at 290° K. The vapor pressure of the deuterium compound is greater than that of the hydrogen compound also in the case of the acetic acids, but it is less in the case of the two kinds of water and ammonia and with deuterium and hydrogen chloride. It was pointed out that the first two pairs are alike in being highly associated in the gaseous phase while the last three are not.

Long, Hildebrand and Morrell[2] determined the variation in the association factors of gaseous hydrogen fluoride and deuterium fluoride with pressure and temperature, showing deuterium fluoride to be more associated. They confirmed the earlier results of Simons and Hildebrand[3], who found that the association of hydrogen fluoride could be reproduced over a wide range by assuming the single equilibrium, $6HF = (HF)_6$, with evidence for smaller polymers below a degree of association represented by the association factor, 1.3. It has been recognized that polymers other than $(HF)_6$ may be present also in the range of higher association, and that the single equilibrium that has been assumed may represent only an average of a more complex scheme of association. The only reason for a preponderance of a hexamer would appear to be a closed ring with its additional hydrogen bond and with corresponding preferred bond angles.[4] However, no independent evidence for ring structure has yet been discovered, and the recent measurements of dielectric constant by Benesi and Smyth indicate linear polymers.[5]

This does not interfere with the purpose of this communication, which is to calculate the partial pressures of the monomers, p_{HF} and p_{DF}, in the saturated vapors in order to learn whether, in the liquid state, the hydrogen compound is less strongly associated than the deuterium compound, as in the cases of water and ammonia.

The following table gives the total pressures at saturation according to Claussen and Hildebrand together with the corresponding partial pressures of the monomers, calculated by the aid of the equations of Long, Hildebrand and Morrell. The ratio, p_{HF}/p_{DF}, is greater than unity, indicating stronger association of the deuterium compound in the liquid, and bringing these com-

Chromatography of Some Common Indicators

BY J. V. KARABINOS[1] AND P. M. HYDE

Alumina,[2] calcium carbonate, talc, Super Cel and Hyflo Super Cel have been used successfully as adsorbents for the chromatography of coal tar dyes and indicators.[3] We wish to add to this list Silene EF[4] which has already found extensive use in the carbohydrate series.[5]

The relative degree of adsorption of the indicators on Silene EF–Celite 535[6] (5:1 by weight) was determined as follows. The indicator (0.75 mg.) dissolved in 0.4 ml. of 90% dioxane (90 ml. dioxane–10 ml. water) was put on a Tswett column (10 × 100 mm.) previously wetted with 0.5 ml. of the solvent and the indicator was developed with 5.0 ml. of 90% dioxane. The position of the colored zone was easily determined since the length of the column was calibrated in mm. (0, bottom; 100 mm., top). Checks were obtained in duplicate runs. Comparative data on the relative adsorption of the indicators on Silene EF–Alumina–Celite 535 (5:5:2 by weight) are also presented.

TABLE I

RELATIVE DEGREE OF ADSORPTION OF SOME INDICATORS

Indicator	Position of zone, mm. (color) Silene EF	Silene EF–Alumina
Aurin tricarboxylic acid, ammonium salt	99–100 (Br)	99–100 (Br)
Indigo carmine	99–100 (Bl)	99–100 (Bl)
Alizarin red S	98–100 (R)	98–100 (R)
Alizarin yellow R	98–100 (Y)	98–100 (Y)
Methyl violet	68–100 (Bl)	60–93 (Bl)
Dichlorofluorescein	91–96 (O)	97–98 (Y-O)
Congo red	85–90 (R)	97–100 (O)
Brom phenol blue	73–80 (P)	95–99 (P)
Brom cresol green	62–70 (Bl)	96–99 (Bl)
Chlor phenol red	60–70 (P)	95–98 (P)
Brom cresol purple	15–25 (P)	65–75 (P)
m-Cresolsulfonphthalein	15–25 (Y)	57–63 (O)
Methyl orange	5–20 (Y)	51–60 (Y)
Tropaeolin 00	8–18 (Y)	45–55 (Y)
o-Cresolphthalein	8–18 (Y)	47–55 (Y)
Thymol blue	0–10 (Y)	25–35 (Y)
Cresol red	8–15 (Y)	48–52 (Y)
Brom thymol blue	0–4 (Y)	0–2 (Y)
m-Nitrophenol	0	0

Preparation of Resacetophenone

BY JOSEPH R. KILLELEA AND H. G. LINDWALL

The zinc chloride method commonly employed for the preparation of resacetophenone[1] involves a vacuum distillation and yields 65% of colored product. Since the vacuum distillation of high-melting solids is a troublesome process, we have adopted a boron fluoride method which eliminates the necessity of the distillation and gives superior yields of colorless product. Details are given below.

A mixture of resorcinol, 55.0 g. (0.5 mole), acetic anhydride, 54.5 g. (50.0 ml., 0.53 mole) and commercial anhydrous ether, 75 ml., is saturated with gaseous boron fluoride in an ice-bath. The mixture is then stored in a refrigerator for ninety-six hours. The heavy, yellow crystalline mass is broken up with a glass rod and the contents of the flask transferred to a beaker containing 200 g. of crushed ice. The ether is distilled off on a water-bath or allowed to evaporate in a good hood. The light yellow solid is washed with cold water. It weighs 73.0 g. (96%) and melts at 138–142°. It may be recrystallized from 1200 ml. of boiling water (Norit), the recovery being 69.0 g. of colorless solid (91%) melting at 144–145°.

A mixed melting point of this product with a sample prepared by the zinc chloride method showed no depression. The dibenzoate, prepared by Baker's method[2] melted at 80–81° mixed with the dibenzoate prepared from Cooper's product, 80–81°.

The boron fluoride method exemplified above has been employed, with slight modifications, in this Laboratory for the preparation of other polyhydroxyacetophenones.

Vanadium Oxide, a Hydrogenation Catalyst[1]

BY V. I. KOMAREWSKY, L. B. BOS AND J. R. COLEY

Vanadium oxide is widely used as an oxidation catalyst. It has also been reported to be an effective catalyst for the dehydrogenation of hydro-

---

[1] Presented before the Division of Petroleum Chemistry at the Atlantic City Meeting of the American Chemical Society, April 14, 1947.

carbons,[2] the hydrogenolysis of phenols[3] and of aliphatic alcohols.[4]

In this work a direct hydrogenation of unsaturated hydrocarbons in the presence of vanadium oxide catalyst is described.

Experimental

Apparatus and Procedure.—The catalytic hydrogenation procedure employed consisted of passing a three to one (by volume) mixture of hydrogen and vaporized unsaturated hydrocarbon over a granular (8–10 mesh) catalyst bed (volume, 50 cc.) maintained at uniform temperature by an electrically heated furnace. The rate of passage of the reactants through the Pyrex glass or steel reaction tubes (i. d. 15 mm.) was varied in the range of 0.01 to 1.00 liquid space velocity. The methods of feeding the reactants and condensing and collecting the products were conventional for vapor phase catalytic procedure.

Catalysts.—The vanadium oxide–aluminum oxide (V_2O_5, 35%–Al_2O_3, 65%) catalyst was prepared by coprecipitation from solutions of sodium vanadate and aluminum nitrate. The precipitation was accomplished by the addition of a calculated amount of a sodium hydroxide–sodium vanadate solution to a well-cooled solution of aluminum nitrate. The composition of the catalyst was checked by chemical analysis.

Analysis of Products.—The per cent. unsaturation of the liquid products was determined by the bromine number method.[5] The gaseous products were analyzed by the Gockel method.[6] The per cent. of butadiene in the gaseous product was determined by the maleic anhydride method.[7] The percentage of conversion of benzene to cyclohexane was determined by the refractive index.

Discussion of Results

Olefins, diolefins and acetylene when subjected to the action of vanadium oxide–aluminum oxide (V_2O_5, 35%–Al_2O_3, 65%) catalysts at 400° and atmospheric pressure were readily hydrogenated. The per cent. hydrogenation of isobutylene, hexene-1 and octene-1 obtained was in excess of 95%.

The optimum temperature for the olefin hydrogenation procedure was found to be 400°, which corresponds closely to the optimum temperature for the activated adsorption of hydrogen on vanadium oxide, as presented by Griffith[8] (see Fig. 1).

The space velocity proved to be a critical variable for this reaction. An increase in liquid space-velocity in excess of 0.05 gave a sizeable decrease in the effectiveness of the hydrogenation at atmospheric pressure. However, it was found that the maximum allowable space velocity could be materially increased by operation under increased pressure. The limiting space velocity was increased to 0.25 by operation at 21 atmospheres pressure (Table I).

TABLE I

DATA ON THE HYDROGENATION OF OLEFIN HYDROCARBONS AT 400°

Reactant	Pressure, atm.	Liquid space velocity, hr.$^{-1}$	Per cent. hydrogenation
Isobutylene	1	0.046	98.6
Isobutylene	1	.150	60.2
Isobutylene	1	.345	15.0
Octene-1	1	.010	98.6
Octene-1	21	.25	94.9
Octene-1	21	.50	82.2
Octene-1	21	1.00	58.9

Butadiene was readily hydrogenated at 400° and atmospheric pressure. The reaction product consisted of n-butane, 77.1% and butadiene 22.9%. No butenes were detected in the product.

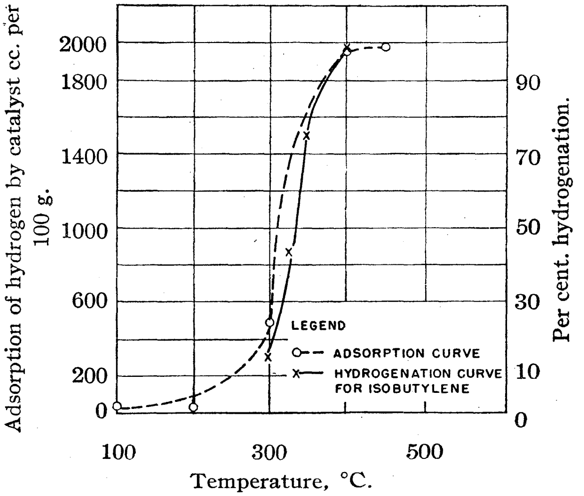

Fig. 1.—Comparison of hydrogenation curve for isobutylene and hydrogen adsorption curve—vanadium oxide catalyst.

Acetylene was hydrogenated successfully under the same reaction conditions. The reaction product consisted of 92.9% ethane, 0.2% acetylene and 6.9% ethylene.

Attempts to hydrogenate benzene at atmospheric pressure and 400° were unsuccessful. However, at 475° and 115 atmospheres, a yield of 27% cyclohexane was obtained. These particular high pressure experiments were carried out in a rotating autoclave.

An important feature of the vanadium oxide catalyst is its resistance to sulfur poisoning. The addition of 1% by weight of thiophene to hexene-1 and t-amyl mercaptan to octene-1 did not produce any noticeable decrease in the per cent. hydrogenation of either of these olefins. Sulfur analyses showed that 61.0% of the organic sulfur was removed by the catalytic hydrogenation for the hexene-1–thiophene mixture.

Vanadium oxide was shown to be an effective high temperature, low pressure, sulfur resistant

levo-2,3-Dinitroxybutane

BY A. F. MCKAY, R. H. MEEN AND GEORGE F WRIGHT

In 1938, a diastereomeric mixture of 2,3-dinitroxybutanes was reported in 16% yield as one of the products arising from electrolysis of sodium methylethylacetate in aqueous solution of sodium nitrate.[1] Later sodium pentanoate was electrolyzed in the same way to yield a little of the nitrate ester, which was in the *dd, ll* form according to the dicarbanilide which it yielded after iron–acetic acid reduction.[2] Dinitroxybutane was finally reported in good yield from 2,3-butanediol, but the author does not specify the stereochemical configuration of this diol.[3]

In connection with studies involving plasticization of nitrocellulose, we wished to obtain 2,3-dinitroxybutane as a pure stereochemical compound. The availability of *levo*-butanediol through the courtesy of the Canadian National Research Council made this possible. The nitrate-esterification with mixed acid proceeded without incident. The crude product was sufficiently pure that its refractive index was not changed by subsequent fractional distillation. The distilled product was still clear after four years, when it gave an Abel Heat Test of two minutes at 100°. Its sensitiveness to impact between steel surfaces (glancing blow) was approximately the same as that of crystalline TNT. The compound was found to be a poor plasticizer for nitrocellulose of 13.1% nitrogen content.

Although the 2,3-butanediol from which this ester was prepared had a high *levo* rotation (−12.89°) the *levo* rotation of the resulting dinitroxybutane was less than 1°. This low rotation suggested that racemization might have occurred during nitration. This was found not to be the case. Catalytic reduction with the catalyst recommended by Kuhn[4] regenerated 2,3-butanediol with *levo* rotation of −12.90°.

Experimental

To a mechanically stirred solution of 228 cc. (5.4 moles) of 98% nitric acid in 219 cc. (3.79 moles) of 96% sulfuric acid was added dropwise, over one hundred and sixty minutes, 185.5 g. (2.06 moles) of *levo*-2,3-butanediol, b. p. 81.0° (18 mm.), $n^{25}D$ 1.4315, $[\alpha]^{20}D$ −12.89°. The reaction temperature was held at 0–5° during this addition and was maintained thus for a further fifteen minutes. The cold solution was then poured into 100 g. of ice and further diluted with 500 cc. of water. The oily layer was not freed completely from acid by washing with 1 liter of 2% sodium carbonate solution. The deacidification was therefore completed by further washing with 200 cc. of 2% aqueous ammonia and then with water until neutral to litmus.

The product was dried under 25-mm. pressure to weigh 337.5 g. or 91% of theoretical, $n^{20}D$ 1.4405. This refractive index was not changed by distillation at 99–100° (15 mm.) or 91.5° (10 mm.). *levo*-Dinitroxybutane melts at 0 to 4°. Other constants are: d^{20}_4 1.297; MR_D calcd. 36.94,[5] found 36.63; $[\alpha]^{20}D$–0.88.

Reduction of 2,3-Dinitroxybutane.—A 10% solution of 20 g. (0.11 mole) of 2,3-dinitroxybutane in absolute ethanol was reduced with 0.54 mole of hydrogen, initially at 500 lb. gage pressure, in presence of 0.5 g. of the palladium-on-charcoal catalyst recommended by Kuhn. It was necessary to heat the bomb to 48° in order to complete this reduction in seven hours. The hydrogenolysis was complete in twenty-two minutes when 2 g. of catalyst was used per 6 g. of ester. There was less evidence of ammonia formation in the quick reduction, but the reaction mixture became quite hot. The catalyst was filtered off and the filtrate distilled, finally under 14 mm. The yield of 2,3-butanediol distilling at 75–76° was 9.6 g. or 96% of theoretical. Its rotation was $[\alpha]^{20}D$° −12.90°.

Preparation and Properties of 2-Nitramino-Δ^2-1,3-diazacycloalkenes

BY A. F. MCKAY AND GEORGE F WRIGHT

Davis and his co-workers[1,2] have shown that monoalkylamines react with nitroguanidine in aqueous solution to give the corresponding N-alkyl-N′-nitroguanidines. If these alkylnitroguanidines are treated with excess alkylamine then the nitramino group is replaced to give, among other products, the *sym*-dialkylguanidines.[3] One might then expect that, if nitroguanidine were treated with an alkyldiamine, both reactions would occur to give a cyclic derivative from which the nitramino group had been eliminated. However, the reaction follows an alternative course. Ammonia is, indeed, liberated by the reaction of the amino group in nitroguanidine with one of the amino groups in the diamine, but the second evidently adds to the imino group in the resulting

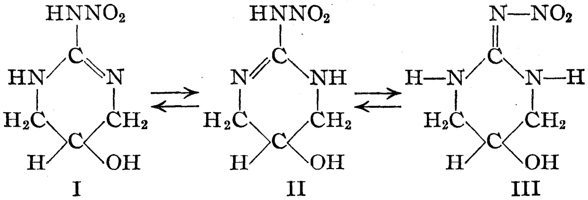
aminoalkylnitroguanidine to give a cyclic nitramine after a second molecule of ammonia is liberated. Five, six and larger membered rings can thus be synthesized.

It has been found[4] that the yields of alkylnitroguanidines can be improved over those previously reported, by treating nitroguanidine dissolved in aqueous alkali with the alkylamine hydrochloride. The mixture is heated to 60–70° for twenty to thirty minutes, cooled and the product recovered by filtration. This revised method is also found considerably to increase (by 15–55%) the yields of 2-nitramino-Δ^2-1,3-diazacycloalkenes (1, $n = 2$ to 4) obtained from the reaction of alkyldiamines with nitroguanidine. The synthesis is found to be successful with diamines containing branched as well as straight chains. The compounds which have been prepared thus far are listed in Table I. No tautomeric forms have yet been detected. Although the products isolated from the reaction of the unsymmetrical diamines with nitroguanidine are chemical individuals, we cannot at present assign definite positions to the methyl groups.

It is interesting to note that in the substituted 2-nitramino-Δ^2-1,3-diazacycloalkenes described in Table I an asymmetric carbon atom occurs. Thus the 4(or 5)-methyl-2-nitramino-Δ^2-1,3-diazacyclopentene and 4(or 6)-methyl-2-nitramino-Δ^2-1,3-diazacyclohexene are racemates. Especially interesting is the 5-hydroxy-2-nitramino-Δ^2-1,3-diazacyclohexene. If a labile tautomerism exists between I and II, or if the acid salts of I are resonance hybrids, then resolution would be impossible. If, on the other hand, the tautomeric nitrimino form III were stable then resolution of the allene-like structure should be possible.



I II III

Work on structure and synthesis of these 2-nitramino-Δ^2-1,3-diazacycloalkenes is in progress. The authors are grateful to Messrs. Scott and Farmer of London, England, from whom the original idea of cyclization was obtained. The National Research Council of Canada has supported this work by a grant-in-aid.

Experimental

Preparation of 2-Nitramino-Δ^2-1,3-diazacycloalkenes.—One mole of nitroguanidine is dissolved in 250–300 cc. of water containing two moles of potassium hydroxide and then one mole of the diamine dihydrochloride is added with stirring. A thick sludge forms which is heated at 65–70° with stirring over a period of twenty to thirty minutes. During this time the sludge becomes less viscous and it may dissolve completely. At the end of the reaction time, the reaction mixture is cooled to 1° in an ice–salt-bath and the white solid is recovered by filtration. The occluded potassium chloride may be removed by trituration with water. The final yields vary from 40–65% of theoretical, depending on the specific compound.

The Addition of Methyl Alcohol to Fluoroethylenes[1]

BY WILLIAM T. MILLER, JR.,[2] EDWARD W. FAGER[3] AND PAUL H. GRISWOLD[4]

The addition of alcohols to tetrafluoroethylene and to chlorotrifluoroethylene[5] has been reported in the patent literature. In the present work, which was carried out independently, the base catalyzed addition of methyl alcohol to these substances and to *unsym*-dichlorodifluoroethylene was shown to occur. Reaction occurred rapidly and exothermically at from zero to room temperature with a reagent prepared by dissolving two moles of sodium in 500 cc. of absolute methanol. The tetrafluoroethylene was added in portions as a gas at 20 atm. pressure to the methylate solution in a steel bomb of the rocker type with the temperature maintained below 40°. The other olefins were added at atmospheric pressure to the stirred methylate solution cooled in an ice-bath.

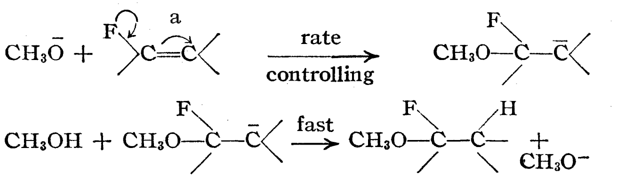
Trichlorofluoroethylene was also observed to react readily but with some loss of halogen acid, while tetrachloroethylene did not react at 0°.

The physical properties and analytical data for the three ethers obtained pure are summarized in Table I. All three ethers were saturated to permanganate solution. They yielded fluoride ion in large amount when heated with alcoholic potash along with trace amounts of chloride ion from the chlorine containing compounds. The structures assigned are consistent with the above observation, and the presence of $-CF_2-$groupings alpha to oxygen explained the observed stability toward the sodium methylate reagent.

The mechanism of addition is postulated as follows



The role of fluorine relative to chlorine in promoting addition of nucleophilic type reagents and effecting the orientation of addition is considered to be due to its greater tendency to enter into resonance with the double bond so as to predispose the system to polar activation of the type indicated above (arrow *a*). There is also considerable reason to believe that fluorine is capable of electron release relative to chlorine as an activation mechanism.[7] The general electron withdrawal (inductive effect) by the halogens on the double bond favors the development of acceptor activity by activation in marked contrast to the exclusively nucleophilic reactivity shown by simple ethylenic hydrocarbons.

Occurrence of Pectic Materials in Wood

BY W. W. PIGMAN, E. ANDERSON AND R. L. LEAF, JR.

Hardwoods contain small amounts (usually less than 0.5%) of materials that yield furfural and carbon dioxide when distilled with 12% hydrochloric acid.[1,2] After hydrolysis of a hemicellulose fraction of beechwood O'Dwyer[1] isolated a cinchonine salt similar to that reported for D-galacturonic acid. Anderson has isolated fractions from hardwoods and softwoods that have specific rotations and solubility characteristics similar to fruit pectins.[2] By hydrolysis of the material in the presence of bromine he produced mucic acid. This evidence proves qualitatively the presence of galacturonic acid in the original wood, which on the basis of O'Dwyer's identification is apparently the D-isomer.

In order to demonstrate more conclusively the presence of pectic materials[3] in a typical wood, it was decided to isolate galacturonic acid n ithe form of the difficultly soluble sodium calcium D-galacturonate[4] after enzymic hydrolysis[5] of wood pectic material. To give some quantitative aspects to the procedure the results were compared with those obtained with citrus pectic acid under the same conditions. Unfortunately for the quantitative aspects, the yields are greatly affected by the purity of the pectic material.[6]

Pectic material isolated from the inner bark of black spruce, in which it occurs in fairly large amounts (10%),[7] was treated with a commercial enzyme preparation. Crystalline sodium calcium galacturonate was isolated in a yield of 28% of the theoretical. Citrus pectic acid under the same conditions gave a yield of 53%. The product had the same calcium analysis and specific rotation as described by Isbell and Frush.[4] On oxidation with bromine under slightly acid conditions it gave mucic acid in a yield of 64% of the theoretical.

On the basis of this work there is no doubt that D-galacturonic acid occurs in the inner bark of the black spruce in a polymerized form. Since enzymic reactions are generally very specific, it is likely that the polymerized form is structurally similar to citrus pectic acid and that wood pectins are closely related to citrus pectins.

Experimental

The pectic acid was made by direct extraction with 5%

ammonium hydroxide of the inner bark of the black spruce (*Picea mariana* B. S. P.) and of holocellulose from the inner bark.[7] It was precipitated as calcium pectate. By treatment with hydrochloric acid the calcium pectate was converted to an impure pectic acid with $[\alpha]^{20}D$ +80° (3% NaOH) and containing 66.5% uronic anhydride (on an oven-dry basis).

A control experiment using commercial pectic acid[8] containing 77% uronic anhydride gave sodium calcium galacturonate in 53% of the theoretical yield.

The hydrolyses were carried out according to the directions of Isbell and Frush[6] except that: (1) an aqueous dispersion of pectic acid was treated with sodium bicarbonate until the *p*H was 3.8; (2) the hydrolysis time was twelve days at 38°; 12 g. of pectic substance (oven-dried) was used.

From 13 g. of wood pectic material (containing 11% moisture) 3.1 g. of sodium calcium D-galacturonate $[NaCa(C_6H_9O_7)_3 \cdot 6H_2O]$ was obtained; this yield is 28% of the theoretical value. The equilibrium specific rotation in 0.1 *N* nitric acid was $[\alpha]^{20}D$ +43.4 (*c*, 2%), whereas Isbell and Frush reported $[\alpha]^{20}D$ +44.0. The product contained 5.26% calcium; this value compares with 5.35% calculated for the above formula.

When 0.601 g. of the above product was dissolved in dilute hydrochloric acid and treated with bromine for four hours at room temperature 0.257 g. of insoluble material separated. A further crop of 0.066 g. was obtained from the mother liquor. The melting point of the material was 208–210° (dec.). Upon the basis of the insolubility and melting point the material must be mucic acid. The yield was 64% of the theoretical value.

Trimethylhalosilane Preparations[1]

BY B. O. PRAY,[2] L. H. SOMMER, G. M. GOLDBERG, G. T. KERR, P. A. DI GIORGIO[3] AND F. C. WHITMORE

Previously reported preparations of trimethylfluorosilane have utilized the reaction of trimethylchlorosilane with zinc fluoride,[4] and with antimony trifluoride in the presence of antimony pentachloride.[5]

We have found that trimethylfluorosilane can be prepared directly in about 80% yield by the addition of ammonium fluoride to a solution prepared from hexamethyldisiloxane and concentrated sulfuric acid.[6]

$$(CH_3)_3SiOSi(CH_3)_3 \xrightarrow[H_2SO_4]{NH_4F} 2(CH_3)_3SiF$$

A similar procedure, using ammonium chloride, constitutes an excellent method for the preparation of trimethylchlorosilane in good yield (85%) and high purity. This method for trimethylchlorosilane gives better yields and is more convenient than that involving reaction of methylmagnesium halide with silicon tetrachloride.[7] The latter forms an azeotrope with trimethylchlorosilane[8] and careful fractionation is required to effect separation from dimethyldichlorosilane and methyltrichlorosilane which are also formed.[7] The present method gives only trimethylchlorosilane. Thus, hexamethyldisiloxane is a convenient starting material for three of the trimethylhalosilanes.[9]

In the present work, trimethylbromosilane[9] and trimethyliodosilane have been prepared by fission of the phenyl–silicon bond in phenyltrimethylsilane with bromine and iodine, respectively.[10]

$$C_6H_5Si(CH_3)_3 \xrightarrow{X_2} C_6H_5X + (CH_3)_3SiX$$

The above synthesis of trimethyliodosilane completes the series of trimethylhalosilanes. Trimethyliodosilane is a colorless liquid which fumes vigorously in moist air and acquires an iodine color on standing.

Experimental

Hexamethyldisiloxane from Ethyl Orthosilicate.[11]—Ethyl orthosilicate, 8.7 moles, was added with vigorous stirring during thirty minutes to 28 moles of methylmagnesium bromide in 12 liters of ether while keeping the reaction mixture at 10°. Stirring and cooling were continued for one hour followed by refluxing for two hours. Ether and product were then distilled. After removal of the ether, the product was dissolved in 700 cc. of concentrated sulfuric acid, and the resulting solution was added to ice. Fractionation of the upper layer, after washing and drying, gave 380 g. (2.35 moles) of hexamethyldisiloxane, b. p. 99–100°, $n^{20}D$ 1.3771, 54% yield.

Trimethylfluorosilane.—Ammonium fluoride, 24.2 g. (0.7 mole) was added from a dropping bottle to a stirred ice-cold solution of 32.4 g. (0.2 mole) of hexamethyldisiloxane in 60 cc. of concentrated sulfuric acid during one hour. Warming gave 31 g. of distillate of clear colorless liquid. Fractionation gave 3.2 g., b. p. 15.4°, and 27.8 g., b. p. 15.8° at 734 mm., of pure trimethylfluorosilane.

Anal. Calcd. for C_3H_9SiF: F, 20.6. Found: F, 20.3, 20.4.

A molecular weight determination by the vapor density method gave mol. wt. 92 (calcd. 94).

Trimethylchlorosilane.—Dry powdered ammonium chloride, 321 g. (6 moles), was added during three hours with vigorous stirring to a solution prepared from 324 g. (2 moles) of hexamethyldisiloxane and 1000 g. of concentrated sulfuric acid. During the addition the flask was cooled in an ice-bath. Upon completion of the addition, *the upper layer was separated as quickly as possible.* Fractional distillation gave 369 g. (3.4 moles) of trimethylchlorosilane, b.p. 58° (734 mm.), $n^{20}D$ 1.3884, d^{20} 0.8581, a yield of 85%.

Trimethylbromosilane.—Using the method of Bygden,[12] phenyltrimethylsilane, b. p. 168 (734 mm.), $n^{20}D$ 1.4900, was prepared in 72% yield by the reaction of phenyltrichlorosilane with methylmagnesium bromide. Liquid bromine, 162 g. (1 mole), was added with stirring to 150 g. (1 mole) of phenyltrimethylsilane in a flask cooled with cold tap-water, and the reaction mixture was heated on the steam-bath for one hour. Fractional distillation gave

Competitive Reactions between Trialkylchlorosilanes and Alkylmagnesium Bromides[1]

BY LEO H. SOMMER, GEORGE T. KERR AND FRANK C. WHITMORE

In connection with studies in the chemistry of trialkylsilyl compounds, it was of interest to determine the effect of structural variations on the reactivity of trialkylchlorosilanes with alkylmagnesium bromides. Three studies of this type are reported in the present paper.

In one experiment, methyl- and ethylmagnesium bromides, 0.42 mole of each, were allowed to compete for 0.42 mole of triethylchlorosilane. The latter reacted exclusively with the methylmagnesium bromide.

$$CH_3MgBr + C_2H_5MgBr + (C_2H_5)_3SiCl \longrightarrow (C_2H_5)_3SiCH_3 \quad (1)$$

This result is in line with the generally observed greater reactivity of the shorter-chain aliphatic Grignard reagents with purely organic compounds.[2]

Treatment of a mixture of trimethylchlorosilane and triethylchlorosilane, 0.5 mole of each, with ethylmagnesium bromide, 0.5 mole, gave ethyltrimethylsilane and tetraethylsilane in a mole ratio of approximately 2 to 1.

$$2(CH_3)_3SiCl + (C_2H_5)_3SiCl + 3C_2H_5MgBr \longrightarrow 2(CH_3)_3SiC_2H_5 + (C_2H_5)_4Si \quad (2)$$

n-Propylmagnesium bromide, which is generally less reactive than ethylmagnesium bromide, gave stronger emphasis to the difference in the reactivity of trimethyl- and triethylchlorosilane. No appreciable amount of *n*-propyltriethylsilane was found.

$$(CH_3)_3SiCl + (C_2H_5)SiCl + C_3H_7MgBr \longrightarrow (CH_3)_3SiC_3H_7 \quad (3)$$

In general, the decreased activity toward Grignard reagents with increased size of the alkyl groups on silicon, as in reactions 2 and 3, is paralleled by a similar change in reactivity with structure of other trialkylsilyl compounds toward other reagents. For example, trimethylsilanol is far more susceptible toward intermolecular dehydration to the disiloxane than is triethylsilanol.[3]

Experimental

Reaction of Triethylchlorosilane with Methyl- and Ethylmagnesium Bromides.—In a 3-liter, three-necked flask, fitted with a mercury-sealed stirrer, a reflux condenser and a separatory funnel, were placed 139 cc. (0.42 mole) of methylmagnesium bromide and 165 cc. (0.42 mole) of ethylmagnesium bromide. To a mixture of Grignard reagents in ether solution was added, during fifteen minutes, with stirring and cooling, 63.0 g. (0.42 mole) of triethylchlorosilane. The mixture was refluxed for four hours, and then the reaction flask was fitted with a condenser for distillation of material volatile at steam-bath temperature. Completion of the distillation after four hours was followed by heating of the residue on the steam-bath for eight hours. The distillate was then returned to the flask, and 500 cc. of water was slowly added with stirring in order to decompose unreacted Grignard reagent. The resulting product was steam-distilled, the organic layer was separated and the aqueous layer extracted with 65 cc. of ether. Ether was removed from the product by distillation and the residue was refluxed with dilute hydrochloric acid for eight hours in order to convert any triethylsilanol (from the hydrolysis of unreacted triethylchlorosilane) to hexaethyldisiloxane. The organic layer was separated, washed free of acid, and dried over anhydrous magnesium sulfate. Fractionation in a glass-helix packed column of about 20 theoretical plates gave 36.1 g. (0.28 mole) of methyltriethylsilane,[4] b. p. 126° (729 mm.), n^{20}_D 1.4160, and no tetraethylsilane.

Reaction of Ethylmagnesium Bromide with Trimethyl- and Triethylchlorosilanes.—Addition of a mixture of trimethyl- and triethylchlorosilane (0.5 mole of each) to ethylmagnesium bromide (0.5 mole) was followed by a treatment similar to that employed above. Fractionation gave: 18.3 g. (0.18 mole) of ethyltrimethylsilane,[4] b. p. 62° (734 mm.), n^{20}_D 1.3819–1.3821, and 13.6 g. (0.095 mole) of somewhat impure tetraethylsilane,[4] b. p. 152–156° (734 mm.), n^{20}_D 1.4259–1.4245. In addition, there were obtained 18.5 g. (0.091 mole) of 1,1,1-trimethyl-3,3,3-triethyldisiloxane,[5] b. p. 172° (724 mm.), n^{20}_D 1.4104 and 25.1 g. (0.101 mole) of hexaethyldisiloxane,[6] b. p. 128° (30 mm.), n^{20}_D 1.4335.

Reaction of *n*-Propylmagnesium Bromide with Trimethyl- and Triethylchlorosilanes.—Addition of a mixture of trimethyl- and triethylchlorosilane (0.5 mole of each) to *n*-propylmagnesium bromide (0.5 mole) was followed by treatment of the reaction mixture in a manner similar to that above, except that the crude reaction product was treated with 50 cc. of cold concentrated sulfuric acid prior to fractionation in an attempt to separate tetraalkylsilane, which is known to be insoluble in concentrated sulfuric acid, from the disiloxanes which are soluble. The upper layer, containing tetraalkylsilane, was washed free of acid with water and sodium bicarbonate solution, and was then dried with anhydrous sodium sulfate. Fractionation of the product gave 33.3 g. (0.287 mole) of *n*-propyltrimethylsilane,[4] b. p. 89° (729 mm.), n^{20}_D 1.3930, and no appreciable quantity of *n*-propyltriethylsilane. In addition, there was obtained 22.1 g., (0.090 mole) of hexaethyldisiloxane, b. p. 129° (30 mm.), n^{20}_D 1.4340.

Some Reactions of Trialkylaminosilanes[1]

BY D. L. BAILEY,[2] L. H. SOMMER AND F. C. WHITMORE

In continuation of previous studies on the chemistry of trialkylsilyl compounds, the present paper reports reactions of triethylaminosilane (I)[3] and α-chloroethyldiethylaminosilane (II).

Compounds I and II were prepared from the corresponding chlorosilanes[4,5] by treatment with liquid ammonia, a method previously used by Sauer.[3]

$$R(C_2H_5)_2SiCl + 2NH_3 \longrightarrow R(C_2H_5)_2SiNH_2 + NH_4Cl$$

(R is C_2H_5— in compound I, and CH_3CHCl— in compound II)

Conversion of compounds I and II to halosilanes[6] was achieved with hydrogen chloride, hydrogen bromide, concentrated hydrochloric acid, concentrated hydrofluoric acid, and hydrobromic–sulfuric acid mixture.

$$R(C_2H_5)_2SiNH_2 + 2HX \longrightarrow R(C_2H_5)_2SiX + NH_4X$$

These reactions indicate possible use of trialkylaminosilanes as intermediates for the preparation of other halosilanes from chlorosilanes. They further emphasize the great differences in the reactions of the silicon–amino and carbon–amino bonds.

Experimental

Triethylaminosilane.[3]—A description of our procedure may be useful in view of the low yield (26%) originally reported for this compound.

In a 200-cc., three-necked flask equipped with dropping funnel, mercury-sealed stirrer and reflux condenser there was placed 100 cc. of liquid ammonia. The flask was then immersed in a Dry Ice and acetone-bath and 75 g. (0.5 mole) of triethylchlorosilane was added from the dropping funnel during one-half hour. After stirring for one hour, the excess ammonia was evaporated and the contents of the flask were diluted with ether and filtered to remove ammonium chloride. The ether was then removed from the product which was fractionally distilled in a glass-helix packed column of about 20 theoretical plates. There was obtained 46 g. (0.35 mole) of triethylaminosilane, b. p. 134°, $n^{20}\mathrm{D}$ 1.4267, a yield of 70%. Weighed samples added to a mixture of methanol and excess standard acid followed by back-titration with standard alkali gave a neutral equivalent of 132. Calcd. neutral equivalent for complete hydrolysis of the silicon–amino bond, 131. The compound was also analyzed by the Kjeldahl method.

Anal. Calcd. for $C_6H_{17}SiN$: N, 10.69. Found: N, 10.69, 10.70.

α-Chloroethyldiethylaminosilane.—Addition of 93 g. (0.5 mole) of α-chloroethyldiethylchlorosilane[5] to 100 cc. of liquid ammonia and use of a procedure similar to that employed for the triethylaminosilane gave 72 g. (0.44 mole) of α-chloroethyldiethylaminosilane, b. p. 93° (38 mm.), $n^{20}\mathrm{D}$ 1.4570, d^{20} 0.9604, a yield of 88%.

Anal. Calcd. for $C_6H_{16}SiClN$: Cl, 21.40; neut. equiv., 166. Found: Cl, 21.36; neut. equiv., 166.

Reactions

A. With Concentrated Hydrochloric Acid.—In a 200-cc., three-necked flask equipped with a reflux condenser, dropping funnel, and mercury-sealed stirrer, there was placed 160 cc. of concentrated hydrochloric acid. This was cooled in an ice-bath and 13 g. (0.1 mole) of triethylaminosilane was added by means of the dropping funnel. After stirring for thirty minutes, the reaction mixture was placed in a separatory funnel and the two layers were separated. Upon drying with sodium sulfate, the undistilled triethylchlorosilane, 14.5 g. (0.09 mole), analyzed for 23.3% Cl (calcd. for triethylchlorosilane, 23.5%). Distillation of this material gave 12 g. (0.08 mole) of triethylchlorosilane, b. p. 144–145°, d^{20} 0.8977, a yield of 80%.

α-Chloroethyldiethylaminosilane, 13 g. (0.08 mole), was treated with concentrated hydrochloric acid by a procedure similar to that used for triethylaminosilane. Distillation of the product gave 11.5 g. (0.062 mole) of α-chloroethyldiethylchlorosilane,[5] b. p. 178–179°, d^{20} 1.0399, a yield of 79%.

B. With Hydrofluoric Acid.—In a 200-cc. flask there was placed 60 cc. of 48% hydrofluoric acid. This was cooled in an ice-bath and 12 g. (0.09 mole) of triethylaminosilane was added from the dropping funnel during five minutes. After agitation of the reaction mixture for ten minutes, the resulting two layers were separated and the upper layer dried over sodium sulfate. Distillation gave 10.5 g. (0.08 mole) of triethylfluorosilane,[7] b. p. 109–110°, d^{20} 0.8380, F, 13.9% (calcd. 14.1%), a yield of 89%.

Treatment of α-chloroethyldiethylaminosilane, 11 g. (0.066 mole), with hydrofluoric acid (48%) gave 9 g. (0.053 mole) of α-chloroethyldiethylfluorosilane,[5] b. p. 149–150°, d^{20} 0.9961, F, 11.3% (calcd. 11.3%), in 82% yield.

C. With Hydrogen Chloride.—In a 200-cc. three-necked flask equipped with a reflux condenser, mercury-sealed stirrer, and gas delivery tube there were placed 150 cc. of dry ether and 20 g. (0.152 mole) of triethylaminosilane. Dry hydrogen chloride was passed into the reaction mixture until the solution was saturated. The ammonium chloride was filtered and the ether was evaporated on the steam-bath. Distillation of the residual liquid gave 16 g. (0.106 mole) of triethylchlorosilane, b. p. 143–145°, d^{20} 0.8974, Cl, 23.4% (calcd. 23.5%), a yield of 70%.

An ether solution of α-chloroethyldiethylaminosilane, 18 g. (0.11 mole) was treated with hydrogen chloride gas to give 15.5 g. (0.084 mole) of α-chloroethyldiethylchlorosilane,[5] b. p. 179–181°, d^{20} 1.0385, $n^{20}\mathrm{D}$ 1.4553, a yield of 76%.

D. With Hydrogen Bromide.—An ether solution of triethylaminosilane, 39 g. (0.30 mole) was treated with dry hydrogen bromide by a procedure similar to that used for the reaction of hydrogen chloride with this compound. There was obtained 41.5 g. (0.21 mole) of triethylbromosilane,[8] b. p. 162–163°, $n^{20}\mathrm{D}$ 1.4563, d^{20} 1.1403, a yield of 70%.

Conductivities of Aqueous Solutions of Dodecylammonium Chloride

BY A. W. RALSTON AND D. N. EGGENBERGER

We are currently engaged in a study of the effects of inorganic electrolytes and of various organic compounds upon the electrical behavior of solutions of cationic colloidal electrolytes. During the course of this investigation we have redetermined the equivalent conductivities of aqueous solutions of dodecylammonium chloride at various temperatures and have found that the values are somewhat lower than those which we have previously reported.[1,2] We are of the opinion that the dodecylammonium chloride which was used in our earlier work contained traces of impurities, since our present values have been reproduced with several quite pure samples of this amine salt prepared by different investigators. The values herein reported, when plotted against the square root of the volume normality, $\sqrt{N_v}$, show a decidedly less steep slope within the first range, although the concentrations of amine salt at the critical points for micelle formation are in agreement with those reported previously.

The values of the equivalent conductivities of aqueous solutions of dodecylammonium chloride at various temperatures are shown in Table I.

TABLE I

Experimental

Preparation of Dodecylammonium Chloride.—Commercially distilled dodecylamine was fractionated through a Stedman packed column and the fraction boiling at 111.5° at 4 mm. retained. This fraction melted at 28.30°. The amine (200 g.) was dissolved in benzene (2 liters) and treated with dry hydrogen chloride. Upon cooling, crystals of dodecylammonium chloride precipitated. The crystals were removed by filtration and crystallized three times from benzene. The sample was analyzed by a previously described procedure.[3] (*Anal.* Calcd. for $C_{12}H_{25}NH_2$, 83.54; Cl, 16.00. Found: $C_{12}H_{25}NH_3$, 83.84; Cl, 16.06).

Conductivity Determinations.—Conductivities were determined in the manner and with the equipment previously described.[1]

Trimethylgermanium Chloride

BY EUGENE G. ROCHOW[1]

The preparation of methylgermanium trichloride and dimethylgermanium dichloride by the

---

(1) Research Laboratory, General Electric Company.

action of methyl chloride upon elementary germanium in the presence of a copper catalyst has been described in a previous paper.[2] In that investigation, no trimethylgermanium chloride was found in the product of the direct reaction, although the compound may have been present in an amount too small to be recovered in the distillation.

In order to round out the series of methylgermanium chlorides, some of the pure dimethylgermanium dichloride obtained in the direct reaction has been methylated with Grignard reagent.

Experimental

One-half mole of methylmagnesium chloride was allowed to drip slowly into a solution of 0.5 mole of dimethylgermanium dichloride in 300 cc. of dry ether. The mixture stood overnight and the magnesium chloride was filtered off. Ether was distilled from the liquid product, and the residue was fractionated. Nineteen grams of trimethylgermanium chloride was isolated. *Anal.* Calcd.: Cl, 23.15. Found: Cl, 23.3, 23.5. Because of the complete analysis of its progenitor[2] and the impossibility of halogen exchange in the system used, no further analyses were considered necessary.

Trimethylgermanium chloride is a colorless liquid which boils at 115°, melts at −13°, and has a refractive index of 1.4314 at 29° for sodium light. It hydrolyses rather slowly in water to form volatile products.

This compound completes the series

$GeCl_4$	b. p.	83.1°
CH_3GeCl_3	b. p.	111°
$(CH_3)_2GeCl_2$	b. p.	124°
$(CH_3)_3GeCl$	b. p.	115°
$(CH_3)_4Ge$	b. p.	43.4°

It is seen that the substitution of methyl groups for chlorine in $GeCl_4$ does not bring about a gradual lowering of the boiling point to that of $(CH_3)_4Ge$, but causes a rise and then a decline, with a maximum at $(CH_3)_2GeCl_2$. The "abnormally" high maximum boiling points for the disubstituted compounds $(CH_3)_2SiCl_2$ and $(CH_3)_2GeCl_2$ correspond to a lower reactivity in some reactions,[3] and the association therefore may be considered as a form of self-stabilization.

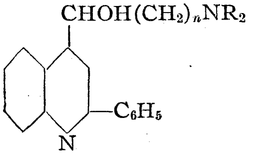
Synthesis of Antimalarials. VIII.[1] 1-(7-Chloro-2-phenylquinolyl-4)-6-diethylaminohexanedione-1,3 and Certain Other Compounds

BY JOSEPH C. SHIVERS[2] AND CHARLES R. HAUSER

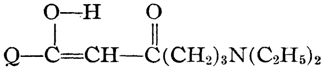
Various workers[3] have synthesized 4-quinolinemethanols (I) certain of which possess considerable antimalarial activity. The present note describes the synthesis of the β-diketone (II),[4] which, in its enol form (III),[4] resembles 4-quinolinemethanols. An attempt was made to prepare the 1,3-diol (IV)[4] from the β-diketone but a pure product was not isolated.



(I)

$Q{-}COCH_2CO(CH_2)_3N(C_2H_5)_2$

(II)



$Q{-}\overset{\text{O—H}}{\overset{|}{C}}{=}CH{-}\overset{\text{O}}{\overset{\|}{C}}(CH_2)_3N(C_2H_5)_2$

(III)

$Q{-}CHOHCH_2CHOH(CH_2)_3N(C_2H_5)_2$

(IV)

$CH_3CO(CH_2)_3N(C_2H_5)_2$

(V)

$Q{-}CO_2C_2H_5$

(VI)

The crude β-diketone (II–III)[4] was obtained in good yield by acylating ketone (V) with ester (VI)[4] by means of sodium amide; however, the pure product was isolated in only 15% yield. The acylation practically failed in the presence of sodium ethoxide. An attempt to acylate ketone (V) with ethyl 2-(3′-nitrophenyl)-cinchoninate by means of sodium amide produced tars.

Experimental[5]

2-Phenyl-7-chlorocinchoninic acid was prepared from benzaldehyde, *m*-chloroaniline and pyruvic acid by the Doebner reaction using a modification of the procedure kindly furnished by Elderfield, Gensler and Brody of Columbia University who based their procedure on that of earlier workers.[6] Our modification[7] consisted in first isolating N-benzal-3-chloroaniline and in treating it in refluxing commercial absolute ethanol with the pyruvic acid; the yield of 2-phenyl-7-chlorocinchoninic acid was 30%. The intermediate anil, b. p. 155° at 2 mm. (reported b. p. 338° at atm. press.)[8] was obtained in 90% yield by allowing a mixture of benzaldehyde and *m*-chloroaniline to stand overnight, extracting with ether and distilling the dried ether solution.

Ethyl 2-phenyl-7-chlorocinchoninate (VI), m. p. 88° (reported m. p. 89–89.5°)[9] was obtained in 75% yield by esterification of the crude acid using the common sulfuric acid method.

2-(3′-Nitrophenyl)-cinchoninic acid was obtained in 47% yield from pyruvic acid and 3-nitrobenzalaniline (m. p. 68°, reported m. p. 66°)[10] which was prepared in 86% yield from 3-nitrobenzaldehyde and aniline. After recrystallization from glacial acetic acid, a sample of the acid melted at 257°, darkening at 245°.

Anal. Calcd. for $C_{16}H_{10}O_4N_2$: C, 65.30; H, 3.43; N, 9.52. Found: C, 65.12; H, 3.72; N, 9.70.

Ethyl 2-(3′-nitrophenyl)-cinchoninate, m. p. 110–112°, was obtained in 70% yield by the esterification of the crude acid by the sulfuric acid method, and recrystallization from ethanol–water using charcoal. A second recrystallization gave light tan crystals, m. p. 112–113°.

Anal. Calcd. for $C_{18}H_{14}O_4N_2$: C, 67.07; H, 4.38; N, 8.70. Found: C, 67.39; H, 4.50; N, 8.86.

1-(7′-Chloro-2′-phenylquinoline-4′)-5-diethylaminohexanedione-1,3 (II) was prepared by acylating 1-diethylaminopentanone-4 (V) with ethyl 2-phenyl-7-chlorocinchoninate (VI) by means of sodium amide according to an adaptation of the method developed in this Laboratory.[11] To a stirred suspension of 0.4 mole of sodium amide[11] in 500 ml. of liquid ammonia was added rapidly 0.4 mole of the ketone in 75 ml. of dry ether. After replacing the ammonia by ether,[11] 0.2 mole of the ester in one liter of dry ether was added and the mixture refluxed five hours and then allowed to stand overnight. The mixture was poured onto 750 ml. of 10% acetic acid and crushed ice; after shaking thoroughly, the ether phase was extracted with 500 ml. of 10% acetic acid and combined with the aqueous phase. To the combined acetic acid solution was added cold 20% sodium hydroxide solution to a *p*H of 11 (oil separating). Carbon dioxide was passed into the mixture to a *p*H of 9, and the oil extracted with ether. The solvent was distilled from the dried ether solution leaving the crude oily β-diketone (79%) which, after drying over phosphorus pentoxide in a vacuum desiccator, was recrystallized from a mixture of benzene and 30–60° petroleum ether, freezing out with dry ice. There was obtained a 15% yield of pure β-diketone, melting at 88°; this melting point was not raised by further recrystallization but was depressed by admixture with the cinchoninic ester (VI).

Anal. Calcd. for $C_{25}H_{27}O_2Cl$: C, 70.98; H, 6.44; N, 6.62. Found: C, 70.96, 70.61; H, 6.34, 6.17; N, 6.63, 6.40.

The β-diketone gave a deep red enol test with alcoholic ferric chloride, and formed a 2,4-dinitrophenylhydrazone which soon became oily. Attempts to convert the crude β-diketone to a picrate, pyrazole, hydrochloride or a copper salt failed. The crude β-diketone, which was entirely soluble in dilute hydrochloric acid, appeared to decompose on distillation at 0.1 mm., since the distillate, b. p. 175–190°, was not entirely soluble in the acid.

Hydrogenation of the crude β-diketone in glacial acetic acid at room temperature and low pressure in the presence of Adams catalyst[12] absorbed the calculated amount of hydrogen within two hours and produced an oil, b. p. 240–250° at 0.1 mm., which, as should be expected, failed to give the enol test with alcoholic ferric chloride; however, the pure 1,3-diol or a solid derivative of it has not been isolated.

Identification of Esters of Dibasic Acids by the Use of Ethanolamine

BY WILLIAM H. RAUSCHER AND WILLIAM H. CLARK

In an attempt to find a rapid and satisfactory method for the identification of esters, their ammonolysis by ethanolamine in the absence of water has been investigated. It was hoped that on refluxing esters with ethanolamine that solid amides which would suitably characterize the acid would be formed, and that the alcohol simultaneously formed could be distilled out of the reaction mixture in such a state of purity that it could be easily identified in the usual manner.

On refluxing a number of esters with ethanolamine it was found that they were rapidly ammonolyzed, and that the alcohol could be distilled from the reaction mixture at a temperature very close to its boiling point. A redistillation of the alcohol from a simple distilling flask gave a product of correct boiling point from which a standard solid derivative of correct melting point was made. The reaction mixture from which the alcohol had been distilled did not yield solid amides on cooling in the case of most esters of monobasic acids which were investigated. However, the series of esters of dibasic acids shown in the table did give solid amides on cooling the reaction mixture after distilling off the alcohol. After a recrystallization the amides proved to have melting points suitable for purposes of identification.

Experimental

The reflux apparatus consisted of a 50-cc. flask and water cooled reflux condenser, both with ground joints. A mixture of 5 g. of the ester and 15 g. of ethanolamine was refluxed for fifteen minutes. After cooling below the boiling point of the alcohol, the condenser was replaced by a short Vigreux column and the alcohol distilled off. The residue was cooled to room temperature to obtain a solid product in the case of the esters of dibasic acids listed in the table. The amides were recrystallized from a 1:1 solution of alcohol and benzene. The alcohol which had been distilled from the reaction mixture was redistilled from a simple distilling flask, its boiling point checked and at least one solid derivative prepared from the distillate by standard procedures.

TROY, N. Y.

RECEIVED AUGUST 12, 1947

NEW COMPOUNDS

α-Amino-β-mercapto-*n*-valeric Acid Hydrochloride

α-Amino-β-mercapto-*n*-valeric acid hydrochloride was prepared by following the procedure of Carter, Stevens and Ney[1] for the corresponding butyric acid.

2-Phenyl-4-*n*-propylidene-5-oxazolone was synthesized by the method of Carter, Handler and Melville[2] using

---

(1) Carter, Stevens and Ney, *J. Biol. Chem.*, **139**, 247 (1941).

(2) Carter, Handler and Melville, *ibid.*, **129**, 359 (1939).

slight modifications. The mixture of 72 g. of hippuric acid, 33 g. of anhydrous sodium acetate and 200 ml. of acetic anhydride was maintained at 30° under a reflux condenser while 250 ml. of propionaldehyde was added over a period of one hour. The mixture was then heated about forty-five minutes at 50–60° until an almost clear orange solution resulted. Decomposition with ice yielded a semi-crystalline mass which was washed several times with ice water. The small amount of oil present was dissolved by adding 300 ml. of 70% ethanol and the resulting mixture was filtered by suction to give light yellow crystals. These crystals were sucked as dry as possible, washed several times with water and air dried. The yield of crude azlactone was 30–33 g., m. p.[3] 79–81°. Recrystallization from 50% ethanol gave white needles, m. p. 81–83°.

Anal. Calcd. for $C_{12}H_{11}NO_2$: N, 6.96. Found: N, 6.94.

If the temperature of the reaction were allowed to rise above 60° or the time of heating were prolonged, the yield suffered markedly and the majority of the resultant product was the dark red oil. The crude material was entirely satisfactory for the next step.

α-Benzoylamino-β-benzylmercapto-*n*-valeric Acid.—To a solution of 0.67 g. of sodium in 140 ml. of dry methanol was added 17.2 g. of benzyl mercaptan. Then a solution of 27 g. of 2-phenyl-4-*n*-propylidene-5-oxazolone in 140 ml. of dry benzene was added, with stirring, over a period of one hour. The mixture was allowed to stand at room temperature for fourteen hours. The product was isolated as described for the butyric acid derivative[1] except that the mixture was stirred and heated on the steam-bath for five hours. It was chilled and diluted with 250 ml. of water. A dark brown, gummy mass precipitated and tended to solidify after standing for several hours. It was washed with water and dissolved in 150 ml. of benzene. The water which had been entrapped was removed and the benzene solution was filtered. The solution was diluted with 500 ml. of gasoline causing the separation of an oil that soon solidified into light gray crystals. The yield of crude α-benzoylamino-β-benzylmercapto-*n*-valeric acid was 15 g., m. p. 102–104°. A small sample was recrystallized from the benzene–gasoline mixture, m. p. 103–105°.

Anal. Calcd. for $C_{19}H_{21}NO_3S$: N, 4.08. Found: N, 3.84.

The crude material was sufficiently pure for use in the following step.

A larger run from 60 g. of the oxazolone yielded 60 g. of the acid melting at 102–104°.

α-Amino-β-benzylmercapto-*n*-valeric Acid.—A mixture of 30 g. of α-benzoylamino-β-benzylmercapto-*n*-valeric acid, 230 ml. of commercial formic acid (87%), 230 ml. of concentrated hydrochloric acid and 230 ml. of water was heated under reflux for twelve hours. After the mixture had been cooled in an ice-bath, starting material (15 g.) was removed by filtration. The clear filtrate was evaporated to dryness *in vacuo* and the residue was taken up in 500 ml. of water. A small amount of a brown insoluble substance was removed by filtration. The filtrate was made slightly alkaline with ammonium hydroxide and then was evaporated to remove excess ammonia. α-Amino-β-benzylmercapto-*n*-valeric acid crystallized in white plates, yield 7.5 g., m. p. 172–174°. A small sample was recrystallized from water, m. p. 177–179°.

Anal. Calcd. for $C_{12}H_{17}NO_2S$: N, 5.87. Found: N, 5.98.

α-Amino-β-mercapto-*n*-valeric Acid Hydrochloride.—Sodium (about 2.5 g.) in small pieces was added with vigorous stirring to a solution of 7 g. of the above acid in 100 ml. of liquid ammonia. The metal was added until a deep blue color persisted. This color was discharged by the addition of sufficient solid ammonium chloride. The ammonia was then allowed to evaporate, eventually at reduced pressure to remove final traces. The residue was washed with ether and again evaporated *in vacuo*. The white product was dissolved in 50 ml. of dilute hydrochloric acid and the solution was extracted twice with 50-ml. portions of ether. Again the solution was evaporated to dryness *in vacuo*.

This residue was extracted with 150 ml. of absolute ethanol and the ammonium and sodium chlorides were removed by filtration. The alcohol solution was evaporated to dryness at reduced pressure. The light yellow solid was redissolved in 100 ml. of absolute ethanol and this solution was treated with decolorizing charcoal, filtered and evaporated *in vacuo*.

The white crystalline solid was dissolved in 75 ml. of absolute ethanol. Anhydrous ether was added until a slightly cloudy solution resulted. After the mixture had stood for fiteen minutes, the amino acid hydrochloride began to crystallize in small, white platelets. The mixture was then chilled for several hours and filtered. The yield of white, crystalline α-amino-β-mercapto-*n*-valeric acid hydrochloride was 3 g., m. p. 154–156°. More acid was obtained by working up the ether–ethanol mother liquor. The product gave a strong nitroprusside test to indicate the presence of the sulfhydryl rather than sulfide group.

After two further recrystallizations, the melting point was 163–165°. The nitroprusside test was still strongly positive.

Anal. Calcd. for $C_5H_{11}NO_2S{\cdot}HCl$: N, 7.54. Found: N, 7.32.

Throughout this synthesis no attempt was made to separate the two theoretically possible racemic modifications in pure form or to determine if more than one form were present.

4-Fluoroanthranilic Acid

4-Fluoro-2-nitrotoluene.—3-Nitro-4-toluidine (228 g., 1.5 moles)[1] was suspended in a mixture of 313.5 cc. of concd. hydrochloric acid and 450 cc. of water, chilled to 0° and diazotized using 130 g. of sodium nitrite (as a 35% solution). The filtered diazonium solution was stirred at 0° while 451 g. of 40% fluoboric acid solution was added (*ca.* ten minutes), and stirred for half an hour. After washing (ice-water, methanol, and ether), the cream-colored crystalline diazonium borofluoride was dried, first in air, then *in vacuo* (over paraffin and phosphoric anhydride); yield, 202 g. (54%).

The diazonium borofluoride was decomposed by heating it alone or mixed with an equal weight of acid-washed sand in an apparatus with wide-bore tubing (25 mm.) connected to several traps (*cf.* ref. 2). All products of the reaction, including the residual ashes in the decomposition flask, were combined and distilled with steam. The distillate was extracted with ether, and the extracts freed of phenolic matter by washing with 5% sodium hydroxide and saturated salt solution. After drying (Na_2SO_4), the extract was fractionated[3]; 125–134 g. (67–71%) of yellow liquid was collected at 75–76° (5 mm.) or 108–109° (23 mm.), $n^{25}\mathrm{D}$ 1.5212. 4-Fluoro-2-nitrotoluene was previously obtained by the nitration of 4-fluorotoluene[4]; b. p. 102.4° (20 mm.), $n^{25}\mathrm{D}$ 1.51997.

Ethyl α-Ethoxalylvalerate

The Claisen reaction of diethyl oxalate with ethyl valerate[1] was carried out in dry benzene using commercial sodium methoxide in essentially the manner described for ethyl α-ethoxalylpropionate.[2] An excess of ethyl valerate was used. The crude ester was difficult to distil satisfactorily, and the pure ethyl α-ethoxalylvalerate was obtained in yields of 20–24.5%, based upon diethyl oxalate employed; a 25-cm. vacuum-jacketed Vigreux column was required in the distillation, b. p. 78–80° (0.2 mm.), $n^{25}\text{D}$ 1.4319. This compound was prepared, but not obtained in a pure condition, by Adickes and Andresen.[3]

Anal. Calcd. for $C_{11}H_{18}O_5$: C, 57.38; H, 7.88. Found[4]: C, 57.18; H, 7.66.

To determine the position of entrance of the ethoxalyl group, a sample of the ester was heated at 165–175° with powdered glass during three hours. Decarbonylation led to a 53% yield of diethyl propylmalonate, b. p. 78–80° (2 mm.), $n^{25}\text{D}$ 1.4201. An authentic sample of the malonic ester boiled at 79–81° (2 mm.), $n^{25}\text{D}$ 1.4206.

The **2,4-dinitrophenylhydrazone**, prepared in the customary fashion, separated from 80% alcohol in the form of golden leaflets, m. p. 87–87.5° (lit.[3] value, 85–86°—only this derivative was prepared, using crude ester).

Anal. Calcd. for $C_{17}H_{22}N_4O_8$: N, 13.65. Found: N, 13.80.

COMMUNICATIONS TO THE EDITOR

THE STRUCTURE OF CITRININ

Sir:

Hetherington and Raistrick[1] degraded citrinin (I, $C_{13}H_{14}O_5$) with dilute acid to II ($C_{11}H_{16}O_3$), which was fused with alkali to give III ($C_9H_{12}O_2$), which in turn was methylated and oxidized to two carboxylic acids IV ($C_{11}H_{14}O_4$) and V ($C_{10}H_{12}O_4$). The compound 4-methyl-5-ethylresorcinol has now been synthesized by two methods, and a comparison of this substance with III (prepared from citrinin) shows that they have the same structure. Two acids, 2-ethyl-4,6-dimethoxybenzoic acid and 2-methyl-3,5-dimethoxybenzoic acid have also been synthesized, and their properties correspond to those reported for IV and V, respectively. No degradation products of citrinin have been previously synthesized.

Formylation of 5-ethylresorcinol[2] with zinc cyanide and hydrogen chloride produced 2-ethyl-4,6-dihydroxybenzaldehyde[3]; the two phenolic hydroxyl groups were methylated to give 2-ethyl-4,6-dimethoxybenzaldehyde, which was in turn oxidized to 2-ethyl-4,6-dimethoxybenzoic acid, m. p. 99–100° (Hetherington, *et al.*,[1] reported a melting point of 98–99° for IV).

Anal. Calcd. for $C_{11}H_{14}O_4$: C, 62.84; H, 6.71. Found: C, 62.76; H, 6.71.

Reduction of 2-ethyl-4,6-dimethoxybenzaldehyde to 2-methyl-3,5-dimethoxyethylbenzene, followed by demethylation of the two methoxyl groups produced 4-methyl-5-ethylresorcinol, m. p. 67–69°. A mixed melting point of this compound

---

[1] Hetherington and Raistrick, *Trans. Roy. Soc.* (London), **B220**, 1–10 (1931).

[2] This compound was prepared by the procedure of Asahina and Ihara, *J. Pharm. Soc. Japan*, **48**, 28 (1928).

[3] This substance had been prepared previously by Geissman and Tulagin (unpublished work).

with III[4] prepared from citrinin gave no depression. The bis-(*p*-nitrobenzoate) of 4-methyl-5-ethylresorcinol was prepared (m. p. 205–6°) and compared with the bis-(*p*-nitrobenzoate) of III (m. p. 205–6°). A mixed melting point determination gave 205–206°. *Anal.* Calcd. for $C_{23}H_{18}O_8N_2$: C, 61.33; H, 4.03. Found: C, 61.50; H, 4.03.

Methylation of the hydroxyl groups of 2-methyl-3,5-dihydroxybenzoic acid (prepared by the method of Jacobsen and Wierss[5]) gave 2-methyl-3,5-dimethoxybenzoic acid, m. p. 157–158° (Hetherington, *et al.*,[1] reported m. p. 142–146° for V). *Anal.* Calcd. for $C_{10}H_{12}O_4$: C, 61.21; H, 6.16; neut. equiv., 196.2. Found: C, 61.35; H, 6.55; neut. equiv., 195. This acid was converted to the amide which was treated with methylmagnesium bromide to give 2-methyl-3,5-dimethoxyacetophenone, m. p. 46–47°. Reduction of this ketone with hydrazine followed by demethylation produced 4-methyl-5-ethylresorcinol, m. p. 67–69°. Admixture of this sample with III or with the sample prepared from 5-ethylresorcinol produced no depression.

The above evidence completely eliminates the formulas advanced by Coyne, Raistrick and Robinson[6] for citrinin, II, III, IV and V.

Terminal-methyl number determinations were run on citrinin (2.68 and 2.76) and on II (2.57 and 2.51). Since II couples with two moles of benzenediazonium chloride in an apparently normal manner (Gore, *et al.*[4]), and since the molecule must have at least three terminal methyl groups, II would appear to be 4-methyl-5-(1-methyl-2-hydroxypropyl)-resorcinol. The synthesis of this substance has been undertaken.

[4] Hetherington, *et al.*,[1] reported a melting point of 97–99° which changed to 65–70° after the sample stood for some time. Gore, Panse and Venkatarumen [*Nature*, **157**, 333 (1946)] reported 65–70° and Spranger and Ruoff [*J. Org. Chem.*, **11**, 189 (1946)] 67–70° as the melting point of III.

[5] Jacobson and Wierss, *Ber.*, **16**, 1960 (1883).

REDUCTION OF CARBON DIOXIDE TO METHANOL BY LITHIUM ALUMINUM HYDRIDE[1]

Sir:

Carbon dioxide is rapidly absorbed by lithium aluminum hydride in ether solution. From such mixtures formaldehyde was isolated, as the dimethone derivative and as hexamethylenetetramine, in yields not over 25%. Schlesinger and Finholt[2] found two moles of carbon dioxide absorbed per mole of hydride, which is consistent with reduction to the formaldehyde stage but does not exclude further reduction followed by partial carbonation of the resultant methoxide.

We then found that, with lithium aluminum hydride in excess, 0.75 mole of hydride is consumed per mole of carbon dioxide and hence that the reduction under these conditions proceeds to the methanol stage.

However, the isolation of methanol proved troublesome. The best of many different procedures for the recovery of small amounts of methanol from ether–water mixtures gave yields, based on carbon dioxide, of less than 50%. The conventional procedure for effecting reductions with lithium aluminum hydride was eventually abandoned in favor of one which is better with respect to yield and better adapted to isotopic synthesis since it involves fewer operations.

A relatively non-volatile solvent, diethyl carbitol, replaces diethyl ether, and a high-boiling alcohol, *n*-butylcarbitol, is used both to decompose the excess hydride and to liberate methanol by alcoholysis. Methanol, the most volatile component of the system, is then obtained in a simple distillation employing an inert entraining gas. The over-all process is shown below:

First Stage

$$4CO_2 + 3LiAlH_4 = LiAl(OCH_3)_4 + 2LiAlO_2$$

Second Stage (R = *n*-butylcarbityl)

$$LiAlH_4 + 4ROH = LiAl(OR)_4 + 4H_2$$

$$LiAl(OCH_3)_4 + 4ROH = LiAl(OR)_4 + 4CH_3OH$$

In a typical experiment, the carbon dioxide generated from 13.0 g. of barium carbonate by the slow addition of 30% perchloric acid, and diluted by a stream of nitrogen, was passed through drierite into a solution of 3.8 g. of lithium aluminum hydride in 500 cc. of diethyl carbitol. Shortly thereafter, 120 g. of *n*-butylcarbitol was added and, with continued flow of nitrogen gas, the mixture was heated. The product, collected in a trap cooled by a Dry Ice freezing mixture,[3] was redistilled to separate a small residue of high-boiling material and there was obtained as distillate 1.71 g. of methanol, $n^{20}\text{D}$ 1.3310, identified further as the N-(α-naphthyl)-carbamate, m. p. 124°. The yield of methanol was thus 81% based on barium carbonate. A small fraction, 1.7%, of unreacted carbon dioxide was collected in an ascarite tube through which the effluent gas passed.

THE PREPARATION OF TECHNETIUM METAL

Sir:

Element number 43, technetium, which was discovered by Perrier and Segre[1] has now been prepared in metallic form from two separate samples of technetium compounds which were obtained from Dr. G. W. Parker of Clinton Laboratories, Oak Ridge, Tennessee. Both original samples were reported to be the ammonium "per" salt, probably NH_4TcO_4 and were shown by spectrographic analysis to contain negligible amounts of impurities.

The first sample was obtained from Oak Ridge as a pink deposit, weighing 119 micrograms, on a platinum plate. Hydrogen sulfide was passed, for a period of one hour, over a pink solution of the solid in 100 microliters of 4 *N* hydrochloric acid in a microcone placed in a water-bath at 80°, and a brownish, flaky precipitate formed slowly. This was centrifuged, washed and dried *in vacuo* at room temperature. A sample of this sulfide which was submitted for analysis gave an X-ray diffraction pattern which has not yet been interpreted.

The sulfide was transferred to a thin-walled quartz capillary (i. d. 0.15 mm., wall thickness 0.015 mm.) which was attached to a vacuum line in such a manner that hydrogen could be admitted onto the heated sulfide and then removed by pumping.

When the compound was treated with hydrogen at 1000° for three two-minute intervals with intervening evacuation a black cindery mass resulted and a yellow material sublimed out, presumably sulfur. The black material was transferred to an X-ray capillary and submitted for X-ray analysis. It was reported by Dr. R. C. L. Mooney to be technetium metal, isomorphous with rhenium, osmium and ruthenium.[2]

The second sample of technetium was obtained as a pink sirup in a sealed quartz tube. The sirup, which was reported to contain *ca.* 200 micrograms of technetium, was dissolved in 100 microliters of 4 *N* hydrochloric acid as before. This time when hydrogen sulfide was passed over the heated solution a black precipitate immediately formed. This compound gave no X-ray diffraction pattern.

On treatment of the dried solid with hydrogen at 900°, a substance was formed yielding an X-ray diffraction pattern totally unlike that obtained before. The product was then treated with hydrogen at 1000° and the pattern obtained was again different but may have contained some metal. Finally, it was treated with hydrogen at 1100° and a silvery, sintered mass was obtained which proved to give the same pattern as the first metal obtained.

Technetium metal does not dissolve in hydrogen peroxide–ammonium hydroxide mixture or in hydrogen peroxide alone as does rhenium metal, nor does it dissolve in hydrochloric acid.

The patterns obtained at 900 and 1000° may be due to lower sulfides of technetium and these compounds will be investigated further.

The disparate results on the precipitation of the technetium sulfides may be due to the fact that two distinct oxidation states were involved.

PREPARATION OF CARBON MONOXIDE[1]

Sir:

Because of the wide interest in carbon monoxide as an intermediate in the synthesis of isotopically labeled organic compounds, and in view of the recent report by Kummer[2] on the preparation of $C^{14}O$ by an exchange reaction with $C^{14}O_2$, I am prompted to describe a method which, because of its extreme simplicity, is applicable not only to the preparation of isotopic carbon monoxide, but also to the ordinary laboratory preparation of this gas. It consists simply in heating a mixture of calcium carbonate and zinc dust, whereupon the following reaction occurs

$$CaCO_3 + Zn \longrightarrow CaO + ZnO + CO$$

This reaction was reported many years ago by Kinnicutt[3] and Schwartz,[4] but appears to have been overlooked, since the only subsequent reference found is a brief mention by Mellor. Investigation revealed that at 700–750° a mixture of dry, powdered calcium carbonate with twice the theoretical quantity of zinc dust[5] gives a quantitative yield of carbon monoxide of high purity. For small-scale preparations (1–10 mM.) it was found convenient to heat the reactants in a quartz tube attached to an evacuated system of known volume, the rate and extent of gas evolution being measured by means of a manometer. In a typical run, 10 mM. of calcium carbonate and 20 mM. of zinc yielded 216 ml. N.T.P. of gas consisting of CO, 99.1%; CO_2, 0.9%; H_2 and H_2O, traces; as determined by mass-spectrometric analysis. Larger-scale preparations (up to 5 liters) have been made at atmospheric pressure by heating the reactants in a Pyrex test-tube and collecting the gas by displacement of a liquid (water or oil).

The rate of gas evolution is easily controlled by varying the temperature of the reaction vessel. The reaction doubtless depends upon dissociation of calcium carbonate, since the more stable barium carbonate gives no trace of carbon monoxide under the same conditions.

---

(1) This work was sponsored by the Sun Oil Company, Philadelphia, Pa.

(2) Kummer, THIS JOURNAL, **69**, 2239 (1947).

(3) Kinnicutt, *Am. Chem. J.*, **5**, 43 (1883).

(4) Schwartz, *Ber.*, **19**, 1141 (1886).

(5) An excess of zinc is necessary because some distils at the temperature employed.

Although this procedure was investigated primarily for the synthesis of C^{13} labeled methanol, it should also be useful for the preparation of isotopic phosgene and perhaps other compounds. An important advantage of this method, particularly with C^{13}, is that there is no dilution of the isotope concentration, as would occur in an exchange reaction.

NEW BOOK

Essentials of Physiological Chemistry. By ARTHUR K. ANDERSON, Professor of Physiological Chemistry, The Pennsylvania State College. Third Edition. John Wiley and Sons, Inc., 440 Fourth Ave., New York 16, N. Y., 1947. vii + 395 pp. 38 figs. 15 × 23.5 cm. Price, $3.50.

This excellent elementary text-book has been revised and reasonably well brought up to date. It can be recommended either for students taking a one semester course in biochemistry or for others who have had a satisfactory background of organic chemistry but who have not been able to take a formal course in biochemistry. The fundamental facts of biochemistry are set forth in an interesting manner. Good reviews of carbohydrates and lipids are presented. It is to be regretted, however, that no serious attempt has been made to give the student an adequate picture of the protein molecule as established by modern physical and chemical methods of investigation. The usual topics, such as enzymes, hormones, vitamins, metabolism and blood chemistry, have been handled well. In a later edition, it might be advisable to adopt uniformly the current method for representing the benzenoid ring. As is usual with any text-book, criticisms may be directed at certain statements; considering the excellence and general accuracy of the text, however, such criticisms become relatively unimportant.

Reactions of Trimethylsilyl Sulfate[1]

BY LEO H. SOMMER, GEORGE T. KERR AND FRANK C. WHITMORE

The Flood Reaction.—In 1933 Flood reported that treatment of a concentrated sulfuric acid solution of hexaethyldisiloxane with ammonium chloride or fluoride gives triethylchlorosilane or the corresponding fluoro compound.[2] In connection with studies of organosilicon compounds, we have found this reaction extremely convenient for the preparation of large amounts of trialkylchloro- and trialkylfluorosilanes, when certain modifications of the procedure reported by Flood are employed.[3] During a study of the mechanism of the reaction, we isolated trimethylsilyl sulfate, a white crystalline solid, m. p. 56–58°, from the reaction of hexamethyldisiloxane with fuming sulfuric acid.[4]

In the present work it has been found that the use of concentrated sulfuric acid and continuous extraction of the reaction mixture with pentane gives improved yields and a consistently purer product.

$$[(CH_3)_3Si]_2O + H_2SO_4 \longrightarrow [(CH_3)_3Si]_2SO_4 + H_2O \quad (1)$$

To 162.0 g. (1.00 mole) of hexamethyldisiloxane was added dropwise over a two-hour period, with stirring and salt–ice cooling, 260 g. (2.5 moles) of concentrated sulfuric acid. The final reaction mixture was a white, crystalline slurry. It was continuously extracted with dry pentane for forty-eight hours while keeping the reaction mixture ice-cold. The pentane was removed from the extract under vacuum and there was obtained 161.0 g. (0.67 mole) of white crystalline trimethylsilyl sulfate. A weighed sample gave: % SO_4, 38.9 (calcd., 39.6). The acid residue remaining after extraction was hydrolyzed and there was recovered 48 g. (0.30 mole) of hexamethyldisiloxane. The yield of sulfate was 66% based on the total starting material and 94% based on unrecovered starting material.

Treatment of a heptane solution of trimethylsilyl sulfate with hydrogen chloride gas in the presence of ammonium sulfate gives an instantaneous reaction affording an 88% yield of trimethylchlorosilane.

$$[(CH_3)_3Si]_2SO_4 + 2HCl \longrightarrow 2(CH_3)_3SiCl + H_2SO_4 \quad (2)$$

Dry hydrogen chloride passed into a mixture of 20.0 g. (0.15 mole) of ammonium sulfate and 200 cc. of a *n*-heptane solution of 30.0 g. (0.124 mole) of trimethylsilyl sulfate gave immediate precipitation of droplets of sulfuric acid. After completion of the reaction (one and one-half hours), the upper layer was fractionated to give 24.0 g. (0.22 mole) of trimethylchlorosilane, b. p. 56–58°, 88% yield.

Reactions 1 and 2 suggest that the preparation of trialkylchlorosilanes by the Flood reaction involves (a) formation of the sulfate from disiloxane and sulfuric acid, and (b) reaction of the sulfate with hydrogen chloride to give the chlorosilane.

$$(R_3Si)_2O + H_2SO_4 \longrightarrow (R_3Si)_2SO_4 + H_2O \quad (a)$$
$$(R_3Si)_2SO_4 + 2HCl \longrightarrow 2R_3SiCl + H_2SO_4 \quad (b)$$

Both of these reactions are reversible. Hydrolysis of trimethylsilyl sulfate with water readily gives the disiloxane. An effective reversal of (b) has been utilized by Patnode and Schmidt[5] in the preparation of trimethylsilyl sulfate from trimethylchlorosilane and concentrated sulfuric acid.

In the Flood reaction, isolation of trimethylchlorosilane in good yield is made possible by the presence of ammonium bisulfate, from the reaction of ammonium chloride with sulfuric acid, which effectively prevents the reversal of (b).

Addition of 108 g. (1.0 mole) of trimethylchlorosilane to a mixture of 245 g. (2.5 moles) of concentrated sulfuric acid and 99 g. (0.75 mole) of ammonium sulfate, followed by stirring for fifteen minutes gave a very slight evolution of hydrogen chloride. Separation of the upper layer,

[5] Patnode and Schmidt, *ibid.*, **67**, 2272 (1945).

followed by fractionation, gave 94.6 g. (0.87 mole) of trimethylchlorosilane, a recovery of 87%.

Although hydrogen chloride gave no apparent reaction with a solution prepared from hexamethyldisiloxane and concentrated sulfuric acid in the absence of added ammonium sulfate, the following procedure gave a 65% yield of trimethylchlorosilane. Dry hydrogen chloride was passed into a stirred solution (at 0°) prepared from 162 g. (1.0 mole) of hexamethyldisiloxane and 250 g. (2.5 moles) of concentrated sulfuric acid, while adding ammonium sulfate intermittently to the reaction mixture over a three-hour period until a total of 200 g. (1.5 moles) had been added. Hydrogen chloride was then passed in for an additional two hours, until fumes of hydrogen chloride were evolved from the condenser. The upper layer was separated and fractionated, yielding 141 g. (1.13 moles) of trimethylchlorosilane, 60% yield. On cooling, the residue from the fractionation gave 68.0 g. (0.25 mole) of trimethylsilyl sulfate crystals. Thus 90% of the hexamethyldisiloxane was accounted for.

It has recently been reported that hydrogen chloride and hexamethyldisiloxane react to give trimethylchlorosilane.[6] Thus it is possible that the following reaction of hexamethyldisiloxane, or an oxonium salt thereof, should be added to reactions (a) and (b) above in order to fully represent the Flood reaction.

$$(R_3Si)_2O + 2HCl \longrightarrow 2R_3SiCl + H_2O \qquad (c)$$

Reaction (c), like (a) and (b), is reversible.

Other Reactions of Trimethylsilyl Sulfate.—Like trimethylchlorosilane,[7] trimethylsilyl sulfate reacts with ammonia gas to give hexamethyldisilazane, and with dilute alkali to give azeotropic hexamethyldisiloxane–trimethylsilanol and hexamethyldisiloxane.

$$[(CH_3)_3Si]_2SO_4 \xrightarrow{NH_3} [(CH_3)_3Si]_2NH$$

$$[(CH_3)_3Si]_2SO_4 \xrightarrow[H_2O]{NaOH} [(CH_3)_3Si]_2O + (CH_3)_3SiOH$$

Treatment of 300 cc. of an ether solution of 35.0 g. (0.145 mole) of trimethylsilyl sulfate with dry ammonia gas gave immediate reaction. When ammonia was no longer absorbed (three hours), filtration of the product to remove the precipitated ammonia salt followed by fractional distillation gave 16.5 g. (0.102 mole) of hexamethyldisilazane, b. p. 124°, $n^{20}D$ 1.4077, 71% yield.

Trimethylsilyl sulfate, 60 g. (0.25 mole), dissolved in 150 cc. of dry ether, was added (two hours) with vigorous stirring to 200 cc. of ice-cold 20% aqueous sodium hydroxide by means of a separatory funnel having a capillary stem extending below the surface of the alkali. The ether layer was separated, the aqueous layer extracted with three 100-cc. portions of ether, and the ether solution of the product dried with potassium carbonate. Fractionation gave 14.7 g. of azeotropic hexamethyldisiloxane–trimethylsilanol, b. p. 90–93°, $n^{20}D$ 1.3778–1.3790, and 13.3 g. of hexamethyldisiloxane, b. p. 97–100°, $n^{20}D$ 1.3774.

Trimethylsilyl sulfate gave the tetraalkylsilane in good yield when treated with ethyl- or *n*-propylmagnesium bromide. Isopropylmagnesium bromide gave mainly trimethylbromosilane in one experiment, and a 34% yield of isopropyltrimethylsilane in another experiment when a longer reaction time was used.

Ethylmagnesium Bromide.—A solution of 30.0 g. (0.33 mole) of trimethylsilyl sulfate in 200 cc. of dry ether was added, with stirring, to 0.9 mole of ethylmagnesium bromide in 250 cc. of ether during ten minutes. There was no vigorous reaction at first, but addition of about two-thirds of the sulfate resulted in the formation of two layers. The reaction mixture was then slowly heated on the steam-bath until all of the volatile material was distilled and collected. After heating for six hours, the solid in the flask appeared to be dry, and was allowed to cool. Hydrolysis with dilute acid and extraction gave no additional product. After removal of ether, the distillate from the reaction mixture was fractionally distilled. There was obtained 36.0 g. (0.55 mole) of ethyltrimethylsilane,[8] b. p. 62°, $n^{20}D$ 1.3820, a yield of 83.5%.

***n*-Propylmagnesium Bromide.**—Using a procedure similar to that above, 0.8 mole of *n*-propylmagnesium bromide was treated with 73 g. (0.3 mole) of trimethylsilyl sulfate. Fractional distillation indicated that the product was a mixture of *n*-propyltrimethylsilane and trimethylbromosilane.[9] Since these compounds were somewhat difficult to separate, the trimethylbromosilane (*ca.* 10%) was removed by hydrolysis followed by treatment with concentrated sulfuric acid which dissolved the formed hexamethyldisiloxane and left *n*-propyltrimethylsilane as a clear upper layer. The yield of *n*-propyltrimethylsilane,[8] b. p. 90°, $n^{20}D$ 1.3929, was 55%.

Isopropylmagnesium Bromide. Run 1.—A solution of 73 g. (0.30 mole) of trimethylsilyl sulfate in 150 cc. of dry ether was added to 0.7 mole of isopropylmagnesium bromide in 350 cc. of ether. The reaction mixture was stirred at room temperature for one hour and was then heated on the steam-bath for six hours to distil all of the volatile product. The distillate fumed vigorously on exposure to air. Fractionation gave 47.5 g. (0.31 mole) of trimethylbromosilane,[9] b. p. 80°, a yield of 51.5%.

Run 2.—A run similar to that above was made, except that the reaction mixture was stirred at reflux temperature for eight days before distillation of the product. Fractionation gave 15.7 g. (0.155 mole) of isopropyltrimethylsilane, b. p. 89°, $n^{20}D$ 1.3958, a yield of 34%.

Anal. Calcd. for $C_6H_{16}Si$: Si, 24.1. Found: Si, 23.9.

The physical properties of this material check those of another sample prepared from *i*-propyltrichlorosilane[10] and methylmagnesium bromide.

Heating of trimethylsilyl sulfate with dry ammonium chloride gave trimethylchlorosilane in fair yield.

$$[(CH_3)_3Si]_2SO_4 \xrightarrow{NH_4Cl} 2(CH_3)_3SiCl$$

In a 250-cc. distilling flask were placed 40.0 g. (0.166 mole) of trimethylsilyl sulfate and 16.0 g. (0.33 mole) of dry powdered ammonium chloride. The flask was fitted with a thermometer, whose bulb was just below the side-arm, and a water-cooled condenser attached to an adaptor. The reaction mixture was heated gently and almost immediately vapor entered the condenser. The reaction mixture was heated until it was dry, and the distillate was fractionally distilled. There was obtained 15.0 g. (0.138 mole) of trimethylchlorosilane,[11] b. p. 56–58°, 32.5% Cl (calcd. 32.6% Cl), 42% yield.

Using a procedure similar to that above, very poor yields of trimethylchlorosilane (5–10%) were obtained with cupric chloride and cuprous chloride.

It is of interest to note that one of the most striking differences between trimethylsilyl sulfate and alkyl sulfates is the tendency of the latter to give reaction of only one of the alkyl groups.[12]

This is in line with the increase in reactivity of electronegative groups which generally results from substitution of silicon for carbon.

Summary

1. Trimethylsilyl sulfate has been prepared by an improved method.

2. Reactions of trimethylsilyl sulfate have been studied.

3. A mechanism for the Flood reaction has been proposed.

The Isolation of β-Amyrin and a Fatty Acid of High Molecular Weight from *Solidago leavenworthii* T. and G.

BY R. C. BURRELL AND FORREST G. HOUSTON

In the usual process for obtaining rubber from goldenrod the leaf material is first exhaustively extracted with acetone to remove waxes and resinous materials. On evaporation of the acetone from this extract a dark green tar is obtained. Polhamus[1] reports a mean of 21.03% of tar from five samples of *Solidago minor*. At the Southern Regional Research Laboratory of the U. S. D. A., Guthrie, *et al.*,[2] obtained a good yield of quercitrin and its aglycone from such tar prepared from the leaves of *Solidago leavenworthii* T. and G. Through the kindness of Dr. Guthrie a sample of this tar was obtained by us and the benzene soluble fraction of it was subjected to further investigation.

Experimental Results

Isolation of β-Amyrin.—Three kg. of the above mentioned tar were extracted with 2 l. of boiling benzene followed by five extractions with one-liter portions of hot benzene. The combined extracts were filtered through paper pulp and the green pigments removed by treatment with activated charcoal. A dark brown solution resulted from which the benzene was distilled, thereby yielding 950 g. of a brown viscous oil. This oil was refluxed for two hours with 1500 cc. of 20% alcoholic potassium hydroxide. The mixture was cooled and 2 liters of water added. It was made slightly acid to litmus with 10 *N* sulfuric acid. Two layers were formed, the upper a brown oil and the lower a greenish colored water solution. The oily layer was separated and treated with one liter of 10% sodium hydroxide solution and 3 liters of water and shaken vigorously for an hour. This mixture was then repeatedly extracted with ether, the extracts united, washed and dried over anhydrous sodium sulfate.

The sodium hydroxide solution which remained after the ether extraction was set aside for further investigation.

The ether was distilled from the dried extract leaving a deep yellow greasy residue. This was dissolved in one liter of acetic anhydride and refluxed for two hours. After standing overnight a heavy deposit of yellow needles formed. The liquid was then decanted and the crystals washed twice with one-liter portions of hot 95% ethyl alcohol and finally with petroleum ether until colorless. Nineteen grams of vacuum dried crystals was obtained, amounting to a yield of about 0.13% of the dried leaf material.

These crystals (acetate) melted at 231–233°. The saponification equivalent was 467 to 471 and the specific rotation in chloroform was $[\alpha]^{28}\text{D}$ +78°. The saponified compound after recrystallization from a large volume of 95% ethyl alcohol gave long colorless needles which melted at 190–192°. The benzoate melted at 229–230°. The Liebermann–Burchard reaction was positive. These properties correspond quite closely to those recorded for β-amyrin.[3,4]

Isolation of a High Molecular Weight Fatty Acid.—The fraction of saponified oil that was soluble in 10% sodium hydroxide (see β-amyrin preparation above) was neutralized with 10 *N* sulfuric acid. A brown oily liquid rose to the surface. This oil was removed by extraction with ether, the ether extract was thoroughly washed with water and dried, the ether removed by distillation and the residue dissolved in 1500 cc. of hot 95% ethyl alcohol. This solution was partially cleared with activated charcoal. On cooling a slightly yellow flocculent precipitate formed. This was reprecipitated four times from 95% alcohol. The 5 g. of colorless, amorphous material thus obtained was saponified for six hours with 20% alcoholic potassium hydroxide. This solution was then cooled and diluted with an equal volume of water. A slightly yellowish soapy precipitate formed which was filtered off, washed with dilute sulfuric acid, dried over a steam-bath and dissolved in 30 cc. of hot glacial acetic acid. On slow cooling colorless rosets of crystals were deposited (dry wt. 1 g.) which melted at 82°. The molecular weight by the Rast method was 433. Due to the hydrocarbon-like properties of the compound neutralization equivalent values were erratic. The acid amide melted at 108–110°.

Anal. Calcd. for $C_{28}H_{56}O_2$ (424.4): C, 79.17; H, 13.29. Found: C, 79.27; H, 13.25.

Summary

The isolation of β-amyrin and a high molecular weight fatty acid from the acetone extract of leaves of *Solidago leavenworthii* T. and G. is described.

Some Hemiacetals of Chloral with Cyclic Alcohols

BY W. T. SUMERFORD[1] AND F. MAIER CRONIC[2]

Introduction

Some interest has been shown in the hemiacetals of chloral, $CCl_3CHOH(OR)$, as neurophilic agents.[3] This paper describes the synthesis of some hemiacetals of chloral with cyclic alcohols, and reports preliminary pharmacological data on one of them.

Experimental

The chloral used in this work was obtained by mixing U. S. P. grade chloral hydrate with 1.8 times its weight of concentrated sulfuric acid, allowing the chloral to separate, and then distilling it off in an all-glass apparatus. The cyclohexanol and *p*-methylcyclohexanol, obtained from the Eastman Kodak Company, the 1-ethynylcyclohexanol from Farchan Laboratories, and the 3,3,5-trimethylcyclohexanol from the Carbon and Carbide Chemicals Corporation, were dried over anhydrous sodium sulfate, and used without further purification.

One-tenth mole each of chloral and the cyclic alcohol in separate flasks were cooled to 2°. The alcohol was added in ten equal portions at ten-minute intervals to the chloral, placing both flasks in the refrigerator after each addition. The mixture was kept at 2° until it solidified, which required not more than three days, stored for several days in an evacuated desiccator containing calcium chloride and then recrystallized from petroleum ether, b. p. 75–85°.

TABLE I

HEMIACETALS OF CHLORAL WITH CYCLIC ALCOHOLS $CCl_3CHOH(OR)$

R	Formula	Yield, %	M. p., °C.	C analyses, % Calcd.	C analyses, % Found	H analyses, % Calcd.	H analyses, % Found
Cyclohexyl	$C_8H_{13}O_2Cl_3$	82	64	38.88	39.01	5.25	5.45
p-Methylcyclohexyl	$C_9H_{15}O_2Cl_3$	30	60	41.30	41.24	5.73	5.74
1-Ethynylcyclohexyl	$C_{10}H_{14}O_2Cl_3$	41	55	44.19	43.71	4.78	4.70
3,3,5-Trimethylcyclohexyl	$C_{11}H_{19}O_2Cl_3$[a]	33	73	45.61	46.05	6.57	7.17

[a] This compound was prepared also from a sample of 3,3,5-trimethylcyclohexanol which is distributed under the name "Cyclonol" as a synthetic substitute for menthol by W. J. Bush and Co., Inc.

The high solubility of these hemiacetals (Table I) in a wide variety of solvents makes difficult their isolation and purification. Of the many solvents and combinations of solvents tried, only ligroin was suitable, and the fraction boiling between 75–85° gave the best results.

Several cyclic alcohols, *o*-methylcyclohexanol, *m*-methylcyclohexanol and *p*-*t*-butylcyclohexanol, gave hemiacetals with chloral which did not solidify under the experimental conditions. Efforts to purify them by careful distillation at pressures ranging from 2 to 20 mm. and at atmospheric pressure, with the use of glass wool,[4] resulted in their almost complete dissociation into chloral and the alcohol.

Pharmacological.—1-Cyclohexoxy-2,2,2-trichloroethanol in a dosage of 800 mg./kg. narcotized all of five rats injected for an average latent period of fifty minutes, and in a dosage of 1500 mg./kg. gave 100% mortality in a like number of rats.

Acknowledgments.—The authors wish to thank the Advisory Faculty Council of the University Center in Georgia for a grant-in-aid in support of this work. The pharmacological data on the 1-cyclohexoxy-2,2,2-trichloroethanol was kindly supplied by Dr. Y. SubbaRow of the Lederle Laboratories, Inc., Pearl River, N. Y.

Summary

Four new hemiacetals of chloral with cyclic alcohols have been synthesized and described. The relative narcotic activity and toxicity in rats of one of these compounds have been ascertained.

Studies in the Santonin Series. III.[1,2,3] The Introduction of Nitrogen into the Desmotroposantonin Molecule

BY HUANG-MINLON[4] AND SHAO-CHI CHENG

Some time ago E. Wedekind[5] studied the introduction of nitrogen in the form of a salt-forming group into the desmotroposantonin molecule (I), with a view to obtain basic derivatives resembling the alkaloids and to determine pharmacologically the possible variation of the physiological properties of santonin. He attempted to transform benzene-azo-*d*-β-desmotroposantonin (II),[6] prepared from *d*-β-desmotroposantonin (I),[7] into aminodesmotroposantonin (III) by reduction with stannous chloride and hydrochloric acid. However, he obtained not the desired product but an amino acid melting at 206°, which as he recognized arose from benzene-azo-desmotroposantonin through the simultaneous reduction of the lactone ring. The product, therefore, according to him is an aminodesmotroposantonous acid (IV). He further reported that the attempt to employ nitrodesmotroposantonin (V) as the starting material for the preparation of aminodesmotroposantonin had likewise a negative result, and therefore emphasized in his report that in general the preparation of such a substance, on account of the sensitiveness toward reducing agents, would be difficult.

After we had found the interesting rearrangement and isomerization of santonin and desmotroposantonin[2] as well as of its bromination products[3] we wished to ascertain whether or not nitrogen containing derivatives of santonin and desmotroposantonin could give similar reactions. We started with the preparation of nitrodesmotroposantonins (V). The nitro derivative of *d*-β-desmotroposantonin had already been prepared by Andreocci,[8] but under the conditions briefly described by him the nitration did not proceed uniformly. Nitric acid, even in the cold, produces a small amount of the desired nitrodesmotroposantonin and a product melting at 250°, which is perhaps identical with the so-called hydroxynitrodesmotroposantonin obtained by Andreocci[8] by the nitration of *d*-β-desmotroposantonin at room temperatures.

When the nitration is carried out in glacial acetic acid solution and under the controlled conditions described in the experimental part a much better yield of the nitrodesmotroposantonins was obtained. We have prepared up to the present only two of them: the dextro-rotatory nitro-*d*-β-desmotroposantonin, melting at 191–192°, from *d*-β-desmotroposantonin, and the new levo-rotatory nitro-*l*-α-desmotroposantonin, melting at 216°, from *l*-α-desmotroposantonin. The nitro compound melting at 216° can also be prepared by treatment of the addition product of santonin and nitric acid (VI)[9] with acetic anhydride and a drop of concentrated sulfuric acid, followed by

saponification of the resulting acetate (VII) which melts at 230–231°. Compound VII has been proved to be identical with the acetylation product of nitro-*l*-α-desmotroposantonin, melting at 230–231°. The mechanism of the reaction is similar to that of the transformation of santonin into *l*-α-desmotroposantonin.[2] But it is more interesting in this case since, in addition to the aromatization of the first ring the rearrangement of the angular methyl group, an indirect nitration has taken place.

The nitrodesmotroposantonins (V), unlike the desmotroposantonins[2] and bromodesmotroposantonins,[3] are not so readily transformable into each other. They remain unchanged after treatment with sulfuric acid and decompose readily on alkali fusion. On reduction under mild conditions with zinc dust and ammonium chloride in alcoholic solutions both of the nitrodesmotroposantonins give the corresponding, previously unknown, aminodesmotroposantonins (III): the dextro-rotatory amino-*d*-β-desmotroposantonin, melting at 197–198°, and the levo-rotatory amino-*l*-α-desmotroposantonin, melting at 170°. Both of the amino compounds are soluble in alcohol but not in water and sodium carbonate solution, and they form water-soluble hydrochlorides. From the aqueous solution of their salts the corresponding aminodesmotroposantonins can be precipitated by the addition of sodium carbonate solution.

The constitution of amino-*d*-β-desmotroposantonin was established by the fact that by the Sandmeyer reaction it is transformed into the already known bromo-*d*-β-desmotroposantonin (VIII).[3] Besides, it is reconverted into *d*-β-desmotroposantonin (I) on diazotization and replacement of the diazo group with hydrogen. These transformations further demonstrate that amino-*d*-β-desmotroposantonin and of course nitro-*d*-β-desmotroposantonin, in respect to the three asymmetric carbon atoms in the lactone ring, must have the same configuration as their parent substance, *d*-β-desmotroposantonin.

Owing to the scarcity of material amino-*l*-α-desmotroposantonin has not yet been converted into compounds of known constitution. We believe, however, that there should be little doubt about this conversion because the *l*-α-isomer is obtained by the same methods and under exactly the same experimental conditions, from *l*-α-desmotroposantonin, as those under which amino-*d*-β-desmotroposantonin is formed from *d*-β-desmotroposantonin. Its levo-rotatory character, as well as its conversion to a dextro-rotatory amino acid which will be discussed later, further illustrates that it retains the configuration of *l*-α-desmotroposantonin with regard to the lactone ring. As in the case of the nitrodesmotroposantonins, the attempt to convert the aminodesmotroposantonins by acid or alkali into their respective stereoisomers gave negative results.

By reduction with zinc dust and acetic acid amino-*d*-β-desmotroposantonin and amino-*l*-α-desmotroposantonin are converted into the corresponding aminodesmotroposantonous acids (IV) melting at 190 and 197°, respectively. These aminodesmotroposantonous acids, like desmotroposantonous acids, show directions of specific rotation opposite to those of their respective parent substances so that they are denoted as amino-*l*-β-desmotroposantonous and amino-*d*-α-desmotroposantonous acid.

Both of these amino acids can also be obtained directly from the appropriate nitrodesmotroposantonin (V), but our amino-*l*-β-desmotroposantonous acid is not identical with that obtained by Wedekind, although he also used *d*-β-desmotroposantonin as the starting material. Our acid and its hydrochloride are levorotatory and it forms an unstable hydrochloride in opposition to the properties of Wedekind's acid; furthermore, the melting point of our acid is lower than and depressed by admixture of Wedekind's acid.

We believe that our compound is the true amino-*l*-β-desmotroposantonous acid because all known desmotroposantonous acids and their substitution products show a direction of specific rotation opposite to that of their parent compounds. The specific rotation reported by Wedekind is that of the hydrochloride rather than that of the free amino compound, but we do not believe that a change of sign of rotation accompanies salt formation in this case since all the hydrochlorides of the amino compounds of the santonin series show the same direction of rotation as the free amino compounds.[10]

Owing to lack of specific information exact repetition of Wedekind's work was not feasible, but on treatment of benzene-azo-*d*-β-desmotroposantonin with stannous chloride we did obtain an amino acid melting at 206° and not identical with amino-*l*-β- and amino-*d*-α-desmotroposantonous acid, which probably is the same product that Wedekind had. Unfortunately lack of material prevented further characterization of the 206°-acid. Contrary to his findings, however, we also isolated amino-*d*-β-desmotroposantonin from the reduction mixture.

Experimental

Nitro-*d*-β-desmotroposantonin (V).—A suspension of ground *d*-β-desmotroposantonin (10 g.) in glacial acetic acid (100 cc.) was cooled to 6–7°. A 10% solution of concentrated nitric acid in glacial acetic acid (40 cc.) was added dropwise from a buret to the stirred suspension in eighty minutes. Stirring was continued for ten more minutes after complete addition; the mixture was poured into ice-water and filtered. Recrystallization of the separated solid from alcohol gave nitro-*d*-β-desmotroposantonin (8 g.) as yellow prisms, m. p. 191–192°, $[\alpha]^{24}\text{D}$ +119.5° (*c*, 0.4% in alcohol).

Anal. Calcd. for $C_{15}H_{17}O_5N$: C, 61.88; H, 5.88. Found: C, 62.19; H, 5.79.

---

[10] Examples for the generalization concerning the sign of rotation are: amino-*d*-β-desmotroposantonin and *d*-hydrochloride, amino-*l*-α-desmotroposantonin and *l*-hydrochloride (see text), *l*-aminohyposantonin and *d*-aminohyposantonous acid hydrochloride [Asahina and Momose, *Ber.*, **71**, 1425 (1938)].

Amino-*d*-*β*-desmotroposantonin (III).—Nitro-*d*-*β*-desmotroposantonin (8 g.) and ammonium chloride (1.5 g.) were dissolved in dilute alcohol (600 cc. of alcohol in 300 cc. of water) and heated to 62–67°, when zinc dust (1.5 g.) was added slowly. The reaction mixture was kept at this temperature for one hour. The filtrate on cooling precipitated long thin plates (2.85 g.), m. p. 195–196°. The mother liquid, after distillation of the major part of the alcohol, gave a second crop (0.88 g.). The combined precipitate was then recrystallized from alcohol; amino-*d*-*β*-desmotroposantonin was obtained as plates, m. p. 197–198°, $[\alpha]^{23}\mathrm{D}$ +113.8°, (*c*, 0.44% in alcohol).

Anal. Calcd. for $C_{15}H_{19}O_3N$: C, 68.95; H, 7.31. Found: C, 69.24; H, 7.03.

It gave the hydrochloride as long prisms by dissolving in a small amount of hot 5% hydrochloric acid and cooling; m. p. 265–267° (dec.), $[\alpha]^{25}\mathrm{D}$ +66.4° (*c*, 0.34% in alcohol).

Anal. Calcd. for $C_{15}H_{20}O_3NCl$: Cl, 11.92. Found: Cl, 11.47.

Amino-*l*-*β*-desmotroposantonous Acid (IV).—(a) Nitro-*d*-*β*-desmotroposantonin (10 g.), zinc dust (37 g.) and 70% acetic acid (300 cc.) were refluxed for ten hours. The filtrate was diluted with 4–5 times its volume of water, when a white precipitate settled out. Dissolution of the separated solid in sodium carbonate solution followed by acidification of the filtrate gave the product in a purer state. The purified solid was then recrystallized from alcohol; amino-*l*-*β*-desmotroposantonous acid (1.44 g.) separated as plates, m. p. 190°, $[\alpha]^{25}\mathrm{D}$ −56.3°, (*c*, 0.8% in alcohol). (b) Amino-*d*-*β*-desmotroposantonin (1 g.), zinc dust (5 g.) and 70% acetic acid (43 cc.) were treated as described in (a); m. p. 189–190°, not depressed by admixture with the product obtained from nitro-*d*-*β*-desmotroposantonin.

Anal. Calcd. for $C_{15}H_{21}O_3N$: C, 68.41; H, 8.03. Found: C, 68.38; H, 8.10.

The hydrochloride was prepared by dissolving the amino acid in small amount of hot alcohol and followed by addition of concentrated hydrochloric acid; m. p. 245–246°, $[\alpha]^{24}\mathrm{D}$ −59.2° (*c*, 0.6% in alcohol). The fact that several determinations gave about the same but lower value for the chloride content may be due to the loss of hydrogen chloride during drying, because the substance reverts to the free base on standing overnight in a vacuum desiccator over potassium hydroxide or on recrystallization from alcohol.

Anal. Calcd. for $C_{15}H_{22}O_3NCl$: Cl, 11.83. Found: Cl, 10.65.

Conversion of Amino-*d*-*β*-desmotroposantonin into Bromo-*d*-*β*-desmotroposantonin.—A mixture of copper sulfate (1 g.), copper powder (0.35 g.), sodium bromide (2.5 g.), concentrated sulfuric acid (0.3 cc.) and water (16 cc.) was boiled for three to four hours until the solution had become yellow. Amino-*d*-*β*-desmotroposantonin (0.4 g.) dissolved in a little water containing three drops of sulfuric acid was diazotized with sodium nitrite (0.12 g.) in the presence of copper sulfate (0.1 g.). The diazotized mixture was then poured into the cuprous bromide solution at 60–70°. After cooling the brown precipitate was filtered and dissolved in alcohol. Narrow thin plates separated overnight. After being decolorized with bone char it was recrystallized from alcohol giving bromo-*d*-*β*-desmotroposantonin in prismatic needles (0.03 g.), m. p. 209–210°, unchanged by admixture with an authentic specimen of bromo-*d*-*β*-desmotroposantonin.[3] The product gave a positive Beilstein test. Its racemic compound with bromo-*l*-*β*-desmotroposantonin[3] was found to be identical with bromo-*dl*-*β*-desmotroposantonin[3] both in crystal form and in melting point. A mixture of the two showed no melting point depression.

Conversion of Amino-*d*-*β*-desmotroposantonin into *d*-*β*-Desmotroposantonin.—Amino-*d*-*β*-desmotroposantonin (0.2 g.) dissolved in alcohol (10 cc.) containing two drops of concentrated sulfuric acid was diazotized with sodium nitrite (0.06 g.). After standing for twenty minutes in an ice-bath the diazotized compound was decomposed by boiling for twenty minutes in the presence of a small amount of zinc dust. Dilution of its filtrate with water gave a yellow precipitate (0.1 g.) which was then dissolved in alcohol and decolorized with bone char. Concentration and cooling of the decolorized filtrate yielded *d*-*β*-desmotroposantonin in prisms, m. p. 259–260°, unchanged by admixture with an authentic specimen of *d*-*β*-desmotroposantonin. The product gave with *l*-*β*-desmotroposantonin a racemic compound that was identical with *dl*-*β*-desmotroposantonin.[2]

Nitro-*l*-*α*-desmotroposantonin (V).—(*a*) This was obtained from *l*-*α*-desmotroposantonin (10 g.) by the same procedure as described in the nitration of *d*-*β*-desmotroposantonin. It crystallized from alcohol as yellow prisms (7.8 g.), m. p. 216–217°, $[\alpha]^{25}\mathrm{D}$ −105°, (*c*, 0.4% in alcohol).

Anal. Calcd. for $C_{15}H_{17}O_5N$: C, 61.88; H, 5.88. Found: C, 62.20; H, 5.46.

(*b*) Santonin (2 g.) was dissolved in concentrated nitric acid while warm. Upon cooling there separated the addition compound of santonin and nitric acid of m. p. 140–142°, which after filtration and drying over potassium hydroxide in the desiccator was added with water cooling to acetic anhydride (8 cc.) containing a drop of concentrated sulfuric acid. The reaction mixture was heated on a water-bath for about ten minutes. Dilution with water gave the acetate (VII) at first as an oil and then as a semisolid which, after recrystallization from chloroform–alcohol, melted at 230–231°, unchanged by admixture with the acetylation product of nitro-*l*-*α*-desmotroposantonin.

For saponification the product was refluxed with a 10% postassium hydroxide solution for half an hour when it dissolved rapidly to form a deep red solution. Acidification of the resulting reaction mixture gave the nitro compound in prisms, m. p. 215–216°. This was shown to be identical with the product obtained from (a) in crystal form, solubility and melting point. A mixture of the two showed no melting point depression. It was reconverted into the acetate of m. p. 230–231° on being refluxed with acetic anhydride for half an hour.

Amino-*l*-*α*-desmotroposantonin (III).—On reduction under the same conditions as those described in the reduction of nitro-*d*-*β*-desmotroposantonin, nitro-*l*-*α*-desmotroposantonin (1 g.) gave amino-*l*-*α*-desmotroposantonin as prisms (0.41 g.), m. p. 170°, $[\alpha]^{25}\mathrm{D}$ −157.5° (*c*, 0.4% in alcohol).

Anal. Calcd. for $C_{15}H_{19}O_3N$: C, 68.95; H, 7.31. Found: C, 69.34; H, 7.42.

Amino-*l*-*α*-desmotroposantonin Hydrochloride.—This hydrochloride (0.13 g.) was obtained from amino-*l*-*α*-desmotroposantonin (0.15 g.) by the same procedure as that described for the preparation of amino-*d*-*β*-desmotroposantonin hydrochloride. It crystallized from 5% hydrochloric acid solution as plates, m. p. 273–274°, $[\alpha]^{25}\mathrm{D}$ −125°, (*c*, 0.4% in alcohol).

Amino-*d*-*α*-desmotroposantonous Acid (IV).—This was obtained from either nitro-*l*-*α*-desmotroposantonin or amino-*l*-*α*-desmotroposantonin. The procedures were exactly the same as those described in the preparation of amino-*l*-*β*-desmotroposantonous acid. It crystallized from alcohol as prisms, m. p. 197°, $[\alpha]^{25}\mathrm{D}$ +76.2° (*c*, 0.4% in alcohol); yield, 0.12 g. from 1 g. of nitro-*l*-*α*-desmotroposantonin.

Anal. Calcd. for $C_{15}H_{21}O_3N$: C, 68.41; H, 8.03. Found: C, 68.29; H, 8.05.

Amino-*d*-*β*-desmotroposantonin and the Amino Acid of m. p. 206° from Benzene-azo-desmotroposantonin.—A hot solution of benzene-azo-desmotroposantonin (0.6 g.) in glacial acetic acid (110 cc.) was added to a solution of stannous chloride (4 g.) in boiling concentrated hydrochloric acid (20 cc.). After dilution with water the reaction mixture was treated with hydrogen sulfide. The filtrate was evaporated at first on a water-bath and then distilled under vacuum until a white precipitate separated.

Treatment with sodium carbonate solution separated the precipitate into a soluble and an insoluble portion. The latter on recrystallization from alcohol gave amino-*d*-β-desmotroposantonin in plates, m. p. 196–197°, unchanged by admixture with an authentic specimen of amino-*d*-β-desmotroposantonin. Acidification of the sodium carbonate soluble portion followed by recrystallization of the separated solid from alcohol gave a product in prismatic needles, m. p. 205–206°, depressed to 170° by admixture with amino-*l*-β-desmotroposantonous acid and to 176° by admixture with amino-*d*-α-desmotroposantonous acid. Its hydrochloride crystallized from dilute hydrochloric acid in plates.

Summary

1. Amino-*d*-β- and amino-*l*-α-desmotroposantonin have been prepared from the corresponding nitro compounds, the former also from benzene-azo-α-β-desmotroposantonin.
2. The corresponding aminosantonous acids were prepared from the aminodesmotroposantonins.
3. The constitution and configuration of the new compounds are discussed.

Cinchoninaldehyde and Reactive Methylene Compounds. IV[1]

BY ARTHUR P. PHILLIPS

This paper reports the reaction of cinchoninaldehyde (I)[2] with a variety of malonic acid type compounds, with several of the lower nitroalkanes, and with cyclohexanone.

Cinchoninaldehyde (I) reacted so rapidly with one equivalent of malononitrile that no catalyst was used and a nearly theoretical yield of II was obtained. Use of two molecular equivalents of malononitrile in this reaction, in an attempt to obtain the "2 to 1" type of condensation product, gave only II though in poorer yield.

Cyanoacetic acid, cyanoacetic ester, cyanoacetamide, malonic ester and malonic acid, when condensed with I in alcohol, aqueous or aqueous alcohol solution, with diethylamine (or piperidine) catalyst gave excellent yields of the products: III, IV, V, VI, IX.

When cyanoacetic ester was condensed with I by means of sodium ethylate in ethanol, acidification of the reaction mixture gave only the corresponding acid, III. Hydrolysis had resulted presumably as a consequence of using the aldehyde hydrate. Esterification of this acid by the Fischer method produced the same substance, IV, obtained earlier by combination of the reactants in the presence of diethylamine.

The malonic ester product was obtained in poorer yield (60%) and no sharp boiling point was observed. Since the base showed no tendency to crystallize, this product was purified as its hydrochloride.

When the condensation with malonic acid was varied by the use of pyridine as solvent with a little piperidine as catalyst, excellent yields of quinolyl-4-acrylic acid (X) resulted rapidly and

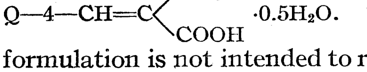
[a] A = ethanol; Aq = H_2O; Py = pyridine; H = hexane; B = benzene; E = ether; Et = ethyl acetate; Nt = reprecipitated from dilute alkali with dilute acid. [b] At 100°. [c] At room temperature. [d] At reflux temperature. [e] 4.5 g. of I and 3.6 g. malonic acid in 100 cc. of EtOH and piperidine catalyst. Heated on steam-bath for four hours, when a white solid gradually formed and settled out. [f] 4.5 g. of I and 3.6 g. malonic acid in 10 cc. EtOH and piperidine. Mixture was heated 1–2 minutes on steam-bath to dissolve reactants, then on addition of catalyst a heavy white precipitate formed instantaneously. [g] The product first obtained from the reaction mixture by treatment with an excess of concentrated HCl was XIII·HCl. XIII base was obtained by neutralization of the HCl with NH_3. [h] This compound was previously known, see ref. 3.

simply. This compound had been prepared earlier by other workers by the hydrolysis of the condensation product of lepidine and chloral.[3] The ethyl ester (XI) of this acid was made by the Fischer method and was characterized as its hydrochloride.

A variation from the normal malonic acid product, IX, was obtained by modifying the reaction conditions slightly. Thus, condensation of malonic acid and I in more concentrated solution with secondary amine catalyst and no heating gave rapid and nearly quantitative precipitation of a quite different substance. Carbon, hydrogen, and neutral equivalent determinations agree well with a compound having an empirical structure:



$$Q\text{—}4\text{—}CH{=}C\begin{matrix}\diagup COOH\\ \diagdown COOH\end{matrix}\cdot 0.5H_2O$$

This hemi-hydrate formulation is not intended to represent the molecular formula of the compound. In fact, it would seem quite unreasonable to hypothesize a simple hydrate as differing persistently from the normal product, IX, since all of these acid compounds were purified by repeated reprecipitations from dilute aqueous alkaline solutions by addition of dilute mineral acids. Thus, if the hydrate represented a stable structure under those conditions it should have been impossible to get the other product, IX, under the identical conditions of purification. A more reasonable structure for this substance is XII, particularly in view of the previously observed tendency of cinchoninaldehyde to form stable aldol-like addition products. XII, having the same empirical formula as the hemi-hydrate, likewise fits the analytical data.

When compound IX was refluxed with strong (20%) hydrochloric acid the acrylic acid X resulted by decarboxylation. When either IX or XII was heated in pyridine solution in the presence of a trace of piperidine good yields (70%) of X were formed.

Since under certain conditions condensation with malonic acid permitted the easy attainment of the cinnamic acid analog, it was hoped that reaction with cyanoacetic acid under the same conditions might lead to the cinnamonitrile-like product. Contrary to expectations, however, when pyridine was used as solvent with piperidine as catalyst different results were obtained. When only a moderate excess of cyanoacetic acid was used and the heating period was brief (thirty minutes) a good yield of the product III resulted,

[a] Molecular weights listed here are actually neutral equivalents × number of acid groups.

with no decarboxylation. But when 2.5–3 moles of cyanoacetic acid per mole of aldehyde was used and when heating was more extended (four hours) the product was VIII, which involves condensation between one mole of aldehyde and two moles of acid with loss of the two carboxyl groups.

The cyanoacetic acid product III was also obtained by condensation of the reactants in aqueous potassium hydroxide. III was further obtained in good yield by the hydrolysis of the corresponding ethyl ester IV by refluxing with 20% hydrochloric acid, or by allowing it to stand at room temperature with aqueous potassium hydroxide, followed by acidification.

Cinchoninaldehyde condensed readily with nitromethane, nitroethane, 1-nitropropane and 2-nitropropane in 50% aqueous alcohol with a trace of diethylamine as catalyst and a reaction time of several hours at room temperature. The yields were well over 90% and the products were of the aldol-like nitroalcohol type (XIII, XIV, XV, XVI), although usually the products obtained from aromatic aldehydes and nitroalkanes possess the  $\mathrm{RCH{=}\underset{|}{C}{-}NO_2}$ structure. This represents another instance of the strong tendency of cinchoninaldehyde to form products with a stable aldol-like configuration. Thus, nitromethane was condensed with the aldehyde in the presence of aqueous potassium hydroxide with subsequent liberation of the product by addition of concentrated hydrochloric acid. Under these conditions many aromatic aldehydes give nitrostyrenes, but cinchoninaldehyde gave the same aldol, XIII, resulting under the milder conditions.

Cyclohexanone condensed readily with I in equimolecular amounts in aqueous or alcoholic solution in the presence of potassium hydroxide to give good yields of XVII. In very dilute aqueous alkaline solution small amounts of XVIII were also produced.

Acetophenone with I in 50% aqueous alcohol and alkali gave XIX previously reported by Kwartler and Lindwall.[4] Further work with ketones is in progress.

Experimental details are listed in Tables I and II.

Acknowledgment.—Thanks are due Mr. Samuel W. Blackman for the microanalyses included here.

Summary

The condensation of certain reactive methylene compounds with cinchoninaldehyde has been reported.

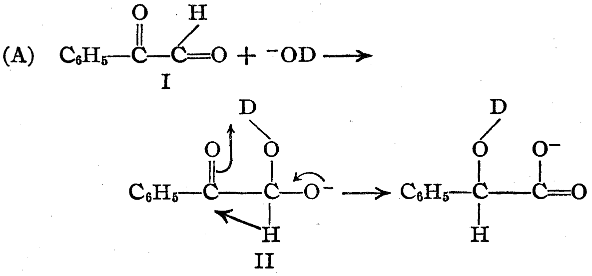
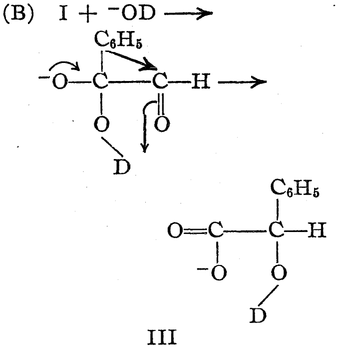
Mechanism of the Conversion of Phenylglyoxal to Mandelic Acid

BY W. V. E. DOERING, T. I. TAYLOR AND E. F. SCHOENEWALDT

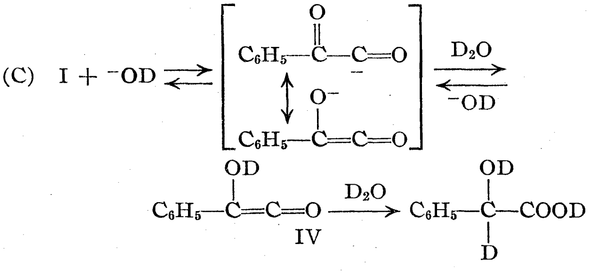
Three reasonable mechanisms may be considered for the base-catalyzed conversion of phenylglyoxal (I) to mandelic acid. Mechanism A,[1] an intramolecular version of one of the attractive mechanisms of the Cannizzaro reaction,[2] involves the intramolecular migration of a hydrogen atom in the intermediate anion II. Mechanism B,[1]



similar to that of the benzil–benzilic acid conversion,[3] involves migration of the phenyl group in III, an intermediate



closely related to II. Finally, in mechanism C direct removal of a proton from I establishes equilibrium with the tautomeric hydroxy-ketene IV which adds water forming mandelic acid.

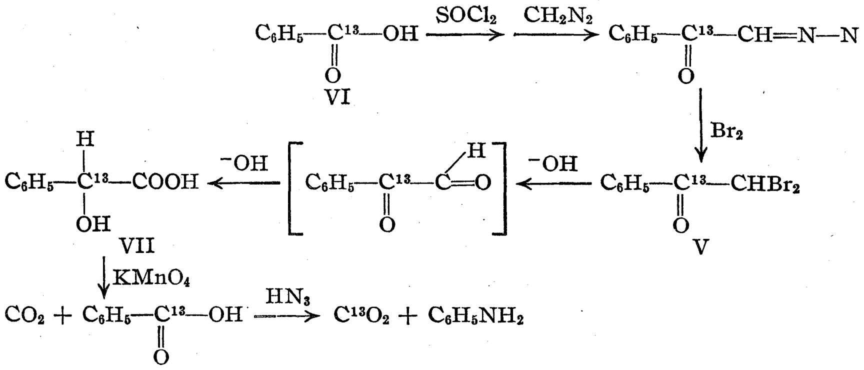


however, impossible to distinguish between mechanisms A, B and C on a kinetic basis alone.

Alexander, finding that the rate of the phenylglyoxal–mandelic acid reaction follows second-order kinetics, has supported mechanism A. It is,

Fredenhagen and Bonhoeffer[4] have invalidated mechanism C for the conversion of glyoxal to glycolic acid only by showing that solvent deuterium does not intervene in this reaction. They have not extended their experiments to I or any other monosubstituted glyoxal.

The following experiments afford evidence that there is no rearrangement of the carbon skeleton in the phenylglyoxal–mandelic acid transformation, mechanism B thereby being excluded. ω,ω-Dibromoacetophenone (V), prepared in two steps from benzoic acid containing 2.32% C^{13} in the carboxyl group (VI), is hydrolyzed with potassium hydroxide.[5] Oxidation of the resulting mandelic acid (VII) with permanganate has given carbon dioxide of normal C^{13} content and benzoic acid from which carbon dioxide containing 2.24% C^{13} has been obtained by the Schmidt reaction.[6,6a]



Extension of Bonhoeffer's work[4] to phenylglyoxal has invalidated mechanism C for a monosubstituted glyoxal. When I is treated with barium oxide in deuterium oxide there is obtained mandelic acid which, after equilibration with excess 0.5 N barium hydroxide,[7] contains no deuterium.

Only mechanism A is consistent with the available facts: no rearrangement of the carbon skeleton; the intramolecular transfer of hydrogen; the facile reaction of mesitylglyoxal[8]; and the

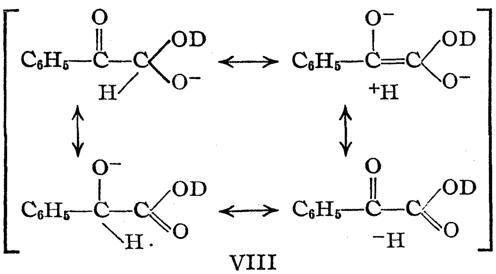
second order kinetics.[2] While this mechanism has been considered to involve the shift of a hydride ion,[9] we believe that the reactive intermediate is better described by a transition state involving at least four resonance structures (VIII).



VIII

Experimental

Determination of C^{13} in Benzoic Acid (VI).—A mixture of 0.0330 g. of benzoic acid containing an enriched content of C^{13} in the carboxyl group, 0.25 cc. of purified chloroform and 0.25 cc. of concentrated sulfuric acid was introduced into a reaction vessel through which was passed continuously a slow stream of prepurified nitrogen, freed of carbon dioxide and saturated with dry chloroform at 45°. C. P. sodium azide (0.1036 g.) was tapped from a side-arm into the stirred, heated (40–44°) reaction mixture. The effluent gas was bubbled through two traps (separatory funnels) containing clear solutions of 0.26 *N* barium hydroxide. After thirty minutes, the precipitated barium carbonate was collected under nitrogen, washed with carbon dioxide-free water, and dried (29.3 mg., 55% yield).

Carbon dioxide for the mass spectrometric analyses was liberated from the barium carbonate in a standard sample conversion apparatus.[10] The abundance ratios of $C^{12}O_2$ to $C^{13}O_2$ were determined with a Nier-type mass spectrometer.[11] From a plot of the positive ion current against the accelerating voltage it was found that because of incomplete resolution ions of mass 44 ($C^{12}O_2^+$) contributed about 5% to the peak at mass 45 ($C^{13}O_2^+$). Consequently a correction of 5% was made on the averages of the observed abundance ratios.

Anal. Abundance ratio $C^{12}O_2/C^{13}O_2$: 39.7, 41.5, 41.8, 39.5, 38.9: 40.3 ± 1.1. Corrected for resolution: 42.3, corresponding to 2.32% $C^{13}O_2$.

Normal carbon dioxide abundance ratio: 81.8, 80.9, 81.2, 81.5: 81.4 ± 0.3. Corrected for resolution: 85.5, corresponding to 1.16% $C^{13}O_2$.

Preparation of Labeled Mandelic Acid (VI).—An ethereal solution of benzoyl chloride prepared from 0.3014 g. of benzoic acid (I) (2.32% C^{13} in the carboxyl group) by treatment with thionyl chloride was added dropwise to an eight-fold excess of ethereal diazomethane[12] at −10 to −5°. After being sixteen hours at 4°, crude diazoacetophenone, recovered by evaporation of the solvent *in vacuo*, was dissolved in 50 cc. of anhydrous ether and treated with a dilute ethereal solution of bromine.[13] After the initially vigorous evolution of nitrogen and the development of a persistent red color, the reaction mixture was washed with sodium bisulfite and water. Crude ω,ω-dibromoacetophenone (V) obtained as a yellowish-amber oil by evaporation of solvent *in vacuo*, was converted to VII by refluxing for twenty-five minutes in 5% aqueous potassium hydroxide.[14] The filtered reaction mixture was clarified with Norit-A, acidified with concentrated hydrochloric acid and extracted with four portions of ether. Evaporation of the dried ether solution gave crude mandelic acid which was recrystallized from benzene; 0.09 g. of light tan crystals; m. p. 112–114° (24% of the theoretical yield based on I). Two more recrystallizations afforded 0.0641 g. of purer VI, m. p. 117–118.5°, showing no depression on admixture with an authentic sample.

Determination of C^{13} in Mandelic Acid (VII). (a) Oxidation with Acidic Permanganate.—A solution of 0.0627 g. of the mandelic acid obtained above (m. p. 117–118.5°) in 1.75 cc. of 10% sulfuric acid was oxidized[15] by 0.14 g. of potassium permanganate in the same apparatus used above for the Schmidt reaction, the nitrogen being purified by passing through two solutions of barium hydroxide. After the reaction mixture had been heated for ten minutes at 80–95°, the barium carbonate was collected as described above (0.1138 g., 140% yield).

Anal. Abundance ratio $C^{12}O_2/C^{13}O_2$: 78.3, 78.8, 78.5, 78.8, 78.6 ± 0.2. Corrected for resolution: 82.5 ± 0.2, corresponding to 1.20% $C^{13}O_2$.

From the reaction mixture 0.0365 g. (72.5% yield) of benzoic acid (IX), m. p. 122–123°, was isolated.[16]

(b) Oxidation with Neutral Permanganate.—The sublimed residues from the recrystallization of the mandelic acid (11.1 mg., m. p. 80–103°[17]) were dissolved in 0.36 cc. of water and oxidized with 0.05 g. of potassium permanganate, 8.3 mg. of barium carbonate being collected in the usual manner (57.5% yield).

Anal. Abundance ratio $C^{12}O_2/C^{13}O_2$: 81.0, 77.5, 78.5, 77.5, 76.6, 77.4: 78.1 ± 1.1. Corrected for resolution 82.0 ± 1.1, corresponding to 1.21% $C^{13}O_2$.

Pure benzoic acid, m. p. 121.6–122°, was isolated from the reaction mixture by extraction and sublimation.

(c) Determination of C^{13} in Benzoic Acid (IX).—As in the previously described Schmidt procedure, 0.0350 g. of benzoic acid was decarboxylated to 18.2 mg. of barium carbonate (32.2% yield).

Anal. Abundance ratio $C^{12}O_2/C^{13}O_2$: 41.6, 41.5, 42.8, 41.6, 42.1, 40.7, 40.8: 41.6 ± 0.5. Corrected for resolution: 43.7 ± 0.5, corresponding to 2.24% $C^{13}O_2$.

Determination of Deuterium.—Essentially the procedure described by Cohn[18] was employed with minor modifications. For the extended procedure recommended for the purification of the water of combustion, we have substituted a single sublimation in order to permit analysis of smaller samples of organic material. This simplification has resulted in an increased error, deuterium-free compounds giving water apparently containing 0.02–0.04% deuterium oxide.

Rearrangement of Phenylglyoxal Hydrate to Mandelic Acid (X).—Phenylglyoxal was obtained as its hydrate, m. p. 74–77°, by the oxidation of acetophenone with selenium dioxide[19]; phenylosazone, m. p. 150.6–151.4°; reported[20] m. p. 151–2°.

Anal. Calcd. for $C_8H_6O_2{\cdot}H_2O$: C, 63.10; H, 5.30. Found: C, 63.61; H, 5.76.

A cooled mixture (incompletely dissolved) of 0.587 g. of phenylglyoxal hydrate in 9.085 g. of water containing 7.25 weight per cent. of deuterium oxide (corrected for water of hydration) was shaken vigorously with 0.59 g.

of barium oxide. After twenty hours at 28°, the reaction mixture was acidified with concentrated hydrochloric acid and extracted with six 10-cc. portions of ether. Evaporation gave 0.425 g. (72.5%) of crystalline mandelic acid which was dissolved in 10 cc. of 0.5 *N* barium hydroxide. The solution was filtered, allowed to stand one hour, acidified, and extracted with ether. After repetition of the equilibration and sublimation, 0.317 g. (54.2%) of mandelic acid was obtained. Recrystallized from benzene, pure X was obtained, m. p. 118.5–119.3°, showing no depression on admixture with an authentic sample.

Anal. Calcd. for $C_8H_7D_{(7.25\%)}O_3$: D_2O, 0.906. Found: D_2O, 0.036.

The above procedure was repeated using 10.24 g. of water containing 27.6 weight per cent. (corrected for water of hydration) of deuterium oxide and 0.61 g. of phenylglyoxal hydrate. There was obtained 0.360 g. (59%) of crude mandelic acid. Recrystallization afforded 0.296 g., m. p. 118–119°.

Anal. Calcd. for $C_8H_7D_{(27.6\%)}O_3$: D_2O, 3.45. Found: D_2O, 0.039.

α-Hydroxyphenylacetic-*d* Acid.—Mandelic acid (1.470 g.) was refluxed under nitrogen for one week with 13.52 g. of 29.56% deuterium oxide and 1.23 g. of barium oxide. The deuterated mandelic acid, recovered by acidification with concentrated hydrochloric acid, extraction with ether and evaporation *in vacuo*, was equilibrated twice by refluxing for eighteen hours with 17 cc. of water under nitrogen. The recovered equilibrated acid was recrystallized from benzene giving a first crop (A) weighing 0.876 g.

Anal. Calcd. for $C_8H_7D_{(29.56\%)}O_3$: D_2O, 3.70. Found: D_2O, 3.57.

Sample A was twice reëquilibrated by treating with 23 cc. of 0.5 *N* baryta for seventy-five minutes at room temperature.

Anal. Found: D_2O, 3.57, 3.57, 3.57.

Summary

Using phenylglyoxal in which the ketone carbon is marked with C^{13}, it has been proved that there is no rearrangement of the carbon skeleton in the alkali-catalyzed conversion to mandelic acid. The failure of solvent deuterium to become attached to the alcohol carbon atom of mandelic acid prepared from phenylglyoxal in heavy water has allowed exclusion of a proton-removal mechanism and has substantiated a mechanism involving intramolecular transfer of hydrogen. The present status of the mechanism is discussed.

Configuration and Adsorption. A Comparison of the Adsorption of the *cis* and *trans* Isomers of Dichloroethylene on Activated Carbon

BY DAVID H. VOLMAN AND LAWRENCE J. ANDREWS

In an attempt to account for the data of adsorption from the vapor phase on activated carbon adsorbates may be separated into three classifications: first, molecules which can undergo hydrogen bonding; second, molecules which do not form hydrogen bonds but which possess permanent dipole moments; third, molecules which do not form hydrogen bonds and do not have permanent dipole moments.

Only the first classification is known definitely to behave abnormally in adsorption on carbon. For this type of compound the correlation of adsorbability and condensation properties of the gas has been pointed out recently by Volman and Klotz.[1] It was proposed that the initial adsorption does not reflect the hydrogen bonding properties of the molecule even though the relative pressures do, and the apparent anomalies in adsorption are to be explained by the values assigned to the relative pressure axis for the isotherms. For both of the other classifications no anomalies comparable to those found with a compound of the first classification such as water are known. However, it seemed of interest to determine the effect of the existence of a permanent dipole moment on van der Waals adsorption on carbon. A near approach to a comparison of this nature should be obtained by studying the adsorption of molecules differing only in geometric configuration. Thus by choosing *cis*- and *trans*-dichloroethylene the principal difference in interaction effects would seem to be the large difference in dipole moment, zero for the *trans* and 1.8 debyes for the *cis* compound.[2] In addition the isomers are easily obtained in a pure state and have convenient physical properties for adsorption studies.

Further interest in the problem derives from the fact that no comparisons of the adsorption of *cis–trans* isomers from the vapor phase have been made. However, in recent years extensive studies directed toward the separation of *cis–trans* isomers by chromatographic adsorption have been carried out.[3] These studies have all been made from solution and primarily with stereoisomers of carotenoids. In addition the adsorption of maleic and fumaric acids from aqueous solution on activated carbon has been carried out.[4] Here the adsorption is mainly dependent on the degree of ionization of the acids in solution. It was expected that a study of gas phase adsorption of *cis-trans* isomers would yield information on the possibility of separation of such isomers by adsorption techniques.

Experimental

Preparation of Materials.—The *trans* compound was obtained by fractionation of Eastman Kodak Co. *trans*-

dichloroethylene through a four-foot column packed with glass helices. The fraction retained boiled at 48.1° at 756 mm. The *cis* compound was obtained from the *trans* by isomerization according to the method of Jones and Taylor.[5] The *cis* isomer (b. p. 60.5° at 766 mm.) was isolated from the resulting mixture by fractionation on the four foot column.

The activated carbon was obtained from the Pittsburgh Coke and Chemical Company. It was screened to 20–30 mesh, dried at 140° for twenty-four hours and stored in dry air.

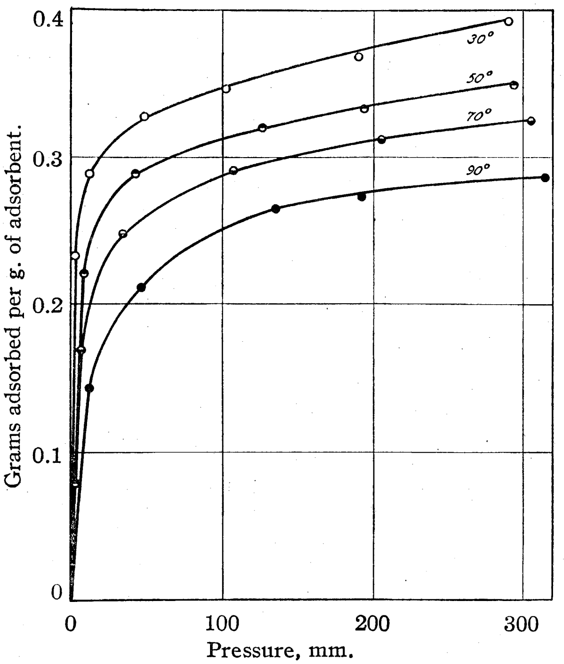

Fig. 1.—*trans*-Dichloroethylene adsorption isotherms.

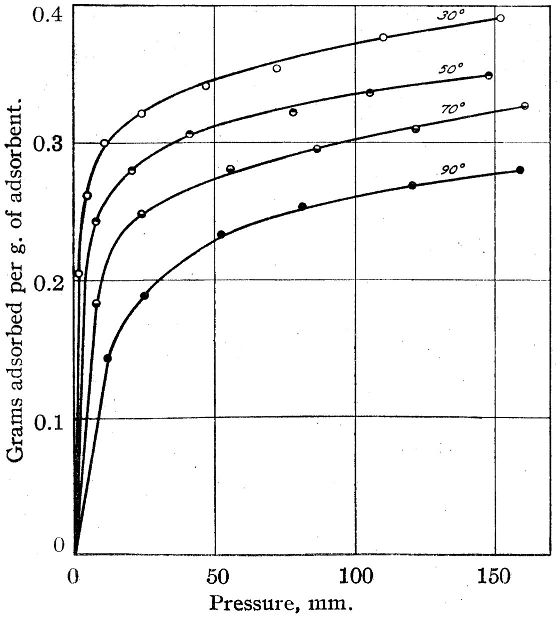

Fig. 2.—*cis*-Dichloroethylene adsorption isotherms.

Adsorption Method.—Adsorptions were determined by a simple gravimetric apparatus. Two grams of the activated carbon was weighed directly into an adsorption chamber. The sample was then outgassed at 100° for twenty-four hours. With proper manipulation of the stopcocks the adsorption chamber may be removed and weighed without breaking the vacuum over the carbon. The adsorption chamber is then replaced in a thermostat at the isothermal temperature, and after evacuation of the air contaminated region the carbon is allowed to come to equilibrium with enough adsorbate to give the desired pressure. The adsorption chamber may then be removed and weighed and the procedure repeated for the full range of pressures used. Although this simplified apparatus is of limited accuracy, the data are sufficiently reliable for the purposes of this experiment.

Results and Discussion

Comparison of Isotherms.—Figures 1 and 2 show the adsorption isotherms obtained for the *trans* and *cis* configurations, respectively, at temperatures 30, 50, 70 and 90°. In order to compare the area of surface covered by the two adsorbates at the same relative pressures it is necessary to determine the areas covered in adsorption. This may be calculated from a knowledge of the weight adsorbed provided the area occupied per molecule is known. A reasonable assumption is that the area occupied by an adsorbed molecule on the surface is the same as the cross section obtained by considering the molecules to be hexagonally close packed in the liquid. Then the average area per molecule is given by

$$A = 4(0.866)\left[\frac{M}{4\sqrt{2}N\rho}\right]^{2/3} \qquad (1)$$

where M is the molecular weight of the gas, N is Avogadro's number and ρ is the density of the liquefied gas.[6] Even if this is not an exact expression for the area of an adsorbed molecule, the assumption of the dependence of A on $1/\rho^{2/3}$ appears to be the significant one for comparative purposes since the exact area is not important.

The densities of the isomers were determined over a range of temperatures from 25 to 48° by means of a Westphal balance and agreed well with already published data.[7] Since the coefficient of thermal expansion is

$$\alpha = \frac{1}{V}\left(\frac{\partial T}{\partial V}\right)_p \qquad (2)$$

a plot of log density *vs.* T should yield a straight line if α is sufficiently constant in the region used. From such a linear plot, Fig. 3, the density at temperatures greater than 48° may be obtained.

To obtain the relative pressures for a comparison of adsorption it was necessary to know the saturation vapor pressures. In the region below the boiling point these values may be obtained from the data of Herz and Rathmann.[7] At higher temperatures the saturation pressures were calculated by use of the Clausius–Clapeyron equation assuming a constant heat of vaporization. The values used are shown in Table I. In Table II a

comparison of the areas covered at the same relative pressures for the *cis* and *trans* isomers is given. The values are seen to be in very good agreement, especially since the P_0 values above the boiling point are of limited accuracy.

TABLE I

SATURATION VAPOR PRESSURES AND AVERAGE ADSORBED MOLECULAR AREAS OF *cis*- AND *trans*-DICHLOROETHYLENE

Temp., °C.	Saturation vapor pressure, mm.		Molecular areas, sq. Å.	
	Cis	*Trans*	*Cis*	*Trans*
30	251	380	27.5	27.9
50	537	776	28.0	28.4
70	1050	1440	28.5	28.9
90	1900	2570	29.0	29.4

TABLE II

COMPARISON OF ADSORPTION OF *cis*- AND *trans*-DICHLOROETHYLENE AT THE SAME VALUES OF RELATIVE PRESSURE

Temp., °C.	Relative pressure, P/P_0	Area of surface covered, sq. m./g.	
		cis	*trans*
30	0.1	561	567
	.2	603	602
	.3	632	626
	.4	653	647
	.5	667	663
	.6	680	678
50	.1	543	532
	.2	587	580
	.3	613	608
70	.1	532	532

The close correspondence for area covered at the same relative pressures in the above data indicates that the forces important in adsorption are the same as those which account for condensation even at low relative pleasure values. Brunauer, Emmett and Teller[8] have derived a theory of adsorption isotherms on the assumption that the same forces that produce condensation are also responsible for adsorption. Our findings indicate that this is valid where the principal intermolecular forces are van der Waals with or without a contribution due to the existence of a permanent dipole moment. On the basis of the discussion of Volman and Klotz,[1] molecules which form hydrogen bonds in the liquid but not in the vapor state are excluded from the above generalization.

Surface Area and Heat of Adsorption.—The shape of the adsorption isotherms and the exten-

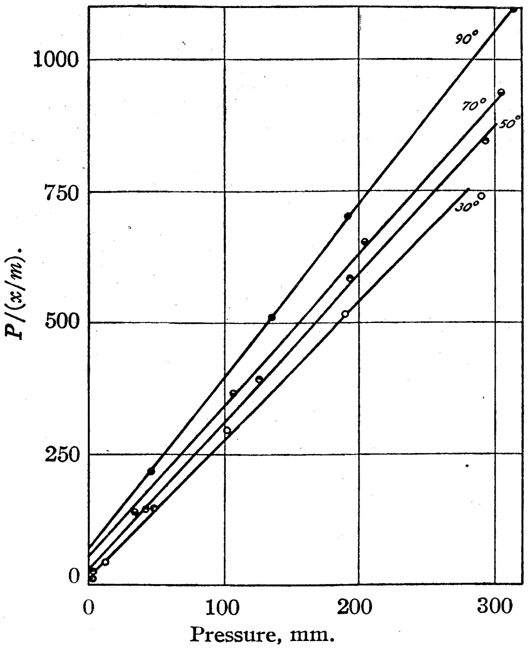

Fig. 4.—Adsorption isotherms of *trans*-dichloroethylene, plotted according to the Langmuir equation x/m in grams per g. of adsorbent.

(8) Brunauer, Emmett and Teller, THIS JOURNAL, **60**, 309 (1938).

sive evidence of Brunauer and Emmett[9] for unimolecular adsorption on activated carbon suggested the advisability of Langmuir equation plots of the adsorption data. Figures 4 and 5 show the results obtained.

Using the B.E.T.[8] equation for unimolecular adsorption in the form

$$\frac{p}{(x/m)} = \frac{p_0}{c(x/m)_M} + \frac{p}{(x/m)_M} \qquad (3)$$

where $(x/m)_M$ is the weight adsorbed per g. of adsorbent equivalent to a monolayer, the area corresponding to a monolayer may be determined from the slopes of the plots in Figs. 4 and 5. Since c in the above equation is defined by

$$c = \frac{a_1b_2}{b_1a_2}e^{(E_1 - E_L)/RT} \qquad (4)$$

where $E_1 - E_L$ is the difference between the heat of adsorption and the heat of liquefaction, $E_1 - E_L$ may be determined from the intercepts of the curves if a_1b_2/b_1a_2 is assumed unity as is customary.

Although it has been common to use the unimolecular adsorption equation for isotherms which are not approximated by the $n = \infty$ form of the B.E.T. equation, it has been pointed out[10] that the limiting B.E.T. equation for $n = 1$ is not valid except for isotherms which have an n value very close to unity. Joyner, Weinberger and Montgomery[10] have shown that the B.E.T. equation may be written

$$\frac{\Phi(n,X)}{(x/m)} = \frac{1}{c(/x/m)_M} + \frac{\theta(n,X)}{(x/m)_M} \qquad (5)$$

where

$$\Phi(n,X) = \frac{X(1 - X^n) - nX^n(1 - X)}{(1 - X)^2}$$

and

$$\theta(n,X) = \frac{X(1 - X^n)}{1 - X}$$

X is the relative pressure and n is the number of layers to which the gas is limited.

For the proper choice of n, a plot of $\Phi(n,X)/(x/m)$ *vs.* $\theta(n,X)$ should yield a straight line. Figures 6 and 7 show the results obtained when $n = 1.60$ is used. The plots are seen to be linear and are superior to the $n = 1$ plots, especially for the 30° data which cover the greatest relative pressure region. The area and $E_1 - E_L$ values obtained for $n = 1$ and $n = 1.60$ are presented in Table III. The use of the more correct $n = 1.60$ in place of $n = 1$ results in considerably lower and more constant monolayer areas. However, the $E_1 - E_L$ values are not appreciably altered.

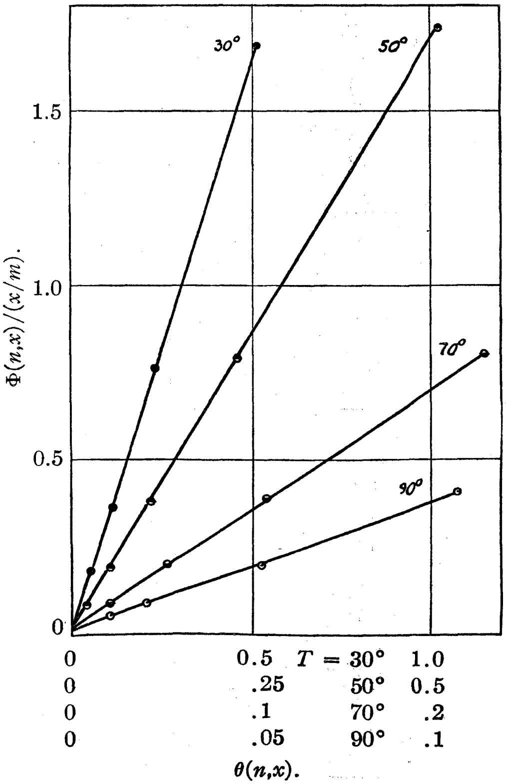

Fig. 6.—Adsorption isotherms of *trans*-dichloroethylene according to B. E. T. theory for $n = 1.60$.

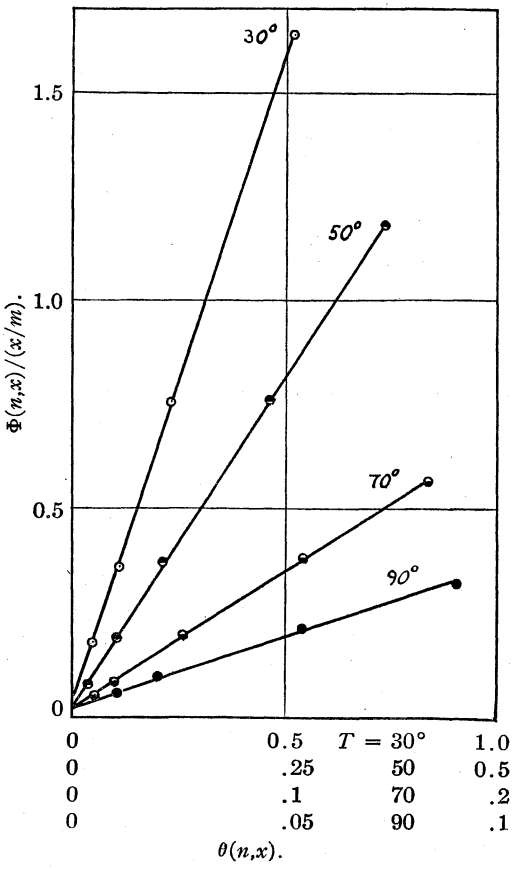

Fig. 7.—Adsorption isotherms of *cis*-dichloroethylene according to B.E.T. theory for $n = 1.60$.

TABLE III

COMPARISON OF MONOLAYER AREAS AND DIFFERENCE BETWEEN HEAT OF ADSORPTION AND VAPORIZATION FOR *cis* AND *trans*-DICHLOROETHYLENE.

Temp., °C.	Area of monolayer, sq. m./g.				$E_1 - E_L$ kcal./mole			
	cis		*trans*		*cis*		*trans*	
	$n = 1$	$n = 1.6$	$n = 1$	$n = 1.6$	$n = 1$	$n = 1.6$	$n = 1$	$n = 1.6$
30	6.8×10^2	5.6×10^2	6.9×10^2	5.6×10^2	2.5	2.7	2.7	2.7
50	6.4	5.6	6.6	5.6	2.7	2.7	2.8	3.0
70	6.4	5.6	6.4	5.4	2.9	3.3	3.0	3.3
90	5.7	5.6	5.7	5.2	3.4	3.2	3.5	3.3

The differential heat of adsorption is ordinarily considered to be given by the Clausius–Clapeyron type equation

$$\frac{q}{R} = \left(\frac{\partial \ln p}{\partial(1/T)}\right)_a \qquad (6)$$

where the amount of adsorbate on the surface is the same. Then the heat of adsorption may be calculated from isosteres constructed on the basis of constant amount adsorbed. However, Wilkins[11] has correctly pointed out that the above equation should be applied to isosteres based on a constant area of surface covered rather than constant weight adsorbed.

In Fig. 8 plots of log p *vs.* $1/T$ are shown for equal areas covered in the temperature range 30–70°. The q values found are 8.5 kcal./mole for the *trans* and 9.0 kcal./mole for the *cis* compound. Using 7.0 and 7.4 kcal./mole as the heats of vaporization for the *trans* and *cis* compounds, respectively,[7] these differences are seen to be about the same as for the heats of vaporization. The values of $q - E_L$ obtained are correspondingly 1.5 and 1.6 kcal./mole. If the calculation is made on the basis of constant amount adsorbed, one obtains values of 3.9 and 3.8 kcal./mole, respectively. Wilkins[11] has predicted that the values based on constant weight should be lower than those based on constant area covered. However, it may be readily seen that the slope of curves constructed on the basis of constant weight adsorbed would be steeper than the ones shown in Fig. 8. For example if the point corresponding to the highest temperature were the same for both methods of calculation, then at a common lower temperature the pressure corresponding to an equal area covered must be greater than the pressure corresponding to an equal weight absorbed if the density of the adsorbate decreases with increasing temperature.

The above values are to be compared with the $E_1 - E_L$ values reported in Table III, approximately 3.0 kcal./mole. The discrepancy is not unexpected since the E_1 values are integral values while the isosteric values are differential ones. Actually the isosteres were taken near a monolayer where the differential heat of adsorption would be expected to be lower than the integral heat of adsorption since the differential heat of adsorption generally decreases with increasing adsorption even within a monolayer.[12]

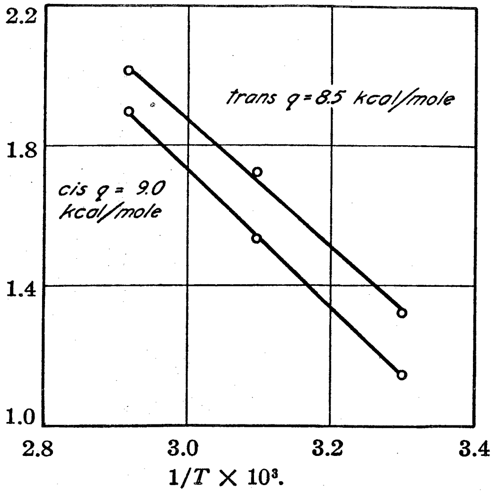

Fig. 8.—Isosteric heat of adsorption of the dichloroethylenes: area covered equal to 531 sq. m./g.

Note on the Separation of *cis–trans* Isomers by Adsorption.—It is of interest to speculate on the possibilities of separation of the *cis–trans* isomers by adsorption on activated carbon from the gas phase. A separation factor for a single stage in adsorption may be defined by

$$\gamma = (x_c/X_t)/(p_c/p_t) \qquad (7)$$

where x_c/x_t is the ratio of weights of *cis* and *trans* isomers on the adsorbent and p_c/p_t is the ratio of partial pressures of *cis* and *trans* isomers in the gas phase in equilibrium with the adsorbent. This equation is analogous to the separation factor usually defined for isotopic separation.

Let us now consider the separation factor obtained for an equimolar gas phase mixture of *cis* and *trans*-dichloroethylenes. Assume that in the mixed adsorption the individual adsorptions are in the same ratio what would obtain if they were adsorbed singly at a pressure equal to the total. For a pressure of 5.0 mm. for each isomer this leads to a value of $\gamma = 1.07$ for data from the 30° isotherms. This value is in the same general range usually obtainable in single stage separations of isotopic mixtures and implies that separation of most *cis–trans* isomers by gas phase adsorption would be a multi-stage process. The recent results of Isom and Hunt[13] obtained in an attempt to separate diastereoisomers by gas phase adsorption on activated carbon confirm this conclusion. However, it may be observed that Claesson,[14] has obtained considerable success in gas phase separations by using the displacement development techniques of chromatography.

Summary

1. Adsorption isotherms on activated carbon were determined for *cis* and *trans*-dichloroethylene over a range of temperatures in the gas phase.

2. The adsorption for both isomers followed the B.E.T. theory if the number of layers possible in adsorption was taken as 1.6. The surface areas and heats of adsorption based on the theory were determined.

3. Isosteric heats of adsorption based on a constant fraction of the surface covered rather than constant weight adsorbed were calculated.

4. The adsorption of the *cis* and *trans* isomers were found to be the same when a comparison of surface area covered at fixed relative pressures was made.

5. It was concluded that the condensation properties of molecules adequately determine the adsorption where the only intermolecular forces are van der Waals with or without permanent dipole interaction.

6. It was shown that the separation of *cis–trans* isomers by adsorption on charcoal from the gas phase could be effected only in a multi-stage apparatus.

The Partial Molal Volume of Acetic Acid in Sodium Acetate and in Sodium Chloride Solutions[1]

BY HENRY E. WIRTH

It has been shown[2] that the partial molal volumes of certain electrolytes depend on the total (volume) ionic strength of the solution as predicted by the Debye–Hückel theory. Redlich and Klinger[3] and Gucker[4] have shown experimentally that the apparent molal volumes of certain non-electrolytes are linear functions of the volume concentration. Redlich and Nielsen[5] found that the apparent molal volume of acetic acid (Φ_3)[6] could be represented by the equation

$$\Phi_3 = 51.8397 + 0.14184m_3 \qquad (1)$$

in the range 0.2–5 *m*, where *m* is the molality. Since the partial molal volume ($\overline{V}_3$) can be obtained from the apparent molal volume by the relation

$$\overline{V}_3 = \Phi_3 + m_3\partial\Phi_3/\partial m_3 \qquad (2)$$

$\overline{V}_3$ is also a linear function of the molality in this concentration range. In this paper the effects of electrolytes on the partial molal volume of acetic acid are reported.

Methods.—Densities at 25° were determined by the sinker method using apparatus described previously.[2] A stock solution of acetic acid was analyzed by adding a weighed excess of standard carbonate-free sodium hydroxide solution and titrating the excess base with dilute hydrochloric acid solution using phenolphthalein as the indicator. The stock solution contained 0.37584 ± 0.00004 g. of acetic acid per gram of solution.

Solutions for the density determination were prepared by weight from the stock acetic acid. Sufficient anhydrous salt (sodium chloride or sodium acetate, previously dried at 200° for six hours) was added to give the required concentration of electrolyte.

The observed density differences were used to calculate the volume of solution containing 1000 grams of water (V) and the apparent molal volume of acetic acid in each of the solutions investigated. The partial molal volumes were obtained from the apparent molal volumes by use of equation 2.

Results

The equation

$$V = 1002.935 + 51.832m_3 + 0.1394m_3^2 \qquad (3)$$

which represents the experimental values of V in an aqueous acetic acid solution (Table I) with an average deviation of ±0.004 ml. can be arranged to give $\Phi_3 = 51.832 + 0.1394m_3$. The values of Φ_3 reported here average 0.013 ml. per mole less than those reported by Redlich and Nielsen.[5] This compares to the probable experimental error of 0.008 ml. per mole due to errors in concentration alone quoted by these authors.

Differentiation of equation 3 gives

$$\overline{V}_3 = 51.832 + 0.2788m_3 \qquad (4)$$

which agrees with the values of $\overline{V}_3$ calculated directly from the data with an average deviation of ±0.008 ml. per mole. Equations 2, 3 and 4 are valid only in the concentration range 0.16–2.5 molal, since in solutions less than 0.16 *m* the increased ionization of acetic acid causes Φ_3 and $\overline{V}_3$ to decrease toward the limiting value (40.68) characteristic of H^+ and $C_2H_3O_2^-$ at infinite dilution.

For aqueous sodium chloride solutions the equation

$$V = 1002.935 + 16.670m_2 + 1.636_3m_2^{3/2} + 0.170_5m_2^2 \qquad (5)$$

represents the experimental results with an aver-

m_3	$\frac{(d_3 - d_1)}{1000}$	V, ml.	$\Delta V \times 10^3$ (Eq. 3)	Φ_3	$\overline{V}_3$	$\Delta \overline{V}_3 \times 10^3$ (Eq. 4)
0.04269	0.360	1005.143	−5	51.72	51.8	
.04129	0.353	1005.066	−9	51.62	51.7	
.16317	1.351	1011.390	−6	51.829	51.90	20
.16889	1.399	1011.687	−6	51.824	51.90	20
.38251	3.110	1022.782	1	51.887	51.942	3
.36874	3.003	1022.065	−2	51.881	51.934	−1
1.0724	8.327	1058.688	3	51.983	52.137	5
1.0015	7.814	1054.985	1	51.972	52.115	3
2.4360	17.319	1130.028	2	52.171	52.520	8
2.5225	17.837	1134.569	3	52.182	52.544	7

age deviation of ±0.001 ml. In addition to those terms involved in equations 3 and 5, only two additional terms are required to represent all the data on mixed solutions of acetic acid and sodium chloride with an average deviation of $\pm 0.005_6$ ml. (Table II). The complete equation is

$$V = 1002.935 + 16.670m_2 + 1.636_3 m_2^{3/2} + 0.170_5 m_2^2 + 51.832m_3 + 0.1394m_3^2 + 0.3070m_2m_3 - 0.1212m_2^{3/2}m_3 \quad (6)$$

The addition of another term involving either $m_2m_3^2$ or $m_2^2m_3$ does not improve the fit. Differentiation of equation 6 gives

$$\overline{V}_3 = 51.832 + 0.2788m_3 + 0.3070m_2 - 0.1212m_2^{3/2} \quad (7)$$

The average deviation between the partial molal volumes of acetic acid calculated directly from the data and calculated from equation 7 is ±0.012 ml. per mole.

Figure 1 shows that in dilute sodium chloride solutions (0.04–0.36 molal) the partial molal volume of acetic acid in a solution of given total molality ($m_2 + m_3$) is the same as in an aqueous solution of the same molality. At higher sodium chloride concentrations (1.0 and 2.2 molal) $\overline{V}_3$ is less than in solutions of equal molality containing only acetic acid.

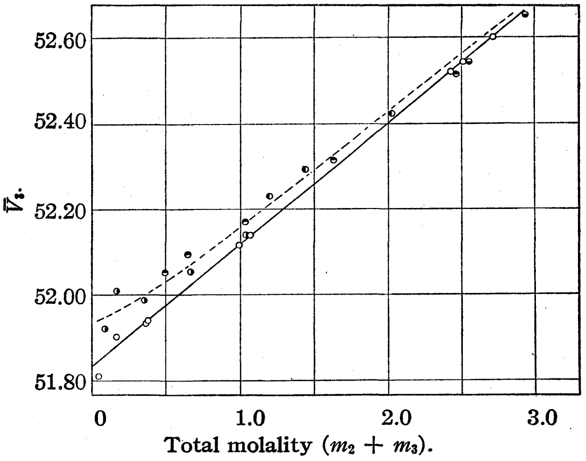

Fig. 1.—Partial molal volume of acetic acid in sodium chloride solution: ○, m_2 = 0.04; ◐, m_2 = 0.16; ⊖, m_2 = 0.36; ◑, m_2 = 1.0; ◓, m_2 = 2.19. The solid line represents the partial molal volume of acetic acid in aqueous solution.

In aqueous solutions containing only sodium acetate the equation

$$V = 1002.935 + 39.274m_2 + 1.881m_2^{3/2} + 0.114m_2^2 \quad (8)$$

represents the experimental values with an average deviation of ±0.0016 ml. Values of Φ_3 calculated from the derived relation $\Phi_3 = 39.274 + 1.881m_2^{1/2} + 0.114m_2$ deviate from the values reported by Redlich and Nielsen[5] by ±0.040 ml. per mole as compared to a deviation of ±0.029 ml. per mole found for their equation: $\Phi_3 = 39.244 + 1.86c_3^{1/2} + 0.209c_3$.

An equation similar to equation 6 was found to

$$V = 1002.935 + 39.274m_2 + 1.881m_2^{3/2} + 0.114m_2^2 + 51.832m_3 + 0.1394m_3^2 + \alpha m_2m_3 + \beta(m_2m_3)^{3/2} \quad (9)$$

represent the experimental values for a given sodium acetate concentration but was not valid for all sodium acetate concentrations. Values of α and β are: 3.464, −10.13 (m_2 = 0.04); 0.9968, −0.920 (m_2 = 0.16); 0.5855, −0.2255(m_2 = 0.365); 0.3733, −0.0461 (m_2 = 1.0); and 0.3094, −0.0193 (m_2 = 2.25), respectively.

			$m_2 = 0.99911$, $d_2 = 1.036202$					
0.20864	1.178	1055.058	−1	− 5	52.20	52.23	0	20
0.44858	2.488	1067.600	2	−11	52.239	52.294	10	17
1.0387	5.543	1098.488	−6	− 4	52.297	52.424	0	−12
1.7214	8.750	1134.346	8	0	52.390	52.601	7	−22
			$m_2 = 2.2541$, $d_2 = 1.078767$					
0.30881	0.944	1114.625	−5	− 6	52.51	52.55	− 10	0
0.68920	2.028	1134.642	4	−16	52.573	52.653	13	4
1.5026	4.144	1177.530	0	10	52.657	52.832	4	42

The simplest equation that would represent all the data was found to be

$$V = 1002.935 + 39.274m_2 + 1.881m_2^{3/2} + 0.114m_2^2 + 51.931m_3 + 0.1394m_3^2 + 0.2391m_2m_3 + 0.005187m_2^{-1}m_3 - 0.02000m_2^{-1/2}m_3 - 0.00338m_2^{-1}m_3^2 \quad (10)$$

The average deviation between observed and calculated values is ±0.005 ml. This equation is adequate for interpolation but cannot be used for extrapolation to solutions more dilute in acetic acid and sodium acetate than those used in this work.

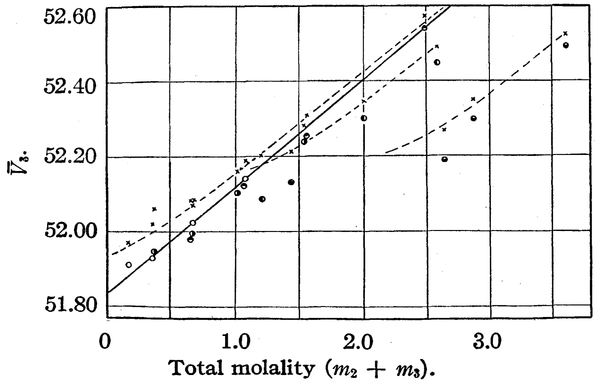

Fig. 2.—Partial molal volume of acetic acid in sodium acetate solution: ○, m_2 = 0.04; ◐, m_2 = 0.16; ◒, m_2 = 0.365; ◑, m_2 = 1.0; ◓, m_2 = 2.25. The solid line represents the partial molal volume of acetic acid in aqueous solution.

By differentiation of equations 9 and 10 the following equations for the partial molal volume were obtained:

$$\bar{V}_3 = 51.832 + 0.2788m_3 + \alpha m_2 + 3/2\beta m_2^{3/2}m_3^{1/2} \quad (11)$$

(average deviation ±0.010 ml. per mole) and

$$\bar{V}_3 = 51.931 + 0.2788m_3 + 0.2391m_2 + 0.005187m_3^{-1} - 0.02000m_2^{-1/2} - 0.00676m_2^{-1}m_3 \quad (12)$$

(average deviation ±0.021 ml. per mole) (Table III).

The observed values of $\bar{V}_3$ in sodium acetate solutions are greater than in aqueous acetic acid solutions of equal molality (Fig. 2). The greatest differences are found in the more dilute solutions. This is to be expected from the decreased ionization of acetic acid in the sodium acetate solutions.

Summary

The volume of solution containing 1000 g. of water, the apparent molal volume of acetic acid, and the partial molal volume of acetic acid are reported for solutions containing acetic acid and

either sodium chloride or sodium acetate. Empirical equations representing the data are developed.

As a rough approximation the partial molal volume of acetic acid in a solution containing electrolyte is the same as in an aqueous solution of the same total molality. This approximation does not hold in solutions of sodium chloride with molalities greater than 0.4.

Long Life Zirconium from Uranium 235 Fission

BY A. V. GROSSE[1] AND E. T. BOOTH

In our first paper on radioactive zirconium and columbium from uranium fission[1a] we described, outside of the 17.0-hour zirconium, also a long life zirconium, with a period of more than twenty days. In the following few months additional evidence was obtained, but publication was postponed due to other urgent atomic energy investigations. In the intervening years this fission product was investigated as part of the Plutonium Project,[2] but no details have appeared as yet. In 1940 Hahn and Strassmann[3] claimed to have discovered a 26-day zirconium. This they cancelled, however, in a short note in 1943[4] and simultaneously announced the long life zirconium to be described below. In the recently published Nuclear Physics Tables[5] the properties of our isotope have been inadvertently mixed with those of Hahn and Strassmann's 26-day zirconium. It thus seems worthwhile to publish our original findings.

Our zirconium proved to have a half-period of sixty-six days; this was followed for nearly three hundred days. As mentioned previously, it emitted electrons of about 0.25 MEV. energy. Chemical evidence proved unambiguously that the carrier of β-activity was the element zirconium. It produced a long life columbium isotope with very soft radiation, whose period was not determined.

Experimental Part

A typical experiment was carried out as follows: A 100-cc. solution of 70 g. of uranyl nitrate was bombarded by slow neutrons from the Columbia cyclotron on and off for a number of days. This was diluted to 1000 cc. of a 25% hydrochloric acid solution (by adding 588 cc. of 36% hydrochloric acid). Ten cc. of zirconium oxychloride solution, containing 135 mg. of zirconium dioxide, was added as carrier, together with various solutions containing a few milligrams each of stable isotopes to act as carriers for the radioactive fission products (*i. e.*, Rb, Cs, Sr, Ba, Y, La, Mo, Sb, Te, Ce, Cb, Br and I). On addition of 10-fold molar excess of phosphoric acid a fine, nicely settling precipitate of *zirconium phosphate* (ZrP_2O_7) was obtained, containing some insoluble columbic acid ($HCbO_3$).

This precipitate was washed with 25% hydrochloric acid and then purified twice from possible *natural* radioactive contaminations by addition of a few milligrams of Th, Bi, Pb, La + Ba and Fe as carriers. The radio-pure zirconium phosphate, still containing the added columbic acid and some iron oxide, was converted to zirconium dioxide by melting with a 10-fold quantity of sodium potassium carbonate in a platinum–gold dish; 143 mg. of zirconium dioxide and a trace of ferric oxide were obtained. These were further purified and fractionated as shown in Fig. 1; 19.0 mg. was painted on an aluminum disc (Al, 45) and measured. The rest was converted into acid soluble zirconium hydroxide (by sodium bisulfate melt and ammonia precipitation) and fractionally crystallized as $ZrOCl_2 \cdot 8H_2O$ from concentrated hydrochloric acid. The head or purest fraction of oxychloride was converted to oxide (56.5 mg. of snow white zirconium dioxide) and all of it painted on Al 47. Intermediate fractions were discarded. The residual zirconium was precipitated from the mother liquor, after diluting with hydrochloric acid, as a pure zirconium phosphate; all of it, equivalent to 16.7 mg. of zirconium dioxide, was painted on Al 48. The columbium was precipitated, from the sodium potassium carbonate-melt solution, with dilute acid; 51 mg. of columbium pentoxide, containing small amounts of zirconium dioxide, was obtained and painted on Al 46 for measurement.[5a] The scheme of the chemical separation is illustrated in Fig. 1. All measurements were made using an F. P. 54 amplifier and through 1 or 5 mil Al foil. The results of our measurements through 1 mil aluminum are plotted in Fig. 2. We see that all three zirconium preparations decay with the same period, namely, sixty-six days.

The specific activity *per 1.0 mg. of zirconium dioxide* of all three preparations, after correcting to *zero time*, was as follows:

Al 45, initial material = 4.9×10^{-3} div./sec.
Al 47, head fraction = 4.9×10^{-3} div./sec.
Al 48, tail end = 5.2×10^{-3} div./sec.

Thus, they are, within experimental error, identical. Zirconium is the only element, except ekatantalum (no. 91) and hafnium, which is precipitated from concentrated hydrochloric acid by phosphoric acid. Ekatantalum can be carefully separated from zirconium by the procedure we originally used to separate protactinium[6] and as was also subsequently demonstrated by the separation of ekatantalum^{233} from thorium + *n* products.[7] Hafnium is only separated slowly from zirconium by tedious fractionation.[8] Thus the constancy of the specific activity, together with the other chemical evidence, is strong proof

that the sixty-six-day activity is due to zirconium; hafnium is excluded both because of its high atomic mass and the relatively high intensity of our activity.

A blank run was made on the uranium solution we used in order to exclude any contamination from various possible cyclotron sources and targets; any possible contamination of the zirconium preparation was found to be below 1% of our activity.

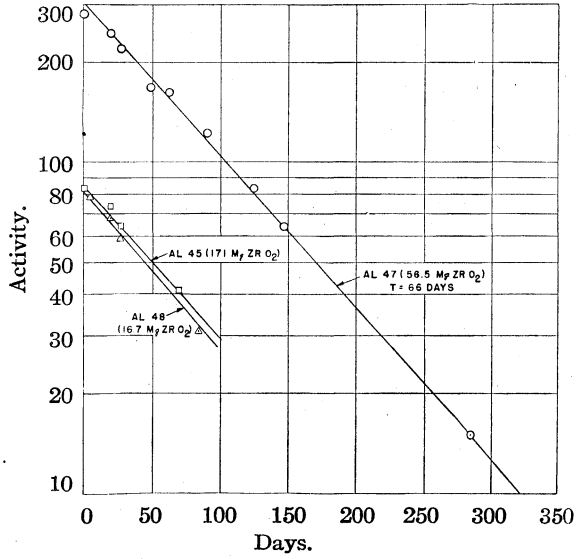

Fig. 2.—Zirconium of sixty-six days half period.

Discussion

Thus the existence of two zirconium isotopes of 17.0 hours and 66 days half-time seems assured. The fission yield of the first isotope was found to equal 6.1% in a joint investigation with H. Anderson and E. Fermi.[9]

Subsequently, these two isotopes have been confirmed by workers on the Plutonium Project.[2] Furthermore, their mass numbers have been established and the fission series determined as follows[10]:

$$(1)\quad Kr^{97} \xrightarrow[\text{short}]{\beta^-} Rb^{97} \xrightarrow[\text{short}]{\beta^-} Sr^{97} \xrightarrow[\text{short}]{\beta^-} Y^{97} \xrightarrow[\text{short}]{\beta^-} Zr^{97}_{17.0h} \xrightarrow{\beta^-} Cb^{97}_{75min.} \xrightarrow{\beta^-} Mo^{97}_{stable}$$

Fission yield = 6.1% (A. F. and G.[9])

$$\begin{tikzcd} & & Cb^{95}_{90h} \arrow[d] & \\ (2)\quad Y^{95}_{<1.5h} \arrow[r, "\beta^-"] & Zr^{95}_{66d} \arrow[ur, "2\%"] \arrow[r, "\beta^-", "98\%"'] & Cb^{95}_{63d} \arrow[r, "\beta^-"] & Mo^{95}_{stable} \end{tikzcd}$$

Fission yield = 6.4% (P. P.[2])

Both in G. Seaborg's 1940 report[11] and the Nuclear Physics Tables[5] of 1946, the mass assignments are erroneous, namely, 95 for 17.0 hr. Zr and 75 min. Cb and 93 for the 66 day zirconium.

Hahn and Strassmann have withdrawn their claims[1] to a twenty-six day zirconium[4]; as we suspected earlier, it was very likely due to a contamination of their very weak preparation with UX.

Other radioactive zirconium isotopes from uranium fission are to be expected, since the 93 mass series ending in the stable Cb^{93} and the 97, 98 and 100 series, ending in the corresponding stable molybdenum isotopes, *should pass through* such radioactive bodies. Furthermore, all series from masses 90 to 100 should have high fission yield from 5.0% to a maximum of about 6.4% since they all lie on the light group *hump* of the fission curve.

However, no reliable information is available on such isotopes. The Plutonium Project (p. 2421) lists a Zr^{93} with a half time of 2.5 minutes as questionable and is left out of the otherwise well-known mass 93 series. It will be the object of future research to find these isotopes.

This work was carried out from February to August, 1940, in the Department of Physics of Columbia University. Pressure of National Defense Work prevented earlier publication.

Acknowledgments.—We wish to acknowledge the continued interest of Dean G. Pegram and Dr. John Dunning in this investigation.

Summary

A long life zirconium of 66-day half period is described as a product of uranium 235 fission.

Other zirconium isotopes from U-fission are critically reviewed.

Photochemical Studies. XXXIX. A Further Study of the Fluorescence of Acetone

By Roy E. Hunt[1] and W. Albert Noyes, Jr.[2]

The problem of energy exchange between polyatomic molecules is one about which relatively little is known experimentally and for which the theory can be stated only in general, and somewhat unsatisfactory, terms. There is, perhaps, no more fundamental problem in the field of reaction kinetics, and studies of fluorescence offer one means of obtaining data essential to a more satisfactory statement of the theory. Interpretations of this type of data are difficult and are usually based on classical assumptions which do not add materially to the field.

Studies of the fluorescences of acetone and of biacetyl have been numerous and yet there are still many points of ambiguity. The present study was started with a view to obtaining a better insight into the behavior of these fluorescences. While certain points have been clarified, much remains to be done before a final understanding of all of the data will be possible.

Summary of Previous Work

The fluorescence of acetone vapor seems to have been described first by Damon and Daniels[3] who observed both green and blue parts, the former at least six times as intense as the latter. Damon[4] and Fugassi[5] extended the study to acetone–oxygen mixtures, the change in visual color from blue to green being an indication of the disappearance of oxygen. Fugassi[5] showed the quantum yield of oxygen disappearance to be equal to that of acetone disappearance in an oxygen-free system.

The existence of fluorescence might normally indicate a discrete absorption spectrum. Such an absorption was found by Norrish, Crone and Saltmarsh[6] and further studied by other authors.[7] However, the existence of a threshold[8] for exciting the fluorescence has not been confirmed, and it is now generally agreed that acetone fluoresces at both 3130 Å. and 2537 Å. although more weakly at the latter wave length. A complete description of the absorption spectrum is not possible at the present time. There may be a continuum underlying the whole absorption region from about 2400 Å. to about 3200 Å. The bands may have a diffuse character, indicating the possibility of predissociation, but with a complex molecule of this type any definite conclusions in this connection are unwarranted. In any case there seems to be no fundamental difference (other than magnitude of certain quantum yields) between the photochemical behaviors of acetone at 3130 Å. and at 2537 Å.[9] Acetone shows many sharp bands in the region below 2000 Å.,[10] but no fluorescence could be observed by excitation with wave lengths between 1800 and 2000 Å.[11]

The first attempt at a quantitative study of the fluorescence of acetone with 3130 Å. radiation showed that plots of I_a/I_f *vs.* pressure gave reasonably straight lines (I_a = intensity loss due to absorption of radiation, I_f = intensity of fluorescence.)[12] Due to the experimental method long exposures were used, and while the total fluorescence (green plus blue) was measured, the major portion of the fluorescence was undoubtedly in the green.[3] Moreover, only relatively high pressures (over 30 mm.) could be studied and the true effect of collisions could not be ascertained. An attempt to repeat this work[13] by a different method indicated that the fluorescent intensity was a function of time. The green parts of the fluorescences of biacetyl and of acetone were shown to be identical. This led Matheson and Zabor[14] to examine the fluorescences of other compounds containing the CH_3CO- group, thus showing the same fluorescence to be found in acetaldehyde and methyl ethyl ketone. The emitter seems to be the same (for the green) for all of these compounds and is probably biacetyl.

The most precise work on the fluorescences of acetone and of biacetyl is due to Almy and his co-

(9) A disagreement is indicated from the ratios of ethane to carbon monoxide found by R. Spence and W. Wild, *J. Chem. Soc.*, 352 (1937); 590 (1941), and by D. S. Herr and W. A. Noyes, Jr., This Journal, **62**, 2052 (1940), respectively. The ratios obtained by the former authors would indicate little or no biacetyl to be formed at 3130 Å. The probable explanation of this discrepancy is found in the work of Damon and Daniels[3] and of G. M. Almy and S. Anderson, *J. Chem. Phys.*, **8**, 813 (1940), which showed that biacetyl (probably mistaken for diacetone alcohol by Damon and Daniels) does not accumulate indefinitely in the system, particularly when polychromatic light is used. The work of J. G. Roof and F. E. Blacet, This Journal, **63**, 1126 (1941), showed that the photochemical decomposition of biacetyl is a chain reaction under some conditions and the reaction should be initiated, therefore, by free radicals from acetone. For a review, see W. Davis, Jr., *Chem. Rev.*, **40**, 201 (1947).

workers.[15] This work confirms and extends earlier work. The main conclusions from all work thus far may be summarized briefly as follows: (1) The green fluorescence is associated with the presence of biacetyl and the biacetyl molecule is probably the emitter.[13,14,15] (2) The weak blue fluorescence is found in carefully purified acetone and also in acetone with oxygen present and is probably due to the acetone molecule.[3,4,5,15,19] (3) The quantum yield of fluorescence is low for both acetone and biacetyl, not over 2 or 3% in the most favorable case in acetone and probably much less for the blue alone; in biacetyl an efficiency of 14 per cent. is found.[15] (4) The lifetime of the excited state in biacetyl is quite long, of the order of 1.5×10^{-3} sec.[15,16] (5) At temperatures over about 100° there is very little green fluorescence,[14] indicating that biacetyl is not produced from acetone at such temperatures.[17] (6) Either the emission process in biacetyl is not the direct reverse of the absorption process or only a small fraction of the absorbing molecules reach the state which can fluoresce. Lewis and Kasha[18] designate the upper state as triplet and describe the fluorescence as phosphorescence due to the long life. (7) While the fluorescences of biacetyl excited by 4358 Å. and 4047 Å. are normal in the sense that they are quenched by collisions,[15] that excited by 3660 Å. shows the reverse effect.[19,15] This can be explained by assuming that molecules excited by 3660 Å. are capable of dissociating unless stabilized by collisions, whereas those produced by the other two wave lengths are not. (8) As acetone is irradiated, the blue fluorescence grows weaker as the green grows stronger.[15] (9) The green fluorescence reaches nearly full intensity when the biacetyl pressure is very low[13,19,15] (not over a few tenths of a millimeter) compared to the acetone pressure (100 mm. or more), thus indicating some mechanism which is quite specific and which is not inhibited markedly by the acetone. (10) Experiments with deutero-biacetyl indicate that there is probably little reaction of the type $CH_3 + CD_3COCOCD_3 = CH_3COCD_3 + COCD_3$[20] at temperatures up to 62°. (11) The blue fluorescence is observed in solid acetone and possibly also in other solid ketones.[21]

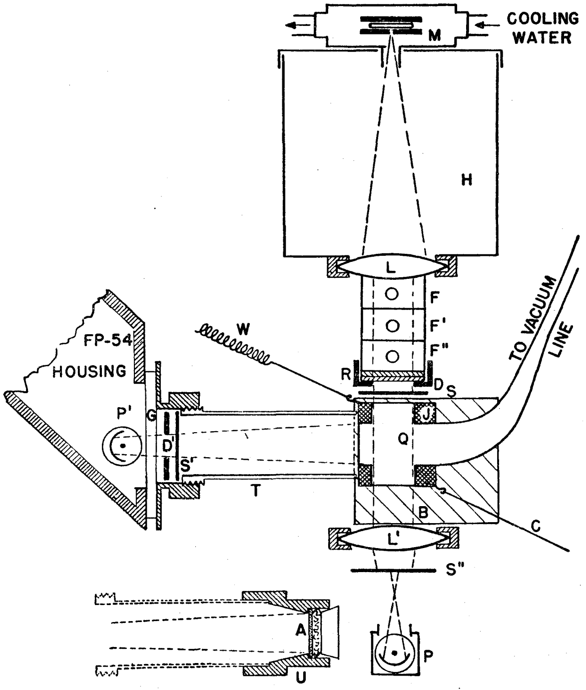

Fig. 1.—Diagram of optical set-up, including fluorescence cell, light source and filters, and transmission and fluorescence photocells: A, radium-activated phosphor disc; B, bench on which cell can move; C, cord removing cell from beam; D,D', diaphragms; F,F',F", filter solutions; G, glass filter, Corning no. 738; H, housing to enclose light; J, jacket of copper around cell; L,L', lenses (quartz 14-cm. focus); M, mercury arc (H-6 shown); P,P', photocells, GL-929; Q, quartz fluorescence T-cell; R, red-purple Corex glass filter; S,S',S", shutters; T, tube for constant light path; U, unit for calibrating fluorescence photocell circuit; W, wire spring to return cell.

From the above it may be stated that two points, among others, need clarification: (a) the mechanism of excitation of the fluorescence ascribed to biacetyl when acetone is the absorbing molecule; (b) the relationship of the blue fluorescence to the green. The present work was performed with the object of clarifying some of the steps in the mechanism of these fluorescences.

Experimental

The acetone (J. T. Baker C. P.) was fractionally distilled after standing for two days in the dark over anhydrous calcium chloride. The middle half was collected and the distillation repeated. The middle half from this second distillation was stored under vacuum over anhydrous calcium sulfate and fractionally distilled from a temperature of 0° to one of −7°. The middle half from this final step, amounting to about 4 cc., was kept in a blackened storage reservoir separated from the line by a mercury cut-off.

Oxygen was prepared by heating C. P. potassium permanganate, passed through glass wool and a trap immersed in liquid nitrogen. It was stored in a one-liter bulb separated from the line by a mercury cut-off.

For most of the experiments a General Electric AH-6 high pressure mercury arc was used. The optical system, including the color filters, is shown schematically in Fig. 1. The color filter combination consisted of a 5-cm. length of 0.0005 *m* potassium chromate, 5 cm. of 0.356 *m* nickel chloride, and 1.0 cm. of 0.0245 *m* potassium biphthalate. The emission lines from this type of arc are

very broad, and hence the radiation is not strictly monochromatic, although at least 95% lies in the region of 3075–3250 Å.[21a]

A Hanovia 150-watt Uviarc was used for part of the work. This arc operates at a much lower pressure than the AH-6 and with the color filter combination at least 95% of the radiation lay in the group of lines at 3130 Å.

The beam incident on the fluorescence cell was parallel and practically homogeneous. It filled 90% of the transmission arm with little or no radiation hitting the walls. Scattered radiation reaching the photoelectric cell used to measure the fluorescent intensity amounted to less than 0.1% of the fluorescent intensity in most cases. Even in the most unfavorable case (determination of the fluorescence at very low pressures) scattered radiation was not over 20% of the total.

Incident intensity was varied by means of fine mesh screens oxidized in a flame and used singly or in pairs. The meshes varied from 20 to 150 per inch with transmissions from 30 to 60%. The intensity was calculated from the measured transmissions of the screens in each case.[22]

The fluorescence cell, which had the form indicated in Fig. 1, was made of fused quartz with windows about 1.5 mm. in thickness. All portions of the cell except the windows were painted black. It was attached to the rest of the vacuum system by 6 feet of 8 mm. tubing, thus permitting it to be moved into and out of the light beam. For experiments at higher temperatures the cell was enclosed in a copper block cut in two sections and surrounded with a layer of asbestos, a winding of resistance wire and a second layer of asbestos. Temperatures were measured with a thermocouple inserted in a well drilled in the copper block.

Transmitted radiation was condensed with a quartz lens on a GL-929 photocell with a S-4 surface and the current measured with a galvanometer using an Ayrton shunt to vary the sensitivity.[23]

The fluorescent radiation was measured with a GL-929 photocell and d. c. amplifier employing an FP-54 electrometer tube and a modified DuBridge circuit.[24] The stability of the circuit was excellent except in very humid weather. The fluorescent radiation passed through a Corning glass filter no. 738, 2 mm. in thickness, which removed more than 99% of the ultraviolet radiation incident upon it.

The fluorescence amplifier circuit was calibrated by applying a fixed voltage to the control grid of the FP-54 tube and recording the resulting scale deflection. A one inch radium activated phosphor disc, emitting blue radiation at a brightness of 0.25 microlambert, was used as an absolute source of calibration.[25]

The circuit for measuring the transmitted intensity was calibrated with a small automobile light operating at exactly 5.55 volts from a storage battery. This circuit was checked before and after (and occasionally during) each run. This was necessary because of the extreme sensitivity of the galvanometer used. The reproducibility of the sensitivity left something to be desired.

At low acetone pressures the largest error lies in the experimental determination of the absorption by the acetone since this is determined as the small difference in two large quantities. Neither the constancy of the light source nor the constancy of the galvanometer sensitivity were adequate for this purpose. Especially after the accumulation of photochemical decomposition products and after the addition of other gases such as oxygen, the complete removal of the acetone by condensation with liquid air through the long tubing connecting the cell with the trap proved to be slow and unreliable. Hence, the procedure was adopted of removing the cell from the light path and determining the intensity of the beam directly. This coupled with a determination of the mean transmission of the two windows of the cell permitted a calculation of the intensity incident on the ketone if it is assumed that the two windows absorb and reflect to equal extents. The assumption of Beer's law for these very low absorptions is valid even if the light is not strictly monochromatic.

The procedure used may be described in the following steps: (1) measurements were made of I_t^0, I_0, and again of I_t^0 where I_t^0 is the light transmitted by the cell when the ketone is condensed by liquid nitrogen (but foreign gas, if any, is present) and I_0 is the intensity of the beam when the cell is removed from the light path; (2) the measurement of I_s^0, *i. e.*, the intensity of the scattered light; (3) remeasurement of I_0 and I_t^0 and a check of the zero reading of the transmission photocell with the shutter at S″ (Fig. 1) closed; (4) vaporization of the ketone into the cell, measurement of I_0, I_t (the light transmitted by the filled cell), and again of I_0; (5) measurement of I_f (the intensity of the fluorescence) and of I_t; (6) remeasurement of I_0 and I_t and a recheck of the zero readings of the transmission and fluorescent photocell circuits; (7) repetition of the empty cell readings after freezing down or pumping out the ketone.

The value of T (the fraction of total radiation transmitted through the first window) was obtained from an average of the empty cell readings before and after each run. Corrections were applied on the basis of calibrations made each day and for changes in shunt readings. The value of I_a was obtained from a corrected value of I_t. Dividing I_f and I_t by I_0 corrected for small changes in lamp intensity.

The value of $1/Q$ used in this article is the ratio I_a/I_f, where I_a is the actual loss in intensity in passing through the absorbing gas expressed in arbitrary units, where each unit is 1.6×10^9 quanta/second/cc. and I_f is the intensity of the fluorescence in arbitrary units.

The line for handling the gases and measuring pressures need not be described in detail. No stopcocks using grease were present in the line. Low pressures of gases not condensed by liquid nitrogen were measured with the McLeod gage. Foreign gases, such as oxygen, could be admitted from storage bulbs by the use of a Toepler pump. Pressures of the ketone were read directly on a manometer. The main disadvantage in the entire system resided in the long tubing between the cell and the trap, made necessary by the need of moving the cell into and out of the light path. This resulted in slow condensation of the ketone in the presence of non-condensable gases and also in slowness of diffusion back into the cell of biacetyl. The latter would vaporize more slowly than acetone after condensation by liquid nitrogen.

The transmitted light was photographed with a small Bausch and Lomb Littrow-type spectrograph and the fluorescence was photographed with a wide aperture glass prism spectrograph. Eastman I-F and I-G plates were used. Due to the low intensity of the fluorescence, particularly in the blue, a wide slit was necessary, thus render-

(21a) W. Davis, Jr. and R. E. Hunt, THIS JOURNAL, **69**, 1415 (1947).

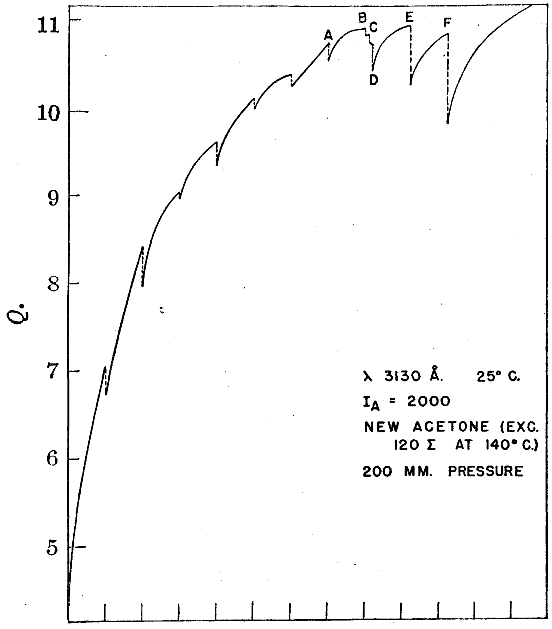
(22) The validity of varying light intensity in this way has been discussed by R. G. Dickinson (see W. A. Noyes, Jr., and P. A. Leighton, "The Photochemistry of Gases," The Reinhold Publishing Company, New York, 1941, p. 202.) The screens were placed just in front of the window through which radiation was incident on the ketone. This method reduces the total radiation but does not decrease the intensity per unit area for the portions illuminated. Other methods which might have been used to vary the light intensity would not have been valid unless the radiation were highly monochromatic. Comparison of results with the Uviarc and the AH-6 arc, while not extensive enough to warrant definite conclusions, did not show any striking differences in behavior. The latter arc was about 25 times as intense as the former.

(23) The light intensities absorbed by the ketones in the fluorescence cell were calculated from the values of the intensities of the transmitted light using the method of R. E. Hunt and T. L. Hill, *J. Chem. Phys.*, **15**, 111 (1947).

(24) The d. c. amplifier was designed and constructed by Dr. J. B. Platt of the Department of Physics and loaned for this work by Prof. Brian O'Brien of the Institute of Optics, University of Rochester.

(25) The disc was obtained from the United States Radium Corporation, which also furnished the brightness calibration. The brightness of this disc was of the same order of magnitude as that of the blue fluorescence.

ing uncertain any conclusions about the discrete character of the fluorescence. Microphotometer tracings were obtained in the recording microphotometer in the Institute of Optics.



Exposure: 1 division = 10 min. (20Σ).

Fig. 2.—Variation of total fluorescent efficiency (Q) with exposure as a function of intermittent dark periods. Unlettered breaks in curve are 5-min. dark periods; points A-C, 10-min. periods; D, 40 min.; E, 240 min.; F, 2 days.

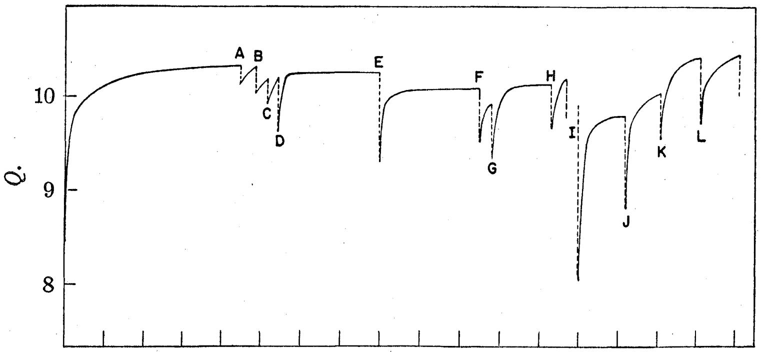
Discussion of Results

The trend of $1/Q$ (or of Q) as a function of several variables is more important than actual numerical values, and hence the results are presented graphically in Figs. 2–9, inclusive. The variables employed were absorbed intensity at constant pressure, pressure at constant absorbed intensity, and temperature.

At the start of a run with carefully purified acetone, the green fluorescence is weak or entirely absent but increases with time quite rapidly at room temperature. The blue fluorescence simultaneously decreases. Therefore, the radiation measured by the photoelectric cell consists mainly of green after the first few minutes except at elevated temperatures. Determination of the behavior of the blue as a function of various variables was accomplished satisfactorily only at temperatures above about 120° where the green was absent. Oxygen may eliminate the green entirely, but it also strongly decreases the intensity of the blue. At 0.4 mm. pressure of oxygen the green was absent and the blue decreased by a factor of ten.

Figures 2 and 3 indicate some of the reasons for difficulties in reproducing results. In Fig. 2 the quantity of Q (defined as the ratio I_f/I_a where I_f is the intensity of the fluorescence and I_a is the decrease in intensity due to absorption by the vapor) is shown as a function of time. Since these measurements were made with a photoelectric cell, they include both the green and the blue, although the green is at least three-quarters of the total intensity after the curve has ceased its rapid rise. The breaks in the curve are brought about by various dark periods as indicated in the caption. The decrease in Q after a dark period may be due either to a slow diffusion of some substance, presumably biacetyl, from the fluorescence cell into the rest of the apparatus or to a disappearance of this substance either due to a chemical reaction or perhaps due to polymerization. That it invariably occurred even after long periods of illumination would indicate that it is not entirely due to diffusion because eventually biacetyl would be expected to attain a more or less uniform concentration throughout the entire system. Earlier work[26] has given some indication of removal of biacetyl from the gas phase by a process which does not depend on illumination.

In Fig. 3 somewhat similar data are shown except that the acetone at the beginning of the curve had already been exposed to radiation for an appreciable length of time. Although in this instance the curves had reached approximate constancy during illumination, the value of Q was always found to be low after a dark period. The



Exposure: 1 division = 10 min. (20 Σ).

Fig. 3.—Variation of total fluorescent efficiency (Q) with exposure as a function of dark period duration and liquid nitrogen cooling: acetone sample had been used for two weeks under wide variety of conditions of intensity and temperature; pressure 163.7 mm.; temperature 24°; wave length 3130 Å.; $I_a = 2000$. Points A-E are dark periods of 5, 10, 20, 40, 80 min.; F-H, periods of 40, 40, 80 min. At point I, ketone was cooled with liquid nitrogen to −196° for 10 min., 20 mm. remaining unfrozen in the line due to slow diffusion through non-condensable products. After vapor had warmed to room temperature, fluorescence readings were begun at once. At J, after 10 min. at −196°, vapor stood 45 min. at 24° before readings were begun; at K, only 4.5 min. was allowed for diffusion. At L, liquid nitrogen was kept on ketone trap 3 min. only, with 4.5 min. allowed subsequently for diffusion.

---

[26] Unpublished results obtained by Dr. V. R. Ells.

effect of freezing out the acetone and any condensible reaction products with liquid nitrogen for varying periods of time is shown by points I, J, K and L. In this instance the lower rate of evaporation of biacetyl as compared to acetone almost certainly leads to a temporary deficiency of biacetyl in the fluorescent cell and Q is low until the concentration of this compound has been replenished through irradiation.

It has been shown[13] that the amount of biacetyl does not determine the intensity of the fluorescence providing it has reached a certain value, probably not over a fraction of a millimeter. There are also indications[15] that biacetyl reaches a steady state when acetone is illuminated. Data on this point are difficult to obtain and especially since it is not known whether the steady state concentration, if there is one, is the same when approached from both directions. The only clue to this point would be obtained from the data of Roof and Blacet[9] which indicate that under some conditions the photochemical decomposition of biacetyl is a chain reaction. It might, therefore, be initiated by free radicals from acetone.

The data in Figs. 2 and 3 do indicate, however, that Q for total fluorescence attains an approximately constant value after long periods of illumination. The blue intensity goes down about 50% during the period when the green builds up to its maximum. This is in agreement with the work of Almy and Anderson.[15]

The so-called green fluorescence consists of several "bands" whose wave lengths have been measured by other authors.[6,13,14,27] The blue fluorescence extends from about 3850 Å. to about 5000 Å. This fluorescence has one weak maximum which occurs near the long wave end of this region (see Fig. 4). This weak maximum may possibly be associated with the so-called green bands commonly ascribed to biacetyl. Evidence for this is uncertain, but the separation in wave numbers between the various maxima indicate that this conclusion has some merit. If the fluorescence due to the biacetyl occurs mainly from low vibration levels in an upper electronic state,[28] the transition corresponding to the maximum around 4650 Å. would have to be either to a lower vibration level in the ground state or from a higher vibration level of the upper state than the transitions ascribed to the other bands.

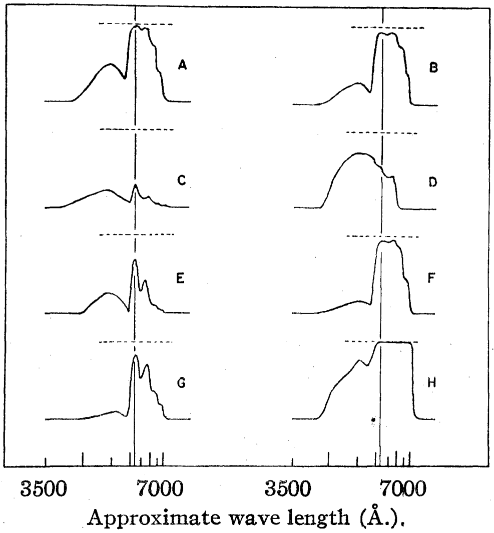


Fig. 4.—Representative microdensitometer tracings showing spectral distribution of acetone fluorescence under various conditions of excitation and exposure. Eastman I-F plates were used sensitized to 7000 Å. except for curve D for an I-G plate with the limit of 5800 Å. was used. A small glass spectrograph with 0.9 mm. slit was used. Acetone at a pressure of 170 mm. was irradiated by monochromatic 3130 Å. ultraviolet light except for curve H (see below). Exposure times with ten minutes except C and D. A New acetone 25°, irradiated 21 minutes, integrated intensity 90 Arbitrary Units. B. Same as A except time of irradiation 128 minutes, integrated intensity 550 Arbitrary Units. C. Old acetone irradiated at 120° with an integrated intensity of 820 Arbitrary Units plus irradiation at 25° for 1600 Arbitrary Units (30 min. exposure.) D. Solid acetone at −196°. Identical curve obtained after two hours of irradiation (5 min. exposure). E. Old acetone previously irradiated for 1200 Arbitrary Units at 25°, 0.01 to 0.04 mm. oxygen initially present. F. Old acetone previously irradiated for 2300 Arbitrary Units at 2500–3600 Å. at 25°, after which products non-condensable with liquid nitrogen were removed. Identical curve after 74 minutes additional irradiation. G. Old acetone exposed over a period of several minutes at 25°, slit width 0.5 mm. H. Old acetone irradiated at 2500–3600 Å. with two day intermediate dark period prior to photographing fluorescence. Exposure taken during irradiation with 2500–3600 Å.

The effect of temperature on the green and blue fluorescences is indicated in Fig. 5. It is to be noted that the intensity of the green fluorescence decreases markedly with increase in temperature whereas the blue shows only a very gradual change and its value at 200° is still 20% of its value at 25°. The fact that the curve obtained with decreasing temperature lies lower than the curve obtained as the temperature increases may indicate a small decomposition of biacetyl at high temperature. This must be due to a photochemical reaction (perhaps with a high quantum yield) rather than a pure thermal reaction. On the other hand, even when biacetyl is known to be present the green is absent at temperatures of about 125° and above. Thus the increase in temperature has two effects: (1) it prevents formation of biacetyl, probably due to the instability of the acetyl radical and (2) it inhibits in some way the mechanism for exciting the green fluorescence.

Figures 6 and 7 show the effect of absorbed intensity on the fluorescence. In Fig. 6 the total fluorescence, blue plus green, is shown as a function of intensity, the intensity being varied by a

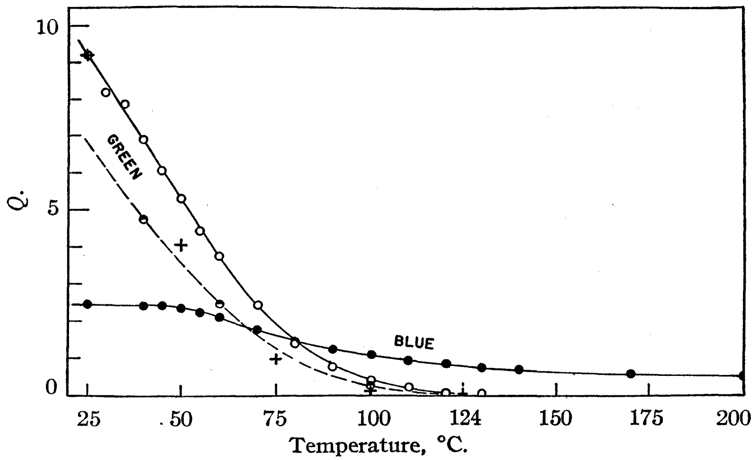

Fig. 5.—Fluorescent efficiency ($I_f/I_a = Q$) as a function of temperature for blue and green acetone fluorescence: pressure 165 mm.; wave length 3130 Å.: ●, blue, obtained spectrographically 25–140°, photometrically 140–200° (not corrected for varying spectral sensitivity of photocell)*; temperature increasing between points. ○, green, obtained photometrically, correcting total deflections for presence of blue; increasing temperatures. ◓, green, same; decreasing temperatures. +, green, obtained spectrographically; increasing temperatures.

factor of about 50. This particular sample had previously been exposed for some minutes at room temperature, part of the time with oxygen present. The variation with intensity is so slight as to be well within experimental error. In Fig. 7 the curve labeled "green" is obtained at room temperature and is really total fluorescence, mainly "green." Again there is no variation in intensity greater than experimental error. The measurements of the blue in Fig. 7 were made at 145° where the green is absent, and show at most an extremely small variation with intensity, certainly not much larger than experimental error.

In Figs. 8 and 9, $1/Q$ is shown as a function of pressure. In this instance the data are not so reliable as might be desired due to the difficulties of measuring percentage absorption at low pressures. It is believed that the values for the blue fluorescence in Fig. 8 for which the absorbed intensity is calculated from Beer's law at low pressures are most reliable.

$1/Q$ for the green, in contrast to the blue, shows some tendency to increase at low pressures. The curve in Fig. 9 is for total fluorescence; correction for the presence of the blue would cause a somewhat greater rise for the green alone at low pressures.

The detailed mechanisms for the blue and the green fluorescences can be discussed only in general terms. The interpretations given by Almy and his co-workers[15] are supported in broad outline, although some differences seem to be necessary.

A Stern–Volmer mechanism is not obeyed for either the blue or the green, although $1/Q$ *vs.* pressure at high pressures is a straight line in agreement with earlier data.[12] The relative insensitivity of $1/Q$ to large changes in pressure when the pressure is above about 50 mm. may indicate one of two things: (1) the molecule or radical responsible for the fluorescence has such an extremely short life in the activated state that it does not have time to be deactivated; or (2) the molecule or radical is extremely insensitive to collisions with acetone molecules. With the former assumption lifetimes perhaps as short as 10^{-8} second would be required, whereas Almy has shown that the lifetime of the active molecule responsible for the green is about 10^{-3} second.

A better estimate of the probable lifetime of the species responsible for blue emission can be obtained from the effect of oxygen which, as already stated, decreases the intensity of the blue when it is present at a pressure of 0.1 mm. Using the assumption that collisions of excited molecules with acetone have no effect and that collisions with oxygen are 100% efficient, one calculates a mean life for the excited species of about 10^{-5} second. This may be considered to be a lower limit. If the mechanism proposed by Almy and co-workers[15] whereby the biacetyl molecules are excited by collision of the second kind with excited ace-

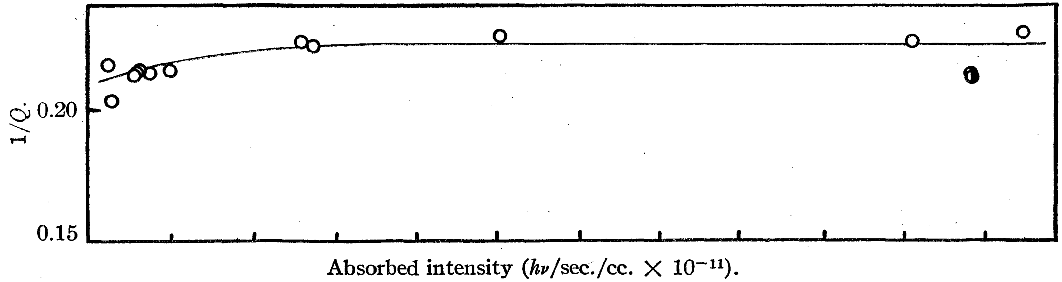

Fig. 6.—Quenching of total acetone fluorescence as a function of (low) absorbed intensity at constant pressure and temperature; sample pre-exposed 30Σ (8Σ with O_2); uviarc, λ3130 Å. 29°; pressure, 208 mm.: ○, at decreasing intensity (adding resistance in circuit to cool arc); ◑, following day with hot arc.

---

* Corrected quantum efficiencies of blue are about half that shown on graph.

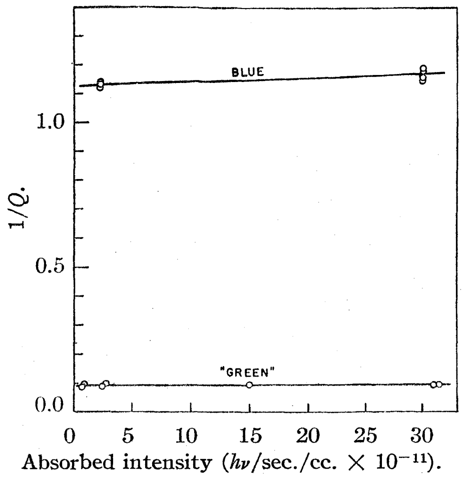

Fig. 7.—Quenching of blue and "green" acetone fluorescence as a function of absorbed intensity at constant pressure and temperature, high intensity: blue measured at 145° and 209 mm. pressure (not corrected for variable spectral sensitivity of photocell); "green" is total fluorescence at 25° and 164 mm., as measured; *ca.* 25% of observed deflection is due to blue.

tone molecules is accepted, the lifetime might be even longer.

The most significant aspect of the data concerning the green fluorescence is its decrease in intensity with increase in temperature even when biacetyl is known to be present. The decrease in intensity parallels semi-quantitatively the decrease in stability of the acetyl radical. This might indicate that the mechanism of excitation involves, in some way, the acetyl radical. The further fact that in starting with carefully purified acetone the blue decreases only 50% while the green increases from practically zero to a large value during continued exposure, indicates that the mechanism for the blue and the mechanism for the green are not identical and may possibly not be related.

The variation of $1/Q$ with pressure for the blue at 140° necessitates a marked sensitivity to collision at low pressures and the attainment of a statistical distribution among various energy levels, largely independent of pressure once the pressure reaches about 50 mm.

The principal data concerning the blue fluorescence may be described adequately by a series of simple steps resembling those used previously to describe other fluorescences[29,28] in which molecules are transferred from one state to another by collisions. This mechanism may be written

$$\mathrm{A} + h\nu = \mathrm{A}'; \; k_1'I_a \qquad (1)$$

$$\mathrm{A}' = \mathrm{CH_3COCH_3} + h\nu; \; k_2(\mathrm{A}') = I_b' \qquad (2)$$

$$\mathrm{A}' + \mathrm{A} = 2\mathrm{A}(\text{or } \mathrm{A} + \text{dissociation products}); \; k_3(\mathrm{A}')(\mathrm{A}) \qquad (3)$$

$$\mathrm{A}' + \mathrm{A} = \mathrm{A}'' + \mathrm{A}; \; k_4(\mathrm{A}')(\mathrm{A}) \qquad (4)$$

$$\mathrm{A}'' = \mathrm{CH_3COCH_3} + h\nu; \; k_5(\mathrm{A}'') = I_b'' \qquad (5)$$

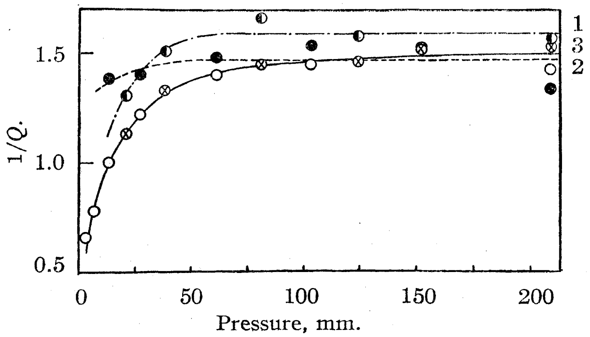

Fig. 8.—Quenching of blue fluorescence as a function of acetone pressure at 140°, wave length 3130 Å.: ◐, constant absorbed intensity (I_a = 2.5 ± 0.5 × 10^{11} hν/sec./cc.), values of I_a measured experimentally; ⊗, constant absorbed intensity; I_a calculated, assuming Beer's law; ●, constant incident intensity (I_0 = 4.9 × 10^{13} hν/sec./sq. cm.); I_a measured experimentally; ○, constant incident intensity; I_a calculated. Curve 3 (solid) is drawn through both sets of points for which calculated values of I_a were used. The broken curves are for points using I_a measured experimentally, at constant I_a (curve 1) and constant I_0 (curve 2).

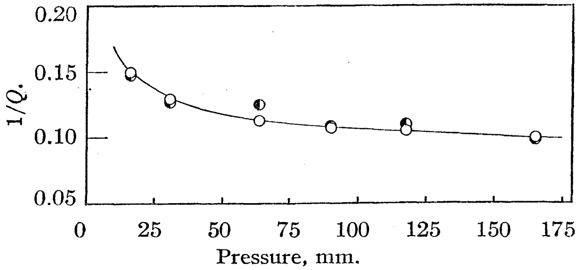

Fig. 9.—Quenching of total fluorescence (predominantly green) as a function of acetone pressure at 25° and constant absorbed intensity; I_a = 4 ± 1 hν/sec./cc.; wave length 3130 Å.

The constant k_1' indicates that only part of the molecules which undergo the act of absorption form excited molecules, or at least form excited molecules capable of the following reactions. From considerations of the photochemistry of acetone the vast majority must undergo a dissociation into CH_3CO and CH_3. From this series of equations one obtains the relationships

$$\frac{I_b' + I_b''}{I_a} = Q_b = \frac{k_1(k_2 + k_4(\mathrm{A}))}{k_2 + k_3(\mathrm{A})} = \frac{k_1(1 + k_4(\mathrm{A})/k_2))}{1 + k_3(\mathrm{A})/k_2 + k_4(\mathrm{A})/k_2} \qquad (6)$$

where $I_b' + I_b''$ = total quanta of blue radiation emitted per cubic centimeter per second and I_a is the number of quanta of incident radiation absorbed per cubic centimeter per second. If more states are used, equation (6) takes the form of a ratio of polynomials. When the pressure is very high, Q_b should be independent of pressure thus agreeing with the data in Fig. 8. If the pressure is extremely low Q_b should again be independent of pressure, but this levelling off will be important

---

(29) J. P. Howe and W. A. Noyes, Jr., THIS JOURNAL, **57**, 1262 (1935).

only below 0.1 mm., a pressure lower than could be studied. With $k_3/k_2 = 0.24$, $k_4/k_2 = 0.088$, $k_4/k_3 = 0.37$, and $k_1 = 2.36$ (pressures in millimeters are used), equation (6) reproduces the experimental data well within experimental error. Since k_1 includes several factors it has no simple theoretical meaning, but the ratio of k_4 to k_3 means that the initially formed state is converted into the metastable state at about one third the rate it is deactivated. The metastable state must be very insensitive to collisions to explain the flat portion of the curve at high pressures, and hence no deactivation step is included for A″.

The absolute values of these constants cannot be calculated without making some assumptions. If every collision is assumed to cause the initially formed state to undergo either (3) or (4) and if the collision diameter is assumed to be 4×10^{-8} cm., $(k_3 + k_4)$ has the value 8×10^6 if the pressure in millimeters is used. Thus k_2 would be about 3×10^7 sec.$^{-1}$ and the mean life of the initially formed state would be about 3×10^{-8} sec. There is no way of estimating the mean life of the metastable state A″ due to the very small deactivating effect of collisions at high pressures.

The data on the quenching of the blue fluorescence by oxygen are not very extensive and, for various reasons, could not be made very precise. However, when the acetone pressure was 200 mm., 0.4 mm. of oxygen reduced the intensity by a factor of approximately 10. The following equations may now be added

$$A'' + O_2 = A + O_2;\ k_6(A'')(O_2) \qquad (7)$$

$$A' + O_2 = A + O_2;\ k_7(A')(O_2) \qquad (8)$$

and equation (6) becomes

$$Q_b = \left[\frac{k_1}{1 + (k_3/k_2 + k_4/k_2)(A) + k_7(O_2)/k_2}\right] \left[1 + \frac{k_4(A)/k_2}{1 + k_6(O_2)/k_5}\right] \qquad (9)$$

The term in k_7 should be negligible at the low pressure of oxygen used and hence from the data one can estimate k_6/k_5 to be 49 if the concentration of oxygen is replaced by millimeters pressure. If a collision diameter of 3×10^{-8} cm. is taken for collisions between metastable acetone molecules and oxygen, one can estimate k_6 and hence k_5. The latter is 10^5 sec.$^{-1}$ giving a mean life of the metastable acetone molecules of 10^{-5} second. This may be taken as a lower limit, and the actual value may be much larger if this state shows a low efficiency for quenching by oxygen molecules.

These lives of 10^{-8} and 10^{-5} second for the active and for the metastable molecules, respectively, are only orders of magnitude, but they do indicate that the picture of the blue fluorescence embodied in equations (1) to (5) is adequate to explain all of the known facts at constant temperature. The value of $1/Q$ is independent of intensity and independent of pressure at high pressures.

The mechanism embodied in equations (1) through (8) indicates that the ratio $(A'')/A$ is given by $k_4(A)/k_5 = 22\ P_{\text{mm.}}$ (in the absence of O_2). k_4 is probably more temperature dependent than k_5, and hence the fraction of A″ would increase with temperature. Since A″ is not appreciably deactivated by collisions, this would cause an increase in blue with temperature. This is contrary to the facts and hence the temperature effect must be explained in some other way. Equation (3) is the most logical step to use, particularly in view of the increase in quantum yields of decomposition with temperature. An activation energy of 2500 to 3000 cal. for reaction (3) would be adequate to explain the decrease in blue fluorescence with increase in temperature.

Finally it is necessary to include some deactivation of A″ by biacetyl since the blue does decrease slightly as the green increases in intensity. Due to its short life A′ would not be deactivated at low biacetyl pressures. If A″ is the only form deactivated in this way, the decrease in the blue is semiquantitatively explained.

Later work has shown structure to exist in the blue fluoresence. Thus dissociation accompanying the fluorescent act need not be postulated.

These general conclusions are the only ones warranted concerning the character of the blue fluorescence. Two types of information would still be desirable: (1) a study of the quenching down to very low pressures, *i. e.*, below 0.1 mm.; (2) a spectrographic study of the fluorescence at all pressures with high dispersion and high resolution. Both types of data would be exceedingly difficult to obtain due to the weakness of the blue fluorescence.

The interpretation of the green fluorescence must also be given in general terms. Two facts seem to be of paramount importance in this connection: (1) the intensity of the green is not dependent to any marked extent on the quantity of biacetyl once the latter has reached a value in the neighborhood of 0.1 mm.; (2) the intensity of the green decreases with increase in temperature even when biacetyl is known to be present and parallels at least qualitatively the decrease in stability of the acetyl radical.

Two general methods of exciting biacetyl to fluorescence when acetone is the absorbing molecule may be imagined; (1) inelastic collision of the second kind; (2) a recombination of two free radicals using biacetyl as the third body.

The very gradual decrease in intensity of the blue and the rapid decrease in the green with rise in temperature indicate that the two processes are not completely dependent on each other. The effect of pressure on $1/Q$ (Fig. 9) is also not at all similar to the effect on the blue fluorescence and indicates that collisions tend to enhance the fluorescence. This resembles the behavior of the fluorescence of pure biacetyl when excited by radiation of wave length 3660 Å.[15,19] and is best explained by assuming that the level initially formed is capable of predissociation and that fluorescence only occurs after loss of some energy through collisions.

If the absence of green fluorescence at 140° is due directly or indirectly to the instability of the acetyl radical, the three body process

$$CH_3 + CH_3CO + B = B' + CH_3COCH_3; \quad k_8(CH_3)(CH_3CO)(B) \qquad (10)$$

must be responsible, where B is a molecule of biacetyl. The effect of oxygen in quenching the green would be due, in that event, to reaction with free radicals.

A complete set of equations satisfying the photochemical as well as the fluorescence data can be written down using equation (10) as the means of producing excited biacetyl. The resulting equation for $1/Q$ is, however, very complex and while it has the correct form there is no means of showing that it is a unique solution to the problem. Since $1/Q$ decreases slightly with increase in pressure, it is necessary to postulate that the active molecule B′ can dissociate unless it is stabilized by collisions. At higher pressures $1/Q$ is practically independent of pressure so that an additional state B″ (or perhaps several additional states) must be postulated. Some of these would be metastable and incapable of fluorescence. The fluorescing states would be converted into the other and vice versa by collisions. These suggestions agree with those made by Almy and coworkers.[15]

If a mechanism for exciting biacetyl based on collisions of the second kind is used, the decrease in green intensity with increase in temperature would be ascribed to two effects: (1) a decrease in the concentration of activated and metastable acetone molecules (A′ and A″, respectively); (2) an increased tendency for the activated or metastable biacetyl molecules to decompose. The first of these effects is insufficient in itself to provide an adequate explanation since the decrease in intensity of the blue fluorescence is explained by some inhibiting step with an activation energy of 2500–3000 cal., while the green demands a step with an activation energy of 4500–5000 cal.

Since it has been shown that biacetyl fluorescence is normally quenched when excited by 4060 and 4370 Å. radiation,[15] whereas collisions enhance the fluorescence when it is excited by 3660 Å. radiation,[15,19] one can estimate a maximum activation energy required to raise the fluorescing molecules to such a state that they can predissociate. Taking the difference in calories per gram molecule corresponding to 4060 and 3660 Å. quanta, respectively, one finds 7600 calories. The correct figure may be less. Another guess can be made from the absorption spectrum of biacetyl described by Henri[30] who gives the longest wave absorption band as 4670 Å. and the onset of predissociation as 4400 Å. The difference corresponds to 3900 cal. per molecule, and this, if the spectrum has been correctly interpreted, should correspond to the minimum activation energy required to bring an excited non-vibrating molecule to the predissociating state. These figures, while probably inaccurate, lend some small support to the interpretation of the temperature effect on the fluorescence.

Several authors have studied the photochemistry of biacetyl.[31,32,33] A detailed interpretation of the data is not possible because many processes must be involved. The low yield at room temperature may be due to a recombination reaction and part of the increase with temperature due to the instability of the acetyl radical. However, at long wave lengths (>3660 Å.) where fluorescence occurs, the effect of temperature on activated molecules must be considered.

The effect of oxygen on green fluorescence is to be ascribed to two effects: (1) inhibition of biacetyl synthesis through reaction with acetyl radicals; (2) inhibition of the fluorescence even when biacetyl is present. The latter effect, in turn, must be due to two causes: (1) decrease in the number of excited or metastable acetone molecules if the energy transfer is by collisions of the second kind or reaction with radicals if excitation is by some process, such as equation (10); (2) quenching of excited or metastable biacetyl molecules. There is ample evidence for both of these steps in the effect of oxygen on the blue and on the fluorescence of pure biacetyl.[15] Undoubtedly both effects are important.

It should be emphasized finally that while these fluorescence studies throw much light on the photochemistry of acetone, particularly with long exposures, they do not affect in any essential way the mechanism previously presented for the photochemistry of acetone.[9] No precise estimate of absolute fluorescence efficiency can be given, but that of the blue does not exceed one or two per cent. and may be much less.

Summary

1. The quenching of the "blue" and "green" fluorescences of acetone has been studied as a function of intensity, pressure, added oxygen, and temperature.

2. Since screens were used to vary intensity, the variation with intensity is valid only if the excited molecules or radicals involved have long lives. This is probably true for the "green" but may not be true for the "blue." No variations of quenching with intensity were observed.

3. The fluorescent efficiency of the "blue" decreases as the pressure increases and approaches a constant value. That of the green increases as the pressure increases and also approaches a constant value.

4. The efficiency of the "blue" decreases gradually with increase in temperature and is still

20% of its room temperature value at 200°. The green decreases much more rapidly and is practically absent at 135°.

5. Alternative explanations of the various phenomena are discussed, and several suggestions concerning mechanism are made. There must be two states of acetone, one with a much shorter life than the other. The biacetyl may be excited by either of two processes: (a) collision of the second kind; (b) radical recombination using biacetyl as the third body. In either case the "active" biacetyl molecules must have a greater probability of decomposition at high temperatures than at low.

Interaction of Ions and Dipolar Ions. IV. The Solubility of Cupric Iodate in Glycine and in Alanine Solutions

BY R. M. KEEFER

In previous communications[1,2] it was shown that the solubility of certain 1–1 and 2–1 type salts in dipolar ion solutions could be expressed by equations of the type

$$\frac{1}{Z_1Z_2}\log\frac{S}{S_\infty} = 0.506\left(\frac{78.54}{D_s}\right)^{3/2}\frac{\sqrt{\mu}}{1 + A\left(\frac{78.54}{D_s}\right)^{1/2}\sqrt{\mu}} + 0.0625\,\frac{R^2}{a_{id}}[\mathrm{HR}^{\pm}] \quad (1)$$

where Z_1 and Z_2 are the valences of the ions; S_∞ is the theoretical solubility at $\mu = 0$ and $[\mathrm{HR}^{\pm}] = 0$; D_s is the dielectric constant of the solution; A is $0.3288a_i$ where a_i is the distance of closest approach of the ions; R is the dipole distance in the dipolar ion; a_{id} is the distance of closest approach of an ion to a dipolar ion; and $[\mathrm{HR}^{\pm}]$ is the concentration of the dipolar ion. The solubility of silver iodate and lead iodate in glycine and alanine solutions[3] is much higher than would be predicted by eq. (1). The increased solubility was accounted for by assuming complex ions consisting of one negative ion of the amino acid to one silver or lead ion. This investigation was undertaken to obtain information on the stability of a complex between one negative ion of the amino acid[4] and cupric ion.

Experimental

Cupric Iodate.—Equal volumes of 0.2 *M* potassium iodate and 0.1 *M* cupric nitrate were added dropwise with constant stirring to 3 liters of water at 60°. After six hours the precipitate was filtered off and allowed to equilibrate with water overnight. The precipitate was sedimented several times and the smaller particles were discarded. The preparation was air dried before using. After drying for two hours at 250–270° the dried cupric iodate when analyzed iodometrically was 100.1% cupric iodate.

The solubility determinations and general technique have been described in a previous communication.[1] The iodometric determinations were modified for the presence of cupric ion using the method of Foote and Vance.[5] Duplicate solubility determinations agreed to 2 parts in 1000.

The *p*H of the solutions was determined using a Model G Beckman *p*H meter and is accurate to ±0.01 *p*H unit. The definition of *p*H used in this work is the negative logarithm of the hydrogen ion activity.

Results

The solubility (moles/1000 g. H_2O) of cupric iodate in potassium chloride solutions at 25.00° is given in Table I. The solubility of cupric iodate in water is much lower than the value (3.693×10^{-3} *M*) reported by Peterson and Meyers.[6] Column 3 of Table I gives the solubility of cupric iodate calculated by means of equation (2).

$$\log[\mathrm{Cu}^{++}][\mathrm{IO}_3^-]^2 = -7.1353 + \frac{3.036\sqrt{\mu}}{1 + 1.08\sqrt{\mu}} \quad (2)$$

The distance of closest approach of the ions is then 1.08/0.3288 or 3.28 Å.

TABLE I

SOLUBILITY OF CUPRIC IODATE IN POTASSIUM CHLORIDE SOLUTIONS AT 25°

(*M* is Moles/1000 g. H_2O and *S* is *M* of Cupric Iodate)

KCl, *M*	$Cu(IO_3)_2$, $M \times 10^3$	Calcd. $Cu(IO_3)_2$, $M \times 10^3$
0	3.245	3.243
0.00501	3.398	3.396
.01002	3.517	3.521
.02005	3.730	3.730
.03511	3.975	3.969
.05017	4.166	4.166
.07529	4.453	4.454
.1005	4.694	4.697

Table II gives the solubility of cupric iodate in glycine and in alanine solutions together with the *p*H of the resulting solution. Since the *p*H values are all less than the isoelectric point of the amino acids (6.1), it is evident that reactions are taking place which produce hydrogen ion. Assuming

complex ion formation similar to the case of silver iodate and lead iodate,[3] then

$$\mathrm{Cu^{++} + HR^{\pm} \rightleftarrows CuR^{+} + H^{+}} \quad K_1 = \frac{\mathrm{(CuR^{+})(H^{+})}}{\mathrm{(Cu^{++})(HR^{\pm})}} \qquad (3)$$

$$\mathrm{HR^{\pm} + H^{+} \rightleftarrows H_2R^{+}} \qquad (4)$$

In Fig. 1 the concentration of combined copper (eq. 7) is plotted against the amount of hydrogen ion produced including the hydrogen ion used up in eq. 4. Below 5×10^{-3} M combined cupric ion there is more combined cupric ion than there is hydrogen ion produced. This indicates the formation of a complex not liberating hydrogen ion as indicated in the equation.

$$\mathrm{Cu^{++} + HR^{\pm} \rightleftarrows CuHR^{++}} \qquad K_\alpha = \frac{\mathrm{[CuHR^{++}]}}{\mathrm{[Cu^{++}][HR^{\pm}]}} \qquad (5)$$

Pedersen[7] has shown that cupric ion tends to form complexes with acetate ion. The replacement of a hydrogen by the positively charged NH_3^+ group would tend to decrease the possibility of formation of such a complex.

TABLE II

SOLUBILITY OF CUPRIC IODATE IN GLYCINE AND ALANINE SOLUTIONS AT 25°

(Moles/1000 g. H_2O).

Glycine, M	$Cu(IO_3)_2$, $M \times 10^3$	pH	Cor. pH

.1516	10.22	3.48	3.47
.2027	12.30	3.49	

Above 5×10^{-3} M combined cupric ion there is more hydrogen ion produced than cupric ion combined, indicating the probable reaction

$$\mathrm{Cu^{++} + 2HR^{\pm} \rightleftarrows CuR_2 + 2H^{+}}$$

$$K_2 = \frac{\mathrm{(CuR_2)(H^{+})^2}}{\mathrm{(Cu^{++})(HR^{\pm})^2}} \qquad (6)$$

Attempts to explain the results assuming CuR_2 and $CuHR^{++}$ or CuR_2 and CuR^+ to be the only complex ions failed to give constant equilibrium constants. The following method was used to evaluate the three equilibrium constants.

The amount of combined cupric ion is given by

$$S - \mathrm{[Cu^{++}]} = \mathrm{[CuR_2] + [CuR^{+}] + [CuHR^{++}]} \qquad (7)$$

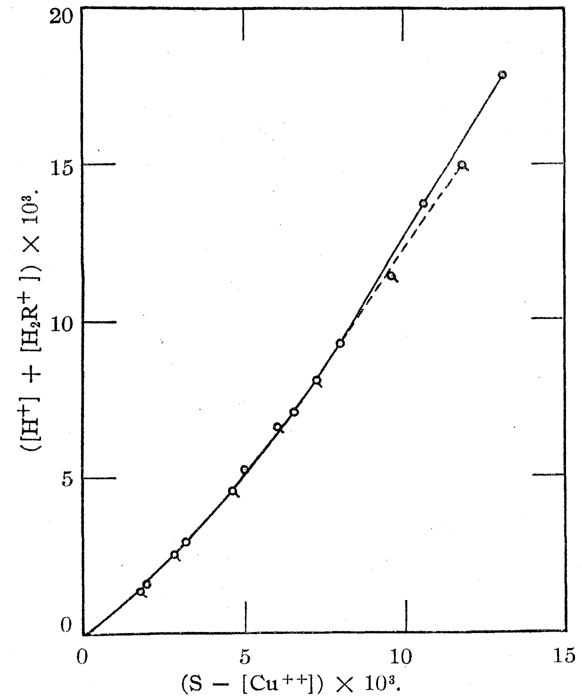

Fig. 1.—Hydrogen ion produced *versus* cupric ion complex formed in glycine and alanine solutions saturated with cupric iodate: ○, glycine solutions; ♂, alanine solutions.

The concentration of hydrogen ion produced will be equal to

$$\mathrm{[H^{+}] + [H_2R^{+}] = 2[CuR_2] + [CuR^{+}]} \qquad (8)$$

$$\mathrm{[HR^{\pm}]_i = [HR^{\pm}] + [H_2R^{+}] + 2[CuR_2] + [CuR^{+}] + [CuHR^{++}]} \qquad (9)$$

where $\mathrm{[HR^{\pm}]_i}$ is the total concentration of dipolar ion used. The ionic strength of the solution is given by

$$\mu = 2(\mathrm{[Cu^{++}] + [CuHR^{++}]}) + {}^1/_2(\mathrm{[CuR^{+}] + [H^{+}] + [H_2R^{+}] + [IO_3^{-}]}) \qquad (10)$$

or by substituting (7) and (8) in (10)

$$\mu = 2S - \mathrm{[CuR^{+}] - [CuR_2]} \qquad (11)$$

In the amino acid solutions saturated with cupric iodate there are eight unknowns (exclusive of activity coefficients) as follows: $\mathrm{[Cu^{++}]}$, $\mathrm{[CuR^{+}]}$, $\mathrm{[CuHR^{++}]}$, $\mathrm{[CuR_2]}$, $\mathrm{[H_2R^{+}]}$, $\mathrm{[HR^{\pm}]}$, $\mathrm{[H^{+}]}$ and μ. Although individual ion activity coefficients may not be determined, the general calculations are somewhat simplified if they are assumed to be given by equation 1 after substitution of $-1/Z_i^2 \log \gamma_i$ for $1/Z_1Z_2 \log S/S_\infty$. R was assumed to be 3.89 Å. for glycine[2] and 3.60 for alanine[2]. For cupric ion a_i was assumed to be the same in solutions containing glycine as in potassium chloride solutions. For CuR^+ and H_2R^+ a_i was assumed to be the radius of the dipolar ion plus one-half the distance of closest approach of cupric ion and iodate ion. At the ionic strengths involved an error of 0.1 Å. in a_i introduces a 1% error in the activity coefficient. The activity coefficients of CuR_2 and

[a] Calculated using CuG_2 calculated by assuming $K_2 = 2.65 \times 10^{-4}$.

HR^+ were assumed to be unity. To solve for the above 8 unknowns there are seven equations (1, 4, 7, 8, 9, 11) including the definition of pH. To obtain the eighth equation a value of K_1 was assumed and the equations solved. Then K_2 was calculated. By successive trials a value of K_1 was chosen so that K_2 would be constant for the series of runs. First a value of μ was selected using eq. 11 and then the concentration of cupric ion was calculated using eq. 1. $[H^+]$ and $[H_2R^+]$ were calculated using activity coefficients from eq. 1 and the pK_A of the amino acid (glycine[8] 2.350, alanine[9] 2.348). A value of K_1 was chosen and $[CuR^+]$ calculated. Using eq. 8 $[CuR_2]$ was evaluated. In the final calculations errors in pH measurement were smoothed out by using values from Fig. 1 for the total amount of hydrogen ion produced. The corrections involved are given in column 4 of Table II. With $[CuR_2]$ known, values of K_2 were calculated. The series of calculations was repeated until constant values of K_2 were obtained. Table III gives the concentrations of the ions and the equilibrium constants. Column 7 gives the concentration of $[CuHG^{++}]$ determined from eq. 7 after K_1 and K_2 were evaluated. The concentration equilibrium constant, K_α, for eq. 5 was calculated and appears in column 9 of Table III. $K\alpha$ should show little variation with ionic strength since the effect on Cu^{++} should be practically the same as the effect on $CuHR^{++}$. Equilibrium constants are not included for any case in which the concentration of complex ion falls much below $1 \times 10^{-3}M$.

Pedersen[6] has studied the equilibrium

$$Cu^{++} + Ac^- \rightleftarrows CuAc^+ \quad K_\beta = 146 \qquad (12)$$

The strength of monocarboxylic acids[10] may be calculated from the known constant of acetic acid by introducing corrections for each group replacing a hydrogen as in the equation

$$\log K = \log K_{HAc} + \frac{A_\alpha \Sigma I \alpha^{i_\alpha}}{1 + B|\Sigma I \alpha^{i_\alpha}|} \qquad (13)$$

K is the dissociation constant of the substituted acid. A_α is a constant equal to 0.3. I is the inductive effect for each group replacing a hydrogen. α is the fractional decrease in the inductive effect for each transmission across an atom and is equal to 1/2.8. The number of atoms between the group added and the α carbon atom of the carboxylic acid is i_α. If the complex ion $CuHR^{++}$ involves a linkage between the carboxylate group and the cupric ion, K_α should be given by equation 13 by replacing K by $1/K_\alpha$, K_{HAc} by $1/K_\beta$, and including the inductive effect of the NH_3^+ group (12.3 for the + charge and 1.3 for the N atom). Solving the equation with the above substitutions gives $K_\alpha = 0.2$ which would indicate that the ion would be much less stable than the experimental value of 39 indicates. Thus the linkage is probably between cupric ion and the amine group rather than between cupric ion and the carboxylate group. Values of the concentration dissociation constant[11] for CuG_2 and CuA_2 have been reported. By using the second ionization constants of glycine[8] and alanine[9] (1.67×10^{-11} and 1.36×10^{-10}) and estimating the activity coefficients involved, values of K_2 (eq. 6) may be approximated. The values are 2.2×10^{-4} for glycine and 1.1×10^{-4} for alanine. The agreement is good considering the approximations

involved in estimating the activity coefficients.

Summary

The solubility of cupric iodate in glycine and in alanine solutions has been determined. The solubility results may be explained by assuming three complex ions, namely, $CuHR^{++}$, CuR^{+} and CuR_2. The equilibrium constants for the reaction of cupric ion and the amino acids to form the above complex ions have been evaluated.

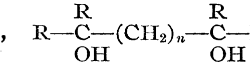
A Study of Organic Parachors. IX. The Additive Nature of Structural Units in the Parachors of Ditertiary Glycols and Chlorides[1,2]

BY THOMAS P. JOHNSTON[3] AND OSBORNE R. QUAYLE

Parachor, first considered primarily an additive property, has been shown to be highly susceptible to minor differences in structure, as, for example, those existing between two isomeric tertiary alcohols. This sensitivity would at first seem to decrease its usefulness as a method of correlating the physical properties of organic compounds with their structure. If such differences are capable of evaluation, however, the parachor immediately becomes a more delicate tool. Results have been obtained with series of tertiary alcohols[4,5] and chlorides[6,7] evaluating the inherent constitutive variations so that the parachor of any tertiary alcohol or chloride having normal alkyl groups may be predicted with reasonable accuracy. These results have been published in the form of tables[5,7] from which reliable theoretical values for such types may be conveniently calculated. It is to be emphasized that the actual value of CH_2 in all cases is considered essentially a constant, 40.0,[8,9] and that constitutive variations are attributed to the alteration of valence forces around the tertiary carbon atom and the attached chlorine or hydroxyl.

The neglect of minor structural effects in the calculation of parachor values is a common cause of considerable deviation between theoretical and calculated values. If structural groups exhibiting constitutive variations can be evaluated, they should in turn be primarily additive in more complex molecules. To test this assumption the parachors of a number of symmetrical ditertiary glycols and chlorides were measured and compared with calculated theoretical values. Parachors for the structural units of each molecule, divided as nearly as possible at the center of symmetry, were calculated and added to obtain the theoretical parachor for the whole molecule. The validity of treating structural units of a complex molecule in an additive manner once the constitutive divergence has been evaluated is upheld by the experimental data presented in this paper.

Ditertiary glycols (Table I) of the general formula,



$$\mathrm{R{-}\overset{R}{\underset{OH}{C}}{-}(CH_2)_{\mathit{n}}{-}\overset{R}{\underset{OH}{C}}{-}R}$$

in which R is methyl, ethyl and propyl and *n* is 2, 4, 7 and 8, were prepared by the standard method of adding the appropriate dibasic ester to the Grignard reagent.[10] The 2,10-, 3,11- and 4,13-diols have not been previously reported in the literature. The yield in the preparation of the 4,13-diol from dimethyl sebacate was least satisfactory; a yield of less than 5% of purified crystals was separated from the predominant viscous non-crystallizable oil. The Grignard addition complexes were hydrolyzed with either saturated aqueous ammonium chloride or cold dilute sulfuric acid, preferably the former. Toluene was the usual solvent for crystallization. These glycols are somewhat more stable than the simple tertiary alcohols in that they all withstand the temperature of boiling toluene and subjection to temperature up to 80° *in vacuo* and at least one, the 3,11-diol, may be distilled without decomposition at a relatively high temperature, about 140° at less than 1 mm. Parachors of only the lower melting glycols were measured, since solid compounds do not lend themselves to ready parachor measurement with the apparatus presently installed in this Laboratory.

The dichlorides (Table I) corresponding to the above ditertiary glycols were in general made by passing dry hydrogen chloride into an anhydrous ether solution of the glycol at a low temperature. A small amount of methanol was added to increase the solubility. After standing twenty-four hours the solvent was removed under reduced pressure

and the dichloride or its chloroform solution dried over sodium sulfate and sodium carbonate. Further purification can be effected by a modification of the method of Whitmore and Williams.[11] The following dichlorides were prepared: 2,5-dichloro-2,5-dimethylhexane, 3,6-dichloro-3,6-diethyloctane, 4,7-dichloro-4,7-dipropyldecane, 2,7-dichloro-2,7-dimethyloctane, 3,8-dichloro-3,8-diethyldecane, 4,9-dichloro-4,9-dipropyldodecane, 2,10-dichloro-2,10-dimethylundecane, 3,11-dichloro-3,11-diethyltridecane, 2,11-dichloro-2,11-dimethyldodecane, 3,12-dichloro-3,12-diethyltetradecane, 4,13-dichloro-4,13-dipropylhexadecane.

Average over-all yields were about 75%; the average yield exclusive of those purified by sulfuric acid was about 85%. Only the 2,5- and 2,7-dichlorides have been previously reported.[12] These dichlorides should be kept anhydrous and cold to prevent decomposition over an extended period of time.

The parachors of all the above dichlorides and five of the glycols have been measured (Table II). Surface tensions were determined by the maximum bubble pressure method, the apparatus used being a modification of that of Sugden.[5] The type of pycnometer employed in the determination of density was designed for volatile liquids[13] but has been found satisfactory for the rather viscous dichlorides and even for the melts of the low-melting solids. The experimental precision in the measurement of surface tension was estimated to be not less than one part in five hundred, the more precise values being attainable at the lower temperatures. The over-all precision in the determination of the parachor was approximately one part in two thousand. It is recognized that the lack of direct methods of purification, the measurement of surface tension and density at relatively high temperatures and the inherent instability of tertiary chlorides especially at elevated temperatures have undoubtedly tended to increase the experimental error. It is felt, however, that definite conclusions concerning the problem as stated above may be derived from the experimental data obtained.

A sample calculation of the theoretical value for a parachor, that of 3,8-dichloro-3,8-diethyldecane, follows in which values for the structural units (tertiary chlorides) are taken from the table published by Smart and Quayle[7]; the atomic parachor of hydrogen used (15.5) is that reported by Quayle, Day and Brown[9]: (2 × ethylethylethylchloromethane) − (2 × hydrogen) = parachor of 3,8-dichloro-3,8-diethyldecane. (2 × 338.8) − (2 × 15.5) = 646.6. This method is based upon the assumption that, once evaluated, the parachors of the component groups may be added to ascertain the parachor for the larger molecule. In the compounds in which functional groups are separated by a small number of carbon atoms, a new constitutive factor involving the influence of one functional group on the other was recognized as a possibility. Thus in cases where n is 2, deviations from the calculated parachor were anticipated since no appraisal of this new constitutive effect has been included. It would be expected that the observed parachor would be less than the calculated value. This is evident in the data of Table III.

[a] Mean probable error not over ±0.03.

The parachor of the compound cited above calculated from values of Mumford and Phillips[8] for the individual atoms includes a strain constant (−3.0) for secondary branching of the carbon chain, which was not considered to vary with the length of the chain involved: Parachor of $C_{14}H_{28}Cl_2$ = (14 × 9.2) + (28 × 15.4) + (2 × 55.0) + (2 × −3.0) = 664.0.

TABLE III

COMPARISON OF EXPERIMENTAL AND CALCULATED PARACHORS

The experimental parachor at 25° is given in all cases in which such measurement was possible. Experimental values listed for glycols were obtained by extrapolation to 25°.

Compound	Parachor Exp.	Parachor Calcd.	JQ[a] % dev.	Previous calcd. values % Dev. (uncor.)[b] %	Previous calcd. values Dev. (cor.)[c]
3,6-Diol	511.2[d]	519.8	1.7	5.6	4.5
3,11-Diol	712.1	708.9	−0.45	3.9	3.1
2,11-Diol	615.9	603.0	−2.1	0.67	−0.31
3,12-Diol	756.6	748.0	−1.1	3.1	2.3
4,13-Diol	906.1	903.2	−0.32	3.7	3.1
2,5-Di-Cl	425.2[e]	427.8	0.61	1.1	−0.28
3,6-Di-Cl	566.2	575.2	1.6	4.2	3.1
4,7-Di-Cl	720.6	731.4	1.5	4.0	3.2
2,7-Di-Cl	505.2[f]	502.8	−0.48	0.95	−0.24
3,8-Di-Cl	649.5	646.6	−0.48	3.1	2.4

chlorides			−4.4	16.5	9.8

[a] Based on tables of references (5) and (7). Fourth CH_2 in longest alkyl group of dichlorides taken as 39.5 instead of devious 38.6. [b] Derived from atomic constants only with no correction for branching of chain. [c] Mumford and Phillips' correction for branching of chain used. [d] 5° increment taken as 0.3. [e] Average of 70 and 75°. [f] Average of 60, 65 and 70°.

In Table III the experimental parachors are compared with values calculated as in the above examples and also with values based simply on Mumford and Phillips' atomic parachors with no correction for branching.

It should be pointed out that while the use of an average correction value or strain constant greatly reduces the total deviation in a series, it does not distinguish between two isomers both with the same type of branching. Such isomers always differ from each other. It is seen from Table III that for the five glycols reported the average deviation between calculated and observed values is 1.1%; the minimum, 0.3%; the maximum, 2.1%. Strictly additive values give an average deviation of 3.4%, a minimum of 0.7% and a maximum of 5.6%. The application of an average correction for secondary branching gives an average deviation of 2.7%, a minimum of 0.3% and a maximum of 4.5%. For the eleven dichlorides reported the average deviation between the observed and predicted values is 0.7%; the minimum, 0.05%; the maximum, 1.6%. Strictly additive values give an average deviation of 2.3%, a minimum of 0.6% and a maximum of 4.2%. The application of an average correction for branching gives an average deviation of 1.6%, a minimum of 0.05% and a maximum of 3.2%. Exclusive of dichlorides in which the number of separating methylene groups is two, the average deviation is 0.6% for the parachors in which individual constitutive values are included, whereas the average deviation is 1.4% for parachors in which an average correction is applied.

Experimental

The ditertiary glycols and chlorides were all prepared by standard methods. Detailed procedures are given below for two typical examples.

2,10-Dimethyl-2,10-undecanediol.—Thirty-two grams of dimethyl azelate (0.15 mole) in 170 cc. of dry ether was added dropwise under moderate reflux to methylmagnesium iodide prepared by the addition of 46 cc. of methyl iodide in 60 cc. of dry ether to 17.4 g. of magnesium in 170 cc. of dry ether.[14] The addition mixture was warmed under gentle reflux over a water-bath for two hours (with agitation if possible) after all the ester had been added. It was then allowed to cool and was hydrolyzed by working into the mass saturated aqueous ammonium chloride solution until separation of a supernatant ether layer occurred.[15] The ether layer was decanted and the hydrolysis mass washed several times with small portions of ether. (If a red color due to iodine develops, it may be removed by washing with 5% aqueous thiosulfate solution.) The combined ether extracts were dried over Drierite. Most of the ether was removed from the extract by distillation. Final traces of ether and other volatiles were removed by heating up to 70° under reduced pressure. On cooling the residue readily crystallized to a red-brown solid. The first series of crystallizations from toluene gave 29 g. of slightly brown solid (91% crude). After four recrystallizations 24 g. (75%) of colorless, odorless crystals, m. p. 67–67.5°, was obtained.

2,10-Dichloro-2,10-dimethylundecane.—Ten grams of 2,10-dimethyl-2,10-undecanediol was dissolved in 162 cc. of anhydrous ether (8% solution) to which was added 30 cc. of methanol.[16] The temperature was maintained between −10 and −20° by an ice–salt-bath. Anhydrous hydrogen chloride was bubbled through with mechanical agitation until the solution was saturated or nearly so (twenty hours). After standing overnight in an ice–salt mixture the reaction mixture was concentrated by drawing dry air through under reduced pressure. Evaporation was continued in a large test-tube until the mixture became cloudy, at which point it was allowed to settle into two layers. The top ether layer was pipetted into a cold glass-stoppered bottle. The above extraction was repeated twice with small volumes of cold ether. The combined ether extracts were aerated further to remove as much of the remaining hydrogen chloride as possible, a small volume of chloroform was added and the solution was dried in the cold over 1:1 sodium sulfate and carbonate for twenty-four hours. Nine and six-tenths grams of oil with slight odor and color was recovered from the filtered chloroform solution by aeration as described above. Further evaporation and extraction of the original reaction residue gave 1.3 g. of brown oil for a total yield of 11.2 g. of crude dichloride (96%). The first fraction was further purified by the following general procedure. Ten cc. (9.6 g.) of the 2,10-dichloride was dissolved in 15 cc. of chloroform. The chloroform solution and 5 cc. of concentrated sulfuric acid were cooled to −15° in separate small glass-stoppered bottles, mixed and shaken thoroughly at intervals in the cold for twenty minutes. The mixture was allowed to stand in an ice–salt-bath for twenty-five minutes before the chloroform layer was pipetted off, centrifuged five to ten minutes, dried twenty-four hours in the cold over sodium sulfate–carbonate mixture and concentrated by aeration under reduced pressure as above. This final evaporation of solvent required about four hours toward the end of which a water-bath at 45° was applied. The yield of dried and filtered, colorless and odorless oil was 8.6 g. (74% over-all).

Summary

Three new ditertiary glycols and nine new ditertiary chlorides have been prepared.

The parachors of a number of ditertiary glycols and chlorides have been measured and shown to compare satisfactorily with predicted values.

These results indicate that large structural units after evaluation may be treated in general in an additive manner in predicting the parachor of a large molecule. As expected the agreement is closer when the functional groups are separated by four or more carbon atoms.

EMORY UNIVERSITY, GA. RECEIVED JULY 31, 1947

---

[14] Good mechanical agitation is essential since the Grignard addition products of dibasic esters of high molecular weight tend to separate as tough solid masses and stop the stirrer.

[15] Hydrolysis procedure outlined by Fieser, "Experiments in Organic Chemistry," 2nd ed., D. C. Heath and Co., New York, N. Y., 1941, p. 410.

[16] Concentration of solution and volume of methanol added was varied according to the solubility of a particular glycol at low temperatures.

Condensation of Cyclohexanone with Nitriles

BY HERMAN A. BRUSON, EDWARD RIENER AND THOMAS RIENER

The reaction of phenols with nitriles in the presence of aluminum chloride (Houben–Hoesch method) to yield ketimines and ultimately ketones suggested the possibility that cyclohexanone might react in its enolic form with acetonitrile and aluminum chloride to yield 2-acetylcyclohexanone.

Upon addition of a mixture of acetonitrile and cyclohexanone to a cooled, stirred suspension of anhydrous aluminum chloride in carbon disulfide a semisolid reaction mass forms which soon prevents further stirring. After decomposition of the product with ice water the mixture yields a crystalline solid (I) melting at 140° and having the formula $C_{14}H_{23}O_2N$. This product corresponds to a composition of two moles cyclohexanone and one mole acetonitrile. It may be more readily obtained by using ethylene dichloride instead of carbon disulfide as a solvent, since the reaction mixture then remains fluid and homogeneous, and can be continuously stirred during the reaction period.

The chemical properties of (I) are as follows:

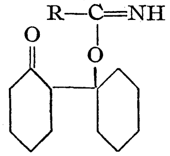
It is a ketone since it yields a crystalline monoxime and a crystalline mono-semicarbazone. It is a base since it dissolves readily in concentrated hydrochloric acid but not in water at room temperature and is reprecipitated unchanged from the acid solution by the addition of excess sodium hydroxide solution.

When the product is steam distilled from an admixture with dilute sulfuric acid the nitrogen is split off as ammonia and an oil steam distills over. The oil was found to be 2-cyclohexenylcyclohexanone. Acetic acid is found in the aqueous steam distillate layer. Since cyclohexanone upon steam distillation from dilute sulfuric acid under the same conditions gave no detectable amount of cyclohexenylcyclohexanone it may safely be concluded that (I) is derived from 2-cyclohexenylcyclohexanone or 2-cyclohexylidenecyclohexanone and not from cyclohexanone itself.

To test this hypothesis, acetonitrile was treated with 2-cyclohexenylcyclohexanone in the presence of an aluminum chloride suspension in ethylene dichloride and the same crystalline product (I) melting at 140° was obtained, although in poorer yield.

That the methyl group of the acetonitrile is not involved in the reaction is shown by the fact that benzonitrile reacts in an analogous manner with cyclohexanone and aluminum chloride to yield a crystalline product (II) melting at 120–121° and having the formula $C_{19}H_{25}O_2N$ corresponding to a molar ratio of cyclohexanone to nitrile of 2:1. Propionitrile likewise reacted with cyclohexanone to yield a crystalline product (III) melting at 92–93° and having the formula $C_{15}H_{25}O_2N$ corresponding to a molar ratio of cyclohexanone to nitrile of 2:1.

A consideration of the above data makes it highly probable that these products are all derived from the aldol of cyclohexanone by the addition of the hydroxyl group thereof to the cyano group to form an iminoether[1] containing a free ketonic group as shown in formula (A).



(I) R = CH_3
(II) R = C_6H_5
(III) R = C_2H_5

(A)

This structure is consistent with all of the above-mentioned facts and reactions except for the possibility that such a formula might *a priori* be suggestive of a rather unstable molecule. The crystalline products obtained by us are however remarkably stable. The product $C_{14}H_{23}O_2N$ (I) obtained from acetonitrile and cyclohexanone or 2-cyclohexenylcyclohexanone is, for example, distillable *in vacuo*. It is also steam distillable from neutral solution and can be boiled for short periods of time with aqueous 10% sodium hydroxide solution without evolution of ammonia or any noticeable change. Only in acid solution does it undergo the complete breakdown upon prolonged standing or upon short boiling which is so characteristic of iminoethers in general.

Experimental

(I) Condensation of Cyclohexanone with Acetonitrile.—To a stirred suspension of 133.5 g. anhydrous, powdered, sublimed aluminum chloride in 300 cc. of carbon disulfide there was added dropwise with cooling to 30–35°, a mixture of 41 g. of acetonitrile and 196 g. of cyclohexanone during the course of forty-five minutes. After about half of this mixture had been added the solid nature of the product prevented further stirring. On standing for about three hours the mixture became a little more fluid and was stirred for eighteen hours at room temperature. It was then poured into 1 liter of chipped ice. After the ice had melted the oil layer was separated and the aqueous layer was extracted with benzene. The combined oil and extract was washed several times with water and the solvent was removed by evaporation in vacuum on a steam-bath. The residue (155 g.) partially solidified on cooling and scratching to a chocolate-colored crystalline magma. For purification it may be recrystallized from diisobutylene or methylcyclohexane with the help of Norite to remove the color; yield 55–75 g. of white crystals, m. p. 140–141°.

Anal. Calcd. for $C_{14}H_{23}O_2N$: C, 70.89; H, 9.70; N, 5.90; mol. wt., 237. Found: C, 71.20; H, 9.72; N, 5.86; mol. wt. (ebullioscopic in acetone), 241.

It is soluble in alcohol, benzene, ether, but insoluble in cold petroleum ether. It is somewhat soluble in boiling water and crystallizes out on cooling.

---

[1] A. Pinner, "Die Imidoäther und ihre Derivate," Berlin, 1892; Pinner and Klein, *Ber.*, **10**, 1889 (1877).

The use of 200 cc. of ethylene dichloride instead of the carbon disulfide in the above preparation allows better stirring. The yield of product in this case was 44 g.

Semicarbazone of (I).—This was prepared by heating on a steam-bath under reflux for three hours a mixture of 4.7 g. of (I), 25 cc. of ethanol, 15 cc. of water, 7 g. of sodium acetate and 5.5 g. of semicarbazide hydrochloride. The product was allowed to stand several days at 5° and the white crystalline deposit filtered off. It was recrystallized three times from water to a constant melting point of 194–195° and dried *in vacuo* at 100° for analysis.

Anal. Calcd. for $C_{15}H_{26}O_2N_4$: C, 61.22; H, 8.84; N, 19.04. Found: C, 61.55; H, 9.27; N, 19.00.

A mixed melting point with the semicarbazone of 2-cyclohexenylcyclohexanone of m. p. 195–196° showed a 15° depression.

Oxime of (I).—This was prepared by heating on a steam-bath under reflux for three hours a mixture of 2 g. of (I), 30 cc. of ethanol, 30 cc. of water, 3.3 g. of sodium acetate and 1.7 g. of hydroxylamine sulfate. Since the product did not crystalline on cooling, the solution was evaporated to dryness *in vacuo* and extracted with ether. Upon evaporation of the ether extract a soft mass was obtained which solidified when rubbed with 20 cc. of petroleum ether. The solid material was recrystallized from nitromethane and then from petroleum ether (b. p. 90–100°) to form white crystals, m. p. 163–164°.

Anal. Calcd. for $C_{14}H_{24}O_2N_2$: C, 66.66; H, 9.52; N, 11.11. Found: C, 66.53; H, 9.66; N, 10.85.

(I) **Condensation of Acetonitrile with 2-Cyclohexenylcyclohexanone.**—To a stirred suspension of 89.5 g. of powdered, sublimed, anhydrous aluminum chloride in 150 g. of ethylene dichloride, there was added dropwise a mixture of 27.5 g. of acetonitrile and 118 g. of 2-cyclohexenylcyclohexanone[2] while cooling the reaction mixture to 20–30°. After stirring for twenty-one hours at room temperature the mixture was added to chipped ice and the oil layer separated, washed with water and dried *in vacuo*. The residual oil (109 g.) was distilled under reduced pressure and the fraction boiling at 175–225° (0.5–1 mm.) was collected; yield 17 g. It was recrystallized from petroleum ether (b. p. 90–100°) and formed white crystals, m. p. 140–141°, which gave no depression in melting point with the product (I) obtained from cyclohexanone and acetonitrile.

Hydrolysis of (I).—A mixture of 1000 g. of 10% sulfuric acid and 179 g. (I), prepared from cyclohexanone and acetonitrile was blown with steam for five hours and the distillate (3500 cc.) collected. The oil layer was separated from the distillate and the aqueous layer extracted with ether. The combined oil and ether extract upon distillation *in vacuo* at 10 mm. yielded 52 g. of 2-cyclohexenylcyclohexanone, b. p. 133–136° (10 mm.), identified by its semicarbazone, m. p. 194–195°, and by its mixed melting point with an authentic sample of the semicarbazone of 2-cyclohexenylcyclohexanone of m. p. 195–196° with which it gave no significant depression.

(II) **Condensation of Cyclohexanone with Benzonitrile.**—The procedure given for (I) above was followed, using 133.5 g. of anhydrous aluminum chloride, 300 cc. of ethylene dichloride, 103 g. of benzonitrile and 196 g. of cyclohexanone. The crude product was a brown oil weighing 264 g. Upon extraction with hot petroleum ether (b. p. 90–100°) a light brown powder (82 g.) was left behind as a residue. This was recrystallized several times with considerable loss from petroleum ether and finally from ethylcyclohexane to a constant m. p. 120–121°.

Anal. Calcd. for $C_{19}H_{25}O_2N$: C, 76.25; H, 8.36; N, 4.68. Found: C, 76.74; H, 8.58; N, 4.66.

(III) **Condensation of Propionitrile with Cyclohexanone.**—The procedure given for (I) above was applied to a mixture of 133.5 g. of anhydrous aluminum chloride, 200 cc. of ethylene dichloride, 55 g. of propionitrile and 196 g. of cyclohexanone. The crude product was a brown oil (154 g.) which gradually crystallized in part after several days standing. The sticky crystalline product was spread out on porous tile which absorbed the oily impurity leaving about 80 g. of pinkish crystals. This material was recrystallized from petroleum ether (b. p. 90–100°) to a constant m. p. 92–93°; yield 60 g.

Anal. Calcd. for $C_{15}H_{25}O_2N$: C, 71.71; H, 9.96; N, 5.68. Found: C, 71.88; H, 10.18; N, 5.55.

Summary

Cyclohexanone condenses in the presence of aluminum chloride with nitriles R–CN to yield crystalline compounds which appear to be iminoethers of the aldol of cyclohexanone having the general formula

A New Synthesis of Organosilicon Compounds[1]

BY E. W. PIETRUSZA,[2] L. H. SOMMER AND F. C. WHITMORE

In a previous communication[3] we reported the preparation of *n*-octyltrichlorosilane in almost quantitative yield from the reaction of 1-octene with trichlorosilane in the presence of a small amount (7 mole %) of diacetyl peroxide. The use of a weak ultraviolet source as the catalyst gave a 24% yield.

$$\mathrm{RCH{=}CH_2 + SiHCl \xrightarrow[\text{or U. V. L.}]{(CH_3COO)_2} RCH_2CH_2SiCl_3} \quad (1)$$

In extension of these results, the present paper reports that this new synthesis[4] is generally applicable to the addition of $SiHCl_3$ to olefins of varied structure, *i. e.*, $RCH{=}CH_2$, $RCH{=}CHR$, $R_2C{=}$

[a] Diacetyl peroxide, 3.8 mole%, based on olefin used. [b] Ultraviolet light applied externally. [c] Reaction was performed in a Vycor flask. (1-Octene when placed in a Pyrex flask and exposed to ultraviolet light for seventy-two hours gave a 24.3% yield of product, and when placed in a quartz flask and exposed to ultraviolet light for twenty-four hours gave a 31% yield of product.) [d] Quartz flask. [e] Pyrex glass, sealed ampule. [f] Values were obtained by treating a weighed sample with excess standard base and back-titrating with standard acid. [g] In this case, only the chlorines attached to silicon are neutralized by 0.1 *N* base. See Sommer, Dorfman, Goldberg and Whitmore, THIS JOURNAL, 68, 488 (1946). [h] Empirical formulas are given when the mode of addition of $SiHCl_3$ is uncertain. [i] F. p. 15–16°. [j] 0.2 mole. [k] 0.33 mole.

CH_2, $R_2C{=}CHR$, $R_2C{=}CR_2$, where R is alkyl, and to allyl chloride.

Olefins having these structures give excellent yields of the alkyltrichlorosilane when R is a straight-chain group such as methyl, *n*-amyl, or *n*-hexyl. However, if R is a highly-branched group, such as *t*-butyl or neopentyl, with the branching close to the olefinic linkage, the yield is considerably reduced. The low yield of isobutyltrichlorosilane may possibly be due to the volatile nature of the olefin which in our case necessitated the use of a low reaction temperature.

Comparison experiments using peroxide and ultraviolet light as catalysts indicate that the former generally gives faster reaction. However, use of the latter with 2-methyl-2-butene gave a better yield of product.

It is of interest that the alkyltrichlorosilanes formed in these reactions are incapable of undergoing further reaction with olefins under the conditions used. This leads in most cases to a product of high purity. In this respect the present method compares favorably with the Grignard method and the direct method which generally give mixtures of alkylchlorosilanes.[4]

The synthesis of 1,1,2-trimethylpropyltrichlorosilane from 2,3-dimethyl-2-butene and trichlorosilane is of interest, since reported preparations of tertiary alkyl silicon compounds have previously been limited to the use of tertiary alkyl lithium compounds[5] which are somewhat difficult to prepare in good yield.

The results of a preliminary study of the reactions of 1-octene with silicon hydrides other than trichlorosilane indicate that the latter reacts far more readily. *n*-Propyldichlorosilane gave a low yield (6%) of impure product when diacetyl peroxide was used. Triethoxysilane gave no reaction using either catalyst. Triethylsilane gave no reaction using peroxide, and a low yield of impure product (3%) when light was used. Diethylsilane gave a fair yield of a product which appeared to be mainly the mono addition product, but which could not be purified because of the small amount of starting material used.

Silicon tetrachloride failed to react with 1-octene using either catalyst.

While no detailed proof is available for the formulation of the addition of trichlorosilane to olefins as a free-radical chain reaction,[3] such an assumption seems reasonable on the basis of the following points: (1) Extensive evidence for the decomposition of diacetyl peroxide and other peroxides into free radicals on heating is beyond question. (2) Catalysis by ultraviolet light is evidence for a free-radical mechanism. (3) The small amounts (3.8 mole %) of diacetyl peroxide used in the present syntheses leave little doubt that these are chain reactions.

Experimental

Trichlorosilane was prepared in excellent yield by passing dry hydrogen chloride over ferrosilicon.[6] The olefins used were synthesized and carefully purified by Dr. N. C. Cook of this laboratory, who kindly donated samples for this study. Crystalline diacetyl peroxide

(6) See Whitmore, Pietrusza and Sommer, *ibid.*, **69**, 2108 (1947), for the procedure used and for references to earlier preparations.

was prepared by the method of Gambarjan as modified by Kharasch,[7] and dissolved in the olefin used. The peroxide content was determined by analysis.[8]

A detailed description of the procedure used in a typical trichlorosilane addition to an olefin is given. Essentially this same procedure was employed for the reactions given in Table I.

Olefin, Trichlorosilane and Diacetyl Peroxide.—1-Octene, 17.9 g., 0.16 mole, and trichlorosilane, b. p. 32°, 135.5 g., 1.0 mole, were placed in a three-necked flask with dropping funnel, thermometer, and a reflux condenser connected through a trap cooled in Dry Ice–acetone to a mercury seal 20 cm. in height. The system was swept with nitrogen for two hours, and the reaction mixture was heated to 45° under the slight extra pressure of the mercury. Crystalline diacetyl peroxide, 1.5 g., 0.013 mole, dissolved in 19.1 g., 0.17 mole, of 1-octene was then added during two hours. The mixture was heated at 50–63° for an additional nine hours.

After removal of excess trichlorosilane, the residue was distilled at reduced pressure and then redistilled at atmospheric pressure, giving 80.9 g. of clear colorless liquid, b. p. 231–232° at 728 mm., $n^{20}\text{D}$ 1.4480, 99% yield.

Anal. Calcd. for $C_8H_{17}SiCl_3$: Cl, 43.0. Found: Cl, 42.9, 43.0.

n-Octyltrichlorosilane from silicon tetrachloride and *n*-octylmagnesium bromide boils 233° at 731 mm.; 119° at 28 mm.[9]

Treatment of a portion of the product with ethanolic potassium hydroxide gave no hydrogen, indicating the absence of Si-H bonds.[10]

Reaction of the product, 24.8 g., 0.1 mole, with 0.35 mole of methylmagnesium bromide (using a procedure known to form the tetraalkylsilane from *n*-octyltrichlorosilane)[9] gave 13.0 g. of *n*-octyltrimethylsilane, b. p. 201.5° at 733 mm., $n^{20}\text{D}$ 1.4242, 74% yield. Constants for this compound[9] are: b. p. 202° at 760 mm., $n^{20}\text{D}$ 1.4242. All the data thus conclusively confirm equation (1).

Olefin, Trichlorosilane, and Ultraviolet Light.—1-Octene, 22.4 g., 0.2 mole, and trichlorosilane, 81.3 g., 0.6 mole, were placed in a 500 cc. quartz flask with thermometer and a reflux condenser connected through a trap cooled in Dry Ice–acetone to a mercury seal of 20 cm. height. The system was swept with nitrogen for a half hour, and the reaction mixture was heated to 46° under the slight extra pressure of the mercury. Ultraviolet light was applied from an external source and the solution was heated for twenty-four hours at a temperature range of 46–52°.

After removal of excess trichlorosilane, the residue was distilled at reduced pressure and then redistilled at atmospheric pressure, giving 15.3 g. of clear, colorless liquid, b. p. 231–232° at 728 mm., $n^{20}\text{D}$ 1.4481, 31% yield.

Anal. Calcd. for $C_8H_{17}SiCl_3$: Cl, 43.0. Found: Cl, 42.8, 42.9.

Treatment of a portion of the product with ethanolic potassium hydroxide gave no hydrogen, indicating the absence of Si-H bonds.[10]

The above product corresponds completely to the product of the peroxide catalyzed reaction. When ultraviolet light is applied for longer periods of time, better yields of the octyltrichlorosilane are obtained.

Reactions of 1-Octene with Other Silicon Hydrides.—These were carried out under essentially the same conditions as those described above.

Summary

1. A new synthesis of organosilicon compounds is described which involves the addition of trichlorosilane to olefins differing widely in structural type. These reactions are catalyzed by small amounts of diacetyl peroxide or ultraviolet light.

2. New alkyltrichlorosilanes of varying complexity were prepared by this method in good yield.

Reaction of Lithium Aluminum Hydride with Compounds Containing Active Hydrogen

BY J. A. KRYNITSKY, J. E. JOHNSON AND H. W. CARHART

The new compound, lithium aluminum hydride, discovered by Finholt, Schlesinger, *et al.*,[1,2] has been shown to be a vigorous agent for the reduction of various types of organic compounds.[3] In addition, many compounds containing active hydrogen decompose the reagent to liberate hydrogen. The purpose of this investigation was to study the latter type of reaction and to explore the possibility of using lithium aluminum hydride as a reagent for the determination of active hydrogen.

In a previous study, it was found that ether solutions of lithium aluminum hydride could be analyzed quantitatively by decomposing with excess water at 0° and measuring the evolved hydrogen by changes in pressure.[4] In the present work, an apparatus was devised so that a known amount of material could be added to an excess of lithium aluminum hydride–ether solution at 0° and the liberated gas measured by changes in pressure. By this method, the apparent active hydrogen content of a number of organic compounds was determined.

Experimental

Apparatus.—A diagram of the apparatus used is shown in Fig. 1. The reaction flask consisted of a 500-ml. round-bottom flask bearing a 35/20 spherical socket joint. A take-off arm was attached to the neck and connected to a manometer by small bore tubing through a T-tube. The T-tube was joined to a drying tube with rubber tubing which could be closed by a pinch clamp. The reaction flask was closed by a spherical ball joint carrying a 12 × 130 mm. guide tube. A clamp with an efficient locking

device was used to hold the joint together in order to prevent leakage. The supporting hook was made from glass rod joined to a sealed glass tube containing an iron core. The over-all length of the supporting hook was such that its lower end almost touched the bottom of the flask when the magnet pack was in the lowered position. The magnet pack consisted of two Alnico magnets in opposition mounted so that the pack passed over the guide tube easily. The sample cup was made from 15 mm. tubing and had a capacity of approximately 2 ml. A handle was provided so that the cup could be suspended from the supporting hook.

Before using the apparatus, the volume of the system was determined. In addition to this apparatus, a second one similar in construction but using a one-liter reaction flask was used for many of the determinations.

Procedure.—The reaction flask was clamped into place, connected to the manometer and surrounded with crushed ice and ice water. Approximately 100 ml. of cold lithium aluminum hydride–ether solution (0.3 to 0.7 molar) was placed in the flask and the assembled apparatus allowed to stand with the pinch clamp closed. If a pressure change was observed in five minutes, the pinch clamp was opened momentarily and the standing process repeated until equilibrium was reached. Sometimes over one hour was required to attain this equilibrium.

The material under investigation was weighed into a sample cup which was then hung on the supporting hook. The iron core end of the hook was placed in the guide tube with the magnet pack in the raised position. This assembly was attached to the flask and the joint locked in place.

After equilibrium was re-established (usually ten to fifteen minutes), the magnet pack was lowered so that the sample was brought into the solution. Pressure readings were taken at appropriate time intervals (usually five minutes) until no further change was observed. In some cases, when reaction was slow, the mixture was agitated slightly by raising and lowering the magnet pack.

The apparatus was readied for a subsequent analysis by releasing the pressure and withdrawing the sample cup and supporting hook. The next determination was then started immediately using a fresh sample cup and supporting hook.

The apparent number of active hydrogen atoms in the molecule was calculated from the equation

$$\text{No. active H atoms} = \frac{\text{pressure (mm.)} \times \text{net free vol. (ml.)}}{\text{millimoles sample} \times 17{,}030}$$

The pressure is the observed pressure increase less the small pressure increase found by carrying out a blank determination without a sample. The net free volume is the total volume of the system less the volume of solutions added and the volume of the supporting hook. The factor 17,030 combines the constants R and T.

In general, the size of the sample was chosen so that a pressure change of approximately 100 mm. was obtained. For the apparatus described, the amount of material ordinarily used varied from 0.1 to 0.4 g. depending on its molecular weight and the number of active hydrogen atoms. Materials which were suspected of not being dry were dried using anhydrous calcium sulfate or phosphorus pentoxide.

Results and Discussion

The values found for the apparent active hydrogen content of a number of typical organic compounds are presented in Table I.

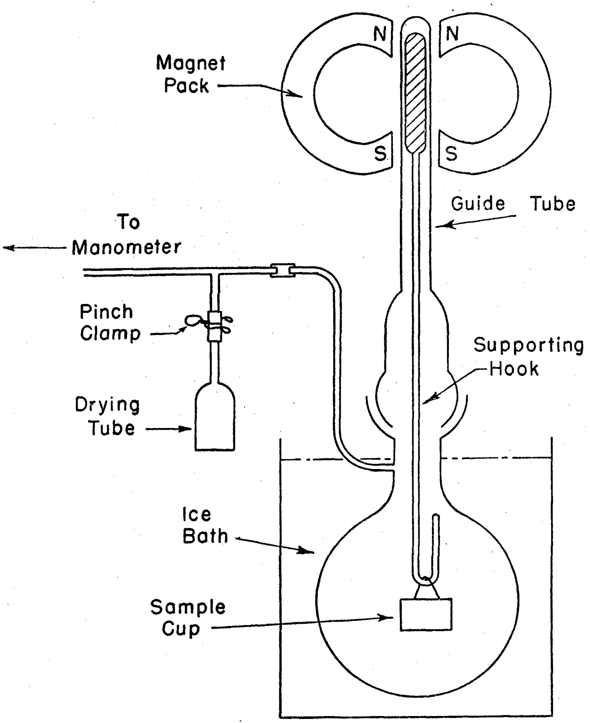

Fig. 1.—Apparatus for determining active hydrogen.

From this table, it can be seen that many of the simple alcohols, phenols and acids react with lithium aluminum hydride in ether to liberate hydrogen in the expected manner and give results which are in good agreement with the theoretical values. Although the reactions usually appeared to be complete within a few seconds, several minutes were required to reach equilibrium. The inconclusive results obtained with hydroquinone, succinic acid and terephthalic acid may be due to the formation of insoluble material which coats the crystals and inhibits further reaction. The anomalous results obtained with resorcinol may be due to the formation of an insoluble product or to partial reaction in the keto form. With the Grignard reagent, resorcinol has been reported to show from one to two atoms of active hydrogen.[5,6,7]

The amines and amides tested showed the expected number of active hydrogen atoms, and with the exception of acetanilide required prolonged reaction periods. The extreme slowness of the reaction of diamylamine was unexpected. The liberation of two hydrogens by primary amines and unsubstituted amides by this reagent at 0° is of interest since it has been reported that the Grignard reagent liberates one hydrogen from such compounds at ordinary temperatures and the second on heating.[8] Whereas the time required

Diethyl benzylmalonate	5–10	.19	.21
Miscellaneous			
Acetophenone	5–10	0.07	0.05
Propiophenone	5–10	0.05	0.08
Octyl mercaptan	5–10	1.00	1.01
Dioctyl thioether		None[b]	
Ethyl palmitate		None[b]	
Phenylhydrazine	70–125	Erratic[c]	

[a] Reaction with these compounds was slight and too slow to obtain significant results. [b] These compounds gave less than 0.02 atom of active hydrogen. [c] Values obtained were 3.01, 2.68, 3.47, 3.90 and 3.20.

for complete liberation of hydrogen by primary amines and unsubstituted amides was rather long, in every case the first hydrogen was liberated rapidly, usually within five minutes. This behavior was also observed for all other compounds tested showing more than one atom of apparent active hydrogen.

Nitrobenzene and nitrotoluene showed two apparent active hydrogen atoms. With the Grignard reagent nitrobenzene has been reported as showing from 1.0 to 1.9 active hydrogens depending on the reagent used.[9] In contrast to the aromatic nitro compounds, nitromethane gave erratic results showing more than two apparent active hydrogens. With the Grignard reagent, values of less than one have been reported for nitromethane.[5,10]

The reaction of lithium aluminum hydride with compounds exhibiting keto–enol tautomerism was rapid and the results indicated that the compounds tested behaved as though they were partially enolized. In this connection it is interesting to note that diethyl malonate reacted as though it were approximately 56% enolized, yet the substituted diethyl malonates gave values which ranged from 18 to 28%. With the Grignard reagent acetylacetone, ethyl acetoacetate and diethyl malonate have been reported to react as though they existed entirely in the mono-enol form.[6,8] In contrast to the Grignard reagent, it appears that lithium aluminum hydride reacts with the keto form of these compounds rapidly enough so that complete enolization cannot occur.

Definite conclusions cannot be drawn from the values obtained for acetophenone and propiophenone. However, it is indicated that these compounds reacted as though they were partially enolized. In this respect, it is of interest that acetophenone has been reported to react with the Grignard reagent as though it were approximately 12–15% enolized in isoamyl ether and 78% in pyridine or dioxane.[11,12]

Although the reaction of phenylhydrazine with lithium aluminum hydride gave erratic results, it was surprising that in three out of five determinations, more than three apparent active hydrogen atoms were found. This suggested partial cleavage of the N–N bond. Confirmation of this cleavage was obtained by detection of ammonia upon hydrolysis of such a reaction mixture. In every case, the liberation of the first two hydrogens was rapid and occurred within five minutes.

Acknowledgment.—The authors are indebted to Dr. W. E. Weaver of this Laboratory who courteously furnished the substituted malonic esters used in this work.

Summary

The apparent active hydrogen content of a number of organic compounds was determined by means of an ether solution of lithium aluminum hydride. In the majority of cases, this reagent behaved in a manner similar to that of the Grignard reagent and the expected number of hydro-

gen atoms was found. However, in some instances, the reaction was more vigorous in that it proceeded at a lower temperature and further toward completion.

With lithium aluminum hydride, the keto–enol tautomers investigated behaved as though they were only partially enolized, whereas similar compounds with the Grignard reagent act as though they exist in the enol form only.

Claisen Condensation of Methyl Esters

BY E. EARL ROYALS

Investigations of the acetoacetic ester condensation[1] have been largely confined to the study of ethyl esters; particularly, relatively few methyl ester condensations have been reported in the literature. The present commercial availability of sodium methoxide, and observations[2] that sodium methoxide is a condensation catalyst considerably less sensitive to adverse experimental conditions than sodium ethoxide make further investigation of methyl ester condensations desirable. The present research was undertaken to determine the utility of sodium methoxide as a reagent for the condensation of the simpler methyl esters, and, more specifically, to develop methods of synthesis for certain keto-esters which have not previously been satisfactorily prepared by direct ester condensation.

McElvain and co-workers made an extensive study of the self-condensation of ethyl esters in the presence of sodium ethoxide under both equilibrium and forcing conditions.[3] Our results on the self-condensation of methyl esters, shown in Table I, are quite similar to those of McElvain in the ethyl ester series. Our forcing procedure, however, is considerably simpler and requires less of the pure ester than the one described by McElvain.

The condensation of methyl benzoate with methyl acetate has been reported to give yields of methyl benzoylacetate ranging from 45 to 85% depending on the conditions employed.[4] Dorsch and McElvain[5] condensed ethyl benzoate in the presence of sodium ethoxide with ethyl acetate, propionate, and *n*-butyrate and obtained yields of 37, 19 and 4%, respectively, of the α-benzoyl esters. We have investigated the condensation of methyl benzoate with methyl acetate, propionate and *n*-butyrate; our results are summarized in Table II. The methyl propionate condensation was chosen for pilot work. The yield of methyl α-benzoylpropionate from equivalent quantities of the two esters and sodium methoxide was found to be essentially the same whether the reactants were directly mixed, or whether the propionate was added dropwise to a mixture of methoxide and benzoate. The yield was not increased by lengthening the reaction time from four to twenty-four hours. It was found, however, that the use of excess methyl propionate and sodium methoxide greatly increased the yield of methyl α-benzoylpropionate (calculated on methyl benzoate); indeed, the second and third equivalents of propionate were utilized in inter-ester condensation with almost the same efficiency as the first. Similar results were obtained in the condensation of methyl acetate with methyl benzoate; somewhat lower yields were obtained, however, than in the corresponding methyl propionate condensations. The best conditions found for the condensation of methyl benzoate with methyl propionate were applied to the analogous methyl *n*-butyrate condensation. A negligible yield of methyl α-benzoylbutyrate was obtained. It was observed, however, that even with a reaction period of forty hours, considerable quantities of methyl *n*-butyrate were recovered unreacted, indicating that the low yield of inter-ester condensation product might be due to an unfavorable equilibrium rather than to a preference of methyl *n*-butyrate for self-condensation. Accordingly, methyl *n*-butyrate (4 moles) was condensed with methyl benzoate (1 mole) in the presence of sodium methoxide (2

[f] Plus 2 moles excess methyl *n*-butyrate. [g] Characterized through 4-ethyl-3-phenyl-isoxazolone-5, m. p. 90.5–92.0°. Haller and Bauer, *loc. cit.*, report m. p. 91°.

moles), the methanol formed in the reaction being azeotropically distilled with the excess methyl *n*-butyrate during a reaction period of thirty hours. A yield of 41% of methyl α-benzoylbutyrate was obtained.

The results here reported for condensations of methyl benzoate with aliphatic methyl esters indicate that such inter-ester condensations, involving one ester incapable of self-condensation, may be of more general usefulness than previous investigations would indicate. Our results on inter-ester condensations are to be regarded as exploratory; further investigations along this line are in progress in our laboratory.

Experimental

Materials.—The methyl esters used were either purchased from the Eastman Kodak Company or were prepared by standard procedures. All of the esters were dried over calcium chloride, distilled, then dried over and distilled from phosphorus pentoxide through an 18-inch column packed with a nichrome spiral of the Podbielniak type. The sodium methoxide was a commercial product purchased from the Mathieson Alkali Works, Niagara Falls, N. Y.

Procedures.—The experiments described below will illustrate the general methods used. Self-condensations under non-forcing conditions were run essentially according to the procedure[3c] described by Roberts and McElvain. The forced self-condensation of methyl phenylacetate was run according to the general procedure[3b] of Briese and McElvain.

Forced Self-Condensation of Methyl Propionate.—A mixture of 317 g. (3.6 mole) of methyl propionate and 32.4 g. (0.6 mole) of sodium methoxide was placed in a 500-cc. flask under an 18-inch, nichrome spiral packed column with a Whitmore-Lux type head. The entire apparatus was protected from atmospheric moisture by suitably placed calcium chloride tubes. The reaction flask was heated in an oil-bath at 100°. The reaction mixture became homogeneous within about one hour. The column was operated at a jacket temperature of 65° with slow take-off and frequent total reflux. A total of 112 g. of distillate was collected (vapor temperature 65–68°) during a reaction period of sixteen hours. The residue on cooling to room temperature set to a solid cake. This cake was broken up, 150 cc. of ether added, and the slurry was cooled in an ice-bath. An ice-cold solution of 50 cc. of glacial acetic acid in 100 cc. of water was added in portions with stirring. Stirring was continued at ice-bath temperature until the solid material had all dissolved. The organic layer was separated, and the aqueous layer was twice extracted with 100-cc. portions of ether. The ether solutions were combined, washed once with water, and dried over sodium sulfate. Removal of the drying agent and ether, followed by distillation of the residue through the spiral-packed column referred to above gave 61 g. (70.5%) of methyl α-propionylpropionate, b. p. 74–76° (10 mm.), $n^{25}D$ 1.4211.

Condensation of Methyl Benzoate with Methyl Propionate.—A mixture of 68 g. (0.5 mole) of methyl benzoate, 44 g. (0.5 mole) of methyl propionate, and 27 g. (0.5 mole) of sodium methoxide was placed in a 500-cc., three necked flask fitted with a modified Hershberg stirrer[6] and reflux condenser protected by a calcium chloride tube. The reaction mixture was stirred in an oil-bath at 80° for six hours. After two hours, and again after four hours, additional quantities of 44 g. of methyl propionate and 27 g. of sodium methoxide were added. The reaction mixture was cooled to room temperature, and 100 cc. of ether was added to give a fluid system. This slurry was cooled in an ice-bath, then poured into an ice-cold solution of 125 cc. of glacial acetic acid in an equal volume of water. (This hydrolysis step is critical; early attempts to effect the hydrolysis by dropwise addition of the cold acetic acid solution to the reaction mixture with stirring in an ice-bath led to the formation of large amounts of benzoic acid, presumably from acid cleavage of the keto-ester.) When all of the solid material had disappeared (about five minutes), the organic layer was separated, and the aqueous layer was twice extracted with 100-cc. portions of ether. The ether solutions were combined, washed once with water, then with saturated sodium bicarbonate solution until free of acid, and again with water. The ether solution was dried over sodium sulfate, then overnight over drierite. Removal of the drying agent and ether, and distillation of the residue through the column referred to above gave 58 g. (60.5%) of methyl α-benzoylpropionate, b. p. 120–123° (2 mm.), $n^{25}D$ 1.5206. A forerun, 35 g., was obtained, b. p. 63–69° (4 mm.), $n^{25}D$ 1.4735, the physical constants indicating a mixture of methyl α-propionylpropionate and unreacted methyl benzoate.

Forced Condensation of Methyl *n*-Butyrate with Methyl Benzoate.—A mixture of 191 g. (1.88 mole) of methyl *n*-butyrate, 64 g. (0.47 mole) of methyl benzoate, and 53.5 g. (0.94 mole) of sodium methoxide was placed in

---

(6) Hershberg, *Ind. Eng. Chem., Anal. Ed.*, **8,** 313 (1936).

a 500-cc., two-necked flask under the column described above. A modified Hershberg stirrer was mounted in the second neck of the flask. The reaction mixture was stirred and heated in an oil-bath at 120–130° for thirty hours, while distillate was slowly taken off through the column jacketed at 65°. A total of 64 g. of distillate was collected. The residue was cooled in an ice-bath and worked up by the procedure described above under the condensation of methyl propionate with methyl benzoate.

Distillation of the reaction product through the spiral-packed column referred to above gave: (I) 8 g., probably methyl benzoate, b. p. 67–85° (9 mm.), (II) 47 g. methyl α-butyrylbutyrate, b. p. 85–90° (9–7 mm.), (III) 6 g. intermediate, (IV) 40 g. (41.3% on methyl benzoate) of methyl α-benzoylbutyrate, b. p. 115–120° (1 mm.), $n^{25}D$ 1.5215.

Summary

Sodium methoxide has been used to effect the acetoacetic ester type of condensation of several methyl esters. Procedures have been described for the self condensation of methyl propionate and of methyl *n*-butyrate to give good yields of β-ketoesters without the use of very large excesses of the esters. It has been found possible to effect satisfactory syntheses of methyl α-benzoylpropionate and of methyl α-benzoyl-*n*-butyrate by direct ester condensation.

Some Dialkylaminoalkyl Sulfides and Ethers Derived from Quinoline and Acridine Heterocycles

BY R. O. CLINTON AND C. M. SUTER

Although the literature contains references to a very large number of heterocyclic nitrogen compounds substituted by basic side chains linked to the nucleus by an imino (—NH—) group, few compounds of this type in which the linkage is oxygen or sulfur have been described. It was the purpose of the present study to determine the effect of replacement of the —NH— by the —O— or —S— linkage upon the therapeutic activity of these compounds, particularly toward the malaria parasite.

The literature[1] describes several quinolines in which 2-dialkylaminoethoxy side chains are linked to the nucleus in the 2- or 4-position, and further substituents (*e. g.*, methyl, phenyl, carboxamide) appear in the quinoline ring. Bachman, *et al.*,[2] have reported the preparation of 3-amino-4-(3-diethylamino-2-hydroxypropylmercapto)-quinoline by the alkylation of the corresponding aminoquinolinethiol with 3-diethylamino-1,2-epoxypropane. In addition, several quinolyl sulfides of related types are listed by Wiselogle,[3]

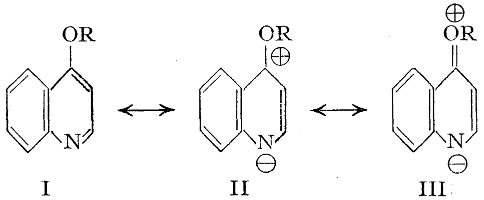
a number of which were originally prepared in the present work. A few acridyl sulfides, analogous to those presently described, have been prepared by Das-Gupta.[4]

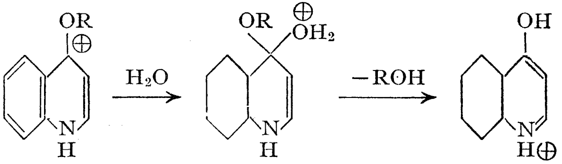
In the present work a series of quinolines and acridines substituted by ω-dialkylaminoalkylmercapto side chains has been prepared by reaction between a sodio-ω-dialkylaminoalkanethiol and a suitable nitrogen heterocyclic chloro compound. These syntheses offered little difficulty, and the desired products were usually isolated readily in high yields by distillation or crystallization.[5]

The synthesis of the oxygen-linked side chains from a sodio-ω-tertiary-aminoalcoholate and a nitrogen heterocyclic chloro compound[6] (*e. g.*, 4-chloroquinoline) gave excellent yields of crude products; purification proved difficult, however, since distillation even in high vacuum at comparatively low temperatures brought about partial thermal cleavage of the oxygen linkage. The oxygen linkage was also readily cleaved by acids, the ease of cleavage being related to the type of nitrogen heterocyclic nucleus and the type of basic side chain. It is apparent that these compounds can exist as resonance hybrids (I–III) and that the hybrid forms II and III are vinylogs of an imino ether rather than the normal phenolic ether type.



I II III

Hydrolytic cleavage in acid solution probably involves the attack of a water molecule on IV, the proton-coupled form of II, to give V, with subsequent release of an alcohol molecule to yield the hydroxyquinoline, VI.



IV V VI

The hybrid form III will not undergo cleavage, since it merely forms an oxonium salt in acid solution. For the 9-dialkylaminoalkoxyacridines the nuclear increase in resonance energy involving the third ring, and consequent stabilization of the forms analogous to II and III, decreases the stability of the oxygen-linked side chain compounds to the point at which they will undergo hydrolytic cleavage even with weak acids at room temperature within a few hours. A similar situation prevails with the corresponding sulfur-linked side chain compounds, although to a lesser degree because of the increased resonating property of the sulfur atom as compared with the oxygen atom, and consequent greater stabilization of the form corresponding to III.

It is interesting to note that in the corresponding imino-linked series the quinoline compounds are stable in acid solution for an indefinite period, whereas an acridine such as quinacrine does hydrolyze slowly under these conditions. This increased resistance of the imino-linked series toward hydrolytic cleavage is readily related to the greater stabilization of the resonance forms analogous to III, this stability being greater in the quinolines than in the acridines. Reaction rate

(4) Das-Gupta, *J. Indian Chem. Soc.*, **20**, 137 (1943); *C. A.*, **37**, 6665 (1943).

(5) Gilman and co-workers (THIS JOURNAL, **67**, 1845 (1945)) have reported that the treatment of 2-chloroquinoline with 2-diethylaminoethanethiol or the corresponding 3-propane analog, in an ethanolic solution of sodium ethoxide, results in the formation of the corresponding bis-(diethylaminoalkyl)-disulfides and not the expected quinolyl sulfides. This discrepancy with the present work cannot by explained.

(6) The converse reaction between the nitrogen heterocyclic hydroxy compound and an ω-dialkylaminoalkyl halide leads exclusively to N-substitution in most cases. *cf.* U. S. Patent 1,941,312

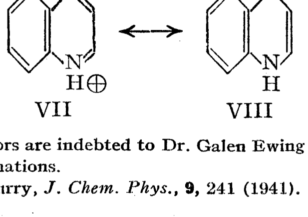
measurements on these three types of compounds would undoubtedly furnish interesting results.

A representative number of the compounds prepared in the present work were also investigated spectrophotometrically. These data and data on certain analogous imino-linked compounds are given in Table I.[7]

From these data it is readily apparent that the substitution of oxygen for the imino-linkage causes a pronounced hypsochromic and hypochromic effect coupled with diminution in the number of principal maxima. These effects are the result of the decreased number of resonance forms involved in the proton-coupled form of the molecule, as compared with a compound such as no. 7 (Table I). As would be expected,[8] the higher inherent resonance energy of the sulfur atom as compared to the oxygen atom produces a large bathochromic and hyperchromic effect (compare nos. 2 and 5), and indeed the principal maxima are further into the visible than those observed with the corresponding imino-linked compounds if weighting effects are taken into account. This indicates that the resonance hybrids, VII–VIII, possess a higher potential energy than the corresponding imino-linked compounds. This effect, however, is not nearly so apparent in the acridine series, in which the resonance of the acridine nucleus contributes a much larger part of the total resonance energy. Diminution in number of principal maxima in the sulfur-linked series is here again evident, however.



VII VIII

As would be expected, the use of aqueous base as solvent produces the normal hypsochromic shift (compare nos. 5, 6 and 7, 8), although the data available are insufficient to indicate possible isosbestric points. Certain anomalies are also apparent, *e. g.*, the disappearance of the twinned principal maxima in nos. 2 and 3, although this effect may be only apparent, due to lack of sufficient resolution.

A number of the compounds prepared in the present work were screened against Avian malaria with negative results. However, in screening tests against certain other organisms, including in particular *Brucella abortus*, some of the compounds proved highly active *in vitro*.[9]

Experimental[10]

Sulfur-linked Side Chains.—These compounds were prepared by the reaction between a sodio-dialkylaminoalkanethiol and a nitrogen heterocyclic chloro compound in absolute alcohol solution. Examples of this method follow; most of the compounds prepared are described and characterized in Table II. The yields in all cases were nearly quantitative. All but one of the thiols used in the present work have been previously described.[11]

5-Isopropylaminopentanethiol.—This compound was prepared from 5-isopropylaminopentyl chloride hydrochloride by methods previously described.[11] **5-Isopropylaminopentylisothiouronium chloride hydrochloride** (94% yield) formed rosets of white needles from absolute alcohol–acetone, m. p. 149–151°.

Anal. Calcd. for $C_9H_{23}Cl_2N_3S$: N, 15.21; Cl, 25.66. Found: N, 15.48; Cl, 25.40.

The isothiouronium salt was converted in 73% yield to the thiol: colorless oil, b. p. 94.0° at 8 mm., $n^{25}{}_D$ 1.4682.

Anal. Calcd. for $C_8H_{19}NS$: N, 8.68. Found: N, 8.52.

The **picrolonate** formed large, blunt yellow needles from alcohol, m. p. 175–177°.

Anal. Calcd. for $C_{18}H_{27}N_5O_5S$: basic nitrogen, 3.29. Found: basic nitrogen, 3.27.

7-Chloro-4-(2-diethylaminoethylmercapto)-quinoline.—Ten and one-tenth grams of 2-diethylaminoethanethiol was added in one portion to a warm solution of 1.75 g. of sodium in 50 ml. of absolute alcohol, contained in a 250-ml., three-necked flask equipped with a reflux condenser, mechanical stirrer and dropping funnel. The solution was heated under reflux with stirring and there was added dropwise during twenty minutes a solution of 15.0 g. of 4,7-dichloroquinoline[12] in 100 ml. of absolute alcohol. There was an almost immediate precipitation of sodium chloride. The mixture was refluxed and stirred for an additional four hours, cooled, and then filtered. After removal of the alcohol *in vacuo* the residual orange oil was distilled *in vacuo.*

4-(2-Diethylaminoethylmercapto)-3,8-dimethylquinoline.—The reaction between sodio-2-diethylaminoethanethiol and 4-chloro-3,8-dimethylquinoline[13] was carried out as described above. The crude product, after removal of the alcohol *in vacuo,* was dissolved in 5% hydrochloric acid and the solution was made neutral to congo red by the addition of solid sodium acetate. The mixture was extracted thoroughly with ether to remove any unreacted chloroquinoline, the aqueous layer made strongly basic with 35% sodium hydroxide solution, and the precipitated oil extracted with ether. After drying and removal of the ether *in vacuo* the residual oil[14] was dissolved in alcohol and treated with somewhat more than two equivalents of picric acid in alcoholic solution. The resulting dipicrate crystallized from glacial acetic acid–alcohol solution in long, feathery, canary-yellow needles.

The dipicrate was reconverted to the base with 10% hydrochloric acid–ethyl acetate, etc., in the usual manner, and the recovered base was treated in acetone solution with an excess of ethereal anhydrous hydrogen chloride (15% by weight). Crystallization from absolute alcohol–ethyl acetate–ether gave short, pale yellow needles of the dihydrochloride.

The dihydrochloride loses one hydrogen chloride molecule on prolonged heating at 100° *in vacuo.*

6-Chloro-9-(2-diethylaminoethylmercapto)-2-methoxyacridine.—Fifty-three and two-tenths grams of 2-diethylaminoethanethiol was added to a solution of 9.2 g. of sodium in 1000 ml. of absolute alcohol. One hundred eleven and two-tenths grams of 6,9-dichloro-2-methoxyacridine was added to the resulting warm solution in one portion, and the heterogeneous mixture was refluxed and stirred for seven hours. Solution of the dichloroacridine was complete after about two hours; sodium chloride precipitation was rapid. After filtration the filtrate was concentrated *in vacuo* to a volume of 500–600 ml., made turbid by the addition of water, and cooled in ice. The mixture readily crystallized on scratching, and further dilution with water precipitated the base completely. After thorough drying the base was crystallized twice from Skellysolve B at −50°, to give a nearly quantitative yield of product as small yellow needles, m. p. 57–58°.

Anal. Calcd. for $C_{20}H_{23}ClN_2OS$: N, 7.47; Cl, 9.46. Found: N, 7.44; Cl, 9.40.

The monohydrochloride was precipitated from an acetone solution of the base by the addition of exactly a one mole proportion of concentrated hydrochloric acid; yellow needles, m. p. 200.5° (dec.).

Anal. Calcd. for $C_{20}H_{23}ClN_2OS \cdot HCl$: N, 6.81; Cl, 17.24. Found: N, 6.71; Cl, 17.02.

Attempts to prepare the dihydrochloride gave an orange-red crystalline product of m. p. 218–200° (dec.), containing varying amounts of water and more than two moles of hydrogen chloride (compare ref. 4).

6-Chloro-9-(4-diethylamino-1-methylbutylmercapto)-2-methoxyacridine.—This compound was prepared by a method analogous to the above procedure. The free base could not be obtained crystalline. The **monohydrochloride** formed orange-yellow needles, m. p. 167–168°.

Anal. Calcd. for $C_{23}H_{29}ClN_2OS \cdot HCl$: N, 6.18; S, 7.07. Found: N, 5.81; S, 6.93.

Oxygen-Linked Side Chains.—These compounds were prepared by the reaction between a sodium alcoholate and a nitrogen heterocyclic chloro compound in toluene solution. An example is given in detail below; most of the compounds prepared appear in Table II.

7-Chloro-4-(4-diethylamino-1-methylbutyoxy)-quinoline.—Sixty-three and six-tenths grams of redistilled 4-diethylamino-2-pentanol was added in one portion to a refluxing, stirred suspension of 6.9 g. of sodium in 100 ml. of dry toluene. After three hours the sodium had completely reacted. There was then added, in one portion, 59.4 g. of dry 4,7-dichloroquinoline, and the resulting clear solution was refluxed and stirred for twenty-four hours. The cooled mixture was filtered, and after removal of toluene *in vacuo* the residual oil was dissolved in 400 ml. of cold 4 *N* hydrochloric acid. The clear solution was neutralized to congo red by the addition of solid sodium acetate and extracted twice with ether. The aqueous layer was made strongly basic with 35% sodium hydroxide solution and the precipitated oil taken up in ether. After drying, the ether was removed *in vacuo* and the residual oil distilled up to a bath temperature of 150° at 0.20 mm. to remove the excess of 4-diethylamino-2-pentanol. The residual crude base was converted to the dipicrate by treatment with excess picric acid in alcohol solution.

The dipicrate was reconverted to the base by means of cold 10% hydrochloric acid–ethyl acetate, and after recovery from the hydrochloric acid solution the base was treated in absolute alcohol solution with a slight excess of citric acid monohydrate. The citrate formed rosets of white needles from absolute alcohol–ethyl acetate.

6-Chloro-9-(2-diethylaminoethoxy)-2-methoxyacridine was obtained in good yield in the above manner. A small amount of acridone (insoluble in toluene) also was formed in the reaction. The dried crude product was crystallized twice from Skellysolve B at −20°, forming bright yellow needles, m. p. 60.5–61.5°.

Anal. Calcd. for $C_{20}H_{23}ClN_2O_2$: N, 7.81; Cl, 9.88. Found: N, 7.81; Cl, 9.67.

Summary

There have been described a number of quinolines and acridines substituted by basic side chains linked to the nucleus by oxygen or sulfur. The spectroscopic relation of these compounds to the analogous imino-linked series, and their hydrolytic cleavage has been investigated.

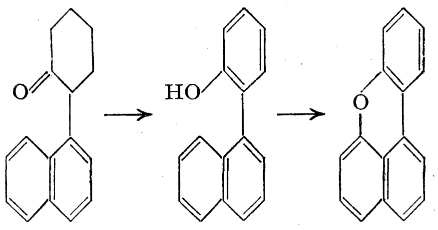
Aromatic Cyclodehydrogenation. VI. Synthesis of Ring Oxygen Compounds[1]

BY MILTON ORCHIN[2]

In an effort to confirm the structure of 2-(1-naphthyl)-cyclohexanone, I, required in another investigation, this compound was dehydrogenated with palladium-on-charcoal in the liquid phase in an attempt to obtain the known 1-phenylnaphthalene. The benzene solution of the product from the reaction fluoresced in ordinary light and showed a brilliant blue fluorescence in ultraviolet light. The strongly fluorescent material was separated by chromatographic adsorption and it was possible to isolate from this fraction a colorless crystalline compound, $C_{16}H_{10}O$, melting point 108°; picrate, deep red needles, melting point 123°. The intense fluorescence of the compound, its melting point and composition, and the color and melting point of its picrate all correspond exactly to the properties of 1,9-benzoxanthene, III, isolated from coal tar by Kruber.[3] Kruber's proof of structure consisted of hydrogenation of the benzo ring followed by oxidative degradation of it to the known xanthone.

The formation of III from I can be explained by presuming the intermediate formation of 2′-hydroxy-1-phenylnaphthalene, II, followed by the unusual loss of hydrogen between the hydroxyl group and position 8 of the naphthalene nucleus

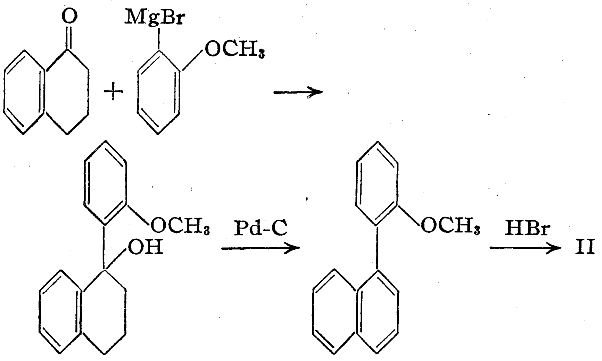


I II III

In order to substantiate this mechanism, 2′-hydroxy-1-phenylnaphthalene, II, was synthesized and treated with palladium-on-charcoal under the same conditions as prevailed in the similar treatment of I. The compound presumed to be 1,9-benzoxanthene, identical with that obtained from I, was isolated from the reaction mixture.

The intramolecular loss of hydrogen between a suitably situated hydroxyl group and an aromatic nucleus presents interesting synthetic possibilities. In an extension of the reaction, *o*-phenylphenol was treated with palladium-on-charcoal and diphenylene oxide was isolated in 8% yield from the products of the reaction. Diphenyl was also present in the products, indicating that the hydrogen liberated in the ring closure was utilized in a hydrogenolysis reaction. When the reaction was carried out in a sealed tube a 14% yield of diphenylene oxide and an 8% yield of diphenyl were obtained.

The synthesis of 2′-hydroxy-1-phenylnaphthalene was achieved by a three-step process, starting with the reaction between *o*-anisylmagnesium bromide and 1-tetralone



IV V

The carbinol, IV, was obtained in 74% yield. One-step dehydration–dehydrogenation with palladium-on-charcoal gave V directly in excellent yield. The over-all yield was not improved by the isolation of the intermediate 1-*o*-anisyl-3,4-dihydronaphthalene. Both the methyl ether, V, and the hydroxy compound, II, formed two different crystalline modifications. II was not extracted from its benzene solution by aqueous alkali.

Experimental[4]

2-(1-Naphthyl)-cyclohexanone, I.—1-Naphthylmagnesium bromide was prepared from 105 g. 1-bromonaphthalene (purified by fractionation), 13 g. magnesium, 200 cc. of dry ether and 350 cc. dry benzene. To this Grignard reagent there was added, with stirring, 66.0 g. of *o*-chlorocyclohexanone.[5] The dropwise addition of the ketone caused a vigorous reaction. After all the ketone was in, the mixture was refluxed for sixteen hours, then poured onto ice and steam distilled. Twenty-nine grams of naphthalene was collected in the distillate. The residue was a tacky red solid. It was taken up in ether, the ether solution washed with hydrochloric acid and water, dried, and the ether evaporated. The residue was distilled and 50 g. of a very viscous oil was collected between 170–240° (1 mm.). Since attempts to obtain crystalline material from this residue were unsuccessful, the mixture was dissolved in alcohol and treated with 25 g. of semicarbazide hydrochloride and 18.3 g. of sodium acetate. From the more soluble fractions of the semicarbazone mixture, 4.86 g. of semicarbazone, m. p. 213–215°, was obtained. To 4.5 g. of this semicarbazone there was added 25 cc. of water and 50 cc. of concentrated hydrochloric acid, and the mixture was refluxed for one hour. The aqueous solu-

tion was decanted from the oil on the sides of the flask, the oil washed with water, and the water decanted completely. The oil was refluxed with benzene, the benzene solution concentrated, and petroleum ether added. On cooling, 3.25 g. of crystalline material, m. p. 81–84°, was obtained. The sample for analysis was crystallized twice from petroleum ether and had melting point 83.5–85.0°. *Anal.*[4a] Calcd. for $C_{16}H_{16}O$: C, 85.7; H, 7.2. Found: C, 85.9; H, 7.2. The semicarbazone of the pure 2-(1-naphthyl)-cyclohexanone was obtained from dioxane-ethanol as a white powder, m. p. 213–215° (put in the bath at 204°). *Anal.*[4a] Calcd. for $C_{17}H_{19}N_3O$: N, 15.8. Found: N, 15.3.

1,9-Benzoxanthene from 2-(1-naphthyl)-cyclohexanone.—A mixture of 1.0 g. of the ketone, I, and 0.1 g. of 30% palladium-on-charcoal[6] was heated at 310–320° for forty minutes and at 325–340° for about twenty minutes. During this time about 133 cc. (N. T. P.) of hydrogen was evolved (1.4 moles of hydrogen per mole compound). The mixture was dissolved in benzene, filtered, and the filtrate extracted with aqueous potassium hydroxide. Acidification of the alkaline extract gave a trace of material which was discarded. The neutral fraction was chromatographed. Two brands were observed in the column. The less strongly adsorbed band fluoresced brilliantly in ultraviolet light; it was separated and eluted with benzene. The benzene was replaced with methanol and on cooling the solution about 60 mg. of colorless needles, m. p. 107–108°, was obtained. Recrystallization from methanol gave fine needles, m. p. 107.4–108.0°. The picrate was crystallized from ethanol and had the melting point 123.0–123.8°. The complex with *s*-trinitrobenzene was obtained as beautiful, brilliant red crystals (from methanol), melting point 147.8–148.4°. *Anal.*[4a] Calcd. for $C_{16}H_{13}N_3O_7$: N, 9.7. Found: N, 10.4. The ultraviolet absorption spectrum[7] of III (Fig. 1), its melting point, the melting points of the picrate and *s*-trinitrobenzene complex, were identical with those of III obtained from II as described below.

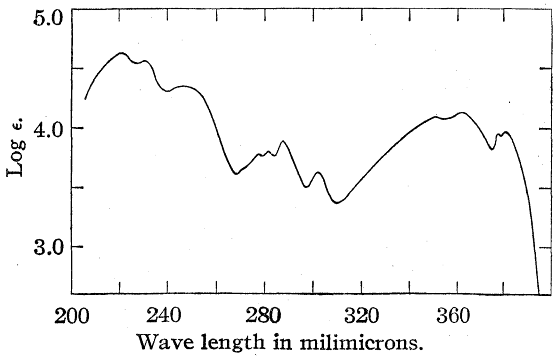

Fig. 1.—Ultraviolet absorption spectrum of 1,9-benzoxanthene.

1-*o*-Anisyl-1-hydroxy-1,2,3,4-tetrahydronaphthalene, IV.—*o*-Anisylmagnesium bromide was prepared in quantitative yield (titration) from 82.2 g. of freshly distilled *o*-anisyl bromide, 12.0 g. of magnesium and 325 cc. of dry ether. To the clear brown-black solution there was added dropwise, with stirring, a solution of 64.0 g. of pure vacuum fractionated 1-tetralone in 150 cc. of dry ether.[8] After all of the tetralone was added the mixture was refluxed for seventeen hours; during this time about 200 cc. of ether was replaced with an equivalent volume of benzene. The mixture was poured onto ice and ammonium chloride. The organic layer was separated, washed well with water and saturated sodium chloride solution, and filtered through sodium sulfate. After removal of most of the solvent *in vacuo*, beautiful colorless crystals separated; these weighed 30.58 g. and melted at 96.0–100.2°. Concentration of the mother liquor gave 47.04 g. of additional carbinol of the same melting point. The mother liquor was evaporated and the residue distilled. The fraction of distillate boiling at 145–160° (2 mm.) was dehydrogenated with sulfur and 4.61 g. of 1-*o*-anisylnaphthalene, V, identical with that prepared below, was obtained. The total yield of carbinol, IV, was thus 74%. The sample of IV taken for analysis was crystallized from petroleum ether and had melting point 98.5–100.0°. *Anal.*[4a] Calcd. for $C_{17}H_{18}O_2$: C, 80.3; H, 7.1; methoxyl, 12.2. Found: C, 80.5; H, 6.9; methoxyl,[9] 12.2.

1-*o*-Anisyl-3,4-dihydronaphthalene.—A mixture of 10 g. of IV and 50 cc. of 90% formic acid was refluxed for one hour. Separation and distillation of the dihydro compound gave 7 g. of a colorless glass, boiling point 160–162° (2–3 mm.), $n^{20}\text{D}$ 1.6265. Scratching caused crystallization and after recrystallization from petroleum ether the compound was obtained as thick, colorless crystals, m. p. 66.6–67.6°. *Anal.*[4a] Calcd. for $C_{17}H_{16}O$: C, 86.4; H, 6.8; methoxyl, 13.4. Found: C, 85.9; H, 6.9; methoxyl,[9] 13.2.

1-*o*-Anisylnaphthalene.—(a) A mixture of 30.0 g. of the carbinol, IV, and 1.0 g. of 30% palladium-on-charcoal[6] was heated with stirring at 240–250° for two hours, and for forty-five minutes at 250–300°. About 2 g. of water distilled from the mixture. The mixture was dissolved in benzene and filtered, and the benzene replaced with alcohol. Concentration of the alcohol solution gave 25.5 g. of colorless crystalline material, m. p. 87–90°. The mother liquor gave 0.3 g. additional material, thus making the total yield of crude material 93.5%. Recrystallization from alcohol gave crystals, m. p. 91.2–92.6°. *Anal.*[4a] Calcd. for $C_{17}H_{14}O$: C, 87.2; H, 6.0; methoxyl, 13.2. Found: C, 86.5; H, 5.9; methoxyl,[9] 13.2. During a recrystallization of this material from petroleum ether it was noted that the crystals appeared different from those previously obtained. These crystals had melting point 98.6–99.8°. When some of the low-melting form was dissolved in ethanol and the solution seeded with the high-melting form, material of melting point 98.6–99.8° was obtained. When the high-melting form was dissolved in ethanol and the solution seeded with the low-melting form, material of melting point 91.2–92.6° was obtained. When the low-melting form was melted and allowed to cool, the melting point of the solidified material was 91.0–98.5°.

(b) A mixture of 2.0 g. of 1-*o*-anisyl-3,4-dihydronaphthalene and 0.2 g. of palladium-on-charcoal[6] was heated at 280–320° for ninety minutes. During this time the theoretical quantity of hydrogen was evolved. Distillation of the mixture gave 1.77 g. of oil which crystallized on standing. Crystallization from benzene–ethanol gave material, m. p. 90.8–92.4°, identical with that obtained from the one step dehydration–dehydrogenation of IV.

2′-Hydroxy-1-phenylnapthalene, II.—A solution of 8.84 g. of V in 250 cc. of acetic acid and 90 cc. of 48% hydrobromic acid was refluxed for five hours. The solution was poured onto ice and the mixture extracted with ether–benzene. The organic layer was washed successively with water, sodium bicarbonate, water, and saturated sodium chloride solution. After drying the solvent was evaporated and the residue distilled to give 7.85 g. (94.5%) of colorless oil, boiling point 163–170° (3 mm.). The oil was crystallized with difficulty by cooling and scratching. On attempted recrystallization the compound separated in beautiful needles from alcohol or petroleum ether, but as soon as the solvent was removed the crystals lost their shape and became semi-fluid. If the resulting sticky material was scratched and allowed to stand, firm crystalline material was again obtained which had melting point 55–60°. A small sample was purified by chromatography on alumina–celite and the pure sample

recrystallized twice from petroleum ether by seeding with previously crystallized material. The final sample had melting point 60–61.5°. *Anal.*[4p] Calcd. for $C_{16}H_{12}O$: C, 87.2; H, 5.5. Found: C, 86.7; H, 5.8.

In one demethylation experiment the benzene solution of the products was extracted with alkali. Acidification of the alkaline extract gave only a small quantity of II; the bulk of II was found in the neutral fraction.

An infrared absorption spectrum showed a strong band in the 2.8 micron region, thus establishing the presence of a hydroxyl group.[7]

1,9-Benzoxanthene from 2′-Hydroxy-1-phenylnaphthalene.—A mixture of 3.0 g. of II and 0.3 g. of palladium-on-charcoal[6] was heated in a nitrogen atmosphere for two hours at 320–350°. The mixture was treated with benzene and filtered. To the concentrated benzene solution there was added 0.7 g. of 2,4,7-trinitrofluorene.[10] On cooling there separated 1.3 g. of dark brown crystals, m. p. 178–190°. Recrystallization from acetic acid gave 1.0 g. of the crystalline complex of 1,9-benzoxanthene and 2,4,7-trinitrofluorenone, m. p. 214.0–214.6°. The complex was dissolved in benzene and the solution poured onto a column of activated alumina. The benzoxanthene was eluted with benzene and the benzene solution evaporated to dryness, leaving 0.41 g. (13.5%) of III. Two crystallizations from ethanol gave the compound in long needles, m. p. 107.5–108.0°. *Anal.*[4p] Calcd. for $C_{16}H_{10}O$: C, 88.1; H, 4.6. Found: C, 87.8; H, 4.6.

Diphenylene Oxide from *o*-Phenylphenol.—A mixture of 5.00 g. of *o*-phenylphenol[11] was heated with 0.5 g. of 30% palladium-on-charcoal catalyst at 285–290° for three hours. The mixture was treated with petroleum ether and filtered. The filtrate was washed with aqueous alkali; acidification of the alkaline extract gave 4.25 g. of recovered phenylphenol. The petroleum ether solution containing the neutral material was dried and chromatographed on a mixture of activated alumina and celite. The components of the mixture were selectively eluted from the column by using mixtures of petroleum ether–benzene containing increasing quantities of benzene; percolate receivers were changed at 100-cc. intervals. The solutions in all receivers were separately evaporated to dryness and the residue, if any, weighed and its melting point determined. The first fractions gave a total of 140 mg. of material, m. p. 66–69°; mixed melting point with diphenyl gave no depression. The later fractions gave a total of 400 mg. (8%) of diphenylene oxide, m. p. 81.5–83.0°; mixed melting point with authentic diphenylene oxide gave no depression. When 5.0 g. of phenylphenol was heated in a sealed tube at 315° for fourteen hours with 0.5 g. of palladium charcoal, a yield of 14% pure diphenylene oxide and 8% diphenyl was obtained. The balance of the material was unconverted phenylphenol.

Summary

Liquid phase treatment of 2-(1-naphthyl)-cyclohexanone with palladium-on-charcoal gave a small yield of a compound whose properties were identical with those reported for 1,9-benzoxanthene. 2′-Hydroxy-1-phenylnaphthalene was probably the intermediate in this conversion since on similar treatment it also gave the compound presumed to be 1,9-benzoxanthene.

o-Phenylphenol when treated with palladium-on-charcoal gave diphenylene oxide. The intramolecular loss of hydrogen between an aromatic hydroxyl group and a suitably situated aromatic nucleus appears to be a general reaction.

1-*o*-Anisylnaphthalene was synthesized in 69% yield in two steps by condensing 1-tetralone with *o*-anisylmagnesium bromide and treating the resulting carbinol with palladium-on-charcoal.

The Preparation of Some 6-Substituted-2-thiouracils[1]

BY MARY JACKMAN, A. J. BERGMAN AND S. ARCHER

Recently Astwood[1a] has shown that certain 6-alkyl- and 6-aralkyl-2-thiouracils, prepared by Anderson and co-workers[2] were powerful goitrogens. In the 6-alkyl-2-thiouracil series maximum activity was reached when the substituents ranged from ethyl through butyl and then dropped off rapidly. The most potent compounds, 6-*n*-propyl-2-thiouracil and 6-benzyl-2-thiouracil (an aralkyl derivative) appeared to be about ten times as active as thiouracil, heretofore considered to be the best antithyroid drug. Astwood screened only one 6-cycloalkyl derivative, namely, 6-cyclohexyl-2-thiouracil, and found that it was equal to thiouracil in effectiveness.

In the course of our work in this field we had occasion to prepare and test some thiouracils joined at the six position, either directly or through an aliphatic chain to alicyclic, heterocyclic and aromatic rings. In addition, 6-methylthiomethyl-2-thiouracil was prepared. The β-keto esters required for condensation with thiourea were prepared by one of the methods given below, depending upon the availability of the starting materials.

$$\mathrm{RCOOC_2H_5 + CH_3COOC_2H_5 \xrightarrow{NaOC_2H_5} RCOCH_2COOC_2H_5} \quad \text{(A)}$$

$$\mathrm{RCOCl + CH_3COCHNaCOOC_2H_5 \longrightarrow RCOCH(COCH_3)\,COOC_2H_5 \xrightarrow{NH_3} RCOCH_2COOC_2H_5} \quad \text{(B)}$$

$$\mathrm{RCOCH_3 + (C_2H_5)_2CO_3 \xrightarrow{NaNH_2} RCOCH_2COOC_2H_5} \quad \text{(C)}$$

Ethyl furoylacetate[3] and ethyl nicotinoylacetate[4] were prepared according to method A and then condensed with thiourea to form the corresponding

Methylthiomethyl	B[c]	12	142–150	29	47.70	6.87	48.05	7.06

[a] The yield of keto ester when prepared by method B was 24%. Both esters yielded identical thiouracils. [b] The required acids were prepared from ethyl phenylmalonate using the appropriate iodide as the alkylating agent, thus

$$C_6H_5CH(COOC_2H_5)_2 + RI \longrightarrow C_6H_5CR(COOC_2H_5)_2 \longrightarrow C_6H_5CR(COOH)_2 \longrightarrow C_6H_5C(R)COOH$$

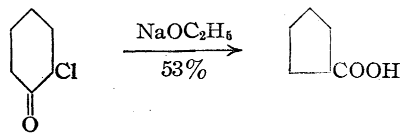
[c] The acid chloride was prepared according to the equations

$$HSCH_3COOH \longrightarrow CH_3SCH_2COOH \longrightarrow CH_3SCH_2COCl$$

thiouracils. It was hoped that a water-soluble thiouracil would prove to be active. Accordingly, 6-(3-pyridyl)-2-thiouracil was converted to the hydrochloride and tested as such. However, it was found that this substance was devoid of any antithyroid action.

With one exception, all of the other β-keto esters were prepared according to equation B. The method used was a slight modification of previously described procedures.[2,5] Whenever a water-insoluble amide was expected as a by-product in the ammonolysis step, the reaction mixtures were concentrated and the residues taken up in petroleum ether to effect a separation of the keto esters from solid material.

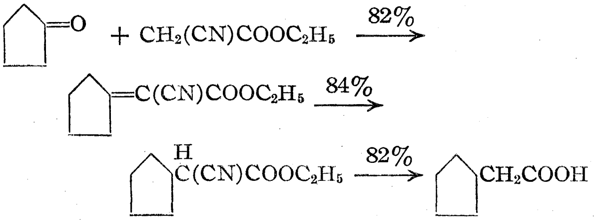
Cyclopentanecarboxylic acid was prepared conveniently from chlorocyclohexanone and sodium ethoxide, a reaction first described by Favorski.[6] The acid fraction obtained from the action of two moles of the base on one of the chloro-ketone was practically pure cyclopentanecarboxylic acid. The neutral fraction appeared to be a complex mixture and was not examined further. The next higher homolog was prepared by a three-stage synthesis from cyclopentanone in over-all yields of 57%.



---

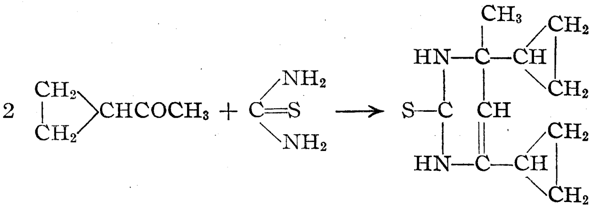
(5) Archer and Pratt, THIS JOURNAL, **66**, 1656 (1944).

(6) Favorski, *Chem. Zentr.*, **86**, I, 984 (1915).



Ethyl β-cyclopropyl-β-ketopropionate was prepared according to method B in 24% over-all yield based on the acid chloride. The carbethoxylation of cyclopropyl methyl ketone in the presence of sodium amide proved to be a more convenient synthesis since the yield in this one step method was 57%. Cyclopropyl methyl ketone condensed readily with ethyl oxalate to form the corresponding glyoxalate which, however, proved to be resistant to decarbonylation in the presence of iron and powdered soft glass.

In one experiment in which an impure sample of ethyl β-cyclopropyl-β-ketopropionate was used in the preparation of the thiouracil, an alkali-insoluble by-product separated when the reaction mixture was poured into water. This substance, m.p. 204–206°, was recovered unchanged after refluxing in either acid or basic media. We suggest that the compound is the thiotetrahydropyrimidine (I) since it could be prepared from cyclopropyl methyl ketone and thiourea in sodium ethylate solution.



I

This is in accord with the observations of Folkers and Johnson[7] who found that the major product arising from the interaction of acetophenone and urea was 4,6-diphenyl-4-methyl-2-oxotetrahydropyrimidine. This compound was also quite stable to the usual hydrolytic agents. Thiourea and acetophenone behaved similarly.[8] We are inclined to believe that (I) was formed from the ketone present as an impurity present in the keto-ester, since it was not encountered when pure ester was used in the preparation of 6-cyclopropyl-2-thiouracil.

Experimental[9]

Ethyl β-Cyclopropyl-β-ketopropionate.—To a stirred suspension of finely divided sodium amide (23.4 g.) in 150 ml. of dry ether cooled in an ice-bath there was added 25.2 g. of cyclopropyl methyl ketone. The mixture was then gently refluxed for one-half hour, cooled, and 70.8 g. of ethyl carbonate was added dropwise. The mixture was then refluxed for two hours, cooled and alcohol added to destroy excess sodium amide. The solution was added to 500 g. of ice and acidified to congo red. The organic layer was separated and the aqueous part extracted three times with ether. The combined ethereal extracts were washed with water, dilute sodium carbonate solution, again with water and then dried. After removal of the ether and a forerun consisting largely of ethyl carbonate the keto-ester was collected at 97.5–101° (11 mm.), 27 g. (57%). On redistillation almost all was collected at 99–101° (11 mm.).

Ethyl γ-Cyclopropyl-α,γ-diketobutyrate.—A mixture of 73 g. of ethyl oxalate and 42 g. of cyclopropyl methyl ketone was added dropwise to a solution of 11.5 g. of sodium in 150 ml. of absolute alcohol while the temperature was maintained below 40°. A yellow solid separated during the course of the reaction and after stirring for three hours the mixture was allowed to stand overnight. The pasty mass was added to 1.5 liters of water and the suspension was acidified with dilute sulfuric acid. When all the solid had disappeared the oil was drawn off and the aqueous layer then extracted with benzene. The combined organic layers were concentrated and the residue distilled at reduced pressure. Fifty grams of glyoxalate was collected at 149–154° (23 mm.) (55%). A fraction of b. p. 149° (23 mm.) was analyzed.

Anal. Calcd. for $C_9H_{12}O_4$: C, 58.69; H, 6.57. Found: C, 58.59; H, 6.42.

6-Cyclopropyl-2-thiouracil.—After 131 g. of thiourea had dissolved in a stirred, boiling solution of 56.7 g. of sodium in 1225 ml. of absolute ethanol, 192 g. of *crude* ethyl β-cyclopropyl-β-ketopropionate was added dropwise in the course of one hour. Heating and stirring were continued overnight. Most of the alcohol was then removed and the residue added to 3 liters of water. The insoluble fraction was removed by filtration and the clear filtrate acidified to *p*H 3. The solid that separated was collected and crystallized from boiling water, wt. 97 g. (42%), m. p. 234–235° (cor.).

The alkali-insoluble fraction which weighed 14 g. was crystallized from alcohol twice; m. p. 204–206°. The melting point was not depressed when mixed with the compound described below.

Anal. Calcd. for $C_{11}H_{16}N_2S$: C, 63.43; H, 7.74; N, 13.45. Found: C, 63.51, 63.33; H, 7.97, 7.86; N, 13.26.

4,6-Dicyclopropyl-4-methyl-2-thiotetrahydropyrimidine.—A solution of 9.2 g. of sodium, 15.2 g. of thiourea and 32.8 g. of cyclopropyl methyl ketone in 200 ml. of ethanol was refluxed for three and one-half hours before being poured into 2 liters of water. The solid was filtered and recrystallized several times from ethanol, m. p. 207–208.2° (cor.).

Anal. Calcd. for $C_{11}H_{16}N_2S$: N, 13.45; S, 15.39. Found: N, 13.20; S, 15.38.

Cyclopentanecarboxylic Acid.—To a stirred solution of 83 g. of sodium in 2 liters of absolute alcohol there was added dropwise 240.5 g. of chlorocyclohexanone[10] over a period of several hours. The mixture was left overnight before the alcohol was removed on the steam-bath and replaced by an equal volume of water. The aqueous solution was extracted with ether and then acidified to *p*H 3. The oily acid that separated was gathered in ether, washed with water, dried over sodium sulfate and distilled. The acid boiled at 120–123° (27 mm.), wt. 110 g. (53%).

Ethyl Cyclopentylidenecyanoacetate.—A solution of 56.5 g. of ethyl cyanoacetate, 50.5 g. of cyclopentanone, 3.85 g. of ammonium acetate and 6 g. of acetic acid in 50 ml. of dry benzene was refluxed in an apparatus described by Cope[11] until the formation of water was complete. The mixture was cooled, extracted thoroughly with water and distilled to yield 72.3 g. (82%) of the unsaturated ester, b. p. 152–156° (18 mm.). The compound which

solidified on cooling was recrystallized from petroleum ether, m. p. 55–57°.

Anal. Calcd. for $C_{10}H_{13}NO_2$: N, 7.82. Found: N, 7.54.

Cyclopentylacetic Acid.—When 17.9 g. of the above ester was reduced with the aid of Adams catalyst, there was obtained 15 g. of the saturated cyanoacetate. The ester (81 g.) was added dropwise with stirring to a boiling solution of 110 g. of potassium hydroxide in 130 ml. of water. The mixture was heated for six hours, cooled and acidified. The resulting di-acid was taken up in ether, washed with water and dried over sodium sulfate. The ether was removed and the residue heated to effect decarboxylation. The cyclopentylacetic acid was collected at 135–137° (27 mm.), yield, 47 g. (82%).

Summary

1. Twelve new 6-substituted thiouracils and their antithyroid activities are presented. Of the group 6-cyclopropyl-2-thiouracil and 6-cyclohexylmethyl-2-thiouracil appear to be the most interesting pharmacologically.

2. Ten new β-keto esters are described.

3. Convenient syntheses of cyclopentylacetic acid, cyclopentanecarboxylic acid and ethyl β-cyclopropyl-β-ketopropionate are reported.

4. A by-product formed in the reaction between crude ethyl β-cyclopropyl-β-ketopropionate and thiourea is shown to be 4,6-dicyclopropyl-2-thioketohydropyrimidine by an independent synthesis.

The Synthesis of Some 6-Substituted-2-thiouracils[1]

BY WILBUR H. MILLER, ALICE M. DESSERT AND GEORGE W. ANDERSON

The synthesis of 5- and 6-substituted-2-thiouracils from β-oxoesters and thiourea has been reported recently by Anderson, *et al.*[2] These compounds were evaluated in rats as antithyroid drugs[3] and several were found to be more active than the parent compound, 2-thiouracil, which has been used extensively for the treatment of hyperthyroidism in man.[4] In this paper several new 6-substituted-2-thiouracils are described. Some are closely related to the more active compounds previously reported.[2] Others are of new types in which various heterocycles are used as substituents.

These thiouracils have been prepared by condensing thiourea with the appropriate β-oxoester. For the preparation of most of these esters the *t*-butyl malonate method was used.[5] In several cases the acyl derivative of diethyl malonate was isolated along with the β-oxoester and these compounds are described in Table I. The acid chlorides were prepared in good yield using the appropriate acid and benzoyl chloride[6] or thionyl chloride.

Ethyl β-oxo-γ-(*p*-nitrophenyl)-butyrate was readily prepared by the acetoacetic ester method (ref. 2, Method A), but only a 28% yield in one of three attempts was obtained by the *t*-butyl malonate method. In the two unsuccessful experiments after adding *p*-toluenesulfonic acid large amounts of *p*-nitrophenylacetic acid were formed, apparently by decomposition of its *t*-butyl ester. Subsequent experiments showed that this ester was readily decomposed to the acid by *p*-toluenesulfonic acid in benzene, whereas the ethyl ester was stable. The β-oxoester on reaction with thiourea gave a product which could not be purified.

When ethyl β-oxo-β-(3-pyridyl)-propionate was prepared by the *t*-butyl malonate method the yield was low (14%) and appreciable quantities of an unidentified by-product (m. p. 161.5–162.5°) were obtained. This β-oxoester was obtained much more easily by the reaction between ethyl nicotinate and ethyl acetate[7] (25%).

When ethyl β-oxo-β-mesitylpropionate reacted with thiourea the thiouracil was not obtained and 75% of β-oxoester was recovered unchanged. The condensation for thiouracil formation perhaps occurs stepwise as in pyrazolone formation,[8] first by elimination of water from the β-oxoester and thiourea followed by a splitting out of alcohol from the intermediate compound. The two methyl groups *ortho* to the carbonyl in the mesityl portion of the ester may interfere at the first stage of the condensation either sterically or by reducing the activity of the ester through inductive effects.

The unsaturated β-oxoesters, ethyl 3-oxo-4-hexenoate, ethyl cinnamoylacetate and ethyl 3-oxo-5-hexenoate, yielded no definite product on the attempted reaction with thiourea. The last, prepared from allylmagnesium bromide and ethyl cyanoacetate, was not a pure product although it boiled over a very narrow range (Table I). When this product reacted with thiourea a 46% crude yield of 6-amino-2-thiouracil was obtained indicating the presence of ethyl cyanoacetate. No other thiouracil was found. The unsaturated esters were considered to be unstable under the usual

The two analyses are indicated in this case because of the variance from theory.

conditions for the condensation reaction. Even at room temperature for twenty-four hours using ethyl 3-oxo-4-hexenoate no definite compound could be isolated although satisfactory yields of 6-*n*-butyl-2-thiouracil were obtained with ethyl β-oxoenanthate.

Of the twelve new 6-substituted-2-thiouracils shown in Table II three show greater antithyroid activity than 2-thiouracil in rats, but only 6-α-ethylpropyl-2-thiouracil shows sufficient activity to be considered promising for the treatment of hyperthyroidism. While its activity is less than those reported for the 6-*n*-propyl- and 6-benzyl-2-thiouracils,[3] it is over five times as active as the isomeric *n*-amyl compound. The specificity of the benzyl compound is great since it is about ten

Kuck, to whom we are indebted for these data. [c] Prepared from ethyl-β-oxo-β-trifluoromethylpropionate, b. p. 47–49° at 25 mm., obtained in 83% yield by method of Swarts, *Bull. Acad. Belgique*, **5**, 12 (1926). [d] Reported also in THIS JOURNAL, **70**, 497 (1948), by Jackman, Bergman and Archer of the Sterling-Winthrop Research Institute. [e] From β-oxoesters supplied through the courtesy of Dr. A. Weissberger of Eastman Kodak Company. [f] Prepared from ethyl β-oxo-β-(2-furyl)-propionate, b. p. 139–140° at 12 mm., obtained in 48% yield by method of Barger, Robinson and Smith, *J. Chem. Soc.*, 721 (1937). [g] 20% based on ester used since 22% of β-oxoester recovered unchanged.

times as active as the 6-phenyl- and the 6-phenethyl-2-thiouracils[2,3] and since substituents in the benzyl reduce the activity markedly (Table II). The discrepancy between the activities of the 6-(2-thenyl)- and the 6-benzyl compounds also is greater than expected from a similar comparison of compounds with other physiological activity.[9] Theories about these variations could be put forth on a much more valid basis if more were known about the blood concentrations of the various compounds.

Experimental

Acid chlorides were prepared in most cases using 1.5 moles of thionyl chloride for each mole of acid. The mixture was refluxed for four and one-half hours on a steam-bath in a flask with a condenser protected by a Drierite tube. Excess thionyl chloride was distilled *in vacuo* and then the product was fractionated: α-ethylbutyryl chloride,[10] b. p. 138–142° (80%); α-phenylbutyryl chloride,[11] b. p. 111–114° (15 mm.) (88%); *p*-isopropylphenylacetyl chloride,[12] b. p. 107–110° (5 mm.) (86%); *p*-chlorophenylacetyl chloride,[13] b. p. 127–129° (15 mm.) (91%); *m*-chlorobenzoyl chloride,[14] b. p. 104–106° (14 mm.) (91%); 2-thienylacetyl chloride,[12,15] b. p., 62–65° (3 mm.) (70%); *p*-nitrophenylacetyl chloride,[16] m. p. 47–48° cor. (54%); nicotinyl chloride,[17] b. p. 89–91° (15 mm.) (84%). Prepared using the benzoyl chloride method[6] without modification were: methoxyacetyl chloride,[18] b. p. 112–113° (57%); crotonyl chloride,[6] b. p. 120–122.5° (51%); and acrylyl chloride,[19] b. p. 73–74° (72%).

β-Oxoesters for the most part were prepared by Method B, Ref. 5. The difficulties encountered for two of the esters have been described above. A combination procedure was necessary in a third preparation, that of **ethyl β-oxo-γ-(2-thienyl)-butyrate** as indicated in Table I. In this case after adding *p*-toluenesulfonic acid only a little gas was evolved. The product was worked up and vacuum distilled. At this point it was shown that the batch of *t*-butylmalonate which had been used contained much diethyl malonate. Consequently our distillate was treated according to the Riegel–Lilienfeld method (Table I, *a*) for the decomposition of acylated malonic esters by heating with β-naphthalenesulfonic acid. Based on 2-thienylacetyl chloride an over-all yield of 22% of β-oxoester was obtained. The 2-thienylacetyl derivative of diethylmalonate was also isolated.

***t*-Butyl *p*-Nitrophenylacetate.**—In order to test the reactivity of this compound toward *p*-toluene sulfonic acid, it was prepared according to the general method for the preparation of *t*-butyl esters.[20] The product was a olid, and after two recrystallizations from alcohol, 7.1 g. or 30% yield, m. p. 37–38° cor., was obtained.

Anal. Calcd. C, 60.8; H, 6.4; N, 5.9. Found: C, 59.0; H, 6.4; N, 5.8.

One gram of *t*-butyl *p*-nitrophenylacetate, 1.4 cc. of benzene and 0.02 g. of *p*-toluenesulfonic acid monohydrate (Eastman Kodak Co.) were heated together under reflux and the gas evolved collected over water. After making correction for the blank 108 cc. of gas was obtained. Theory for isobutylene was 95 cc. The gas decolorized bromine water. *p*-Nitrophenylacetic acid, m. p. 150–154°, was recovered in 88% of the theoretical amount. When ethyl *p*-nitrophenylacetate, m. p. 64°,[21] was treated similarly it was recovered unchanged.

Thiouracils were prepared as described previously.[2] Those 6-substituted-2-thiouracils purified by recrystallization from water and the parts of boiling water required to dissolve them (crude) were: 6-trifluoromethyl, 50; 6-α-ethylpropyl, 200; and 6-methoxymethyl (after hot extraction with alcohol), 50. Those recrystallized from glacial acetic acid and the cc. per g. (crude product) were: 6-α-phenyl, 20; 6-*p*-chlorobenzyl, 100; 6-*m*-chlorophenyl, 20. Those purified by hot extraction with alcohol and then recrystallized from glacial acetic acid (cc. per g. of product) were: 6-(*p*-methoxyphenyl), 14; 6-(*m*-methoxyphenyl), 75; 6-(2-furyl), 50; 6-(2-thenyl), tarry product removed by alcohol extraction and discarded, residue recrystallized from 20 cc. acid per g. of resulting product. By carefully acidifying to *p*H 4 a solution of the sodium salt and extracting this residue with acetone 6-(3-pyridyl) was obtained and the resulting product was recrystallized from cellosolve, 75 cc. per g. The 6-(*p*-isopropylbenzyl) was purified by several hot extractions[2] with alcohol in which it is moderately soluble.

Acknowledgment.—We are indebted to Dr. R. O. Roblin, Jr., of these Laboratories for advice and suggestions and to Dr. E. B. Astwood, Joseph H. Pratt Diagnostic Hospital, Boston, Massachusetts, for suggestions and for the data on antithyroid activity.

Summary

1. The syntheses of several new 6-substituted-2-thiouracils and of several new β-oxoesters have been carried out. Certain of the β-oxoesters prepared could not be converted to thiouracils and the implications are considered.

2. The antithyroid activities of the new compounds varied widely. While several of the compounds were more active in rats than 2-thiouracil, only 6-α-ethylpropyl-2-thiouracil approaches the activity of the best compounds reported previously.

The Reaction of Pyrrolealdehyde with Rhodanine and Hydantoin[1]

BY WERNER HERZ[2] AND KARL DITTMER

In attempts to prepare β-2-pyrrolealanine, 2-pyrrolealdehyde was condensed with compounds containing active methylene groups. Unexpected products were obtained from the reaction of 2-pyrrolealdehyde with diketopiperazine and 2-acetyl-3-thiohydantoin. To elucidate the structures of these products will require further investigation. Likewise, the reaction of the aldehyde with hippuric acid appears to be more complex than reported.[3] Rhodanine and hydantoin, however, condensed with pyrrolealdehyde to give the expected compounds.

We wish to report at this time the reaction of 2-pyrrolealdehyde with rhodanine and hydantoin, and the hydrolysis of pyrrolalrhodanine to 2-pyrrolethiopyruvic acid. The reaction of 2-pyrrolealdehyde with hydantoin in acetic anhydride in the presence of sodium acetate gave a very small yield of what is believed to be pyrrolalacetylhydantoin. An analogous product was obtained by Barger and Easson[4] in the synthesis of β-2-thienylalanine.

Experimental

2-Pyrrolalrhodanine.—A finely ground mixture of 7 g. of pyrrolealdehyde,[5] 10 g. of rhodanine and 7 g. of anhydrous sodium acetate was refluxed with 40 ml. of glacial acetic acid for twenty minutes. It was cooled and filtered; the reddish-brown product was thoroughly washed with water to remove acetic acid. Dilution of the filtrate with water produced more pyrrolalrhodanine. The combined material was recrystallized from alcohol; by working up the mother liquors, a total of 6.5 g. (42%) was obtained, m. p. 286° on a Dennis melting point bar. The ochre plates were soluble in ethanol, acetone, ethyl acetate, partially soluble in ether, benzene and carbon tetrachloride and insoluble in water.

Anal. Calcd. for $C_8H_8N_2OS_2$: N, 13.32. Found: N, 13.11.

2-Pyrrolethiopyruvic acid.—Six grams of the preceding compound was powdered and suspended in 120 ml. of water containing 30 g. of barium hydroxide. The mixture was heated on the steam-bath until solution of the red material was complete. The solution was filtered and the filtrate cooled in an ice-bath. It was then carefully neutralized with dilute hydrochloric acid until precipitation was complete. The yellow product was filtered, washed with water and dried in a vacuum desiccator. The yield was 3.5 g., m. p. 130° (dec.). When exposed to air it decomposed rapidly. Attempts to recrystallize or reprecipitate it were unsuccessful, so that the crude material was used for the analysis.

Anal. Calcd. for $C_7H_7NO_2S$: N, 8.28; neut. equiv., 169. Found: N, 9.05; neut. equiv., 175–180.

The neutral equivalent could not be determined with accuracy because of the color of the solution.

Reaction of 2-Pyrrolealdehyde with Hydantoin.—A finely ground mixture of 1.7 g. of pyrrolealdehyde, 1.7 g. of hydantoin, and 1.7 g. of anhydrous sodium acetate was refluxed with 10 ml. of acetic anhydride for two and one-half hours. After cooling and extracting with water, a blackish-green residue remained. It was extracted with 50 ml. and again with 25 ml. of hot ethanol. The combined ethanol extracts, which showed a violet fluorescence, were treated with charcoal, evaporated to 25 ml., again treated with charcoal and evaporated to a volume of 15 ml. On chilling, 0.13 g. of light-green needles, m. p. 184–185°, separated. The compound was partially soluble in ether and cold ethanol and soluble in hot ethanol, water and acetic acid. The product imparted a violet fluorescence to its solutions.

Anal. Calcd. for $C_{10}H_9N_3O_3$: N, 19.17. Found: N, 19.18.

Fusion of the aldehyde, hydantoin and sodium acetate by the method of du Vigneaud and co-workers[6] at various temperatures resulted in tars only. Pyrrolealdehyde heated with hydantoin in absolute ethanol in the presence of catalytic amounts of methylamine hydrochloride and sodium carbonate led to tarry materials and recovery of unreacted hydantoin. When equivalent amounts of aldehyde and hydantoin in piperidine were heated at reflux for two minutes only unidentified compounds were isolated.

Alkylation of Substituted Malonic and Cyanoacetic Esters with 2-Diamethylaminomethylpyrrole. A Proposed Synthesis of β-2-Pyrrolealanine[1]

BY WERNER HERZ,[2] KARL DITTMER AND STANLEY J. CRISTOL

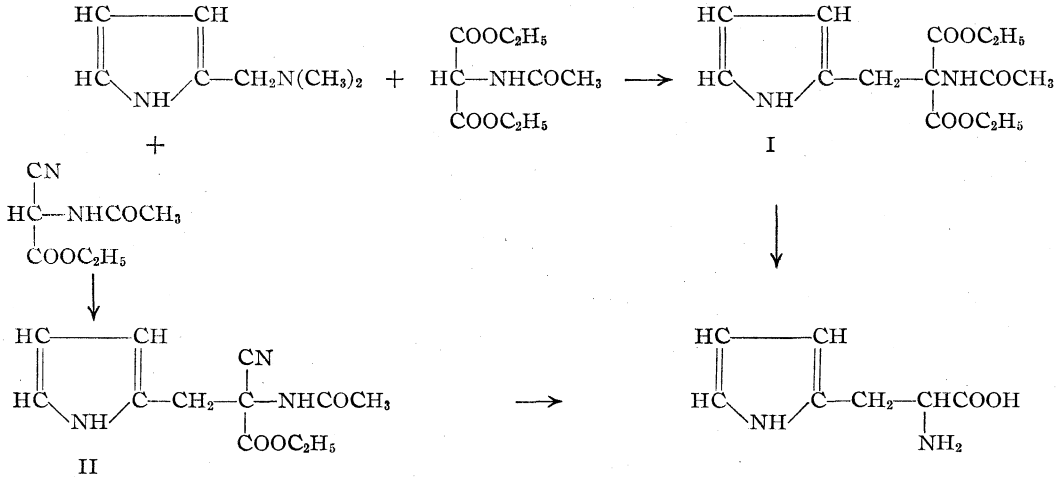
β-2-Thienylalanine[3,4,5] and β-2-furylalanine[6] have been shown to inhibit microbial growth, presumably due to their structural similarity to phenylalanine. The corresponding nitrogen analog, β-2-pyrrolealanine, is not described in the literature. As part of a program to correlate the structure of amino acids with their biological activity, it seemed desirable to prepare this substance so that it might be available for microbiological study.

Attempts to synthesize β-2-pyrrolealanine by condensation of 2-pyrrolealdehyde with compounds containing active methylene groups[7] were abandoned when adaptation of recently-developed methods for the synthesis of tryptophan[8,9,10] appeared more promising.

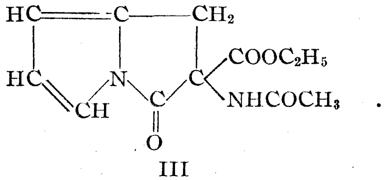
The present paper describes the use of 2-dimethylaminomethylpyrrole[11] in alkylation reactions with ethyl malonate, ethyl cyanoacetate, ethyl acetamidomalonate, ethyl acetamidocyanoacetate, and ethyl phthalimidomalonate and hydrolysis experiments of such of these products as were intermediates for the projected synthesis.

Pure β-2-pyrrolealanine could not be isolated, but fractions containing it were obtained. The amino acid was characterized by its phenylurea derivative. These fractions showed strong inhibition of growth of certain microörganisms, and this inhibition was found to be reversed by phenylalanine.

Alkylation with Dimethylaminomethylpyrrole.—The scheme outlined for the preparation of β-2-pyrrolealanine was



Howe and co-workers[10] alkylated ethyl acetamidomalonate with gramine (dimethylaminomethylindole) by heating these reagents in refluxing toluene or xylene in the presence of catalytic amounts of solid sodium hydroxide. Substitution of dimethylaminomethylpyrrole for gramine, however, did not lead to the expected product (I). On cooling the reaction mixture, there was obtained a substance in 70–80% yield, which has the correct molecular weight and analysis for structure (III).



III

Lactams of this type from substituted pyrroleacrylic and pyrrolepropionic acids have been reported.[12,13]

Under the same conditions, attempted alkylation of ethyl cyanoacetate and ethyl cyanoacetamidoacetate produced much decomposition and yielded dark oils and tars on evaporation of the

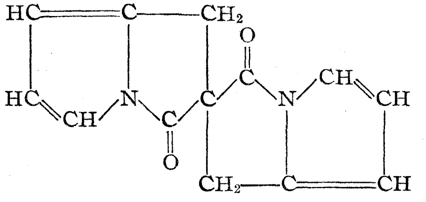
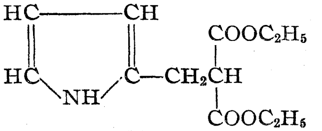
solvents which probably contained some of the condensation products but were not investigated due to the difficulties of purification. The alkylation of malonic ester produced, in addition to some oil, a small amount of white solid for which structure IV is suggested, such a compound arising by di-alkylation of malonic ester and lactam formation.



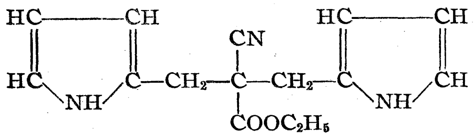
IV

In an effort to avoid lactam formation with ethyl acetamidomalonate and to obtain purer products with the other esters, use was made of an earlier procedure[8,14] which employed a quaternary salt of the tertiary amine, usually the methiodide, as alkylating agent and an inert solvent such as dioxane or dibutyl ether. Under these conditions, dimethylaminomethylpyrrole methiodide and ethyl acetamidomalonate also gave the lactam (III), though in lower yield, while malonic ester and ethyl cyanoacetamidoacetate gave dark uncharacterized oils.

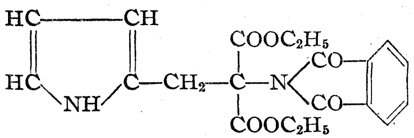
Albertson and co-workers[9] obtained the expected intermediate in the synthesis of tryptophan by the use of cold absolute ethanol as solvent for gramine and the malonate through the slow addition of dimethyl sulfate which served to quaternize the amine. Under similar conditions (I) was obtained from dimethylaminomethylpyrrole and ethyl acetamidomalonate in 85–95% yield. In the same fashion, using ethyl cyanoacetamidoacetate, (II) was formed in 90% yield. Alkylation of malonic ester produced an oil which was identified as (V) by conversion to the diamide. Ethyl cyanoacetate and ethyl phthalimidomalonate also could be alkylated; from the former the product (VI) in which both active hydrogen atoms were replaced by 2-pyrrole-methyl radicals was isolated and identified as the amide, while the yield of pure crystalline material (VII) from the phthalimidomalonic ester condensation was very low. An attempt to alkylate hydantoin by this method failed.



V



VI



VII

Hydrolysis to β-2-Pyrrolealanine.—Early attempts to prepare β-2-pyrrolealanine by the basic hydrolysis of some of the compounds described in the preceding paragraphs made use of the lactam (III) before its structure had been recognized. These efforts were not successful. On the other hand, sodium hydroxide hydrolysis of (I), followed by hydrolysis in neutral and again in basic solution, produced a mixture which on neutralization gave a strong ninhydrin test, although neither of the two possible intermediates, 2-pyrrolemethylacetoamidomalonic acid and the acetyl derivative of pyrrolealanine, separated in the course of the hydrolysis. Evaporation *in vacuo*, extraction with absolute ethanol and dilution with acetone or anhydrous ether gave fractions which were identical with the material obtained by the hydrolysis of (II).

The latter compound, because of greater convenience, was employed in preference to the acetamidomalonate. Hydrolysis with sodium hydroxide ranging in concentration from 10–25%, neutralization and evaporation *in vacuo* produced partially organic material which gave a positive Ehrlich and ninhydrin test. It inhibited the growth of *S. cerevisiae* and *E. coli* and was reversed by phenylalanine.

By the action of phenyl isocyanate on this material there was obtained a well-defined crystalline compound whose neutral equivalent, analysis and chemical properties agreed with those expected of the phenylurea derivative of β-2-pyrrolealanine. This derivative showed little inhibitory activity, but hydrolysis with barium hydroxide in an autoclave at 120° regenerated the activity. Attempts to obtain pure pyrrolealanine by evaporation of the phenylurea hydrolysate *in vacuo* yielded colored material which quickly decomposed but still produced some inhibition.

These results left little doubt that the original crude material contained some pyrrolealanine contaminated primarily with inorganic salts. So far, however, we have failed in all our attempts to isolate pure pyrrolealanine by precipitation from water with organic solvents and salts, or by the formation of derivatives such as the benzoyl, naphthylurea, naphthalenesulfonamide and the carbobenzoxy derivatives.

Experimental

Dimethylaminomethylpyrrole Methiodide.—Eleven and one-half grams of dimethylaminomethylpyrrole[11] was dissolved in 75 ml. of absolute ethanol and treated with 15 g. of methyl iodide in the course of fifteen minutes. Heat was developed and a precipitate appeared. Since discoloration occurred when the flask was allowed to remain in the light, it was kept in the dark at room tem-

---

[14] Snyder, Smith and Stewart, This Journal, **66**, 200 (1944).

perature for two hours and then placed in the refrigerator. The yield of pink dimethylaminomethylpyrrole methiodide, which decomposed in air and became black above 160°, averaged 17–18 g. (63–68%).

Reaction of Dimethylaminomethylpyrrole with Ethyl Acetamidomalonate. (A) In Toluene.—Sixty ml. of toluene or xylene containing 1 g. of powdered sodium hydroxide was heated to boiling in a flask fitted with nitrogen inlet, stirrer and condenser. Then 9.3 g. of dimethylaminomethylpyrrole and 16.2 g. of ethyl acetamidomalonate were added and the mixture was refluxed in an atmosphere of nitrogen with stirring for two hours. During this time the color of the solution became dark red. The mixture was filtered by means of a preheated funnel and cooled. The yield of beige-colored material was 13–15 g. (70–80%). Recrystallization from hot water gave compound (III) as white needles, m. p. 151°, which gave a positive Ehrlich test and was soluble in ethanol, hot water, methanol and chloroform, partially soluble in ether, and insoluble in cold water.

Anal.[15] Calcd. for $C_{12}H_{14}N_2O_4$: C, 57.59; H, 5.64; N, 11.19; mol. wt., 250. Found: C, 57.59; H, 5.57; N, 11.05; mol. wt. (Rast), 259.

(B) **In Dioxane, Using the Methiodide.**—By following the procedure of Snyder and Smith,[8] 6.6 g. of dark-colored product was obtained from 11.3 g. of ethyl acetamidomalonate and 13.2 g. of dimethylaminomethylpyrrole methiodide after partial removal of the solvent and dilution with water. It was purified by recrystallizing from an ethanol–water mixture and again from 15% ethanol. M. p. of the white crystals was 147°, mixed m. p. with the material from (A), 151°.

(C) **In Absolute Ethanol with Methyl Sulfate.**—In a flask fitted with a stirrer, condenser and a dropping funnel were placed 100 ml. of absolute ethanol and 1.72 g. of clean sodium. After all the sodium had dissolved, 16.2 g. of ethyl acetamidomalonate and then 9.3 g. of dimethylaminomethylpyrrole were added. While the flask was cooled in an ice-bath and the mixture was stirred, 15.8 g. of methyl sulfate was added dropwise at such a rate that the temperature did not exceed 35°. After completion of the addition, the mixture was stirred for one hour and allowed to stand at room temperature overnight. The alcohol was evaporated *in vacuo;* the residue was diluted with 200 ml. of water and chilled. 21 g. (94%) of slightly-colored product separated. It was purified by dissolving in a little acetone, treating with charcoal, filtering, chilling, diluting with ice water and keeping in the refrigerator overnight. The shiny white platelets of compound (I) melted at 91° and were soluble in ethanol, acetone and hot water.

Anal. Calcd. for $C_{14}H_{20}N_2O_5$: N, 9.46. Found: N, 9.45.

Reaction of Dimethylaminomethylpyrrole with Ethyl Malonate.—Following procedure (A), 8.2 g. of malonic ester was allowed to react with 6.2 g. of dimethylaminomethylpyrrole in boiling toluene. No crystals separated from the cooled reaction mixture. Removal of the solvent gave a red oil which did not crystallize. Trituration with 50 ml. of ethanol caused most of the oil to dissolve; 0.5 g. of white solid remained undissolved. It gave a positive Ehrlich test and was recrystallized from a very small amount of benzene. The white crystals of (IV), m. p. 157°, were soluble in chloroform, methanol, hot benzene and hot alkali, and sparingly soluble in water and cold benzene.

Anal. Calcd. for $C_{13}H_{10}N_2O_2$: C, 69.02; H, 4.43; N, 12.38; mol. wt., 226. Found: C, 68.85; H, 4.74; N, 12.08; mol. wt. (Rast), 228.

Hydrolysis of the alcohol solution of the oil with ethanolic potassium hydroxide gave a very impure organic acid which decomposed rapidly.

Following procedure (C), 12 g. of ethyl malonate was alkylated with 9.3 g. of dimethylaminomethylpyrrole. The oil obtained on dilution of the alcohol residue with water was extracted with two 25-ml. portions of ether. The dried ether extracts were distilled in a vacuum. After some unreacted malonic ester and dimethylaminomethylpyrrole had been collected, the temperature rapidly rose to 180°; 6 g. (33%) of (V), boiling at 184–187° (17 mm.) and somewhat colored, was obtained as a viscous oil.

The product was treated with ten times its volume of concentrated ammonium hydroxide, shaken and allowed to stand for a few days. The diamide derivative of (V) separated in 60% yield in long needles and was recrystallized from a little ethanol. It melted at 202° with previous darkening above 195°, gave a positive Ehrlich test and was soluble in water, less soluble in alcohol and acetone. On boiling with sodium hydroxide, the odor of ammonia was noted.

Anal. Calcd. for $C_8H_{11}N_3O_2$: N, 23.19. Found: N, 23.05.

Ethyl α-Acetamido-α-cyano-β-(2-pyrrole)-propionate (II).—Following procedure (C), 9.3 g. of dimethylaminomethylpyrrole was used to alkylate 12.7 g. of ethyl cyanoacetamidoacetate. On evaporation of the alcohol *in vacuo*, dilution with water and cooling, 17 g. (90%) of nearly white crystals separated. They were purified by dissolving in acetone, treating with charcoal, filtering, diluting with water and chilling for several hours. The white plates of (II) melted at 122° and were soluble in ethanol, acetone, benzene and hot water, insoluble in petroleum ether.

Anal. Calcd. for $C_{12}H_{15}N_3O_3$: N, 16.86. Found: N, 16.92.

Ethyl bis-(2-Pyrrolemethyl)-cyanoacetate (VI).—The alkylation of 11.3 g. of ethyl cyanoacetate with 9.3 g. of dimethylaminomethylpyrrole by procedure (C) produced a colored oil which could not be crystallized. It was taken up in ether, dried, and distilled *in vacuo.* After some unreacted ester had come over, 3 g. (30%) of a heavy yellow oil, boiling at 169–170° (6 mm.), was collected. It gave a positive Ehrlich test and became glassy on chilling.

The amide of (VI) was prepared by shaking the oil with ten times its volume of concentrated ammonium hydroxide, allowing the mixture to stand at room temperature for several days and finally chilling it for two days. The needles obtained in 45% yield were recrystallized from hot water and gave a positive Ehrlich test. They were melted at 153° and were soluble in ethanol, acetone and methanol, insoluble in hydrocarbon solvents.

Anal. Calcd. for $C_{13}H_{14}N_4O$: N, 23.13; mol. wt., 242. Found: N, 23.20; mol. wt. (Rast), 242.

Diethyl 2-Pyrrolemethylphthalimidomalonate (VII).—Only a viscous yellow oil was obtained by the alkylation of 23.5 g. of diethyl phthalimidomalonate with 9.3 g. of dimethylaminomethylpyrrole in the usual manner. Extraction with ether and removal of the ether *in vacuo*, and similar treatment with ethanol, produced a dark semisolid mass which had not crystallized after two months. Part of this material was dissolved in much acetone and passed through an activated alumina column. The acetone was evaporated to small volume, cooled and diluted with water. On chilling, slightly colored crystals separated in very poor yield. An acetone solution of this product was treated with charcoal, filtered, diluted with water and chilled. The white plates melted at 133.5° and gave a positive Ehrlich test.

Anal. Calcd. for $C_{20}H_{20}N_2O_6$: N, 7.29. Found: N, 7.15.

Hydrolysis of Ethyl α-Acetamido-α-cyano-β-(2-pyrrole)-propionate (II).—Twenty grams of (II) was refluxed with a solution of 25 g. of sodium hydroxide in 200 ml. of water for twenty-one hours. The red solution was neutralized carefully (vigorous evolution of carbon dioxide was noted, filtered from silica, decolorized with charcoal) and cooled. It was then acidified to *p*H 3 with

---

[15] This carbon-hydrogen analysis was determined by E. W. D. Huffman, Denver, Colorado.

concentrated hydrochloric acid, quickly extracted with four 200-ml. portions of ether to remove acetic acid, neutralized to *p*H 6–7, and evaporated to dryness *in vacuo*. After addition of absolute ethanol, the residue was again evaporated to dryness to remove the last traces of water. The residue (10 g.) gave a positive ninhydrin test.

Extraction with 100 ml. of hot absolute ethanol, treatment with norite, filtration, evaporation to small volume, dilution with anhydrous ether and chilling gave a small amount of brown solid. Further dilutions with ether, followed each time by cooling for a day, produced a total of 1.75 g. of impure amino acid-salt mixture.

Pure pyrrolealanine has so far not been obtained from these fractions by various techniques including selective extraction, fractional precipitation, insoluble salt formation, crystallization, electrophoresis and ion exchange. Analyses for carbon, hydrogen and nitrogen were consistently about two-thirds of the required amounts.

However, when treated with phenyl isocyanate, the crude salt-amino acid mixture gave a 22% yield of a phenylurea derivative analyzing for that of pyrrolealanine. Likewise, all of the crude fractions obtained from the basic hydrolysis of (II) inhibited the growth of *S. cerevisiae* (Fleischmann strain 139) and *E. coli* (ATCC 9723) when tested by the techniques previously described.[4] For half-normal inhibition a concentration of 28–32 γ per tube of crude material was required (each tube contained 6.5 ml. of medium and 1 ml. of addenda). The toxicity of the crude pyrrolealanine was counteracted by phenylalanine. The phenylurea derivative showed only slight inhibition at levels of 200 γ per tube, but hydrolysis with barium hydroxide restored the original high degree of activity. Further attempts are underway to obtain the pyrrolealanine in pure form.

Hydrolysis of Ethyl 2-Pyrrolemethylacetamidomalonate (I).—Ten grams of the ester was refluxed with 80 ml. of 15% sodium hydroxide for seven hours, treated with charcoal, filtered, neutralized to *p*H 5–6 and cooled. The ninhydrin test was negative. Concentration to small volume at this stage yielded no organic precipitate. The slightly acid solution was refluxed for two hours, treated with 12 g. of solid sodium hydroxide and boiled for an additional eleven hours. It was neutralized carefully, filtered, acidified to *p*H 3 and quickly extracted with ether, neutralized again, treated with charcoal, filtered and evaporated to dryness *in vacuo*. The residue gave a strong ninhydrin test and was extracted as described in the preceding paragraph. The yield of crude product, representing the sum of the various fractions, averaged 3–5 g. This crude material was identical in behavior with the material obtained from the hydrolysis of II.

Phenylurea Derivative of β-2-Pyrrolealanine.—Two grams of crude salt-amino acid product was dissolved in 10 ml. of water. To the well-cooled solution there were added 6 ml. of 2 *N* sodium hydroxide in 1-ml. portions and 1.2 ml. of phenyl isocyanate in 0.2-ml. portions with vigorous shaking. When the odor of phenyl isocyanate could no longer be noticed, the mixture was filtered from the slight precipitate of diphenylurea, decolorized with charcoal, made barely acid with dilute hydrochloric acid and cooled overnight. The yield of pink solid was 0.8 g. An additional 0.22 g. was obtained by further acidification of the filtrate. Recrystallization from aqueous ethanol gave 0.78 g. (22%) of white crystals. After drying *in vacuo*, the product melted at 182–183° (capillary) and at 206° on a Dennis melting point bar within three seconds. It decomposed in air and was stored in a vacuum desiccator.

Anal. Calcd. for $C_{14}H_{15}N_3O_3$: C, 61.51; H, 5.53; N, 15.38; neut. equiv., 273. Found: C, 61.6; H, 6.04; N, 15.19; neut. equiv., 275.

Hydrolysis of the Phenylurea.—Preliminary studies indicated that the phenylurea of phenylalanine could be hydrolyzed by 5% barium hydroxide. Fifty milligrams of the phenylurea of pyrrolealanine was placed in a test-tube together with 0.5 g. of barium hydroxide monohydrate and 9.5 ml. of water and heated at 120° in a pressure autoclave for six hours. The mixture was neutralized to *p*H 7 with 1 *N* sulfuric acid, filtered, and the volume adjusted to 20 ml. Of this neutralized filtrate 0.32 ml. of a 1 to 10 dilution inhibited the growth of *E. coli* to 50% of normal. Evaporation *in vacuo* gave 18 mg. of a brown residue, which decomposed very quickly, left a black residue on burning, and inhibited the growth of *E. coli*, but not as strongly as the solution.

Acknowledgments.—The authors wish to express their appreciation to Mrs. Charmion McMillan for the microbiological tests, and to Mr. Frank Rainwater for some of the carbon and hydrogen analyses; also to Professor Irving Goodman for the many hours spent in consultation during this work.

Summary

Dimethylaminomethylpyrrole was used to alkylate ethyl malonate, ethyl cyanoacetate, ethyl acetamidomalonate, ethyl cyanoacetamidoacetate, and ethyl phthalimidomalonate. The structures of the products have been given.

The product of the reaction between dimethylaminomethylpyrrole and ethyl cyanoacetamidoacetate on hydrolysis gave impure fractions of β-2-pyrrolealanine which was characterized as the phenylurea derivative.

These fractions inhibited the growth of *S. cerevisiae* and *E. coli*. The inhibition was reversed by phenylalanine.

BOULDER, COLORADO RECEIVED AUGUST 25, 1947

[Contribution from the Division of Chemistry and Pharmacy of the Reed and Carnrick Institute for Medical Research]

Synthetic Estrogens. I. 3,4-bis-(*m*-Methyl-*p*-hydroxyphenyl)-2,4-hexadiene, 3,4-bis-(*m*-Methyl-*p*-hydroxyphenyl)-hexane and Some of their Organic Esters

By V. Niederl, C. A. Siconolfi, A. Bloom and C. T. Van Meter[1]

It is generally agreed that 3,4-bis-(*p*-hydroxyphenyl)-3-hexene (diethylstilbestrol) has been a valuable medicinal agent. Equally apparent for some time now, however, has been the fact that the administration of diethylstilbestrol is not infrequently accompanied by certain physiological disturbances commonly regarded as manifestations of toxicity. As in other similar instances, this situation has encouraged considerable research designed to produce related compounds which retain sufficient estrogenic activity to have practical value, and which at the same time are sufficiently non-toxic as to have favorable therapeutic indexes.

The structure of diethylstilbestrol suggests at once certain simple chemical alterations worthy of investigation. Thus various esters and ethers have been prepared and tested, as have also many other compounds differing from diethylstilbestrol primarily in degree of saturation, presence of alkyl and other substitutents in the hexane residue, and points of attachment of the benzene nuclei to the aliphatic chain. Various closely related intermediates and by-products formed during the synthesis of such compounds have also been tested for estrogenic activity.[2]

To date, however, little attention has been given to the possibility of producing derivatives with improved properties through the introduction of alkyl groups on the benzene nuclei while at the same time retaining the six carbon aliphatic chain.

Kaiser and Svarz[3] have prepared the 3,3′-diallyl, and dipropenyl diethylstilbestrols and the 3,3′-diallyl, dipropenyl, and di-*n*-propyl hexestrols, but found them to be weakly estrogenic. Other somewhat similar compounds have been prepared and tested, but they differ from the compounds pertinent to this study either in length of the main aliphatic chain or in points of attachment of the benzene nuclei thereto.[4–12]

It is the primary aim of this research to prepare and investigate for estrogenic activity and toxicity derivatives containing one methyl group in each benzene ring, with and without simultaneous changes in the degree of saturation in the hexane residue. In this report *m*-methyl derivatives of 3,4-bis-(*p*-hydroxyphenyl)-2,4-hexadiene and 3,4-bis-(*p*-hydroxyphenyl)-hexane, along with some of their esters, are described.

Pharmacology

In common with other groups of related estrogens the potency of individual members in the series herein reported varies considerably. Tested on ovariectomized rats by the vaginal smear method, the two dihydroxy compounds are more active on injection than when given orally, but this order of relative activity is reversed in at least some of the esters. As in the diethylstilbestrol and hexestrol series, esters of monobasic aliphatic acids higher than propionic show decreased activities, and certain special esters such as the alkylcarbonates, acid succinates, and *m*-sulfobenzoates show their usual relatively high activities. Hydrogenation of a potent hexadiene compound to the corresponding hexane compound increases the activity.

The estrogenic activities (rats, vaginal smear) of the more potent compounds are shown in Table I. These activities were determined according to the method of the League of Nations Health Organization.[13] Vaginal smears are regarded as positive (a) if cornified cells only are present, or (b) if a smear of many nucleated and some cornified cells and no leucocytes is followed by a smear showing many cornified and nucleated cells with few leucocytes. Control rats received U.S.P. Reference Estrone as the standard estrogenic substance.

The estrogenic activities in Table I assume added importance when considered in conjunction with the following typical toxicity data. Compounds (2) and (7) have been administered orally to mice, daily over a three week period, in doses up to five times the toxic dose for diethylstilbestrol with no abnormal findings on autopsy.

Injected intraperitoneally as suspensions in acacia, the M.L.D.$_{50}$'s (mice) are: diethylstilbestrol 18 mg., compound no. (2) 36 mg., and compound no. (7) 36 mg.

Favorable therapeutic indexes for these compounds are thus to be expected and early clinical work verifies this expectation.[14]

[a] Solutions in oil except (10) which was given in aqueous solution. [b] Per cent. of rats showing smears consisting predominantly of cornified cells.

The general plan of synthesis involves a Fries isomerization of *o*-cresyl propionate, esterification of the resulting *p*-hydroxyphenone, reduction of this phenone ester to the corresponding pinacol, dehydration of the pinacol to a 2,4-hexadiene derivative and finally hydrogenation to a hexane type of compound.

Experimental

_o_-Cresyl Propionate.[15]—One mole of *o*-cresol was esterified with 1.1 moles of propionyl chloride. That fraction distilling at 104–106° (14 mm.) was collected as the ester; b. p. 218° (1 atm.); yield, quantitative.

3-Methyl-4-hydroxypropiophenone.[15]—One mole of *o*-cresyl propionate dissolved in 500 cc. of nitrobenzene was subjected to a typical Fries rearrangement at room temperature using 1.1 moles of anhydrous aluminum chloride. After hydrolysis of the aluminum complex the nitrobenzene solution was extracted with 10% sodium hydroxide. Acidification of this extract precipitated a mixture of the *o*- and *p*-hydroxypropiophenones which was collected, dried and distilled under vacuum. The fraction boiling at 150–155° (1 mm.) was collected as 3-methyl-4-hydroxypropiophenone; m. p. 86°; yield, 75%.

The 2,4-dinitrophenylhydrazone was prepared; m. p. 238°.

Anal. Calcd. for $C_{16}H_{16}N_4O_5$: N, 16.28. Found: N, 16.13.

3-Methyl-4-propionoxypropiophenone.—One-half mole of 3-methyl-4-hydroxypropiophenone was placed in a 500-cc. round-bottom flask fitted with a reflux condenser and a dropping funnel through which 0.55 mole of propionic anhydride was slowly added. The mixture was heated gently with a small flame during this addition and strongly enough thereafter to maintain gentle ebullition for one hour. Propionic acid and excess propionic anhydride were then distilled from the reaction mixture. The residual oil on cooling yielded 109 g. (99%) of solid material, m. p. 48–50°. Recrystallization from petroleum ether gave small white crystals, m. p. 52–53°.

Anal. Calcd. for $C_{13}H_{16}O_3$: C, 70.88; H, 7.32. Found: C, 70.69; H, 7.43.

The 2,4-dinitrophenylhydrazone was prepared; m. p. 179–180°.

Anal. Calcd. for $C_{19}H_{20}N_4O_6$: N, 14.00. Found: N, 14.05.

Instead of separating the isomeric hydroxyphenones obtained in the Fries rearrangement and then propionylating the desired isomer as described above, the mixture of hydroxyphenones may be subjected to the propionylation reaction and the mixture then fractionally distilled. The 4-propionoxy isomer distils at 141–143° (2 mm.). Less thermal decomposition occurs in this alternative procedure.

3,4-bis-(_m_-Methyl-_p_-propionoxyphenyl)-3,4-hexanediol.—This pinacol was first prepared by the reduction of 3-methyl-4-propionoxypropiophenone according to the method of Dodds, *et al.*,[16] for *p*-methoxypropiophenone, using aluminum amalgam and moist ether. The following method, however, was much more convenient and gave much higher yields.

One hundred grams of 3-methyl-4-propionoxypropiophenone was dissolved in 750 cc. of ethyl acetate which previously had been saturated with water. Forty grams of aluminum foil (strips, 2″ × 1/2″) was etched with 10% sodium hydroxide solution, thoroughly amalgamated with 0.5% mercuric chloride solution, and washed successively with water, ethanol and ethyl acetate. The amalgam was then added quickly to the reaction flask and the mixture stirred for thirty minutes. During this time the temperature of the mixture had risen to a maximum of about 70° and had started to fall. After cooling aluminum hydroxide and unreacted aluminum were filtered off and washed several times with fresh portions of ethyl acetate. Removal of the ethyl acetate by distillation yielded a very sticky viscous oil which solidified slowly on long standing. Trituration of this solidified mass with a small quantity of cold isopropyl ether facilitated the separation of a white solid. After washing with isopropyl ether and recrystallizing from 70% ethanol, small white crystals of the pinacol were obtained; m. p. 152–153°.

Anal. Calcd. for $C_{26}H_{34}O_6$: C, 70.56; H, 7.74. Found: C, 70.73; H, 7.91.

In the over-all synthesis it is unnecessary to separate the pure pinacol as described above. Instead, the viscous oil remaining after removal of ethyl acetate may be subjected directly to the dehydration reaction to form the hexadiene compound. In this manner over-all yields of 50% (phenone ester to diene) were obtained.

3,4-bis-(_m_-Methyl-_p_-hydroxyphenyl)-3,4-hexanediol.—This compound was prepared by reducing 75 g. of 3-methyl-4-hydroxypropiophenone with 40 g. of aluminum foil as described above; yield, 26 g. (35%) of crystalline pinacol; m. p. 180–183°. Recrystallization from dilute acetic acid gave small white crystals of the pinacol, m. p. 182–183°.

The *p,p'*-dibenzoate of this pinacol, prepared by the Schotten–Baumann reaction, was obtained as small white needles, m. p. 252°.

Anal. Calcd. for $C_{34}H_{34}O_6$: C, 75.81; H, 6.36. Found: C, 75.59; H, 6.53.

3,4-bis-(*m*-Methyl-*p*-acetoxyphenyl)-2,4-hexadiene.—Five grams of 3,4-bis-(*m*-methyl-*p*-hydroxyphenyl)-3,4-hexanediol was suspended in a mixture of 15 cc. of acetic anhydride and 10 cc. of acetyl chloride, and the mixture refluxed gently for thirty minutes. After cooling the reaction mixture was poured into ice-water and allowed to stand with occasional stirring for two hours. The solid which separated was filtered, washed with water and then triturated with about 10 cc. of cold methanol. After filtering and drying 4.4 g. (80%) of solid material remained, m. p. 160–163°. Recrystallization from ethanol gave white crystals, m. p. 166–168°.

The tetrabromo derivative, prepared by bromination in carbon tetrachloride and purified by recrystallization from ethanol, formed white crystals, m. p. 148° dec.

Anal. Calcd. for $C_{24}H_{26}Br_4O_4$: Br, 45.79. Found: Br, 45.60.

3,4-bis-(*m*-Methyl-*p*-propionoxyphenyl)-2,4-hexadiene.—This compound was prepared as described above for the acetoxy analog using 5 g. of 3,4-bis-(*m*-methyl-*p*-propionoxyphenyl)-3,4-hexanediol, 15 cc. of acetic anhydride and 10 cc. of acetyl chloride; 4.1 g. (90%) of solid material was collected, m. p. 132–135°; recrystallization from ethanol gave white crystals; m. p. 139–140°.

3,4-bis-(*m*-Methyl-*p*-hydroxyphenyl)-2,4-hexadiene.—Two grams of 3,4-bis-(*m*-methyl-*p*-propionoxyphenyl)-2,4-hexadiene was suspended in 20 cc. of Claisen solution (100 g. of potassium hydroxide dissolved in 100 cc. of water and diluted, after cooling, with an equal volume of methanol). The mixture was warmed on a steam-bath until the solid was completely dissolved and then allowed to stand at room temperature overnight. After diluting to 150 cc. with water, the mixture was filtered and then acidified with 10% hydrochloric acid to a *p*H of about 3. The white flocculent precipitate which separated was filtered, washed with water and dried; yield, 1.4 g. (95%), m. p. 180–185°. Recrystallization from 50% ethanol gave white needles, m. p. 187–189°.

3,4-bis(*m*-Methyl-*p*-butyroxyphenyl)-2,4-hexadiene.—One gram of 3,4-bis-(*m*-methyl-*p*-hydroxyphenyl)-2,4-hexadiene was dissolved in 10 cc. of anhydrous pyridine, 1.1 g. of butyric anhydride added and the mixture refluxed gently for ninety minutes. After cooling the reaction mixture was poured into 150 cc. of water and stirred for thirty minutes. The solid which separated was collected, washed with water and recrystallized from methanol, yielding one gram of small white crystals, m. p. 123–124°.

3,4-bis-(*m*-Methyl-*p*-palmitoxyphenyl)-2,4-hexadiene.—One and one-half grams of 3,4-bis-(*m*-methyl-*p*-hydroxyphenyl)-2,4-hexadiene was dissolved in 10 cc. of anhydrous pyridine, 3 g. of palmityl chloride added and the mixture refluxed gently for thirty minutes. After cooling, the reaction product was poured into 100 cc. of water and allowed to stand for fifteen minutes. The mixture was then extracted with 150 cc. of ether and the ether solution then washed successively with 40 cc. of 10% hydrochloric acid, 40 cc. of 5% sodium hydroxide and then with water until the washings were neutral to litmus. After drying over anhydrous calcium chloride the ethereal solution was filtered, evaporated to dryness and the residue then recrystallized from ethanol, giving a white amorphous powder, m. p. 69–70°.

3,4-bis-(*m*-Methyl-*p*-benzoxyphenyl)-2,4-hexadiene.—This compound was prepared by the Schotten–Baumann method using 1 g. of 3,4-bis-(*m*-methyl-*p*-hydroxyphenyl)-2,4-hexadiene. Recrystallization from ethanol gave white needles, m. p. 207–208°.

Disodium Salt of 3,4-bis-(*m*-Methyl-*p*-(*m'*-sulfobenzoxy)-phenyl)-2,4-hexadiene.—Three grams of 3,4-bis-(*m*-methyl-*p*-hydroxyphenyl)-2,4-hexadiene was added slowly to a solution of 5 g. of benzoic acid-*m*-sulfochloride in 15 cc. of pyridine maintained at 80°. After all the hydroxy compound had been added, the mixture was heated for two hours at 80° and then poured into 150 cc. of water. The solution was then filtered, treated with saturated aqueous sodium chloride and centrifuged. The solid thus obtained was then dissolved in a minimum of water and the resulting solution was again treated with sodium chloride and centrifuged. This process was repeated once more and this time the resulting precipitate was pressed between filter papers and dried over sulfuric acid. The dried material was dissolved in a minimum of hot ethanol and the solution treated with benzene, whereupon the compound was obtained as a white, flocculent precipitate which was collected and dried. The compound decomposed at high temperatures.

bis-Acid Succinate of 3,4-bis-(*m*-Methyl-*p*-hydroxyphenyl)-2,4-hexadiene.—One gram of 3,4-bis-(*m*-methyl-*p*-hydroxyphenyl)-2,4-hexadiene was dissolved in 10 cc. of pyridine, 1 g. of succinic anhydride added, and the mixture gently refluxed for two hours. After cooling the reaction mixture was diluted with 40 cc. of acetone and an excess of concentrated hydrochloric acid added. A viscous oil separated which was washed with water and recrystallized from dilute acetic acid to give small white crystals, m. p. 193°.

bis-Methylcarbonate of 3,4-bis-(*m*-Methyl-*p*-hydroxyphenyl)-2,4-hexadiene.—One gram of 3,4-bis-(*m*-methyl-*p*-hydroxyphenyl)-2,4-hexadiene was dissolved in 15 cc. of pyridine and cooled to 0° in an ice-bath. Four cc. of methyl chlorocarbonate was added dropwise with shaking and cooling. The mixture was then allowed to come to room temperature and was poured into 100 cc. of water. The solid which separated was collected, washed first with water, and then with several small portions of ethanol and dried. Recrystallization from ethanol gave small white crystals, m. p. 171–172°.

bis-Ethylcarbonate of 3,4-bis-(*m*-Methyl-*p*-hydroxyphenyl)-2,4-hexadiene.—This compound was prepared as described immediately above by using ethyl chlorocarbonate. Recrystallization from ethanol yielded white crystals, m. p. 150–151°.

3,4-bis-(*m*-Methyl-*p*-propionoxyphenyl)-hexane.—Two grams of 3,4-bis-(*m*-methyl-*p*-propionoxyphenyl)-2,4-hexadiene was dissolved in 200 cc. of hot absolute ethanol and hydrogenated at 70° and about 70 atm. in the presence of Raney nickel. The mixture was then cooled, filtered and evaporated to dryness, whereupon 2 g. of solid material remained. Recrystallization from ethanol gave 1.6 g. (80%) of white crystals, m. p. 114–115°.

This compound was also prepared by hydrogenating the same quantity of the diene compound dissolved in 20 cc. of acetone, using 20 mg. of palladium black and an initial gage pressure of 48 lb. per sq. in. The theoretical pressure drop was attained in ten minutes; yield, 80% of pure product.

A study of the stereochemical aspects is in progress and will be reported later.

3,4-bis-(*m*-Methyl-*p*-hydroxyphenyl)-hexane.—Two grams of 3,4-bis-(*m*-methyl-*p*-propionoxyphenyl)-hexane was saponified by treatment with 20 cc. of Claisen solution as described under 3,4-bis-(*m*-methyl-*p*-hydroxyphenyl)-2,4-hexadiene. Recrystallization from dilute acetic acid gave white crystals, m. p. 145°.

Esters of 3,4-bis-(*m*-Methyl-*p*-hydroxyphenyl)-hexane.—Using identical methods, the same esters described in the hexadiene series were prepared.

Analytical data for all new compounds are summarized in Table II.

Acknowledgment.—Grateful acknowledgment is hereby expressed to Miss E. F. Deckert, Director of the Division of Pharmacology of the Reed and Carnrick Institute for Medical Re-

Steroid Acids and their Transformation Products. I. Thiol Esters[1a]

BY ROBERT H. LEVIN, A. VERN MCINTOSH, JR., GEORGE B. SPERO, DOUGLAS E. RAYMAN AND ELIZABETH M. MEINZER

The use of Raney nickel catalyst for the desulfurization and reduction of sulfur compounds has recently been extended to the preparation of aldehydes[1] and alcohols[2] from carboxylic acids via the corresponding thiol compounds. Among the acids used by Jeger and co-workers[2a] were 3β-acetoxy-*etio-allo*-cholanic acid and 3β-acetoxy-Δ^5-*etio*-cholenic acid. For the broader use of the thiol esters as starting materials for the side chain degradation of steroids we have prepared a number of these previously unreported esters.

The steroid thiol esters were prepared by two methods:[3] (A) reaction of the acid chloride with an excess of mercaptan in pyridine; and (B) treatment of the acid chloride with a suspension of lead mercaptide[4] in ether. Generally speaking method A gave slightly better yields of crystalline thiol ester, but the products from B were easier to purify to constant m. p. Table I summarizes our data. Several of these compounds were chromatographed over alumina. It was found that the acetoxy thiol esters could be readily purified in this way. However, a number of the crystalline formoxy compounds became oily when put over the column, probably because of deformylation at the 3-position.

Ethyl 3α-hydroxy-12α-acetoxy-*nor*-thiolcholanate (III) was obtained from 3α-hydroxy-12α-acetoxy-*nor*-cholanic acid (II)[5] using method A. This involves the interesting preparation of a non-aromatic hydroxy acid chloride by the use of thi-

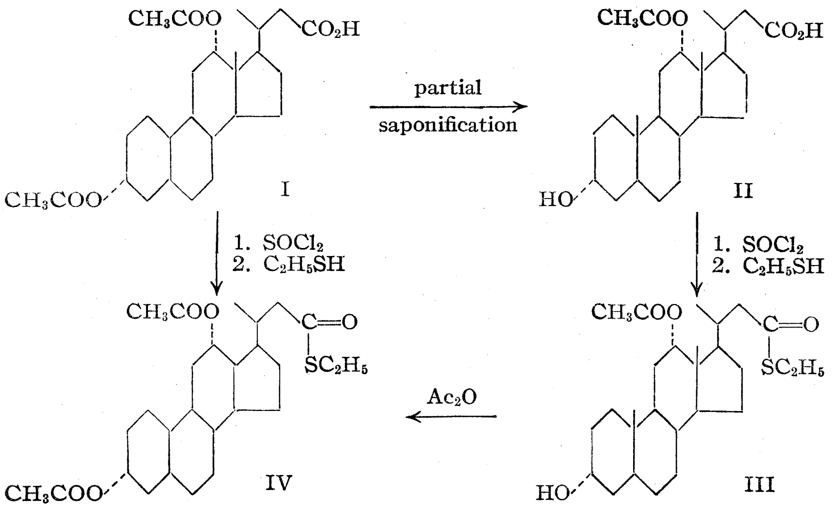
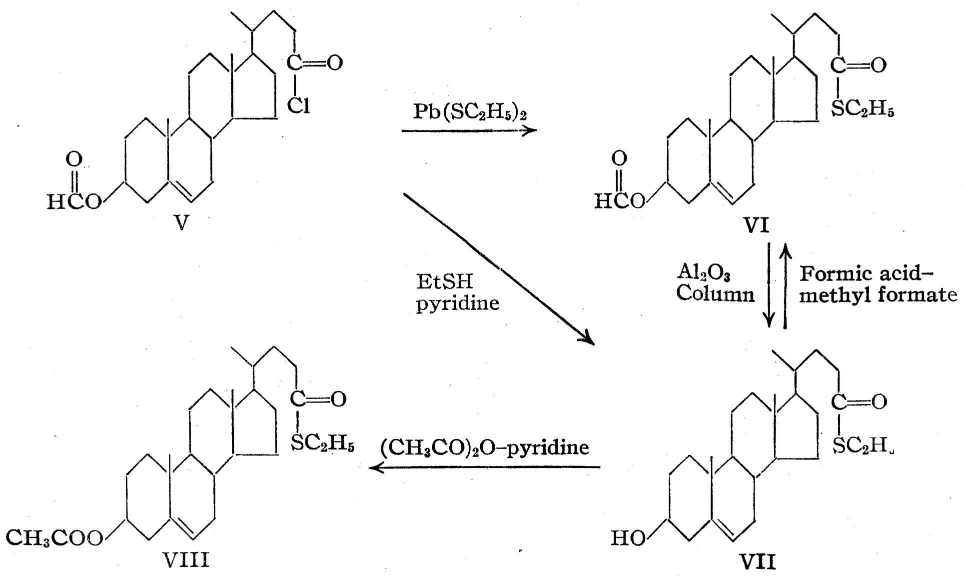
onyl chloride without protection of the hydroxyl group.[6] Compound III was isolated as an oil which did not crystallize after chromatography. However, on acetylation with acetic anhydride and pyridine, ethyl 3α,12α-diacetoxy-*nor*-thiol cholanate (IV) was formed and proved to be identical with the compound similarly prepared from 3α,12α-diacetoxy-*nor*-cholanic acid (I).



The lability of the 3-formoxy group is illustrated by reactions in the 3β-hydroxy-Δ^5-cholenic acid series. When 3β-formoxy-Δ^5-cholenyl chloride (V) was treated with lead ethyl mercaptide, ethyl 3β-formoxy-Δ^5-thiolcholenate (VI), m. p. 80–82°, was formed. Esterification of the acid chloride (V) with ethyl mercaptan and pyridine produced a compound, m. p. 108.5–109.5°, which was characterized as 3β-hydroxy-Δ^5-thiolcholenate (VII) by the reactions shown.



When 3β-formoxy-Δ^5-thiolcholenate (VI) was chromatographed over alumina, the hydroxy compound was obtained as the main fraction. Reformylation of VII with formic acid and methyl formate produced VI. Acetylation of the hydroxy compound (VII) gave 3β-acetoxy-Δ^5-thiolcholenate (VIII), identical with the compound produced by esterification of 3β-acetoxy-Δ^5-cholenic acid by methods A or B. The acetoxy thiol ester (VIII) was recovered unchanged after passage over the alumina column. When 3β-hydroxy-Δ^5-cholenic acid was treated with thionyl chloride and then ethyl mercaptan and pyridine, ethyl 3-chloro-Δ^5-thiolcholenate was formed in good yield and readily purified over an alumina column.

The treatment of these steroid thiol esters with Raney nickel will be discussed in a future paper.

We wish to acknowledge the technical assistance of Jeane F. DeWitt in part of this work.

Experimental

Preparation of Thiol Esters.—An example of each method will be given in detail.

Method A. Benzyl 3α,12α - diacetoxy - *nor* - thiolcholanate.—To 1.5 g. (0.0033 mole) of 3α,12α-diacetoxy-*nor*-cholanic acid was added 6 ml. (9.8 g., 0.082 mole) of purified thionyl chloride.[7] The acid dissolved within five minutes and the solution was allowed to stand, with occasional swirling, at room temperature for one hour. Twenty milliliters of a 1:1 mixture of anhydrous benzene and ether was then added and the whole was evaporated to dryness *in vacuo* at 40°. This process of treatment with benzene–ether was repeated twice in order to ensure the complete removal of excess thionyl chloride.

To the resulting acid chloride dissolved in 10 ml. of anhydrous benzene was added 0.4 ml. (0.005 mole) of dry pyridine and 2 ml. (1.12 g., 0.009 mole) of benzyl mercaptan. A precipitate formed. After standing for

[t] Chlorine analysis. [u] These over-all yields have been calculated from starting acid. Varying amounts of unreacted acid were recovered, which would raise actual yield.

twenty-four hours at room temperature the mixture was diluted with 15 ml. of water and 15 ml. of ether. The precipitate dissolved and the ether–benzene phase was separated. The aqueous portion was extracted with two 15-ml. portions of ether and the combined ether–benzene layer was washed with 30-ml. portions of water, 1% sodium hydroxide, 1% hydrochloric acid and finally with water again. The neutral fraction was dried over anhydrous sodium sulfate and the solvent evaporated to dryness *in vacuo*. The residual oil was crystallized from 50 ml. of 95% alcohol to give 1.38 g. (73%) of product, m. p. 147–152°. After three recrystallizations from alcohol 1.23 g. (65.5%) of benzyl thiol ester with a constant m. p. of 154–156° (cor.) was obtained.

Method B. **Ethyl 3α,12α-Diformoxythiolcholanate.**—The acid chloride (prepared from 4.5 g. (0.01 mole) of 3,12-diformoxydesoxycholic acid in the manner described under A) was dissolved in 30 ml. of anydrous ether and added to 1.8 g. (0.0055 mole) of lead ethyl mercaptide covered with 20 ml. of anhydrous ether. The mixture was allowed to stand at room temperature with occasional swirling. The yellow lead mercaptide was gradually replaced by white lead chloride. After twenty-four hours the solution was filtered and the precipitate washed with 50 ml. of ether. The combined ether filtrate was washed with 100 ml. of 1% sodium hydroxide and 300 ml. of water, then dried over anhydrous sodium sulfate and evaporated to dryness *in vacuo* on the steam-bath. The residual oil was dissolved in 50 ml. of hot alcohol and 10 ml. of water was added. On cooling under the water tap an oil separated, taking with it all the color in the solution. Crystallization then took place in the clear colorless solution, giving 2.2 g. of material. An additional 0.32 g. of crystals was obtained by crystallizing the oil from alcohol. The total yield was 2.6 g. (53% of the theoretical), m. p. 105–110°. After three recrystallizations the m. p. was constant at 111–112° (cor.).

Ethyl 3α-Hydroxy-12α-acetoxy-*nor*-thiolcholanate, (III).—A solution of 2.1 g. of 3α-hydroxy-12α-acetoxy-*nor*-cholanic acid[5] in 8 ml. of thionyl chloride was allowed to stand an hour at room temperature. After removal of the thionyl chloride, the 3α-hydroxy-12α-acetoxy-*nor*-cholanyl chloride was dissolved in 10 ml. of benzene by warming. The solution was cooled and 0.6 ml. of pyridine, then 1.9 ml. of ethyl mercaptan added. The reaction mixture was allowed to stand a day at room temperature, then diluted with 100 ml. of ether and washed successively with water, 1% sodium hydroxide, dilute hydrochloric acid and water. After drying of the ether and evaporation, the residue weighed 2.3 g. (96% of theoretical). Attempts to crystallize the thiol ester from various solvents failed. On chromatography over alumina[8] 81% of the recovered material was eluted in the main fraction, but could not be crystallized.

Ethyl 3α,12α-Diacetoxy-*nor*-thiolcholanate (IV).—A solution of 501 mg. of ethyl 3α-hydroxy-12α-acetoxy-*nor*-thiolcholanate in 10 ml. of acetic anhydride and 10 ml. of pyridine was heated on the steam-bath for one and one-half hours and the solvent was then distilled *in vacuo*. The residue was partly crystalline. It was chromatographed and the fractions eluted with benzene were combined and crystallized from alcohol and water, giving a yield of 120

---

(8) The alumina used in our chromatographic work was "Fisher Adsorption Alumina" obtained from the Fisher Scientific Company and used without further treatment.

mg., m. p. 85–87°. Recrystallization gave a product, m. p. 90–91°, identical with that obtained by esterifying $3\alpha,12\alpha$-diacetoxy-*nor*-cholanic acid.

Ethyl 3β-Hydroxy-Δ^5-thiolcholenate (VII).—The acid chloride prepared from 30.0 g. (0.075 mole) of 3β-formoxy-Δ^5-cholenic acid was dissolved in 200 ml. of benzene and treated with 37 ml. (0.50 mole) of ethyl mercaptan and 10 ml. of pyridine. After standing overnight at room temperature the reaction mixture was diluted with 250 ml. of water and extracted with 250 ml. of ether in portions. The ether layer was washed with 1% sodium hydroxide, 1% hydrochloric acid and water. After drying the ether was distilled and the residue crystallized from 300 ml. of alcohol and 50 ml. of water, giving 23 g. (72%) of ethyl 3β-hydroxy-Δ^5-thiolcholenate, m. p. 98–100°. Several recrystallizations from hexane–benzene raised the m. p. to 108.5–109.5°.

Deformylation of Ethyl 3β-Formoxy-Δ^5-thiolcholenate (VI) over Alumina.—Two hundred mg. of ethyl 3β-formoxy-Δ^5-thiolcholenate, m. p. 78.5–81.5°, was dissolved in 8 ml. of benzene and passed through a 10-g. alumina[8] column. The column was eluted, using the free flow method, with 8-cc. portions of benzene, benzene + 0.4% methanol, benzene + 1% methanol, benzene + 2% methanol, benzene + 4% methanol, benzene + 8% methanol and methanol. The benzene eluate contained 35 mg.% of crystalline material of m. p. 78–82° (starting material). The methanol fraction contained 135 mg. of crystalline material of m. p. 95–100°. After several recrystallizations from 3A alcohol[9] and from hexane (Skellysolve "B") the m. p. became constant at 105–108°. An admixture with a sample of ethyl 3β-hydroxy-Δ^5-thiolcholenate, m. p. 108.5–110°, melted at 108–110°. An admixture with starting material melted at 63–100°.

Formylation of Ethyl 3β-Hydroxy-Δ^5-thiolcholenate (VII).—A mixture of 710 mg. of ethyl 3β-hydroxy-Δ^5-thiolcholenate, m. p. 108–109.5°, 25 ml. of formic acid (87%) and 12.5 ml. of methyl formate was heated under reflux on the steam-bath for two and one-half hours; then the reaction mixture was evaporated *in vacuo* and the residue dissolved in ether. The ether solution was washed with 0.5% sodium hydroxide, then with water, and was dried over sodium sulfate. Evaporation *in vacuo* gave 452 mg. of ethyl 3β-formoxy-Δ^5-thiolcholenate (VI), m. p. 78–79.5.° Several recrystallizations from methanol, water and from alcohol brought the m. p. up to 80–82°. A mixture m. p. with authentic formoxy ester was not depressed.

Acetylation of Ethyl 3β-Hydroxy-Δ^5-thiolcholenate.—Three hundred mg. of ethyl 3β-hydroxy-Δ^5-thiolcholenate, m. p. 108–109.5°, was mixed with 5 ml. of acetic anhydride and 5 ml. of pyridine. After refluxing for two and one-half hours the mixture was evaporated to dryness on the steam-bath *in vacuo*. The residue was taken up in alcohol. The alcohol solution was diluted with water and extracted with ether. After washing with 1% sodium hydroxide and water the ether solution was dried over sodium sulfate and evaporated to dryness. The residue was crystallized from 3A alcohol to yield 290 mg. of ethyl 3β-acetoxy-Δ^5-thiolcholenate (VIII), m. p. 101–104°. After several recrystallizations, the melting point became constant at 101–102.5°. An admixture with a sample of authentic ethyl 3β-acetoxy-Δ^5-thiolcholenate, m. p. 101–103°, showed no melting point depression. An admixture with starting material melted at 79–82°.

Hydrolysis of 300 mg. of the thiol ester (VIII) with 1 g. of sodium hydroxide in 2.5 ml. of water and 15 ml. of alcohol gave an almost quantitative yield of 3β-hydroxy-Δ^5-cholenic acid.

Summary

A number of thiol esters of steroid acids have been prepared and characterized using ethyl, isopropyl, *t*-butyl, *n*-hexyl, benzyl and phenyl mercaptans; and the following acids: 3β-hydroxy-Δ^5-cholenic, 3β-hydroxy-5-chloro-*nor*-cholenic, 3-β-hydroxy-Δ^5-*bisnor*-cholenic, desoxycholic, *nor*-desoxycholic and lithocholic.

Chemical Interactions of Amino Compounds and Sugars. III.[1] The Conversion of D-Glucose to 5-(Hydroxymethyl)-2-furaldehyde[2]

BY M. L. WOLFROM, R. D. SCHUETZ[3] AND LIEBE F. CAVALIERI[3]

It is well established that D-glucose and other hexoses are converted to 5-(hydroxymethyl)-2-furaldehyde on heating with acids.[4] Scallet and Gardner[5] have previously demonstrated that 5-(hydroxymethyl)-2-furaldehyde is formed from D-glucose on refluxing in water alone.

The purpose of the work herein reported was to determine whether ultraviolet spectroscopy would give any insight into the mechanism and intermediates in the conversion of D-glucose to 5-(hydroxymethyl)-2-furaldehyde. Hydrochloric acid was the catalyst chosen for these studies.

When an aqueous solution (initial *p*H 6.5) of D-glucose was prepared from triply distilled water and refluxed, a series of changes could be detected in the ultraviolet absorption spectrum; these are shown in Figs. 1 and 2. After three and one-half hours (curve 1, Fig. 1) a distinct band with a maximum at 228 mμ was evident. After eight hours of

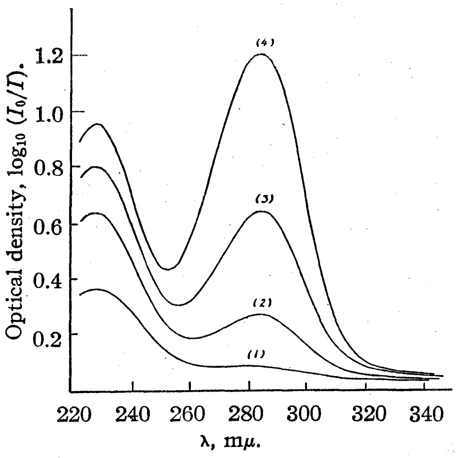

Fig. 1.—Absorption spectra of a 0.0500 molar aqueous D-glucose solution, initial *p*H 6.5, after refluxing for various time intervals: curve 1, after three and one-half hours; curve 2, after eight hours; curve 3, after twelve hours; curve 4, after seventeen hours. Beckman spectrophotometer (Model DU), 1-cm. cell, slit width 0.30–0.35 mm., optical densities 0.05–1.405.

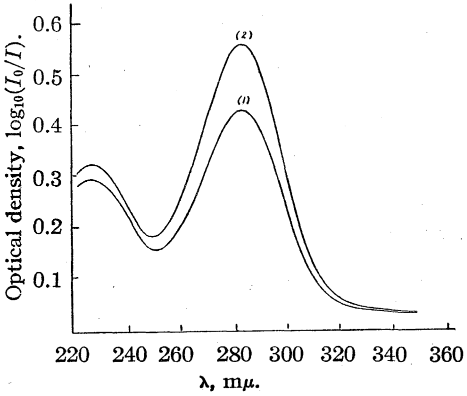

Fig. 2.—Absorption spectra of a 0.0500 molar aqueous D-glucose solution, initial *p*H 6.5, after refluxing for various time intervals. Samples were diluted four to one for absorption measurements: curve 1, after twenty hours; curve 2, after twenty-three hours; Beckman spectrophotometer (Model DU), 1-cm. cell, slit width 0.30–0.35 mm., optical densities 0.05–0.57.

heating (curve 2, Fig. 1), the maximum at 228 mμ was more pronounced and a second band was developing in the region of 285 mμ. At the end of twelve hours (curve 3, Fig. 1) the maximum at 228 mμ had increased and that at 285 mμ was increasing at an even greater rate. On continued heating for seventeen hours (curve 4, Fig. 1) the ratio of the substance producing the band at 285 mμ to the other (producing the band at 228 mμ) became very large. Finally, after a period of heating somewhat greater than twenty and twenty-three hours (curves 1 and 2, Fig. 2), respectively, the typical absorption spectrum of 5-(hydroxymethyl)-2-furaldehyde (Fig. 5) was developing.

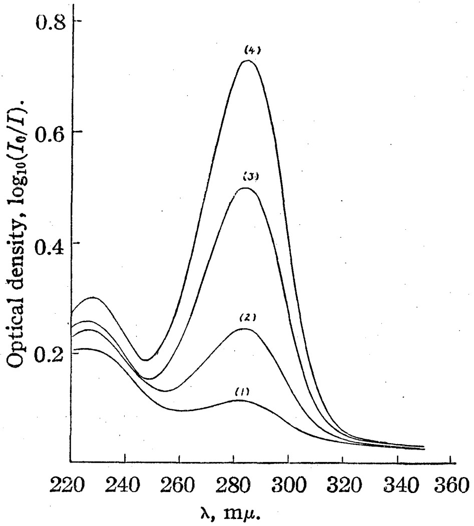

Fig. 3.—Absorption spectra of a 0.0500 molar aqueous D-glucose solution adjusted to an initial *p*H of 4.3 with hydrochloric acid, after refluxing for various time intervals: curve 1, after three and one-half hours; curve 2, after eight hours; curve 3, after twelve hours; curve 4, after fifteen hours. Beckman spectrophotometer (Model DU), 1-cm. cell, slit width 0.30–0.35 mm., optical densities 0.05–0.75.

When an aqueous solution of D-glucose was adjusted to an initial *p*H of 4.3 with hydrochloric acid and refluxed, a similar series of curves was obtained (Fig. 3). Here both bands are evident after three and one-half hours (curve 1) and again the band at 228 mμ was more pronounced. After eight hours (curve 2) both maxima, at 228 mμ and at 285 mμ, were of about equal intensity. At the end of twelve hours (curve 3) the ratio of

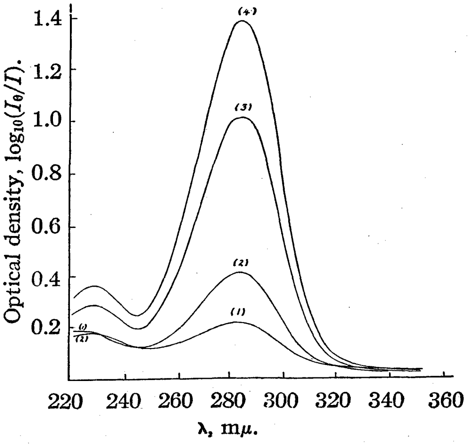

Fig. 4.—Absorption spectra of a 0.0500 molar aqueous D-glucose solution adjusted to an initial *p*H of 2.0 with hydrochloric acid, after refluxing for various time intervals: curve 1, after three and one-half hours; curve 2, after eight hours; curve 3, after twelve hours; curve 4, after fifteen hours. Beckman spectrophotometer (Model DU), 1-cm. cell, slit width 0.30–0.35 mm., optical densities 0.05–1.405.

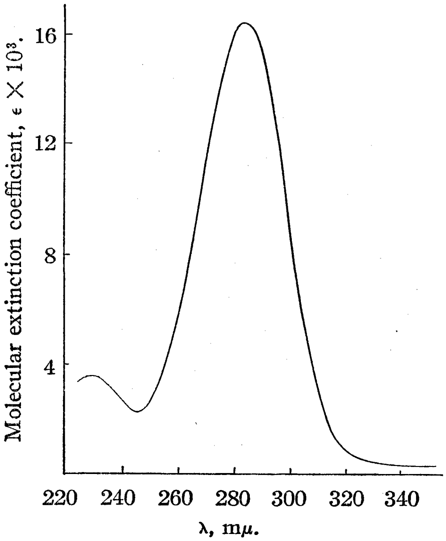

Fig. 5.—Absorption spectrum of pure 5-(hydroxymethyl)-2-furaldehyde[1] in water; concentration, 6.3627×10^{-5} mole per liter; $\epsilon = 1/c \ln (100/T)$ wherein c is the molar concentration and T is the percentage transmission; $\epsilon = 16{,}500$, max. 285 mμ (major peak), $\epsilon = 3{,}620$, max. 228 mμ (minor peak); slit width 0.32–0.35 mm., optical densities 0.016–1.048.

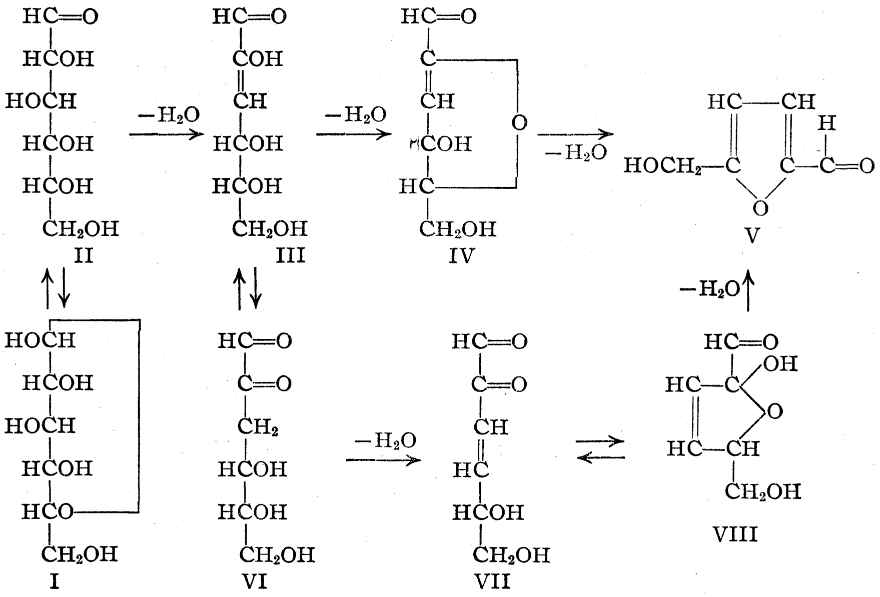
material producing the band at 285 mμ to that causing the band at 228 mμ had again become quite large. Finally, after heating for a period of fifteen hours (curve 4), the general absorption curve for 5-(hydroxymethyl)-2-furaldehyde (Fig. 5) was well developed.



The series of absorption curves (Fig. 4) resulted when an aqueous solution of D-glucose, adjusted with hydrochloric acid to an initial *p*H of 2.0, was refluxed. In curve 1, Fig. 4, after three and one-half hours, the maximum at 285 mμ was more pronounced than that at 228 mμ. After eight hours (curve 2, Fig. 4), the ratio of the compound responsible for absorption at 285 mμ to the one causing absorption at 228 mμ had again become large, and after twelve hours of continued refluxing, this ratio had further increased (curve 3, Fig. 4). Finally, after fifteen hours of heating, the typical absorption curve for 5-(hydroxymethyl)-2-furaldehyde resulted (curve 4, Fig. 4).

It is to be noted that the ultraviolet absorption spectra presented, at various time intervals, and at increasing initial *p*H values, during the conversion of D-glucose to 5-(hydroxymethyl)-2-furaldehyde are all very similar. Such differences as exist lie only in the rate at which the bands at 228 mμ and 285 mμ are developed. This indicates that the reaction mechanism involved in the formation of 5-(hydroxymethyl)-2-furaldehyde from D-glucose is independent of the initial *p*H value in the range studied (*p*H 6.5 to *p*H 2). These absorption curves, however, show that the reaction rate is dependent upon the acidity of the reaction medium, increasing with increasing acidity.

Further, it can be pointed out (curve 1, Fig. 1) that after three and one-half hours where the reaction is slowest (due to no added acid), there is absorption only at 228 mμ. That the substance producing this band is not 5-(hydroxymethyl)-2-furaldehyde is apparent from the fact that the major peak at 285 mμ is missing. In addition, the intensity of absorption at 228 mμ increased to a maximum after seventeen hours (curve 4, Fig. 1) where both peaks at 228 mμ and 285 mμ are present and then decreased to a corresponding value for 5-(hydroxymethyl)-2-furaldehyde as the reaction proceeded. It is probable that the intermediate producing the high absorption at 228 mμ is a conjugated acyclic diene as (or enal) since, Mulliken[6] and also Booker, Evans and Gillam[7] have shown, the cyclic dienes, which are necessarily oriented *cis*, would have shown a much weaker absorption in this region.

The absorption intensity at 228 mμ does not reach a very large value when aqueous solutions of D-glucose are refluxed at the lower initial *p*H.

---

(6) R. S. Mulliken, *J. Chem. Phys.*, **7**, 121 (1939).

(7) H. Booker, L. K. Evans and A. E. Gillam, *J. Chem. Soc.*, 1453 (1940).

This is due to the increased rate of conversion through the intermediates to 5-(hydroxymethyl)-2-furaldehyde. This is shown by curves 1 in Figs. 1, 3, 4, and curve 3 in Fig. 4.

To explain these absorption curves we can postulate that D-glucose, represented by I (other anomers and ring structures than I are possible), is transformed first into II or its aldehydrol. The intermediate III then results from II by loss of water, producing a conjugated enal. Evidence for III is found in both the region and the magnitude of absorption shown in curve 4, Fig. 1. Evans and Gillam[8] have demonstrated that α,β-unsaturated aldehydes (R—CH=CR'CHO) show high absorption in the general region of 230 mμ. In this intermediate (III), R is $(CHOH)_2CH_2OH$ and R' is the hydroxyl group. A similar type of intermediate was shown to be present in the conversion of 2,3,4,6-tetramethyl-D-1,2-glucoseen into 5-(methoxymethyl)-2-furaldehyde[9] in acid solution. There the 6-methyl ether of the conjugated enonal VII was established as an intermediate in this conversion by isolation as its crystalline phenylosazone.

The postulated intermediate III could produce IV by cyclic dehydration. The 5-(hydroxymethyl)-2-furaldehyde (V) could result from IV by a final dehydration producing a third double bond in conjugation with the two already present. The mechanism proposed here for the conversion of D-glucose to 5-(hydroxymethyl)-2-furaldehyde through the intermediates II, III and IV, is based upon that originally suggested by Hurd and Isenhour,[10] who, however, offered no experimental evidence to support it. The route through the intermediates VI, VII and VIII receives experimental support in the work of Wolfrom, Wallace and Metcalf.[9] The dehydrations postulated are the well-established ones of an hydroxyl group in the β position to a carbonyl. The resulting dehydrated products are α,β-unsaturated carbonyl compounds and we offer spectroscopic evidence for such intermediates.

Experimental

Materials.—The D-glucose used in this work was a very pure grade of the monohydrate.[11] It was crystallized from triply distilled water.

Absorption Measurements.—The D-glucose was weighed into a 500-ml. round-bottom Pyrex flask with a ground glass joint and connected to a reflux condenser. The solvent was added, and in the experiments where hydrochloric acid was used, the pH was adjusted at this point. The aqueous D-glucose solutions were refluxed by means of a Glas-col type electric heater. At definite time intervals aliquots were removed, cooled rapidly to room temperature, and immediately read in the spectrophotometer.

Acknowledgment.—The assistance of Clare B. Spitler and Doris K. Cavalieri is gratefully acknowledged.

Summary

The course of the formation of 5-(hydroxymethyl)-2-furaldehyde from D-glucose in the absence and presence of hydrochloric acid has been followed by ultraviolet absorption spectra measurements and on the basis of this, structures are proposed for several intermediates.

The Role of 5-(Hydroxymethyl)-furfural in the Discoloration of Sugar Solutions

BY BHAGAT SINGH,[1] G. R. DEAN AND SIDNEY M. CANTOR[2]

The acid catalyzed hydrolysis of starch at elevated temperature for the commercial production of D-glucose results in the formation of considerable coloring matter.[3] Under the same conditions of temperature and concentration the decomposition of pentoses to yield furfural and of hexoses to yield 5-(hydroxymethyl)-furfural (hereafter abbreviated in most cases to HMF) and levulinic and formic acids are well known phenomena. Various hypotheses have been advanced for the mechanism of color formation. Porst[4] believed that the color change might be due to furfural derived from the sugars and to traces of phenols and other derivatives which come from the decomposition of the small amount of protein contained in the starch. The possible participation of furfural and levulinic acid to form coumarone has been suggested as the cause of "humins" and color by Meunier.[5] The

[3] During the course of this investigation this laboratory became associated with the coöperative project on non-enzymatic browning sponsored by the Committee on Food Research of the Quartermaster Corps of the U. S. Army. The relationship between this work and the general problem of color development in sugar containing systems was called to the attention of other laboratories in the project and a portion of the data was presented in the symposium on Non-Enzymatic Browning of the Division of Food and Agricultural Chemistry at the Chicago Meeting of the American Chemical Society in September, 1946, in an introductory paper entitled, "A Review of Some Sugar Reactions which Give Rise to Color," by Sidney M. Cantor and Charles D. Hurd.

[4] Porst, Orig. Com. 8th Intern. Congr. Appl. Chem., **13**, 205 (1912).

[5] Meunier, *Chemie et Industrie*, Special No. 583, February (1929).

literature on this subject has been reviewed recently.[6] Experience in this Laboratory had indicated that the major portion of the coloring matter arises from decomposition of the glucose molecule and that HMF is the precursor of coloring matter in starch hydrolyzates. It has been postulated that HMF polymerizes to give colored products of varying degrees of solubility.[7] The HMF molecule, arising from the dehydration of glucose, has a triene structure and shows absorption in the ultraviolet. It seems reasonable to suppose that polymerization (condensation) of this molecule might give rise to a molecule possessing the requisite number of conjugated double bonds for the selective absorption in the visible region. Modern concepts concerning the color of linear conjugated systems show that the presence of six to eight double bonds in a molecule gives rise to color.[8] This work was undertaken to make a quantitative spectrophotometric[9] study of (1) the destruction of glucose as a function of concentration, time and *p*H value of the system, (2) the role of HMF and levulinic acid in color formation, and (3) the possibility of condensation between glucose and amino acids under conditions employed for the commercial hydrolysis of starch, and its relation to the total color of the system.

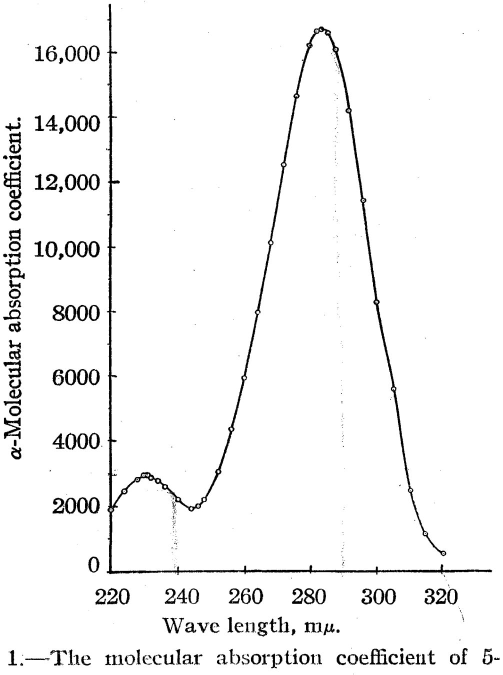

Fig. 1.—The molecular absorption coefficient of 5-(hydroxymethyl)-furfural.

Experimental

Dextrose.—Bureau of Standards D-**glucose** no. 41 or a sample of equivalent purity,[10] was used in all the experiments. Absence of absorption in the ultraviolet was used as a criterion of purity.

5-(Hydroxymethyl)-furfural.—HMF was prepared from sucrose by using the procedure of Middendorp.[11] The light yellow material was twice distilled under high vacuum (m.p. 31.5–32.0°, uncor.).

Levulinic Acid.—The white, crystalline solid (m.p. 32°, uncor.) was obtained after four recrystallizations of technical grade material.

Leucine (C. P. Pfanstiehl).—A Beckman Spectrophotometer (model DU) was used in this work for the examination of the ultraviolet and the visible spectra. The instrument was calibrated by using purified potassium chromate as an absorption standard and the performance compared with that recorded in the literature.[12] High temperature experiments were conducted in sealed tantalum bombs of approximately 20 ml. capacity. These bombs are test-tube shaped and are equipped with tantalum lined closures which are sealed by means of a screw and nut collar device. They were fabricated to specification by the Fansteel Metallurgical Corp.

All solutions were made up using doubly distilled water.

The results are given in optical density ($\log I_0/I$) *versus* wave length in millimicrons (mμ) except in cases where pure compounds, such as HMF and levulinic acid, were examined. For HMF and levulinic acid the molecular absorption coefficient, α, was calculated from Beer's law. Two centimeter fused silica cells were used for the ultraviolet region and one centimeter glass cells for the visible region.

All HMF values were determined in dilutions that gave an optical density between 0.5 and 1.0 at 284 mμ (slit width = 0.34 mm.). Color readings were obtained by integration of transmission curves throughout the visible spectrum range.

An arbitrary unit of color was used equal to 2.5 sq. in. of area under the curve.

Results

The absorption spectrum of pure HMF is shown in Fig. 1 and that of a dilute solution of a starch hydrolyzate in Fig. 2. The HMF spectrum shows two maxima, a major peak at 284 mμ and a minor one at 230 mμ.[13]

The molecular absorption coefficients compared with similar constants from other researches are shown in Table I.

The band around 280 mμ is usually taken as evidence for the carbonyl group; the intensity of this transition is determined partly by conjugation.

An estimate of the extent of destruction products in starch hydrolyzates was obtained by hydrolysis of a suspension of defatted corn starch. Conditions for hydrolysis were: starch concentration, 17.0% by weight; temperature, 145°; time, thirty minutes; acid concentration, 0.03 *N* HCl. After thirty minutes of reaction time 0.068% HMF (g./100 g. solution) was present and the color of the solution was 5.6 units. The final solution contained 18.5% of dry solids (approx. 16.7% D-glucose).

The ultraviolet spectra of heated 16% glucose solutions (0.03 *N* HCl, 145°) for the first ten minutes are shown in Figs. 3 and 4. There is evidence first of a band around 280 mμ and later a band around 230 mμ appears. The data are summarized in Table II.

Since starch hydrolyzates contain a small amount of nitrogenous substance (about 0.09% nitrogen on dry substance basis), the possibility of a glucose–(amino acid) condensation product was investigated. Of the two amino acids, glutamic acid and leucine, present in corn gluten in large amounts, leucine, the simpler of the two, was chosen for this study. The ultraviolet spectral data of 10% glucose (*p*H 5) and 10% glucose plus 0.4% leucine (*p*H 6), refluxed for three hours at 100°, are shown in Fig. 8.

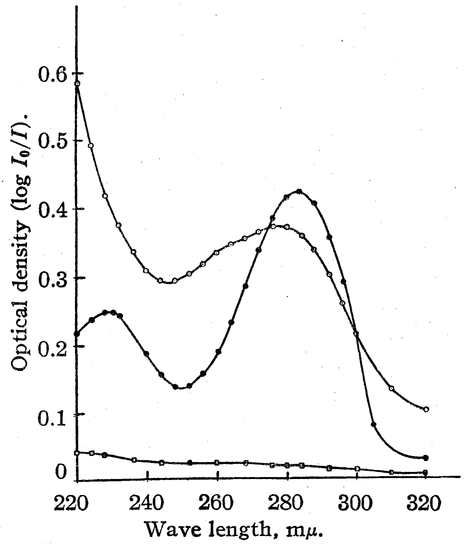

Fig. 7.—Ultraviolet spectra of destruction products of D-glucose and methyl α-D-glucoside; conditions: 145.5°, 30 minutes, *p*H 6 (2-cm. cells): ⊙, 10% methyl α-glucoside after heating; ●, 10% glucose (diluted 1:100) after heating; ⊡, 5% methyl α-glucoside before heating.

Discussion

The results of hydrolysis of defatted corn starch indicate that a satisfactory definitive mechanism for the extent of the destruction reaction in starch hydrolyzates must be able to account for the presence of HMF (0.068%) and color (5.6 units). Solutions of 16% glucose heated under the same conditions contained 0.064% HMF and 5.6 units of color (Table II). Although the concentration of glucose during starch hydrolysis is variable (increases from zero to 16.7% in thirty minutes), nevertheless it is quite clear that the major portion of HMF and coloring matter in starch hydrolyzates can be accounted for by the destruction of the glucose molecule.

The destruction of glucose as a function of time (Fig. 3) shows first the appearance of a molecule containing the carbonyl group (absorption band around 280 mμ). That this substance is not HMF is apparent from the fact that the minor peak around 230 mμ is missing. The concentration of the substance, calculated as HMF, is 0.00145 g. per liter. HMF solutions of this order of concentration show two peaks. Shortly thereafter the spectrum of an HMF-like molecule appears in the sense that the absorption spectrum shows the two characteristic peaks at 285 mμ and 230 mμ. The changes in the relative heights of these peaks, however, suggest the presence of other substances besides HMF. Presumably, the first reaction is the opening of the pyranose ring and the development of the carbonyl group followed by dehydration. The ultraviolet spectral evidence for the first ten minutes (Fig. 4) shows the presence of HMF alone and then the rapid development of coloring matter. Such an induction period in the formation of coloring matter has been observed in other systems and has been attributed to some autocatalytic mechanism. However, the appearance of HMF during this induction period, together with the demonstration that coloring matter is formed from pure HMF as starting material, support the theory that HMF is the precursor of coloring matter during the acid decomposition of hexose-containing carbohydrates.

Table III shows that the rate of destruction of glucose with formation of HMF is independent of the glucose concentration, indicating a first order mechanism for the reaction. A slight rise in the first order rate constant might be anticipated in more concentrated glucose solutions because of the effect of glucose in increasing the hydrogen ion activity of the solution.[14] The destruction of glucose as a function of *p*H value[15] (Fig. 5) demonstrates the surprising stability of the glucose molecule in the neighborhood of a *p*H value of three where only one-fifth as much HMF and one-thirteenth as much coloring matter is produced as at *p*H 1.6. Ring stability appears to approach a maximum at this point.[16] The results seem to follow the concepts of prototropy developed by Lowry[17] and are reminiscent of the catalytic catenary of Dawson[18] connecting the velocity of a hydrolytic reaction in water with the corresponding *p*H value. Dawson studied the enolization of acetone (followed by rapid substitution of iodine) and the hydrolysis of ethyl acetate. The velocity

of mutarotation of glucose[19] as a function of pH goes through a similar minimum. With sucrose and D-fructose there is no such minimum and the destruction is much greater than in glucose. As might be anticipated,[20] L-ascorbic acid undergoes extensive destruction under the conditions of the experiment (Table V).

The reaction in HMF solutions of different concentrations under starch hydrolysis conditions to produce coloring matter shows that about the same percentage of HMF is destroyed indicating a first order reaction (Table VI). Teunissen[21] has shown that the rate of decomposition of HMF at 100°, as followed by titration of organic acid decomposition products, follows a first order mechanism. No change occurred in levulinic acid solution on heating except a slight increase in ultraviolet absorption (Fig. 6). This is another demonstration of the fact that HMF is the sole precursor of coloring matter and that levulinic acid plays no part in this process.[22] The importance of the functional grouping on the aldehydic carbon atom of the glucose molecule to the destruction reaction is evident from the data on methyl α-glucoside under identical conditions (Table VIII and Fig. 7). Methyl α-glucoside shows a slight hydrolysis with subsequent destruction of the glucose formed (as evidenced by the development of the carbonyl group (Fig. 7)) while glucose gives rise to HMF and coloring matter.

The possibility of glucose–(amino acid) condensation is rather remote under the specified conditions (Fig. 8). Although the glucose solution containing leucine shows a slightly greater absorption in the far ultraviolet, the two spectra coincide around 280 mμ. Evidently about the same amount of HMF is produced in the two cases. Similarly, under these conditions no difference in HMF or color content could be noted between glucose solutions with or without leucine. Moreover, these experiments indicate no specific catalytic action of leucine in small concentration on formation of either HMF or coloring matter. Any such catalytic action at relatively high concentrations of amino acids is probably due to contribution either to the total ionic strength of the reacting system or to the hydrogen ion activity.

The results of this study suggest the importance of HMF, and consequently of hexoses, to the color problem. A recent report has indicated that furfural or HMF is partially responsible for color development in certain dried fruits.[23] Heretofore considerable attention has been devoted to the reaction between reducing sugars and amino acids or polypeptides (the Maillard[24] reaction) as the cause of browning in various foodstuffs, but this conclusion has been drawn only on the basis of model reactions between amino acids and aldoses and the presence of these substances in foodstuffs. It would now appear that the pH value of the food system in addition to the specific constituents of the system is an important factor in determining the course by which colored bodies are formed.

Summary

It is shown that a major portion of 5-(hydroxymethyl)-furfural and coloring matter in starch hydrolyzates comes from the destruction of the glucose molecule.

The absorption spectrum of 5-(hydroxymethyl)-furfural has been studied and it is found that there are two peaks, a major one around 284 mμ and a minor one around 230 mμ.

In the destruction of the glucose molecule on heating in an acid medium there is evidence first of an absorption band around 280 mμ and later a band around 230 mμ appears. It is postulated that the first reaction is the opening of the pyranose ring, development of the carbonyl group followed by dehydration. Later, color develops in the solution for which 5-(hydroxymethyl)-furfural is the precursor.

Solutions of different concentrations of 5-(hydroxymethyl)-furfural on heating in an acid medium show development of color and about the same percentage of destruction indicating a first order reaction. Levulinic acid in solution shows no apparent destruction on heating.

The glucose destruction reaction as a function of pH goes through a minimum around a pH value of 3. No such minima were found for D-fructose and sucrose. The extent of destruction for sucrose and D-fructose as compared with glucose is greater in acid media.

The importance of the functional grouping on the number one carbon atom in glucose is shown by the comparative destruction of glucose and methyl α-glucoside under comparable conditions. Glucose solutions produce 5-(hydroxymethyl)-furfural with consequent color while no destruction takes place in methyl α-glucoside solutions.

No evidence was found for condensation between glucose and leucine under the conditions of this study.

It is suggested as a result of the study that a similar mechanism may be partially responsible for the color which develops in certain natural products containing reducing sugars.

Open-Chain Sugars. I. Absorption in Ultraviolet of D-Glucose and L-Arabinose in Acid Solution

BY EUGENE PACSU AND LEJAREN ARTHUR HILLER, JR.

In 1913 Willstätter and Zechmeister[1] observed that the optical activity of D-glucose in hydrochloric acid increased to a great extent with the concentration of hydrogen chloride. Thus the specific rotations[2] of D-glucose in 41.4 and 44.5% hydrochloric acid were found to be, respectively, +106° and +165°, instead of the constant value of +52.6° in aqueous solution. In a later work Zechmeister[3] published the results of his systematic investigation of this interesting phenomenon. He found that the simple sugars in 42.0% hydrochloric acid at about 6 to 10° possessed the specific rotations: D-glucose, +113.3°; D-galactose, +160.4°; D-mannose, +54.6°; D-fructose, −180.0°; L-arabinose, +202.9°; D-xylose, +96.6°; L-rhamnose, −31.1°. Further increase in the hydrogen chloride content of the solvent resulted in the remarkably high specific rotation of +202° for D-glucose at −12° in 46.7% hydrochloric acid solution. The rates of these rotational changes were generally so rapid that they could not be determined at room temperature. However, they became measurable at 0°, giving, *e. g.*, for D-glucose in 40.6% hydrochloric acid ($[\alpha]^{0}\text{D} + 96.2°$; *c*, 0.990) $k = 1.6 \times 10^{-2}$ (decimal logarithms, minutes). For comparison, the rate of mutarotation of D-glucose in pure water at 0.7° is given as 7.4×10^{-4}. The reversibility of the process in 40.0% acid was proven when it was found that after neutralization of the various solutions with sodium bicarbonate the sugars were recovered unchanged or nearly so, quantitatively, each of them showing the respective normal value of constant rotation in the corresponding salt solution. Zechmeister also found that, *e. g.*, a 1.5% D-glucose solution in 40.0% hydrochloric acid at 10° remained practically colorless during a twenty-one hour period of time, thus indicating that very little, if any, decomposition had taken place.

For explanation of these experimental facts Zechmeister assumed that in concentrated hydrochloric acid two reactions were taking place with unequal rates: the instantaneous establishment of a new equilibrium between the α- and β-forms of the sugars, and, at sufficiently low temperature, the measurably slow, partial conversion of the latter into "a high-rotating modification." It had already been known for some time from the work of Armstrong and Hilditch[4] that, *e. g.*, D-glucose in 0.1 *N* hydrochloric acid rapidly acquires the ability to reduce potassium permanganate solution, a property which is completely lacking in the aqueous solution of either anomeric form of the sugar. They explained this curious behavior by assuming that a small amount of a new isomer, "γ-glucose," with ethylene oxide ring structure was being formed in acidic solution. This new modification was supposed to be responsible for the potassium permanganate reaction. Zechmeister pointed out that the formation in somewhat larger quantity of such a "γ-sugar" might account for the observed high optical activity and for the measurable rate and the reversible nature of the process. However, he also stated that it was difficult to see how a sugar molecule with ring structure could exist in fuming hydrochloric acid without suffering cleavage of its hemiacetal linkage. He suggested that combination between a hydrogen chloride molecule and the free aldehyde group of the sugar might give rise to a structure with very high optical rotational value.

In connection with our work on the acid-catalyzed degradation of cellulose it became necessary to know the specific rotations of D-glucose in strong mineral acids of various concentrations. We found[5] that solutions of D-glucose in 85% phosphoric acid and in 50.5% sulfuric acid ($d^{20}{}_4$ 1.40) gave the constant values $[\alpha]^{20}\text{D} + 68.0°$ and $[\alpha]^{20}\text{D} + 61.0°$, respectively, ten minutes after solution. We also found[6] that potassium permanganate in 0.25 *N* sulfuric acid solution selectively attacked cellulose by oxidizing its reducing group to carboxyl group. Since the potential reducing groups of the carbohydrates with ring structures are not oxidized by this reagent in neutral medium, we have concluded that in acidic environment a shift into the open-chain form of the sugars might occur with the formation of carbonyl groups which are then attacked by dilute potassium permanganate. Since it is known from Henri's work[7] that aldehydes possess a characteristic absorption band at the wave length of about 2800 Å., we undertook the measurements in ultraviolet of the acidic solutions of D-glucose to verify our deduction. First we measured at 25° the absorption of a 16% aqueous D-glucose solution ($[\alpha]^{20}\text{D} + 52.9°$) in the ultraviolet region 3100 to 2400 Å., by using a Beckmann photoelectric quartz spectrophotometer. Contrary to the finding of J. E. Purvis[8] and in agreement with statements in the general literature[9]

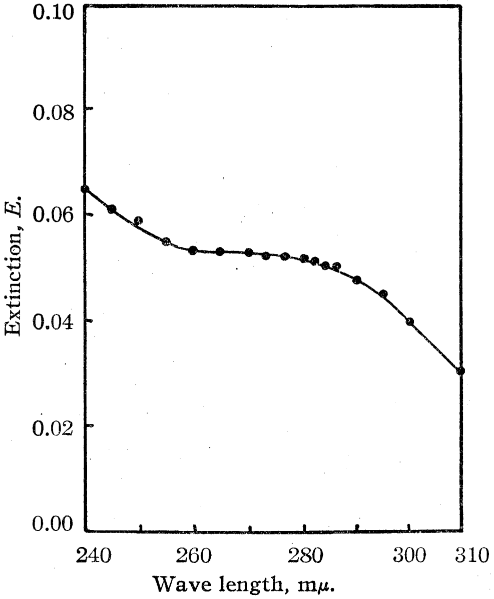

Fig. 1.—Absorption spectrum of a 16% D-glucose solution in water.

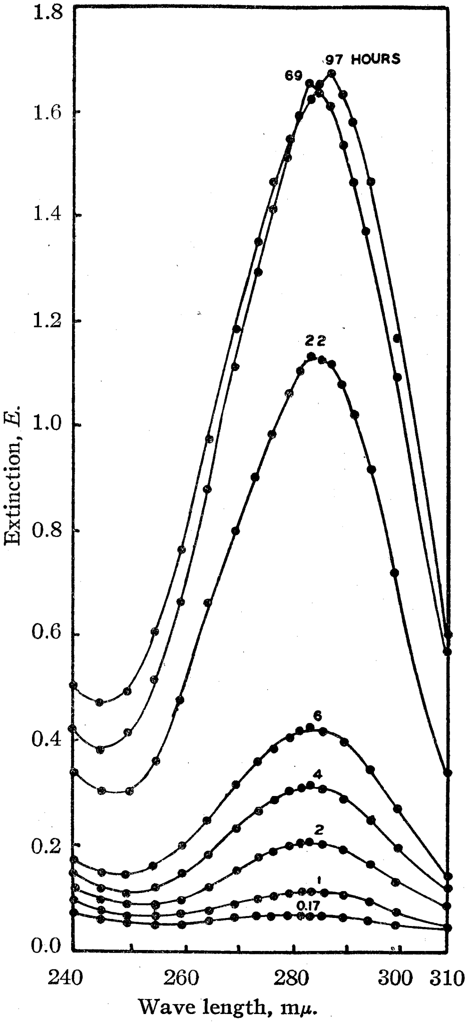

Fig. 2.—Change with time of the absorption spectrum of a 17.3% D-glucose solution in 50.5% sulfuric acid.

we found no selective absorption that would have indicated the presence of the oxo-form of glucose in the aqueous solution (Fig. 1). Then a 17.3% D-glucose solution in 50.5% sulfuric acid ($d^{20}{}_4$ 1.40) was employed with the result shown in Fig. 2. The absorption became evident ten minutes after dissolution of the sugar and showed a maximum at the wave length 2840 Å. The absorption steadily increased in intensity during the ensuing sixty-nine hours thus indicating that conversion of the non-absorbing cyclo-form of the sugar into the absorbing oxo-form took place gradually.[10] After the maximum intensity had been reached with the extinction value $E_\infty = 1.665$ the solution began to show a slight discoloration. Ninety-seven hours after the beginning of the experiment the absorption band had shifted slightly to 2880 Å., while only negligible increase (0.005) had occurred in the value of optical density. Since a plot of the difference between the logarithms of $E_\infty - E_0$ and $E_\infty - E_t$ against t time gave a straight line, it was concluded that the conversion of D-glucose with normal ring structure into the carbonyl-containing modification represented a first order reaction. From the slope of the line between the points for one hour and twenty-two hours the rate constant was calculated to be $k = 3.6 \times 10^{-4}$. In a similar experiment the absorption of L-arabinose was determined (Fig. 3). According to Zechmeister the rate of conversion in 40.6% hydrochloric acid of L-arabinose into a high-rotating form was so rapid as to make quantitative measurements even at 0° impossible. We used a 4.0% solution of L-arabinose in 50.5% sulfuric acid and recorded the change in the optical density of the solution with time at the peak of the absorption curve, namely, at the wave length 2840 Å. From a logarithmic plot of the observed data the rate constant was calculated to be $k = 4.5 \times 10^{-4}$.

It has been stated above that the rotational value of D-glucose in 50.5% sulfuric acid, $[\alpha]^{20}\text{D} + 61.0°$, was obtained about ten minutes after the sugar had first come into contact with the solvent. For an explanation of the fact that the optical rotation remains constant while the absorption develops, it may be assumed that two processes are taking place in the acid solution. The first reaction is probably the reversible formation of an

---

[10] The absence of hydroxymethylfurfural was demonstrated when 100 cc. of a twenty-two hours old 10% glucose solution in 50.0% sulfuric acid was, after dilution, extracted with ether and the concentrated ether layer was tested with resorcinol dissolved in concentrated hydrochloric acid with negative result. For comparison, 5 cc. of a 1% sucrose solution in 1 N sulfuric acid was boiled for three minutes and then extracted with ether; the ether extract gave a very strong positive test for hydroxymethylfurfural with the same reagent. Also, the absence of levulinic acid in the aged glucose solution was proved by the negative outcome of the iodoform test carried out on the aqueous residue of the moist ether extract.

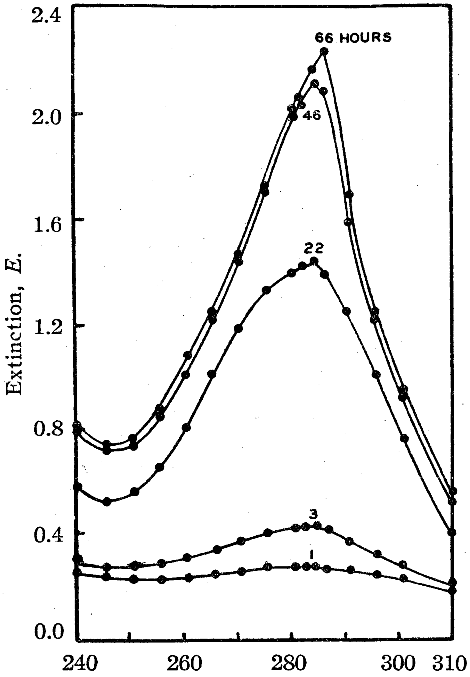

Fig. 3.—Change with time of the adsorption spectrum of a 4.0% L-arabinose solution in 50.5% sulfuric acid.

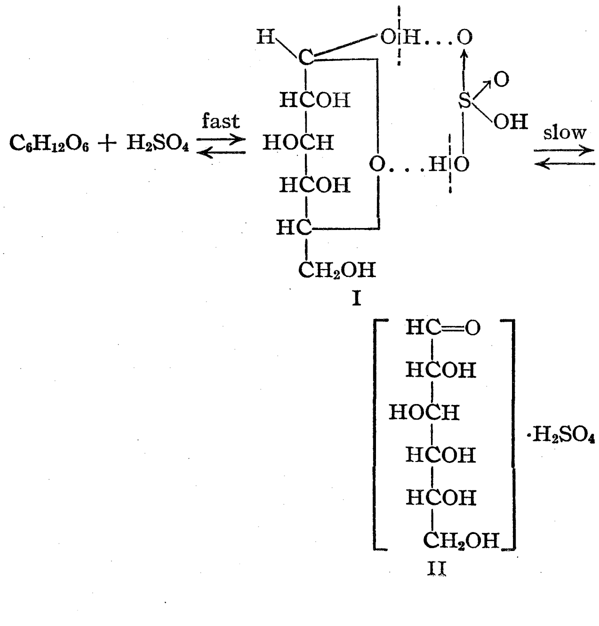
addition complex (I) between the anomeric forms of D-glucose and the acid molecule, which event proceeds with an unmeasurably high rate. The observed rotational value of $[\alpha]^{20}\text{D} + 61.0°$ would correspond to the optical activities of the components in the equilibrium mixture. This fast reaction would then be followed by a comparatively slow process which essentially consists of the opening of the ring structure in complex (I) to give rise to the carbonyl form of the sugar (II). Although this phase of the reaction becomes noticeable by the sensitive method of absorption measurement, yet the concentration of (II) is probably so small under our experimental conditions that the presence of this form remains undetected when the much less sensitive polarimetric method is employed.



Zechmeister postulated that the rotational value, $[\alpha]^{0}\text{D} + 62.0°$, obtainable by extrapolation to 0 time from the rate constant, $k = 1.6 \times 10^{-2}$, corresponded to a new equilibrium between the α- and β-form of D-glucose in the moment of dissolution of the sugar. In support of this argument he pointed out that this extrapolated value lies between the known specific rotations of the two anomeric forms. However, it seems to us more likely that the acid molecules play a decisive role in this reaction which, according to our assumption, should generally be initiated by the formation of molecular compounds like (I) between the sugar and acid molecules.

According to Zechmeister's experiments neutralization of the concentrated hydrochloric acid solutions of the sugars by sodium bicarbonate restored the constant specific rotations which were shown by the respective sugars in sodium chloride solutions of corresponding concentrations. We had, therefore, expected that after neutralization of our sulfuric acid solution with sodium bicarbonate the characteristic carbonyl band would

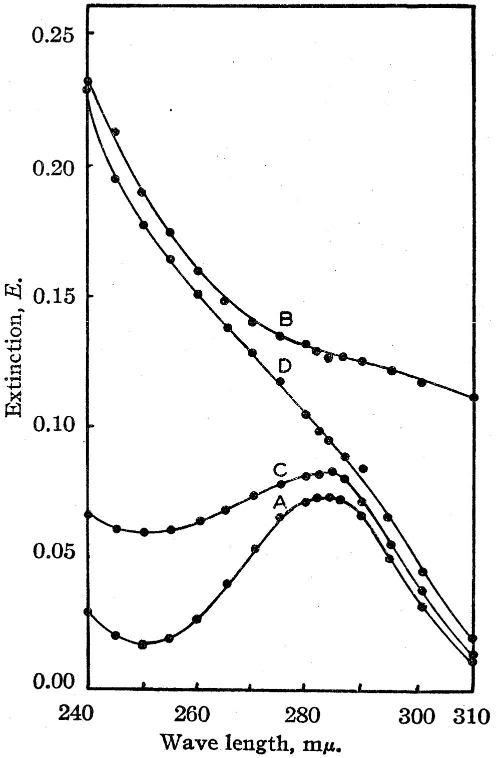


Fig. 4.—Disappearance of peak in neutralized D-glucose solution (2%): A, 1 day of standing; B, 1 day of standing + 2 drops alkali; C, 8 days of standing; D, 16 days of standing.

disappear and the solution would show the general absorption as has been found for D-glucose in neutral solution (Fig. 1). Pertinent experiments have revealed the remarkable fact that this is only true if the solution, after treatment with sodium bicarbonate, becomes slightly alkaline. In slightly acidic solution, however, the assumed open-chain form of the sugar persists for a comparatively long period of time. It is seen in Fig. 4 (C) that eight days after "neutralization" the slightly acidic solution still exhibited the characteristic absorption at 2840 Å., although the peak was not as sharp as that measured after the first day (A). It took altogether sixteen days until the absorption band completely disappeared in the slightly acidic solution (D). On the other hand, addition of two drops of dilute alkali to the one-day old solution resulted in the immediate disappearance (B) of the peak at 2840 Å.

In view of the present theory of mutarotation[11] these facts can not be interpreted readily. Further investigations are necessary before the significance of our observations to the true mechanism of mutarotation can be evaluated. We have already made initial attempts to isolate the postulated open-chain form of D-glucose by using superconcentrated hydrochloric acid solutions. So far we have not been able to isolate the free sugar in crystalline form, but we have succeeded in obtaining an amorphous acetate as the single product which, unlike the α- and β-pentaacetate, in chloroform solution shows strong selective absorption at the wave length of 2840 Å. The investigation is being continued.

Summary

It has been found that D-glucose and L-arabinose in 50.5% sulfuric acid solutions show strong absorption at wave length 2840 Å. which is characteristic for carbonyl-containing compounds. After neutralization with sodium bicarbonate the slightly acidic solution still exhibits this band which, however, instantaneously disappears on rendering the solution barely alkaline. A possible mechanism is suggested for explanation of the behavior in strong acids of sugars with ring structures by assuming the formation of molecular compounds between the acid molecules and the open-chain forms of the sugars.

From D-glucose in superconcentrated hydrochloric acid solution an amorphous acetate has been obtained which compound, unlike the α- and β-pentaacetate, in chloroform solution exhibits strong absorption at 2840 Å.

Preparation of α-Carbalkoxyalkyl Methacrylates by Pyrolysis of the Corresponding α-Acetoxyisobutyrates

BY E. M. FILACHIONE, M. L. FEIN, J. H. LENGEL AND C. H. FISHER

In an earlier paper[2] it was demonstrated that α-carbalkoxyalkyl methacrylates[3] (II) can be made in satisfactory yields by pyrolyzing the corresponding α-acetoxyisobutyrates (I, R = Me or H; R′ = Me or Et).

$$\underset{\text{I}}{\mathrm{CH_3COOC(CH_3)_2COOCH(R)COOR'}} \xrightarrow[550^\circ]{450\text{ to}} \underset{\text{II}}{\mathrm{CH_2{=}C(CH_3)COOCH(R)COOR'}} + \mathrm{CH_3COOH}$$

The present paper records results obtained in a further study of the pyrolysis method of preparing methacrylates (II). The additional esters made pyrolytically are the methacrylates of allyl glycolate and of allyl, methallyl, tetrahydrofurfuryl, benzyl and β-chloroethoxyethyl lactates.

The α-acetoxyisobutyrates (I) used in the pyrolysis experiments were prepared in high yields by treating allyl glycolate and several lactic esters (allyl, methallyl, tetrahydrofurfuryl, benzyl and β-chloroethoxyethyl) with α-acetoxyisobutyryl chloride. The resulting acetoxyisobutyrates (Table I) were decomposed by passage through a Pyrex glass tube heated at about 450° (Table II).

Although the esters (I) pyrolyzed had three esterified carboxyl groups, decomposition occurred preferentially at the acetate group, the principal products being acetic acid and the corresponding methacrylates (II, yields, 65–85%). On the basis of these and earlier[2] findings, it is concluded that the pyrolysis method is generally useful for the preparation of methacrylates (II) of alkyl glycolates and lactates. Presumably the method is useful also for preparing esters (II) in which R is ethyl or higher, but less suitable for esters (II) in which R′ is a secondary or tertiary alkyl group. It is anticipated that only relatively low yields of carbalkoxyisopropyl methacrylates ($\mathrm{CH_2{=}C(CH_3)}$-$\mathrm{COOC(CH_3)_2COOR}$) would be obtained in the pyrolysis of $\mathrm{CH_3COOC(CH_3)_2COOC(CH_3)_2COOR}$,

a more probable decomposition product[4] being $CH_2{=}C(CH_3)COOR$.

The methacrylates (Table III) were mass polymerized at 60 to 65° in the presence of a small quantity (0.1 to 0.15%) of benzoyl peroxide. With the exception of the β-chloroethoxyethyl ester (a soft, flexible, amber polymer that became brittle at approximately −5°), all the polymeric methacrylates were hard at room temperature and virtually colorless. The polymeric benzyl and tetrahydrofurfuryl esters became soft at approximately 45° and 35°, respectively. Presumably the polymeric allyl and methallyl esters, insoluble and infusible, were cross-linked.

The authors are indebted to Frances J. Cooper, Mary J. Welsh and C. L. Ogg for the saponification equivalents and ultimate analyses and to W. P. Ratchford and E. J. Schaeffer for pyrolyzing the acetoxyisobutyrates.

Experimental

Allyl Glycolate.—Water was distilled from a mixture of 210 g. of technical-grade glycolic acid (72.4% concentration) and 0.5 ml. of concentrated sulfuric acid for three hours at 100° and 20 to 30 mm. pressure. The resulting

---

[4] This assumption is based on the pyrolysis behavior[2] of $CH_3COOCH(CH_3)COOCH(CH_3)COOCH_3$, which yields methyl acrylate as the principal product.

residue (123 g. of polyglycolic acid having an equivalent weight on titration of 64.75; *i. e.*, 117.5% by weight as glycolic acid) was semi-solid.

A mixture of 32.4 g. of the polyglycolic acid (equivalent to 0.5 mole of glycolic acid and containing 0.13 ml. of sulfuric acid) and 2.5 moles of allyl alcohol was heated in a bomb (glass liner) for six hours at 120–139°. Anhydrous sodium acetate (0.6 g.) was added to the reaction mixture and the mixture was distilled to separate allyl glycolate (66% yield; b. p. 60–72° (8 mm.); d^{20}_{4} 1.0901; $n^{20}\mathrm{D}$ 1.4418; $M^{20}\mathrm{D}$ 28.09 (calculated, 28.00); saponification equiv., 122.5 (calculated, 116.1)). Muskat and Strain[5] prepared allyl glycolate but did not describe it.

Allyl Lactate.—This compound, previously described,[6,7,8] was prepared by the reaction of allyl alcohol with condensation products of glycerol and lactic acid. Water (116 g.) was distilled through a Vigreux column from a mixture of 81.7% edible-grade lactic acid (equivalent to 3 moles), 1 mole of glycerol and 0.75 ml. concentrated sulfuric acid for three hours. This was accomplished by heating the mixture on a water-bath while the system was at a pressure of 40–50 mm. The pale yellow, viscous residue (307 g.) had a saponification equivalent, including free acidity, of 101.4 (glyceryl trilactate, 102.7). A mixture of 50.5 g. of the glycerol–lactic acid product (equivalent to 0.5 mole of lactic acid) and 2.5 moles of allyl alcohol was heated in a bomb (glass liner) for two hours at 120–30°. The reaction mixture was treated with 0.5 g. of anhydrous sodium acetate and distilled in vacuum. Allyl lactate, b. p. 60–61° at 7 mm., $n^{20}\mathrm{D}$ 1.4363, was isolated in 73% yield.

Benzyl Lactate.—A mixture of 1 mole of methyl lactate, 4 moles of benzyl alcohol and 1 g. of aluminum isopropoxide was heated under a Vigreux column fitted with a variable take-off distilling head, methanol being distilled as formed (temperature of the reaction mixture increased gradually from 170 to 192°, and 36 ml. of distillate was collected during four to five hours). The reaction mixture was then distilled under reduced pressure. The yield of benzyl lactate, b. p. 103–104° at 1.3 mm., was 82%. The refractive indices, $n^{20}\mathrm{D}$, of two different preparations were 1.5143 and 1.5155. This compound has been made by the alcoholysis of ethyl lactate[9] and by the interaction of benzyl chloride and sodium lactate.[10]

Methallyl lactate was prepared by direct esterification of lactic acid with methallyl alcohol, some modifications of the previously reported method[6] being incorporated. A mixture of 110 g. of 81.7% of edible lactic acid, containing 1.0 mole of available lactic acid and 216 g. (3.0 moles) of methallyl alcohol, was refluxed and the vapors were led through a Vigreux column to a Barrett-type Dean-and-Stark moisture trap. The receiver of the moisture trap was jacketed and cooled by circulating cold water. After approximately seven hours removal of water virtually ceased, and 37 ml. of aqueous layer was collected. The reaction mixture was then distilled. There was obtained 86 g., or 60% of the theoretical amount of methallyl lactate, b. p. 85–90° at 15 mm., $n^{20}\mathrm{D}$ 1.4390.

Tetrahydrofurfuryl Lactate was prepared essentially as described previously[11,12] by alcoholysis of methyl lactate. The alcoholysis, however, was carried out in the absence of a catalyst. By refluxing a mixture of 10 moles of methyl lactate and 30 moles of tetrahydrofurfuryl alcohol with the continuous removal of methanol, an 85% yield of tetrahydrofurfuryl lactate was obtained; b. p. 84–86° at 0.1 mm., $n^{20}\mathrm{D}$ 1.4571, d^{20}_{4} 1.1360.

β-Chloroethoxyethyl Lactate.—Direct esterification of β-chloroethoxyethanol (diglycol chlorohydrin) with lactic acid, as previously described,[13] was used to obtain this ester, b. p. 91° at approximately 0.1 mm., $n^{20}\mathrm{D}$ 1.4567.

α-Carbalkoxyalkyl α-Acetoxyisobutyrates.—Acetoxyisobutyryl chloride was prepared and used to acylate the hydroxy esters as previously described.[2] Physical properties of the acyl derivatives (obtained in 80 to 90% yields) are recorded in Table I.

Pyrolysis.—In general the previous procedure was followed.[2] The acylated hydroxy esters were pumped[14] to the top of a vertical Pyrex glass tube (25 mm. diameter) heated electrically over a length of 33 cm. The thermocouple was located 10 cm. from the bottom of the heated zone. The pyrolysis tube was packed with short lengths of Pyrex glass tubing, and the free space of the heated zone was 78 ml.

The pyrolyzates, containing hydroquinone, were distilled in a 56-cm. Vigreux column in an atmosphere of carbon dioxide (Table II). The acetic acid fraction was collected at water pump pressure (in a solid carbon dioxide trap), whereas the methacrylates and undecomposed esters were isolated at pressures below 1 mm.

The constants of the methacrylates (Table III) were obtained on redistilled fractions. The methacrylates of tetrahydrofurfuryl lactate, benzyl lactate and chloroethoxyethyl lactate partly polymerized during distillation, resulting in losses.

Solubilities of the Polymeric Carbalkoxyethyl Methacrylates.—The polymeric methacrylates (0.1 g.) were allowed to stand at room temperature with approximately 1 ml. of solvent. The polymethacrylate of tetrahydrofurfuryl lactate swelled in toluene, benzene, ethylene dichloride, nitromethane, dioxane, acetone, methyl lactate and ethyl acetate. The polymethacrylate of benzyl lactate was soluble in nitromethane and partly soluble in toluene, benzene, ethylene dichloride, dioxane, acetone, methyl lactate and ethyl acetate. The polymethacrylate of β-chloroethoxyethyl lactate was soluble in toluene, benzene, ethylene chloride, nitromethane, dioxane, acetone, methyl lactate, and ethyl acetate. The polymers listed above were insoluble in heptane and ethanol, but dissolved slowly at room temperature in 10% sodium hydroxide. The polymers after swelling by acetone dissolved much more rapidly in the sodium hydroxide, presumably by saponification of the esterified lactic acid carboxyl group.

Summary

The method of producing α-carbalkoxyalkyl methacrylates ($CH_2{=}C(CH_3)COOCHRCOOR'$; R = H or Me) by pyrolysis of the corresponding α-acetoxyisobutyrates ($CH_3COOC(CH_3)_2COO$-$CHRCOOR'$) was used satisfactorily to prepare the methacrylates of allyl glycolate and of allyl, methallyl, benzyl, tetrahydrofurfuryl, and β-chloroethoxyethyl lactates. It is concluded that the pyrolytic method is generally useful for making α-carbalkoxyalkyl methacrylates.

The methacrylates polymerized readily when heated in the presence of benzoyl peroxide. The polymeric methacrylate of β-chloroethoxyethyl lactate was amber and flexible, the allyl and

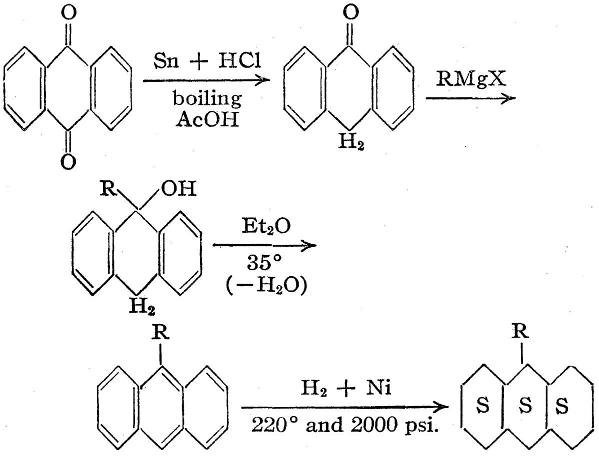
Higher Hydrocarbons.[1] V.[2] Alkyl Anthracenes and Alkyl Phenanthrenes

BY ROBERT W. SCHIESSLER, ANTON W. RYTINA AND FRANK C. WHITMORE[2a]

As part of our studies of the synthesis, purification and properties of high molecular weight hydrocarbons, the preparations of several alkyl-anthracenes and -phenanthrenes, together with the corresponding perhydro derivatives, have been completed. They are 9-*n*-butylanthracene, 9-*n*-butylperhydroanthracene, 9-*n*-dodecylanthracene, 9-*n*-dodecylperhydroanthracene, 9-*n*-dodecylphenanthrene and 9-*n*-dodecylperhydrophenanthrene.

The alkyl anthracenes were synthesized by a modification of the method of Sieglitz and Marx.[3] The method consists of the addition of anthrone to alkylmagnesium halides, followed by dehydration of the resultant tertiary alcohol to the desired alkyl anthracene:

Synthesis of 9-Alkylanthracenes.—



9-*n*-Dodecylphenanthrene was prepared by the addition of lauronitrile[2,4] to 9-phenanthrylmagnesium bromide[5] followed by reduction of the resulting 9-phenanthryl hendecyl ketone to the hydrocarbon by the modified Wolff–Kishner method.[6]

The perhydro derivatives of the hydrocarbons were prepared by complete hydrogenation over nickel catalyst[7] at 100–230° and 2300 p.s.i. hydrogen pressure.

It must be emphasized that the perhydro derivatives reported are mixtures of geometric isomers, and the properties given were determined on these mixtures of unknown composition. The difficulty of separating and identifying the various *cis-trans* structures precludes following any other course for our work.

Several of the important physical properties of the hydrocarbons are listed in Table I. The methods of determining the properties and their precision were discussed in the first paper of the series.[2] Numerous other properties have been determined and will be reported in the appropriate journals.

Experimental

Intermediates.—In order to simplify the purification of the final hydrocarbons, great care has been taken with the purification of intermediates. Where possible, distillation of intermediates through fractionating columns of 35–40 theoretical plates was carried out. The boiling points of the intermediates are uncorrected. The properties listed are for the constant boiling, constant refractive index fractions.

(a) ***n*-Butyl Bromide.**—Edwal Laboratories *n*-butyl bromide was carefully fractionated: b. p. 100° (733 mm.); n^{20}_{D} 1.4392.

(b) **Lauryl bromide**[8] was prepared by passing hydrogen bromide (from the direct combination of bromine and hydrogen) into Eastman Kodak Company technical lauryl alcohol at 120°. After washing twice with half its volume of cold (0–5°), concd. sulfuric acid and then with an equal volume of 95% methanol, the crude lauryl bromide was dried over anhydrous potassium carbonate and fractionally distilled through a 35–40 plate all glass column. The yield of pure bromide was 50% from this crude alcohol: b. p. 122° (4 mm.); n^{20}_{D} 1.4586.

(c) **Anthrone.**—Eastman Kodak Company anthraquinone (highest purity) was reduced to anthrone in 60% yield,[9] m. p. 156–157°.

(d) **9-Bromophenanthrene.**—Reilly Tar & Chemical Co. 90% phenanthrene was purified by the method of Cohen and Carmier[10]; m. p. 99.0–99.5°. A total of 508 g. of 9-bromophenanthrene was prepared in 55% yield following Austin[11]; m. p. 65–66°.

[a] Melting was complete at this temperature. [b] Supercooled sample. [c] Corrected for air buoyancy.

(e) **Lauronitrile**.—Prepared by the passage of ammonia through molten lauric acid (from the saponification of pure methyl laurate; m. p. of acid 44–44.5°) in 70% yield as described previously,[2,4] except that a few ml. of 85% phosphoric acid was added as a catalyst, substantially reducing the reaction time.[12]

9-*n*-Dodecylanthracene.—A Grignard solution was prepared in the usual manner from 1668 g. (6.7 moles) of lauryl bromide and 163 g. (6.7 moles) of magnesium in 92% yield, using 3.5 l. of diethyl ether as a solvent. An ether suspension of 368 g. (2.0 moles) of anthrone was added to this solution at 15°. After stirring for ten hours the reaction products were poured on a mixture of 1100 g. of ammonium sulfate and 1500 g. of ice with stirring. The ether layer was removed by distillation and the residue dissolved in 1200 ml. of toluene. The toluene solution was extracted exhaustively with 3% aqueous sodium hydroxide until the extracts were colorless. The toluene was distilled off and the residue dissolved in 1200 ml. of purified pentane, which was then passed successively through four 80 × 2 cm. columns of silica gel.[13] Upon evaporation of the pentane, 375 g. (49.5% yield) of crude hydrocarbon melting at 48–49° was obtained. The crude product was fractionally distilled through the high vacuum column[14] at 0.5 mm., yielding 371 g. of constant viscosity[15] constant melting 9-*n*-dodecylanthracene (see Table I).

9-*n*-Butylanthracene was prepared from *n*-butylmagnesium bromide and anthrone in the same manner as under 9-*n*-dodecylanthracene above. A total of 360 g. (43% yield) of constant melting, constant viscosity[15] hydrocarbon was obtained (refer Table I) after fractional distillation at high vacuum.[14]

9-*n*-Dodecylphenanthrene.—A Grignard reagent was prepared in 95% yield from 508 g. (1.98 moles) of 9-bromophenanthrene and 48.1 g. (1.98 moles) of magnesium turnings in a mixture consisting of 500 ml. of diethyl ether and 500 ml. of benzene. To this solution was added 293 g. (1.61 moles) of lauronitrile at reflux temperature. After stirring for sixteen hours the reaction product was decomposed with 110 ml. of concd. sulfuric acid, and 1500 g. of ice. The organic layer was dried by distillation of the solvents and yielded 465 g. of 9-phenanthryl hendecyl ketone: 80% yield; m. p. 72–73°; 2,4-dinitrophenylhydrazone m. p. 145.0–145.5°. The ketone was reduced in 0.5 mole portions by the modified Wolff–Kishner method,[6] yielding a total of 415 g. of 9-dodecylphenanthrene in 73% yield: m. p. 78–79° (mixed m. p. with 9-phenanthryl hendecyl ketone 65–71°). To ensure the complete removal of ketone, the hydrocarbon was treated with 0.5 mole of phenylmagnesium bromide. After decomposition with dilute sulfuric acid, drying over anhydrous potassium carbonate, and removal of the solvent, the hydrocarbon was treated with silica gel[13] in pentane solution and fractionated through the high vacuum column[14] to yield 408 g. of constant melting, constant viscosity[15] 9-*n*-dodecylphenanthrene (refer Table I).

9-*n*-Dodecylperhydroanthracene.—Prepared as a mixture of stereoisomers by the hydrogenation of 237 g. of pure 9-*n*-dodecylanthracene over 20 g. of nickel catalyst[7] at 100–230° and 2250–1000 p. s. i. of hydrogen pressure. In order to ensure complete hydrogenation, the crude material was passed through a train of silica gel[13] and fractionated through the high vacuum column.[14] The material boiling at 176–182° (0.3 mm.), 226 g., was rehydrogenated and treated as above to yield 218 g. of hydrocarbon boiling at 174° (0.1 mm.). The product was then passed through a column of activated silica gel[13] to remove traces of polar impurities.

9-*n*-Butylperhydroanthracene.—Hydrogenation of 155 g. of pure 9-*n*-butylanthracene employing the same method as listed above in three successive steps to ensure complete hydrogenation, yielded 141 g. of purified hydrocarbon after high vacuum fractionation,[14] boiling at 105° (0.3 mm.); n^{20}D 1.5048–50 (supercooled sample). The product is a mixture of stereoisomers, and was given a final treatment with silica gel[13] to remove traces of polar impurities.

9-*n*-Dodecylperhydrophenanthrene.—Prepared by the three-step hydrogenation of 218 g. of pure 9-dodecylphenanthrene over nickel catalyst[7] at 2600–1500 p. s. i. and 100–225°. The mixture of *cis–trans* isomers obtained from the third fractionation through the high vacuum column[14] boiled at 178° (0.2 mm.); n^{20}D 1.4926; 203 g. A final silica gel treatment was employed as described above.

Acknowledgment.—The authors express their appreciation to the American Petroleum Institute for the grant which made this research possible.

Summary

1. The methods of preparation, yields, and five important properties are given for two alkyl anthracenes, one alkyl phenanthrene, and the corresponding perhydro derivatives. The aromatic hydrocarbons are pure, but the perhydro derivatives are known to be mixtures of *cis–trans* isomers.

2. Data on the preparation, yields and properties of six intermediates are given.

STATE COLLEGE, PA. RECEIVED SEPTEMBER 6, 1947

Reaction of Methylcyclopentane with Propene in the Presence of Aluminum Bromide–Hydrogen Bromide

BY HERMAN PINES AND V. N. IPATIEFF

It has been reported previously[1] that methylcyclopentane reacts with olefinic hydrocarbons in the presence of either sulfuric acid or hydrogen fluoride to form alkylcyclohexanes and products resulting from a hydrogen transfer reaction. This study has now been extended in order to investigate the interaction of propene with methylcyclopentane in the presence of aluminum bromide–hydrogen bromide catalyst. The main purpose of this investigation was to determine whether the alkylation of methylcyclopentane can proceed without isomerization, which usually results in the expansion of the alkyl pentamethylene ring into an alkyl hexamethylene ring.

Since aluminum halide–hydrogen halide catalysts cause the isomerization of alkylcyclopentanes to alkylcyclohexanes[2] at room temperature, it was decided to carry out the alkylation reaction at −42°; at this low temperature the rate of isomerization of alkylcyclopentanes is relatively slow.

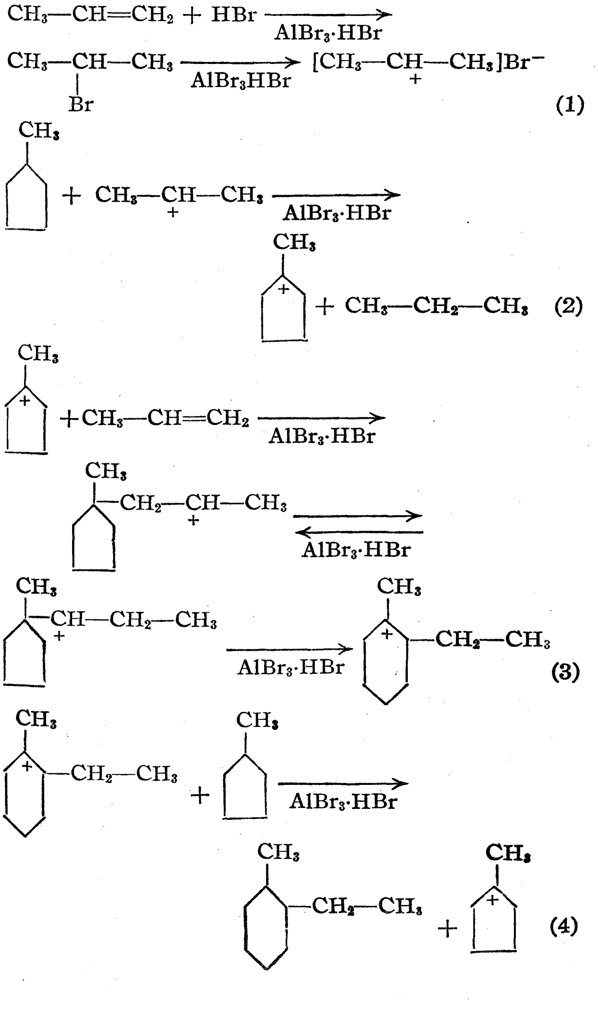
The alkylation of methylcyclopentane was carried out by passing propene and a small amount of hydrogen bromide into an agitated suspension of aluminum bromide in methylcyclopentane. The reaction product was then cooled to −76° and the liquid poured into water. The supercooling of the liquid before hydrolysis was necessary in order to avoid isomerization, which could occur if the decomposition were carried out at a higher temperature. The product obtained from this reaction, which consisted of saturated hydrocarbons, was distilled and analyzed. About 50% of the methylcyclopentane used for the reaction was recovered; the total hydrocarbons recovered from the reaction contained less than three per cent. of cyclohexane.

The higher boiling product consisted of a mixture of hydrocarbons, the major part of which distilled at 153–160°; and corresponded to a product of interaction of one mole of methylcyclopentane with propene. This hydrocarbon, which amounted to about 25 mole per cent. based on the propene used in the reaction, when passed over platinized alumina at 260°,[3] underwent almost quantitative dehydrogenation to aromatic hydrocarbons. The ease with which the dehydrogenation occurred indicates that the C_9H_{18} hydrocarbons consisted of alkylcyclohexanes. The gases obtained from the dehydrogenation reaction consisted of hydrogen only, which shows that geminal carbon atoms were not present in the cyclohexane ring.[4]

The aromatic hydrocarbons which were obtained from the dehydrogenation yielded, on oxidation with dilute nitric acid, about 70% of *o*-toluic acid. The presence of this acid indicates that the original product contained 1-methyl-2-ethylcyclohexane, which on dehydrogenation yielded *o*-ethyltoluene, and the latter oxidized to *o*-toluic acid.

The fractions boiling above 160° were also composed of alkylcyclohexanes since these compounds also underwent dehydrogenation to aromatic hydrocarbons: the structures of these compounds, however, were not identified because of their complexity.

The mechanism by which methylethylcyclohexane was formed from the interaction of methylcyclohexane and propene is the same as described previously.[1] The following are the probable steps that occur in this reaction



$$CH_3—CH=CH_2 + HBr \xrightarrow[AlBr_3·HBr]{} \quad CH_3—\underset{\underset{Br}{|}}{CH}—CH_3 \xrightarrow[AlBr_3HBr]{} [CH_3—\underset{+}{CH}—CH_3]Br^- \qquad (1)$$

The above indicated chain mechanism is similar to the one proposed by Schmerling[5] for the alkylation of isoparaffins. The exchange reaction indicated in equation II is similar to the one described by Bartlett, Condon and Schneider.[6]

Experimental

The apparatus consisted of a reaction flask provided with a Dry Ice cooled reflux condenser, mercury-sealed stirrer and inlet tubes for aluminum bromide and for the gaseous reagents. The outlet tube was connected in series to ice and Dry Ice traps and the latter was connected to a gas holder. The reaction flask was surrounded with boiling propane in order to maintain the temperature constant at −42°. Propene, which was stored in an aluminum bomb, was dried over anhydrone; hydrogen bromide was dried by passing it over aluminum bromide.

The flask and all tubings were thoroughly dried by passing dry nitrogen through them for several hours. Methylcyclopentane was introduced into the flask while dry nitrogen was passing through. An ampoule containing aluminum bromide was inserted in the apparatus and was broken therein while nitrogen was passing through. The flow of nitrogen was then discontinued and propene was passed into the flask over a period of two hours. Simultaneously with the propene, hydrogen bromide was passed into the reaction flask. The liquid reaction product, while still at −42°, was transferred into a trap maintained at −76°. The contents of the trap were then poured into 500 ml. of water contained in a three-neck flask and agitated by means of a mercury-sealed stirrer. The flask was connected to a series of traps in order to collect any escaping gases, if such were present. No evolution of heat was noticed when the product was added into water.

The hydrocarbon layer was separated, washed with alkali, water, dried over calcium chloride and distilled on a column of about fifteen-plate efficiency and at a reflux ratio of 20:1. The various narrow boiling fractions were redistilled and analyzed.

EXPERIMENTAL CONDITIONS AND RESULTS

Reagents employed, *M*:

Methylcyclopentane	63 g.	0.75
Propene	23 g.	.55
Aluminum bromide	20 g.	.075
Hydrogen bromide per min.	10–20 cc.	

Experimental conditions:

Temperature	−42°
Duration of reaction	2 hours

Product recovered, g.:

Gases	None
Hydrocarbon layer, g.	78.9
Organic material obtained from the hydrolysis of the catalyst layer, g.	1.1

Cut 1.—According to the index of refraction, Cut 1 is composed of 95% of methylcyclopentane and 5% of cyclohexane.

It underwent only slight dehydrogenation when passed over platinized alumina at 270°. The yield of methylcyclopentane–cyclohexane fraction based on total material recovered was 62%.

INVESTIGATION OF THE PRODUCT

Sixty-three grams of the hydrocarbon layer, after being washed and dried, was distilled. The following fractions were separated:

	B. p.	G.	$n^{20}D$
(1)	70–72°	31	1.4109
(2)	72–153	1.8	1.4273
(3)	153–157	15.0	1.4391
(4)	157–170	2.4	1.4405
(5)	170–180	1.5	1.4419
(6)	180–200	1.9	1.4453
(7)	200–210	6.7	1.4484
(8)	>210	6.2	1.4662

Cut 3.—According to physical constants, Cut 3 corresponds to C_9H_{18}. The yield of this fraction based on methylcyclopentane reacted was 53 mole per cent. or 27.4 mole per cent. based on propene reacted.

Thirteen grams of the hydrocarbon was passed, at a rate of 7 cc. per hour and a temperature of 265°, over 25 g. of 10–14 mesh size activated alumina containing 7% of platinum. Seven liters of gas was formed containing 89.6% of hydrogen. Ninety-one per cent. of liquid hydrocarbons was recovered with $n^{20}D$ 1.4946. Based on the hydrogen produced, virtually all of the material submitted to dehydrogenation was converted to aromatic hydrocarbons.

The dehydrogenated product distilled as follows: (1) b. p. 149–158°, 14%, $n^{20}D$ 1.4810; (2) 158–161°, 38%, 1.4922; (3) 161°, 37%, 1.5008; (4) 161°, 11%, 1.4998.

One half gram of Cut 3, obtained from the dehydrogenation, was refluxed for twelve hours with an acid consisting of 15 ml. of concentrated nitric acid and 25 ml. of water. About 0.35 g. of a crystalline product was obtained which was filtered and crystallized from hexane.

The crystalline material in the form of needles melted at 103°. It did not show depression in melting point when mixed with a known sample of *o*-toluic acid. Sharp depression in melting point, over 25°, was noticed when the sample was mixed with *m*-toluic acid, melting at 111°.

Anal. Calcd. for $C_8H_8O_2$: C, 70.59; H, 5.88. Found: C, 69.67; H, 5.90.

Cut 7.—According to physical constants, Cut 7 corresponds to $C_{12}H_{24}$.

Anal. Calcd. for $C_{12}H_{24}$: C, 85.63; H, 14.37. Found: C, 85.59; H, 14.31.

Four grams of this product was dehydrogenated by passing it over platinized alumina at 200°. About 1.5 liters of gas was liberated, consisting of 98% hydrogen. The dehydrogenated product had an $n^{20}D$ 1.4921. The results obtained indicate that the product was composed of about 90% of aromatic hydrocarbons.

Summary

The reaction of methylcyclopentane with propene in the presence of aluminum bromide–hydrogen bromide catalyst has been investigated. The reaction was carried out at −42°.

The product obtained from the reaction consisted of alkylated cyclohexanes composed mainly of 1-methyl-2-ethylcyclohexane and of alkylcyclohexanes of the formula $C_{12}H_{24}$.

Under the condition of the reaction, methylcyclopentane underwent but slight isomerization. A mechanism of the alkylation is suggested.

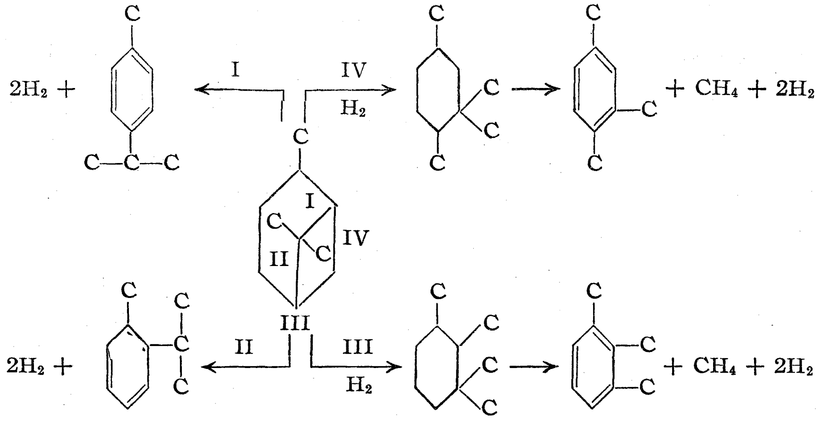
Studies in the Terpene Series. VIII.[1] Effect of Catalyst, Solvent and Temperature on the Dehydrogenation of Pinane and *p*-Menthane[2]

BY HERMAN PINES, R. C. OLBERG[3] AND V. N. IPATIEFF

Pinane has been reported to yield *p*-cymene and a small amount of *o*-cymene on dehydrogenation with such catalysts as platinized charcoal,[4] platinized asbestos[5] and nickel.[6]

In view of the fact that pinane on destructive hydrogenation[1] yielded a mixture of hydrocarbons consisting predominantly of 1,1,2,3-tetramethylcyclohexane and containing smaller amounts of 1,2-methylisopropylcyclohexane, 1,4-methylisopropylcyclohexane and 1,1,2,5-tetramethylcyclohexane, and in the light of the close similarity between hydrogenation and dehydrogenation, it was decided to reinvestigate the dehydrogenation of pinane and to determine whether or not polymethylated benzenes might be formed along with the previously reported *o*- and *p*-cymene.

In the present study it was found that when pinane was passed over platinized alumina, platinized pumice or platinized charcoal at 240–300° and at an hourly liquid space velocity of 0.2, dehydrogenation took place to yield a complex mixture of liquid products and gases consisting of hydrogen and methane. In addition to *o*- and *p*-cymene the liquid product contained 1,2,4- and 1,2,3-trimethylbenzene in considerable quantity. The relative amounts of the various hydrocarbons produced depended upon the conditions employed. Based upon previous hydrogenolysis studies with pinane and nickel–kieselguhr catalyst[1] in which 1,1,2,3-tetramethylcyclohexane was shown to be the principal hydrogenolysis product, the above results may be presumed to be obtained by the reactions.



It is believed that the hydrogen liberated in the formation of *o*- and *p*-cymene acts upon the unreacted portion of pinane to form 1,1,2,3- and 1,1,2,5-tetramethylcyclohexane which then, in part, may undergo dehydrogenation and demethanation to 1,2,3- and 1,2,4-trimethylbenzene, respectively. 1,2- and 1,4-methylisopropylcyclohexane may also be formed upon hydrogenolysis which upon subsequent dehydrogenation yield *o*- and *p*-cymene. However, at high temperatures or at conditions of low hydrogen concentration pinane gives increased yields of *p*-cymene suggesting that another reaction takes precedence. Therefore, the cleavage of the four-membered ring of pinane appears to take place by at least two different and concurrent reactions: (a) a hydrogenolysis to favor the formation of 1,1,2,5- and 1,1,2,3-tetramethylcyclohexane in approximately 2:1 molal ratio and 1,2-methylisopropylcyclohexane; the two tetramethylated cyclohexanes on subsequent dehydrogenation and demethanation yield 1,2,4- and 1,2,3-trimethylbenzene while 1,2-methylisopropylcyclohexane on dehydrogenation yields *o*-cymene; and (b) a straightforward rupture favoring the formation of *p*-cymene.

A study was made of the factors influencing the relative ease of cleavage of the four bonds constituting the four-membered ring of pinane. The role of temperature, nature of diluent, catalyst support and added hydrogen were investigated. The temperature was varied between 175 and 300°. Three types of diluents were employed: (1) hydrogen acceptors, such as pentenes and benzene, (2) hydrogen donors, such as methylcyclohexane and (3) "neutral acting" diluents such as *n*- and isopentane. In order to facilitate the cleavage of the four-membered ring, hydrogen gas was added to the reactions carried out at 175° with platinized alumina catalyst and at 300° with the less active platinized pumice catalyst.

The effect of temperature on the rupture of the

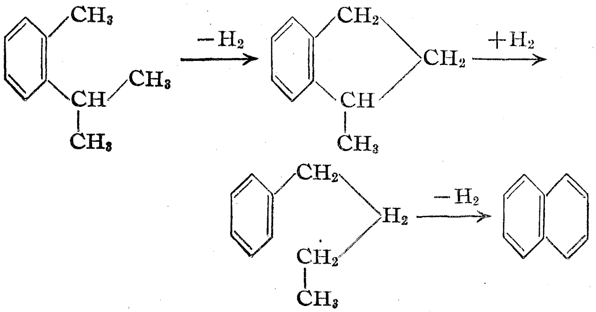
bonds constituting the four-membered ring of pinane is shown in Table I; platinized alumina was used as a catalyst.

Higher temperatures favor the formation of larger amounts of *p*-cymene; this is especially evident when a "neutral" diluent such as *n*-pentane is used. *n*-Pentane in 4:1 molal ratio appears to enhance the Bond I cleavage to form *p*-cymene at 300° but has no effect at 240°. However, the extent of dehydrogenation appears to be increased at 240° when *n*-pentane is used as a diluent as evidenced by the fact that an equivalent or greater yield of aromatics is obtained in only one pass over the catalyst as compared to three passes when no diluent is used. Lower temperature and the absence of a diluent appears to favor the cleavage of Bond II to form 1,2-methylisopropylcyclohexane and *o*-cymene. At 300° small amounts of naphthalene were detected in the reaction product which may have been formed by the cyclodehydrogenation of *o*-cymene. When pure *o*-cymene was passed over platinum–alumina at 300° the reaction product contained 10–15% naphthalene, 50–60% unreacted *o*-cymene and 25–40% unidentified product, which may be 1-methylindane, but owing to the unavailability of pure 1-methylindane as a reference sample for infrared spectra analysis no proof of its presence could be obtained. Naphthalene was separated, recrystallized and identified by its melting point and mixed melting point with pure naphthalene. Its formation from *o*-cymene may be explained if one assumes the intermediate formation of 1-methylindane followed by ring fission and cyclic dehydrogenation to naphthalene.



The formation of new rings under conditions of catalytic dehydrogenation is not new.[7] Moreover, the formation of naphthalene from 1-methylindane by catalytic dehydrogenation over palladized charcoal at 450°[8] and from 1-methylindane and 1-methyloctahydroindene over platinized charcoal at 300° supports the above interpretation.

If, as postulated above, *p*-cymene formation is favored by the higher temperatures and conditions of low hydrogen concentration, it follows that the yield of *p*-cymene should be increased if the dehydrogenation is carried out in the presence of substances which would remove the hydrogen from the reaction zone as it is formed. Thus, the hydrogenolysis of the pinane should be minimized. The straight and branched chain pentenes and benzene were therefore used as hydrogen acceptors. It was thought that the pentenes should be particularly effective as hydrogen acceptors because of the ease with which they undergo hydrogenation of the pentanes.

The results obtained with both the branched and straight chain pentenes in the ratio of one mole of pentenes to one mole of pinane support the above advanced supposition. The pentenes act as true hydrogen acceptors and are completely converted to the pentanes. Bond I cleavage to form *p*-cymene is markedly facilitated since the hydrogen removed from the surface of the catalyst retards the hydrogenolysis of pinane. However, when the molal ratio of the pentenes to pinane

[8] L. Ruzicka and E. Peyer, *Helv. Chim. Acta*, **18**, 676 (1935).

is increased to 4:1, the dehydrogenation reaction is completely inhibited even at 300°. Presumably, the pentenes in this concentration so completely saturate the surface of the catalyst that the adsorption of pinane is prevented and pinane is recovered unchanged. Even *p*-menthane, which undergoes dehydrogenation almost quantitatively at 300° in the absence of a solvent, yields only 8% *p*-cymene under the above conditions; this amount of dehydrogenation occurred at the beginning of the run before the catalyst surface was completely saturated.

Although benzene may also act as a hydrogen acceptor, only about 3% of it was converted to cyclohexane at 300° when used in a ratio of 4 moles of benzene to 1 mole of pinane. Presumably, benzene is not as strongly adsorbed to the surface of the catalyst as the pentenes and therefore does not inhibit the dehydrogenation. The extent of dehydrogenation under the above conditions is somewhat increased and the Bond I cleavage to yield *p*-cymene is slightly enhanced. At 240° benzene, like *n*- and isopentane, has little effect upon the ratio of products obtained except that the *o*-menthane and *o*-cymene resulting from Bond II cleavage is diminished.

TABLE II

THE EFFECT OF HYDROGEN AND HYDROGEN-DONOR DILUENT

Experiment no.		1	12
Temperature, °C.		175	240
Diluent, kind		H_2	Methylcyclohexane
Diluent:Pinane, molal ratio		1.5:1	1:1
Number of passes over catalyst		3	1
Per cent. aromatic		0	25
Bond cleavage			
Bond I	*p*-Menthane	21	0
	p-Cymene	0	15
Bond II	*o*-Menthane	7	0
	o-Cymene	0	6
Bond III	1,1,2,3-Tetramethylcyclohexane	30	30
	1,2,3-Trimethylbenzene	0	0
Bond IV	1,1,2,5-Tetramethylcyclohexane	30	41
	1,2,4-Trimethylbenzene	0	0
Unidentified		11	8

Increasing the molal ratio of pentanes to pinane from 1:1 to 4:1 at 300° results in a greatly increased yield of *p*-cymene at the expense of 1,2,3- and 1,2,4-trimethylbenzene. There appears to be no difference in the action of *n*- and isopentane. These effects are shown in Table I.

In order to determine the effect of a hydrogen donor diluent, an equimolal mixture of methylcyclohexane and pinane was passed over platinized alumina at 240°. It was found that the methylcyclohexane underwent dehydrogenation and the hydrogen liberated facilitated the hydrogenolysis of Bonds II, III and IV. Only 15% of Bond I cleaved to form *p*-cymene. The same effect was experienced when hydrogen in 1.5:1 mole ratio was added to pinane at 175°, a temperature too low for dehydrogenation to occur. The hydrogenolysis of the four-membered ring of pinane was complete; bonds III and IV were predominantly cleaved. The effect of added hydrogen and hydrogen donor diluent is shown in Table II.

In order to determine whether the catalyst support influences the cleavage of the various bonds, platinized alumina, platinized charcoal and platinized pumice were used as catalysts. It was found that platinized alumina and platinized charcoal are of comparable high activity, but that platinized pumice has very low activity presumably because of its lower adsorptive capacity. The results obtained in the absence of a solvent at 300° are given in Table III.

The effect of hydrogen in causing the hydrogenolysis reaction to occur is clearly shown when platinum–pumice is used as the catalyst. In the absence of added hydrogen no noticeable reaction takes place, while in the presence of hydrogen

TABLE III

EFFECT OF CATALYST SUPPORT AT 300°

Experiment no.		3	13	14	15

[a] Small amount of hydrogen was passed over the catalyst.

42% of aromatic hydrocarbons are formed and the reaction product did not contain any unreacted pinane. Also, when platinized alumina is flushed with nitrogen before pinane is passed very little dehydrogenation occurs until the concentration of hydrogen has increased to the point where the hydrogenolysis reaction can readily take place. The above experiments indicate that the products of hydrogenolysis of pinane undergo dehydrogenation more readily than pinane itself.

In order to gain a better insight into the effect of temperature, solvents and catalyst support on the dehydrogenation activity of the catalyst toward pinane, a comparative study of the same variables on the dehydrogenation of *p*-menthane (1-methyl-4-isopropylcyclohexane) was made.

The dehydrogenation of *p*-menthane was carried out at 240° and 300° using platinized alumina catalyst. At 300° without solvent or in the presence of either pentane or benzene in 4:1 molal ratio dehydrogenation is virtually complete and *p*-cymene is obtained in 95–100% yield. The use of pentene as a solvent in 1:1 molal ratio likewise favors the complete conversion to *p*-cymene and pentane is obtained in the product. However, when the mole ratio of pentenes is increased to 4:1, *p*-cymene is obtained in only 8% yield at 240°, 270° or 300°. The dehydrogenation which does take place occurs at the beginning of the experiment before the catalyst surface has been completely covered with adsorbed pentenes.

The effect of various diluents upon the dehydrogenation of *p*-menthane in the presence of platinized alumina has been studied. The reaction has been carried out at 240° using a molal ratio of diluents to *p*-menthane of 4:1. The results are given in Table IV.

TABLE IV

EFFECT OF DILUENTS AT 240° ON DEHYDROGENATION OF *p*-MENTHANE

Solvent, molal ratio 4:1	*p*-Cymene, %
None	55
n-Pentane	78
Isopentane	80
Benzene	95
Pentenes	8

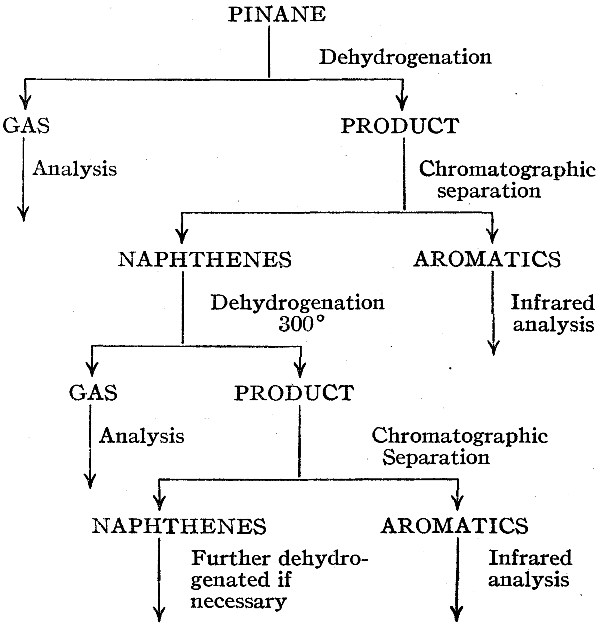
n-Pentane, isopentane and benzene used as diluents increase the extent of dehydrogenation; there is no difference in the effect of *n*- and isopentane. Benzene has the most beneficial effect, the dehydrogenation of *p*-menthane being virtually complete at 240°. Pentenes, however, in 4:1 molal ratio inhibit the dehydrogenation.

Experimental Part

Apparatus and Procedure.—The apparatus consisted of a graduated buret and a pump connected to a Pyrex glass reaction tube containing the catalyst bed, a water-cooled receiver–condenser, a Dry Ice–acetone cooled trap, and a calibrated gas-collecting bottle containing saturated salt solution. The reaction tube was heated in a thermostatically controlled vertical furnace, brought to the desired temperature, ranging from 175 to 300°, in a slow stream of hydrogen. The pinane of *p*-menthane, with or without diluent, was added at an hourly rate approximately equal to two-tenths the volume of the catalyst bed. The liquid product was collected in the water-cooled condenser–receiver and the dehydrogenation gas was freed of entrapped solvent by passing it through a Dry Ice–acetone cooled trap and collected in a gas bottle over saturated salt solution. The temperature and barometric pressure were recorded along with the volume of the gas obtained. In some instances the liquid product was repassed through the catalyst tube until no further reaction occurred. In the absence of solvents the extent of dehydrogenation could also be followed from the change in the refractive index with each successive pass. If a solvent was present it was removed by distillation through a distilling column of an efficiency of seven theoretical plates.

A diagrammatic sketch of the procedure for the determination of the composition of product obtained on the dehydrogenation of pinane is given below.

DIAGRAMMATIC SKETCH: DEHYDROGENATION OF PINANE



The aromatic hydrocarbons which were produced during the dehydrogenation were separated chromatographically according to the method of Mair and Forziati.[9] This was accomplished by diluting the solvent freed reaction product with four or five parts of pentane and by passing the mixture through a five-foot column containing 200–300 mesh silica gel. An almost quantitative separation of the aromatics and naphthenes was effected in this manner. The aromatic and naphthene portions were each distilled, and the aromatic portion was analyzed. The naphthene portion was again dehydrogenated and the aromatics formed were separated chromatographically and analyzed. This procedure was repeated until very little naphthene remained which was assumed to have the same composition as the naphthenes from which the last portion of aromatics was obtained.

Analytical Part

The naphthenic product obtained from the dehydrogenation of pinane, according to infrared spectral analysis, contained no pinane and corresponded to the monocyclic hydrocarbons $C_{10}H_{20}$.

Anal. Calcd. for $C_{10}H_{20}$: C, 85.63; H, 14.37. Found: C, 85.70; H, 14.27.

---

[9] B. J. Mair and A. F. Forziati, *J. Research Natl. Bureau Stand.*, **32**, 151, 165 (1944).

The mixture of *o*- and *p*-cymene were separated by fractional crystallization of their sulfonamide derivatives[10,11] from hot benzene. The less soluble *o*-cymene sulfonamide crystallized out in fine needle crystals, m.p. 152.5–153.5°, and gave no depression in melting point when mixed with a known sample of *o*-cymene sulfonamide.

Anal. Calcd. for $C_{10}H_{15}NO_2S$: C, 56.31; H, 7.09; N, 6.57. Found: C, 56.56; H, 6.77; N, 6.64.

***p*-Cymene sulfonamide** crystallized out from benzene in irregular plates, m.p. 115–116°.[10,11] *p*-Cymene was further characterized by chromic acid oxidation to terephthalic acid, the dimethyl ester of which melted at 141–141.5°.

1,2,4-Trimethylbenzene was characterized by conversion to the trinitro derivative,[12] m.p. 184–185°. It showed no depression in melting point when mixed with a trinitroderivative of a known sample of 1,2,4-trimethylbenzene.

1,2,3-Trimethylbenzene was identified by conversion to the tribromo derivative, m.p. 242–243°, which gave no depression in melting point when mixed with a synthetic sample of tribromo-1,2,3-trimethylbenzene.

Naphthalene was identified by its melting point 79.5–80°; it did not depress the melting point of a known sample of naphthalene.

Gaseous Product.—The gas was analyzed by absorption and combustion using a Goeckel type[13] gas analysis apparatus.

Infrared Spectral Analysis (by W. S. Gallaway).[14]—The analyses were made according to the procedure described previously.[1] The wave lengths used for calculating the composition of the various samples are given in Table V.

Materials

Pinane was prepared by the hydrogenation of α-pinene which was obtained from the Hercules Company as Pinene 111 and is reported to contain less than 2% of camphene. The α-pinene was further purified by distillation through a column of twelve-plate efficiency using a reflux ratio of twelve to one. The middle portion boiling at 155–156°, n^{20}_{D} 1.4660, was dissolved in an equal volume of pentane and hydrogenated in a rotating autoclave at 50°, using nickel–kieselguhr catalyst[15] (10% by weight of α-pinene charged) and 100 atm. initial hydrogen pressure. The pinane distilled at 165–166°, n^{20}_{D} 1.4605, and did not contain any olefins.

***p*-Menthane** was prepared by the hydrogenation of *p*-cymene. The *p*-cymene was purified by washing repeatedly with sulfuric acid and distilling through a twelve-plate column. The portion boiling at 176.5°, n^{20}_{D} 1.4998, was hydrogenated in a rotating autoclave at 115° with nickel–kieselguhr catalyst and 100 atm. initial hydrogen pressure. The *p*-menthane produced contained no aromatics and distilled at 167°, n^{20}_{D} 1.4398.

***o*-Cymene** was prepared from *o*-bromotoluene and acetone via the Grignard reaction. The *o*-tolyldimethylcarbinol produced from this reaction was dehydrated by passing it over activated alumina at 320°. *o*-Isopropenyltoluene boiling at 171–173°, n^{20}_{D} 1.5253, was obtained in an over-all yield of 48% based upon the bromotoluene. *o*-Isopropenyltoluene was hydrogenated to *o*-cymene in a rotating autoclave at 40° with nickel–kieselguhr catalyst and an initial hydrogen pressure of 61 atm. The theoretical amount of hydrogen was absorbed. The *o*-cymene distilled at 174°, n^{20}_{D} 1.4994.

Platinum–Alumina Catalyst was prepared by heating platinum, 12.0 g., on a steam-bath with aqua regia, until solution was complete. The excess acid was removed by evaporating the solution almost to dryness and then adding a 100-cc. portion of water and again evaporating down; this procedure was repeated ten times. The chloroplatinic acid was dissolved in 200 cc. of distilled water and suction filtered to remove any contaminants. The clear filtrate was added to 150 cc., 120 g., of alumina (Alorco 10–12 mesh). The liquid completely covered the alumina. The solution was evaporated on a steam-bath with thorough stirring. When dry the catalyst has a uniform yellow-orange color. It was heated in a vertical furnace at 100° in an atmosphere of hydrogen for several hours. The temperature was then raised to 200° and the heating continued for several more hours. Finally, it was heated at 254° for two hours prior to use for dehydrogenation. The reduced catalyst has a uniform gray color.

Platinum–pumice catalyst was prepared according to the same method described for platinum–alumina catalyst, using 10.1 g. of platinum to 125 cc., 54.5 g. of pumice.

Platinum charcoal catalyst was prepared according to the method described by Linstead and co-workers[4] except that activated Burrell cocoanut charcoal (10–14 mesh) was used in place of norit charcoal in order to facilitate its use in a vertical catalyst tube.

Acknowledgments.—We are indebted to Dr. W. S. Gallaway of Universal Oil Products Company for the infrared spectral analyses, to Mr. M. Stross of Universal Oil Products Company for the gas analyses and to Mrs. Margaret L. Ladyard of Northwestern University for the microanalyses.

Summary

Pinane on dehydrogenation yields in addition to the previously reported *p*- and *o*-cymene also a large amount of 1,2,4- and 1,2,3-trimethylbenzene, the ratio of products obtained depending upon the temperature, solvent and catalyst support employed.

The cleavage of the four-membered ring of pinane appears to occur by two different reactions; a thermal cleavage to favor the formation of *p*-cymene and a hydrogenolysis which favors the formation of 1,1,2,3- and 1,1,2,5-tetramethylcyclohexane and *o*-menthane. The hydrogen liberated from the former reaction causes the latter reaction to occur. At high temperatures the tetramethylcyclohexanes undergo demethanation and dehydrogenation to the corresponding trimethylbenzenes.

The dehydrogenation of pinane is inhibited when it is diluted with four moles of pentenes. Pentane and benzene enhance the extent of dehydrogenation of pinane.

A comparative study of the dehydrogenation of *p*-menthane using the same variables was made.

Copolymerization. IV. The Validity of the Tripolymer Equation for the Systems: Styrene–Vinyl Chloride–Methyl Acrylate and Styrene–Vinyl Chloride–Acrylonitrile

BY EARL C. CHAPIN, GEORGE E. HAM AND REID G. FORDYCE

The theory of the propagation step in copolymerizations developed by Alfrey and Goldfinger,[1] Mayo and Lewis[2] for two components was later extended to three component systems by Alfrey and Goldfinger[3] and finally to the more general case of n monomers by Walling and Briggs.[4] While a considerable amount of experimental data has been reported for two-component systems,[2,5–11] apart from the original experiments of Walling and Briggs[4] further experimental confirmation of the tripolymer equation has been lacking. It is the purpose of this paper to present additional copolymerization rate data in order to test the applicability of the tripolymer equation to systems other than those described by Walling and Briggs. It is also our purpose to present data based on tripolymer samples isolated at low conversions where the simple differential form of the tripolymer equation can be employed for direct comparison with experimental results.

The systems vinyl chloride–styrene–methyl acrylate and vinyl chloride–styrene–acrylonitrile were chosen since the tripolymer composition could be determined with accuracy by analysis. Thus chlorine, carbon and hydrogen analyses on products from the former system, and chlorine and nitrogen analyses on tripolymers from the latter system were sufficient to define the relative proportions of combined comonomers in each case.

The monomer reactivity ratios for the systems styrene–methyl acrylate[7] and styrene–acrylonitrile[5,10] have been reported. Since the tripolymer equation involves the monomer reactivity ratios of the three separate two component systems involved, it was necessary to determine first, monomer reactivity ratios for the systems, styrene–vinyl chloride, vinyl chloride–methyl acrylate and vinyl chloride–acrylonitrile. These data were then used to predict the compositions of tripolymers produced from different compositions of the three component systems cited above. Experimental data comparing the actual compositions with the calculated values were then obtained.

In determining the monomer–polymer composition curves for the three two-component systems, copolymerizations were allowed to proceed to low conversions (mainly <4%) and the initial product was isolated and purified. The amount of combined vinyl chloride was determined in all cases by chlorine analyses. Likewise for the tripolymer experiments, products at low conversions (mainly <4%) were isolated, purified and analyzed as indicated above.

Results and Discussion

The shapes of the monomer–polymer composition curves for the system vinyl chloride–styrene determined by solution and by emulsion polymerization are shown in Figs. 1 and 2, respectively. The experimental data are summarized in Table I. The following monomer reactivity ratios[12] gave the best curve fit to the data obtained:

	Solution polymerization	Emulsion polymerization
Styrene	35	35
Vinyl chloride	0.067	0.077

TABLE I

VINYL CHLORIDE–STYRENE COPOLYMERIZATIONS

Monomer mole % styrene	Time at polymerization temp., hours	Wt. % conversion	Chlorine Analyses I	Chlorine Analyses II	Copolymer mole % styrene
Solution polymerization, acetone, 48°, 0.5% Bz_2O_2					
83.6	18.2	3.0	0.31	0.32	99.0
71.6	24.0	2.6	.48	.52	98.5
60.6	24.0	4.4	1.00	1.00	97.2
49.6	24.0	4.0	1.12	1.16	96.7
38.8	24.0	2.0	1.35	1.79	95.5
13.1	67.0	4.0	6.87	7.27	80.9
9.9	166.0	1.2	9.06	9.14	76.0
7.6	239.5	4.6	14.79	15.17	62.8
3.2	339.5	3.6	35.27	35.33	26.8
Emulsion polymerization, 50°, 0.5% H_2O_2					
88.6	6.0	2.0	0.40	...	98.8
78.4	46.0	3.0	.63	0.99	98.6
58.9	46.0	1.0	1.62	...	95.3
39.7	70.0	1.9	3.17	...	91.0
9.7	70.5	0.6	16.18	16.55	59.8

In accordance wth arguments previously advanced,[10,11] the close proximity of the two curves shows that an oil-phase mechanism of emulsion polymerization is operative for this system. The data also show that styrene monomer has a much greater tendency than vinyl chloride to add either to a styrene free radical or to a vinyl chloride free

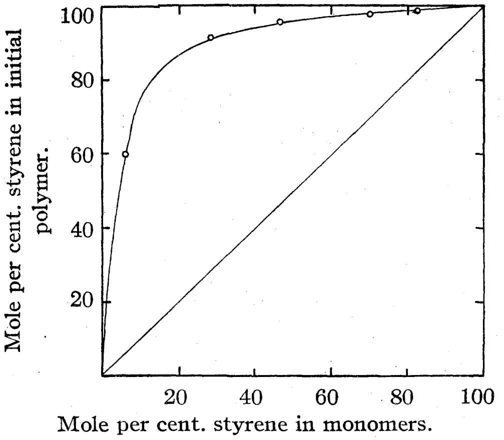

Fig. 2.—Monomer–polymer composition curve for the system vinyl chloride–styrene emulsion polymerization.

radical. Hence styrene–vinyl chloride batch copolymerizations carried to completion must necessarily produce samples highly heterogeneous with respect to composition. Inspection of the polymerization times required (Table I) shows that styrene–vinyl chloride copolymers do not form readily and copolymerize at a much slower rate than either constituent alone.

TABLE II

VINYL CHLORIDE–METHYL ACRYLATE COPOLYMERIZATIONS

Monomer mole % methyl acrylate	Time at polymerization temp., hours	Wt. % conversion	Chlorine analyses I	Chlorine analyses II	Copolymer mole % methyl acrylate

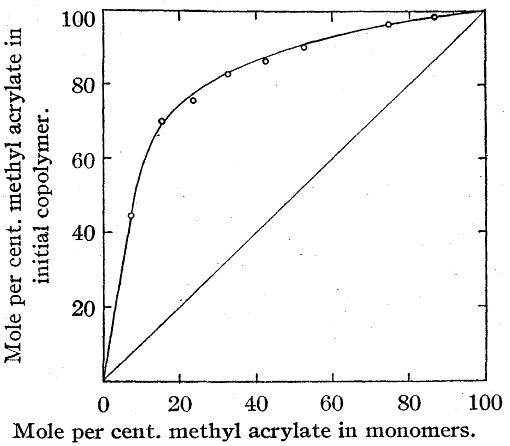

Fig. 3.—Monomer–polymer composition curve for the system vinyl chloride–methyl acrylate, mass polymerization.

The monomer–polymer composition curve for the system vinyl chloride–methyl acrylate copolymerized in mass is shown in Fig. 3, and the experimental data for this series of experiments are given in Table II. The monomer reactivity ratios for the two free radicals were found to be: vinyl chloride 0.083, methyl acrylate 9.0.

The relationship of monomer composition to copolymer composition for the system vinyl chloride–acrylonitrile determined in solution is represented in Fig. 4. The experimental data from which this curve[13] was drawn are given in Table III. The monomer reactivity ratios giving a good curve through the experimental points were found to be: vinyl chloride 0.074 and acrylonitrile 3.7.

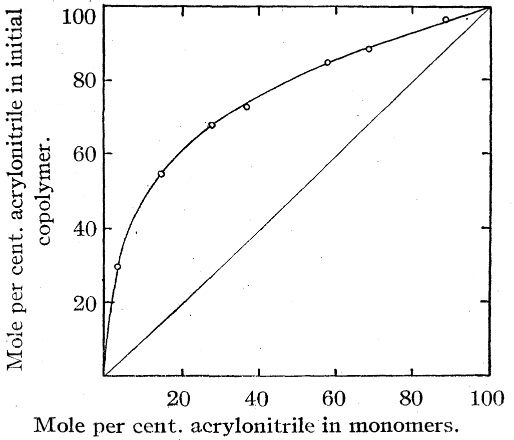

Fig. 4.—Monomer–polymer composition curve for the system vinyl chloride–acrylonitrile solution polymerization.

The monomer reactivity ratios reported above were determined by varying their values in the copolymer equation until a good curve through

---

[13] After completing this manuscript, U. S. Patent 2,420,330 by Shriver and Fremon was issued, showing a similar curve for this system.

TABLE III

VINYL CHLORIDE–ACRYLONITRILE COPOLYMERIZATIONS

[a] 0.5 wt. % Bz_2O_2. [b] 0.7 wt. % Bz_2O_2.

the experimental points was obtained. It is difficult, by this method, to define the limits of accuracy of the values since the curve fit is a matter of opinion. For example, relatively small changes in the r_1, r_2 values for the systems vinyl chloride–methyl acrylate and vinyl chloride–acrylonitrile result in curves which do not pass through the experimental points at all. The parameters reported for these systems, therefore, are probably accurate to within at least 10%. On the other hand, the monomer reactivity ratios for the system styrene–vinyl chloride must be considered to be less accurate. Relatively large changes in the r_1, r_2 values of this type of curve (large r_1—small r_2 values) do not result in a marked alteration of the curve shape. Moreover, the curve fit technique for a system of this type gives undue emphasis to certain experimental points, particularly in the region where the curve "breaks." Consequently, small analytical errors for such points produce considerable changes in the r_1 and r_2 values obtained by curve-fitting.

The Alfrey and Goldfinger equations[3] for predicting the initial polymer composition from a monomeric mixture of three components are of the form

$$\frac{d[M_1]}{d[M_2]} = \frac{\frac{[M_1][M_2]}{r_{21}r_{32}} + \frac{[M_1]}{r_{31}}\left(\frac{[M_1]}{r_{21}} + \frac{[M_3]}{r_{23}}\right)}{\frac{[M_1][M_2]}{r_{12}r_{31}} + \frac{[M_2]}{r_{32}}\left(\frac{[M_3]}{r_{12}} + \frac{[M_3]}{r_{13}}\right)} \cdot \frac{[M_1] + \frac{[M_2]}{r_{12}} + \frac{[M_3]}{r_{13}}}{[M_2] + \frac{[M_1]}{r_{21}} + \frac{[M_3]}{r_{23}}}$$

$$\frac{d[M_1]}{d[M_3]} = \frac{\frac{[M_1][M_2]}{r_{21}r_{32}} + \frac{[M_1]}{r_{31}}\left(\frac{[M_1]}{r_{21}} + \frac{[M_3]}{r_{23}}\right)}{\frac{[M_1][M_3]}{r_{13}r_{21}} + \frac{[M_3]}{r_{23}}\left(\frac{[M_2]}{r_{12}} + \frac{[M_3]}{r_{13}}\right)} \cdot \frac{[M_1] + \frac{[M_2]}{r_{12}} + \frac{[M_3]}{r_{13}}}{[M] + \frac{[M_1]}{r_{31}} + \frac{[M_2]}{r_{32}}}$$

where $[M_1]$, $[M_2]$ and $[M_3]$ represent monomer concentrations of the three components, $d[M_1]$, $d[M_2]$ and $d[M_3]$ represent the amounts of combined comonomers, respectively, in the polymer molecules first formed, and r_{12}, r_{21}, r_{13}, r_{31}, r_{23} and r_{32} are the monomer reactivity ratio parameters for the three two component systems involved, as defined recently by Alfrey, Mayo and Wall.[12]

Experimental data for the system styrene (M_1)–methyl acrylate (M_2)–vinyl chloride (M_3) are given in Table IV. Utilizing data previously published,[5,7,10] together with the monomer reactivity ratios reported above, the following values were used to predict polymer composition for this system: $r_{12} = 0.75$, $r_{13} = 35$, $r_{21} = 0.20$, $r_{23} = 9.0$, $r_{31} = 0.067$ and $r_{32} = 0.083$. A comparison of the predicted composition with the composition actually obtained is given

	Initial monomer composition	Weight per cent. Predicted polymer composition	Polymer composition by analysis
Styrene	20	45.2	47.6
Methyl acrylate	60	53.7	52.0
Vinyl chloride	20	1.1	1.3
Styrene	60	75.7	76.1
Methyl acrylate	20	23.6	22.8
Vinyl chloride	20	0.7	1.1

Similarly, the experimental data for the system styrene (M_1)–acrylonitrile (M_2)–vinyl chloride (M_3) are given in Table IV, and the following parameters were employed in calculating polymer composition: $r_{12} = 0.41$, $r_{13} = 35$, $r_{21} = 0.04$, $r_{23} = 3.7$, $r_{31} = 0.067$ and $r_{32} = 0.074$. The following results were obtained for this system

	Initial monomer composition	Weight per cent. Predicted polymer composition	Polymer composition by analysis
Styrene	32.0	66.1	67.1
Acrylonitrile	48.8	33.4	32.5
Vinyl chloride	19.2	0.5	0.4
Styrene	30.2	71.0	70.4
Acrylonitrile	15.4	26.8	26.2
Vinyl chloride	54.4	2.2	3.4

Agreement between the predicted and actual compositions shown above provides support for the monomer reactivity ratios reported and tends to confirm the validity of predictions based on the tripolymer equations.

Experimental

Vinyl Chloride Monomer.—Redistilled Dow Chemical Co. material was used for all experiments.

Styrene Monomer.—Redistilled Dow Chemical Co. N-100 material was used for all experiments.

Acrylonitrile.—Redistilled American Cyanamid Co. material was used.

Methyl Acrylate.—Redistilled Rohm & Haas material was used.

Benzoyl Peroxide.—The product of the Lucidol Corp. was used.

Acetone.—Redistilled material from the Commercial Solvents Corp. was employed.

Vinyl Chloride–Styrene Copolymerizations

Solution.—A solution comprising 50 g. of acetone and 50 g. of total monomer was taken for all experiments. Appropriate amounts (Table I) of styrene, acetone and benzoyl peroxide weighed into a 200-ml. pressure bottle were gradually cooled in a Dry Ice-bath to −50°. A suitable volume of liquid vinyl chloride also cooled to Dry Ice temperatures was added. A metal cap with tinfoil liner was tightly screwed on the bottle which was allowed to warm to room temperature and weighed.

TABLE IV

TRIPOLYMER MASS POLYMERIZATIONS

Monomer wt. %		Temp., °C.	Time, hours	Wt. % conversion	Analyses	Polymer wt. %
Vinyl chloride	20				C, 72.40, 72.79	1.5
Styrene	20	50	5.3[a]	3.0	H, 7.66, 7.84	46.5
Methyl acrylate	60				Cl, 0.74, 0.74	52.0
Vinyl chloride	20				C, 83.28, 83.41	1.2
Styrene	60	50	4[a]	2.3	H, 7.66, 7.72	76.0
Methyl acrylate	20				Cl, 0.55, 0.65	22.8
Vinyl chloride	19.2	50	5[b]	2.7	N, 8.57, 8.61	0.35
Styrene	32.0	25	48		Cl, 0.24, 0.25	67.1
Acrylonitrile	48.8					32.5
Vinyl chloride	54.4	50	11[b]	5.0	N, 6.93, 6.94	3.4
Styrene	30.2	25	48		Cl, 1.87, 1.97	70.4
Acrylonitrile	15.4					26.2

[a] 0.05 wt. per cent. Bz_2O_2. [b] 0.2 wt. per cent. Bz_2O_2.

Vinyl chloride added was determined by difference. The bottle was rotated end-over-end in a constant temperature water-bath regulated to 48 ± 0.05°. When a slight increase in viscosity was observed the bottle was removed, cooled to room temperature and weighed. Weight losses during the polymerization averaged 0.1–0.2 g. A mean value was taken for vinyl chloride concentrations during the polymerization, assuming total loss to be vinyl chloride monomer. The metal screw cap was punctured with an ice pick and utilizing the pick as a "needle valve," unpolymerized vinyl chloride was allowed to escape slowly without entrainment or frothing losses of the solution. The screw cap was then removed, the solution poured into 500 ml. of stirred 2B ethanol and the bottle and cap rinsed twice with 10-ml. portions of acetone. The polymer which precipitated as a fine powder was filtered on a Buchner funnel and washed with three fresh 500-ml. portions of denatured alcohol vigorously agitated in a Waring blender. The sample was finally filtered, dried in a circulating air oven at 50° for twenty-four hours and weighed. The product was analyzed in duplicate for chlorine by the Parr bomb method. Polymerization times, conversions and analytical data are summarized in Table I.

Emulsion.—A master emulsifier solution buffered to *p*H 8.0, comprising 500 g. of a 0.1 molar boric acid solution, 39.7 g. of 0.1 *N* sodium hydroxide, 10 g. of Santomerse D (the product of Monsanto Chemical Co.) and 8.3 g. of a 30% hydrogen peroxide solution was prepared. All emulsion polymerizations employed 100 ml. of this solution and 50 g. of total monomers. Appropriate amounts (Table I) of styrene and emulsifier solution weighed into 200-ml. pressure bottles were cooled in a Dry Ice-bath. A suitable volume of liquid vinyl chloride also cooled to Dry Ice temperatures was added. A metal cap with tin-foil liner was tightly screwed on the bottle which was allowed to warm to room temperature and weighed. Vinyl chloride added was determined by difference. The bottle was rotated end over end in a constant temperature water-bath regulated to 50 ± 0.05°. Polymerization times are shown in Table I. No convenient method was found for determining when low conversions had been attained, consequently many experiments were carried out to obtain the few results reported. On cooling to room temperature, the bottle was weighed. Weight losses during polymerization were 0–0.2 g. and, as explained above, a mean value was used for vinyl chloride monomer concentrations. The ice pick technique was used for venting vinyl chloride monomer, particular care being necessary in this case because of frothing. The screw cap was then removed and the emulsion poured into 500 ml. of 2B ethanol vigorously agitated in a Waring blender and the bottle and cap rinsed twice with 10-ml. portions of distilled water. The resulting suspension was heated to 60° and allowed to stand overnight to complete the coagulation. The product was filtered on a Buchner funnel, washed successively with three 1000-ml. portions of fresh alcohol, two 1000-ml. portions of distilled water, two 1000-ml. portions of alcohol, and then dried at 50° in a circulating air oven for twenty-four hours. Duplicate chlorine analyses by the Parr bomb method were obtained. Polymerization times, conversions and analytical data are summarized in Table I.

Vinyl Chloride–Methyl Acrylate Copolymerizations.—These copolymerizations were carried out in mass using 100-g. of total monomers. A polymerization technique identical with that described above for acetone solution polymerizations was employed. The water-bath temperature was regulated to 50 ± 0.05°. Vinyl chloride weight losses were 0–0.1 g. and a mean value was taken as before. After venting vinyl chloride monomer at room temperature, the products from the first four experiments (Table II) were precipitated by pouring the solution into 500 ml. of 2B ethanol vigorously agitated in a Waring blender. The resulting fine powder was filtered on a Buchner funnel, washed with three 1000-ml. portions of fresh alcohol and dried in a circulating air oven at 50° for forty-eight hours, then weighed. Products from the last four experiments were worked up in an identical way except that hexane was used instead of ethanol. In these cases a rubbery fibrous material was obtained instead of a fine powder. Since Parr bomb chlorine determinations gave erratic results for this copolymer series, chlorine analyses in duplicate were made by the Thompson–Oakdale method. Analytical data, conversions and polymerization times are summarized in Table II.

Vinyl Chloride–Acrylonitrile Copolymerizations.—This series was prepared in acetone solution using 50 g. of acetone and 50 g. of total monomers. The technique for charging the bottle and for polymerizing was identical to the method used for the vinyl chloride–styrene system in acetone solution. A water-bath temperature of 50 ± 0.05° was employed. Since the copolymers produced in this system were insoluble in the monomer–acetone solution, conversions were easily estimated from the amount of polymer formed. The bottles were cooled to room temperature, weighed and unpolymerized vinyl chloride released. Weight losses for this series were 0–0.4 g. and a mean value was taken as before. The fine suspension of copolymer was poured into 500 ml. of stirred 2B ethanol, filtered on a Buchner funnel and washed with three 1000-ml. portions of fresh alcohol. After drying at 60° for twenty-four hours in a circulating air oven, the product was weighed and analyzed in duplicate for chlorine by the Parr bomb method. Data for this copolymer series are summarized in Table III.

Tripolymer Experiments

Vinyl Chloride–Styrene–Methyl Acrylate.—These samples were prepared by mass polymerization in sealed

Pyrex tubes using 100 g. of total monomers. Appropriate amounts (Table IV) of styrene, methyl acrylate and benzoyl peroxide were weighed into a heavy-walled Pyrex tube 1″ in diameter, 2′ long and constricted 3″ below the open end. The solution was cooled in a Dry Ice-bath and a suitable volume of cooled vinyl chloride was added. The tube was sealed, allowed to warm to room temperature and the amount of vinyl chloride added determined by weight difference. The tube was immersed vertically in a water-bath regulated to 50 ± 0.05°. When a slight increase in viscosity was observed the tube was removed, cooled to room temperature and weighed. No vinyl chloride was lost in either experiment. The tube was cooled in a Dry Ice-bath, the constricted end opened and the whole allowed slowly to warm to room temperature. The solution was then poured into 500 ml. of 2B ethanol vigorously agitated in a Waring blender. The resulting fine powder was filtered on a Buchner, washed with three fresh 1000-ml. portions of alcohol. After drying the product for twenty-four hours at 50° in a circulating air oven, it was weighed, analyzed in duplicate for chlorine by the Thompson–Oakdale method and for carbon and hydrogen by the micro method. Polymerization times, conversions and analytical data are summarized in Table IV.

Vinyl Chloride–Styrene–Acrylonitrile.—These samples were prepared by mass polymerization in screw-cap 200-ml. pressure bottles using 60 g. of total monomers. The bottle was charged by adding appropriate weights (Table IV) of styrene, acrylonitrile and benzoyl peroxide to the bottle, cooling and adding vinyl chloride as before. The bottle was rotated end over end in a constant temperature water-bath first at 50°, then at 25° for the times shown in Table IV. Weight losses were 0–0.2 g. for the experiments. After venting vinyl chloride, the slightly viscous solution was poured into 500 ml. of stirred 2B ethanol and the bottle and cap rinsed with two 10-ml. portions of benzene. The resulting fine powder was filtered on a Buchner funnel, washed with three 1000-ml. portions of fresh ethanol and dried in a circulating air oven at 60° for forty-eight hours. The sample was weighed, analyzed in duplicate for chlorine by the Parr bomb method and for nitrogen by the Kjeldahl method. Data for these experiments are summarized in Table IV.

Summary

Monomer–polymer composition curves for the systems vinyl chloride–styrene, vinyl chloride–methyl acrylate and vinyl chloride–acrylonitrile have been determined. Coincidence of the solution and emulsion curves for the system styrene–vinyl chloride provides additional evidence for the oil phase mechanism of emulsion polymerization. Numerical values for monomer reactivity ratios for these systems are reported. Using these data an experimental investigation of the validity of the tripolymer equation was made. Good agreement was obtained between calculated compositions and compositions actually obtained.

Analgesics. II. A New Synthesis of Aminophthalidylalkanes

BY GLENN E. ULLYOT, HERBERT W. TAYLOR, JR., AND NORMAN DAWSON

Recently we reported[1] the synthesis of a series of aminophthalidylalkanes, one of which, 1-amino-1-phthalidylpropane hydrochloride, showed considerable activity as an analgesic agent. The method of synthesis resulted chiefly in the lower melting racemic form, isomer B, but both racemic forms (isomers A and B) were isolated by careful fractional crystallization. Pharmacological tests indicated a difference in the toxicity and analgesic activity of these isomers, isomer A being more active and more toxic. For this reason, a need arose for a more convenient method of preparing sufficient amounts of isomer A for further pharmacological and clinical studies. This was accomplished according to Scheme I; only isomer A (VIII) was obtained.

In the synthesis previously reported, the asymmetry of the carbon atom next to the benzene ring was established first. The presence of this asymmetric center undoubtedly operated during the formation of the second asymmetric carbon center, so that there resulted unequal amounts of the two racemic forms of the nitro compound and, consequently, of the amine hydrochloride. In the synthesis reported here, our results may be accounted for by the reversal of the order of establishment of the asymmetric centers.

On attempting to proceed directly from *o*-carboxybutyrophenone without recourse to ester formation, it was found that ethyl nitrite failed to react with an ethereal solution of the ketone in the presence of anhydrous hydrogen chloride. This may have been because the keto acid existed chiefly as a lactol; in any event, the ester V was readily converted to VI.

Catalytic reduction of α-isonitrosoalkylphenyl ketones in the presence of three equivalents of anhydrous hydrogen chloride in absolute alcohol[2] has been shown to proceed first at the isonitroso group and then at the carbonyl group. Catalytic reduction of VI was readily effected; the course of the hydrogen uptake is shown in Fig. 1.

Unless the crude V was thoroughly washed with bicarbonate, considerable decomposition occurred during distillation and resulted in a material contaminated with propylidenephthalide (III). However, even after taking into consideration the amount of propylidenephthalide present in various batches of keto ester, treatment of this material with ethyl nitrite did not result in complete conversion into VI except in the case of ester no. 2

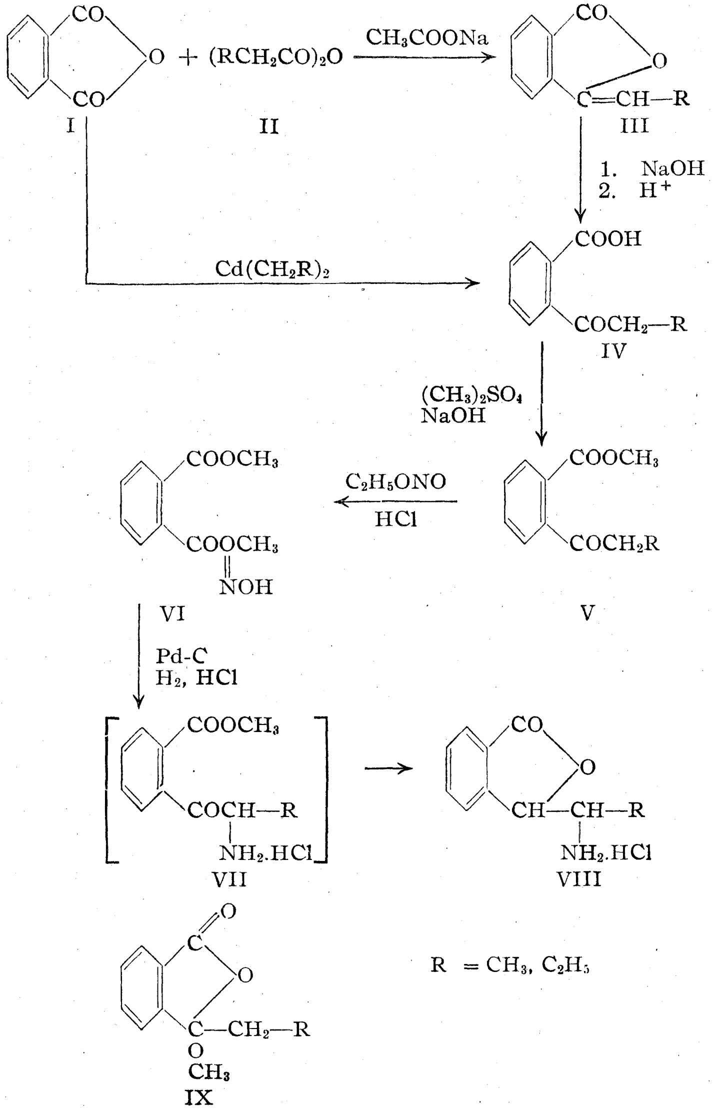
SCHEME I



(see Table I). This may have been due to the presence of pseudo-ester (IX). Preparation of ester under conditions which might have been expected to lead to only IX[3] resulted in a product which gave a 55% yield of VI (Table I, no. 7). Absorption spectra data (Fig. 2) showed that the ester contained no propylidenephthalide and, therefore, it was at first thought to be a mixture of V and IX. However, the absorption curve of this ester (Fig. 2, curve f) was inappreciably different from that of "pure" V (Fig. 2, curve d), as was true of Compound V (Fig. 2, curve e) which was prepared from IV and diazomethane, a condition most likely to give only V. The significance of absorption spectra data and the isonitroso reaction with respect to normal and pseudo esters needs further clarification.

Our inference as to the presence of pseudo ester and its effect on the isonitroso reaction is based on the fact that when ester no. 2 was used in the isonitroso reaction, the reaction was complete and there were no mechanical losses, and on the fact that ester no. 7, which contained no propylidenephthalide, gave only a 55% yield of the isonitroso derivative.

The synthesis of 1-amino-1-phthalidylethane, isomer A (VIII, R = CH_3), also was accomplished according to Scheme I, thus indicating the general applicability of the procedure.

Experimental[4]

o-Carboxybutyrophenone (IV, R = $-C_2H_5$).—This compound was prepared in two ways. (A) The acid was prepared by the general procedure of De Benneville[5a] from dipropylcadmium and phthalic anhydride in a yield of 70%, m. p. 89° (lit.[1] 87–89°). (B) 3-Propylidenephthalide was prepared[5b,c] and hydrolyzed to the keto acid. Sodium acetate (164 g., 2.0 moles), *n*-butyric anhydride (632 g., 4.0 moles) and phthalic anhydride (296 g., 2.0 moles) were heated at 180–190° for seven hours, excess reagents were removed by distillation *in vacuo*, and the mixture was diluted with water and made alkaline with ammonium hydroxide. The propylidenephthalide, after extraction by chloroform and distillation, was obtained in a 70% yield, b. p. 143–145° (5 mm.) (lit.,[5c] b. p. 169–170° (12 mm.), n^{20}_{D} 1.586). The propylidenephthalide was hydrolyzed by warming it to 70° for thirty minutes in 50% isopropanol containing one equivalent of sodium hydroxide. Acidification of the deep red solution gave the product as an orange solid. This was obtained in pure condition in a 75% yield by dissolving it in sodium bicarbonate, adding sufficient acid to liberate 2% of the dissolved material, and extracting the mixture with chloroform. Acidification then precipitated a product which no longer gave a red color upon dissolving it in alkali; m. p. 86–89°. Evaporation of the chloroform extracts left an oil which distilled over the range 125–160° (3 mm.), but chiefly over the range of 125–140° (3 mm.). This gave a bright red solution when dissolved in 10% alkali and a violet-red color when dissolved in sulfuric acid. It may have been impure 2-ethyl-1,3-indanedione,[6] but it failed to give a 2,4-dinitrophenylhydrazone and did not crystallize. The indanedione is reported to boil at 135–140° (7 mm.) and to melt at 53–55°.[6]

Methyl Butyrophenone-o-carboxylate (V, R = —C_2H_5).—o-Carboxybutyrophenone (640 g., 3.33 moles) was esterified in a solution composed of methanol (1200 cc.) and sodium hydroxide (160.2 g., 3.99 moles) in water (240 cc.) by the slow addition with stirring of dimethyl sulfate (506 g., 3.99 moles). The product was extracted by ether, after removal of half the alcohol by distillation and dilution with water, washed thoroughly with one molar sodium bicarbonate solution and with a saturated sodium chloride solution, and dried over sodium sulfate.

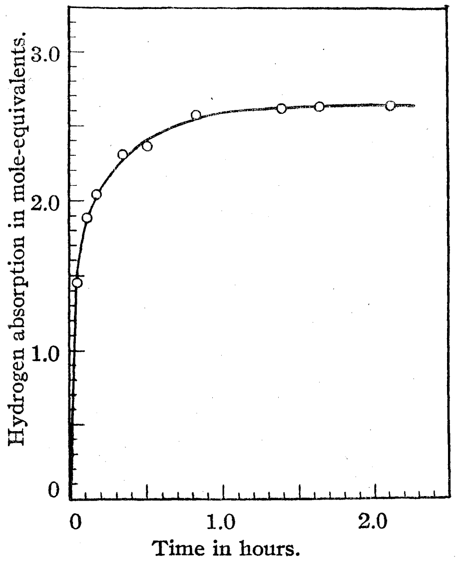

Fig. 1.—Catalytic hydrogenation of 0.158 mole of methyl α-isonitrosobutyrophenone-*o*-carboxylate.

After removal of the drying agent and the solvent, distillation of the residue gave a colorless product, b. p. 137–140° (4 mm.), n^{20}_{D} 1.5164–1.5190, in an 81–86% yield. The 2,4-dinitrophenylhydrazone prepared from this ester was obtained as orange crystals after recrystallization from alcohol, cap. m. p. 143–145°.

Anal. Calcd. for $C_{18}H_{18}O_6N_4$: C, 55.95; H, 4.70; N, 14.50. Found: C, 55.95, 55.97; H, 4.79, 4.80; N, 14.77, 14.59.

Certain preparations of this ester underwent decomposition during distillation. The variation in physical and chemical properties is shown by 1–5 in Table I. Analyses of these ester preparations for propylidenephthalide by absorption spectra data and by quantitative catalytic hydrogenation on a semi-micro scale gave the results shown in the last two columns.

TABLE I

Ester no.	n_D at	T, °C.	Maximum yield of VI in the isonitroso reaction in %	Propylidene phthalide content in mole % by Abspn. spectra[a]	Cat. hydg.

2	1.5309	19.7	77	24	23
3	1.5490	20	42	..	48
4	1.5510	19.7	41	51	51
5	1.5190	20	84	3	2
Propylidene-phthalide	1.586	20	..	..	104
6	1.5161	20.5	87	3	nil
7[b]	1.5171	20.5	55	4	nil

[a] Based on percentage transmission at 310 millimicrons. We are indebted to Mr. Albert Sample and Mrs. Josephine Butler for the data. [b] The acid precursor was prepared by Method A.

Preparation no. 5 differed from no. 4 only in that it was washed before distillation until it was completely free of acid.

It thus appeared that these preparations were mixtures of V, IX and/or III. In an effort to prepare the ester V in a pure state, the acid IV was treated with diazomethane to give ester no. 6. An attempt to prepare pure pseudoester by the Fischer esterification method, using methyl alcohol and hydrogen chloride,[3] resulted in the product, no. 7, whose absorption spectra (Fig. 2, curve f) was unexpectedly found to be inappreciably different from that of ester no. 6 (Fig. 2, curve e).

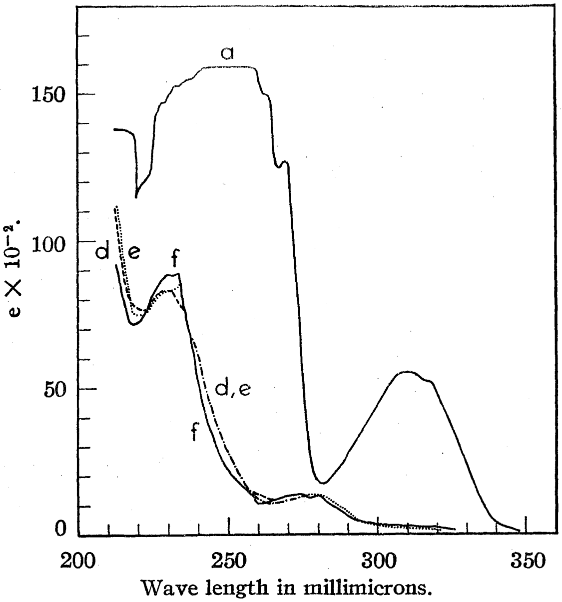

Fig. 2.—Absorption spectra: a, propylidenephthalide; d, ester no. 5, prepared from IV and methyl sulfate; e, ester No. 6 prepared from IV and diazomethane; f, ester No. 7, prepared from IV and methyl alcohol and hydrogen chloride.

Methyl α-Isonitrosobutyrophenone-*o*-carboxylate (VI, $R = -C_2H_5$).—The ester (V, $R = -C_2H_5$) (412 g., 2.0 moles) was dissolved in methylene chloride (1 liter) and treated at 5° successively with gaseous ethyl nitrite (3.0 moles in sixty minutes) and hydrogen chloride (3.0 moles in ninety minutes). One-half the solvent was removed by distillation, the residue was chilled, and the product was collected by filtration in 81–84% yield. Upon recrystallization from isopropanol (92% recovery), its corrected cap. m. p. was 150–151° with softening at 148°.

Anal. Calcd. for $C_{12}H_{13}O_4N$: C, 61.27; H, 5.57; N, 5.95. Found: C, 61.40, 61.75; H, 5.83, 5.62; N, 5.79, 5.98.

1-Amino-1-phthalidylpropane Hydrochloride, Isomer A (VIII, $R = -C_2H_5$).—The isonitroso compound (35 g., 0.158 m.) was dissolved in 95% alcohol (450 cc.). Twenty grams of previously used 10% palladinized charcoal catalyst and 42 cc. of concentrated hydrochloric acid were added. Hydrogenation was carried out in two hours at 30° at an initial hydrogen pressure of 500 lb./sq. in. The course of the hydrogen uptake was as shown in Fig. 1. The rapid absorption of two moles of hydrogen presumably indicates the formation of VII, half of which underwent slow reduction. After removal of the catalyst, the reaction mixture was taken to dryness *in vacuo*. The residue was collected and washed with acetone. The product, 1-amino-1-phthalidylpropane hydrochloride, isomer A, weighed 18.7 g., 55% yield, cap. m. p. 265–268° dec. (lit.[1] 268.5–270°). A sample was recrystallized from alcohol.

Anal. Calcd. for $C_{11}H_{14}O_2NCl$: Cl, 15.57. Found: Cl, 15.56, 15.56.

So far, the water-insoluble by-product of this reduction has not been identified.

Solvents other than 95% alcohol were tried, but all these—glacial acetic acid, or a mixture of dioxane and water to which three equivalents of concentrated hydrochloric acid per mole of compound reduced had been added, or absolute alcohol containing three equivalents of anhydrous hydrogen chloride as reduction media—gave considerably lower yields of amine salt. The yield was much lower when the amount of isonitroso compound reduced per given volume of solvent was greater than 35 g./450 cc., but a decrease in the amount reduced per given volume of solvent failed to increase the yield.

Methyl Propiophenone-*o*-carboxylate (V, R = CH_3).—*o*-Carboxypropiophenone, which was prepared by the methods used to prepare *o*-carboxybutyrophenone, was esterified in 87% yield; b. p. 137 (5 mm.) to 132° (4 mm.), $n^{20}\text{D}$ 1.5260–1.5290 (lit.,[7] b. p. 157–158° (19 mm.), $n^{16.4}\text{D}$ 1.5240).

Methyl α-Isonitrosopropiophenone-*o*-carboxylate (VI, R = CH_3).—This compound was recrystallized from methanol, m. p. 166–169° (Fisher block).

Anal. Calcd. for $C_{11}H_{11}NO_4$: C, 59.72; H, 5.01; N, 6.33. Found: C, 59.84, 59.97; H, 4.93, 4.65; N, 6.33, 6.29.

1-Amino-1-phthalidylethane Hydrochloride, Isomer A (VIII, R = CH_3).—This compound was obtained in 64.9–74.5% yield and after recrystallization melted in the range 286–295° (lit.,[1] 292–296° dec.).

1-*p*-Nitrobenzoylamino-1-phthalidylethane (A) melted 188–189.5° after crystallization from alcohol (lit.[1] 188–189°).

Anal. Calcd. for $C_{17}H_{14}O_5N_2$: C, 62.57; H, 4.29; N, 8.58. Found: C, 62.47, 62.58; H, 4.29, 4.35; N, 8.54, 8.59.

Summary

1. A new synthesis of 1-amino-1-phthalidylalkanes has been reported.
2. This synthesis resulted in only one of the possible racemic forms of 1-amino-1-phthalidylethane and -propane.
3. In the preparation of the intermediate, methyl butyrophenone-*o*-carboxylate, the product underwent partial decomposition to propylidenephthalide unless carefully freed of acid before distillation.
4. Observations have been reported on the relationship between normal and pseudo-esters of butyrophenone-*o*-carboxylic acid in regard to their ultraviolet absorption spectra and their ability to undergo the isonitroso reaction.

The Bitter Principles of Citrus Fruit. I. Isolation of Nomilin, a New Bitter Principle from the Seeds of Oranges and Lemons

BY OLIVER H. EMERSON

Limonin is a well recognized bitter principle in citrus plants that has been regarded as responsible for the bitter taste which sometimes appears in the juice of Navel oranges on standing or heating. Evidence which favors that view is presented here and points to a reaction whereby limonin may be formed from a precursor in orange juice. In addition a new bitter principle, "nomilin," has been isolated from the seeds of oranges and lemons. It appears closely related to limonin, and because of the similarity in properties it may also contribute to the bitter taste.

Limonin was first isolated by Bernay in 1841 and has since been obtained from a series of citrus and related *Rutaceae*,[1,2,3] having been found in the fleshy part of the fruit, the seeds, the bark and the roots. The chemical nature of the bitter principle has recently been discussed by Geissman and Tulagin.[4] It is well established that the substance is a dilactone of the formula $C_{26}H_{30}O_8$. It has no reactive hydroxyl groups, giving no methane with cold methylmagnesium iodide,[5] although Koller and Czerny reported it to give variable amounts when heated, which suggested to them the presence of a carbonyl group capable of enolization, although no carbonyl derivatives have been reported. No methoxyl or methylene dioxy groups have been detected, and the remaining three oxygen atoms are presumably present as cyclic ethers. Drastic treatment with potassium hydroxide yields 0.88 mole of acetone.[4]

The question of a carbonyl group, as postulated by Koller and Czerny, is obviously of importance to the problem of limonin. The absorption spectrum of limonin as measured by Geissman and Tulagin and in this Laboratory (Fig. 1) shows a weak band at about 290 mμ, log $E = 1.4$, which is suggestive of an isolated carbonyl group, though such a weak band could easily result from traces of an impurity. However, we have succeeded in preparing a beautifully crystalline oxime by treating limonin with hydroxylamine in the presence of pyridine, which will often permit the oximation of carbonyl groups that fail to react with hydroxylamine acetate.[6]

Isolimonin.—Besides limonin, Koller and Czerny[5] reported the isolation from orange seeds of an isomer of limonin melting at 258–259° which they called isolimonin. It crystallized from alcohol in thick "warty" crystals in contrast to the thin six-sided plates of limonin and differed from

that substance in being more soluble in alcohol, less soluble in benzene, in readily forming a diacetyl derivative and in giving two moles of methane with methylmagnesium iodide.

A bitter principle from very immature Navel oranges was investigated by Higby[7] who isolated it as shiny plates melting at 262–264°, $[\alpha]^{22}\text{D}$ $-111.5°$. He thought the substance to be isolimonin in view of the similarity in rotation and melting point. From the seeds of Valencia oranges he obtained limonin melting at 292°. Later he reported that the usual bitter constituent, at least in more mature fruit, is limonin,[8] a view in which Geissman and Tulagin concur. While other references to isolimonin occur in the literature,[2,3] it must be admitted that its characterization leaves much to be desired.

The isolation of the bitter principle from Navel orange juice as described by Higby[7] was repeated except that the final purification was done by solution in methylene chloride followed by the addition of alcohol, as described by Feist and Overberg.[9] Limonin was obtained agreeing in melting point[1,4,9] and optical properties[10] with the findings of other workers[1] and with preparations made in this Laboratory from the seeds of Valencia oranges and of lemons. From methylene choride–alcohol limonin separates in part as the characteristic unsolvated plates and in part as a loose solvate with methylene chloride crystallizing in needles, as described by Feist and Overberg for "citrolimonin" from lemon seeds.[11]

In an attempt to obtain isolimonin, ground and defatted Valencia orange seeds were extracted with acetone instead of the previously used alcohol[5] in the belief that the greater solubility of the bitter substances in the former solvent would make it more suitable. However, it was found after fairly exhaustive extraction that the seed meal was still intensely bitter. To water this extracted meal imparted a very bitter taste which disappeared on standing. The bitter substance was not extracted either by absolute or 95% ethanol but was extracted by 50% ethanol, or more conveniently by 1-butanol saturated with water. However, the chief bitter substance isolated was limonin. Thinking that this substance might be present as an unstable derivative soluble in water-containing organic solvents, we tried extraction under a variety of conditions in the hope of securing such a derivative but without success. It was noticed that the solvents which extracted limonin also removed considerable amounts of gummy material which may have interfered with the extraction of limonin by the dry solvents and permitted the formation of a transient, bitter colloidal solution in water. Only about one-third of the total limonin obtained was found in the acetone extract.

Nomilin.—From the mother liquors of limonin from both orange seeds and lemon seeds a second bitter principle was obtained. It was easily separated from limonin since it remained in solution in ethanol containing methylene chloride and also dissolved in hot 2-propanol, in which limonin is very sparingly soluble. It was further purified by recrystallization from methanol, from which it separated in beautiful needles melting at 279°, though unfortunately the melting point is somewhat dependent on the rate of heating.

The substance is notable for its tendency to form solvates with many solvents, which causes the appearance of crystals from different solvents to differ markedly. Several of the solvates required heating at 140° at 1 mm. for their decomposition.

In order to get reliable analytical data samples of the substance were recrystallized from 2-propanol, 1-butanol, ethyl acetate and methylene chloride–petroleum ether. Each sample was dried to constant weight at 140° at 1 mm. and analyzed. The agreement was satisfactory and in conjunction with the accurate Signer method[13,14] indicated the molecular formula to be $C_{28}H_{34}O_9$.

Since the substance is not an isomer of limonin though closely associated with it and presumably related to it chemically the name **nomilin** is proposed. Nomilin may be quite an important constituent of the total bitter material of orange seeds. Thus one batch of 17 kilos yielded 24 g. of limonin and 14 g. of nomilin.

It is conceivable that the isolimonin of Koller and Czerny was impure nomilin, but the Austrian workers reported their substance to give two moles

of methane with methylmagnesium iodide and to yield readily a diacetyl derivative, whereas nomilin has only one active hydrogen and is acetylated with difficulty if at all by refluxing for several hours with acetic anhydride and sodium acetate or with acetic anhydride and pyridine. In both cases the bulk of the nomilin was recovered unchanged, though some material was obtained whose high carbon content indicated the elimination of the hydroxyl rather than its acetylation.

The absorption spectrum of nomilin is shown in Fig. 1.[15] The similarity to that of limonin is striking. Like limonin, nomilin did not react with carbonyl reagents except under the powerful activating influence of pyridine. In contrast to the beautifully crystalline oxime of limonin, the oxime, semicarbazone and 4-phenylsemicarbazone of nomilin were amorphous products whose melting points, owing to decomposition, were indefinite.

Like limonin, nomilin is a dilactone and the lactone groups are readily opened by dilute alkali. In the case of nomilin the reaction was more complicated for acetic acid was split out, and on acidification there was obtained a lactone-acid for which the name *nomilic acid* is proposed. The analysis and titration of the free carboxyl group indicated the formula $C_{26}H_{32}O_8$. The spectrum is shown in Fig. 1. The intensification of the absorption and the shift toward the visible suggests a greater degree of conjugation in nomilic acid than exists in limonin or nomilin.

On fusion with potassium hydroxide at 300–340° nomilin, in contrast to limonin, did not give significant amounts of acetone.

Other Bitter Principles.—A third bitter substance (substance X) was obtained from the crude alcoholic mother liquors of orange seeds. It differed from limonin and nomilin by its very sparing solubility in methylene chloride and acetone. The solubility of the substance was greatest in ethyl and methyl alcohols among the common solvents tried, but even in these the product was only sparingly soluble and had a low temperature coefficient of solubility. The best preparation separated from methanol on concentration or on dilution with water in the form of delicate hair-like needles melting with profound decomposition at 315°. The Molisch test was negative. The analysis agreed with the formula $(C_9H_{12}O_4)_n$, but in view of the strong retention of methanol by nomilin encountered later this may be in error. The spectrum was similar to that of limonin but more generalized, with no suggestion of any definite bands. Purification was difficult because of the presence of amorphous material of similar solubility. Since it was a very minor constituent of orange seeds it was not further investigated. It was not observed in lemon seeds.

Development of the Bitter Substances in Navel Orange Juice.—Navel oranges are an important crop in California and the tendency of the juice to turn bitter is of serious concern. The problem was studied by Higby,[7] who concluded that in the intact orange limonin exists in the albedo and pulp in the form of a water-soluble, non-bitter precursor which might be the salt of the diacid derived by opening both lactone rings, or a glycosidic derivative of it.

The formation of the bitter substance was observed by extracting Navel juice with benzene as soon as possible after the juice was expressed, then again after four hours and again after standing overnight. The juice after the removal of benzene was not perceptibly bitter and the residues from the first and last extractions were only slightly bitter, the bulk of the bitter material being found in the second extract. Since limonin was the only bitter substance isolated from the benzene extracts it must be chiefly responsible for the bitter taste.[16] Also, whatever the precursor, the rate of conversion to limonin was such that in orange juice at *p*H 3.6 comparatively little was formed in the twenty minutes required for the first extraction, but the conversion was essentially complete in four hours. Potassium limonate equivalent to the amount isolated from bitter Navel juice was added to Valencia juice which does not normally turn bitter, also at *p*H 3.6, and the development of bitterness observed appeared to parallel that in Navel juice both in degree and rate.

Higby's[7] suggestion that the precursor of limonin in Navel orange juice is the diacid or a derivative of it such as the glucoside appears to be close to the truth, although conceivably the precursor might be one of the lactone acids since the related lactone acids, limonilic acid[4] and nomilic acid are not bitter. Accordingly, in view of the tendency of the lactone rings to reestablish themselves in acid solution, the precursor can be stable only in more nearly neutral tissues like the albedo, central bundle, and veins of the capillary membrane. The conversion of the precursor to limonin is a process catalyzed by hydrogen ion and by heat and is inhibited by neutralizing the juice which, however, makes it unpalatable. There is at present no evidence that enzymes are involved in the process.

Experimental

Limonin from Navel Oranges.—Immature Navel oranges (140 lb.) collected near Los Angeles about the middle of October, 1945, yielded five gallons of juice, which was strained through cheese cloth and thoroughly extracted with benzene. The pulp strained from the juice was extracted separately and the extract from it was united with that from the juice. The peel, consisting of flavedo with some albedo, was extracted with petroleum ether to remove the oil, pressed as dry as possible in a hydraulic press and then extracted with benzene. The benzene extracts were concentrated to 200 ml. and the limonin precipitated by the addition of three volumes of petroleum ether. Most of the product came from the juice and pulp, and the small amount from the peel may

---

(15) I wish to express my sincerest thanks to Mr. G. F. Bailey and to Mrs. Martha Adkins for measuring the absorption spectra reported in this paper.

(16) The isolation was done before the discovery of nomilin, which could easily have escaped detection.

well have come from albedo accompanying it. The crude limonin was purified by solution in a minimum amount of methylene chloride followed by the addition of three volumes of methanol or ethanol. A few recrystallizations brought the melting point up to 298–300°.[17] In an evacuated tube the substance melted at 301.5–302.5°. Previously reported melting points for limonin are: 299–300°,[1] 302–305,[4] 304.[9] The yield was 1.58 g.

A second lot of oranges (140 lb.) collected from the same area early in November, 1945, yielded 2.5 g. of limonin.

From methylene chloride, on dilution with ethanol or methanol, limonin separated as needles accompanied by the more characteristic plates. On heating *in vacuo* the needles readily lost methylene chloride which was trapped and identified. Needles (144 mg.) picked out with forceps and heated at 80° *in vacuo* lost 18.3 mg. or 12.7% of their weight. The complex $C_{26}H_{30}O_8 \cdot CH_2Cl_2$ contained 15.4% of methylene chloride by calculation. Even on standing in air the needles lost methylene chloride and became opaque.

Anal. Material dried at 80° at 1 mm. for 1 hour. Calcd. for $C_{26}H_{30}O_8$: C, 66.35; H, 6.42. Found: C, 66.45; H, 6.49.[18]

Rotation.—Material dried as above (227.9 mg.) made up to 25 ml. in acetone in a 2-dm. tube at 22° gave a rotation of −6.35 units in a saccharimeter; $[\alpha]^{22}_D$ −121°. Reported $[\alpha]^{20.5}_D$ −129°,[1] $[\alpha]^{25}_D$ −123°.[4]

Isolation of Limonin from Valencia Orange Seeds.—Orange seeds (22 lb.) were ground and defatted with petroleum ether and extracted with acetone. The acetone solution was concentrated to a thin sirup, diluted with ethanol and concentrated again, yielding most of the limonin. A little more was secured by the addition of water. Purification was done by crystallization from methylene chloride and alcohol as described above. The yield was 13 g.

The acetone-treated meal was then well extracted with 1-butanol saturated with water, and the extracts concentrated under reduced pressure. Some gummy water-soluble material separated first and was discarded. The bitter substances present separated in impure form on further concentration. These were filtered off. The butanol was finally concentrated to a sirup, diluted with ethanol and then with a little water, throwing out a last crop of bitter material.

The combined portions of crude bitter material were treated with acetone and a residue of some non-bitter material was removed. The acetone solution was concentrated to small volume and then diluted with ethanol. This precipitated the bitter substances still in an impure state. Purification was made by dissolving this material in methylene chloride and precipitating limonin by the addition of 3 volumes of ethanol.[19] This step was repeated until the limonin had a melting point of 298–300°. The total yield of pure liminon (after recrystallization) obtained from 22 lb. of orange seeds was 40 g., though a second batch of 37 lb., extracted directly with wet butanol, yielded only 24 g.

Isolation of Nomilin.—On concentrating the methylene chloride–alcohol mother liquors of limonin obtained on recrystallizing the bitter fractions described above there separated a mixture of a new substance and limonin. Nomilin was extracted from the mixture by boiling for a few minutes with a minimum amount of 2-propanol and filtering the hot solution. On cooling nomilin separated as stout crystals. Further purification was secured by recrystallization from methanol from which nomilin separated in slender needles. Nomilin is soluble to the extent of 1.5 to 2% in boiling methanol and in boiling 2-propanol, and somewhat more soluble in hot ethyl acetate. In other solvents its solubility is generally similar to that of limonin. The yield of nomilin from 37 lb. of orange seeds was 14 g.

On account of decomposition the melting point of nomilin is not very definite. With a block heated at the rate of 2° per minute it melted at 278–279° with evolution of gas when introduced at 273–275°. The use of a melting point tube sealed *in vacuo* did not sharpen the melting point as it did in the case of limonin.

For analysis samples were recrystallized from ethyl acetate, 2-propanol, 1-butanol and methylene chloride followed by the addition of petroleum ether. Each sample was dried to constant weight at 140° at 1 mm. The results are shown in Table I.

TABLE I

ANALYSES OF NOMILIN

Solvents used for crystallization	C	H	Molecular weight (Signer)
Butanol	65.45	6.90	
Butanol	65.46	6.75	
Isopropanol	65.57	6.81	
Isopropanol	65.26	6.77	
Methylene chloride	65.53	6.73	
Petroleum ether	65.35	6.63	
Ethyl acetate	65.30	6.74	511
Ethyl acetate			516
Average	65.42	6.67	513
Calculated for $C_{28}H_{34}O_9$	65.33	6.67	514.3

Molecular Weight.—This was done by the Signer method as described by Clark.[14] Owing to the difficulty of securing accurately calibrated Pyrex tubing for the volumetric part of the apparatus, ordinary 4.5–5.0 mm. tubing was used, and the lengths of the columns of solution were measured to an accuracy of about one-fourth mm. with a rule having a little foot to rest against the end of the tube. The corresponding volume was determined by means of mercury.

Nomilin (33.5 mg.) from ethyl acetate, dried as above in 1.075 ml. of acetone, was in equilibrium with 12.85 mg. of azobenzene in 1.158 ml., mol. wt., 511. Nomilin (33.2 mg.) in 0.855 ml. of acetone was in equilibrium with 13.81 mg. of azobenzene in 1.006 ml., mol. wt., 516.

Rotation.—Material recrystallized from 2-propanol and dried as above (298.9 mg.) made up to 25 ml. in acetone in a 2-dm. tube gave a rotation of −6.60 units in a saccharimeter at 23°

$$[\alpha]^{23}_D = -\frac{6.60 \times 0.346 \times 100}{2 \times 1.195} = -95.7°$$

Isolation of Limonin and Nomilin from Lemon Seeds.—Lemon seeds (15 lb.) were ground, defatted and extracted with 1-butanol as described for the orange seeds. Nomilin and limonin were separated and isolated as described above. The optical properties of the crystals and melting points coincided with the products from orange seeds.

Rotation of Nomilin from Lemon Seeds.—Material dried as described above, 273.8 mg., made up to 25 ml. in acetone in 2-dm. tube in a saccharimeter at 23°, rotation −6.05 units

$$[\alpha]^{23}_D = -\frac{6.05 \times 0.346 \times 100}{2 \times 1.095} = -95.7°$$

---

(17) All melting points were done in a copper block using short stemmed Anschütz thermometers and the substance was introduced a few degrees below the melting point.

(18) I wish to thank Dr. W. Gordon Rose for instruction and help in running microanalyses.

(19) The use of 2 volumes of 2-propanol instead of 3 volumes of ethanol was later found to be of advantage.

Reaction of Nomilin with Methylmagnesium Iodide.[20]—Nomilin (9.92 mg.) in pyridine gave 0.50 ml. of methane at 22°, 741 mm. Nomilin (11.59 mg.) in pyridine gave 0.57 ml. of methane at 22°, 741 mm. Calcd. for $C_{28}H_{34}O_9$: 1.05, 1.02 atoms of active H.

Action of Dilute Alkali on Nomilin.—Nomilin (237 mg.) was heated on the steam-bath with 40 ml. of 0.1 *N* NaOH with occasional swirling. After half an hour the solution was cooled, filtered from a small amount of undissolved material and acidified with 10 ml. of 0.5 *N* HCl. The crude nomilic acid which soon separated was purified by solution in a minimum amount of acetone followed by the addition of an equal volume of water, separating as beautiful needles, m. p. 205–206°; yield 190 mg. (88%). Further recrystallization brought the melting point up to 208–209° in an evacuated tube.

Anal.—Material dried to constant weight at 100°, 1 mm. Calcd. for $C_{26}H_{32}O_8$: C, 66.07; H, 6.82. Found: C, 66.00, 65.91; H, 6.95, 6.90.

For titration the substance was dissolved in 0.5 ml. of acetone followed by 0.1 ml. of 0.5 *N* sodium acetate and 5 ml. of water. Under these conditions the nomilic acid, displacing acetic acid, remained in solution during the titration. The final end-point was reasonably stable, the faint pink of phenolphthalein fading only after several minutes. A weight buret was used with solutions standardized to weight-normality.

Nomilic acid (10.30 mg.) neutralized 0.466 g. of 0.0485 *N* NaOH. Nomilic acid (10.05 mg.) neutralized 0.443 g. of 0.0485 *N* NaOH. Equivalent weight, 477, 468. Calcd. for $C_{26}H_{32}O_8$, 472.5.

Hydrolysis of Nomilic Acid.—Nomilic acid was warmed on the steam-bath with an excess of 0.0485 *N* NaOH and titrated back with 0.0497 *N* HCl using phenolphthalein.

Nomilic acid (6.03 mg.) was dissolved in 1.440 g. of NaOH solution and back-titrated with 0.0896 g. of HCl solution. Nomilic acid (5.48 mg.) was dissolved in 1.211 g. of NaOH solution, back-titrated with 0.691 g. of HCl solution. Equivalent weight calcd. for 1 COOH, 1 lactone, 236. Found: 238, 224.

Isolation of Acetic Acid.—The aqueous solution from which the nomilic acid had separated (50 ml.) was steam distilled, the volume being maintained approximately constant. The volatile acid neutralized 8.1 g. of 0.0485 *N* NaOH. The neutral solution was concentrated to 2 ml. and the salt converted to the *p*-phenylphenacyl ester. On recrystallization from dilute alcohol and then petroleum ether the ester melted at 110–111° and gave no depression with an authentic specimen of the *p*-phenylphenacyl ester of acetic acid of the same melting point. The optical properties of the crystals were examined by Dr. Francis T. Jones and found identical for the two preparations.

Potassium Hydroxide Fusion of Nomilin.—Nomilin (62 mg.) was dissolved in a solution of 1 g. of potassium hydroxide in 1 ml. of water and gradually heated to 340° in a bath of Wood's metal. The distillate was collected in a solution of 2,4-dinitrophenylhydrazine sulfate. Nothing resembling acetone dinitrophenylhydrazone was observed, which in blank test was isolated in good yields.

Limonin Oxime.—Limonin (100 mg.) and 100 mg. of hydroxylamine hydrochloride were dissolved in 2 ml. of pyridine and 2 ml. of absolute alcohol and refluxed for four hours. The solvent was removed under reduced pressure and the residue washed well with water and recrystallized from dilute alcohol. The product decomposed and melted in the neighborhood of 260–270°, depending on the rate of heating. The product recrystallized from dilute ethanol appeared to hold that solvent very retentively. For analysis it was recrystallized twice from methanol and once from butanol and dried at 100° at 1 mm.

Anal. Calcd. for $C_{26}H_{31}O_8N$: C, 64.30; H, 6.43; N, 2.89. Found: C, 64.22, 64.04; H, 6.41, 6.30; N, 3.06.

Reaction of Nomilin with Hydroxylamine.—This was conducted as in the preparation of limonin oxime. However, nomilin oxime would not crystallize from any solvent or solvent mixture tried. An attempt to chromatograph the substance in a column of calcium carbonate resulted in decomposition. A preparation precipitated from methanol by the addition of water and dried at 100° at 1 mm. gave low C values. Calcd. for $C_{28}H_{35}O_9N$: C, 63.48; H, 6.67; N, 2.65. Found: C, 63.12; H, 6.63; N, 3.00. A sample precipitated from benzene with petroleum ether gave high C values; found C, 64.10; H, 6.80.

The hydroxy-hydroxamic acid which might conceivably result from the reaction of hydroxylamine with a lactone ring should be $C_{28}H_{37}O_{10}N$, requiring C, 61.39; H, 6.82.

Isolation of Substance X.—This substance separated in little aggregates from the alcoholic mother liquors of limonin from orange seeds. The yield of crude material from 22 lb. of orange seeds amounted to about 500 mg., but purification was accompanied by much loss on account of the difficulty of separating it from amorphous material. Solution in methanol followed by concentration or by dilution with water appeared the most effective method tried. The best preparation consisted of hair-like needles melting with profound decomposition at 315°.

For analysis the substance was dried to constant weight at 56° at 1 mm. Calcd. for $(C_9H_{12}O_4)_n$: C, 58.66; H, 6.57. Found: C, 58.62, 58.71; H, 6.55, 6.49.

Acknowledgment.—I wish to express my sincere thanks to Dr. W. C. Platt for the gift of the orange seeds.

Summary

Limonin was the sole bitter principle isolated from pulp and juice of Navel oranges. This substance was also obtained from seeds of lemons and Valencia oranges.

A new bitter principle, $C_{28}H_{34}O_9$, for which the name "nomilin" is proposed, was isolated from orange seeds and lemon seeds. Nomilin has a hydroxyl group that reacts with methylmagnesium iodide, but not readily with acetic anhydride. Like limonin, nomilin is a dilactone, but on treatment with dilute alkali followed by acidification acetic acid is lost and lactone acid, nomilic acid, $C_{26}H_{32}O_8$, is obtained. In contrast to limonin, nomilin does not yield appreciable amounts of acetone on fusion with potassium hydroxide. Limonin and nomilin both react with hydroxylamine in the presence of pyridine, limonin oxime being a beautifully crystalline substance.

The non-bitter precursor of limonin in Navel orange juice behaves like the diacid obtained by opening both lactone rings, but it is possible that the precursor may be a lactone acid or a compound of the diacid or lactone acid such as a glycoside.

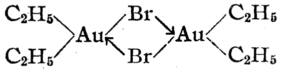
Trimethylgold[1a]

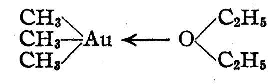
BY HENRY GILMAN AND LAUREN A. WOODS[1b]

The extensive and elegant studies by Gibson and co-workers[2] on organogold compounds have shown that all of the trivalent gold compounds which they investigated were four-covalent. For example, diethylgold bromide was assigned the following structure



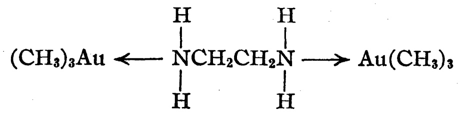
They expressed the view "of the impossibility of existence of compounds having the empirical R_3Au (R = alkyl)."[3] In support of this generalization were the numerous attempts[4] to prepare an R_3Au compound by the Grignard reagent, and by other indirect procedures, under various experimental conditions and with a series of radicals.

We have succeeded in preparing trimethylgold in ether solution by the reaction of methyllithium with gold tribromide or dimethylgold bromide at $-65°$. The free trimethylgold, however, was highly unstable and began to decompose at about -40 to $-35°$. The products of this thermal decomposition were gold, methane, and ethane. No molecular weight was determined for the trimethylgold, but it is possible that there is a co-



ordination in ether[5] and that Gibson's postulate of trivalent gold compounds being four-covalent is valid with our compound. Also it is understandable why the Grignard reagent did not give the R_3Au type, for the R_2AuX type was probably formed in the early stages and this would go more effectively to the R_3Au type with a more reactive organometallic compound like methyllithium and at low temperatures.

The trimethylgold can be stabilized by adding ethylenediamine, 2-aminopyridine, or benzylamine. The resulting coördination compounds may provisionally be represented by structures of which the following is typical



$$(CH_3)_3Au \longleftarrow \overset{\displaystyle H}{\underset{\displaystyle H}{N}}CH_2CH_2\overset{\displaystyle H}{\underset{\displaystyle H}{N}} \longrightarrow Au(CH_3)_3$$

By analogy with triethylgallium, it might be expected that the coördination compound of trimethylgold with amines would be more stable than the coördination compound with ether; for the simple triethylgallium reacts violently with water, the etherate $[(C_2H_5)_3Ga \cdot (C_2H_5)_2O]$ vigorously, and the ammine $[(C_2H_5)_3Ga \cdot NH_3]$ only very slowly.[6] Some other amines appeared not to form stable coördination compounds with trimethylgold. Also, an orienting experiment indicated that ethylenediamine did not stabilize the homologous triethylgold. This observation was not surprising, for other studies[7] have shown that the ethyl derivatives of copper, thallium and other metals appear to be significantly less stable than the corresponding methyl derivatives.

On the basis of some theoretical considerations it appeared that if the radical attached to gold were neopentyl instead of methyl the organogold compounds might be more stable. This found some qualitative support on the basis of the rates of deposition of gold from the organogold compounds; however, it is doubtful whether the stability could be increased sufficiently to make possible the isolation of the free trineopentylgold.

Cleavage Reactions.—Hydrogen chloride readily cleaved trimethylgold, and also its coordination compound with ethylenediamine, to form dimethylgold chloride and methane.

$$(CH_3)_3Au + HCl \longrightarrow (CH_3)_2AuCl + CH_4$$

In the presence of bromide ion, dimethylgold bromide was formed in preference to the chloride even though an excess of hydrochloric acid was present.

Inasmuch as trialkylgold compounds are readily prepared from alkyllithium compounds and gold tribromide, their cleavage by hydrogen chloride at $-65°$ offers a method of choice for the preparation of dialkylgold halides.

Although trimethylgold was not cleaved by phenol or trichloroacetic acid[8] at $-65°$, it was readily cleaved by thiophenol or thioglycolic acid to form dimethylgold thiophenate and dimethyl-

[8] Trichloroacetic acid has been used by W. E. Catlin to measure the rates of cleavage of relatively unreactive organolead and organotin compounds.

gold carboxymethylmercaptide, respectively.

$$(CH_3)_3Au + HSR \longrightarrow (CH_3)_2AuSR + CH_4$$

The ability of RSH compounds to cleave triethylbismuth and tetraethyllead at a much more rapid rate than some phenols and carboxylic acids has been reported.[9]

Trimethylgold did not react with benzoyl chloride at temperatures up to −20°, whereas, under essentially the same conditions, methylcopper reacted with benzoyl chloride to form acetophenone.[10] This lower reactivity of trimethylgold toward some functional groups might have been predicted on the basis of the generalization that in any group or sub-group the higher the ionization potential of a metal the less reactive will be its organometallic compounds.[11a]

Disproportionation and Thermal Decomposition.—When an ether suspension of gold tribromide is added to an ether solution of trimethylgold at −75°, then stirred for two hours and allowed to come to room temperature, dimethylgold bromide is one of the products. This indicates that the following reaction occurred

$$2(CH_3)_3Au + AuBr_3 \rightleftarrows 3(CH_3)_2AuBr \qquad [I]$$

A reaction of this type is rather general with organometallic compounds and a related equilibrium has been reported with organoberyllium compounds[11b]

$$2RBeX \rightleftarrows R_2Be + BeX_2$$

In the disproportionation or redistribution reaction[11c] [I], one might expect to find some methylgold dibromide. This appears to be the case when dimethylgold bromide is refluxed in ether solution. Incidental to the thermal decomposition of methylgold compounds, it should be mentioned that the solid bis-(trimethylgold)-ethylenediamine explodes violently when heated in an open crucible.

Experimental

Trimethylgold.—A suspension of 8.74 g. (0.02 mole) of gold tribromide[12] in 60 cc. of ether was cooled to −65° and stirred while a solution of 0.06 mole of methyllithium in 50 cc. of ether was added over a period of three hours. The mixture gave a negative color test I.[13] The suspension was allowed to warm up slowly to room temperature. At about −40 to −35° a gold mirror began to form on the walls of the flask. The mixture was gently refluxed for two hours and the evolved gas was collected and analyzed. The gas consisted of 0.023 mole (76.8% yield) of ethane, and 0.011 mole (18.4% yield) of methane.

In all reactions involving organolithium compounds a nitrogen atmosphere and dry reagents were used.

bis-(Trimethylgold)-ethylenediamine.—A solution of 1.54 g. (0.005 mole) of dimethylgold bromide in 60 cc. of ether was cooled to −65°, and 0.0065 mole of methyllithium in 25 cc. of ether was added with stirring during fifteen minutes. The resulting clear solution was stirred for one-half hour, and then 1.5 cc. of 95% ethylenediamine was added. The milky solution was stirred for one hour at −65° before it was allowed to warm up to room temperature. No precipitate of metallic gold appeared. The ether solution was washed with 25-cc. portions of water and evaporated. The crystalline residue was dissolved in 10 cc. of ether, and then 15 cc. of petroleum ether (b. p. 28–38°) was added. On slow evaporation of the solution in a refrigerator, colorless crystals were formed and these were dried in a desiccator over phosphorus pentoxide in the dark. The yield was 1.2 g. (88%) of compound free of halogen, soluble in ether, insoluble in ethanol or petroleum ether (b. p., 28–38°), and very sensitive to light. The compound decomposed in a melting point capillary over the range 94–98°.

Anal. Calcd. for $C_4H_{13}NAu$: N, 5.14; Au, 72.40. Found: N, 5.21, 5.15 and 5.4; Au, 72.2 and 71.9.

When 0.2 g. of the complex was warmed in an open porcelain crucible preparatory to analysis, it exploded violently and pulverized the crucible. A drop of concentrated nitric acid added to the dry powder also detonates it. When moistened carefully and treated with dilute acids it precipitates gold. This indicates that the complex may be decomposed to trimethylgold and ethylenediamine and that the trimethylgold then breaks down promptly to gold and the hydrocarbons.

Trimethylgold α-Aminopyridine.—This compound was prepared from 0.005 mole of trimethylgold and 0.0075 mole of α-aminopyridine in ether at −65°. After washing the ether solution with water and then removing the ether by evaporation, the oil was dried over phosphorus pentoxide to give 1.1 g. (65.5%) of compound which gave a negative bromine test, and was partially soluble in petroleum ether (b. p. 60–68°) or benzene. From these solutions, metallic gold precipitated in a short time.

Anal. Calcd. for $C_8H_{15}N_2Au$: N, 8.32; Au, 58.62. Found: N, 8.24; Au, 58.46.

Trimethylgold Benzylamine.—This compound, prepared from 0.005 mole of trimethylgold and 0.0075 mole of benzylamine, was purified with some difficulty by crystallizing several times from petroleum ether (b. p. 28–38°) to give white needles melting at 51.5–53°. The yield was 1.0 g. (57.3%).

Anal. Calcd. for $C_{10}H_{18}NAu$: N, 4.01; Au, 56.40. Found: N, 4.30; Au, 56.75.

Attempts to stabilize trimethylgold with the following nitrogen compounds were unsuccessful: aniline, dimethylaniline, *p*-phenylenediamine, piperidine, ethylamine, dimethylamine and glyoxime.

Cleavage of bis-(Trimethylgold)-ethylenediamine with Hydrogen Chloride.—To a solution of 1.36 g. (0.005 mole) of bis-(trimethylgold)-ethylenediamine in 25 cc. of ether cooled to −65° was added, with stirring and over a twenty-minute period, 0.01 mole of hydrogen chloride in 85 cc. of ether. A white precipitate formed, and after the mixture had warmed up to room temperature it was stirred for one-half hour and then refluxed for five minutes. The evolved gas was collected and found to consist of 0.0049 mole (98% yield) of methane.

The ether solution was washed with 25 cc. of water, and the crude dimethylgold chloride remaining after evaporation of the solvent was purified by recrystallization from petroleum ether (b. p. 28–38°) to yield 1.2 g. (91.6%). The dimethylgold chloride, as well as a mixture with an authentic specimen, melted at 71–72°.

Cleavage of Trimethylgold and Triethylgold with Hydrogen Chloride.—A solution of 0.01 mole of trimethylgold, prepared from dimethylgold bromide and methyllithium in 80 cc. of ether at −65°, was treated with 0.01 mole of hydrogen chloride in 35 cc. of ether. The yield of methane was 0.0088 mole (88%); and the yield of dimethylgold bromide was 2.7 g. (88%) (melting point and also mixed m. p. with an authentic specimen was 67–68°).

A solution of trimethylgold, prepared from 8.74 g.

[13] Gilman and Schulze, THIS JOURNAL, **47**, 2002 (1925).

(0.02 mole) of gold tribromide and 0.074 mole of methyllithium in ether at −65°, was cleaved with 0.04 mole of hydrogen chloride in 50 cc. of ether. The yields of dimethylgold bromide varied from 3.07 to 3.98 g. (50–65%).

By a similar procedure, diethylgold bromide (m. p. 56.5–58°) was prepared in a yield of 57.5%.

Dineopentylgold Bromide.—A suspension of 8.74 g. (0.02 mole) of gold tribromide in 60 cc. of ether was cooled to −65° and rapidly stirred while 0.06 mole of neopentylmagnesium chloride[14] in 125 cc. of ether was added over a period of seventy-five minutes. The mixture was stirred for an additional two hours after which it gave a negative color test I.[13] Then a solution of 0.023 mole of hydrogen chloride in 35 cc. of ether was added during twenty minutes, and after two hours the mixture was allowed to warm up to −15° and then treated with 15 cc. of water. The ether solution was separated and the solvent removed under reduced pressure to leave a crystalline residue. This was extracted with 100 cc. of petroleum ether (b. p. 28–38°), the solution was washed with a little water, dried over sodium sulfate, and allowed to evaporate spontaneously in a refrigerator. The yield of product melting at 121.5–123° was 1.0 g. (11.9%).

Anal. Calcd. for $C_{10}H_{22}BrAu$: Au, 47.02. Found: Au, 46.80.

Cleavage of Trimethylgold with Thioglycolic Acid and with Thiophenol.—A solution of 0.0093 mole of methyllithium in 25 cc. of ether was added to a stirred suspension of 1.54 g. (0.005 mole) of dimethylgold bromide in 60 cc. of ether at −65°. After one-half hour, 0.84 g. (0.0093 mole) of thioglycolic acid in 20 cc. of ether was added slowly. Then, after two hours, the mixture was allowed to warm up to room temperature, poured into 20 cc. of water, and the ether removed by evaporation. The aqueous suspension was treated with 10% hydrochloric acid until precipitation was complete. Crystallization from ethanol yielded 1.5 g. (94%) of crystalline dimethylgold carboxymethylmercaptide.

Anal. Calcd. for $C_4H_9O_2SAu$: Au, 61.94. Found: Au, 62.40.

The cleavage with thiophenol was carried out under the same conditions and concentrations as with thioglycolic acid. After extraction of the product with 2 cc. of 10% potassium hydroxide in 10.0 cc. of water, the residue was dissolved in 80 cc. of warm ether and then 15 cc. of methanol was added. From the resulting solution, by spontaneous evaporation, was obtained 1.49 g. (88.5%) of pale-yellow crystals of dimethylgold thiophenate melting at 132–133° and decomposing above 138°.

Anal. Calcd. for $C_8H_{11}SAu$: Au, 58.62. Found: Au, 58.52 and 58.62.

Phenol and trichloroacetic acid did not react with trimethylgold in ether at −65°.

Trimethylgold and Benzoyl Chloride.—A solution of 0.005 mole of trimethylgold in 75 cc. of ether at −65° was stirred while 0.7 g. (0.005 mole) of benzoyl chloride in 25 cc. of ether was added over a period of ten minutes. After two hours the solution was allowed to slowly warm up to room temperature. Gold was precipitated at about −30°, and gas was evolved. The mixture was refluxed briefly and all of the evolved gas was collected. The yield of ethane was 0.0039 mole (52%), and the yield of methane was 0.0011 mole (7.3%). The ether solution was treated with 40 cc. of 10% potassium hydroxide and 20 cc. of methanol, and the mixture was shaken until the odor of benzoyl chloride disappeared. The yield of benzoic acid was 98%, and there was no qualitative test for ketone. This experiment was repeated with the same results.

Reaction of Methyllithium with Methyl Iodide in Presence of a Small Amount of Gold Tribromide.—A solution of 7.1 g. (0.05 mole) of methyl iodide in 15 cc. of ether was added to a suspension of 1.09 g. (5 mole per cent.) of gold tribromide in 15 cc. of ether. To this mixture was added 0.05 mole of methyllithium in 40 cc. of ether over a period of twenty minutes. The suspension refluxed rapidly and gas was evolved. After standing for five hours, the apparatus was swept out with nitrogen. A bluish-purple suspension, probably colloidal gold, was visible throughout the reaction. The yield of ethane was 0.029 mole (58%), and the yield of methane was 0.013 mole (13%). In a duplicate experiment, the same observations were made, and the yield of ethane was 0.026 mole (52%), and the yield of methane was 0.021 mole (21%).

In a control experiment in which the methyl iodide was omitted, there was obtained 0.0025 mole of ethane and 0.0024 mole of methane.

Thermal Decomposition of Dimethylgold Bromide.—A solution of 1.54 g. (0.005 mole) of dimethylgold bromide in 25 cc. of ether was refluxed for forty-eight hours. The solution turned reddish brown after a short time, and metallic gold separated. The gas resulting from the decomposition amounted to 0.00308 mole of ethane (61.5% based on two methyl groups from dimethylgold bromide).

The red solution was filtered and the residue washed with ether until the washings were colorless, to give 0.612 g. (62%) of gold.

From the ether was recovered 0.144 g. (9.4%) of dimethylgold bromide, by extraction of the residue with petroleum ether (b. p., 28–38°); and by extraction of the residue with chloroform (in accordance with a procedure of Brain and Gibson)[15] there was obtained 0.21 g. (11.3%) of what appeared to be methylgold dibromide on the basis of solubilities.

The residue, remaining after the chloroform extraction, was apparently the water-soluble hydrated gold tribromide, as evidenced by physical properties.

Analytical Procedures.—Nitrogen analyses were carried out by a slow and careful combustion in a micro-Dumas apparatus. It was necessary to have the long burner as hot as practicable to ensure the complete combustion of the low molecular weight hydrocarbons resulting from the sudden decomposition of the gold compounds.

For gold analyses, the weighed sample was wrapped in ashless filter paper, placed in a weighed porcelain crucible and moistened with 10% hydrochloric acid. This crucible was placed in a Gooch crucible and slowly warmed on a hot-plate until the gold compound decomposed. The paper was carefully burned off, and the residue heated for one-half hour to one hour over a Meker burner.

The halogen analyses were carried out by decomposing the compound with warm alcoholic potassium hydroxide, filtering off the metallic gold, acidifying the filtrate with nitric acid, and titrating the halogen by the Volhard method.

Summary

Trimethylgold, the first R_3Au type prepared, has been synthesized by the reaction of methyllithium with gold tribromide or dimethylgold bromide at −65°. The compound is highly unstable, and begins to decompose at about −40 to −35° into gold, methane and ethane.

Coördination compounds with amines like ethylenediamine are more stable. These, like the trimethylgold, are cleaved smoothly by hydrogen chloride and RSH compounds to give dimethylgold salts.

As might have been predicted, trimethylgold is of a low order of chemical reactivity toward some functional groups. It does, however, react with gold tribromide to give dimethylgold bromide.

Triethylgold appears to be distinctly less stable than trimethylgold.

An Apparatus for Refined Thermal Analysis Exemplified by a Study of the System *p*-Dichlorobenzene–*p*-Dibromobenzene–*p*-Chlorobromobenzene

BY A. N. CAMPBELL AND L. A. PRODAN

Introduction

The relative merits of the various types of cooling curve have been discussed by Burgess[1] and by Rosenhain.[2] Although it is easy, in systems showing solid solution formation, to locate the freezing point, *i. e.*, the liquidus, it is not easy to determine the temperature of complete solidification, *i. e.*, the corresponding point on the solidus curve. Theoretically it should be possible to do this, but in practice the change of slope is too ill-defined to admit of certainty. The present paper describes a successful attempt to overcome this difficulty. Our method consists in the application of Plato's method,[3] whereby a straight-line cooling curve is obtained, and the use of an environment of rigidly controlled temperature, together with minor refinements.

During the liquid–solid transformation of a system which forms solid solutions, the temperature does not remain constant but decreases as the solid solution deposits. The gradient remains essentially constant from the freezing point to the melting point, where a break in the cooling curve marks the disappearance of the liquid phase. The solid solution then cools rapidly from this point until the cooling rate of the furnace is re-established.

As a test of the apparatus we chose the ternary system *p*-dichlorobenzene–*p*-chlorobromobenzene–*p*-dibromobenzene, which has been investigated for freezing points only by Bruni and Gorni.[4]

These authors find that all three binary systems form a continuous series of solid solutions, the two systems containing dichlorobenzene as one component each exhibiting a minimum freezing point. Adding chlorobromobenzene to dichlorobenzene produces a depression in the freezing point of the mixture up to a concentration of 3.5%, after which the freezing point of the mixture rises continuously to the freezing point of pure chlorobromobenzene. Similarly, the system dichlorobenzene–dibromobenzene exhibits a minimum freezing point at 2.5% dibromobenzene. In all three systems the freezing curves lie below the straight line joining the freezing points of the components, but the liquidus curve for the system chlorobromobenzene–dibromobenzene approaches very closely to a straight line. Küster[5] examined the freezing curve of the system dichlorobenzene–dibromobenzene but overlooked the minimum freezing point discovered by Bruni and Gorni, who also determined the freezing surface of the ternary system. The liquidus isotherms in triangular projection are all convex toward the lowest temperature (the freezing point of pure *p*-dichlorobenzene, 52.7°), indicating that the freezing surface of the isobaric model is concave downward. Moreover, the surface lies completely below the plane passin through the freezing points of the three pure components. The freezing surface assumes a more interesting form in the dichlorobenzene corner.

The shape of their isotherms clearly characterizes the system as an example of Schreinemakers' type 1.3.3. (c), that is, there should exist a ternary freezing point, at which the compositions of liquid and solid solutions are the same, but which is neither a maximum nor a minimum temperature. Nevertheless, Bruni in the first edition of his book, "Über die feste Lösungen,"[6] states that a minimum freezing temperature exists in the ternary system. This statement is absent from a later edition of the book. Our own results show that in the ternary system, there is neither a minimum freezing temperature nor a point of identity of composition of liquid and solid solutions.

Data for the solidus curves of the binary systems and the solidus surface of the ternary system appear to be almost completely lacking. Kruyt[7] has determined the approximate position of the melting curve for the system dichlorobenzene–dibromobenzene. His results indicate a maximum freezing interval of approximately 14°, but with this our results are in serious disagreement.

Experimental

Construction of the Apparatus

The Environment.—In order to obtain regulated cooling entirely independent of external conditions, an arrangement had to be constructed whereby the loss of heat by radiation from the furnace is constant. The apparatus designed for this purpose is shown in Fig. 1.

A circular tank, 45 cm. in diameter, was constructed from #24 gage copper sheet (1). In the center of this tank a cylinder 15 cm. in diameter was soldered. The central opening was lined with asbestos paper and the annular space was filled with water, the total capacity being about 20 liters. The tank was set on a 0.5 inch thick soft asbestos sheet (10), which served as insulation while the side surface was insulated with two layers of felt cloth (3). Inlet (4) and outlet (5) pipes for the water circulation system were placed at the top and bottom, respectively, the latter pipe being provided with a stopcock for controlling the rate of flow of the water. A circular top (2) for the tank was cut from $^5/_8$ inch Transite asbestos board. A hole 4 cm. in diameter cut in the center of the cover was the only means of access to the interior of the furnace (8), which was fastened to the cover by means of three Transite blocks bolted in place, as shown in the top view of the tank. The leads were brought out to terminals (9) (Fig. 1).

The desired working range of the apparatus was from 20 to 100°; to obtain linear cooling at a reasonably rapid

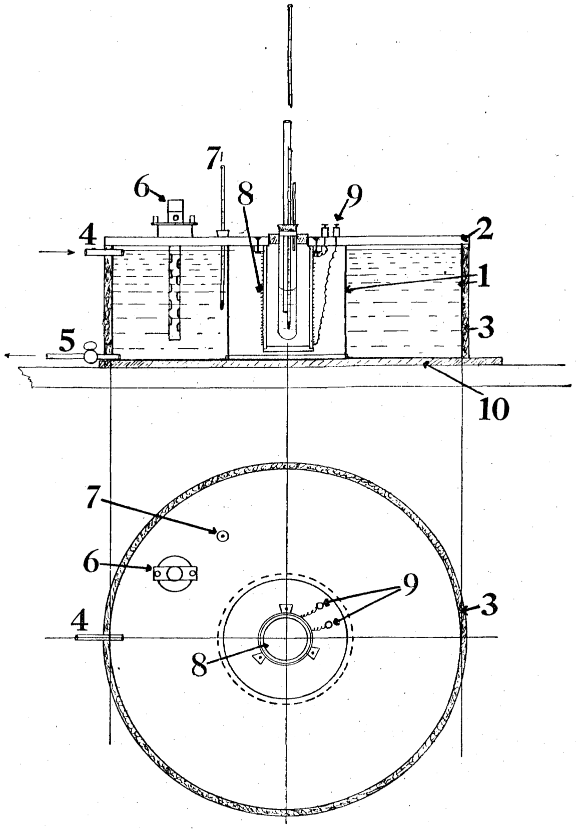

Fig. 1.—Apparatus: scale: $^1/_4''$ = 6 cm.

rate necessitated an environment temperature 10–20° below the lower working limit. An environment temperature of 10° was found by experiment to be adequate, though a lower temperature was preferable. To maintain the temperature of the environment constant a thermostated circulation system was introduced. The temperature of the environment was read on the thermometer (7). A mercury thermoregulator (6), sensitive to 0.02, mounted on the cover, served to control the temperature of the circulating system.

The Cooling Circuit.—The cooling system is shown diagrammatically in Fig. 2. Tank A represents the environment already described. Tank B, containing kerosene, was 30 inches in height and 10 inches in diameter. It was provided with a thick, tightly fitting wooden cover and was insulated with felt. The cooling coil (14) was made from $^3/_8$ inch copper tubing and was actually the freezing coil of a methyl chloride refrigerator unit. The outlet pipe (5) from the tank A directed the water through a copper coil (15), which was immersed in the kerosene, to water pump (12). The outlet pipe from the pump was connected to the inlet (4) of tank A. A rubber tube, not shown in the diagram, was connected to the inner end of the inlet pipe (4); its purpose was to conduct the violent incoming stream of water to the bottom of the tank, thereby producing a rotary circulation of the water in the annular space. This method of stirring proved to be so satisfactory that no mechanical stirrer was required in tank A.

Operation.—The temperature of the kerosene tank (B) was maintained constant at 1 ± 0.5° by means of a bimetallic thermoregulator (16) connected in series with the a. c. line and the refrigerator motor. The kerosene tank was stirred with a vigorous current of air.

The temperature of bath A was kept constant at 10 ± 0.02° by means of regulator (6). Closing of the relay circuit caused the circulating pump to operate. The temperature of bath B, which could not be lower than 0°, defined the lower operating temperature limit of bath A. Due to heat absorption in the connecting lines and pump, bath A could not be operated below 10° without placing undue strain on the pump and its motor. Insulating the connecting lines and pump with heavy felt minimized the heat absorption, but even so the pump operated almost continuously when the furnace was at 90°.

Furnace Construction.—A 14.5 cm. length of 5 cm. diameter hard glass tubing, wall thickness 2 mm., was wrapped with two thicknesses of asbestos paper soaked in sodium silicate solution. Fifty turns of #22 gage B and S nichrome wire were wound on this form. To obtain uniform heating of the melt a flat heating coil was provided

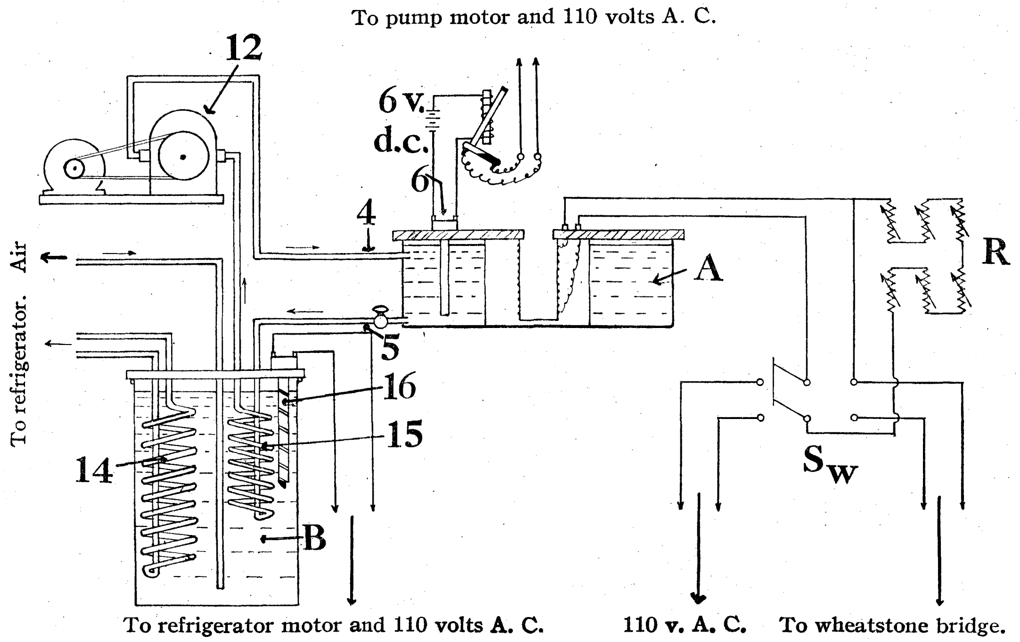

Fig. 2.—Wiring.

at the lower end of the furnace tube; it was wired in series with the main coil. The completed furnace was lined with two layers of asbestos paper and the whole fastened to the water-bath cover as shown in Fig. 1. The total resistance of the furnace was 49 ohms.

The Electrical Circuit.—The control circuit is shown in Fig. 2. Accurate temperature control was obtained by adjustment of an external resistance (R) in series with the furnace and source of current. The resistance consisted of six wire-wound rheostats in series, having a total resistance of 850 ohms and a maximum current capacity of 3 amperes. The source of current was the 110-volt a. c. line, but the fluctuations in line voltage made this a not entirely satisfactory source of power; a battery of storage cells, such as was used by Plato,[3] would have been better. A double-pole double-throw switch (Sw) was wired into the circuit in such a way that in one position the 110-volt line was connected to the furnace and resistance R in series, and in the other position the external resistance alone was connected to a Wheatstone bridge circuit.

Temperature Measurement.—All temperatures were measured on a mercury in glass thermometer, having a scale of 0–110° in 0.1°. The thermometer was calibrated against an identical type of thermometer certified by the National Bureau of Standards. By means of a reading lens temperatures were read to ±0.01°. The exposed stem correction was applied to all readings.

Calibration of the Apparatus.—A Pyrex test-tube, 2.5 cm. in diameter and 13 cm. long, formed the containing vessel for the melt. This tube was fixed in the furnace with a rubber stopper. It was fitted with a rubber stopper on which were mounted the stirrer and the thermometer.

From the results of a large number of trials using paraffin oil and the organic melts in the furnace, a cooling rate of 1.5° in five minutes was decided on. With paraffin oil as the calibrating fluid, the circuit resistance was adjusted so that the thermometer registered 95° with the stirrer running. Then, largely by trial and error, resistance was slowly inserted in the furnace circuit in steps; each increment of resistance was measured by throwing the d. p. d. t. switch to the Wheatstone bridge circuit. Readings were taken every minute to assure a constant cooling rate of 0.3° per minute. It was often necessary to remove resistance from the circuit in order to maintain the linear cooling rate, but all adjustments were recorded. When the temperature range of 95 to 20° had been covered in this manner, temperatures were plotted against resistances. The points so obtained were scattered but it was possible to draw a rough curve. A second calibration run was carried out in a similar manner using the rough calibration curve as a guide. The results of this run were plotted with the data from the first run on the same graph, the rough calibration curve being appropriately modified. A third calibration run based on the modified curve produced the final refined calibration curve. From this curve the exact resistance to be inserted in the circuit every 2.5 minutes to produce a linear cooling rate of 0.3° per minute could be read. Plotting temperature against time a straight line resulted deviating from perfect linearity by no more than 0.2°.

Stirring.—The greatest practical difficulty was encountered in the attempt to devise a flawless stirring mechanism. Mechanical stirrers are useless for this work.

Efficient stirring in a closed system was finally obtained by employing a fluctuating air pressure. The complete stirring assembly is shown diagrammatically in Fig. 3. The motor-driven reciprocating mechanism (1) was coupled to a piston (2) working in a $^{3}/_{8}$ inch bore glass cylinder (3). The piston consisted of a 0.25 inch glass rod 12 inches long, over one end of which a piece of soft rubber tubing was fastened. This piston was a very loose fit in the cylinder. A piece of rubber pressure tubing (4) connected the cylinder to a second piece of glass tubing (5) which, in turn, was joined to a long tube of smaller bore having an outlet closed by a clamp on an attached length of rubber tubing (7). When the U-tube, formed by the two parts of the apparatus, and the reciprocating mechanism were clamped to a suitable stand, the U was filled with mercury. The top end of tube (6) was connected by means of rubber tubing to the stirring tube (8), placed close to the thermometer (11) which was centered in the main container (9). The stirring tube was merely a piece of $^{3}/_{8}$ inch bore glass tubing, whose immersed orifice was slightly constricted. An outlet tube (10) consisting of a 6 inch length of $^{3}/_{16}$ inch bore glass tubing, was connected to the U-tube (12) by a short length of rubber tubing. This U-tube contained concentrated sulfuric acid, partly as a trap to keep moisture out of the apparatus, but chiefly because sulfuric acid offered less resistance than mercury to the oscillating air pressure within the closed system.

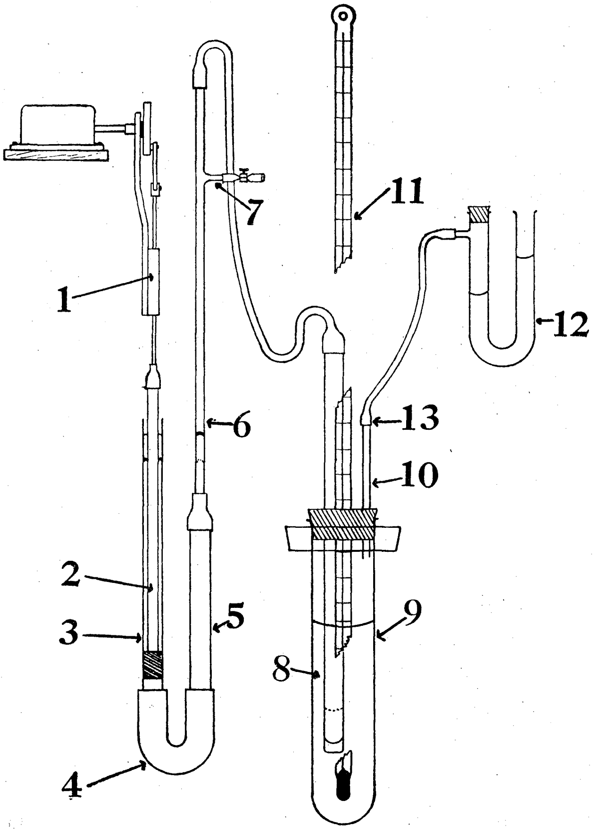

Fig. 3.

As the piston oscillated in the cylinder at a rate of approximately 4 strokes per second, the mercury in the U-tube was forced to oscillate in resonance with it. The oscillation of the mercury column in tube (6) produced a sympathetic oscillation of the air in the system which was transferred to the liquid in the stirring tube (8). The throw of the reciprocating mechanism was adjusted so that the fused melt oscillated a distance of 1.5 inches in the stirring tube. The position of the liquid level in tube (8) could be adjusted quickly by altering the air pressure within the system through tube (7). This apparatus, when properly adjusted, produced a vigorous and efficient agitation of the melt and depositing crystals. The position of the orifice of the stirring tube was critical. For best results it was immersed two-thirds of the total depth of the melt. In contrast with the abrupt cessation of the mechanical stirrers and the attendant break in the cooling curve, the stirring action stopped gradually; the cooling curves showed no evidence of a break when the stirring ceased completely. Employment of the closed system was also advantageous since losses by evaporation were minimized; loss through the stirring tube was very slight.

Performance of the Apparatus.—In order to show the accuracy with which the temperature of complete solidification (solidus line) can be obtained, Fig. 4 is a plot of the cooling data of a binary mixture containing 30.03 mole per cent. dibromobenzene and 69.97 mole per cent. dichlorobenzene. This mixture showed one of the largest cooling intervals. When the results are plotted, as was always done, on millimeter paper so that 1 mm. equals 0.04° of temperature or two minutes of time, the freezing and melting points are clearly defined as 59.49° and 55.20°, respectively. All curves were repeated on the same mixture, and mixtures of approximately the same composition were frequently made up for double checking.

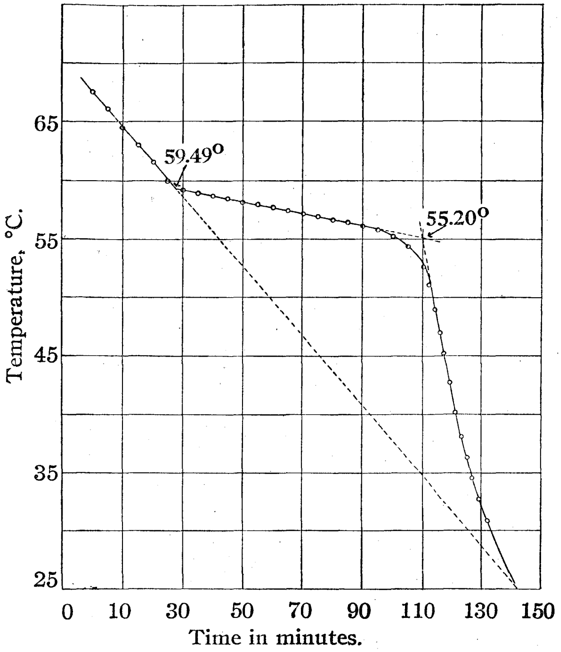

Fig. 4.—A typical cooling curve: freezing point, 59.49°; melting point, 55.20°; internal 4.29°.

Purification of Materials.—Each of the materials, *viz.*, *p*-dichlorobenzene, *p*-dibromobenzene, and *p*-chlorobromobenzene, was steam distilled once from dilute sulfuric acid, once from dilute sodium hydroxide and finally distilled using a short column. The dichlorobenzene thus obtained melted at 52.5°, but a cooling curve showed a freezing interval of 0.8°, indicating impurity. The ortho-isomer (b. p. 179°) was separated from the desired para-isomer (b. p. 173°) by crystallization from ethyl alcohol. After six crystallizations, the material froze at 53.08° with no detectable freezing interval.

The dibromobenzene was treated in a similar manner. Distillation as a means of purification was useless since the *meta*-isomer boils at exactly the same temperature as the *para*-isomer, *viz.*, 219°. Six crystallizations from ethyl alcohol yielded a product freezing at 87.30°.

Distillation is again useless as a method of separating *p*-chlorobromobenzene from its isomers, but purification by crystallization from ethyl alcohol was again effective. Eight crystallizations were necessary to obtain a product which froze at 64.58° with a freezing interval of 0.07°.

All these substances were stored over concentrated sulfuric acid for two months before use.

Results

Freezing Points of the Pure Components.—The freezing point of *p*-dichlorobenzene is variously reported as 52.7° (Bruni)[8]; 52.7° (Küster, *loc. cit.*); 52.8° (Nagornow[9]); 52.9° (Narbutt[10]); 53.1° (Speranski[11]); 53.0° (Kruyt, *loc. cit.*); 53.13° ± 0.02 (Cooper[12]). Our value is 53.08 ± 0.02°.

The freezing point of *p*-chlorobromobenzene is given as 67° by Auwers[13] and by Bruni,[8] as 64.7° by Speranski[11] and as 64.6° by Narbutt.[10] Our freezing point of 64.58° agrees with that of Narbutt.

The dibromobenzene used by Bruni[8] froze at 85.9°. Küster[5] and Narbutt[10] report 86.4° and 86.9°, respectively, while reports by Kruyt[7] and Narbutt[10] give 87.2° and 87.1°, respectively. The value obtained from our cooling curves is 87.30 ± 0.02°, a higher value than any previously reported. There was no crystallization interval, so our preparation was undoubtedly pure.

Transition Temperature of *p*-Dichlorobenzene.—When examining the cooling curves of *p*-dichlorobenzene closely, a break in the line of cooling was discovered. In four experiments, the break resulted at 39.8, 39.7, 39.6 and 39.4°, respectively. The change in slope at 39° was not abrupt and it was thought at first that the effect was due to an error in the calibration of the apparatus. A search of the literature revealed, however, that a transition point had been reported by Beck and Ebbinghaus[14] at 39.5°. Conflicting data have been reported by Wallerant,[15] who concluded from the results of microscopic studies that *p*-dichlorobenzene is trimorphic, the reversible transitions occurring at 29 and 25°. That *p*-dichlorobenzene does exist in at least two forms under atmospheric pressure appears to be an

undisputed fact. From the results of thermal analysis we conclude that a transformation in the solid state occurs at 39.6°.

The Binary System p-Dibromobenzene–p-Chlorobromobenzene.—The complete data for the system dibromobenzene–chlorobromobenzene are given in Table I.

The equilibrium diagram for this system is given in Fig. 5. The liquidus curve appears to be almost a straight line but it is actually S-shaped, the high temperature portion lying above and the low temperature portion below, the straight line joining the freezing points of the pure components. The system is an example of Roozeboom's Type I.

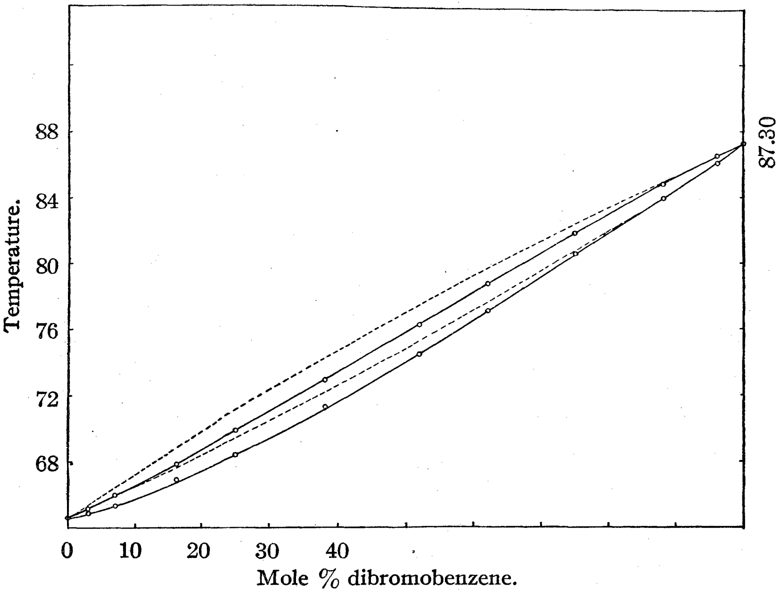

Fig. 5.—The binary system: p-dibromobenzene–p-chlorobromobenzene: —O—, exptl.; - - - - calculated.

Perhaps the most reliable equations for the calculation of solidus and liquidus curves are those of Seltz,[16] in the derivation of which he uses the concepts of activity and fugacity introduced by G. N. Lewis for ideal liquid solutions.

Using these equations and the following heats of fusion, the liquidus and solidus curves were calculated. Heats of fusion[17]: p-$C_6H_4Cl_2$ = 29.50 ± 0.11 cal. per gram = 4340 cal./mole; p-C_6H_4ClBr = 23.42 ± 0.09 cal./gram = 4484 cal./mole; p-$C_6H_4Br_2$ = 20.80 cal./gram = 4908 cal./mole. The solidus and liquidus curves thus calculated are expressed as dotted lines in Fig. 5.

The Binary System p-Dichlorobenzene–p-Dibromobenzene.—The system p-dichlorobenzene–p-dibromobenzene falls under Type III of Roozeboom. Data relevant to this system are given in Table II and the results are expressed graphically in Fig. 6. A distinct minimum freezing temperature of 52.90° was detected at a concentration of 1.22 mole per cent. dibromobenzene. As this minimum freezing mixture contained so little dibromobenzene particular care was exercised in establishing the positions of liquidus and solidus curves in this region. In Fig. 6 the region of the minimum is presented in a separate diagram, greatly enlarged.

The experimentally determined liquidus and solidus curves are both straight lines over a restricted concentration range of approximately 40 to 80% dibromobenzene. As in the system chlorobromobenzene–dibromobenzene, the liquidus curve of this system is S-shaped. At no point does the liquidus curve lie above the straight line joining the freezing points of the pure components.

The Binary System p-Dichlorobenzene–p-Chlorobromobenzene.—Examination of the data in Table III and the plot of these data in Fig. 7 shows that the experimental curves for both liquidus and solids lie far below the straight line joining the freezing points of the pure com-

ponents, and that the experimental curves lie considerably below the calculated curves which straddle the straight line. Calculated and experimental curves agree only in so far as the freezing intervals are approximately the same. As with the system dichlorobenzene–dibromobenzene this binary system possesses a minimum freezing point, lying at 52.96° and 2.57 mole per cent. chlorobromobenzene.

The Ternary System *p*-Dichlorobenzene–*p*-Chlorobromobenzene–*p*-Dibromobenzene.—Table IV contains all data relevant to the freezing and melting points of the ternary mixtures examined. The data have been classified into five sections, corresponding to five quasi-binary[18] systems investigated.

Construction of some of the isotherms of the ternary system by graphical interpolation from the quasi-binary sections gave the diagram of Fig. 8. The isotherms shown are those lying on the solidus surface at the temperatures indicated.

A very similar diagram for the liquidus isotherms was obtained. In the body of the diagram the isotherms were substantially straight lines. This can be seen from Fig. 9, which illustrates the relations between the solidus and liquidus isotherms. Each liquidus isotherm (full curve) with its corresponding solidus isotherm (broken line) constitutes the boundary of a heterogeneous liquid–solid region. Tie-lines have been inserted qualitatively to illustrate the direction of crystallization and composition changes in the ternary system. The exact directions of the tie-lines are not known. They could be determined only by analysis of the first portion of solid phase separating from a liquid solution of known composition.

The liquidus and solidus isotherms in the dichlorobenzene corner are represented on a larger scale in Figs. 10, 11 and 12. The position and the shape of the isotherms preclude any possibility of the existence of a ternary minimum freezing point as was suggested by Bruni.[19] Plotting selected liquidus and corresponding solidus isotherms, the unusual diagram of Fig. 12 was obtained. Tie-lines have been inserted in order that the heterogeneous bands may be easily distinguished. More bands than the three shown were not plotted because of the complexity introduced by overlapping of the very wide bands in this region.

It is apparent that at no point do solidus and liquidus curves coincide and this is convincing evidence that there is no minimum of temperature in the ternary system. Evidence resting purely on temperature measurement might be open to doubt since the extreme temperature range in this region is not more than 0.1°, although we believe that the sensitivity of our apparatus is such that a minimum of temperature would have been detected directly had it existed.

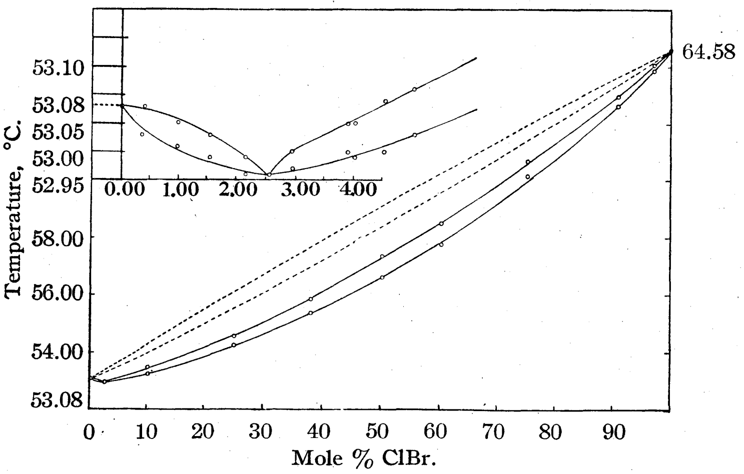

Fig. 7.—The binary system: *p*-dichlorobenzene–*p*-chlorobromobenzene; —O—, experimental; - - - - calculated.

Discussion

The great delicacy of the technique described

---

(18) *Cf.* Marsh, ref. 16, p. 151, for the use of this expression.

(19) G. Bruni, "Über die feste Lösungen," 1901, p. 27.

is proved by the fact that the temperatures of complete solidification and hence the form and direction of the solidus line are clearly discernible on the cooling curves.

The experimental results indicate a temperature of reversible transition for *p*-dichlorobenzene of 39.6°. Cooling curves of those binary mixtures which contained this substance as one of the components were examined for a break. In mixtures containing from 95 to 100% *p*-dichlorobenzene a change in slope of the cooling curve was detected. The effect of the addition of *p*-dibromobenzene or *p*-chlorobromobenzene to the pure *p*-dichlorobenzene was to depress the transition temperature of the latter. Beck and Ebbinghaus[14] have determined the transition curve for the system *p*-dichlorobenzene–*p*-dibromobenzene and find it to be a straight line running from 39.5°, the transition temperature of pure *p*-dichlorobenzene, to −8°, the transition temperature of pure *p*-dibromobenzene. Our apparatus was unable to detect the transformation of *p*-dibromobenzene and, since the break in the cooling curve of pure dichlorobenzene was barely detectable, it is not

surprising that it disappeared completely in mixtures containing more than 5% of either of the other two components.

In view of the great similarity in molecular and crystallographic structure it is not surprising that these dihalogen benzenes should be miscible in all proportions in both liquid and solid states. All three binary systems, however, exhibit a decided tendency toward positive deviation from Raoult's law; at some lower temperature a miscibility gap may come into being.

The p-dichlorobenzene molecule, which is the lightest of the three, is perfectly symmetrical and has no dipole moment. Apparently this molecule possesses properties not associated with the asymmetrical chlorobromobenzene molecule or even with the symmetrical dibromobenzene molecule. Addition of a higher melting foreign material of similar structure such as p-chlorobromobenzene or p-dibromobenzene produces a depression in the freezing point of the pure dichlorobenzene. The heavier, higher melting dibromobenzene produces the greater and more rapid depression. More of the lighter chlorobromobenzene molecule, relative to the quantity of dibromobenzene, is required to produce a given freezing point depression.

Summary

An apparatus is described by means of which it is possible, by means of thermal analysis, to determine not merely the liquidus but also the solidus curve, and therefore the extent of solid solution.

As a test of technique, the system p-dichlorobenzene—p-dibromobenzene – p - chlorobromoben-

zene has been investigated. The results of this investigation are as follows:

The freezing points of pure *p*-dichlorobenzene, *p*-chlorobromobenzene and *p*-dibromobenzene were redetermined as 53.08, 64.58 and 87.30°, respectively. It was confirmed that pure *p*-dichlorobenzene exists in at least two forms under atmospheric pressure, the reversible transformation occurring at 39.6°.

p-Dibromobenzene and *p*-chlorobromobenzene are miscible in all proportions in both liquid and solid states; the freezing points of all solutions lie between the freezing points of the pure components. The binary system *p*-dichlorobenzene–*p*-dibromobenzene exhibits a minimum freezing temperature of 52.90° at a concentration of 1.22 mole per cent. dibromobenzene. The components are miscible in all proportions in both liquid and solid states. The binary system *p*-dichlorobenzene–*p*-chlorobromobenzene exhibits a minimum freezing temperature of 52.96° at a concentration of 2.57 mole per cent. chlorobromobenzene. The components are miscible in all proportions in both liquid and solid states.

The ternary system *p*-dichlorobenzene–*p*-chlorobromobenzene–*p*-dibromobenzene exhibits miscibility in all proportions in both liquid and solid states. No ternary solution of minimum freezing point exists; neither is there any temperature at which the compositions of liquid and solid solutions coincide.

Potentiometric Determination of Oxygen Using the Dropping Mercury Electrode[1]

BY H. A. LAITINEN,[1a] T. HIGUCHI[1b] AND MICHAEL CZUHA[1b]

A dropping mercury electrode in a solution free of capillary-active substances or electro-reducible or oxidizable substances assumes a potential corresponding to the electrocapillary zero potential of mercury. Under these conditions, the electrokinetic potential of mercury, with respect to the solution, is zero. To maintain the dropping electrode at any other potential, it is necessary to supply electrons or to remove electrons from the reservoir of mercury connected to the capillary from which the mercury is dropping. Thus, it is necessary to maintain a continuous flow of electrons to charge electrically the double layer existing between the mercury and the solution because the double layer is continually being formed. The polarographic charging or condenser current is a familiar manifestation of this phenomenon. The charging current as shown in Fig. 1 is negative in sign (corresponding to an anodic process at the dropping electrode) at potentials more positive than the electrocapillary maximum, at which point the charging current changes sign and increases in positive value as the potential is made more negative.

Any substance, such as oxygen, which is reducible on the positive side of the electrocapillary maximum, will yield a polarographic diffusion current which is positive in sign and hence opposed in direction to the charging current. For very small concentrations of oxygen, it is evident that at some value of the potential the diffusion and charging currents will be equal in magnitude but opposite in direction and hence will cancel. Since the instantaneous value of the diffusion current varies with the one-sixth power of the time and is independent of the potential while the charging current at a constant potential varies with the two-thirds power of the time,[2] it is evident that the null potential must vary with time in such a way that the instantaneous current will be zero at all times.

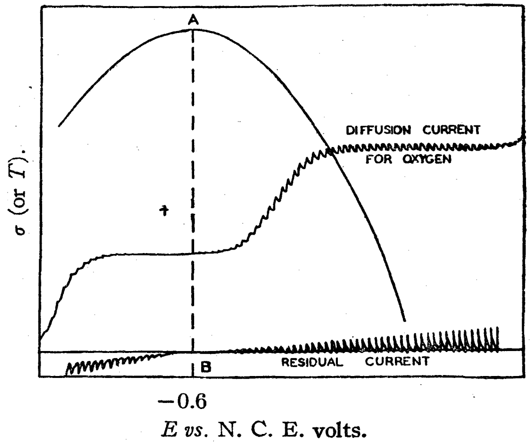

Fig. 1.—Electrocapillary curve.

To calculate the magnitude of the effect, it is convenient to equate the total charge, $(q_c)_t$, held by the drop at any time, t, with the number of coulombs, $(q_d)_t$, lost by the drop through the electro-reduction of oxygen molecules from the beginning of the drop formation to time, t, or

$$(q_c)_t = (q_d)_t \qquad (1)$$

---

[1] This investigation was sponsored by the Office of Rubber Reserve, Reconstruction Finance Corporation, in connection with the government synthetic rubber program.

[1a] Noyes Chemical Laboratory, University of Illinois.

[1b] University of Akron, Government Laboratories.

[2] I. M. Kolthoff and J. J. Lingane, "Polarography," Interscience Publishers, Inc., New York, N. Y., 1941.

The charge held by the drop at any time, t, is given by

$$(q_c)_t = A_t k(E - E_{\text{max.}})_t \qquad (2)$$

where A_t is the area of the drop at time, t, k is the capacity of the double layer per unit area (microfarads per square centimeter), $E_{\text{max.}}$ is the potential corresponding to the electrocapillary maximum and E is the potential of the dropping mercury electrode in volts. From geometric considerations

$$A_t = 4\pi^{1/3}(3/4d)^{2/3}m^{2/3}t^{2/3} \qquad (3)$$

if the spherical drops grow at a uniform rate of m/d cubic centimeter per second where m is the mass of mercury flowing per second and d is the density of mercury. Substituting (3) in (2)

$$(q_c)_t = 4\pi^{1/3}(3/4d)^{2/3}k(E - E_{\text{max.}})_t t^{2/3}m^{2/3} \qquad (4)$$

The charge lost because of reaction of oxygen at the drop surface can be obtained by integrating the Ilkovic equation[3] (where i_t is the diffusion current at time, t)

$$\begin{aligned}(q_d)_t &= {}^{t}i_t\mathrm{d}t = {}^{t}4(7/3)^{1/2}(3/4d)^{2/3}\pi^{-1/6}\, nFD^{1/2}Cm^{2/3}t^{1/6}dt \\ &= 6/7\ 4(7/3)^{1/2}(3/4d)^{2/3}\pi^{-1/6}nFD^{1/2}\, Cm^{2/3}t^{7/6} \qquad (5)\end{aligned}$$

Substituting (4) and (5) into (1) and solving for $(E - E_{\text{max.}})_t$

$$(E - E_{\text{max.}})_t = \frac{6}{\sqrt{21\pi}}\,\frac{nFCD^{1/2}t^{1/2}}{k} = 7.128 \times 10^4\,\frac{nCD^{1/2}t^{1/2}}{k} \qquad (6)$$

where nF is the number of coulombs of electricity involved per mole, D is the diffusion coefficient in square centimeters per second and C is the concentration of reducible substance in millimoles per liter.

To evaluate the final expression for the specific case of oxygen, $n = 2$, $D = 2.6 \times 10^{-5}$, from the polarographic measurements of Kolthoff and Miller[4] and $k = 42.2$ microfarads per square centimeter (0.1 N KCl), the value of Ilkovic.[5]

Since the latter value was determined by Ilkovic from the slope of the polarographic residual current curve, 42.2 was used rather than the value of 48.8 microfarads per square centimeter reported by Philpot.[6] The final expression (6) becomes

$$E - E_{\text{max.}} = 17.2Ct^{1/2} \qquad (7)$$

where the potential shift is measured in volts, the concentration in millimoles per liter and the drop time in seconds.

According to equation (7), the potential difference is zero at the beginning of the drop formation and increases as the square root of the time until the drop breaks. This variation is brought about by the fact that the instantaneous diffusion current is independent of the potential, while the charging current is proportional to the potential difference $(E - E_{\text{max.}})$. Thus, for the observed current to be zero at every instant, the potential difference must fluctuate with time. The voltage fluctuation should be directly proportional to the oxygen content of the electrolyte, but independent of the rate of flow of mercury (m).

If a high capacity condenser is inserted into the circuit to lower the voltage fluctuation to a negligible value, the observed potential will correspond to the maximum potential difference of the undamped system just before the drop breaks. This relationship can readily be derived by equating the total number of coulombs of electricity due to the diffusion current during the life-time of the drop with that due to the charging current at a constant potential. Since the charging current at any instant is determined by the diffusion current, the magnitude of the former is unaffected by the presence or absence of damping condensers. At the time of the drop break, the final charge (equation 2) and therefore the final potential difference is the same in the damped and undamped systems.

Equation (7) relates the potential of the system with the concentration of oxygen actually dissolved in the electrolyte. To determine the actual oxygen content of any non-reducible gas it is necessary only to bring the electrolyte into equilibrium with the gas before measuring the potential.

In such case, equation (7) would take the form

$$\text{Percentage oxygen in gas} = \frac{(E - E_{\text{max.}})}{\dfrac{10\alpha}{22.4}\,17.2t^{1/2}} \qquad (8)$$

where α is the absorption coefficient of oxygen in the electrolyte expressed in cubic centimeters per liter and the total gas pressure is one atmosphere.

At 25°, $\alpha = 28.3$[6a] and the equation reduces to

$$\text{Percentage oxygen} = \frac{(E - E_{\text{max.}})}{217t^{1/2}} \qquad (9)$$

where $(E - E_{\text{max.}})$ is expressed in millivolts.

The object of the present investigation was to determine the effects of the factors "C" and "t" in equation (6) and to determine whether the potential is independent of the rate of flow of mercury.

Apparatus

Design of Cell for Continuous Measurements.—A cell suitable for the present investigation had to fulfill the following requirements: (1) Arrangements had to be made to bring the electrolyte rapidly in equilibrium, with respect to its oxygen content, with the sample gas. (2) The dropping electrode had to be shielded from any turbulence caused by flow of gas through the solution. (3) The reference electrode had to have constant reversible potential and possess relatively low resistance. It had to be placed so that the re-

[6a] The value of 28.3 holds only for pure water. When an appreciable amount of electrolyte is present the value is, of course, lower.

ducible products, if any, of the electrode could not affect the dropping electrode. (4) The mercury from the dropping electrode had to be removed in a manner to minimize contact with the electrolyte. Any mercurous chloride formed through interaction of the mercury with the electrolyte might affect the dropping electrode potential. (5) To permit continuous operation, it was advisable to construct the cell in such a manner as to permit cautious partial replacement of the electrolyte. This prevented accumulation of contaminants over a long period of time.

A schematic diagram of the apparatus which was employed in this study is shown in Fig. 2. The apparatus was designed to meet the conditions previously set forth.

Operation of the Unit.—The electrolyte in a 1-liter stoppered flask (Reservoir A) in Fig. 2 was maintained at constant head in the scrubbing vessel B. The solution was allowed to flow at a predetermined rate of 1.1 ml. per minute through capillary tube C into the dropping mercury electrode cell D, past the silver–silver chloride reference electrode E, to the outlet F.

The gas sample was first saturated with water vapor from the electrolyte solution in vessel G and then part of the gas stream was forced through the fritted glass disc H into the scrubbing vessel B where the electrolyte received a preliminary scrubbing with the gas sample. The final solubility equilibrium between the oxygen in the sample and the electrolyte solution was obtained by passing another portion of the gas stream through the fritted disc I into the dropping mercury electrode cell. The gas was allowed to escape through two spray trap bulbs, J and K, on either side of the cell.

Mercury from reservoir L was forced through the dropping mercury electrode capillary M. The funnel-shaped shield, surrounding the tip of the capillary, served to protect the slowly forming mercury drops from agitation of the rising gas bubbles, and also to direct the mercury drops into the siphon, thus removing them from the cell.

An important feature of the design of the equipment was the continuous removal of any reducible materials such as mercurous chloride and silver chloride which would form at the electrodes in small concentrations in a stationary system. The flow of electrolyte was in such a direction as to prevent the accumulation of calomel around the dropping electrode. For the same reason, the reference electrode was situated in the outflowing stream of electrolyte.

Operational Characteristics of Cell Assembly.—To determine the rate of approach to solubility equilibrium, the rate of change of the potential difference was determined using purified nitrogen as the gas sample. Starting with an air-saturated 0.1 *N* potassium chloride solution throughout the reservoirs and the cell, a thousand-fold decrease in oxygen concentration was observed in one minute.

To check the possible interference from back-diffusion of oxygen, the nitrogen stream was shut off after reaching a constant potential reading. No noticeable change in potential (less than 1 millivolt) was observed after 5 minutes of standing.

Potential Measurements.—A Beckman Research Model G *p*H meter, operated as a millivoltmeter, was used for the measurement of the cell e. m. f. This instrument was found to be particularly suitable because of its sensitivity and rapid response. In an undamped system, the meter was permitted to remain continuously in the circuit, and the maximum e. m. f. developed during the formation of each drop was determined by balancing the slide wire so that the galvanometer showed zero deflection at the end of the drop formation.

To determine whether the e. m. f. in a damped system corresponds to the maximum e. m. f., a condenser of 16 m. f. d. capacitance was connected across the dropping electrode system. The observed non-fluctuating e. m. f. was found to be identical (within 2 millivolts) with the maximum e. m. f. observed in the undamped system, as was expected from the theoretical considerations. Since it was found that a time lag of two to three minutes was introduced by the necessity of charging the condenser, it proved to be more convenient to measure the maximum e. m. f. in the undamped system. However, a damped system would probably be more practicable in a continuously recording apparatus.

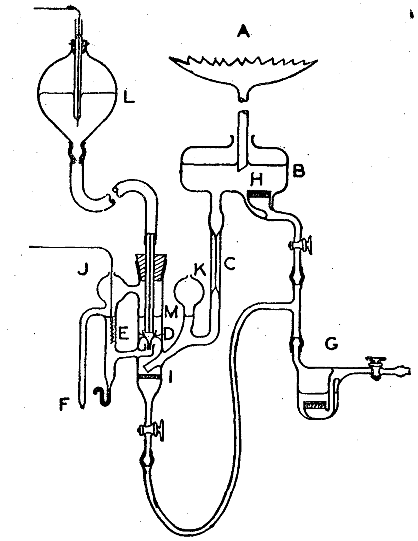

Fig. 2.

Results and Discussions

Variation of Potential with Concentration.—A series of oxygen–nitrogen mixtures of known composition was obtained from General Electric Wire Works, Cleveland, Ohio. The oxygen contents of the samples were 0.200, 0.554 and 1.028%. The mixture with lowest oxygen content was prepared by accurately mixing pure oxygen and nitrogen, while the other mixtures were prepared by mixing and analysis by a combustion method. The oxygen content for each mixture was guaranteed to be accurate to within 0.01 per cent. (absolute).

Air-free nitrogen was prepared by the conventional method of passage over copper turnings heated to 400°. The purity was indicated by the fact that the maximum potential difference developed during the formation of the mercury drops was less than 2 millivolts (corresponding to less than 0.005% of oxygen). The e. m. f. observed with the purified nitrogen against the particular silver–silver chloride electrode in 0.1 *N* KCl was 500 millivolts, as compared with the theoretical value of 558 millivolts calculated from the potential of the electrocapillary maximum (550 millivolts in 0.1 *N* KCl against normal calomel electrode). The disagreement would correspond to 0.1% of oxygen, and a fluctuation of 58 millivolts would then be expected during the drop formation. The discrepancy may be partly attributed to a lack of equilibrium at the silver–silver chloride electrode, but should be further investigated. For all practical purposes, the value of 500 millivolts can be used as the potential corresponding to the electrocapillary maximum because the error could not exceed 0.005% of oxygen.

The observed ΔE values, using 1 N potassium chloride as the electrolyte, are plotted against the oxygen concentration in Fig. 3 (A). The curve is linear for oxygen concentrations from 0 to 0.5% but shows a slight curvature at 1.0%.

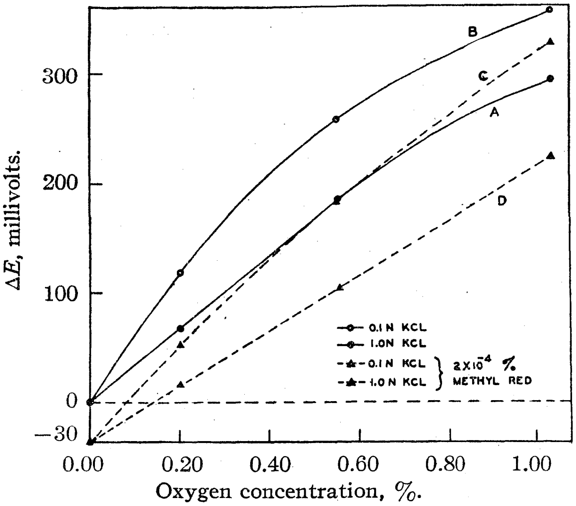

Fig. 3.—Potential shift *vs.* O_2 concentration.

A similar plot, Fig. 3 (B), with 0.1 N potassium chloride as the electrolyte, shows a more pronounced curvature and a greater sensitivity for a given percentage of oxygen. The change in sensitivity can be attributed to the increase in oxygen solubility and to the decrease in capacity of the double layer as the potassium chloride concentration is decreased.

A strict proportionality between ($E - E_{\text{max.}}$) and concentration could not be expected to hold for an ($E - E_{\text{max.}}$) value greater than about 300 millivolts since the diffusion current of oxygen is not reached until a potential of about minus 200 millivolts (with reference to silver–silver chloride). Other factors which could affect the linear relationship are a lack of constancy of the capacity of the double layer at varying potentials, especially in dilute salt solutions, and a maximum on the oxygen-reduction curve induced by effects of electrical stirring.[7] Such a maximum can be suppressed by the addition of capillary-active substances, which compress the electrical double layer at the mercury–solution interface, and therefore would also increase the capacity of the double layer. Thus, the sensitivity would be decreased by the addition of maximum suppressing agents.

These effects were studied by the addition of 2×10^{-4}% of methyl red as a maximum suppressor. The range of linearity was increased and the sensitivity was decreased both in 0.1 N and 1 N potassium chloride, as is shown in Fig. 3 (C and D, respectively). Methyl red undergoes reduction at the dropping mercury electrode at a potential slightly more positive than the electrocapillary maximum. Therefore, the curves can be extrapolated to a false oxygen content at zero potential, because methyl red behaves like oxygen in producing a cathodic current.

Further work is in progress to find a suitable non-reducible oxygen suppressor for practical analytical work.

The data represented in Fig. 3 were obtained at a drop time of approximately 3.7 seconds, except for curve C which was obtained at 2.8 seconds per drop.

Variations of Potential with Flow Rate of Mercury.—According to equation (7), the observed potential difference should be independent of the rate of flow of mercury through the capillary. This would indicate that the experimental readings would be independent of the capillary characteristics, and dependent only on the drop time. Experimental verification of this lack of dependency would be of considerable practical importance for routine analytical purposes.

In Fig. 4, the observed potential values at two known oxygen concentrations are plotted against the rate of flow of mercury for several capillaries chosen to cover a wide range of values of "m." The measurements were made at a constant drop rate to eliminate this variable. It is evident from the curve that the observed potential is for all practical purposes independent of "m" over a twofold change in the flow rate. The slight variation is probably due to a deviation from the Ilkovic equation because of the large drops associated with large "m" values.

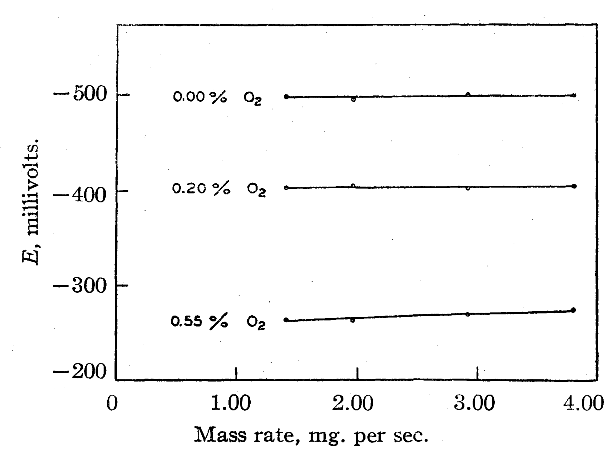

Fig. 4.—Effect of mass rate on observed potential: electrolyte, 0.1 N KCl; drop time, 4.0 sec.

Variation of Potential with Drop Time.—Since the instantaneous potential of the dropping

[7] J. Rasch, *Collection Czechoslovak Chem. Commun.*, **1**, 560 (1929); E. Varasove, *ibid.*, **2**, 8 (1930); B. Rayman, *ibid.*, **3**, 314 (1931); E. Hamamoto, *ibid.*, **5**, 427 (1933).

mercury electrode should vary linearly with the square root of time (equation 8) and is independent of "m," the maximum e. m. f. for a constant oxygen concentration should give a straight line when plotted against the square root of drop time, either for various capillaries or for a given capillary operated at various heights of a mercury column.

In Figure 5, ΔE is plotted as a function of $t^{1/2}$ for a single capillary (m = 2.27 milligrams per second; t = 3.52 seconds at 55 centimeters of mercury pressure) operated at various heights of a mercury column. The three standard oxygen mixtures were studied in 0.1 N potassium chloride in the presence and absence of methyl red. In the absence of methyl red, a distinct curvature was noted at short drop times, under which conditions the oxygen maximum is known to be most pronounced.[8] In the presence of methyl red, a linear relationship was observed over a range of drop time from 2 to 6 seconds, except in cases where the e. m. f. exceeded 300 millivolts, above which the true diffusion current of oxygen is not reached and linearity would no longer be expected.

In practice, it is recommended that a drop time of 3 to 5 seconds be used.

Application to Gases.—The new method should be applicable to a wide variety of gases, such as nitrogen, hydrogen or hydrocarbon gas mixtures, since such gases are in general inert at the dropping mercury electrode at the range of potentials involved. The only serious interferences which can be foreseen would be caused by strong oxidizing agents, such as halogen vapors which are readily reducible at the dropping electrode, and by materials which anodically depolarize the dropping electrode by the formation of insoluble mercury salts or stable mercury complexes. Examples of the latter class of interfering materials are hydrogen sulfide and hydrocyanic acid.

Substances that are readily adsorbed on the mercury surface would be expected to change the sensitivity of the method. For example, naphthalene and mercaptan vapors would be expected to show such adsorption effects. It would seem likely that the addition of maximum suppressing agents which themselves are strongly adsorbed would minimize the interference of adsorbable impurities in the sample. Capillary-active ions such as iodide would shift the electro-capillary maximum in addition to changing the capacity of the double layer.

Application to Water or Aqueous Solutions.—In principle, the method could be applied in the absence of oxygen to the determination of traces of strong oxidizing agents in aqueous solutions.

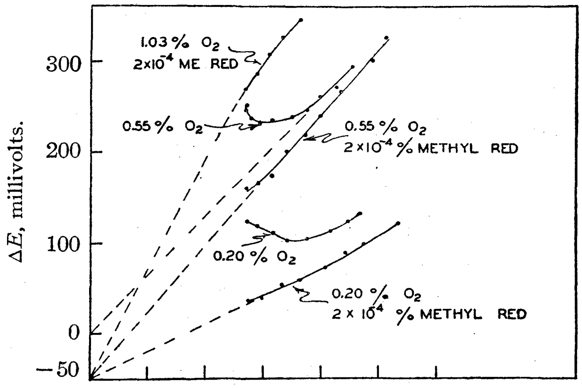

Fig. 5.

In addition to the interferences mentioned for gaseous substances, interference would be caused by many strong oxidizing agents in solution in water. Examples are ferric iron, permanganate and mercurous or mercuric salts, all of which are reducible at potentials more positive than the electrocapillary maximum and which would show the same effect as oxygen.

The change in the capacity of the double layer with changing electrolyte concentration and by adsorbable materials such as soaps or proteins would be a more serious problem in the analysis of solutions, especially in the case of essentially electrolyte-free water.

Conclusions

1. A simple, rapid and sensitive potentiometric method for the determination of traces of oxygen in gases or in solution, based upon measurement of the null potential of a dropping mercury electrode, has been developed.

2. The maximum potential difference developed during the growth of the mercury drops varied linearly with oxygen concentration over a potential range of zero to 300 millivolts, in the presence of maximum-suppressing agents. The potential varied as the square root of the drop time and was independent of the rate of flow of mercury through the capillary at a constant drop time.

3. Using 0.1 N potassium chloride, with a trace of methyl red as a maximum suppressor, the method was sensitive to 0.01 per cent. of oxygen in a gas; linear relationship was attained over the range of zero to 1 per cent. of oxygen.

4. The sensitivity of the method varied with changes in the capacity of the electrical double layer at the mercury solution interface caused by changes in electrolyte concentration or by traces of capillary-active materials.

The Thermodynamics of Hexafluoroethane from Calorimetric and Spectroscopic Data

BY E. L. PACE[1] AND J. G. ASTON

The existence of barriers hindering the mutual internal rotation of methyl groups in a wide variety of compounds has been demonstrated from thermal, spectroscopic and other sources. An empirical method of calculation has been proposed, based on the assumption that the value of the potential barrier hindering the rotation of the groups depends exclusively on repulsive forces between hydrogen atoms.[2] The discovery of barriers in 1,1,1-trifluoroethane[3] and 1,1,1-trichloroethane[4] of the order of 3000 calories per mole raises the question of whether the restricted rotation is uniquely a function of the repulsion of hydrogen atoms. It was the purpose of the present work with hexafluoroethane, the fluorine analog of ethane, to furnish more information to help answer this question.

The Calorimetric Sample.—The calorimetric sample was prepared and purified at the Fluorine Laboratory of The Pennsylvania State College under the direction of Dr. J. H. Simons.

The sample was freed of air and introduced into the calorimeter in the customary manner. The heat capacity, the heat of transition and the heat of fusion were determined with this sample. The remaining measurements were made with the portion of the original sample remaining after the first 1.5 cc. of product withdrawn from the low-temperature column had been discarded. This fractionation was found necessary when a preliminary set of vapor pressures indicated the presence of a small amount of highly volatile impurity. The operation removed about 75% of the volatile impurity and made it possible to obtain a satisfactory set of vapor pressures.

The Heat Capacity Measurements.—The apparatus and method used in the determination of the heat capacities has been previously described.[5a,b] The temperature indications of thermocouple S-7 were used as a standard with thermocouple S-4 as a check. Correction was made for the change in the calibration of these thermocouples based on a recent comparison with oxygen and normal hydrogen vapor pressures. At the oxygen boiling point the indication of thermocouple S-7 was 0.02° and thermocouple S-4 was 0.04° lower than the last comparison. At the hydrogen triple and boiling point S-7 was 0.08° and S-4 0.2° lower than the last comparison. One calorie is taken equal to 4.1833 international joules. The temperatures are reported on the basis of 273.16° K. as the ice-point temperature.

The heat capacities as measured are listed in Table I. The values at rounded temperatures are summarized in Table II. Because the slope of the heat capacity curve in the premelting region showed no abrupt change it was not possible to estimate the temperature at which premelting of the sample began or to extrapolate the curve of heat capacities with no premelting. Therefore no correction was made for premelting in the heat capacities below the melting point.

Allowance was made for vaporization and sublimation of the sample into the filling by making use of the density of the liquid and solid[6] and the measured vapor pressures and heats of vaporization. In the worst case this correction amounted to 3% in the energy and 0.7% in the number of moles of sample.

The accuracy of the calorimeter is normally 0.3% in the temperature range between 30 and 200° K. However, at the higher temperatures because of the uncertainty introduced by the presence of appreciable amounts of the sample in the filling line the accuracy may fall to 0.5%. Below 30° K. the error may rise to 1% at 20° K. and 5% at 12° K. due to uncertainty in the derivative of the resistance thermometer and the insensitivity of the standard thermocouples. Actually, the heat capacities below 20° K. deviate from a smooth curve by less than 1%. Runs made in duplicate over the entire temperature range above 55° K. reproduced the heat capacity curve with a precision well within the value stated above.

The Solid–Liquid–Vapor Triple Point.—The triple point was determined by observing the equilibrium temperature of the solid, liquid and vapor as increasing fractions of the sample were melted by the addition of measured quantities of energy. From these data and the heat of fusion, the amount of liquid soluble, solid insoluble impurity was found to be 0.16 mole per cent. for the first sample introduced into the calorimeter. After removal of this sample from the calorimeter and fractionation through the laboratory low-temperature column, the amount of liquid soluble, solid insoluble impurity was reduced to 0.08 mole per cent.

The solid–liquid–vapor triple point calculated for the pure compound was 173.09 ± 0.05° K. for the first sample and 173.11 ± 0.05° K. for the second. The average value was 173.10 ± 0.05° K. Values reported in the literature are 172.7° K. (−100.5° C.)[6] and 176.9° K. (−106.3° C.)[7].

The Vapor Pressure.—The vapor pressure of the liquid and solid hexafluoroethane was measured in the usual manner.[5a,b] The values listed are for international millimeters of mercury.

The data were fitted by equations derived by the method of least squares. The equation for the liquid is

$$\log_{10}P_{\text{mm.}} = -\frac{1125.329}{T} - 2.33917\log_{10}T - 0.00109858T + 14.22568 \quad (1)$$

and for the solid

$$\log_{10}P_{\text{mm.}} = -\frac{2227.0}{T} - 0.0915\log_{10}T - 0.05161T + 24.307 \quad (2)$$

Vapor pressure determinations made after one third of the sample had been distilled from the calorimeter indicated the presence of a volatile impurity which affected the pressures by an amount corresponding to 0.05° near the normal boiling point.

The observed vapor pressures differed, on the average, from those calculated from the formulas by ±1.4 mm. for the solid and ±0.02 mm. for the liquid. The vapor pressures observed by Ruff and Bretschneider[6] were 6 to 10 mm. higher for the solid and 5 mm. higher to 10 mm. lower for the liquid.

Because of the presence of a small amount of volatile impurity in the sample satisfactory equilibrium was not obtained in the vapor pressure of the solid even though the sample was allowed to stand for several hours before each measurement was made. However, the impurity did not noticeably disturb the equilibrium in the case of the liquid vapor pressures.

The triple point pressure was determined from observation of the equilibrium pressure simultaneously with the equilibrium temperature during the determination of the triple point and purity of the sample.

The equilibrium triple point pressure was calculated by adding to the pressure (extrapolated) at the 100% melted point the pressure rise for the sample from the 50% melted to the 100% melted point. The equilibrium triple point temperature was determined in an analogous manner.

The normal boiling point of hexafluoroethane calculated from the vapor pressure equation (1) is 194.87° K. (−78.29° C.). Values previously reported in the literature are −78.1° C. (195.1° K.; 0.0° C. = 273.16° K.)[6] and −79° to −78.6° C. (194.2 to 194.6° K.)[7]

The Heat of Transition and Transition Temperature.—The method used in measuring these properties in a similar case has been previously described.[5a] The data are summarized in Tables III and IV.

The Heat of Fusion.—The data for the heat of fusion are summarized in Table V. Because the heat capacity curve below the triple point did not have the usual change in shape resulting from the effect of premelting the heat capacity values were used with no premelting correction in applying the $\int C_p dT$ correction. The weight of the sample was corrected for vaporization into the filling line of the calorimeter.

TABLE V

THE HEAT OF FUSION OF HEXAFLUOROETHANE

Mol. wt. 138.02; 0.44183 mole; triple point 173.10 ± 0.05°K.; 0°C. = 273.16°K.; 1 cal. = 4.1833 int. joules.

Temp. interval, °K.	Total cor. heat input, cal./mole	$\int C_p dT$ cal./mole	ΔH, cal./mole
168.471–174.406	894.0	−252.0	642.0
167.333–174.603	948.6	−307.4	641.2
168.543–173.806	863.6	−221.8	641.8
		Average	641.7 ± 1.5

The Heat of Vaporization.—The heat of vaporization was measured in the usual manner.[8] The results are listed in Table VI. The molal heat of vaporization at the normal boiling point calculated from the equation in the table is 3859.7 calories.

The Vapor Density.—The vapor density, determined in the usual manner,[8] is summarized in Table VII.

The molecular weight calculated by the method of limiting density is 138.26. The formula weight of the pure compound is 138.02.

The second virial coefficient at 298.16° K. in the last column of Table IX was calculated from the density data. The discrepancies noted in individual values indicate an uncertainty of about ±10%. The experimental coefficients are in good agreement with the value of −0.268 liter/mole calculated from the modified Berthelot equation of state with a value of 292.9° K. for T_c as given by Swarts[7] and 29.9 atm. for P_c as determined from T_c by the empirical method of Meissner and Redding.[9a] Using the three and five constant equations of state, respectively, derived by Gouq Su[9b] we obtain −0.244 and −0.262.

.47859	.0027161	176.205	176.236	− .223
.00000		176.983[b]		

[a] Calculated from $P/d = 176.983 - 275.07d$. [b] Extrapolated. [c] $B = -0.268$ from Berthelot equation, $B = \left(\frac{9PV_gT_c}{128P_cT}\right)\left(1 - 6\frac{T_c^2}{T^2}\right)$ $T_c = 292.9$°K, $P_c = 29.9$ atm.

The Second Virial Coefficients from Heats of Vaporization and Vapor Pressures.—The second virial coefficients can be determined as a function of temperature from the heat of vaporization and vapor pressure data. The method has been described previously.[10] The data are summarized in Table VIII. In view of the agreement of the value of B obtained above using the five constant equation of Gouq Su with that from the Berthelot equation, further tests of his equation were not made.

The Entropy from Calorimetric Data.—The calculations of the entropy for the liquid at the melting point, for the gas at a temperature of 176.61° K. at which its vapor pressure is $^1/_3$ atm., and for the gas at the normal boiling point are summarized in Tables IXa and IXb.

The Entropy from Molecular and Spectroscopic Data.—The molecular data were taken from the available electron diffraction measurements for several fluorinated hydrocarbons including hexafluoroethane.[11] From these data, a C–F bond distance of 1.35 Å. and a C–C distance of 1.45 Å. were assumed. The CF_3 group was assumed to be tetrahedral.

The resulting moments were $I_x = 306.6 \times 10^{-40}$ g. cm.^{2}, $I_y = I_z = 435.6 \times 10^{-40}$ g. cm.^{2} and $I_{\text{red.}} = I_x/4 = 76.7 \times 10^{-40}$ g. cm.^{2} A symmetry number of six for the rigid molecule was used in the calculations.

The entropy due to translation and external rotation was calculated from

$$S_{t+r} = 4.575\ (3/2 \log M + 4 \log T + 1/2 \log I_xI_yI_z - \log 6) + 265.289 \quad (5)$$

where $I_xI_yI_z$ is the product of the principal moments of inertia.

The entropy contribution for the degree of freedom corresponding to the free rotation of the CF_3 group was obtained from

$$S_f = 4.575\ (1/2 \log T + 1/2 \log I_{\text{red.}}\ 10^{-40} - \log n) - 1.540 \quad (6)$$

in which $n = 3$ is used. Because of the presence of restricted rotation, the contribution S_f was reduced by an amount $(S_f - S)$ as given by Pitzer's tables.[12]

The frequency assignment in Table X[13] is based on the infrared spectrum[14] of the gas obtained by Dr. J. Rud Nielsen of the University of Oklahoma Research Institute along with a value of ν_8 obtained at the Naval Research Laboratory by Dr. Donald Smith, and a Raman spectrum[15] of the liquid obtained in the Spectroscopy Laboratory of The Pennsylvania State College under the direction of Dr. D. H. Rank.

TABLE X

TABLE XI

THE ENTROPY OF HEXAFLUOROETHANE IN THE IDEAL GAS STATE AT CERTAIN TEMPERATURES FROM MOLECULAR AND SPECTROSCOPIC DATA

T, °K.	176.61	194.87
V, cal. per mole	4350	4350
$S_{t,r}$	60.79	61.58
S_f, one degree of freedom	5.73	5.83
S_v	3.97	4.82
$-(S_f - S)$	−2.52	−2.41
Total	67.97	69.82
Calorimetric	67.92	69.88

A potential barrier of 4350 calories per mole restricting the free rotation of the CF_3 group in hexafluoroethane gives the best fit between the theoretical and experimental entropy of the gas.

That a barrier exists is indicated by the appearance of only seven lines in the Raman spectrum. If rotation were free, the activity of the fundamental frequencies of species E_u, when added to that of A_{1g} and E_g which are already active in the Raman spectrum, should result in more lines in the Raman spectrum.

Heat capacity data on the gas would be helpful in confirming the value for the height of the barrier. Its present value indicates that potential barriers are not due to peculiar properties of hydrogen atoms.

Acknowledgments.—We wish to thank Dr. J. H. Simons of the Fluorine Laboratory for the calorimetric sample of high purity. We are indebted to Dr. D. H. Rank of the Spectroscopy Laboratory for the Raman Spectrum and to Dr. J. Rud Nielsen of the University of Oklahoma Research Institute for the infrared spectrum and the aid in its interpretation. The work was made possible by the financial aid provided by the Phillips Petroleum Fellowship.

Summary

1. The heat capacity of hexafluoroethane has been measured from 11.2 to 195.0° K. as well as the density of the gas at 298.16° K.
2. The molal heat of transition of hexafluoroethane has been measured and the average transition temperature determined.
3. The molal heat of fusion together with the solid–liquid–vapor equilibrium temperature of the pure compound has been determined.
4. The vapor pressures of the solid and the liquid to the normal boiling point have been measured.
5. The molal heat of vaporization of hexafluoroethane has been determined for the liquid as a function of the temperature as well as the volumes of the saturated vapor.
6. From the experimental data, the entropy of the gas has been computed at the normal boiling point and at a temperature at which the vapor pressure of the liquid is one-third of an atmosphere.
7. The entropy of the gas has been calculated from a frequency assignment based on the infrared spectrum of the gas and a Raman spectrum of the liquid. A potential barrier of 4350 calories per mole hindering the mutual rotation of the CF_3 groups gives the best agreement between the calculated and the calorimetric entropy.

Equilibrium Moisture and X-Ray Diffraction Investigations of Pectinic and Pectic Acids

BY K. J. PALMER, R. C. MERRILL AND M. BALLANTYNE

In order to obtain some insight into the influence of polar groups on the sorption[2] of water by hydrophilic polymers, the equilibrium moisture contents have been determined for a series of pectinic and pectic acids[3] which have methyl ester contents between 0.2 and 10.9%. This range in methyl ester content corresponds to a variation in free carboxyl groups in the polygalacturonic acid part of the sample of about 23 to 99% when the nonuronide content is taken into account. This series of samples, therefore, offers the opportunity of determining the influence of free and esterified carboxyl groups on the equilibrium moisture content at various relative humidities. There was also the possibility that the data could be used to deduce the amount of water associated with the free and esterified carboxyl groups. Unfortunately, this latter possibility is not realized because, as it turned out, the equilibrium moisture content was essentially independent of the degree of esterification.

It is now quite evident that in addition to the polar groups, the packing of the chains in the crystalline regions plays an important role in determining the equilibrium moisture content of many hydrophilic polymers. For this reason, X-ray diffraction photographs of powders of each sample

[2] The term sorption is used in this paper to indicate the uptake of water; desorption the reverse of this process.

[3] The terms pectinic and pectic acid are used in this paper in accordance with the recommendation of the Committee for Revision of the Nomenclature of Pectic Substances, *Chem. Eng. News*, April 25, 609 (1944).

equilibrated at various relative humidities between zero and 95% were taken. The results of this investigation are reported in this paper.

Experimental

The pectinic and pectic acids were prepared and purified by previously published methods.[4a,b] Table I lists some of the significant analytical data for these compounds. Column one of Table I gives the number of the sample, while column two of Table I gives the methyl ester content as well as the method of de-esterification. The letters A, B and E used in column two of Table I refer to acid,[5] alkaline,[6] and enzymatic[7] de-esterification, respectively. The samples were de-ashed either with ion-exchange resins[4a] or by precipitation in acid alcohol. The ash content of each sample is shown in column three of Table I. The uronic acid content, expressed as uronic acid anhydride, is given in column four of Table I, while column five of this table gives the value of the intrinsic viscosity.

TABLE I

ANALYTICAL DATA FOR THE PECTINIC AND PECTIC ACID SAMPLES USED IN THIS INVESTIGATION

Sample	MeO,[a] %	Ash, %	Uronic acid anhydride, %	Intrinsic viscosity, (η)	De-esterification, %
L51	10.9	0.4	(80)	9.3	(23)
804	8.0 A	1.18	82	4.2	44
L64	7.4 E	0.4	79	5.5	47
L37P	5.8 E	0.4	82	4.8	59
L81	4.5 E	0.5	80	5.2	68
805	3.0 A	1.53	89	2.8	81
L67	2.7 E	0.29	81	3.5	81
619	0.4 B	0.6	86	2.7	97.4
L69	0.2 E	0.2	82	3.7	98.6

[a] The letters A, B and E signify acid, base and enzyme de-esterification, respectively.

Before samples were equilibrated at various relative humidities, they were humidified for forty-eight hours by placing them in a desiccator containing water. Alcohol sorbed as a result of the method of preparation is presumably removed by this procedure.[8] The desorption equilibrium moisture content was obtained in the following manner.[9] Two-hundred milligrams of each humidified sample were put in a small weighing bottle having a ground-glass top. Duplicate bottles of each sample, with tops on edge, were placed in a series of ten vacuum desiccators having relative humidities of 2, 6, 15, 24, 36, 49, 58, 84, 88, and 95%. The relative humidities in the desiccators were controlled by using sulfuric acid solutions of suitable concentrations. The desiccators were then evacuated and allowed to stand in a constant-temperature room held at 25 ± 1° for a period of two weeks. Thereafter the samples were weighed every week. In all cases at the end of five weeks the weights had not varied by more than 0.3 mg. from the weighings of the previous week, except for the samples at 95% relative humidity. In the latter case the weighings fluctuated in general by about 3 mg. This fluctuation was probably due to inadequate temperature control (±1°). At all relative humidities except 95%, equilibrium was assumed to have been reached when the samples maintained constant weight to within 0.3 mg. over a period of one week. At 95% relative humidity, the samples were assumed to be at equilibrium at the end of the five-week period.

The moisture content was determined by heating the samples in a vacuum oven at 70° for sixteen hours and noting the loss in weight. This leads to an essentially constant dry weight, although like the proteins,[10] further heating results in a measurable, though very slight, loss in weight.[11] The percentage loss in weight of the duplicate samples agreed in all cases (except at 95% relative humidity) to within 0.2%. The equilibrium sorption water contents were obtained by placing the vacuum oven-dried samples back into the various constant relative humidity desiccators and determining the gain in weight. The same weighing procedure was followed as described above for desorption.

X-Ray powder photographs were taken by placing some of the equilibrated material in thin-walled soft glass capillaries. The filled capillaries were allowed to stand with one end open in the appropriate sulfuric acid desiccator for an additional week. Upon removal from the desiccators the open end of each of the capillaries was quickly sealed by a small flame. Copper radiation filtered through a thin nickel foil was used.

Results

The equilibrium moisture contents of the various samples investigated, expressed in per cent. of dry weight, are given in Table II. The first column of Table II lists the number of the sample. In the next ten columns the equilibrium moisture contents at 25° are given for the relative humidities shown at the top of the columns. The last column indicates whether equilibrium was attained by desorption or sorption. At relative humidities of 84% and above, the sorption and desorption values were found to be the same within experimental error; therefore, only one value is listed. The moisture contents given for 95% relative humidity are not as accurate as those for the other relative humidities because of the difficulty experienced in reaching what could be reliably taken as a constant weight during equilibration.

Figure 1 shows a plot of the equilibrium moisture content *versus* relative humidity for both sorption and desorption for pectinic acid L81. The moisture isotherm curves are so similar for all the samples investigated that only those for L81 are shown.

The X-ray patterns of pectinic and pectic acids show in general three characteristic reflections,[12] although under certain conditions, such as high water content or heat degradation, several additional reflections appear. A typical X-ray diffraction photograph of a high-molecular weight pectinic acid is shown in Fig. 2. The inner rather diffuse ring is the only one which shows an appreciable variation with water content. Plots of this spacing against moisture content are shown in

Discussion

Equilibrium Moisture Content.—As shown in Table II, one of the results which is immediately evident from this investigation is that the equilibrium moisture content is essentially independent of methyl ester content over the whole relative humidity range with the possible exception of the results obtained at the highest relative humidities. This is rather surprising in view of the fact that the methyl ester content varies between 10.9 and 0.2%. This represents a change from about one free carboxyl per four galacturonide units to one free carboxyl for each galacturonide unit.

The constancy of the equilibrium water content with variation in free carboxyl groups is illustrated in Fig. 6. In this figure the water sorbed is plotted against the per cent. of free carboxyl groups. The latter value was determined from the uronic anhydride values listed in Table I. For example, sample L64 has a methyl ester content of 7.4% and a uronic anhydride value of 79%. This corresponds to 7.4(100/79) = 9.36% methyl ester on the basis of the galacturonide content. On the same basis completely esterified pure polygalacturonic acid would have a methyl ester content of 17.6%; therefore, 46.6% of the carboxyl groups in L64 are not esterified. The results of similar calculations on the other samples are shown in column six of Table I.

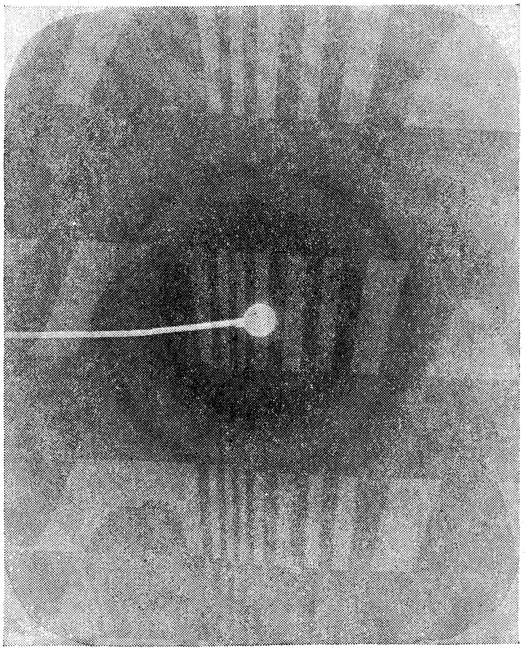

Fig. 2.—X-Ray diffraction photograph of pectinic acid L64, equilibrated at 36% relative humidity. CuKα, Ni filter, camera distance 5.0 cm.

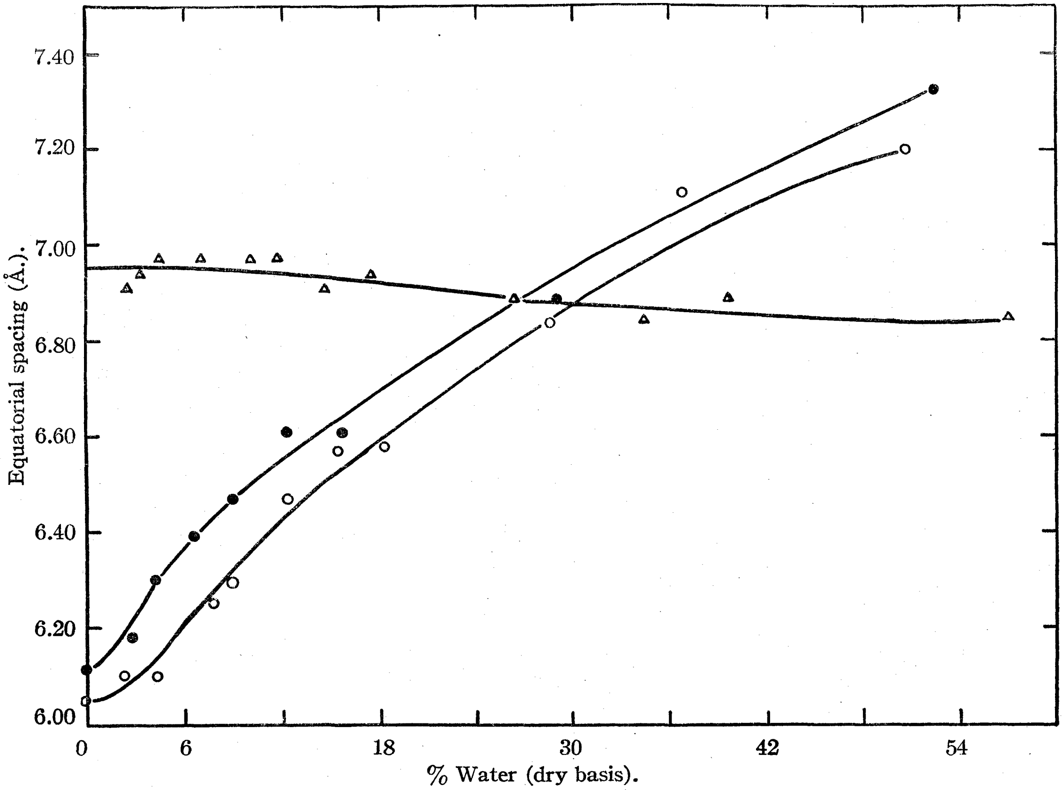

Fig. 3.—Variation of the interplanar spacing calculated from the equatorially accentuated X-ray reflection plotted against moisture content for pectinic acids L51, L81 and for pectic acid L69. Samples equilibrated by sorption: ○ L69, 0.2% MeO; ● L81, 4.5% MeO; △ L51, 10.9% MeO.

The fact that all of the curves in Fig. 6 are essentially horizontal indicates that the number of free carboxyl groups does not affect the equilibrium moisture content of the pectinic acids in the relative humidity range of 2 to 88% at 25°. Results of an equilibrium moisture content study on several proteins[13] indicate that the carboxyl groups in these materials also do not play a major role in determining the water sorption capacity of proteins. On the other hand, a recent study of the equilibrium moisture content of casein and several derivatives in which the amino groups have been benzoylated[14] show that the amino group markedly affects water sorption.

The results obtained in the case of the pectinic acids can be interpreted in several ways. The most obvious is to assume that the hydroxyl groups are primarily responsible for the high water sorption of the pectinic acids. This assumption receives some substantiation from the fact that the equilibrium water content is markedly reduced when the hydroxyl groups are esterified with proprionic acid[15] in contrast to the negligible effect observed when the carboxyl groups are esterified.

On the other hand, the comparatively low water sorption of cellulose and the fact that carboxyl groups usually show a greater affinity for water than hydroxyl groups[16] indicate that the mechanism of water sorption by long-chain polymers involves factors other than the hydration affinity of the polar groups.

One important factor is the availability of the polar groups in the crystalline regions. The fact that water does not penetrate the crystallites in native cellulose, for example, in spite of the numerous polar groups, is well established.[17] The ability of the crystallites in native cellulose, silk and presumably nylon[18] to resist penetration by water is probably due to the fact that the polymer chains can pack well together, because in these substances there are no bulky side chains. The close packing of the chains allows a large number of secondary interchain bonds to be established which, acting together, give rise to a comparatively stable structure.

A second, though closely related, way for a polar

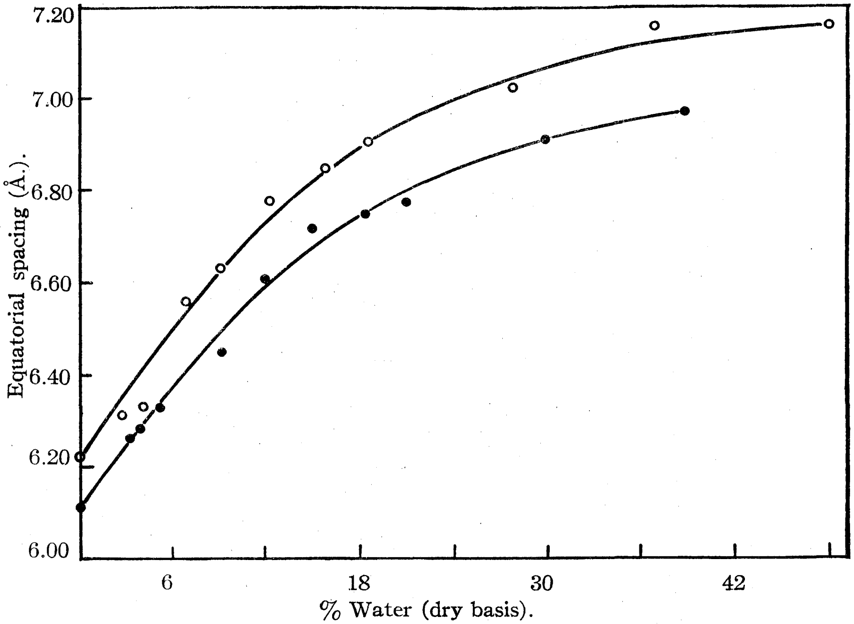

Fig. 4.—Variation of the interplanar spacing calculated from the equatorially accentuated X-ray reflection plotted against moisture content for pectinic acids L64 and L67. Samples equilibrated by sorption: ●, L67, 2.75% MeO; ○, L64, 7.4% MeO.

group to show an unexpectedly low affinity for water is by formation of an interchain bond with another polar group of sufficient strength to resist the dissociating effect of water even though water penetrates between the chains in the crystallites. The pectinic and pectic acids appear to behave in this way. The greater hygroscopicity of the free carboxyl group over the esterified one is probably compensated for in the pectinic acids by the relatively strong interchain hydrogen bonds formed between two adjacent carboxyl groups. The existence of stronger interchain bonds in pectic acid as compared to high methyl ester pectinic acids is substantiated by the fact that pectic acid is not soluble in water at its natural *p*H, whereas the high methyl ester pectinic acids readily go into solution.

Another example of the importance of the availability of the polar groups as sorbing sites in determining the equilibrium moisture content is illustrated by the results found for sodium pectate.[19] The crystallites in sodium pectate sorb a maximum of about 24% water at a relative humidity of 95% at 25°, although the water content of the sample is 64%. The probable reason for this discrepancy is evident from the X-ray photographs. At low moisture contents the X-ray photographs show poor crystallinity; consequently, water readily penetrates between the chains and hydrates the polar groups. When the water content in the crystallites approaches 20% the sodium pectate chains begin to assume a crystalline arrangement. The increase in crystallinity during sorption is apparent from the X-ray photographs.[19] After the hydrated sodium pectate chains have crystallized, the interchain forces (probably involving water bridges) are evidently sufficiently strong to resist further penetration by water molecules. As a consequence the polar groups in the crystallites of sodium pectate are not available for further sorption at relative humidities above about 40% at 25°.

Hysteresis.—In all cases where both desorption and sorption moisture data have been obtained on the pectinic and pectic acids it is evident that a definite hysteresis occurs. Whether the hysteresis is real or due to a very slow approach to equilibrium cannot be stated with certainty, since the definition of equilibrium has been arbitrarily taken as the attainment of a constant weight for one week. The observed hysteresis is reversible in the sense that a sample can be repeatedly taken around the hysteresis loop.

In the two samples L81 and L69 investigated at low relative humidities, the hysteresis appears to persist down to the lowest relative humidities investigated. This has also been observed in many other cases where water sorption is accompanied by swelling,[20] but is not observed, in general, in those cases where the sorbate does not cause swelling.[21] The extension of the hysteresis to essentially zero relative humidity is probably a manifestation of the fact that when swelling occurs the last traces of water to be removed are internally bound, *i.e.*, inside the crystallites, whereas the first water taken up is sorbed in the amorphous regions and on the surface of the crystallites.

This hypothesis is supported by the results obtained on sodium pectate.[19] In this case the X-ray spacings can be more reliably measured than in the case of the pectinic acids and the results show that the interchain separation in the crystallites continues to decrease down to zero moisture content, but on sorption there is a definite lag in the uptake of water by the crystallites. In other words, the crystallites also exhibit a hysteresis which appears to extend to zero moisture content. A similar effect probably occurs in the pectinic acids, although it may be less pronounced and in

any case is more difficult to demonstrate because the X-ray reflection is too diffuse to measure accurately.

Free Energy and BET Constants.—The free energy of water sorption at saturation is given by the equation

$$\Delta F = \frac{-RT}{M}\int_0^1 \frac{a\mathrm{d}x}{x}$$

where a is the weight of water sorbed per 100 g. of dry sample, x is the relative aqueous vapor pressure, R the gas constant, T the absolute temperature, and M the molecular weight of water.[10,22] The values for ΔF_{25} in column three of Table III were obtained by multiplying the area under plots of a/x against x by RT/M. The values so found for the free energy are from 500 to 1000 cal./mole larger than for the proteins investigated by Bull.[10] Extrapolation of the a/x *versus* x curve to x equals one gives the amount of water, $(a_s)_{25}$, sorbed at saturation per 100 g. of sample. In column four of Table III, the values of $(a_s)_{25}$ are listed. These values are only approximate because of the difficulty of getting reliable moisture data at the relative humidity of 95% and the resulting uncertainty involved when the curve is extrapolated.

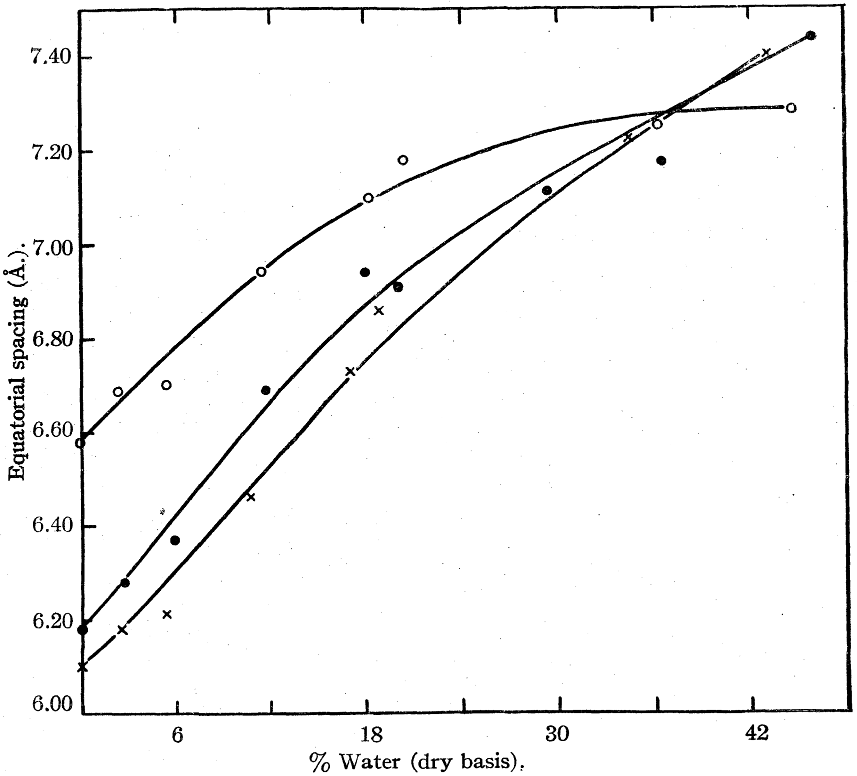

Fig. 5.—Variation of the interplanar spacing calculated from the equatorially accentuated X-ray reflection plotted against moisture content for pectinic acids 804 and 805 and pectic acid 619. Samples equilibrated by desorption: ×, 619, 0.4% MeO; ●, 805, 3.0% MeO; ○, 804, 8.0% MeO.

TABLE III

FREE ENERGY AND BET CONSTANTS CALCULATED FROM SORPTION AND DESORPTION MOISTURE ISOTHERMS

Sample		ΔF_{25} (cal./mole)	$(a_s)_{25}$	a_1	c
L51	Desorption	−1520	78	10.2	16.4
	Sorption			8.3	20.2
804	Desorption	−1620	72	9.1	11.4
L64	Desorption	−1630	76	10.3	16.2
	Sorption			9.5	9.1
L37P	Desorption	−1590	82	10.6	11.1
	Sorption			9.1	7.3
L81	Desorption	−1650	72	10.1	19.8
	Sorption			9.8	7.8
805	Desorption	−1680	72	10.5	15.8
L67	Desorption	−1700	84	10.6	18.9
	Sorption			9.5	19.2
619	Desorption	−1540	56	10.3	14.8
L69	Desorption	−1670	70	9.8	20.4
	Sorption			10.0	6.6

The saturation values, $(a_s)_{25}$, are quite large but appear to be reasonable in view of the high water contents observed at 95% relative humidity.

Stuewer[23] states that ultrafiltration experiments show that an apple pectin in aqueous solution was hydrated to the extent of about one-third of its weight. The values obtained by extrapolation from alcohol solutions indicated hydration to the extent of only about 25%. Both of these values are very much lower than those recorded in Table III.

The application of the adsorption theory of Brunauer, Emmett and Teller (BET)[24] to the observed moisture isotherms of the pectinic and pectic acids has been made in order that the results can be compared with similar analyses on other hydrophilic materials.[10,25]

Plots of $p/a(p_0 - p)$ as a function of x give reasonably straight lines for values of x between 0.15 and 0.45, where a is the grams of water sorbed per 100 g. of dry sample at water vapor pressure p, and p_0 is the water vapor pressure at saturation. The intercept on the ordinate is $1/a_1c$ and the slope is $(c - 1)/a_1c$, where c is approximately

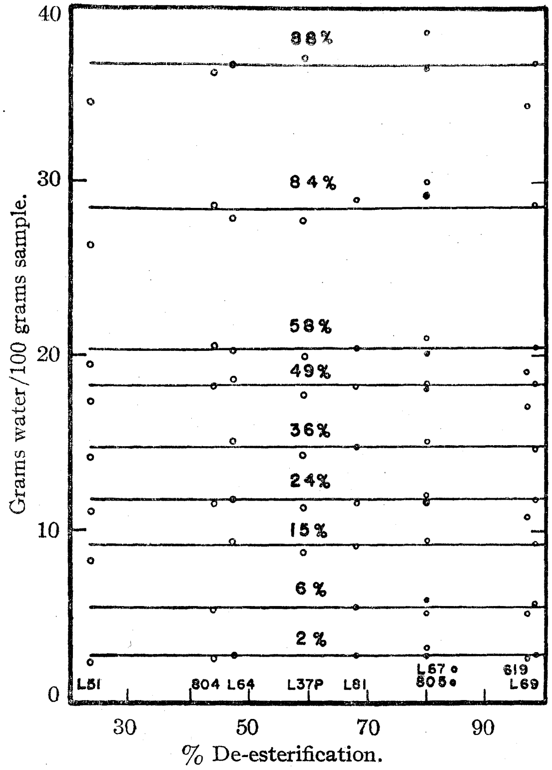

Fig. 6.—Variation of equilibrium moisture content (desorption) with per cent. de-esterification at the nine relative humidities shown on the curves.

equal to $e^{(E_1 - E_e)/RT}$. In the usual application of the BET theory to non-swelling sorbents, E_1 is taken as the heat of adsorption on the first layer, E_e the heat of liquefaction of the sorbate, and a_1 as the grams of sorbate necessary to cover the available surface in 100 grams of sorbent with a monolayer. The values of a_1 and c calculated from the BET plots are given in columns five and six of Table III, respectively.

It is interesting that the magnitude of a_1 is not only approximately constant for all the pectinic acids, but corresponds to about one water molecule per galacturonide unit. This amounts to one water molecule per three polar groups if equal weight is given to the hydroxyl, carboxyl, and esterified carboxyl groups.

X-Ray Spacings.—The X-ray spacing plotted in Figs. 3, 4 and 5 has been shown[12] to arise from planes which are parallel to the polygalacturonide chains. The variation in this spacing, therefore, reflects a change in interchain distance. The curves shown in Figs. 3, 4 and 5 give the variation of this reflection with water content at constant methoxyl content. The variation of this reflection with methoxyl content at constant moisture content can also be deduced from these curves.

It is interesting that when completely dry all but two samples have spacings that fall between 6.05 and 6.22 Å. This difference in spacing is approximately maintained for these same samples throughout the entire moisture range investigated. Of the two anomalous samples, L51 and 804, the pectinic acid sample L51 shows the most striking deviation. As shown in Fig. 3, the X-ray reflection does not appear to change appreciably with water content. This sample has a methoxyl content of 10.9% or about three methyl ester groups per four galacturonide units. The chains in this case evidently cannot coalesce when water is removed because of the prevalence of the methyl ester side chains. The diffuseness of the inner X-ray reflection obtained from L51 increases markedly with decrease in water content, indicating that a very irregular arrangement of the chains occurs when water is removed. At high relative humidities the X-ray reflection under discussion becomes much sharper, and in addition several new rings appear. It is apparent, therefore, that the chains assume a much more regular arrangement when hydrated than when dry. The reason why the interchain distance in L51 does not increase with increase in water content is not known, but may be due to the prevalence along the chain of the hydrophobic methyl groups.

The reason for the slightly different behavior of sample 804 as compared to the other samples may be due to the fact that this sample was acid de-esterified, while L64, which contains a comparable methyl ester content, was enzymatically de-esterified. It has been suggested[4b] that the acid treatment demethoxylates at random, while the enzyme removes the methyl ester groups continuously along the chain with which it is reacting. This results in a significantly different distribution of methyl ester groups after partial demethoxylation and may account for the observed difference in behavior between samples 804 and L64.

The X-ray spacing plotted in Figs. 3, 4 and 5 deviates in a significant way from the similar X-ray spacing of sodium pectate. In the case of sodium pectate, the analogous X-ray spacing increases with water content up to a water content of about 24% and then remains constant.[19] As shown in Figs. 3, 4 and 5, the crystallites in the pectinic and pectic acids, except L51, continue to sorb water throughout the entire range investigated. Swelling in the crystallites appears to be reaching a maximum value in some cases, notably 804, L64 and L67, but at a higher water content than 24%.

This difference in swelling behavior of the crystallites in the pectinic and pectic acids on the one hand, and sodium pectate on the other, is probably due to the higher degree of regularity which exists in the crystallites of sodium pectate as compared to those of the pectinic and pectic acids. The difference in crystallinity is readily apparent from a visual inspection of the X-ray photographs.

It is interesting that the two samples (sodium pectate and L51) in which the crystallites do not swell in the high moisture region are both water soluble, whereas the low methyl ester pectinic acids and pectic acid are not. Evidently the resistance to swelling at high relative humidities at 25° exhibited by the crystallites of sodium pectate and L51 is not related to the behavior of the sample when placed in contact with liquid water.

Acknowledgments.—We wish to express our appreciation to W. D. Maclay, H. S. Owens and R. M. McCready for generously furnishing us with the samples used in this investigation, as well as the analytical data given in Table I. We also wish to thank D. E. Jamison for his help in making some of the BET calculations.

Summary

The equilibrium moisture content at ten relative humidities between zero and 95% are given for seven pectinic and two pectic acids. The moisture content was found to be essentially independent of the methoxyl content.

The free energy change (average about 1600 cal./mole) is considerably higher than found for most proteins.

The BET constants have been calculated. The value of a_1 is nearly the same for all samples and corresponds to approximately one water molecule per galacturonic acid unit.

The variation of the equatorially accentuated X-ray reflection with water content has been determined. These results show that the interchain distance within the crystalline regions increases with increase in water content for all samples, except that having the highest methyl ester content (10.9%). In this latter sample the interchain separation appears to be independent of the water content.

The Near Ultraviolet Absorption Spectra of the Vapors of the Monodeuterated Toluenes

BY A. R. CHOPPIN AND C. H. SMITH[1]

The study of the spectra of compounds in which hydrogen is partially or entirely replaced by deuterium is of importance in that it provides data on molecules having the same force constants but different masses and mass distributions. Such data are of assistance in identifying the vibrational forms corresponding to particular frequencies, and provide the additional frequencies which are often needed for the solution of secular equations and the calculation of numerical values for force constants.

Spectral data on deuterium substituted benzene derivatives are rather meager, although such data on benzene itself is extensive.[2,3,4,5] The infrared[6] and ultraviolet[7] absorption spectra of phenol-*d* and aniline-d_2 have been determined, but no report of work on benzene derivatives with nuclear deuteration has been found. This paper presents the results of a study of the near ultraviolet absorption spectra of the vapors of the following compounds: toluene, toluene-α-*d*, toluene-2-*d*, toluene-3-*d*, and toluene-4-*d*.[8] The spectrum of toluene vapor has been extensively investigated by many workers. The latest study is that of Ginsburg, Robertson and Matsen.[9] Such studies of the deuterated toluenes have not been reported.

Experimental

Preparation of Compounds.—Merck "Reagent Grade" toluene was purified by sulfonation, recrystallization of the sodium *p*-toluenesulfonate from saturated sodium chloride solution and regeneration of the toluene by steam distillation of a solution of the sodium *p*-toluenesulfonate in 80% sulfuric acid. The toluene layer was thoroughly washed with sodium hydroxide solution, cold concentrated sulfuric acid and with water. After drying over sodium and distilling over sodium, the middle fraction of the toluene boiled at 110.6 and had a refractive index (n^{20}D) of 1.4965.

Each of the deuterated toluenes was prepared by treating the Grignard reagent, made from the appropriate halogenated toluene, with an equivalent amount of 99.9% deuterium oxide. Volatile components of the reaction mixture were removed by distillation, using an oil-bath. The temperature of the bath was not allowed to rise above 150°. The distillate was fractionated, using a packed eight-inch column, until the temperature of the vapors had risen to 50°. The distillate from the fractionation contained most of the ether and was discarded. The residue from the fractionation was thoroughly extracted with cold concentrated hydrochloric acid in order to remove the remainder of the ether. Then it was

washed, dried and distilled to obtain the deuterated toluene. The deuterated compounds were prepared from the following halogenated compounds: toluene-*α*-*d* from benzyl chloride; toluene-2-*d* from *o*-bromotoluene; toluene-3-*d* from *m*-bromotoluene; toluene-4-*d* from *p*-bromotoluene. When the spectra of these compounds were determined it was evident that toluene-2-*d*, toluene-3-*d* and toluene-4-*d* contained some ordinary toluene. The spectrum of toluene-*α*-*d* was so similar to that of ordinary toluene that it was impossible to detect any small amounts of toluene that may have been present. From the intensities of the 0,0 bands of toluene in the spectra of the three ring deuterated toluenes, it was estimated that the latter contained from 5 to 10% toluene.[10,11]

Spectroscopic Procedure.—The spectra were determined using a Bausch and Lomb Large Littrow Spectrograph with a Hanovia Hydrogen Discharge Tube as the source of the ultraviolet continuum. Absorption cells, varying in length from 20 to 100 cm., were constructed of Pyrex with optically flat quartz end pieces. Spectra were determined at temperatures varying from 20 to 150°. The cells were heated by liquids circulating in an outer jacket. A slit width of two microns and an exposure time of three minutes were used. Eastman Spectroscopic Plates, Type IV-O, developed for five minutes in Eastman D-19 at 18°, proved most satisfactory. Positions of the absorption maxima were determined using a visual wave length comparator equipped with a Variac to control the intensity of the light source. Wave numbers were determined by interpolation between the wave numbers of lines of the iron arc. The iron arc was photographed along with the absorption spectrum by means of a Hartmann diaphragm. Wave lengths of the iron lines were determined by comparison with standard prints.[12] Wave numbers of the iron lines were calculated from these wave lengths using the data of Kösters and Lampe on the refractive index of air.[13]

Intensities were determined by means of a Leeds and Northrup Recording Photoelectric Microphotometer. The absorption does not follow Beer's law; the bands are widened and flattened as the pressure increases. Intensities are reported on a logarithmic scale giving the strongest line of each compound a value of 1000. In determining intensities, account was taken of the presence of continuous absorption and of the overlapping of bands, thus giving the individual bands an intensity more nearly what they would have if they were not overlapped by other bands. Since all of the bands could not be photographed on a single plate or at the same pressure, it was necessary to adopt secondary standards of intensity from among the bands which could be compared directly with the strongest band. The *relative* intensity of the bands is not greatly changed by a change in pressure. In this way a much better approximation to the intensities was obtained than could have been gotten by the use of Beer's law.

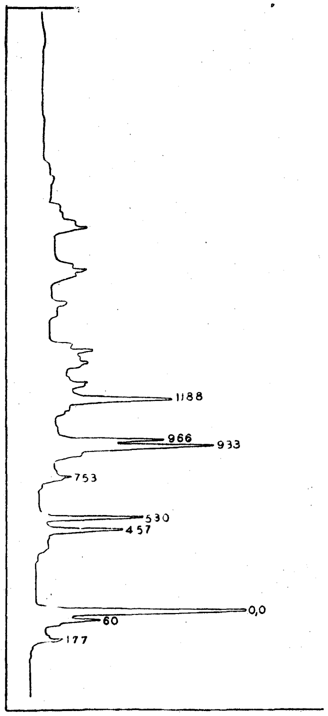

Fig. 1.—Microphotometer trace of the absorption spectrum of toluene.

Experimental Results.—Tables showing the wave numbers, intensities, and wave number differences (from the 0,0 band) and giving a partial analysis of the bands will be available from the American Documentation Institute.[13a] Figures 1 through 5 give microphotometer tracings of the spectra taken at 5 mm. pressure in a 30 cm. cell. Finer details of the spectra are not visible on these small tracings.

The 0,0 Bands.—The position of the vibrationless transition in toluene is fixed at the

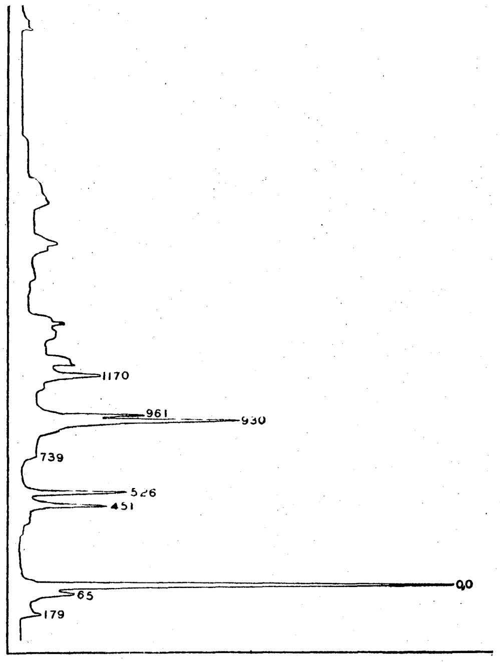

Fig. 2.—Microphotometer trace of the absorption spectrum of toluene-*α*-*d*.

[a] According to the interpretation developed in this article, these frequencies correspond to Class A_1 carbon vibrations.

37478 cm.$^{-1}$ band (strongest of spectrum) by a comparison with the Raman spectrum,[14,15] according to Masaki[16] and Ginsburg, Robertson and Matsen.[17] The corresponding bands in all of the toluenes are as follows (in cm.$^{-1}$)

Toluene	37478
Toluene-α-*d*	37487
Toluene-2-*d*	37513
Toluene-3-*d*	37511
Toluene-4-*d*	37511

The shifts in the position of the 0,0 band are ascribed to the existence of zero-point vibrational energy.

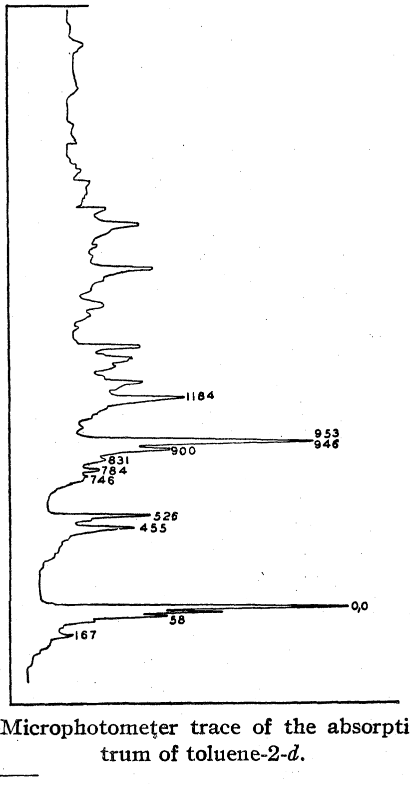

Fig. 3.—Microphotometer trace of the absorption spectrum of toluene-2-*d*.

Difference Frequencies.—On the low frequency side of the 0,0 band of each of the compounds is found a group of strong bands. These bands are interpreted as difference frequencies (1–1 transitions), in agreement with the interpretation of Ginsburg, Robertson and Matsen[17] for toluene.

Fundamental Vibrational Frequencies.—The presence of difference, overtone and combination frequencies renders the identification of fundamentals somewhat difficult. Therefore, the following list must be considered tentative and subject to revision when the Raman and infrared spectra have been studied. Doubtful fundamentals are marked with a question mark. Corresponding lines in the ground and excited states of each compound have been placed on the same line.

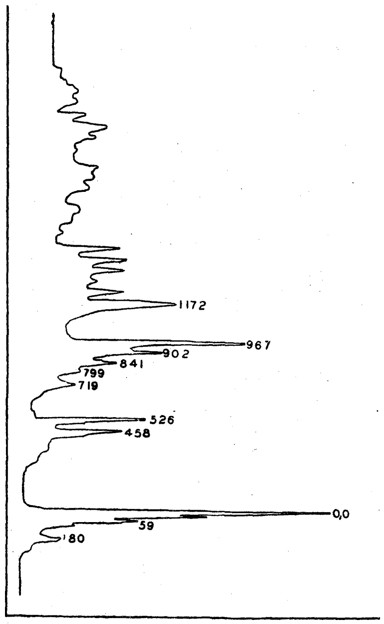

Fig. 4.—Microphotometer trace of the absorption spectrum of toluene-3-*d*.

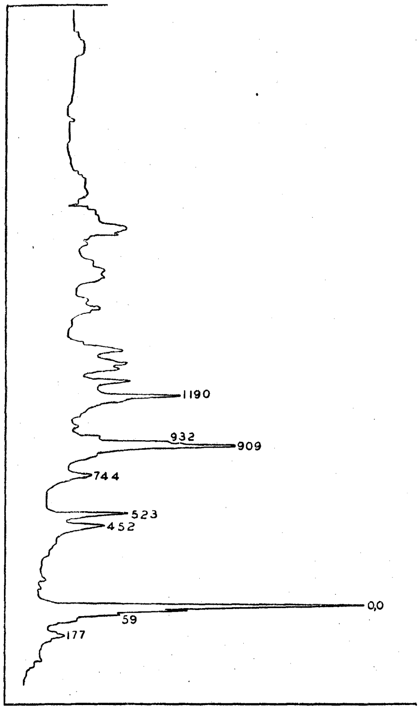

Fig. 5.—Microphotometer trace of the absorption spectrum of toluene-4-*d*.

Theory.—From heat capacity measurements Pitzer and Scott[18] concluded that in toluene the potential hindering methyl group rotation must be extremely small, so that at ordinary temperatures this group has essentially free rotation. In this case, at most positions of the methyl group, the molecule has no symmetry elements. However, on a time average the hydrogens on the methyl group would be smeared out in a cone and the molecule would have C_{2v} symmetry, and at no time would its symmetry vary greatly from C_{2v}. For the following discussion, C_{2v} symmetry is assumed for toluene,[18] toluene-α-*d* and toluene-4-*d*, and C_s symmetry for toluene-2-*d* and toluene-3-*d*.

Herzberg and Teller[19] applied the Franck–Condon Principle to the vibrations of polyatomic molecules during an electronic transition and concluded that, for an allowed transition taking place from the vibrationless ground state, the absorption is intense only when totally symmetrical vibrations are excited in the upper electronic state (the 0,0 band is also intense). For the toluenes of C_{2v} symmetry only the vibrations of class A_1 should appear strongly in the near ultraviolet absorption. However, Ginsburg, Robertson and Matsen[17] assigned one of the stronger lines of the spectrum of toluene (624 cm.$^{-1}$ in the ground state and 530 cm.$^{-1}$ in the excited state) to a Class B_1 vibration. This assignment is supported by the observation of Cleveland[20] that the 624 cm.$^{-1}$ line in the Raman spectrum is depolarized. It agrees with the interpretations of the spectra of fluorobenzene,[21] chlorobenzene,[22] phenol,[23] and aniline.[24] Pitzer and Scott[18] made a complete assignment of the toluene vibrations and assigned the 624 cm.$^{-1}$ line to class B_1.

The authors have developed a different assignment for the toluene vibrations by way of the following steps:

An examination of the spectra of the toluenes shows that, for the excited state, there are no *strong* fundamentals in the region of the hydrogen valence-stretching vibrations. This leads to the assumption that *no hydrogen vibrations appear strongly in the near ultraviolet absorption spectra of the toluenes*. Presumably this statement would hold for other benzene derivatives also. The assumption is reasonable since the absorption largely involves the electrons of the ring carbon atoms.

According to group theory there should be *six* carbon vibrations of class A_1 for each of the toluenes of symmetry C_{2v}. Six strong fundamentals are observed in the excited state of these compounds. This leads to the assumption that *the six strong fundamentals in the excited state of the toluenes of symmetry C_{2v} correspond to the six carbon vibrations of class A_1*. These frequencies are given in Table I. The corresponding ground state frequencies are also given. This assignment differs from the usual one in that the 624 cm.$^{-1}$ line in toluene is assigned to class A_1 instead of Class B_1. Theoretically, the degree of polarization of a Raman line produced by a totally symmetric vibration may vary from total polarization to depolarization. Therefore, the observation that the 624 cm.$^{-1}$ line is depolarized does not exclude the possibility of its belonging to a totally symmetric vibration.

Vibrational Forms.—By a consideration of the frequency changes upon the introduction of deuterium, it is possible to arrive at certain rather hypothetical vibrational forms.

The vibrations at 520 cm.$^{-1}$ and 624 cm.$^{-1}$ in the ground state of toluene are recognized as being due to planar bending of the ring by a comparison with the benzene assignments.[25] The 520 cm.$^{-1}$ frequency is reduced almost equally by substitution of deuterium on the methyl group or on the para carbon atom. This indicates that the methyl group and the para carbon atom form parts of vibrating groups whose amplitudes along the two-fold axis are about the same. The only way that this can happen so as to preserve the center of gravity of the molecule is for the ortho and meta carbon atoms to possess a component of vibration in the same direction as the para carbon atom.

[25] Angus, Bailey, Hale, Ingold, Leckie, Raisin, Thompson and Wilson, *J. Chem. Soc.*, **971** (1936).

The mode of vibration must be very similar to that indicated in 1 of Fig. 6.

The 624 cm.$^{-1}$ frequency in toluene is very little affected by substitution of deuterium on the methyl group but is more affected by substitution of deuterium on the para carbon atom. This indicates that the amplitude of the methyl group is very small but that of the para carbon atom is rather large. The mode of vibration must be similar to 2 of Fig. 6.

The frequency at 1003 cm.$^{-1}$ in the ground state of toluene is recognized by its high intensity, high polarization in the Raman spectrum and by its frequency value, as corresponding to the carbon-to-carbon valence-stretching vibration which is totally symmetric in benzene. Agreeing with this mode of vibration, its frequency is little changed in toluene-*α-d* but is reduced in toluene-4-*d*. The vibrational mode corresponds to 3 of Fig. 6.

In studies with vibrating mechanical models, Teets and Andrews[26] observed a mode in which the methyl group vibrated against the remainder of the molecule. Now Lewis and Houston[27] observed the C–C valence-stretching vibration of ethane in the Raman spectrum at 993 cm.$^{-1}$. If the single C–C bond in toluene has the same force constant, the vibrational frequency of the methyl group against the remainder of the molecule is calculated to be 770 cm.$^{-1}$, taking the change in mass into account. This value is very close to the observed frequency of 787 cm.$^{-1}$ in the ground state of toluene. Furthermore this frequency is reduced much more in toluene-*α-d* than it is in toluene-4-*d*, agreeing with the idea that this vibration chiefly involves the methyl group against the ring, as is shown in 4 of Fig. 6.

The 1188 cm.$^{-1}$ frequency in the excited state of toluene is strongly reduced by substitution of deuterium on the methyl group but not by deuterium on the para carbon atom, indicating that the methyl group has a large amplitude but the para carbon atom does not. Form 5 of Fig. 6 gives a satisfactory mode of vibration.

The 966 cm.$^{-1}$ frequency in the excited state of toluene is reduced much more by substitution on the para carbon atom than it is by substitution on the methyl group, indicating a form similar to 6 of Fig. 6.

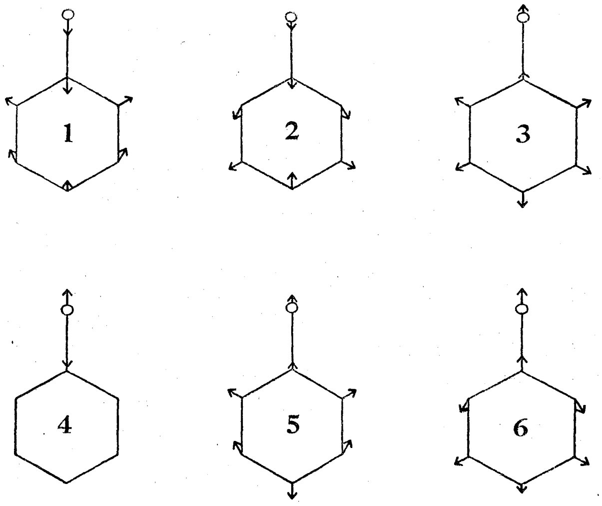

Fig. 6.—Approximate vibrational forms of the toluenes of C_{2v} symmetry. Carbon vibrations of class A_1.

It is realized that these modes of vibration are highly hypothetical. They afford, however, a satisfactory and logical explanation of the data. Both the assumptions and the vibrational forms are to be taken as working ideas, pending further investigations now in progress in this Laboratory.

Toluene-2-d and Toluene-3-d.—These compounds have C_s symmetry and should have eleven totally symmetric carbon vibrations. However, the perturbing effect of deuterium is so slight that the five new vibrations do not appear with such intensity as the six which are totally symmetric in the compounds of C_{2v} symmetry. A greater number of fairly strong fundamentals were found. Additional studies are now being made and will be reported in a subsequent publication.

Summary

The near ultraviolet absorption spectra of the vapors of toluene, toluene-*α-d*, toluene-2-*d*, toluene-3-*d* and toluene-4-*d* have been determined and partially analyzed. It is postulated that the six strong fundamentals in the excited states of the toluenes of C_{2v} symmetry correspond to the six totally symmetric carbon vibrations. The frequencies are correlated with certain hypothetical modes of vibration.

The Electrophoretic Mobility of Type II GR-S Latex[1,2]

By S. H. Maron, D. Turnbull[3] and M. E. Elder

Type II GR-S latex is a negatively charged colloidal dispersion of rubber polymer in an aqueous medium and like any such colloid, it can be made to migrate in an electric field toward the anode. By application of the moving boundary technique it is possible to measure the rate of this electrophoretic migration. Since the electrophoretic mobility is related to the charge on the colloidal particles, and since the charge in turn is responsible to a large degree for the stability of the colloid, such measurements can lead to a better understanding of the factors responsible for latex stability and of the way in which these factors are influenced by various modifications of the latex.

In this paper are presented results obtained on the mobility of Type II latex as a function of solids content, *p*H, temperature, ionic strength and electrolyte type. Also described are some studies made on the effects of creaming and redispersion, and of freezing and thawing of a latex on the mobility. From the mobilities have been calculated also the *zeta* potentials of the latex and the manner in which these potentials vary with temperature, *p*H and ionic strength.

Experimental

The assembly employed for measuring electrophoretic mobility consisted merely of the electrophoretic cell in series with a source of potential, a variable resistance and a milliammeter. The source of potential was a 90–180 volt B-battery bank whose output was regulated by means of the variable resistance. The milliammeter served to indicate the magnitude and constancy of current flow through the cell. Since latex solutions are turbid, the motion of the boundaries could be followed with a cathetometer positioned in front of the cell, which was kept immersed in a thermostat controlled to better than ±0.1°.

The details of the cell construction are shown in Fig. 1. Two microscope slides, S, each about 1.6 mm. thick, were ground to serve as sliding surfaces for formation of the sharp sheared boundaries. Holes about 8 mm. in diameter were drilled on each side of the slides as shown. A Pyrex U-tube, A, with vertical arms and flatly ground ends was then sealed with deKhotinsky or glycerine–litharge cement to the upper slide in such a manner as to make the tube ends flush with the sliding surface. To the lower slide were sealed in like fashion the lower arms, B, of the cell, due attention being given that the tubes be vertical and that their ground ends be flush with the lower sliding surface. These lower tubes were connected by thick gum rubber tubing to the two vessels, E, containing the electrodes. The electrodes consisted of coils of pure silver wire which were converted into thick silver–silver chloride electrodes by electrodeposition of chlorine upon them. Light copper leads were then hard-soldered to the electrodes for external circuit connection.

The cell was supported in the thermostat in the position shown in the figure by a special brass holder which was slotted horizontally to permit the sliding past each other of the surfaces S. With this arrangement the general procedure for making a run was as follows. Tube A was first inverted and filled completely with the latex dispersion to be studied. Next unit B of the cell was slid over the slide connected to the U-tube, shearing off thus the protruding drops of latex solution and enclosing the latex in the U-tube. In this operation slide B was always so displaced that the tube ends of A and B were closed off. To prevent leakage the ground surfaces of the slides were greased with purified vaseline before each experiment. Finally the electrode vessels E were attached to B, the vessels and tubes filled with enough leading and following solution to cover the electrodes, the center portion of the cell inverted and the entire assembly mounted in the thermostat in the position shown in Fig. 1. The latex portion A of the cell had to be kept in the position shown because the latex solutions were less dense than the electrolyte used for leading and following solutions.

The cell thus assembled was allowed to remain undisturbed in the thermostat until thermal equilibrium had been established. When temperature constancy was attained slide A was pushed manually along slide B until the tubes in A and B were continuous. In this manner two sharp sheared boundaries were obtained between the latex in A and the solutions in the two arms of B. After the boundaries were formed the current was turned on, adjusted to the desired value and kept there thereafter. With a high resistance in the circuit the current could be kept constant without any difficulty and any minor variations in resistance of the solution were not enough to upset the current setting. At various time intervals the positions of the two latex-solution boundaries were measured with the cathetometer.

To keep the potential gradient constant throughout the cell it was necessary to adjust the conductances of the leading and following solutions to those of the latex solution. This adjustment was made by using the same electrolyte for making up the latex as was used for the leading and following solutions and by making the concentrations of the latter such as to be identical with conductances of the latex–electrolyte mixtures. This procedure worked well with electrolytes containing chloride and gave no trouble with gassing at or fouling up of the electrodes. However, when electrolytes which did not contain chloride were used, considerable gassing occurred at the anode and a deposit frequently formed on the electrode. To overcome these difficulties enough sodium chloride was added to such electrolytes to make the concentration of chloride about 0.0002 molar. This small quantity of chloride was sufficient to eliminate the gassing entirely at low currents and to prevent the formation of any deposits on the silver–silver chloride anode.

Before initiating systematic measurements, a study was made to ascertain the most favorable currents for mobility determination. For this purpose the mobilities of latex solutions in 0.05 molar disodium phosphate were measured at currents of 5.0 and 1.5 milliamperes. At the latter current strength both ascending and descending boundaries were sharp and the mobilities calculated from their motion checked each other within the experimental uncertainty. When the higher current was used, however, the descending boundary was sharp and gave the same mobility as with a current of 1.5 milliamperes, but the ascending boundary was diffuse and the mobility calculated from its motion did not agree with that for the other boundary. Consequently in all the measurements reported here the current was kept sufficiently low to make both boundaries sharply defined. The optimum current for use with 0.05

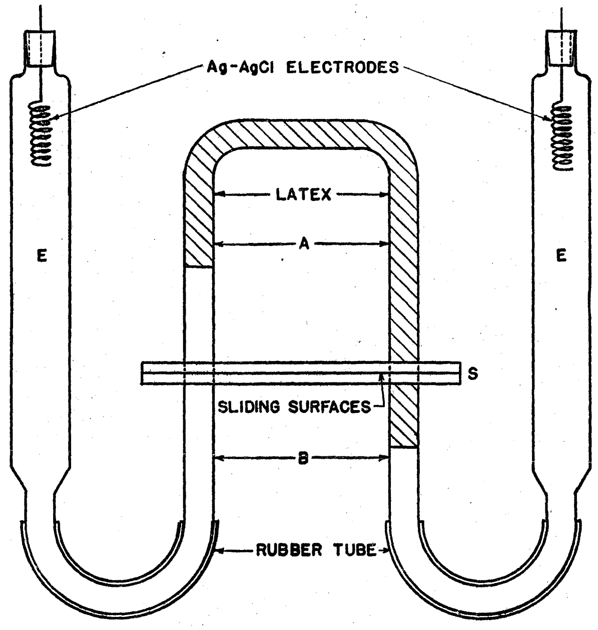

Fig. 1.—Latex electrophoretic mobility cell.

molar disodium phosphate was taken as 1.5 milliamperes and in all other cases the current was varied as the square root of the specific conductance of the solutions, giving thus approximately equal heating values due to current passage in all determinations.

The consistency of the data within a run was judged in all cases by the uniformity of the motion of the two boundaries. The distances which the boundaries traversed were plotted against time and the plots inspected. Any determinations in which the movements of the boundaries were not uniform or in which the boundaries were diffuse were discarded. Actually not many runs had to be eliminated for the reasons stated and these involved generally quite concentrated solutions of electrolyte or latex. A typical plot of migration distance *vs.* time is shown in Fig. 2. The plot is linear and very nearly identical for both boundaries.

The slopes of plots such as Fig. 2 give directly the actual rate of migration. To obtain from these the mobility the potential gradient under which the migration takes place must be known. This gradient follows readily from the specific conductance of the latex–electrolyte solution, L_s, the cross-sectional area of the tubes, S, and the current i, as i/L_sS, and hence the mobility, v, is given by

$$v = (l/t)/(i/L_sS) = lSL_s/it \qquad (1)$$

where l is the distance traversed by the boundaries in time t. In the present work the cross-sectional areas of the migration tubes were determined by calibration with mercury at various heights. In the cells used these areas were uniformly constant within experimental error.

In all experiments except those where the effect of temperature was studied, the temperature was kept constant at 30.0 ± 0.1°. Again, except where mobility as a function of *p*H was investigated, the latter was generally held within the range 8.4–9.0 by addition of disodium phosphate. As will be shown below, in this *p*H range the mobility is very little affected by *p*H change. In fact, over this entire range the variation in mobility amounts to only 0.1 micron/second. Finally, since it was found that the total solids content of the latex had practically no effect on the mobility in the concentration interval 9–15 g. per liter, all measurements were confined to lattices falling within this concentration range.

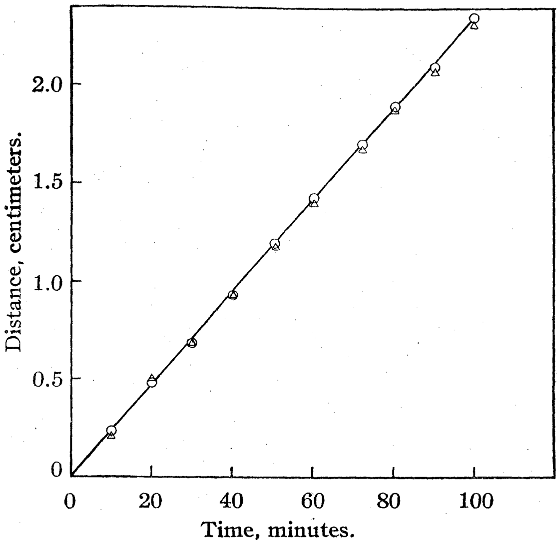

Fig. 2.—Plot of migration distance *vs.* time for Type II Latex no. 3: ○, ascending boundary; △, descending boundary.

The lattices employed in this study were polymerization products stripped of excess butadiene and styrene, and short-stopped. Latex no. 3 had an initial total solids content of 24.2% and a soap content 0.0362 normal, while Latex no. 7 had a solids content of 28.8% and a soap content 0.0474 normal.

All *p*H measurements were made with a Model G Beckman glass electrode assembly.

Effect of Various Factors on Latex Mobility.—In initiating this study it was assumed *a priori* that the mobility of a latex may depend upon (a) the total solids content, (b) the *p*H of the latex–electrolyte solution, (c) the ionic strength of the solution, (d) the temperature and (e) the type of electrolyte used to adjust the latex. In order to check the effects of these possible variables, experiments were designed to vary one variable at a time and to ascertain its effect on mobility.

(a) Effect of Total Solids Content.—Table I shows some results for mobility measurements in 0.05 molar disodium phosphate solutions at 30° on three concentrations of latex ranging from 9.4 to 29.4 g. per liter total solids. These relatively dilute lattices had to be used in the electrophoretic studies because of density difficulties with either much more concentrated or more dilute dispersions. From Table I it may be seen that between 9 and 15 g. per liter total latex solids the mobility is independent of concentration. However, at 29 g. per liter the mobility is already not constant and, hence, all measurements were limited to the lower concentration interval.

Table I

Effect of Total Solids Content on Mobility of Type II Latex No. 3 at 30°

Electrolyte: 0.05 Molar Na_2HPO_4

Total solids, grams/liter	Mobility (microns-cm./volt-sec.) Descending boundary	Ascending boundary	Average
9.4	5.58	5.58	5.58
14.7	5.59	5.62	5.61
29.4	5.38	5.49	5.44

(b) **Effect of *p*H.**—The effect of *p*H on latex mobility was studied at 30° at a constant ionic strength of 0.150. The *p*H's were adjusted to the desired values by addition of appropriate quantities of sodium hydroxide or hydrochloric acid to the disodium phosphate solutions used. The results obtained are summarized in Table II and are shown graphically in Fig. 3.

Table II

Effect of *p*H on Mobility of Type II Latex No. 3 at 30° and $\mu = 0.150$

*p*H	Mobility microns-cm./volt-sec.
5.10	3.1
5.95	4.1
6.37	4.9
6.85	5.4
7.90	5.6
8.60	5.6
10.5	5.8
11.6	6.0

From this figure it may be seen that the mobility decreases slowly and linearly as the *p*H is decreased from about 12 to *p*H 6.85. At the latter *p*H, however, a sharp and again linear drop in mobility sets in. The measurements along the latter branch of the curve could not be carried below the *p*H of 5.10 because at the given ionic strength any further decrease in *p*H resulted in coagulation of rubber. If it be assumed that the course of mobility variation with *p*H below 5.10 is continuous with the curve shown, then the extrapolation of this plot to zero mobility yields a *p*H of 2.7 for the isoelectric point of the latex at $\mu = 0.150$.

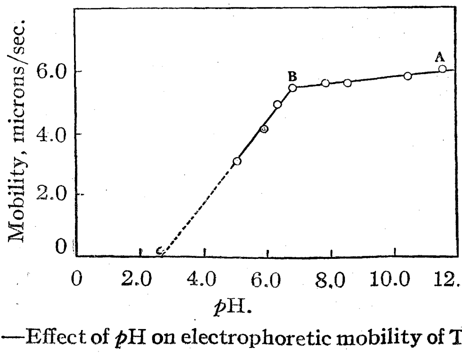

Fig. 3.—Effect of *p*H on electrophoretic mobility of Type II Latex no. 3 at 30° and $\mu = 0.150$.

At *p*H's above about ten the emulsifier in Type II latex is present entirely as the sodium soap of the fatty acids used in polymerization. When the *p*H is lowered progressively below 10 conversion of the soap into a mixture of soap and fatty acid takes place until eventually all the soap is transformed into fatty acid. The slow decrease in mobility along curve AB in Fig. 3 is in all probability to be ascribed to the gradual change of soap into fatty acid, with consequent gradual decrease in the charge on the polymer particles. As the *p*H of 6.9 is reached this transformation of soap into acid is quite advanced and, hence, thereafter mostly fatty acid is present to give the latex stability. It is known that fatty acids are not so strongly adsorbed by the rubber as soap. Further, since fatty acids are weak acids their ionization is small. Consequently, appreciable conversion of soap into fatty acid leads to a decided decrease in charge of the latex particles and hence also to a decided decrease in their mobility. With still further decrease in *p*H all soap is removed and the ionization of the fatty acids is strongly repressed. Hence, the charge and mobility drop rapidly and the latex system becomes sufficiently destabilized to precipitate rubber. From what has been experienced with coagulation difficulties below a *p*H of 5.1 it would appear that it is not necessary to reduce the charge or mobility to zero in order to precipitate rubber. Rather, it is only necessary to reduce the charge and hence mobility to a low critical value, which in this case lies at a *p*H of about 5 at $\mu = 0.150$.

(c) **Effect of Temperature.**—The effect of temperature on Type II latex mobility was studied in disodium phosphate solutions of $\mu = 0.144$ and *p*H 7.9–9.0 over the temperature range 1–35°. The results obtained are summarized in Table III. They can be represented by the linear equation

$$v = 2.40 + 0.107t \qquad (2)$$

as may be seen from the comparison of the observed and calculated mobilities given in the last two columns of the table. This rate of change of mobility with temperature corresponds to an in-

Table III

Effect of Temperature on Electrophoretic Mobility of Type II Latex No. 3 at $\mu = 0.144$

Temp., °C.	Number of determinations	Mobility (microns-cm./volt-sec.) Observed	Calculated equation (2)
1.0	2	2.54 ± 0.03	2.51
20.0	2	4.48 ± .07	4.54
30.0	4	5.62 ± .06	5.61
35.0	1	6.13	6.15

crease of *ca.* 2% per degree at 25° which is of the same order of magnitude as the rate of change of mobility with temperature of ordinary ions.

(d) Effect of Ionic Strength and Electrolyte Type.—To obtain the effect of ionic strength on latex mobility measurements were made at 30° in disodium phosphate solutions ranging from 0.0077 to 0.240 molar, *i. e.*, μ = 0.023–0.720. The mobilities of Latex no. 3 thus obtained as a function of μ are shown in curve 2 of Fig. 4. From this curve it is seen that between $\mu = 0.023$ and $\mu = 0.058$ the mobility increases with ionic strength to go through a maximum at the latter value of μ. Beginning at $\mu = 0.058$ and up to about $\mu = 0.43$ the mobility decreases practically linearly with ionic strength. Thereafter the mobility becomes essentially independent of μ until an ionic strength of *ca.* 0.65 is reached. Beyond the latter value of ionic strength measurements of mobility become very difficult due to particle aggregation and consequent rubber segregation from the latex. However, the result obtained at μ = 0.72 shows, as might be expected, that at salt concentrations very near to those causing rubber separation a very sharp drop in mobility takes place. This particular result was obtained on a latex dispersion in disodium phosphate which did not segregate in the electrophoretic cell but separated on standing for several hours after completion of the run.

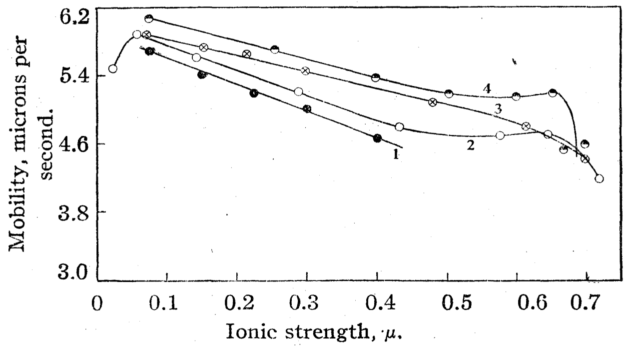

Fig. 4.—Effect of ionic strength on mobility of Latex no. 3 at 30° (*p*H range 8.2–9.0): ○, Na_2HPO_4; ⊗, Na_2HPO_4–Na_2SO_4 (1:3 moles); ●, Na_2HPO_4–NaCl (1:4.5 moles); ◓, Na_2HPO_4–KCl (1:4.5 moles).

Similar data for Latex no. 7 are shown in curve 2 of Fig. 5. These data indicate in essence a similar dependence of mobility on ionic strength except that the maximum appears at a higher value of μ.

In order to ascertain whether ionic strength alone or electrolyte specificity as well are factors determining mobility variation a series of experiments were carried out on latex dispersions in Na_2HPO_4–NaCl, Na_2HPO_4–Na_2SO_4 and Na_2HPO_4–KCl mixtures. These electrolytes were used in presence of Na_2HPO_4 because the desired *p*H control could not be obtained with NaCl, Na_2SO_4 and KCl alone. In using these salts the molar ratio of Na_2HPO_4 to the second salt was kept constant in each series but the over-all concentration of the solution was varied to obtain different ionic strengths. The results obtained are depicted in curves 1, 3 and 4 of Fig. 4 and curves 1 and 3 of Fig. 5. In both figures the measurements on the Na_2HPO_4–NaCl solutions could not be carried to higher ionic strengths than those shown due to rubber segregation from the latex–salt mixtures.

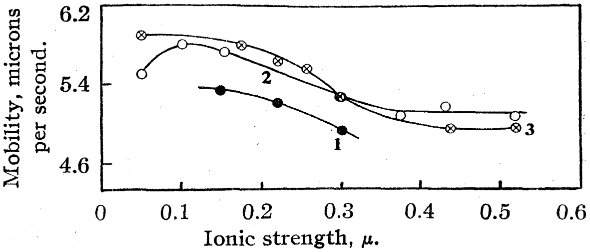

Fig. 5.—Effect of ionic strength on mobility of Latex no. 7 at 30° (*p*H range 7.9–8.7): ○, Na_2HPO_4; ⊗, Na_2HPO_4–Na_2SO_4 (1:3 moles); ●, Na_2HPO_4–NaCl (1:4.5 moles).

From the positions of the various curves in the two figures it is quite evident that ionic strength alone is not the factor responsible for mobility variation, but that the nature of the electrolyte as well is significant. At any given ionic strength NaCl is most effective in lowering mobility, followed in turn by Na_2HPO_4, Na_2SO_4 and KCl. This order is the same as that observed in this laboratory for the effectiveness of the various electrolytes as precipitating agents for rubber from Type II latex. However, the specificity of electrolyte action is not as pronounced as Figs. 4 and 5 would tend to suggest. If the data in Fig. 4 for Latex no. 3 be replotted to show mobility as a function of total cation concentration in equivalents per liter we obtain Fig. 6. Plotted in this manner the data for Na_2HPO_4 and Na_2HPO_4–NaCl can be made to fall along the same curve but the data for Na_2HPO_4–Na_2SO_4 and Na_2HPO_4–KCl mixtures still remain displaced. Essentially the same picture is given by a replot of the data for Latex no. 7 except that here the Na_2HPO_4–

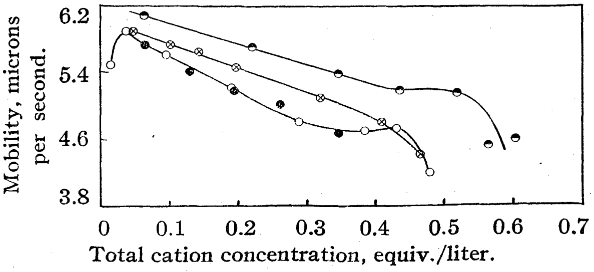

Fig. 6.—Mobility of Latex no. 3 as a function of total cation concentration at 30° (*p*H range 8.9–9.0): ○, Na_2HPO_4; ⊗, Na_2HPO_4–Na_2SO_4 (1:3 moles); ●, Na_2HPO_4–NaCl (1:4.5 moles); ◓, Na_2HPO_4–KCl (1:4.5 moles).

Na_2SO_4 data lie closer to those for Na_2HPO_4 and Na_2HPO_4–NaCl. These observations suggest, at least in the case of the electrolytes containing sodium only, that to a large degree the lowering in mobility is a function of the total cation concentration present but that this action of the sodium ions is modified by the nature of the particular co-ion with which it is associated.

The less effective action of potassium chloride in lowering mobility is in all probability due to exchange of sodium ions in the adsorbed soap layer for potassium. Potassium soaps are much more difficult to salt out from a latex than sodium soaps and this fact may be taken to indicate that electrolytes are less effective in desorbing potassium than sodium soaps. Consequently, the charge on latex particles in presence of potassium ions is preserved more effectively and the mobility does not fall as rapidly with ionic strength as in presence of sodium ions alone.

It is to be expected that all the curves in Fig. 4 and those in Fig. 5 should extrapolate to common values of mobility at zero ionic strength. The course of curves 1, 3 and 4 in Fig. 4 and of curves 1 and 3 in Fig. 5 is such as to suggest that the common extrapolation limit cannot be obtained by prolongation of these curves to $\mu = 0$. Instead, curves 2 in these figures suggest that the extrapolation limit may be obtained by passage of the v–μ curves through a maximum followed by a drop in mobility as $\mu = 0$ is approached. In other words, in all probability the effect of ionic strength is first to increase the mobility at low values of ionic strength up to a maximum value for each electrolyte, followed thereafter by a decrease along the lines shown in the figures.

The initial rise in mobility at low ionic strengths may be due primarily to adsorption of anions. It is felt that the ionic strengths at which this increase takes place are still too low to lead to any significant desolvation of the soap. At the same time the effect of the ionic atmosphere and possible cation adsorption, which would operate to decrease the mobility, come into play, and hence the mobility goes through a maximum and then decreases. The levelling off in this decrease, setting in at μ values of 0.3–0.4, may be due to the counterbalancing action of desolvation, which would tend to increase charge density and hence mobility. The final sharp drops in mobility are definitely due to desorption of soap with attendant discharge of the latex particles. Surface tension studies have shown that near the coagulation point this desorption of soap takes place quite sharply and, hence, the drop in mobility should also be quite sharp near the rubber precipitation point as is actually the case.

Mobility of Creamed and Redispersed Latex.—On addition of a large quantity of sodium chloride to a latex, the rubber precipitated out is highly aggregated and cannot be redispersed. However, by controlled addition of salt it is possible to "cream" a latex, remove part of the serum and then to redisperse the "cream" in water or an electrolyte solution. In such a redispersion the soap which was desorbed in the creaming is not entirely readsorbed, as is evidenced by the comparatively low surface tension of the redispersed latex. It is also quite probable that the mean particle size of the redispersed latex is larger than that present in the original colloid. It is of some interest, therefore, to ascertain how the mobility of the latex is modified by the changes accompanying creaming and redispersion.

A sample of latex was creamed with sodium chloride and after filtering off serum the rubber was redispersed in a disodium phosphate solution of $\mu = 0.145$. The total solids content of the redispersion was about that of the original latex, although some of the rubber did not redisperse. The mobility was then measured again at 30°. It was thus found that the mobility of the redispersed latex was 6.10 microns/second as against 5.62 for the untreated latex; *i. e.*, the mobility of the redispersed latex was about 8.5% higher than the untreated latex at the same ionic strength, temperature and *p*H.

Mobility of Frozen Latex.—Previous work in this Laboratory[4] has indicated that latex may be destabilized and even coagulated by freezing. If the latex is frozen and then rewarmed before any appreciable coagulation occurs, a large number of particles of microscopic size can be detected in the dispersion and the surface tension is found to have dropped to 30–40 dynes/cm. These observations indicate that in the freezing and rewarming operation the particle size is increased and that part of the soap is desorbed.

To ascertain what effect these changes have on mobility latex solutions were frozen, rewarmed and then made up in disodium phosphate solutions of $\mu = 0.145$ as described. A number of mobility determinations were then carried out at 30° on different frozen samples of the same latex. The results thus obtained in ten separate determinations gave for the mobility $v = 6.24 \pm 2.7\%$ as against 5.62 microns/second for the unfrozen samples. This 11% increase in mobility here and the 8.5% increase in the mobility of creamed and redispersed latex are off-hand surprising. However, they may be accounted for by the increase in the particle size attending the above manipulations. Although both creaming and redispersion and freezing and rewarming result in loss of soap by the rubber, nevertheless the higher mobility of the resulting particles indicates that these carry upon them more soap and, hence, a higher charge. By increasing the size of the particles at total constant concentration the number of these is considerably decreased, and apparently whatever soap is available is sufficient to yield a higher surface soap concentration per particle than in the original latex. To test this supposition it would be of in-

---

(4) Results to be published at a future date.

terest to investigate the mobility of latex dispersions with added soap.

Mobility of Soap.—Since latex owes its mobility primarily to the charge imparted to it by the adsorbed soap it is of considerable interest to see how the mobility of soap itself compares with that of the latex particles. To obtain the mobility of soap a single measurement was made upon a 0.01 molar solution of RS soap chips in 0.004 molar sodium chloride at 30° with phenolphthalein as an indicator. The moving boundaries were not as sharp here as with latex; however, the experiment could be carried out to yield for the mobility of the soap 6.31 microns per second. Although the experimental conditions were quite different in the measurements of the latex and soap mobilities, nevertheless it is of importance that the mobilities of the soap and the latex are of the same order of magnitude. In fact, it would not be too surprising to find that they are more or less identical under comparable experimental conditions since it has been shown that the mobilities of proteins and various materials coated with proteins are the same.

The *Zeta* Potentials of Latex.—Type II GR-S latex particles are known to be spherical in shape and of the order of 800–1000 Å. in diameter. For such particles the *zeta* potential, Z, is related to the mobility by the expression[5] at 30° for v in

$$Z = 4\pi\eta v/D = -1.18 \times 10^{-2}\, v \qquad (3)$$

microns per second and where η is the viscosity coefficient of the medium and D is the dielectric constant. The minus sign is included since in fact v is negative. In view of the direct proportionality between Z and v all the conclusions drawn with respect to variation of mobility at 30° with respect to solids, *p*H, ionic strength and type of electrolyte apply equally well to the effect of these on *zeta* potentials.

The effect of temperature on *zeta* potentials of Latex no. 3 at $\mu = 0.144$ and average *p*H of about 8.5, can be obtained from the combination of the mobility data summarized by equation (2) and the effect of temperature on viscosity and dielectric constant. For lattices as dilute as those used here the viscosity is essentially the same as that of pure water. The dielectric constants of water as a function of temperature have been given by Wyman.[6] The *zeta* potentials thus calculated at various temperatures from 0 to 40° are shown in Fig. 7. From this plot it may be seen that the *zeta* potentials of the latex increase continually over the entire temperature range. The increase is quite rapid between 0 and 20°, and then becomes much more gradual thereafter. This increase in *zeta* potentials with temperature is again in accord with the observations in this laboratory, to be published later, that Type II latex shows increased stability in presence of added electrolytes at higher temperatures than at lower ones.

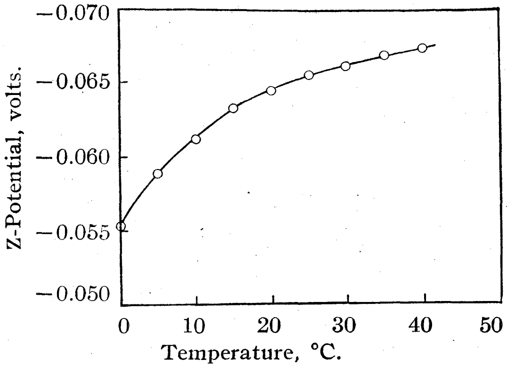

Fig. 7.—Effect of temperature on Z-potentials of Latex no. 3 at $\mu = 0.144$ and *p*H 7.9–9.0.

Summary

A very simple procedure is described for measuring the electrophoretic mobility of latex by the moving boundary method. This method has been applied to the determination of the mobilities of Type II GR-S latex as a function of total solids, *p*H, ionic strength, electrolyte type at 30° and of temperature between 0 and 35°.

The effects of creaming and redispersion and of freezing and thawing of lattices on mobility have also been determined.

The above data were used to estimate the isoelectric point of latex and to calculate the *zeta* potentials as a function of the various variables.

Molecular Structure and Adsorption Sequences of Carotenoid Pigments

BY HAROLD H. STRAIN

The sequence in which carotenoid pigments form bands in Tswett adsorption columns depends upon the adsorbent and the solvent.[1,2,3] This dependence of the relative adsorbability of carotenoid pigments upon the different conditions in the columns indicates that there is a complex relationship between adsorbability and molecular structure.

From the viewpoint of kinetics, separation of mixtures in Tswett columns is contingent upon a reversible distribution of the solutes between the solvent and the adsorbent. Variation of the adsorption sequence with different conditions must result from disproportionate variation of the attractive forces among the adsorbent, the solvent and the solutes. In one instance, the adsorption of fucoxanthin and zeaxanthin in columns of sugar, variation of the attraction between solvent and solutes, as indicated by variation of solubility, has seemed responsible for alteration of the adsorption sequence.[2] Other conditions that might alter the adsorption sequence are variation of the adsorbability of particular structural groups of the carotenoid molecules with different solvents or adsorbents; changes in the structure of the carotenoid molecules induced by adsorbents or solvents; variation in the tendency of the solvents to combine with the adsorbent and thus to displace the adsorbed molecules or particular groups of the adsorbed molecules; etc.

In order to gain further insight into the relationship between the structure and the relative adsorbability of organic molecules, adsorption sequences of several carotenoid pigments have been determined under different conditions. These adsorption sequences have then been compared with the principal structural features of the pigment molecules, with the properties of the adsorbents and solvents and with spectral absorption properties of the pigments. In this way clues to the relative adsorbability of various structural groups have been obtained. Conversely, conditions that determine relative adsorbability and separability of similar organic compounds have been more accurately defined.

Materials and Methods

Natural polyene hydrocarbons, the carotenes, and their hydroxy and oxo derivatives, the xanthophylls, were isolated from common sources by means of partition and chromatographic adsorption methods. These polyene pigments, their sources and the method of preparation, most of which have been described previously,[1,2,4,5] are summarized in Table I.

TABLE I

CAROTENOID PIGMENTS, THEIR SOURCES AND METHOD OF PURIFICATION

Pigments	Sources	Adsorbents	Solvents
	Xanthophylls		
Rhodoxanthin	*Cryptomeria japonica*	Sugar	Pet. ether + 4% acetone
Zeaxanthin	Calyx of *Physalis*	Magnesia	Dichloroethane
Lutein	Leaves of barley	Magnesia	Pet. ether + 25% acetone
Cryptoxanthin	Calyx of *Physalis*	Magnesia	Dichloroethane
	Carotenes		
Lycopene	Tomatoes	Magnesia	Pet. ether + 4% acetone
β-Carotene	Carrots	Magnesia	Pet. ether + 4% acetone
α-Carotene	Carrots	Magnesia	Pet. ether + 4% acetone

Rhodoxanthin, a diketo-dehydro-β-carotene was prepared from the red, winter needles of *Cryptomeria japonica*.[6] It was purified by adsorption from petroleum ether solution in columns of sugar and in columns of Celite 501.

Molecules of each of these carotenoids have many features in common.[7,8] Each pigment contains forty carbon atoms which form similar skeletal structures. The chromophoric group of each pigment consists of eleven or more double bonds at least ten of which occur in conjugation. Oxygen atoms in the four xanthophylls occupy the same relative positions in the molecule; hence, variation of the adsorption sequences due to differences in the location of the oxygen atoms in the molecule was avoided.

Except for lycopene, which has aliphatic instead of cyclic terminal structures, molecules of the several carotenoid pigments differ from one another only in the number and arrangement of the double bonds and in the number and function of the oxygen atoms. A summary of the principal structural features of the pigments is presented in Table II.

TABLE II

PRINCIPAL STRUCTURAL FEATURES OF THE CAROTENOID PIGMENTS

Double bonds are indicated by "="; conjugated double bonds by "conj. ="

Pigment	Formula	=	Conj. =	Conj. C=O	—OH	Rings
Rhodoxanthin	$C_{40}H_{50}O_2$	14	12	2	0	2
Zeaxanthin	$C_{40}H_{56}O_2$	11	11	0	2	2
Lutein	$C_{40}H_{56}O_2$	11	10	0	2	2
Cryptoxanthin	$C_{40}H_{56}O$	11	11	0	1	2
Lycopene	$C_{40}H_{56}$	13	11	0	0	0
β-Carotene	$C_{40}H_{56}$	11	11	0	0	2
α-Carotene	$C_{40}H_{56}$	11	10	0	0	2

Adsorbents employed for determination of the adsorption sequences of the carotenoid pigments were powdered sugar (confectioners powdered sugar with 3% starch to prevent caking, grade XXXXXX[2]), heat-treated siliceous earth (Celite 501) and activated magnesium oxide (Micron

Brand No. 2641) which was usually mixed with twice its weight of Celite in order to accelerate filtration.[1,3,4]

Adsorption columns were prepared by pressing successive portions of the dry adsorbent into the adsorption tubes (1.3 × 25 cm.). Usually a dilute solution of two or more of the pigments in petroleum ether (about 1 mg. per 100 ml.) was filtered through the adsorption column until the uppermost 3 to 5 mm. of the adsorbent was saturated with the pigments (suction about 0.5 atmosphere). Then fresh solvent or the appropriate solvent mixture was filtered through the column until the bands of adsorbed pigment had migrated from 3 to 15 or 20 cm. Comparison of the chromatograms developed in this way revealed the adsorption sequences of the pigments.

Results

Effect of Different Adsorbents on the Adsorption Sequence.—In columns of different adsorbents, mixtures of carotenes and xanthophylls yielded dissimilar adsorption sequences as is shown in Table III. In all the experiments summarized in this table, the major variable was the adsorbent; hence, the several adsorption sequences must be attributed to selective attraction between the adsorbents and the pigments.

TABLE III

ADSORPTION SEQUENCES OF CAROTENOID PIGMENTS IN COLUMNS OF SUGAR, OF CELITE AND OF MAGNESIA

The solvent was petroleum ether plus 4 to 25% acetone. The most adsorbed pigment is listed at the top of each column and the least adsorbed pigment at the bottom. Brackets indicate pigments that were incompletely separated.

Sugar	Celite	Magnesia
(*top of column*)	(*top of column*)	(*top of column*)
Zeaxanthin	Zeaxanthin	Rhodoxanthin
Lutein	Lutein	Lycopene
Cryptoxanthin	Rhodoxanthin	Zeaxanthin
Rhodoxanthin	Cryptoxanthin	Lutein
Lycopene	Lycopene	Cryptoxanthin
β-Carotene	β-Carotene	β-Carotene
α-Carotene	α-Carotene	α-Carotene

Inseparability of the carotenes in columns of sugar and in columns of Celite as indicated in Table III is due, in part, to their weak adsorbability relative to their concentration. At extremely low concentration carotenes are very weakly adsorbed on Celite from petroleum ether solution. Comparison of the amount of colorless solvent obtained by adsorption of equally dilute solutions of each pigment in separate columns revealed lycopene to be more adsorbed than β-carotene and α-carotene. In order to observe this separation one must adsorb the pigments from petroleum ether solutions so dilute that the bands in the columns are barely visible.

Effect of Different Solvents on the Adsorption Sequence.—Use of different solvents for development of the chromatograms in columns of a given adsorbent also gave different adsorption sequences. Results obtained in columns of powdered sugar are summarized in Table IV. Except for the variation of the adsorbability of rhodoxanthin, the different solvents had little effect upon the relative adsorbabilities of the pigments.

TABLE IV

ADSORPTION SEQUENCES OF CAROTENOID PIGMENTS IN COLUMNS OF SUGAR WHEN DIFFERENT SOLVENTS WERE EMPLOYED FOR DEVELOPMENT OF THE CHROMATOGRAMS

Petroleum ether	Petroleum ether plus 4% acetone	Petroleum ether plus 0.5% propanol
(*top of column*)	(*top of column*)	(*top of column*)
Rhodoxanthin	Zeaxanthin	Zeaxanthin
Zeaxanthin	Lutein	Lutein
Lutein	Cryptoxanthin	Cryptoxanthin
Cryptoxanthin	Rhodoxanthin	Rhodoxanthin
Lycopene	Lycopene	Lycopene
β-Carotene	β-Carotene	β-Carotene
α-Carotene	α-Carotene	α-Carotene

Use of different solvents for development of the chromatograms in columns of Celite yielded the results summarized in Table V. With minor exceptions these results are similar to those observed in columns of sugar. In the columns of Celite the presence of propanol in petroleum ether had an unusual effect upon the adsorbability of rhodoxanthin relative to the adsorbability of zeaxanthin and lutein. When these pigments were adsorbed from solution in petroleum ether rhodoxanthin formed a band above the zeaxanthin and lutein. Then as the chromatogram was developed with petroleum ether containing 0.5% propanol the rhodoxanthin appeared below the zeaxanthin and lutein, but upon continued washing of the column with the petroleum ether plus propanol the rhodoxanthin band widened and migrated more slowly so that the zeaxanthin and lutein moved below it.

TABLE V

ADSORPTION SEQUENCES OF CAROTENOID PIGMENTS IN COLUMNS OF CELITE 501 WHEN DIFFERENT SOLVENTS WERE EMPLOYED FOR DEVELOPMENT OF THE CHROMATOGRAMS

Petroleum ether	Petroleum ether plus 4% acetone	Petroleum ether plus 0.5% propanol
(*top of column*)	(*top of column*)	(*top of column*)
Rhodoxanthin	Zeaxanthin	Rhodoxanthin
Zeaxanthin	Lutein	Zeaxanthin
Lutein	Rhodoxanthin	Lutein
Cryptoxanthin	Cryptoxanthin	Cryptoxanthin
Lycopene	Lycopene	Lycopene
β-Carotene	β-Carotene	β-Carotene
α-Carotene	α-Carotene	α-Carotene

In columns of magnesia polar solvents in petroleum ether did not alter the adsorbability of rhodoxanthin relative to the other carotenoid pigments as is shown by the results presented in Table VI.

Effect of Solvents and Adsorbents on Molecular Structure.—Dissolved in polar solvents, many ketonic carotenoid pigments exhibit spectral absorption maxima that are less distinct than the absorption bands of the same pigments

TABLE VI

ADSORPTION SEQUENCES OF CAROTENOID PIGMENTS IN COLUMNS OF MAGNESIA WHEN DIFFERENT SOLVENTS WERE EMPLOYED FOR DEVELOPMENT OF THE CHROMATOGRAMS

Petroleum ether	Petroleum ether plus 25% acetone	Petroleum ether plus 4% propanol
(*top of column*)	(*top of column*)	(*top of column*)
⎡Rhodoxanthin	Rhodoxanthin	Rhodoxanthin
⎢Lycopene	Lycopene	⎡Zeaxanthin
⎣Zeaxanthin	Zeaxanthin	⎣Lycopene

Cryptoxanthin	Cryptoxanthin	Cryptoxanthin
β-Carotene	⎡β-Carotene	⎡β-Carotene
α-Carotene	⎣α-Carotene	⎣α-Carotene

dissolved in nonpolar solvents. This effect, which is not pronounced with carotenes or with hydroxy carotenes,[5] indicates an alteration of the chromophoric structure of the ketonic pigments by the polar solvents.[2,9,10] Analogous effects of polar solvents upon the spectral absorption properties of rhodoxanthin are shown by the characteristic spectral absorption curves of Fig. 1. Compared to the characteristic absorption curves of other xanthophylls plotted on the same scale[2,5] the absorption curves of rhodoxanthin exhibit remarkably indistinct absorption maxima which are shifted to longer wave lengths by the polar solvent.

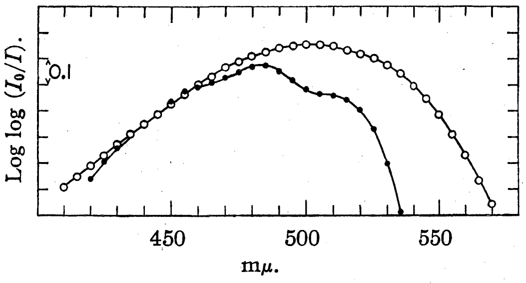

Fig. 1.—Characteristic spectral absorption curves of rhodoxanthin measured at the same concentration in petroleum ether and in 95% ethanol: ●, in petroleum ether; O, in ethanol.

Adsorption of rhodoxanthin either on solids or on liquids also alters the spectral properties of the pigment. Adsorbed on sugar or Celite or magnesia from solution in petroleum ether the keto carotenoid forms a violet-red band; the other carotenoids form orange or orange-red bands. Adsorbed on water droplets by shaking a yellow petroleum ether solution with water, rhodoxanthin causes the emulsion to appear pink. As the emulsion separates, the adsorbed rhodoxanthin liberated at the interface again forms a yellow solution in the petroleum ether.

Discussion

Variation of the adsorbability of the carotenoid pigments in columns of different adsorbents (Table III) can be related to the preferential attraction of the adsorbents for particular structural units in these organic molecules. In columns of sugar adsorbability of the carotenoids is determined to a very limited extent by the conjugated double bonds. Comparison of the structural characteristics of the carotenoids (Table II) with the adsorption sequence observed in columns of sugar (Table III) shows that the single hydroxyl group of cryptoxanthin causes this pigment to be much more adsorbed than the parent hydrocarbon, β-carotene, or the related hydrocarbon lycopene, which contains two additional double bonds. This single hydroxyl group also causes the cryptoxanthin to be much more adsorbed than rhodoxanthin which has three additional unsaturated linkages. Zeaxanthin and lutein, which differ only in the arrangement of one double bond in the molecule, are separable with difficulty in columns of sugar. On the basis of these results sugar is useful as an adsorbent for the separation of carotenoids which differ in the number of hydroxyl or keto groups; it is less useful for separation of pigments which differ only in total unsaturation or in the arrangement of the double bonds.

In columns of magnesia adsorbability of the carotenoids is determined to a large degree by the conjugated double bonds. Comparison of the molecular characteristics of the carotenoids (Table II) with the adsorption sequences (Table III) shows that with magnesia adsorbability of the carotenes increases markedly with the number and with the arrangement of the double bonds, even a small difference in the conjugation of the double bonds being reflected in an appreciable difference in adsorbability as with β-carotene and α-carotene. By contrast with the results obtained in columns of sugar, the two non-conjugated double bonds in lycopene cause this pigment to be more adsorbed than zeaxanthin. These two double bonds in lycopene have, therefore, a slightly greater influence on adsorbability than the two hydroxyl groups in zeaxanthin. Rhodoxanthin with fourteen conjugated, unsaturated linkages is even more adsorbed than lycopene. The small difference between the arrangement of one double bond in zeaxanthin and lutein which has little effect upon the adsorbability of these two pigments in columns of sugar has, by contrast, a great effect upon their adsorbability in columns of magnesia in which they are readily separable. From these experiments, magnesia is much more effective than sugar as an adsorbent for separation of carotenoid pigments which differ principally in the number and arrangement of their double bonds. With respect to adsorption capacity and to the specificity of the adsorption Celite is intermediate between sugar and magnesia (Table III).

Differences between the relative adsorbabilities of carotenoids on sugar and on magnesia must depend upon the nature or quality of the attractive forces of these two adsorbents. Strongly polar, neutral powdered sugar (with eight hydroxyl

---

[10] Polgar and Zechmeister, THIS JOURNAL, **66**, 186 (1944).

groups and three additional oxygen atoms comprising more than 50% of the molecule) probably attracts the polar hydroxyl groups of the xanthophylls and repels the large, non-polar hydrocarbon portions. Strongly alkaline magnesia, on the other hand, must attract the conjugated polyene system of the xanthophylls as well as the hydroxyl groups.

Polar solvents, which affect the relative adsorbability and the spectral absorption properties of rhodoxanthin, may alter the molecular structure of this pigment, probably through variation of the proportions of the enolic and ketonic modifications. Decrease of the relative adsorbability of rhodoxanthin in columns of sugar by polar solvents (Table IV) corresponds to a decrease in the enolic properties of the keto carotenoid. The slight effect of polar solvents on the relative adsorbability of rhodoxanthin in columns of magnesia (Table VI) indicates that a decrease in enolic properties must be accompanied by an increase in ketonic or polyene properties. This latter conclusion is supported by the effect of polar solvents on the spectral absorption properties of rhodoxanthin as shown already in Fig. 1. Increase in the spectral absorption capacity and shift of the spectral absorption maxima to longer wave lengths by polar solvents are equivalent to an intensification of the ketonic or polyene properties.

In view of the affinity of adsorbents for particular molecular structures, the adsorbability of a complex molecule, as represented by the adsorption isotherm, may be the sum of the adsorbabilities of all the reactive groups. Prediction of the effect of any one group upon the adsorbability of a complex molecule will require some knowledge of the relation between this group and the other reactive centers in the molecule. But it must be remembered that the adsorbability may be influenced by the effect of solvents upon the molecular structure of the adsorbed substance and by the affinity among the solvent, the solute and the adsorbent. Solvents that increase the proportion of those structural groups for which the adsorbent has greatest affinity intensify the adsorbability and *vice versa.* Adsorbability is, as a rule, inversely proportional to solubility. Pronounced affinity between solvent and adsorbent tends to diminish adsorbability of the solute.

These effects of solvents and adsorbents upon the adsorbability of different groups in an organic molecule point the way to new improvements and applications of the chromatographic adsorption method. Information about the adsorbability of particular molecular structures serves as a guide in the selection of solvents and adsorbents for separation of mixtures of various organic compounds and aids prediction of the adsorbability of complex molecules. Solvents and adsorbents may be varied so that adsorption of similar molecules involves the structural features in which the greatest differences reside. Under these conditions, maximum separation of similar substances may be expected.

Summary

Relative adsorbability of seven carotenoid pigments was determined by observation of the adsorption sequence of these polyene compounds in Tswett columns of powdered sugar, of Celite and of magnesia. Petroleum ether, petroleum ether plus acetone and petroleum ether plus propanol were used for development of the chromatograms.

The seven carotenoid pigments, rhodoxanthin, zeaxanthin, lutein, cryptoxanthin, lycopene, β-carotene and α-carotene, are related structurally in such a way that certain molecular features may be regarded as constant while others vary. Comparison of the observed adsorption sequences with the molecular structures of the pigments indicated that the relative adsorbability is determined to a large extent by the selective affinity of the adsorbents for different groups or portions of the pigment molecules. Powdered sugar attracts preferentially the polar hydroxyl groups of the xanthophylls; it has little affinity for the unsaturated hydrocarbon portions of carotenes or xanthophylls. Magnesia, on the other hand, attracts the unsaturated portions of both carotenes and xanthophylls as well as the hydroxyl groups of the xanthophylls. Adsorbents that are most effective for the separation of mixtures of similar carotenoid pigments in Tswett columns attract preferentially those portions of the pigment molecules which contain the greatest structural differences.

Solvents that have a pronounced effect upon the absorption spectrum of the diketonic rhodoxanthin also have a great effect upon the relative adsorbability of this pigment.

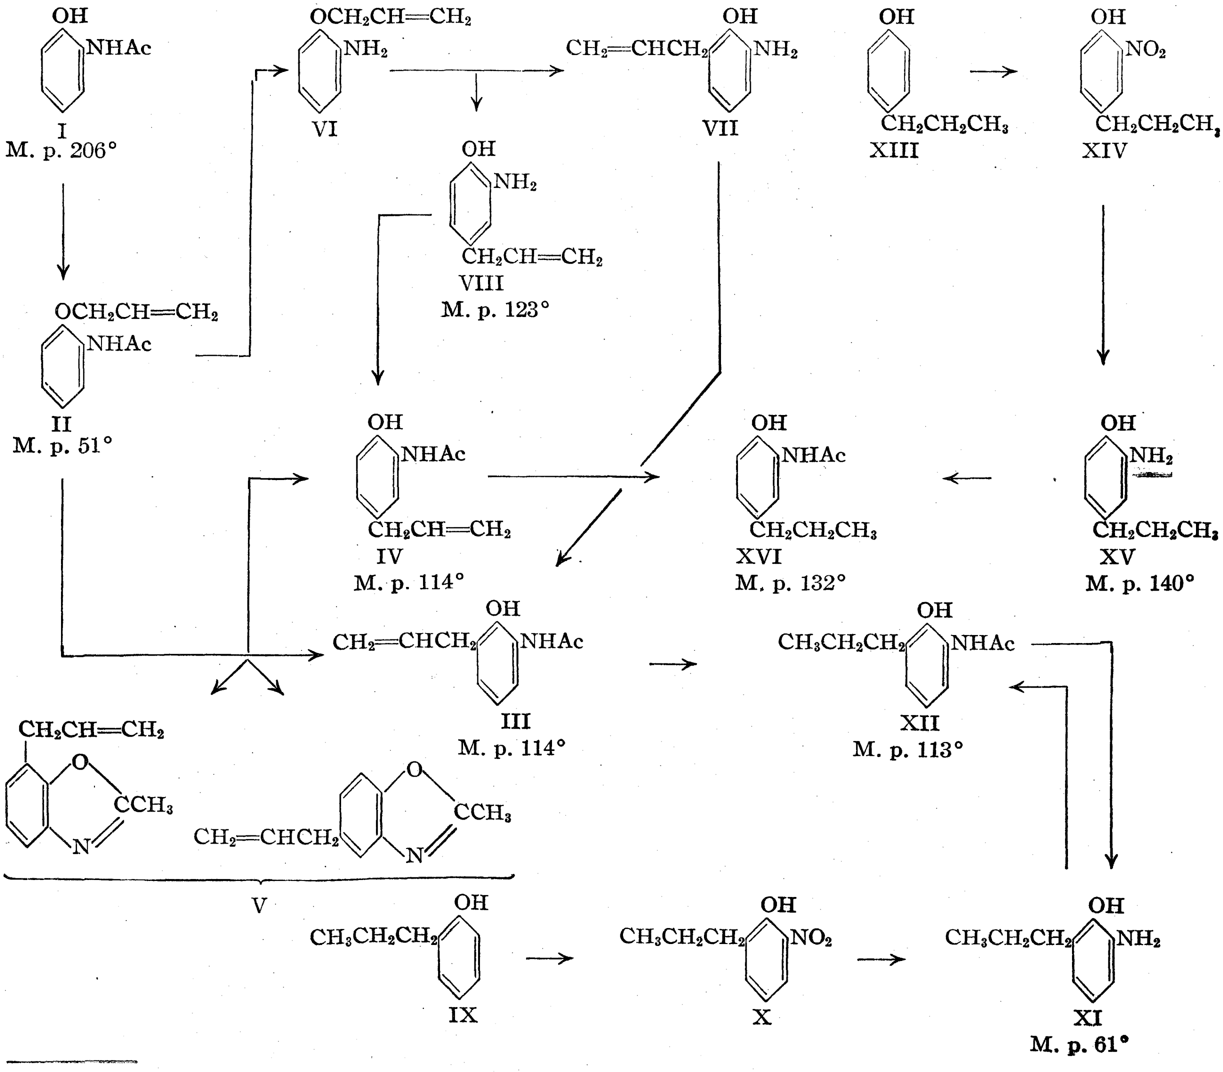
Partial *para*-Migration in the Allylic Rearrangement of *o*-Acetamidophenyl Allyl Ether and of *o*-Aminophenyl Allyl Ether

BY BURRIS D. TIFFANY[1]

In the rearrangement of allyl ethers of phenolic compounds, the allyl group usually migrates exclusively to the *ortho* position if one is free, and the product is obtained generally in good yield.[2] The allylic rearrangement seemed, therefore, to provide a likely avenue for the synthesis of 2-amino-6-propylphenol (XI) which was required in connection with another problem. It was found, however, that the rearrangement of both *o*-acetamidophenyl allyl ether (II) and *o*-aminophenyl allyl ether (VI) gave products which were mixtures of the *ortho*- and *para*-rearranged isomers. Other examples of partial rearrangement to the *para* position are known[2] and it may be significant that each of these involves compounds containing strongly *ortho–para* directing groups, adjacent to the hydroxyl.

When *o*-acetamidophenyl allyl ether (II) was heated in dimethylaniline at 190° for thirty minutes, it was possible to isolate 50% of 2-acetamido-6-allylphenol (III) and 7.6% of the *para* isomer (IV) (*o* to *p* ratio = 6.5:1). Treatment of the acetamido compound at such elevated temperatures, however, also caused the loss of at least 10% of the product, probably by cyclization to 2-methyl-5-allyl-benzoxazole and/or the 7-allyl isomer (V).



---

[1] Present address: Department of Chemistry, University of Wisconsin, Madison, Wisconsin.

[2] Tarbell, "Organic Reactions," Vol. I, John Wiley and Sons, Inc., New York, N. Y., 1944, p. 8.

To avoid the loss through cyclization when the acetyl group was present, *o*-aminophenyl allyl ether (VI) was rearranged. When it was heated in diphenyl ether at 190° for forty minutes and the resulting mixture of aminophenols acetylated, 42% of III and 21% of IV were isolated (*o* to *p* ratio = 2:1). The acetylation of the amino group before the separation of the isomers could be carried out was made necessary by the extreme sensitivity of the aminophenols to air oxidation.

The isomeric acetamido allylphenols (III) and (IV) were reduced to their corresponding propyl derivatives (XII) and (XVI) and the structures of these two compounds proved by synthesis. *o*-Propylphenol (IX) was nitrated *ortho* to the hydroxyl to give X. The nitro group was reduced and the resulting aminophenol (XI) acetylated. The product was shown by mixed m. p. determinations to be identical with XII prepared through the allylic rearrangement. The same procedure beginning with *p*-propylphenol was used to confirm the structure of 2-acetamido-4-propylphenol (XVI).

Acknowledgments.—The author is indebted to Doctors M. A. Spielman and W. J. Close for their assistance and encouragement and to Mr. M. Freifelder for the hydrogenations reported. Furthermore, he wishes to thank Mr. E. F. Shelberg, Mrs. Jane Wood, and Messrs. B. F. Claeboe and R. H. Berg of the Microanalytical Laboratory for their coöperation in providing he microanalytical data.

Experimental Part

***o*-Acetamidophenyl Allyl Ether (II).**—A mixture of 125 g. (0.82 mole) of *o*-acetamidophenol (I), 116 g. (0.82 mole) of anhydrous potassium carbonate, and 300 ml. of acetone was stirred vigorously to ensure intimate mixing. Then 100 g. (0.82 mole) of allyl bromide was added cautiously with stirring at a gentle reflux temperature. Refluxing and stirring was continued eight hours. About 800 ml. of water was added and the resulting mixture extracted with ether. The ether extract was washed with 10% aqueous sodium hydroxide, rinsed with water, dried, and concentrated to yield 156 g. (100%) of brown oil which crystallized completely, m. p. 49–51°. A sample recrystallized from pentane yielded white chalky crystals, m. p. 50–51.5°.

Anal. Calcd. for $C_{11}H_{13}NO_2$: C, 69.09; H, 6.85; N, 7.33. Found: C, 69.27; H, 6.57; N, 7.24.

2-Acetamido-6-allylphenol (III) and 2-Acetamido-4-allylphenol (IV). Method A. Rearrangement of *o*-Acetamidophenyl Allyl Ether.—A solution of 95.5 g. (0.50 mole) of *o*-acetamidophenyl allyl ether (II) in 200 ml. of dimethylaniline was heated at 190° for thirty minutes.[3] The reaction mixture was dissolved in ether and extracted with excess 20% aqueous sodium hydroxide. The alkaline extract was neutralized and extracted with ether. The ether extract was washed with dilute hydrochloric acid, rinsed with water, treated with Norit, dried, and evaporated under reduced pressure. A light brown solid weighing 69.1 g. resulted. By repeated fractional recrystallization from benzene about 35 g. of III, m. p. 112–114°, was obtained. The filtrates were concentrated, seeded with IV and allowed to crystallize slowly. The solution yielded a mixture of dense granular crystals (IV) dispersed among light fluffy needles (III). These were collected, dried, mixed with pentane, and shaken vigorously. The needles (III) were largely held in suspension and were decanted from the denser crystals (IV). Shaking and decanting was repeated several times. The whole process was repeated until the separation of III and IV was essentially complete.

A total of 47.5 g. (50%) of III, m. p. 112–114°, was obtained. Recrystallization from benzene yielded fine white needles, m. p. 113–114°.

Anal. Calcd. for $C_{11}H_{13}NO_2$: C, 69.09; H, 6.85; N, 7.33. Found: C, 69.17; H, 7.01; N, 7.25.

A total of 7.3 g. (7.6%) of IV, m. p. 112–114°, was obtained. Treatment with Norit and recrystallization from 2:1 benzene–cyclohexane yielded white platelets, m. p. 113–114°; mixed m. p. with III, 85–100°.

Anal. Calcd. for $C_{11}H_{13}NO_2$: C, 69.09; H, 6.85; N, 7.33. Found: C, 69.15; H, 6.54; N, 7.33.

By fractionating the oil isolated from the original ether solution, 8.4 g. (10%) of material boiling at 94–96° (1.7 mm.), n^{25}D 1.5444, was obtained. The analysis suggested that this was **2-methyl-5-allylbenzoxazole** and/or the **7-allyl isomer**.

Anal. Calcd. for $C_{11}H_{11}NO$: C, 76.27; H, 6.41; N, 8.10. Found: C, 76.07; H, 6.40; N, 8.29.

Method B. Rearrangement of *o*-Aminophenyl Allyl Ether (VI).—A solution of 14.9 g. (0.100 mole) of freshly distilled *o*-aminophenyl allyl ether (VI) (see below) in 30 ml. of diphenyl ether was heated to 190° in an oil-bath during fifteen minutes and maintained at 190–195° for thirty minutes under nitrogen. The reaction mixture was then dissolved in ether, extracted with 120 ml. of 1 *N* hydrochloric acid, and rinsed with water. The acid solution was treated with Norit, filtered and placed in a 1-liter three-necked flask equipped with a mechanical stirrer, two dropping funnels and a thermometer. With stirring and cooling to 20–25°, 15.3 g. (14.2 ml., 0.150 mole) of acetic anhydride and a solution of 17.6 g. (0.13 mole) of sodium acetate trihydrate in 20 ml. of water were added simultaneously over fifteen minutes so that the acetic anhydride was always in excess. Stirring was continued thirty minutes. The precipitate was collected, dissolved in ether, extracted with 40 ml. of 10% aqueous sodium hydroxide, and rinsed with water. The alkaline solution was made strongly acid and the brown oil which separated was extracted with ether. The ether solution was treated with Norit, dried, concentrated, diluted with Skelly B, and the precipitate collected. When dried it weighed 14.8 g. (77%). The two isomeric products were isolated in a manner similar to that described in Method A.

A total of 8.0 g. (42%) of III, m. p. 112–114°, was obtained. Recrystallization from benzene gave fine white needles, m. p. 113–114° and mixed m. p. with III from Method A, 113–114°.

A total of 4.1 g. (21%) of IV, m. p. 112–114°, was obtained. Treatment with Norit and recrystallization from 2:1 benzene–cyclohexane gave white platelets, m. p. 113–114° and mixed m. p. with IV from Method B, 113–114°.

***o*-Aminophenyl Allyl Ether (VI).**—A mixture of 114.6 g. (109.5 ml., 0.600 mole) of *o*-acetamidophenyl allyl ether (II) and 120 ml. of 6 *N* hydrochloric acid was refluxed for seventy minutes. The resulting solution was made alkaline with 20% sodium hydroxide solution and the red oil which separated was extracted with benzene. The benzene extract was washed with 10% sodium hydroxide solution, rinsed with water, dried, concentrated and fractionated to yield 81 g. (91%) of colorless oil, b. p. 84–85° at 0.6 mm., n^{25}D 1.5628, which darkened on standing.

Anal. Calcd. for $C_9H_{11}NO$: C, 72.45; H, 7.44; N, 9.40. Found: C, 72.57, 72.70; H, 6.91, 6.99; N, 9.52.

2-Amino-4-allylphenol (VIII).—A solution of 18.0 g. (0.120 mole) of freshly distilled *o*-aminophenyl allyl ether (VI) in 100 ml. of diphenyl ether was heated at 185–190° for six hours under nitrogen. The precipitate which formed on cooling was collected and recrystallized repeatedly from an ether–Skelly B mixture. Only about 1 g. of product, m. p. 121.5–123°, was obtained. It was very sensitive to air oxidation.

---

[3] Water distilled out during this heating period. Such a loss of water supports the structure proposed for V.

Anal. Calcd. for $C_9H_{11}NO$: C, 72.45; H, 7.44; N, 9.40. Found: C, 72.80; H, 7.34; N, 9.54.

The acetyl derivative of VIII was prepared in the usual manner. Its m. p. was 112–113°, its mixed m. p. with III was 85–100°, and its mixed m. p. with IV was 112–113°.

2-Acetamido-6-propylphenol (XII).—To 19.1 g. (0.100 mole) of 2-acetamido-6-allylphenol (III) in 250 ml. of 95% ethanol was added 0.2 g. of platinum oxide. The mixture was reduced in twenty minutes at 25° and 2 atmospheres pressure, filtered, diluted with 800 ml. water and the product, 18 g. (94%), collected. Recrystallized from 50% ethanol, its m. p. was 112–113° and its mixed m. p. with XII prepared by the acetylation of 2-amino-6-propylphenol was 112–113°.

Anal. Calcd. for $C_{11}H_{15}NO_2$: C, 68.36; H, 7.82; N, 7.25. Found: C, 68.36; H, 7.69; N, 7.24.

2-Acetamido-4-propylphenol (XVI).—About 0.02 g. of platinum oxide in 75 ml. of 95% ethanol was reduced to platinum black. Then 1.91 g. (0.010 mole) of 2-acetamido-4-allylphenol was added and reduced in thirty minutes at 25° and 2 atmospheres pressure. The reaction mixture was filtered and evaporated to dryness and the residue was recrystallized from benzene, 1.6 g. (83%), m. p. 129–131°. Recrystallized from 60% ethanol, it yielded white needles, m. p. 130.5–132°.

Anal. Calcd. for $C_{11}H_{15}NO_2$: C, 68.36; H, 7.82; N, 7.25. Found: C, 68.42; H, 7.78; N, 7.16.

2-Amino-6-propylphenol (XI).—A mixture of 1.93 g. (0.010 mole) of 2-acetamido-6-propylphenol (XII) in 3 ml. of 6 *N* hydrochloric acid was refluxed for ninety minutes and the product worked up in the usual manner to yield 1.45 g. (77%) of pink platelets of the hydrochloride. The free base was liberated from 0.50 g. of the hydrochloride yielding 0.40 g. (99%) of white platelets, m. p. 60–61°, after recrystallization from ether and Skelly B. The product was very sensitive to air oxidation and was collected under nitrogen.

Anal. Calcd. for $C_9H_{13}NO$: C, 71.54; H, 8.67; N, 9.27. Found: C, 71.48; H, 8.50; N, 9.47.

2-Nitro-6-propylphenol (X).—A solution of 20.4 g. (0.150 mole) of *o*-propylphenol in 20.4 g. (0.34 mole) of glacial acetic acid was added to a mixture of 40.8 g. (0.46 mole) of nitric acid (d. 1.42) and 61.2 g. (1.02 mole) of glacial acetic acid at −4 to −6° with stirring over a period of two hours. The reaction mixture was immediately poured with stirring onto 300 g. of ice. It was then extracted with benzene and the extract washed with water, 5% sodium bicarbonate, and finally with water. The brown benzene solution was steam distilled and the 3 liters of distillate extracted with benzene, dried, concentrated and vacuum distilled twice. The product was an orange oil, 7.0 g. (39%), b. p. 84–89° at 1.2 mm., $n^{25}D$ 1.5542.

Anal. Calcd. for $C_9H_{11}NO_3$: C, 59.66; H, 6.12; N, 7.74. Found: C, 59.80; H, 6.03; N, 7.66.

2-Amino-6-propylphenol Hydrochloride (XIa).—A solution of 7.0 g. of 2-nitro-6-propylphenol in 150 ml. of absolute ethanol was hydrogenated over 1.5 g. of Raney nickel in one hour at 2 atmospheres pressure and at room temperature. The product was isolated in the usual manner. It weighed 6 g. (83%), m. p. 208° (dec.). A sample was converted in 91% yield to 2-acetamido-6-propylphenol (XII), m. p. 111–112°. The mixed m. p. with XII prepared by the reduction of 2-acetamido-6-allylphenol (III) was 111–112°.

2-Acetamido-4-propylphenol (XVI).—To a solution of 9.4 g. (0.050 mole) of 2-amino-4-propylphenol hydrochloride[4] in 15 ml. of water, 6.1 g. (0.060 mole) of acetic anhydride and a solution of 7.5 g. (0.055 mole) of sodium acetate trihydrate in 9 ml. of water, were added simultaneously over five minutes with stirring and cooling. Stirring was continued ten minutes and the product, 9.4 g. (97%), m. p. 130–133°, was collected and dried. A sample recrystallized several times from 60% ethanol melted at 131–132°. Its mixed m. p. with XVI prepared by the reduction of 2-acetamido-4-allylphenol (IV) was 130.5–132°.

Summary

1. The thermal rearrangement of *o*-acetamidophenyl allyl ether has been shown to yield 2-acetamido-6-allylphenol and 2-acetamido-4-allylphenol in the ratio of 6.5 to 1.

2. The thermal rearrangement of *o*-aminophenyl allyl ether has been shown to yield 2-amino-6-allylphenol and 2-amino-4-allylphenol in the ratio of 2 to 1.

3. Several *o*-amino and *o*-acetamido alkyl phenols have been prepared and their structures proved by synthesis.

The Synthesis of D-Fructomethylose by Biochemical Oxidation[1]

BY LAURENS ANDERSON[2] AND HENRY A. LARDY

Two organisms of the genus *Acetobacter*, *A. xylinum* and *A. suboxydans*, have been widely used in the carbohydrate field for the oxidation of the grouping —CHOHCHOHCH$_2$OH to —CHOHCOCH$_2$OH. By this method a considerable number of ketose sugars have been prepared from the corresponding alcohols. As is the case with many biochemical procedures the application of the method is limited to compounds of proper steric makeup. According to "Bertrand's rule,"[3] *A. xylinum* will attack those alcohols in which the configurations about carbons two and three are the same. Hann, Tilden and Hudson[4] suggested that *A. suboxydans* is specific in its ability to oxidize polyalcohols of D-configuration. While these generalizations appear to hold for "normal" sugar alcohols ($C_nH_{n+2}(OH)_n$) of five or more carbon atoms, the results obtained with alcohols having a terminal methyl group have been anomalous. Thus Votoček, Valentin and Rác[5] were unable to oxidize L-rhamnitol (I) with *A. xylinum*, and Müller and Reichstein[6] obtained only slight oxi-

IV V

An opportunity to obtain further information about the action of *A. suboxydans* on this type of alcohol was afforded when in connection with research being carried out in this Laboratory on intermediates in glycolysis it was decided to study the properties of D-fructomethylose (V). This sugar was prepared by Morgan and Reichstein[7] in 12% over-all yield from D-fructose by a procedure involving a Freudenberg–Raschig desoxydation. Since it is the expected product of an *Acetobacter* oxidation of D-rhamnitol (IV) which recently became readily available through a synthesis worked out by Haskins, Hann and Hudson,[8] the possibility of preparing it in this way was investigated. It was found that in contrast to the desoxyhexitols previously cited D-rhamnitol is oxidized by *A. suboxydans* according to the "rules." The yield of ketose in this process is 80%; D-rhamnitol is obtained in 28% yield from methyl α-D-mannoside, the starting material, making the over-all yield 22%. The product has not been obtained in a state of purity comparable to that of the chemically prepared material but could be purified by standard methods. The chief difficulty stems from the fact that the sugar is a sirup which offers little hope of crystallization. The two processes are of about equal length (six steps) and difficulty.

The oxidation proceeded very rapidly, reaching completion in three days. The yield quoted is based on copper reduction analyses of the liquor. The results of these analyses were calculated in terms of glucose since no quantitative data are available for the fructomethyloses. The tagatomethyloses are said to have about 90% of the reducing power of glucose[9]; if the fructomethyloses behave similarly the calculated yield is somewhat low.

In view of the erratic behavior of other methyl hexitols in *Acetobacter* oxidations, it was necessary to obtain rigorous proof that the compound obtained was the anticipated D-fructomethylose. Although Reichstein and collaborators[7] prepared four of the eight possible 6-desoxy-2-ketohexoses, little information as to the properties of these sugars was published by this group. It was noted that they reduced Fehling solution in the cold and were otherwise very reactive.

The sirupy sugar obtained in this investigation caused the appearance of cuprous oxide in a few seconds on being treated with Fehling solution at room temperature and in general had the characteristic reactivity of its class. Thus, in contrast to other ketohexoses, it was about 50% oxidized by hypoiodite in fifteen minutes. It is interesting to note that similar results have been obtained with D-*threo*-pentulose[10] ("D-xyloketose").[11,12] It would seem that the 6-desoxyketohexoses and the ketopentoses closely resemble each other in their behavior with a variety of reagents. This behavior undoubtedly arises from a structural feature common to both types of sugars; *i. e.*, the lack of a hydroxyl more distant from the keto group than the γ carbon atom. This precludes the existence of pyranose rings, leaving as possible structures the more reactive furanose and open chain forms.

The substitution of a methyl for a hydroxymethyl group in the six position apparently alters the susceptibility of a sugar to the Selivanov test. Although definitely positive, the response of D-fructomethylose to this test was weak. Classification of the sugar as a ketose follows from the above considerations and from its reaction with α-methyl-α-phenylhydrazine which is regarded[13,13a] as a ketose reagent. Upon treatment under the prescribed conditions the sirup gave a positive reaction.

In performing the qualitative tests listed samples of D-rhamnose were treated simultaneously with the reagent being used and in all cases the results were completely negative.

The configuration of the sugar was established by converting it to 6-desoxy-D-*arabo*-hexose phenylosazone,[14] phenylosotriazole and *p*-bromophenylosazone, obtainable only from D-fructomethylose and the aldoses D-rhamnose and D-quinovose; D-quinovose would be a very unlikely result of the *Acetobacter* oxidation of D-rhamnitol;

moreover, its reactions are very similar to those of D-rhamnose which is excluded as a possibility by the results of the qualitative tests. The product must therefore be D-fructomethylose. The quantities of the precipitates obtained with all reagents giving them were much greater than could be accounted for by possible impurities in the preparation.

The osotriazole of this series had not been reported in the literature at the time that this work was done. Both antipodes have since been prepared, the D-form by Hardegger and El Khadem[15] and the L-form by Haskins, Hann and Hudson.[16] The results published by these investigators are in good agreement with those obtained in this work as regards both melting point and specific rotation.

Attempts to prepare derivatives characteristic of D-fructomethylose only were not successful. The *o*-nitrophenylhydrazone described in the original paper of Morgan and Reichstein was not obtained, possibly because of impurities in the sugar. It is believed that crystals of the *p*-bromophenylhydrazone appeared at one stage of the reaction with *p*-bromophenylhydrazine but that further reaction to give the osazone occurred during the working up of the reaction mixture. The hydrazone, if it could be prepared, would serve for the preparation of the pure sugar. Acetonation and acetylation of the sugar were both tried. The former gave negative results but the sirupy acetate might be subject to purification, perhaps by vacuum distillation, after which the pure sugar could be obtained by catalytic saponification. Sufficient material to test this possibility was not obtained.

Experimental

D-Rhamnitol (IV) was synthesized from methyl α-D-mannoside according to Haskins, Hann and Hudson.[8] It was found convenient to use refluxing methyl isobutyl ketone in place of acetone in a pressure bottle as the solvent in the tosyl–iodine exchange reaction. Excess sodium iodide is not required when the higher boiling ketone is used. In the last step the D-rhamnose solution obtained from the hydrolysis of the methyl α-D-rhamnoside was hydrogenated directly after treatment with silver carbonate and concentration to a smaller volume.

D-Fructomethylose (V).—The bacterial oxidation was carried out in a cotton stoppered 2-liter Erlenmeyer flask containing 4.5 g. of D-rhamnitol, 0.5 g. of Difco yeast extract, 0.075 g. of potassium acid phosphate and 0.1 g. of glycerol dissolved in 100 ml. of water. After sterilization for fifteen minutes at 15 pounds the medium was inoculated with 1 ml. of a culture of *A. suboxydans* from an original stock maintained by the Department of Agricultural Bacteriology.[17] After incubation for three days at 30° the medium was well covered with pellicle. An aliquot withdrawn at this time and analyzed by the Shaffer–Hartmann method assayed 40.6 mg. reducing sugar per ml., calculated as glucose. One day later the value was 38.4 mg. per ml. After an initial filtration to remove the bacterial cells the liquor was treated with Norite, filtered and evaporated under reduced pressure to a volume of 15 ml. The Norite treatment was repeated twice and the final filtrate was concentrated to a brown sirup. This was taken up in absolute ethanol; the insoluble material was centrifuged off and washed twice with ethanol and the washings combined with the original solution. Samples of the sugar for further experiments were obtained by evaporating the ethanol from aliquots of this solution.

Reaction with Hypoiodite (Willstätter–Schudel Titration).—A sample (0.099 g.) of the sirup was dissolved in a mixture of 40 ml. of 0.05 *N* iodine, 35 ml. of 0.1 *N* sodium hydroxide and 10 ml. of water and allowed to stand fifteen minutes after which it was acidified and the remaining iodine was titrated with standard thiosulfate. The consumption of iodine was 0.662 g. per g. of sugar or 47% of the amount consumed by an equal weight of glucose under identical conditions.

The Selivanov Test was carried out according to Roe[18] except that only qualitative comparisons were made. D-Fructomethylose gave about one-tenth of the amount of color given by an equal quantity of D-fructose. The rhamnose control remained colorless.

6-Desoxy-D-*arabo*-hexose Phenylosazone from D-Fructomethylose.—The osazone was prepared according to directions given by Fieser.[19] After two recrystallizations from ethanol–water the compound melted at 183° (rapid heating) and showed no depression when mixed with 6-desoxy-D-*arabo*-hexose phenylosazone prepared from D-rhamnose. Fischer and Zach[20] found m. p. 185° for "d-rhamnosazon," while Van der Haar[21] gives 182° for the L-isomer and Freudenberg and Raschig[22] reported melting points from 187 to 191° for these osazones depending on the sugar from which they were made.

Anal. Calcd. for $C_{18}H_{22}N_4O_3$ (342.39): N, 16.37. Found: N, 16.17.

It was noted that the addition of the phenylhydrazine reagent to a solution of the crude sirup caused the immediate formation of a small amount of a bright yellow precipitate which did not increase on standing. The material had the same nitrogen content as that obtained by heating. This observation suggests the possibility that a small amount of D-fructomethylosone or other dicarbonyl compound was formed by the bacteria.

6-Desoxy-D-*arabo*-hexose Phenylosotriazole.—The methods described by Haskins, Hann and Hudson[23,24] were followed in preparing this compound from samples of 6-desoxy-D-*arabo*-hexose phenylosazone prepared from D-rhamnose and D-fructomethylose, respectively. For detailed directions the reader is referred to the recent paper[16] by the same authors. Our compound had the following constants: From D-rhamnose, m. p. 137–138°, $[\alpha]^{24}D$ −99.4° (in pyridine, *c* 0.805). *Anal.* Calcd. for $C_{12}H_{15}N_3O_3$ (249.26): N, 16.86. Found: N, 16.80, 16.71. From D-fructomethylose, m. p. 137–138°, $[\alpha]^{26}D$ 98.5° (in pyridine, *c* 0.63). *Anal.* Found: N, 16.79, 16.90.

A mixture of the two samples showed no depression in melting point. Haskins, Hann and Hudson[16] give m. p. 136–137° and $[\alpha]^{20}D$ + 101.5° for 6-desoxy-L-*arabo* hexose phenylosotriazole ("L-rhamnose phenylosotriazole"), and Hardegger and El Khadem[15] give m. p. 140° for the D-isomer ("*d*-chinovose-phenylosotriazole"). The latter workers distilled their material in high vacuum for analysis.

Attempted Preparation of D-Fructomethylose *p*-Bromophenylhydrazone.[25] **6-Desoxy-D-*arabo*-hexose *p*-Bromophenylosazone.**—A solution of 0.5 g. of sirup in 1 ml.

[25] The procedure was adapted from that used by Schmidt and Treiber to prepare the *p*-bromophenylhydrazone of D-*threo*-pentulose.

of water and 2 ml. of ethanol was warmed with 0.6 g. of *p*-bromophenylhydrazine until the reagent dissolved, then placed in a vacuum desiccator over sulfuric acid and potassium hydroxide. After three days apparently colorless crystals which may have been the hydrazone were deposited. After an unsuccessful attempt to dissolve the crystals in warm ethanol the adhering gum was washed from them with liberal quantities of cold ethanol. The product which was now yellow melted at 224° after two recrystallizations from ethyl acetate. Votoček and Valentin[26] give 222–223° as the melting point of "*d*-rhamnose *p*-bromophenylosazone" and Freudenberg and Raschig[22] quote 225° for "*d*-chinovose-*p*-bromophenylosazon."

Anal. Calcd. for $C_{18}H_{20}N_4O_3Br_2$ (500.21): N, 11.20. Found: N, 11.14, 11.22.

Acetylation of a small sample of the sugar with acetic anhydride in pyridine at 0° furnished only a water-insoluble oil which has so far not yielded crystalline material.

We are indebted to Prof. Homer Adkins for providing facilities for the high pressure hydrogenation of the D-rhamnose.

Summary

The oxidation of D-rhamnitol by *Acetobacter suboxydans* was found to proceed normally to give crude D-fructomethylose sirup in 80% yield.

The behavior of the sugar with some standard carbohydrate reagents is described.

Recently reported physical constants of 6-desoxy-D-*arabo*-hexose phenylosotriazole are confirmed.

Methods are indicated by which purification of the crude sugar might be effected.

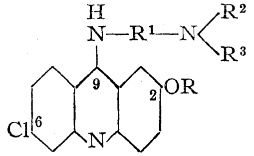
The Hydroxyethyl Analog of Quinacrine

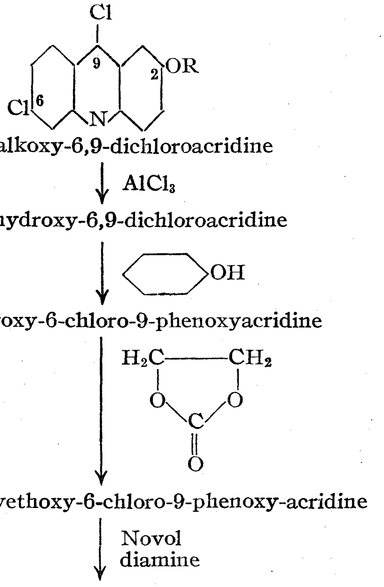
BY WARNER W. CARLSON AND LEONARD H. CRETCHER

Modification of the host toxicity of quinacrine (I) was attempted by hydroxyalkylation at the 2-position of the acridine ring. Literature reports were found of the introduction of the hydroxyl group into (a) the R_1 residue of the aliphatic side-chain,[1] (b) the terminal dialkylamino grouping,[2] and (c) one instance of hydroxylation of both R_1 and R_2 or R_3.[3] Introduction of a hydroxyl grouping into the R_1 residue was somewhat variable in effect, although generally there was a lowering of antimalarial activity unaccompanied by a compensating decrease in host toxicity.[1a,c] The presence of a hydroxyl group in the terminal dialkylamino grouping, either alone or in conjunction with another such radical in the R_1 residue, uniformly lowered antimalarial activity.[2b,3] No previous study was found of the effect of a hydroxyalkyl group at position 2.



I. For quinacrine, R = CH_3—; $R^1{}_2$ = —$CH(CH_3)(CH_2)_3$—; $R^2 = R^3 = C_2H_5$—

The synthesis of the hydroxyethyl analog of quinacrine (VI) was accomplished as outlined in the accompanying diagram. The necessary intermediate II customarily is obtained by ring closure of an appropriately substituted diphenylamine carboxylic acid by means of phosphorus oxychloride,[4] this procedure precluding the presence of a hydroxyalkyl radical at this stage. Direct synthesis of the phenol III was unsatisfactory, while preparation of this compound by the action of various hydrolytic agents on II failed because of the lability of the 9-chloro substituent. Dealkylation of II by anhydrous aluminum chloride afforded the phenol III in good yield. Hydroxyethylation of III, or the 9-phenoxy derivative IV, was difficult because of the ease with which the 9-substituent split off to form an acridone



II. 2-alkoxy-6,9-dichloroacridine

III. 2-hydroxy-6,9-dichloroacridine

IV. 2-hydroxy-6-chloro-9-phenoxyacridine

V. 2-β-hydroxyethoxy-6-chloro-9-phenoxy-acridine

VI. 2-β-hydroxyethoxy-6-chloro-9-[(α-methyl-γ-diethylaminobutyl)-amino]-acridine

[4] Mietzsch and Mauss, *Angew. Chem.*, **47**, 633 (1934).

VII. However, alkylation of IV with ethylene carbonate[5] proceeded smoothly, and the hydroxy ethyl ether V was obtained in good yield. Condensation of V with 1-diethylamino-4-aminopentane then gave the hydroxyethyl analog of quinacrine VI.

The chronic toxicity to white mice of quinacrine and its hydroxyethyl analog was determined by the drug-diet method.[6] The results obtained are listed in Table I, from which it is estimated that the 2-hydroxyethoxy derivative is approximately one-third as toxic as the parent 2-methoxy compound. Determined in another laboratory, the chronic toxicity of VI to white mice has been estimated to be one-half that of quinacrine.[7] In regard to antimalarial activity, the hydroxyethyl derivative has been assigned a quinine equivalent of two[7]; in the same test (F-1), quinacrine was given a quinine equivalent of three.[8]

Experimental

2-Ethoxy-6,9-dichloroacridine (II), as well as the **2-methoxy** derivative, was prepared according to Magidson and Grigorovskii[1b]; over-all yield, 76%.

2-Hydroxy-6,9-dichloroacridine (III).—De-alkylation of II, the 2-ethoxy derivative being preferred, was accomplished by a modification of the method of Magidson, Grigorovskii and Gal'perin.[9] One hundred grams of anhydrous aluminum chloride and 20 g. of II were dissolved and suspended in 300 cc. of xylene in a flask equipped for reflux and stirring. The mixture was heated at 135° (oil-bath temperature) for three-quarters of an hour, cooled, and poured (two liquid layers) into 1.5 liters of ice water containing 60 cc. of concentrated hydrochloric acid, the hydrochloride salt of III precipitating. The product was filtered, washed with ice water, then ether, and dried; yield, 95%. The hydrochloride was ground in aqueous-alcoholic ammonia and crystallized from alcohol, giving the free base (III), m. p. 222°; Magidson, *et al.*,[9] give m. p. 220–222°.

2-Hydroxy-6-chloro-9-phenoxy-acridine (IV).—In a few cases III was hydroxyethylated, but in general better yields were obtained with the 9-phenoxy derivative IV. Conversion of III into IV was accomplished by two methods: (a) by heating III free base in excess phenol at 100° for one hour, adding ether and then precipitating IV hydrochloride; (b) by heating III hydrochloride in phenol containing one mole equivalent of potassium hydroxide, yielding IV free base. Method (a) gave yields of 70–80%, (b) of 85–93%. In a typical reaction (b), 12 g. of III hydrochloride was dissolved in 60 g. of hot phenol containing 3.9 g. of 85% potassium hydroxide. The mixture was heated for one hour at 100°, cooled slightly, 100 cc. of toluene added, and the solution extracted with 500 cc. of 10% sodium hydroxide. The aqueous layer was filtered and treated with carbon dioxide until neutral to phenolphthalein. The precipitated IV was dissolved in acetone, the solution filtered, the IV free base reprecipitated by addition of water: m. p. 219–20°, yield 92%.

Anal. Calcd. for $C_{19}H_{12}O_2NCl$: C, 70.90; H, 3.76; N, 4.36; Cl, 11.03. Found: C, 70.72; H, 3.80; N, 4.25; Cl, 10.94.

2-β-Hydroxyethoxy-6-chloro-9-phenoxyacridine (V).—Because of the sensitivity of the 9-substituent an excess of the hydroxyethylating agent was used as solvent.[5] In a typical experiment a mixture of 8 g. of IV, 10.3 g. of potassium carbonate and 44 g. of ethylene carbonate[5] was heated with stirring for one and one-half hours at 95°, cooled slightly and poured into 200 cc. of ice water containing 40 cc. of concentrated hydrochloric acid, V partly separating as a gum. The acid solution was decanted from the gum and poured into excess cold alkali, precipitating 2.9 g. of V; a trace of IV was recovered from the filtrate by treatment with carbon dioxide. The gummy product from above was taken up in 50% alcohol–acetone, the solution filtered, made alkaline to phenolphthalein and diluted with water, precipitating the hydroxyalkylated base V. The two crops of V were combined and crystallized from aqueous acetone, giving 8.4 g. of yellow needles, m. p. 153°, yield 89%.

Anal. Calcd. for $C_{21}H_{16}O_3NCl$: C, 68.93; H, 4.41; N, 3.83; Cl, 9.70. Found: C, 68.74; H, 4.35; N, 3.71; Cl, 9.78.

2-β-Hydroxyethoxy-6-chloro-9-[(α-methyl-γ-diethylaminobutyl)-aminoacridine] (VI), **SN3055**.—In a typical preparation 3.65 g. (0.01 mole) of V was dissolved in 12 g. of hot phenol, 2.37 g. (0.015 mole) of 1-diethylamino-4-aminopentane was added, the solution was heated with stirring for two hours at 100°, then cooled to 40° and 10 cc. of ethanol added, followed by concentrated hydrochloric acid to congo red. Addition of 100 cc. of 50% acetone–ether precipitated a gum which was dissolved in alcohol; the solution was treated with acetone to turbidity and chilled, VI dihydrochloride separating as a light yellow powder, m. p. 250°; 3.8 g., 82%. From alcohol–ether it was obtained as clusters of pale yellow needles, m. p. 250°.

Anal. Calcd. for $C_{24}H_{34}O_2N_3Cl_3$: C, 57.30; H, 6.82; N, 8.36; Cl, 21.16. Found: C, 57.12; H, 6.75; N, 8.19; Cl, 20.98.

2-β-Hydroxyethoxy-6-chloro-9-acridone (VII).—This compound was obtained both as a by-product in the preparation of V and by the treatment of V for fifteen minutes with boiling 3 *N* alcoholic alkali, VII precipitating from solution upon dilution with water; crystallized from alcohol, m. p. >300°.

Anal. Calcd. for $C_{15}H_{12}NO_3Cl$: C, 62.16; H, 4.18; N, 4.83; Cl, 12.24. Found: C, 62.02; H, 4.15; N, 4.71; Cl, 12.29.

Toxicity of Atebrin and VI.—Estimation of the chronic toxicity to white mice of atebrin and its hydroxyethyl analog (VI) was carried out essentially as described by Bratton.[6b] The two drugs as dihydrochlorides were prepared in powdered Purina dog chow. The drug-diets were placed in the inner member of a double food cup; spilled food thus could be recovered. After being air-dried and sifted from extraneous material recovered diet was weighed and allowance accordingly made in estimating food intake. Male white mice in the weight range 15–20 g. were employed, and the experiment continued for

two weeks, the animals being weighed at frequent intervals. The results are given in Table I.

Summary

The 2-β-hydroxyethyl analog of quinacrine was synthesized and its chronic toxicity to white mice, as determined by the drug diet method, found to be one-third that of the parent drug.

Synthesis of Chromans from Phenols and from ortho-Hydroxy Aromatic Aldehydes[1,2]

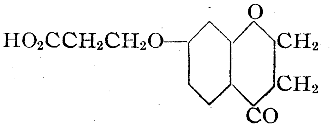
BY G. BRYANT BACHMAN AND HAROLD A. LEVINE[3]

The success of the recently developed synthesis of benzo[f]chromanones by cyclization of β-naphthoxypropionitriles obtained from addition of β-naphthols to acrylonitrile[4] suggested a study of the application of this method to other phenols, especially those in the benzene series. From phenol itself 3-phenoxypropionitrile[5] was obtained in good yield, but a series of cyclization experiments gave only traces of impure ketonic material or no reaction. *p*-Nitrophenol and methyl salicylate did not add, and *o*- and *p*-chlorophenols added only slowly to acrylonitrile. Apparently, electron-withdrawing groups on the benzene nucleus hinder the addition. Even 6-bromo-2-naphthol gave poor yields (10%) of 3-(6′-bromo-2′-naphthoxy)-propionitrile. This cyclized satisfactorily, however, in the presence of sulfuric acid to 8-bromo-1-benzo[f]chromone.

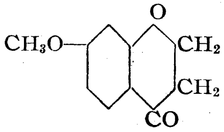
The presence of electron-supplying groups on the benzene ring apparently increases the ease of addition of phenolic hydroxyl groups to acrylonitrile but does not necessarily increase the ease of cyclization of the product because of an increased tendency of such compounds to sulfonate. Resorcinol gives a dinitrile[5] in 40% yields, but treatment with cyclizing agents gives poor yields of a monocyclized product, 7-(2′-carboxy-ethoxy)-chromanone (I). Resorcinol monomethyl ether gives a nitrile in 76% yield. With 85% sulfuric acid this cyclizes to the expected 7-methoxychromanone (II),[6] while with 85% phosphoric acid the uncyclized 3-(3′-methoxyphenoxy)-propionic acid (III)[6] is obtained.

In all of these reactions sulfonation and phosphorylation led to considerable amounts of water-soluble, ether-insoluble products which were not investigated. The desired products were obtained in poor yields.

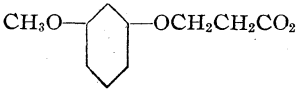
An alternative preparation of derivatives of chroman based on the addition of the hydroxyl group of salicylaldehyde to acrylonitrile followed by an aldol cyclization was also investigated.



I



II



III

When salicylaldehyde was heated in an excess of acrylonitrile in the presence of dimethylbenzylcetyl-ammonium hydroxide (Triton B) as a catalyst, reaction proceeded to only a limited extent. Three crystalline products were isolated from the alkali-insoluble fraction of the reaction mixture in yields of 1–2%. These compounds were identified by qualitative tests and analytical data as 2-(β-cyanoethoxy)-benzaldehyde (IV), 3-cyano-4-chromanol (V), and 3-cyano-1,2-benzopyran (VI). Attempts to increase the yield of V by the use of other condensation catalysts were unsuccessful. When the condensation was carried out at 100° with Triton B as a catalyst, there was a marked increase in the amount of alkali-insoluble product, but pure V could not be isolated. 3-Aminomethyl-4-chromanol (VII) was prepared by reduction of V in acetic anhydride with platinum oxide catalyst,[7] followed by hydrolysis with methanolic sodium hydroxide.

A second synthesis of derivatives of chroman from salicylaldehyde was also developed. The base catalyzed addition of salicylaldehyde to an aliphatic primary nitroölefin followed by an aldol-type of cyclization gives both the nitroalcohol (VIII) and the nitroölefin (IX) of the expected structures. β-Chloronitroparaffins prepared according to the method of Riley[8] were used as sources of the nitroölefins. The two reactions may be accomplished in one step by condensing the chloronitroparaffin with the sodium salt of salicylaldehyde. Of the three chloronitroparaffins tried, 2-chloro-1-nitroethane, 1-chloro-2-nitropropane and 2-chloro-1-nitropropane, only the last gave the desired products. The others gave polymeric material. This result was not unexpected since the intermediate nitroölefins of the type

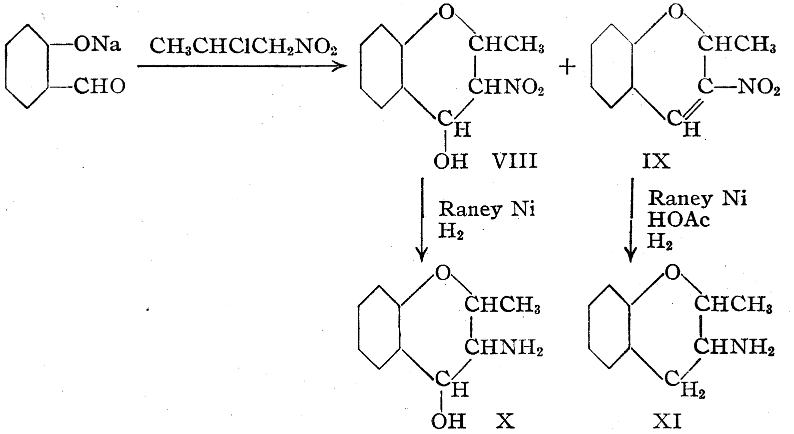
$\mathrm{R{-}\underset{NO_2}{C}{=}CH_2}$ have been reported to polymerize very readily.[9] Since 3-aminochromans structurally resemble known sympathomimetic phenylethylamine derivatives,[10] VIII and IX were converted to the corresponding amines for testing. Catalytic hydrogenation of 2-methyl-3-nitro-4-chromanol (VIII) proceeds smoothly to give the corresponding amino alcohol (X). The preparation of 2-methyl-3-aminochroman (XI) proved to be more difficult. Reduction of IX to the oxime catalytically,[11] or with iron filings and hydrochloric acid,[11] was unsuccessful. Tarry products were obtained. However catalytic hydrogenation with Raney nickel gave the desired amine in low yield.



Pharmacological Testing.—The aminochromans tested as sympathomimetics showed no pressor activity (VII), slight pressor activity (XI) or slight depressor activity (X). In addition X showed no antimalarial, slight antihistaminic, and no analgesic action.

Acknowledgment.—The authors wish to express their appreciation to Eli Lilly and Company and the Purdue Research Foundation for the financial support which made this investigation possible.

Experimental

Reactions of Acrylonitrile with Phenols.—The phenol (0.25 mole) was refluxed with acrylonitrile (2–4 moles) and *Triton B* (dimethylbenzylacetylammonium hydroxide) (2–5 ml.) for about twenty hours. The reaction mixture was diluted with two volumes of a solvent (ether or chloroform), filtered, and washed successively with several portions of 5% aqueous sodium hydroxide, dilute hydrochloric acid and then water. Evaporation of the solvent and distillation or recrystallization of the residue gave the desired product. The yields and physical properties are as follows: (a) 3-phenoxypropionitrile,[5] 67.5%, m. p. 59–60° from benzene–petroleum ether (reported,[5] 70%, m. p. 61–62°); (b) 3-(7′-bromo-2′-naphthoxy)-propionitrile, 10%, m. p. 120° from ethanol. *Anal.* Calcd. for $C_{13}H_{10}NOBr$: N, 5.07. Found: N, 5.03, 4.98. (c) 1,3-Di-(2′-cyanoethoxy)-benzene, 40%, m. p. 110–111° (reported,[5] 53%, m. p. 112°). (d) 3-(3′-methoxyphenoxy)-propionitrile 76.5%, b. p. 145–146° (3 mm.), m. p. 29.5–30.5°. *Anal.* Calcd. for $C_{10}H_{11}NO_2$: C, 67.77; H, 6.26; N, 7.91. Found: C, 67.75, 67.89; H, 6.18, 6.12; N, 8.00, 7.73.

Cyclizations of 3-Aryloxypropionitriles.—No success attended efforts to cyclize 3-phenoxypropionitrile with concd. or 85% sulfuric acid, 85% phosphoric acid, stannic chloride, phosphorus oxychloride, or acetic anhydride and sodium acetate at various temperatures. Either no reaction occurred or water-soluble, ether-insoluble products were formed. The remaining nitriles were treated as follows: 3-(7′-bromo-2′-naphthoxy)-propionitrile, 17.0 g., was mixed with 200 ml. of 85% sulfuric acid, stirred till dissolved, and poured into 2 liters of ice and water. The yellowish-white solid was recrystallized from 50% aqueous ethanol; yield 13.6 g., 80%, m. p. 123°, of 8-bromo-1-benzo(f)-chromanone.

Anal. Calcd. for $C_{13}H_9O_2Br$: Br, 28.48. Found: Br, 28.96, 28.98.

1,3-Di-(2′-cyanoethoxy)-benzene, 5 g., and 85% sulfuric acid, 25 ml., were mixed and stirred at room temperature for three hours, poured into 200 ml. of water and let stand five days. The precipitated solid, collected and recrystallized from water, gave tan needles, 0.7 g. (12.8%) m. p. 171–173°. They were soluble in dilute solutions of sodium bicarbonate and gave a positive ketone test with 2,4-dinitrophenylhydrazine. The analytical data indicate the product to be 7-(2′-carboxyethoxy)-chromanone (I).

Anal. Calcd. for $C_{12}H_{12}O_5$: C, 61.01; H, 5.12. Found: C, 60.92, 60.86; H, 5.17, 5.21.

3-(3′-Methoxyphenoxy)-propionitrile, 5 g., and 85% sulfuric acid, 25 ml. were mixed and stirred at room temperature for three hours and then heated on a steam-bath for one hour. The cooled mixture was poured into 200 ml. of water and extracted with ether. The ether extract was evaporated and the oily residue was recrystallized from water. The product, 7-methoxychromanone (II), was obtained in 0.1 g. yield (2%) as colorless needles m. p. 52–54° (reported,[6] m. p. 50–56°, yield 18–40%).

The product when 85% phosphoric acid was used instead of 85% sulfuric acid was 3-(3′-methoxyphenoxy)-propionic acid[6] (III). The ether extract of the reaction mixture was itself extracted with 5% aqueous sodium hydroxide. This latter extract was acidified and the solid precipitate was recrystallized from water (Norit decolorization). The product, 1.4 g. (25.3% yield), was obtained as colorless plates, m. p. 80–82° (reported[6] m. p. 81–83°, 15% yield).

Reaction of Acrylonitrile with Salicylaldehyde.—A mixture of 61 g. of salicylaldehyde (0.5 mole), 133 g. of acrylonitrile (2.5 mole), and 5 ml. of 40% Triton B was heated at reflux for thirty hours, cooled, poured into a mixture of 40 ml. of concd. hydrochloric acid and 500 ml. of ether, and filtered. The ether layer was extracted with three 200-ml. portions of 5% sodium hydroxide, dried, and evaporated under vacuum to yield 16.0 g. of at an oil. Fractional precipitation from benzene by the addition of petroleum ether (b. p. 90–100°) gave 2.0 g. of a crystalline solid. Recrystallization from benzene gave 1.7 g. (2% yield) of 3-cyano-4-chromanol (V), m. p. 141–142.5°.

Anal. Calcd. for $C_{10}H_9NO_2$: C, 68.56; H, 5.18. Found: C, 68.58, 68.52; H, 5.18, 5.25.

The crystallization mother liquors were evaporated and distilled. Fraction I, b. p. 105–137°, 2.9 g., partially crystallized on cooling to give 1.0 g. (1.3% yield) of 3-cyano-1,2-benzopyran (VI), colorless plates (from methanol), m. p. 48–49°.

Anal. Calcd. for $C_{10}H_7NO$: N, 8.81. Found: N, 8.84, 8.96.

Fraction II, b. p. (2 mm.) 137–170°, 5.5 g., partially crystallized on cooling to give 1.2 g. (1.3% yield) of 2-(2′-cyanoethoxy)-benzaldehyde (IV), m. p. 73–75° (from benzene).

Anal. Calcd. for $C_{10}H_9NO_2$: C, 68.56; H, 5.18. Found: C, 68.69, 68.56; H, 5.12, 5.17.

3-Aminomethyl-4-chromanol (VII) Hydrochloride.—A mixture of 7.0 g. of 3-cyano-4-chromanol (V), 50 ml. of acetic anhydride, and 0.3 g. of platinum oxide catalyst was hydrogenated for nine hours, filtered, and vacuum-evaporated to yield 9.0 g. of the diacetylated amino alcohol, m. p. 160–165°. Eight grams of this material in 50 ml. of methanol and 100 ml. of 15% sodium hydroxide was heated at reflux for twenty-four hours. The hydrolysis mixture was extracted with ether. Addition of anhydrous hydrogen chloride to the dried ether extract followed by recrystallization of the solid product from ethanol-butyl ether gave 4.0 g. (52% yield) of VII hydrochloride, m. p. 175–176° (d).

Anal. Calcd. for $C_{10}H_{13}NO_2 \cdot HCl$: C, 55.68; H, 6.54. Found: C, 55.88, 55.77; H, 6.64, 6.61.

Reaction of 2-Chloro-1-nitropropane with Salicylaldehyde.—A solution of 1 mole of sodium ethoxide in 500 ml. of absolute ethanol was added to a cooled, stirred mixture of 122 g. of salicylaldehyde (1 mole) and 100 ml. of absolute ethanol. The stirred suspension was kept at 10° while 123.5 g. of 2-chloro-1-nitropropane (1 mole) was added dropwise during one hour. The yellow reaction mixture was stirred for five hours at 5–10° and then overnight at room temperature, filtered, and the filtrate evaporated under vacuum. The residual oil partially solidified on cooling. Filtration followed by washing with 500 ml. of 1:4 ethylene dichloride-petroleum ether (b. p. 90–100°) gave 65.0 g. of Solid A, m. p. 98–100°. The filtrate and washings were evaporated and distilled at 3 mm. The fraction of b. p. 135–145° was recrystallized from 75 ml. of methanol; yield 29.5 g. of yellow crystals, m. p. 72–75° Solid B, Crop 1.

Solid A was dissolved in 500 ml. of hot acetic acid, refluxed for thirty minutes, poured into 1500 ml. of water, filtered, and the solid recrystallized from 1 l. of 1:4 ethylene dichloride-petroleum ether (90–100°); yield, 22.4 g. (10.7%) of pure 2-methyl-3-nitro-4-chromanol (VIII), m. p. 135–137°.

Anal. Calcd. for $C_{10}H_{11}NO_4$: C, 57.44; H, 5.26; N, 6.70. Found: C, 57.57, 57.48; H, 5.37, 5.32; N, 6.79, 6.71.

The dilute acetic acid mother liquors were evaporated to 1 liter, cooled and filtered. The yellow residue was combined with the methanol filtrates from Solid B, Crop 1. Evaporation followed by rectification gave an orange oil, b. p. 120–123° (2 mm.). This material was crystallized from 50 ml. of methanol to give 38.0 g. of yellow crystals, m. p. 72–75°; Solid B, Crop 2; total yield 77.5 g. (35.2%). Pure 2-methyl-3-nitro-1,2-benzopyran (IX), m. p. 75.0–75.5°, was obtained by recrystallization from methanol.

Anal. Calcd. for $C_{10}H_9NO_3$: C, 62.85; H, 4.71; N, 7.33. Found: C, 62.63, 62.69; H, 4.79, 4.71; N, 7.48, 7.40.

2-Methyl-3-amino-4-chromanol (X).—A mixture of 18.2 g. of 2-methyl-3-nitro-4-chromanol (VIII), 200 ml. of absolute ethanol, and 5 g. of Raney nickel catalyst was hydrogenated under a pressure of 1400 lb. for seven hours at 40–50°. Recovery of the product and recrystallization from 475 ml. of benzene gave 7.5 g. of colorless needles, m. p. 155–159°. The benzene mother liquors were extracted with four 50-ml. portions of 5% hydrochloric acid. Addition of an excess of sodium hydroxide to this extract gave 4.2 g. of a tan solid, m. p. 146–156°. This material was recrystallized from benzene, combined with the first crop of crystals, and recrystallized again. A total of 9.9 g. (63.6% yield) of pure 2-methyl-3-amino-4-chromanol, m. p. 158–159°, was obtained. Which of the several possible racemic pairs this represents was not determined.

Addition of isopropyl ether to a solution of 2-methyl-3-amino-4-chromanol in methanolic hydrogen chloride precipitated the crystalline hydrochloride, m. p. 229–230°.

Anal. Calcd. for $C_{10}H_{13}NO_2 \cdot HCl$: N, 6.50. Found: N, 6.67, 6.71.

2-Methyl-3-aminochroman (XI).—A mixture of 19.1 g. (0.1 mole) of 2-methyl-3-nitro-1,2-benzopyran (IX), 6.0 g. of acetic acid (0.1 mole), 75 ml. of methanol, and 5 g. of Raney nickel catalyst was hydrogenated at 1400 lb. pressure, first at 40–50° then at 90–100°, filtered, treated with 9 ml. of concd. hydrochloric acid, and evaporated under vacuum. The residue was successively extracted with 125 ml. of water and 100 ml. of 5% hydrochloric acid. The extracts were made basic and extracted with benzene. The red benzene extracts were dried over potassium hydroxide and evaporated. Vacuum distillation of the dark residual oil gave 3.9 g. of a colorless liquid, b. p. 101–105° (4 mm.).

The crude hydrochloride of this product was recrystallized from isopropyl alcohol–isopropyl ether and then twice from purified nitromethane to obtain colorless needles, m.p. 216.0–217.5°.

Anal. Calcd. for $C_{10}H_{13}NO \cdot HCl$: N, 7.02. Found: N, 7.22, 7.28.

Summary

New syntheses of chroman derivatives based on the cyclizations of phenol–acrylonitrile addition products and salicylaldehyde–nitroölefin addition products have been investigated.

LAFAYETTE, INDIANA RECEIVED MAY 29, 1947

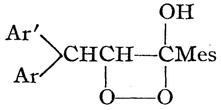
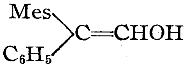
Vinyl Alcohols. XIX.[1] Mesitylphenylacetaldehyde

BY REYNOLD C. FUSON AND TZI-LIEH TAN

Although a number of stable 2,2-diarylvinyl alcohols are known, efforts to synthesize the corresponding diarylacetaldehydes have been unavailing. In particular, attempts to form the aldehydes by isomerization of the vinyl alcohols have failed; treatment with alcoholic hydrogen chloride, a method that had been used to convert several trisubstituted vinyl alcohols to the corresponding ketones,[2] yielded only vinyl ethers.[3] Attempts to synthesize highly hindered diarylacetaldehydes by the decomposition of peroxides of type I produced the corresponding vinyl alcohols.[4] The only evidence for the existence of such aldehydes was the fact that mesitylphenylvinyl alcohol (II) formed a semicarbazone.[4]

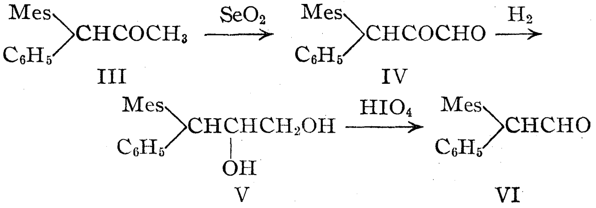


I



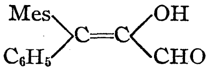
II

We have now tried various other methods of synthesis and have been successful in preparing an aldehyde of the desired type—mesitylphenylacetaldehyde (VI). It was made first by the oxidative cleavage of 3-mesityl-3-phenyl-1,2-propanediol (V), a hydrogenation product of mesitylphenylpyruvaldehyde (IV), which in turn was prepared by selenium dioxide oxidation of 1-mesityl-1-phenylpropanone (III).[5]

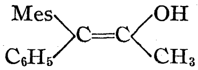


The oxidation of the propanone (III) afforded a very low yield of the glyoxal and produced in addition mesityl phenyl diketone. This benzyl could be made also by oxidation of the glyoxal (IV) with nitric acid. Oxidation with hydrogen peroxide, however, cleaved the glyoxal, yielding mesitylphenylacetic acid.

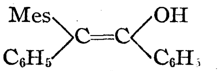
Certain reactions of the glyoxal did not correspond entirely with those to be expected of an α-keto aldehyde. It formed only a mono-oxime and a monosemicarbazone; with acetic anhydride in pyridine it gave an acetate. The glyoxal failed to yield mesitylphenyllactic acid when treated with alkali and could be regenerated by alkaline hydrolysis of the acetate. Moreover, the compound was colorless. In view of these observations it seemed probable that it was to be classed with benzyl phenyl diketone[6] and benzyl mesityl diketone[7] and to be ascribed the enol form, VII. The infrared spectrum of this compound in hexane solution showed absorption maxima at 2.94μ and 6.02μ indicating the presence of a hydroxyl and a conjugated carbonyl group, respectively.[8]



VII



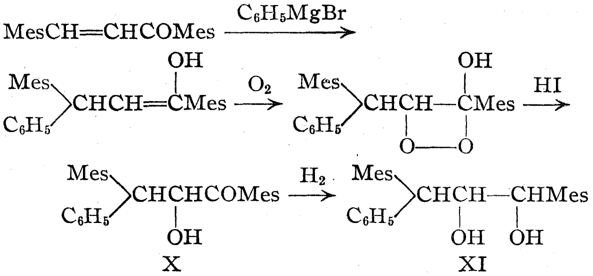
VIII



IX

This enol is an interesting addition to the list of stable trisubstituted vinyl alcohols, especially in view of the fact that the corresponding enols in which the aldehyde group has been replaced by a methyl (VIII) or a phenyl group (IX)[5] are known to be unstable.

Because of the unsatisfactory yields of glyoxal (IV) other methods of preparation of mesitylphenylacetaldehyde were sought. The only attempt to be brought to a successful conclusion involved the oxidative cleavage of 1,3-dimesityl-3-phenyl-1,2-propanediol (XI) with periodic acid. The glycol was prepared from mesitalacetomesitylene by the following series of changes. The hydroxy ketone (X) failed to be cleaved by periodic acid.



A by-product of the cleavage of the glycol (XI) was 2,4,6-trimethylbenzoin. Since this benzoin is known to be produced by the action of ozone on 2-mesityl-2-phenylvinyl alcohol[3] it seems probable that it was formed from mesitylphenylacetaldehyde, perhaps by way of the vinyl alcohol. Attempts were made to extend the synthetic method

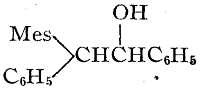
to other aldehydes but without success. When 1,3-dimesityl-3-*p*-tolyl-1,2-propanediol was treated with periodic acid, mesityl *p*-tolylacetic acid was formed.

Mesitylphenylacetaldehyde gave a positive Tollens test and yielded a semicarbazone identical with that prepared earlier from 2-mesityl-2-phenylvinyl alcohol.[4] The structure of the aldehyde was established by its reaction with phenylmagnesium bromide which converted it to 2-mesityl-1,2-diphenylethanol (XII). The carbinol yielded an acetate which proved to be identical with the known compound.[5]



$(\mathrm{Mes})(C_6H_5)CHCH(OH)C_6H_5$

XII

The aldehyde structure was confirmed by the infrared absorption spectrum which showed a maximum at 5.77μ.

Mesitylphenylacetaldehyde showed a pronounced tendency to undergo enolization. The enol form could be produced by treatment with alkali or by heating at 150° for two hours. The rearrangement under the influence of heat offers an explanation of the fact that vinyl alcohols rather than aldehydes were obtained by the thermal decomposition of peroxides of Type I.[4] Heating with acetic anhydride in the presence of sodium acetate converted the aldehyde to the acetate of the enol.[3] However, the aldehyde like the vinyl alcohol did not undergo spontaneous rearrangement, *i. e.*, the tautomeric shift appeared to be inhibited. In this respect the behavior of these compounds is similar to that of the stable trisubstituted vinyl alcohols and the corresponding ketones.[5] In this connection it is interesting to recall the behavior of benzhydryl mesityl diketone which was isolated in both the enol and keto forms by Kohler and Thompson,[9] who ascribed the sluggishness of the tautomeric shift to steric hindrance.

Experimental

Oxidation of 1-Mesityl-1-phenylpropanone with Selenium Dioxide.—A number of runs were made in which the reaction conditions were varied in an attempt to improve the yield. The procedure which gave the best result was as follows:

A mixture of 20 g. of 1-mesityl-1-phenylpropanone, 10 g. of selenium dioxide, 300 ml. of dioxane and 20 ml. of water was stirred and refluxed for six hours. The solution was decanted from the free selenium formed in the oxidation and the solvent was removed by distillation. The residue was distilled *in vacuo,* the fraction boiling at 165–175° (3 mm.) being collected. Addition of hexane caused the precipitation of a brown solid which was fractionally crystallized from hexane and separated by mechanical manipulation into two components. The glyoxal, a white crystalline compound which separated preferentially from hexane, was recrystallized from the same solvent; m. p. 134–135°, yield 2 g.

Anal. Calcd. for $C_{18}H_{18}O_2$: C, 81.18; H, 6.81. Found: C, 81.31; H, 7.06.

The infrared spectrum of this compound in hexane solution showed absorption maxima at 2.94 μ and 6.02 μ indicating the presence of a hydroxyl and a carbonyl (conjugated) group, respectively.

The other component of the mixture, a yellow compound, was recrystallized from ethanol; m. p. 136–137°. A mixed melting point determination with mesityl phenyl diketone showed no depression.

Distillation of the filtrate left after the separation of the brown solid gave a red oil boiling at 149–150° (1 mm.); n^{20}_D 1.5791 (*anal.* Found: C, 82.53; H, 7.50). It was shown by a color test with codeine sulfate solution to be a selenium compound. When treated with sodium ethoxide it was converted in low yield to mesitylphenylacetic acid.

In one run in which dry dioxane was used as solvent no mesitylphenylpyruvaldehyde was formed. Mesityl phenyl diketone and the selenium compound were isolated, however.

Reactions of Mesitylphenylpyruvaldehyde. (A) With Nitric Acid.—A mixture of 0.5 g. of mesitylphenylpyruvaldehyde, 5 ml. of concentrated nitric acid and 15 ml. of water was heated under reflux for forty minutes. The acid solution was decanted and the residue dissolved in hexane. The yellow compound which had separated at the end of two weeks melted at 135–137° and was shown by a mixed melting point determination to be mesityl phenyl diketone.

(B) **With Hydrogen Peroxide.**—A mixture of 0.2 g. of mesitylphenylpyruvaldehyde, 20 ml. of dioxane and 10 ml. of hydrogen peroxide (30%) was heated under reflux for four hours. It was diluted with water and extracted with ether. The ether solution in turn was extracted with sodium hydroxide solution (10%). Acidification of the alkaline extract with hydrochloric acid precipitated a substance which was recrystallized from high-boiling petroleum ether; m. p. 166–168°. A mixed melting point determination with mesitylphenylacetic acid showed no depression.

(C) **With Semicarbazide.**—A mixture of 0.2 g. of mesitylphenylpyruvaldehyde, 1 g. of semicarbazide hydrochloride, 1.5 g. of sodium acetate, 10 ml. of ethanol and 1 ml. of water was boiled for ten minutes and allowed to stand in the cold. The semicarbazone was recrystallized from acetone; m. p. 140–145°.

Anal. Calcd. for $C_{19}H_{21}O_2N_3$: C, 70.55; H, 6.56; N, 13.00. Found: C, 70.21; H, 6.86; N, 13.25.

(D) **With Hydroxylamine.**—A mixture of 0.2 g. of mesitylphenylpyruvaldehyde, 0.5 g. of hydroxylamine hydrochloride, 3 ml. of water, 2 ml. of sodium hydroxide solution (10%) and 20 ml. of ethanol was heated on a steam-bath for twenty minutes. The resulting mixture was filtered to remove the sodium chloride, diluted with water and allowed to stand in the cold. The oxime which separated was recrystallized from hexane; m. p. 142–143°.

Anal. Calcd. for $C_{18}H_{19}O_2N$: C, 76.89; H, 6.82; N, 4.98. Found: C, 77.21; H, 6.96; N, 4.97.

(E) **With Alkali.**—A suspension of 0.2 g. of mesitylphenylpyruvaldehyde in 10 ml. of sodium hydroxide solution (10%) was heated under reflux for thirty minutes, diluted with water and extracted with ether. The aqueous layer was acidified with hydrochloric acid and the acidified solution again extracted with ether. Evaporation of the ether left an oil which could not be induced to crystallize.

(F) **With Acetic Anhydride.**—An acetate was formed by allowing a mixture of 1 g. of mesitylphenylpyruvaldehyde, 4 ml. of acetic anhydride and 6 ml. of pyridine to stand at room temperature overnight. It crystallized from low-boiling petroleum ether in colorless cubes; m. p. 100–101°, yield 0.9 g.

Anal. $C_{20}H_{20}O_3$: C, 77.78; H, 6.54. Found: C, 77.79; H, 6.78.

When the acetate was heated with ethanolic sodium hydroxide for twenty minutes, it was hydrolyzed to

---

[9] Kohler and Thompson, THIS JOURNAL, **59**, 887 (1937).

mesitylphenylpyruvaldehyde. Treatment of the acetate with semicarbazide gave the semicarbazone of the original pyruvaldehyde.

3-Mesityl-3-phenyl-1,2-propanediol.—A mixture of 1 g. of mesitylphenylpyruvaldehyde, 0.02 g. of platinum oxide and 50 ml. of ethanol was treated with hydrogen at atmospheric pressure until two molecular equivalents of hydrogen was absorbed. The catalyst was removed by filtration and the solvent evaporated. The propanediol was crystallized from benzene; yield 0.89 g., m. p. 147–148°.

Anal. Calcd. for $C_{18}H_{22}O_2$: C, 79.99; H, 8.21. Found: C, 79.97; H, 8.41.

The **diacetate** was prepared by allowing a mixture of 0.5 g. of the glycol, 4 ml. of acetic anhydride and 6 ml. of pyridine to stand overnight. It was recrystallized from hexane; m. p. 80–81°.

Anal. Calcd. for $C_{22}H_{26}O_4$: C, 74.55; H, 7.40. Found: C, 74.33; H, 7.45.

Mesitylphenylacetaldehyde.—To a solution of 1 g. of 3-mesityl-3-phenyl-1,2-propanediol in 50 ml. of ethanol was added a solution of 1 g. of potassium periodate in 50 ml. of sulfuric acid (1 *N*). The mixture was stirred for one-half hour at 18° and an additional hour at 33°. Water was then added to dilute the mixture and the precipitate which separated was collected on a filter and dried in the air. It weighed 0.89 g. and melted at 66–72°. Several crystallizations of the aldehyde from low-boiling petroleum ether raised its melting point to 73–74°.

Anal. Calcd. for $C_{17}H_{18}O$: C, 85.67; H, 7.62. Found: C, 85.92; H, 7.85.

The aldehyde gave a positive test with Tollens reagent. Its infrared spectrum showed a peak at 5.77 (presence of an aldehyde group) and no absorption in the hydroxyl and olefinic regions. It was stable under ordinary conditions. However, after standing one year in air it was found to have undergone extensive decomposition.

Reactions of Mesitylphenylacetaldehyde. (A) **With Semicarbazide.**—A mixture of 0.21 g. of mesitylphenylacetaldehyde, 0.15 g. of semicarbazide hydrochloride, 0.25 g. of sodium acetate, 8 ml. of ethanol (aldehyde-free) and 8 ml. of water was heated to boiling. Dilution of the solution with water caused the slow precipitation of the semicarbazone. It melted at 203–205° and did not depress the melting point of the known semicarbazone prepared from 2-mesityl-2-phenylvinyl alcohol.[4]

(B) **With Acetic Anhydride.**—A mixture of 0.1 g. of mesitylphenylacetaldehyde, 0.15 g. of fused sodium acetate and 1.5 ml. of acetic anhydride was heated on a steam-bath for two hours and poured with vigorous stirring into 20 ml. of ice water. The precipitate was collected on a filter, washed with water and recrystallized from dilute ethanol; m. p. 89–90°. A mixed melting point determination with the acetate prepared from 2-mesityl-2-phenylvinyl alcohol[3] showed no depression.

(C) **With Phenylmagnesium Bromide.**—A solution of 0.5 g. of the aldehyde in 12 ml. of absolute ether was added in fifteen minutes to a Grignard reagent prepared from 0.063 g. of magnesium turnings, 0.505 g. of bromobenzene and 10 ml. of absolute ether. Stirring was continued for two hours during which time nitrogen was passed over the reaction mixture and the solution was decomposed with cold hydrochloric acid. The ether layer was removed, washed successively with water, sodium bicarbonate solution and water and dried over magnesium sulfate. Removal of the ether left the 2-mesityl-1,2-diphenylethanol as a white solid which was recrystallized from high-boiling petroleum ether; m. p. 133–134°.

Anal. Calcd. for $C_{23}H_{24}O$: C, 87.29; H, 7.66. Found: C, 87.02; H, 7.65.

When the 2-mesityl-1,2-diphenylethanol was treated with acetic anhydride and pyridine an acetate (m. p. 125–126°) was formed. It did not depress the melting point of an authentic sample of 2-mesityl-1,2-diphenylethyl acetate prepared previously by the reduction of α-mesityldesoxybenzoin with isopropylmagnesium bromide and treatment of the product with acetyl chloride.[5]

(D) **Enolization.**—1. A sample of 0.1 g. of mesitylphenylacetaldehyde was dissolved in a solution of 0.35 g. of potassium hydroxide in 5 ml. of ethanol. The solution was allowed to stand at room temperature overnight, diluted with water and neutralized with hydrochloric acid. The precipitate was collected on a filter and recrystallized from low-boiling petroleum ether; m. p. 112–113°. It was shown by a mixed melting point determination to be 2-mesityl-2-phenylvinyl alcohol.

2. Enolization of the aldehyde was also effected by heating at 150° for two hours. The vinyl alcohol was recrystallized from low-boiling petroleum ether; m. p. 112–113°.

α-Hydroxy-β-mesityl-β-phenylpropiomesitylene.—A mixture of 4 g. of 1,3-dimesityl-3-phenyl-1-propen-1-ol peroxide (m. p. 132–134°),[4] 6.7 g. of potassium iodide and 40 ml. of glacial acetic acid was shaken at room temperature for six hours. It was diluted with 60 ml. of water and the precipitate was collected on a filter. The pure α-hydroxy-β-mesityl-β-phenylpropiomesitylene obtained by recrystallization from ethanol melted at 160–162° and weighed 2 g.

Anal. Calcd. for $C_{27}H_{30}O_2$: C, 83.88; H, 7.83. Found: C, 83.84; H, 7.82.

The **acetate** prepared by treatment with acetic anhydride and pyridine was recrystallized from ethanol; m. p. 195–196°.

Anal. Calcd. for $C_{29}H_{32}O_3$: C, 81.25; H, 7.54. Found: C, 81.14; H, 7.56.

An attempt was made to cleave α-hydroxy-β-mesityl-β-phenylpropiomesitylene with periodic acid. To a solution of 1 g. of the hydroxy ketone in 100 ml. of ethanol was added a solution of 0.6 g. of potassium periodate in 30 ml. of sulfuric acid (1 *N*). The mixture was shaken at room temperature for six hours and then diluted with water. The starting material was recovered.

1,3-Dimesityl-3-phenyl-1,2-propanediol.—A solution of 4 g. of α-hydroxy-β-mesityl-β-phenylpropiomesitylene in 20 ml. of ethanol was heated to 150° and subjected to a pressure of 2200 lb. of hydrogen for two hours in the presence of a copper chromite catalyst. After removal of the catalyst the solution was concentrated to a small volume. The white propanediol which separated when the solution was allowed to stand in the cold was recrystallized from ethanol; m. p. 134–135°, yield 2.9 g.

Anal. Calcd. for $C_{27}H_{32}O_2$: C, 83.45; H, 8.32. Found: C, 83.35; H, 8.58.

The **diacetate** prepared by the use of acetic anhydride and pyridine was recrystallized from ethanol; m. p. 187–188°.

Anal. Calcd. for $C_{31}H_{36}O_4$: C, 78.76; H, 7.69. Found: C, 78.36; H, 7.63.

Oxidative Cleavage of 1,3-Dimesityl-3-phenyl-1,2-propanediol with Periodic Acid.—To a solution of 10 g. of 1,3-dimesityl-3-phenyl-1,2-propanediol in 1000 ml. of ethanol was added a solution of 6 g. of potassium periodate in 300 ml. of sulfuric acid (1 *N*). The mixture was stirred at room temperature for seven hours and diluted with 2 l. of water. The brown oily substance which separated from the water solution was collected and dissolved in 10 ml. of ethanol. The white needles which separated when the solution was allowed to stand in the cold were recrystallized from low-boiling petroleum ether; m. p. 73–74°. A mixed melting point determination with the sample of mesitylphenylacetaldehyde prepared by cleavage of 3-mesityl-3-phenyl-1,2-propanediol with periodic acid showed no depression.

The filtrate remaining after removal of mesitylphenylacetaldehyde was evaporated under diminished pressure and the residue distilled *in vacuo*. The fractions boiling at 89–90° (5 mm.) and 186–187° (5 mm.) were collected separately.

The lower-boiling fraction was identified as mesitaldehyde. Its dinitro derivative was formed by nitration with equal volumes of nitric acid and concentrated sulfuric acid; m. p. 166–167°. The dinitromesitaldehyde formed a phenylhydrazone which melted at 208–209°.[10]

The higher-boiling fraction was dissolved in 2 ml. of low-boiling petroleum ether. The white compound which had separated at the end of two days was recrystallized from low-boiling petroleum ether; m. p. 103–105°. A mixed melting point determination with 2,4,6-trimethylbenzoin showed no depression.

1,3-Dimesityl-3-*p*-tolyl-1-propen-1-ol Peroxide.—The procedure for the preparation of this compound was based on the directions used in the preparation of 1,3-dimesityl-3-phenyl-1-propen-1-ol peroxide.[4] To a Grignard reagent prepared from 14.8 g. of magnesium turnings, 105 g. of *p*-bromotoluene and 400 ml. of absolute ether was added a solution of 116 g. of mesitylacetomesitylene in 300 ml. of dry benzene. The mixture was stirred and heated for two hours and decomposed with cold dilute hydrochloric acid. The organic layer was washed with ice water and placed in a 1-liter Erlenmeyer flask held in an ice-bath. Oxygen was bubbled rapidly through the solution for six hours. The solvent was removed by a stream of air leaving 137 g. of white powder melting at 130–131°. The enol peroxide was recrystallized from a mixture of ether, benzene and low-boiling petroleum ether; m. p. 130.5–131.5°.

Anal. Calcd. for $C_{23}H_{32}O_3$: C, 80.73; H, 7.76. Found: C, 80.92; H, 7.92.

α-Hydroxy-β-mesityl-β-*p*-tolylpropiomesitylene.—A mixture of 8 g. of 1,3-dimesityl-3-*p*-tolyl-1-propen-1-ol peroxide, 14 g. of potassium iodide and 100 ml. of glacial acetic acid was shaken at room temperature for eight hours. It was diluted with 150 ml. of water and the precipitate was collected on a filter. The yield of the crude α-hydroxy-β-mesityl-β-*p*-tolylpropiomesitylene was 7 g.; m. p. 134–136°. After recrystallization from ethanol the compound melted at 136–138°.

Anal. Calcd. for $C_{28}H_{32}O_2$: C, 83.96; H, 8.07. Found: C, 83.96; H, 8.13.

The **acetate**, prepared by treatment with acetic anhydride and pyridine, was recrystallized from ethanol; m. p. 170–171°.

Anal. Calcd. for $C_{30}H_{34}O_3$: C, 81.41; H, 7.76. Found: C, 81.48; H, 7.84.

1,3-Dimesityl-3-*p*-tolyl-1,2-propanediol.—A solution of 4 g. of α-hydroxy-β-mesityl-β-*p*-tolylpropiomesitylene in 20 ml. of ethanol was subjected for three hours to a hydrogen pressure of 2000 pounds and a temperature of 150° in the presence of a copper chromite catalyst. The catalyst was removed by filtration and the solvent evaporated. The 1,3-dimesityl-3-*p*-tolyl-1,2-propanediol crystallized from ethanol in white plates which melted at 147–148°.

Anal. Calcd. for $C_{28}H_{34}O_2$: C, 83.53; H, 8.52. Found C, 83.28; H, 8.73.

The **diacetate** of the glycol, prepared by the use of acetic anhydride and pyridine, was recrystallized from dilute ethanol; m. p. 163–165°.

Anal. Calcd. for $C_{32}H_{38}O_4$: C, 78.98; H, 7.87. Found: C, 79.17; H, 8.01.

Oxidative Cleavage of 1,3-Dimesityl-3-*p*-tolyl-1,2-propanediol with Periodic Acid.—To a solution of 5 g. of 1,3-dimesityl-3-*p*-tolyl-1,2-propanediol in 250 ml. of pure dioxane was added a solution of 3 g. of potassium periodate in 150 ml. of sulfuric acid (1 *N*). The mixture was stirred at room temperature for eight hours, diluted with 600 ml. of water and extracted twice with ether. Evaporation of the ether extract left an oil which could not be induced to crystallize.

When the oil was distilled *in vacuo* fractions boiling at 85–86° (3 mm.) and 163–165° (3 mm.) were collected. The residue that remained in the distilling flask was dissolved in ethanol and the solution allowed to stand in the cold; white crystals separated slowly. When recrystallized from ethanol they formed fine needles; m. p. 116–117°.

Anal. Calcd. for $C_{28}H_{32}O$: C, 87.45; H, 8.39. Found: C, 87.94; H, 8.59.

This compound had the composition of the glycol minus the elements of water and may be a ketone.

The lower-boiling portion of the distillate was identified as mesitaldehyde by nitration, which converted it to the known dinitromesitaldehyde; m. p. 166–167°.[10]

The higher-boiling portion was dissolved in 5 ml. of low-boiling petroleum ether and allowed to stand in the cold. White crystals which separated after several days were recrystallized from high-boiling petroleum ether; m. p. 211–212°. A mixed melting point determination with mesityl-*p*-tolylacetic acid showed no depression.

Summary

Mesitylphenylacetaldehyde has been prepared by the oxidative cleavage of 3-mesityl-3-phenyl-1,2-propanediol and of 1,3-dimesityl-3-phenyl-1,2-propanediol. It rearranged to 2-mesityl-2-phenylvinyl alcohol when heated at 150° or when treated with alkali.

Evidence is presented indicating that mesitylphenylpyruvaldehyde exists in the enol form.

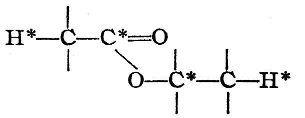
Types of Reaction of Carboxylic Esters with Grignard Reagents[1]

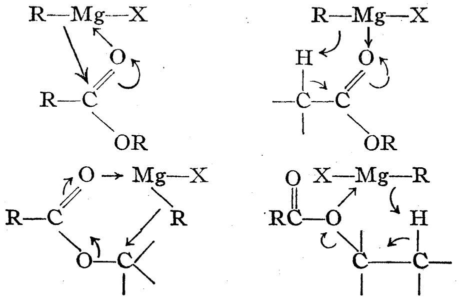
BY CHARLES R. HAUSER, PASSIE O. SAPERSTEIN AND JOSEPH C. SHIVERS

A strong base such as the amide ion[2] is capable of reacting with carboxylic esters at any of the four positions indicated by asterisks in the following general formula: at the carbonyl carbon, the α-hydrogen in the acyl portion, the α-carbon or the β-hydrogen in the alkoxy portion.



Since the strongly basic alkyl or aryl anion is potentially present in Grignard reagents these reagents should be capable of reacting at any of the four vulnerable positions of esters. Actually, reactions at three of these positions have been observed previously; reaction at the fourth position, the β-hydrogen, has been realized in this investigation.

The reactions of the potential alkyl or aryl anions of Grignard reagents at the four vulnerable positions of esters are of different types. Addition occurs at the carbonyl carbon to form a ketone or more often a tertiary alcohol[3]; the α-hydrogen is removed to form the magnesium halide derivative (enolate) of the ester which condenses with unchanged ester to form a β-keto ester (acetoacetic ester condensation); substitution takes place at the α-carbon to form a hydrocarbon; and the β-hydrogen is removed, accompanied by the elimination of the carboxylate group, to form an olefin (β-elimination). Because the magnesium atoms of Grignard reagents probably first coördinate with the carbonyl or alkoxy oxygen atoms of esters it is possible that these four types of reaction take place within the resulting coördination complexes. Indeed, the formation of the coördination complex should activate both the potential alkyl or aryl anion of the Grignard reagent and the electron accepting atom of the ester; moreover, these reactive centers should be brought in close contact within the coördination complex.[4] The electronic changes that may occur within the coördination complexes leading to the four types of reaction may be indicated as



It is well known that ethyl acetate and higher aliphatic homologs as well as ordinary aromatic esters such as ethyl benzoate exhibit mainly the carbonyl carbon reaction with most Grignard reagents. However, t-butyl acetate,[5] which has a relatively unreactive carbonyl carbon, and especially ethyl phenylacetate,[6] which has a relatively reactive α-hydrogen, are self-condensed by isopropylmagnesium bromide. With the more complex Grignard reagent, t-butylmagnesium chloride,[7] ethyl propionate mainly self-condenses, while with mesitylmagnesium bromide[8] even ethyl isovalerate and ethyl isobutyrate self-condense.

In this investigation ethylmagnesium bromide was found to effect the self-condensation of ethyl phenylacetate to the extent of only 8% under the conditions that have produced a 94% yield of the condensation product in the presence of the more complex isopropylmagnesium bromide.[6] Ethyl diphenylacetate was found to react to some extent with isopropylmagensium bromide in refluxing ethyl ether but neither the self-condensation product of the ester nor the carbonyl carbon product was obtained. Since treatment of the reaction mixture with benzoyl chloride gave some ethyl benzoyldiphenylacetate whereas none was obtained from the ester alone with benzoyl chloride, part of the ester must have been converted to its magnesium derivative by the Grignard reagent, thus

$$(C_6H_5)_2CHCO_2C_2H_5 \xrightarrow{(CH_3)_2CHMgBr} [(C_6H_5)_2CCO_2C_2H_5]MgBr \xrightarrow{C_6H_5COCl} C_6H_5COC(C_6H_5)_2CO_2C_2H_5$$

This appears to be the first case in which the magnesium derivative of an ester has been condensed with a component other than the original ester[9];

[8] Spielman and Schmidt, *ibid.*, **59**, 2009 (1937).

[9] An unsuccessful attempt to benzoylate the magnesium derivative of ethyl isobutyrate, prepared by means of mesitylmagnesium bromide, was made previously in this laboratory; Hudson and Hauser, *ibid.*, **63**, 3157 (1941), note 8.

judging from previous results with diethylaminomagnesium bromide[10] the magnesium derivative of most esters condense very rapidly with the original ester. An attempt to carbonate the magnesium derivative of ethyl diphenylacetate failed, presumably because of the instability of the carbonation product.[11]

Substitution at the α-carbon in the alkoxy portion of esters has been observed with certain esters in which the carbonyl carbon is hindered and the α-carbon is attached to relatively strong electron releasing groups. Arnold and co-workers[12] have realized this type of reaction with certain allyl esters, for example allyl mesitoate, with which phenylmagnesium bromide gave a 70% yield of allylbenzene.[13] Fieser and Heymann[14] found that triphenylmethyl acetate reacts with methylmagnesium iodide to form α,α,α-triphenylethane in good yield. In the present investigation triphenylmethyl benzoate has been found to react similarly.

$$C_6H_5CO_2C(C_6H_5)_3 + CH_3MgI \longrightarrow (C_6H_5)_3CCH_3 + C_6H_5CO_2MgI$$

β-Elimination of esters with Grignards has apparently not been reported previously.[15] This type of reaction has been realized in the present investigation with α,β-diphenylethyl mesitoate in which the carbonyl carbon is hindered and the β-hydrogen is activated. With phenylmagnesium bromide in refluxing n-butyl ether this ester yielded the elimination products stilbene and mesitoic acid in yields of 80–90%; this was shown not to be merely a thermal elimination.

$$\text{Mes-}CO_2CH(C_6H_5)CH_2C_6H_5 + C_6H_5MgBr \longrightarrow C_6H_5CH{=}CHC_6H_5 + \text{Mes-}CO_2MgBr$$

With methylmagnesium iodide or ethylmagnesium bromide under similar conditions the yield of stilbene was only 30–40% and another product, 1,2,3,4-tetraphenylbutane, was obtained in 8–9% yield. The latter substance might be accounted for by the dimerization of the intermediate free α,β-diphenylethyl radical.[16] This type of reaction appears to have been observed by Stadnikoff[17] who found that benzhydryl acetate reacts with n-propyl- or n-butyl-magnesium iodide to form partly (6–10%) *sym*-tetraphenylethane along with the corresponding alkane and alkene from the Grignard. Since Kharasch and co-workers[18] have found that cobaltous chloride increases the free radical nature of certain Grignard reactions, α,β-diphenylethyl mesitoate and methylmagnesium iodide have been allowed to react in the presence of a catalytic amount of this salt. In agreement with the radical mechanism, the yield of the dimer was increased from 9% to 16% and no stilbene was found. However, the reaction of the ester with phenylmagnesium bromide and cobaltous chloride produced none of the dimer, although the yield of stilbene was reduced considerably. Actually the best yield (22%) of the dimer was obtained when the reaction was carried out with methylmagnesium iodide using a metal stirrer; no cobaltous chloride was added in this experiment. It might appear that the stilbene could be accounted for by the radical mechanism in which the α,β-diphenylethyl radical underwent disproportionation, but the other product of this reaction, dibenzyl, has not been found. Moreover, the yield of stilbene decreased as the conditions were made more favorable for the radical reaction.

Experimental[19]

Esters.—Ethyl diphenylacetate (m. p. 57°) was synthesized by the carbethoxylation of diphenylmethylpotassium as described previously.[20]

Triphenylmethyl benzoate was prepared by a modification of the method of Gomberg and Davis[21] for triphenylmethyl acetate. A mixture of 43.2 g. (0.15 mole) of triphenylchloromethane and 40.0 g. (0.15 mole) of silver benzoate in 500 ml. of dry benzene was stirred and heated on the steam-bath for six hours, filtered hot and the filtrate concentrated. The precipitate obtained on cooling was filtered off and recrystallized from ethyl acetate yielding 25 g. (50%) of the ester, melting at 162–163°.

Anal. Calcd. for $C_{25}H_{20}O_2$: C, 85.69; H, 5.53. Found: C, 85.35; H, 5.67.

α,β-Diphenylethyl mesitoate was prepared by stirring for four hours a mixture of 37 g. (0.22 mole) of phenylbenzylcarbinol and 40 g. (0.22 mole) of mesitoyl chloride[22] in 200 ml. of dry benzene. The benzene solution was extracted with sodium bicarbonate solution, dried with Drierite and the solvent distilled. The oily residue was recrystallized from 50% ethanol yielding 60 g. (82%) of the ester, melting at 55–57°.

Anal. Calcd. for $C_{24}H_{24}O_2$: C, 83.71; H, 7.03. Found: C, 83.36; H, 7.11.

Grignards.—These reagents were prepared under nitrogen in absolute ethyl or n-butyl ether. The solutions were decanted from unreacted magnesium and analyzed; when not used immediately they were stored under nitrogen in well stoppered flasks in the dark.

Apparatus.—The reactions of esters with Grignards were carried out in three necked round bottomed flasks (of suitable capacity) equipped through ground glass joints with a dropping funnel, a mercury sealed stirrer and a reflux condenser to which was attached a drying tube.

Ethyl Diphenylacetate with Isopropylmagnesium Bromide and Benzoyl Chloride.—To 143 ml. of the stirred ethyl ether solution containing 0.073 moles of isopropylmagnesium bromide was added 17.5 g. (0.073 mole) of ethyl diphenylacetate in 100 ml. of dry ether. Some gas was evolved. On stirring and refluxing for two days the solution became yellow and deposited a few crystals on the sides of the flask. Benzoyl chloride (14 g., 0.1 mole) was then added and the stirring continued for one-half hour. The mixture was decomposed with hydrochloric acid and crushed ice and the ether phase washed with water, dried and the solvent distilled. The brown oily residue was refluxed with 60 ml. of 47% hydriodic acid and 30 ml. of glacial acetic acid for three hours (to hydrolyze the benzoyl chloride and original ester but not the β-keto ester).[20] The resulting mixture was shaken with ether and the ether phase extracted with 2 *M* sodium hydroxide, dried and the solvent distilled. The white crystalline residue was recrystallized from 95% ethanol yielding 3.5 g. (14%) of ethyl benzoyldiphenylacetate, melting at 146° (and at 147° when mixed with an authentic sample,[20] m. p. 148°). Some (5 g., 29%) of ethyl diphenylacetate (m. p. 57°) was recovered from the ethanol filtrate; no attempt was made to recover the diphenylacetic acid that was undoubtedly present in the alkaline extract. The self-condensation product of the ester was not found.

A blank experiment with ethyl diphenylacetate and benzoyl chloride in ether yielded no ethyl benzoyldiphenylacetate. Some (30%) of the original ester was recovered; most of it was probably hydrolyzed in the hydriodic-acetic acid treatment.

In an attempt to effect carbonation the ether solution of equivalents of the Grignard and ester, after stirring and refluxing for two hours, was poured onto excess Dry Ice but no ethyl hydrogen diphenylmalonate was found; most (83%) of the original ester was recovered.

Triphenylmethyl Benzoate with Methylmagnesium Iodide.—To the stirred reagent from 13.5 g. (0.098 mole) of methyl iodide and 2.4 g. (0.098 g. at.) of magnesium in 400 ml. of ethyl ether, was added 6.0 g. (0.015 mole) of triphenylmethyl benzoate (partly as a suspension) in 350 ml. of dry ether. The resulting solution was stirred and refluxed for eight hours (producing a precipitate) and decomposed with ice and acid. The ether phase was extracted with sodium bicarbonate solution, dried and the solvent distilled. The residue (3.8 g.) melted at 65–75°. Recrystallization from 95% ethanol yielded 2.3 g. (45%) of α,α,α-triphenylethane, m. p. 93–94.5° (reported m. p. 93.8–95°).[14] Acidification of the bicarbonate extract yielded 1 g. (85%) of benzoic acid, m. p. 121°.

When triphenylmethyl benzoate was treated with excess diethylamino-magnesium bromide in ether[10] or with potassium amide in liquid ammonia, amines appeared to be formed but their hydrochlorides soon decomposed.

α,β-Diphenylethyl Mesitoate with Grignards. (A). With Phenyl-magnesium Bromide.—Since 75% of the ester was recovered when it was refluxed with the Grignard in ethyl ether for one hour and then allowed to stand overnight, the reaction was carried out in refluxing *n*-butyl ether (b. p. 142–143°). It was first shown that the ester may be refluxed alone in *n*-butyl ether for four hours and most (89%) of it recovered unchanged.

To 100 ml. of the stirred *n*-butyl ether solution containing 0.1 mole of phenylmagnesium bromide (prepared from an ethyl ether solution of the reagent by adding the butyl ether in an atmosphere of nitrogen and distilling off the ethyl ether) was added 13 g. (0.05 mole) of α,β-diphenylethyl mesitoate in 100 ml. of butyl ether. The mixture was stirred and refluxed for four hours and then hydrolyzed with ice and acid. The ether phase was extracted with bicarbonate, washed with water, dried and the solvent distilled. The oily residue on recrystallization from ethanol yielded 5.5 g. (68%) of *trans*-stilbene, m. p. and mixed m. p. 124°. From the ethanol filtrate there was obtained 1.1 g. (13%) of *cis*-stilbene, b. p. 148° (14 mm.) (reported b. p. 148–9° (17 mm.), 145° (13 mm.)).[23] The *trans*- and *cis*-stilbene gave the same dibromide, m. p. 237°.[24] Acidification of the bicarbonate extract yielded 7.3 g. (90%) of mesitoic acid, m. p. 151°.

When the reaction was carried out in the presence of 3 mole per cent. of anhydrous cobaltous chloride[18] (which was first refluxed with the Grignard before adding the ester) the yields of stilbene and mesitoic acid were only 38–40% but other products were not found.

(B) **With Methylmagnesium Iodide.**—The reaction of 35 ml. of a *n*-butyl ether solution containing 0.045 mole of methylmagnesium iodide (prepared in the butyl ether) with 5 g. (0.02 mole) of α,β-diphenylethyl mesitoate in 100 ml. of butyl ether was carried out as in (A). The residue obtained on distilling the solvent consisted of 2 g. of yellow solid from which two products were isolated by fractional crystallization from 95% ethanol. The more soluble substance (1.0 g., 30%) was *trans*-stilbene (m. p. and mixed m. p. 124°). The less soluble substance (0.3 g., 9%) was 1,2,3,4-tetraphenylbutane, m. p. 177–179°,[25] which after treatment with chromic anhydride in glacial acetic acid for five hours was recovered unchanged.

Anal. Calcd. for $C_{28}H_{26}$: C, 92.85; H, 7.18. Found: C, 92.52; H, 7.21.

Acidification of the bicarbonate extract gave 2.6 g. (78%) of mesitoic acid, m. p. 152°.

When the reaction was carried out in the presence of 3 mole per cent. of anhydrous cobaltous chloride[18] the yield of 1,2,3,4-tetraphenylbutane (m. p. 178°) was increased to 16%, a 40% yield of mesitoic acid was obtained but no stilbene or dibenzyl was found. Some (25%) of the original ester was recovered.

(C) **With Ethylmagnesium Bromide.**—The reaction of 22 ml. of a *n*-butyl ether solution containing 0.04 mole of ethylmagnesium bromide (prepared in the butyl ether) with 6.8 g. (0.028 mole) of α,β-diphenylethyl mesitoate in 100 ml. of butyl ether was carried out as in (A). The residue obtained on distillation of the solvent consisted of 2.5 g. of yellow solid from which was isolated 0.3 g. (8%) of 1,2,3,4-tetraphenylbutane (m. p. 178°) and 1.5 g. (45%) of a mixture of *cis*- and *trans*-stilbene (in approximately equal proportions) each of which was converted to the dibromide (m. p. 237°).[24] A 76% yield of mesitoic acid, m. p. 151°, was obtained.

Summary

1. Any of four positions of a carboxylic ester may react with the Grignard reagent. Reaction at one of these, the β-hydrogen in the alkoxy portion of an ester, has been realized for the first time. New examples of reactions at two other positions have also been described.

2. The influence of structure on the four courses of reaction and mechanisms have been considered.

3. Dimerization of the alkyl group in the alkoxy portion of an ester (apparently by a radical mechanism) has been realized.

L(+)Propylene Glycol

BY ERICH BAER AND HERMANN O. L. FISCHER

The preparation and the properties of both enantiomers of propylene glycol have been previously described. The levo-rotatory form has been obtained (a) by reduction of ethyl D-lactate with sodium in ethanol and toluene,[1] (b) by desamination of the levo-rotatory 1-aminopropanol-2 hydrochloride with potassium nitrite[2] or silver nitrite,[3,4] (c) by hydrolysis of dextro-rotatory propylene oxide with sodium hydroxide[5] or hydrolysis of levo-rotatory propylene oxide with formic acid and hydrochloric acid[6] and (d) by phytochemical reduction of acetol.[7,8] The dextro-rotatory form of propylene glycol has been obtained by hydrolysis of dextro-rotatory propylene oxide with formic and hydrochloric acid.[5,6] The specific rotations of both enantiomers obtained by the above methods vary greatly. It is obvious that most of these procedures produce mixtures of the dextro- and levo-rotatory propylene glycol, the ratio depending on the optical purity of the starting material and the prevailing experimental conditions.

We had at our disposal a method which was expected to yield the pure enantiomers of propylene glycol and to reveal their steric relationship to glyceraldehyde, the accepted compound of reference in stereochemistry. It was decided to prepare by means of this method the dextro-rotatory propylene glycol because this isomer had not yet been obtained in as pure an optical state as the levo-rotatory compound for which an excellent biochemical method of preparation already existed.[7] Incidentally, this choice also permitted the use of the much more readily available D-mannitol as starting material. The sequence of reactions employed in the synthesis of L(+)propylene glycol and the steric interrelationship of the various compounds concerned are outlined in the reaction scheme.

The L(+)propylene glycol, obtained from D-mannitol in seven steps and with an over-all yield of approximately 11% of the theory, was in all respects identical with D(−)propylene glycol prepared by the phytochemical reduction of acetol[7] except that its rotation was opposite in sign. The D(−)propylene glycol can be obtained by the same sequence of reactions starting the synthesis with L-mannitol.

With regard to the steric classification of the dextro-rotatory propylene glycol, it should be noted that the transformation of the acetone D-glyceraldehyde into the dextro-rotatory propylene glycol is accompanied by a reversal in configuration. If one were to oxidize the primary hydroxyl group of the dextro-rotatory propylene glycol the result would be either L-lactic aldehyde or L-lactic acid. Thus the dextro-rotatory propylene glycol belongs to the L-series and the levo-rotatory form to the D-series.[9]

This result is in agreement with the fact that the reduction of ethyl D-lactate IX yields the levo-rotatory D-propylene glycol X.

This optical classification of the propylene glycols seemed to be of interest because recently propylene glycol in the form of its phosphate has been isolated from a natural source, cattle brain, where it constitutes about 5% of the acid soluble phosphorus.[10]

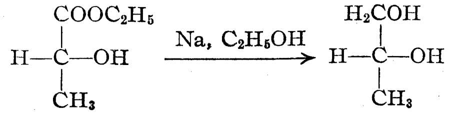
VII L(+)Propylene glycol VIII



IX Ethyl D-lactate X D(−)Propylene glycol

Experimental Part

α-(*p*-Toluenesulfonyl) D-Acetone Glycerol (V).—To a gently agitated and cooled mixture of 38.0 g. of *p*-toluene sulfonylchloride and 20 ml. of dry pyridine was added 26.4 g. of freshly prepared D(+)acetone glycerol ($[\alpha]_D$+ 13.9°). The reaction mixture was kept in an ice-bath until the reaction had subsided (approximately one hour). After standing forty-eight hours at room temperature a crystalline sludge had formed which was poured with stirring into 500 ml. of ice-water. The supernatant liquid was immediately decanted and the heavy oil, dissolved in ether, washed with sodium carbonate solution. The ether solution was dried with anhydrous sodium sulfate and concentrated *in vacuo* to a thick sirup. The residue (48.4 g.) was dissolved in a mixture of 300 ml. of dry ether and 600 ml. of petroleum ether (b. p. 30–60°), the solution cooled to −70° and the thick sludge filtered with suction on a cooled Büchner funnel. The substance, which liquifies at room temperature, was freed *in vacuo* from adhering solvent. The yield of α-(*p*-toluenesulfonyl) D-acetone glycerol (V) was 46.0 g. (80.2%), n^{22}_D 1.5054; d^{24} 1.208. $[\alpha]^{34}_D$ −6.7° in substance; $[\alpha]^{24}_D$ −4.6° in dry ethanol (*c*, 13).

Anal. Calcd. for $C_{13}H_{18}O_5S$ (286.2): C, 54.51; H, 6.29; acetone, 20.3. Found: C, 54.60; H, 6.28; acetone, 20.6, 20.0.

α-Iodo Acetone L-Propylene Glycol (VI).—A solution of 46.0 g. of α-(*p*-toluenesulfonyl) D-acetone glycerol and 65 g. of sodium iodide in 300 ml. of dry acetone was kept in a pressure bottle at 90° for ten hours. The sodium *p*-toluenesulfonate was collected on a Büchner funnel and thoroughly washed with dry acetone. The combined filtrates were brought to dryness at reduced pressure and the reddish-brown solid extracted with four 100-ml. portions of ether. The ether-extract was washed twice with 30-ml. portions of a dilute sodium thiosulfate solution, dried with anhydrous sodium sulfate and concentrated under diminished pressure (bath to 35°). The fractional vacuum distillation of the residue yielded 30.0 g. (77.4%) of pure α-iodo acetone L-propylene glycol (VI), b. p. (6 mm.) 68–69°; n^{25}_D 1.5022; $d^{20.5}$ 1.644; $[\alpha]^{23}_D$ + 54.0° in substance; $[\alpha]^{23}_D$ + 35.5° in dry ethanol (*c*, 12.7).

Anal. Calcd. for $C_6H_{11}O_2I$ (241.9): I, 52.46; acetone, 23.97. Found: I, 52.63; acetone, 24.3.

α-Iodo L-Propylene Glycol (VII).—A solution of 30.0 g. of α-iodoacetone L-propylene glycol in 75 ml. of 85% ethanol was prepared and after the addition of 2.5 ml. of 5 *N* sulfuric acid kept for twenty hours at room temperature. In order to ensure a complete hydrolysis the solution was diluted with 10 ml. of water and refluxed for a period of five minutes. The cold solution was made neutral to litmus with aqueous baryta and concentrated *in vacuo* to a dry sirup at a bath temperature of 35 to 45°. The residue was extracted with four 75-ml. portions of ether and the combined extracts, after drying with anhydrous sodium sulfate, brought to dryness under reduced pressure. The residue (20.2 g., m. p. 47–49°) was recrystallized from chloroform–petroleum ether (b. p. 30–60°) and yielded 19.3 g. (77%) of analytically pure α-iodo-L-propylene glycol (VII). Platelets, m. p. 48.5–49.5°, $[\alpha]_D$ −5.5° in dry ethanol (*c*, 9.5).

Anal. Calcd. for $C_3H_7O_2I$ (201.9): C, 17.83; H, 3.46; I, 62.85. Found: C, 18.09, 18.07; H, 3.79, 3.74; I, 62.70.

L(+)Propylene Glycol (VIII).—A solution of 19.3 g. of α-iodo-L-propylene glycol (VII) and 15 ml. of 10 *N* sodium hydroxide in 300 ml. of 95% ethanol was shaken with 10 g. of Raney nickel catalyst in a hydrogen atmosphere of slightly positive pressure until the absorption of hydrogen ceased. Within thirty minutes 1906 ml. of dry hydrogen (N.P.T.) or 89% of the theoretical amount had been consumed. The solution was freed from the catalyst, treated with carbon dioxide, filtered and the filtrate evaporated to dryness under diminished pressure and a bath temperature of 35–45°. The residue was dissolved in 60 ml. of dry ethanol and 200 ml. of dry ether and the solution dried with approximately 40 g. of anhydrous sodium sulfate. The ether solution was decanted and concentrated under normal pressure. The rest of the solvent was removed under reduced pressure raising the temperature of the bath to 60°. The remaining mixture of propylene glycol and sodium iodide was gradually heated *in vacuo* to 160° and the colorless distillate purified by fractional distillation either at normal pressure or *in vacuo*. The yield of pure L(+)propylene glycol (VIII) was 4.32 g. (70%), b.p. (765 mm.) 186–188°; b. p. (6 mm.) 76–78°, $n^{23.5}_D$ 1.4312, d^{20} 1.04, $[\alpha]^{23}_D$ + 15.4° in substance; $[\alpha]^{23}_D$ + 20.1° in water (*c*, 7.5), $[\alpha]^{22}_D$ + 4.2° in dry ethanol (*c*, 6.6).

Anal. Calcd. for $C_3H_8O_2$(76): C, 47.36; H, 10.52. Found: C, 47.84; H, 10.38.

Summary

Dextro-rotatory propylene glycol was prepared and its L-configuration established by means of the following sequence of reactions: D-acetone glyceraldehyde → D-acetone glycerol → α-(*p*-toluenesulfonyl) D-acetone glycerol → α-iodo acetone L-propylene glycol → α-iodo-L-propylene glycol → L(+)propylene glycol.

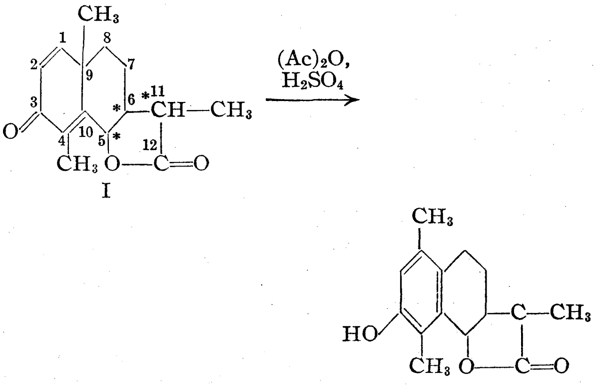
Studies in the Santonin Series. IV.[1,2,3] The Stereochemistry of Santonin and its Derivatives

BY HUANG-MINLON[3a]

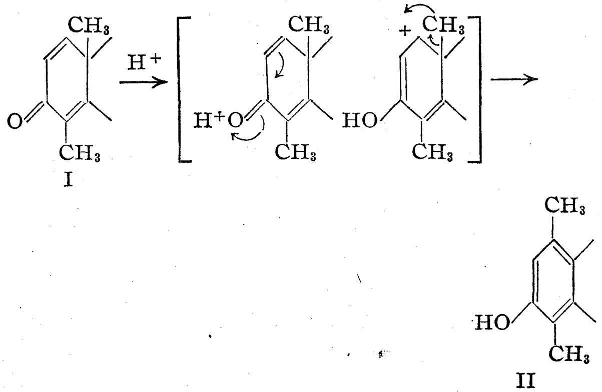
The relative configuration of santonin and of various transformation products has been discussed briefly in an earlier paper.[1] In the meantime sufficient experimental facts have accumulated to extend this discussion.

The almost quantitative rearrangement of santonin (I) into the aromatic *l*-α-desmotroposantonin (II)[3b] induced by acetic anhydride and a trace of sulfuric acid was originally considered as an enol acylation reaction.[1] The enolization, however, is unusual in that, in addition to the prototropic change, an alkylotropy occurs also. This acid-catalyzed rearrangement is similar to a Wagner–Meerwein rearrangement and the mechanism can be formulated as



I

II

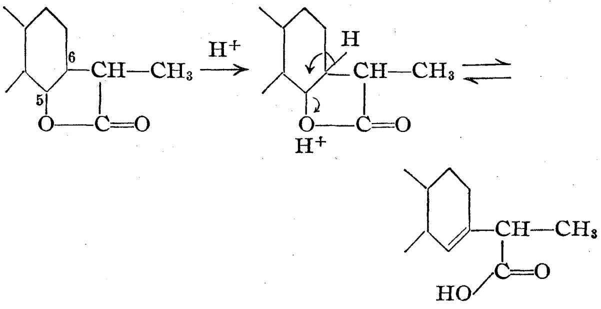


I

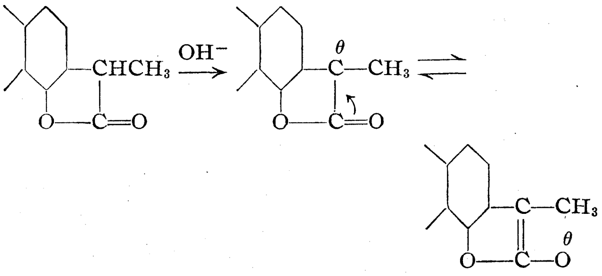
II

Of particular interest is the interconversion of the four isomeric desmotroposantonins by successive treatment with acid and with alkali[1] (see chart[3c]), since this is probably the first instance of a cycle in which the configurations of three asymmetric carbon atoms are changed and then restored to the original state.

(a) Acid conversion:



(b) Alkaline conversion



Plausible mechanisms for the conversions observed with acid and with alkali can now be advanced. Support for the postulated acid-catalyzed reaction is furnished by the formation of the ethyl ester of dihydrosantinic acid (IV) from isohyposantonin (III) by the action of alcoholic hydrochloric acid.[6] Isohyposantonin is *levo*-rotatory; it contains three asymmetric carbon atoms that have the same configuration as that of *l*-α-desmotroposantonin, A (see conversion of III into A, below). The β,γ-unsaturated ester, which contains only one asymmetric carbon atom, is dextrorotatory. The reaction is comparable to the transformation of A to B, but in this case the β,γ-un-

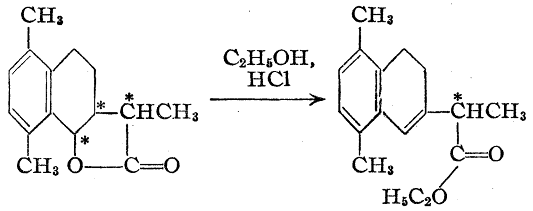
saturated acid postulated in the acid-catalyzed reaction above is tied down by esterification.



III IV

According to the postulated reactions with acid and with base the configurations of C-5 and of C-6 are inverted by acid treatment, whereas the configuration of C-11 is inverted by alkali. Unfortunately, the rule of optical superposition[7] is not obeyed strictly in the case under discussion because the asymmetric centers are adjacent to one another and conseqently vicinal effects are to be expected.[7] However, the [α]D values do correspond with proposed formulations with the exception of B → C and D → A. Furthermore, it is assumed in the following discussion that inversion of one asymmetric center does not cause inversion of another asymmetric center.

The reduction of each optically active desmotroposantonin results in an optically active santonous acid[8] of opposite optical rotation[1] as shown above. In the reduction one center of asymmetry is destroyed (C-5) and, since this loss results in a marked change in the optical rotatory power in all four cases, it can be assumed that this asymmetric center (C-5) makes the largest contribution to the total rotatory power. For this reason the asymmetric center C-5 in 1-α-desmotroposantonin (A) for example, must be levorotatory; the two remaining asymmetric centers (C-6 and C-11) must be dextrorotatory since the corresponding santonous acid (A') is the most dextrorotatory of the four possible santonous acids. Since treatment with acid and then with alkali (for example, A → B → C) or treatment with alkali and then with acid (B → C → D) converts a desmotroposantonin into the antipode, either acid or alkali must change simultaneously the configuration of two carbon atoms. Acid converts one desmotroposantonin into an isomer of opposite rotation (A → B or C → D); when the asymmetry (C-5) of the isomer (B or D) is destroyed by reduction (*e. g.*, B → B') an acid is obtained that is not identical with the acid obtained from the starting material (*i. e.*, B' ≠ A'). These facts are explainable only on the assumption that acid treatment changes the direction of rotation of two asymmetric centers. The postulated acid reaction (a) results in inversion at C-5 and at C-6 and the alkaline reaction (b) results in inversion at C-11, and thus they fit the experimental facts.

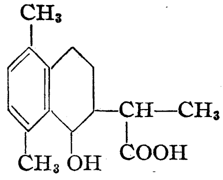
According to the above formulation the desmotroposantonins are all either *cis* or *trans* compounds with reference to the linkage of the lactone ring to the cyclohexyl ring, and are not *cis–trans* isomers. Various experimental facts indicate that the linkage is *cis*. When the lactone ring of a desmotroposantonin is opened by dilute alkali and the basic solution is acidified, the starting material is recovered immediately. The equally instantaneous ring closure of either the α- or the β-form suggests a *cis*-configuration of both forms. From a consideration of molecular models Clemo[5] concludes that the *cis* linkage is the more stable. The physical and chemical properties of the open compounds, (V), of the lactone, (III), hyposanto-

---

(7) For a discussion of the modern theories of optical rotatory power see Kauzmann, Walter and Eyring, *Chem. Rev.*, **26**, 339 (1940).

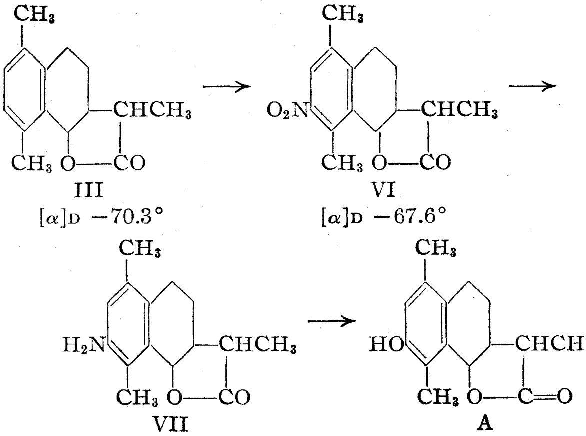
(8) For the sake of convenience the desmotroposantonous acids are named simply santonous acids.

ninic acid (*trans*) and isohyposantoninic acid (*cis*), indicate that the isomerism is geometrical.[9]

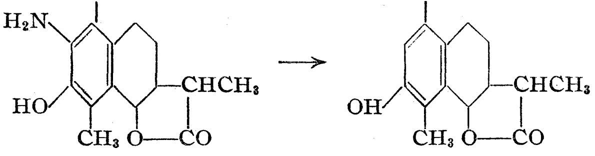


V

Accordingly, hyposantonin (III) is probably the *trans* form because the lactone ring opens readily with the formation of hyposantoninic acid. Isohyposantoninic acid is not stable and even on standing reverts to the lactone, isohyposantonin[9] (III). This *cis* lactone can be converted into *l*-α-desmotroposantonin (A) by the procedure of Asahina,[10] who converted the *trans* lactone in A. The series of transformations, shown in the formulas, do not involve the lactone ring and probably do not affect the mode of juncture. This assumption is supported by the fact that the optical rotation is not affected to any significant extent by the transformation. Furthermore, the transformation of 2-amino-*d*-β-desmotroposantonin (VIII), which is prepared by analogous reaction, into *d*-β-desmotroposantonin (B)[3] demonstrates unequivocally that nitro and amino derivatives retain the configuration of the parent desmotroposantonin. It follows then that *l*-α-desmotroposantonin must also possess the same *cis* linkage as in isohyposantonin and that the other desmotroposantonins are also *cis*.



III $[\alpha]_D$ −70.3°
VI $[\alpha]_D$ −67.6°
VII $[\alpha]_D$ −165.7°
A $[\alpha]_D$ −140°



VIII $[\alpha]_D$ +113.8°
B $[\alpha]_D$ +106.2°

The assumption that the so-called *l*-desmotropo-β-santonin[11] prepared by Clemo[1] from β-santonin is identical with *l*-β-desmotroposantonin (D)[1] has now been established by a direct comparison of crystalline form, of solubility, and of melting point (m. p. 259–260°). The two substances show no depression of melting point on admixture. Equal quantities of Clemo's material and of *d*-β-desmotroposantonin (B) form a racemic product which exhibits no optical activity, melts at 230–231°, and shows no depression in melting point on admixture with *dl*-β-desmotroposantonin.[1] The acetate of the racemic product was likewise compared with the known *dl*-compound[1] and found to be identical. The racemic product on zinc and acetic acid reduction yields an inactive acid (m. p. 181°), which is identical with *dl*-β-santonous acid.[1] The identity of Clemo's compound and D was further confirmed by transformation of both substances into the same santonous acid (D′) (m. p. 175–176°).

Santonin (I) itself probably does not have the *cis* configuration of the lactone ring, even though the aromatization reaction proceeds so readily as to suggest[1] that the steric arrangement is not affected in the transformation into 1-α-desmotroposantonin (A). Santonin oxime is transformed by mild reducing agents mainly into hyposantonin,[12] which has a *trans* configuration and which changes readily into isohyposantonin (*cis*).[13] Hyposantonin and isohyposantonin frequently produce the same reaction products, and many of the derivatives obtained by chemical treatment of hyposantonin, particularly in the presence of acids, are probably in reality derivatives of isohyposantonin. For example, hyposantonin and isohyposantonin form the same nitro product (VI).[10] The rotation of VI and of the amino derivative (VII) is comparable to that of isohyposantonin ($[\alpha]_D$ −70.3°) and not to that of hyposantonin ($[\alpha]_D$ + 32.7°), and therefore nitric acid treatment probably induces isomerization of hyposantonin. Furthermore the so-called aminohyposantonous acid[10] obtained by reduction of the amino derivative (VII) ($[\alpha]_D$ −165.7°) is dextrorotatory ($[\alpha]_D$ + 62.5°) and in this respect is comparable to the changes observed in the reduction of the desmotroposantonins (A $\rightarrow$ A′, etc.). Similarly, the so-called hyposantonous acid (IX)[14] obtained from

both hyposantonin and isohyposantonin by reduction should be designated isohyposantonous acid because it is dextrorotatory, and reductive opening of the lactone ring causes reversal in the direction of rotation.

I am indebted to Prof. L. F. Fieser for his encouragement in the persuance of this investigation and to Mrs. Mary Fieser for help in the preparation of this manuscript.

Summary

The mechanism of the acid-catalyzed rearrangement of santonin to desmotroposantonin and that of the interconversion of the four isomers of desmotroposantonins by acid and alkali has been postulated. The relative configurations of all the known desmotroposantonins have been formulated. *l*-Desmotropo-β-santonin of Clemo has been found to be identical with *l*-β-desmotroposantonin. The spacial configurations of santonin, hyposantonin and isohyposantonin have also been discussed.

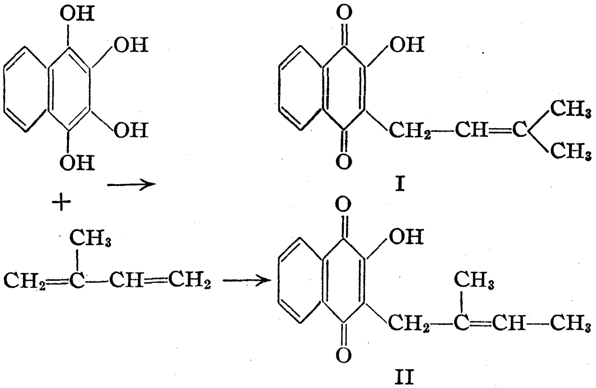
Syntheses in the Lapachol Series

BY MARSHALL GATES AND DOROTHY L. MOESTA[1]

In an extension of the condensation reaction between allylic alcohols and hydroxyhydroquinones reported by Fieser and Gates,[2] we have investigated the condensation of leucoisonaphthazarin with isoprene and with several allylic alcohols related to isoprene. As in earlier examples[2] yields are low, but the inaccessibility of the products by other methods may warrant consideration of this method for the preparation of small amounts.

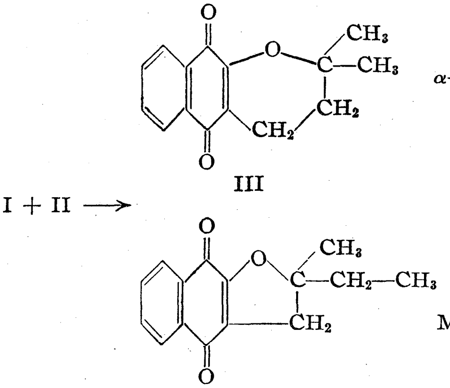
Isoprene condenses with leucoisonaphthazarin in the presence of oxalic acid to yield, after oxidation, a mixture of lapachol (I)[3] and an isomer of lapachol, presumably 2-hydroxy-3-(2′-methyl-2′-butenyl)-1,4-naphthoquinone (II), in roughly equal parts.



I

II

Separation of the two was achieved by fractional crystallization, although the more soluble isomer II was obtained pure only in small amounts by this method. Additional material containing the side-chain carbon skeleton of II could be obtained from the filtrate by cyclization to a mixture of the α-lapachone type isomers III and IV in which the solubility relationships are reversed.



α-Lapachone, m. p. 117°

[2] Fieser and Gates, THIS JOURNAL, **63**, 2948 (1941).

[3] Earlier syntheses of lapachol have been reported by Fieser, *ibid.*, **49**, 857 (1927), and by Hooker, *ibid.*, **58**, 1181 (1936).

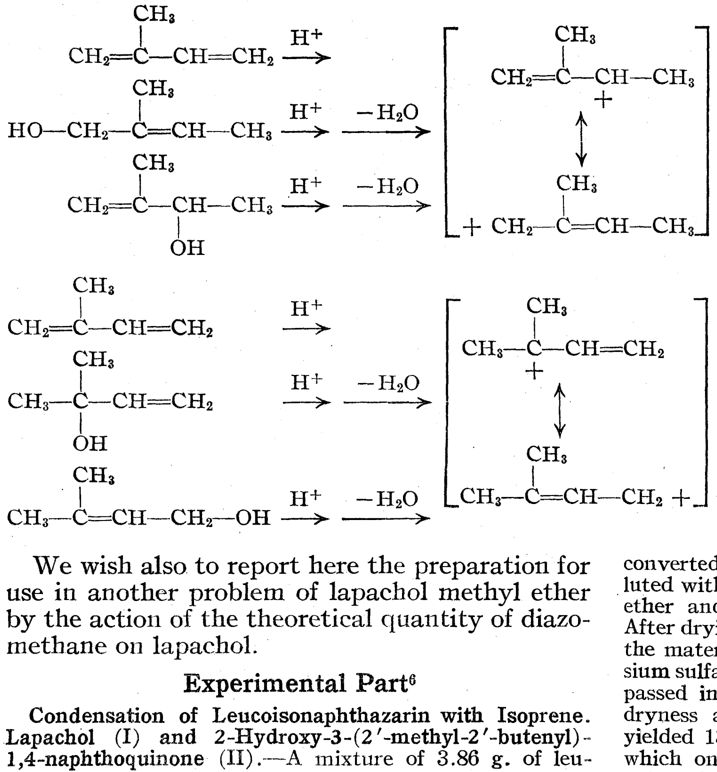
[4] Structure VI is one, although not the preferred one, of three structures originally considered possible for dunnione by Price and Robinson (*J. Chem. Soc.*, 1525 (1939)). If the structure assigned above is correct, VI is eliminated as a possible structure for dunnione since its physical properties do not agree with those of dunnione. Later work by Price and Robinson (*J. Chem. Soc.*, 1493 (1940)) continues to support their original preference (α,α,β-trimethyldihydrofurano-1,2-naphthoquinone) for the structure of this substance.

of 2-methylbutene-2-ol-1 with leucoisonaphthazarin in the presence of oxalic acid. In this case it is the sole hydroxynaphthoquinone isolated and its structure has been assigned on this basis.

Dimethylvinylcarbinol condenses with leucoisonaphthazarin in the presence of oxalic acid to yield lapachol as the sole hydroxynaphthoquinone.

The secondary alcohol 2-methylbutene-1-ol-3 does not yield any hydroxynaphthoquinone when allowed to react with leucoisonaphthazarin under the conditions used in the above condensations.

Any comment on the mechanism of this condensation at present must necessarily, in view of the paucity of data bearing on the question, be largely speculation. It may be noted, however, that the simple postulation of an attack on leucoisonaphthazarin by a carbonium ion produced by the action of acid on either isoprene or the allylic type alcohols used followed by the necessary eliminations[5] is not entirely adequate. For example, an identical resonating carbonium ion should result from isoprene, 2-methylbutene-2-ol-1 and 2-methylbutene-1-ol-3, but only the first two of these give the same product (II), whereas the condensation fails with the third. Isoprene can, in addition, yield the same resonating carbonium ion as dimethylvinylcarbinol and 3-methylbutene-2-ol-1 (not investigated in this work). The first two of these yield lapachol.



We wish also to report here the preparation for use in another problem of lapachol methyl ether by the action of the theoretical quantity of diazomethane on lapachol.

Experimental Part[6]

Condensation of Leucoisonaphthazarin with Isoprene. Lapachol (I) and 2-Hydroxy-3-(2′-methyl-2′-butenyl)-1,4-naphthoquinone (II).—A mixture of 3.86 g. of leucoisonaphthazarin (prepared by hydrosulfite reduction of an ether suspension of isonaphthazarin), 12 cc. of isoprene, 2.5 g. of anhydrous oxalic acid and 50 cc. of dioxane (refluxed and distilled over sodium) was heated at 90 to 100° for sixty hours under nitrogen in a capped bottle. After filtration from some crystalline isonaphthazarin (0.73 g.) the solvent was completely removed by a current of dry air and the residue was taken into ether and extracted four times with dilute sodium carbonate solution. The red-black carbonate extract on acidification with glacial acetic acid and extraction with ether yielded an orange-yellow ethereal solution which was further processed by an additional extraction into carbonate and acidification followed by two chromatographic adsorptions from benzene–hexane onto anhydrous magnesium sulfate. During the second of these a bright yellow band (45 mm. on an 18-mm. diameter column) passed readily into the filtrate and on concentration yielded 446 mg. of bright yellow plates, m. p. 111–126°. Several distinct more strongly adsorbed bands remained on the column and from the two adsorptions a further 0.13 g. of unchanged isonaphthazarin was recovered.

The solid material from the filtrate was subjected to a systematic fractional crystallization from ether–petroleum ether and after numerous crystallizations 156 mg. of lapachol (I) of m. p. 139–140° and 15 mg. of an additional substance (II), m. p. 123–124.5°, were obtained. The lapachol did not depress the melting point of an authentic sample, m. p. 139–140.5°, from the collection of the late Dr. Samuel Cox Hooker, and was further characterized by conversion to β-lapachone, m. p. 154–155°, which likewise did not depress the melting point of an authentic sample from Dr. Hooker's collection. The samples from this collection were kindly placed at our disposal by Professor Louis F. Fieser of Harvard University.

The substance (II) of m. p. 123.5–124.5° crystallizes from ether–petroleum ether in long bright yellow needles and gives a scarlet solution with dilute potassium hydroxide, the color of which can be completely extracted by amyl alcohol.[7] It is isomeric with lapachol.

Anal.[8] Calcd. for $C_{15}H_{14}O_3$: C, 74.36; H, 5.82. Found: C, 74.04; H, 5.57.

As the following example demonstrates it may be converted into an isomer (VI) of β-lapachone by the action of concentrated sulfuric acid: 8.6 mg. was dissolved in about 0.3 cc. of concentrated sulfuric acid, and after standing for five minutes the deep orange-red solution was diluted with water and the precipitated red solid was collected, washed with water and crystallized twice from dilute alcohol to give 3.5 mg. of beautiful scarlet-orange needles, m. p. 118.5–119°.

Anal.[8] Calcd. for $C_{15}H_{14}O_3$: C, 74.36; H, 5.82. Found: C, 74.29; H, 5.78.

Selected filtrates from the fractional crystallization described above were concentrated to dryness, taken into 2 cc. of glacial acetic acid, treated with 0.5 cc. of concentrated hydrochloric acid and heated on the steam-bath for one hour. Under these conditions lapachol is converted to α-lapachone.[9] The reaction mixture was diluted with water and the resultant dark oil was taken into ether and washed with sodium bicarbonate and water. After drying the ether was replaced by benzene–hexane and the material was chromatographed on anhydrous magnesium sulfate. A poorly adsorbed broad canary yellow band passed into the filtrate rapidly and on concentration to dryness and crystallization from ether–petroleum ether yielded 130 mg. of canary yellow plates, m. p. 131–140°, which on two further crystallizations from this solvent pair and a final crystallization from alcohol afforded 72 mg.

---

[5] Bondhus (Dissertation, Bryn Mawr College, 1947) has discussed the mechanism of this reaction as well as the silver salt alkylation used by Fieser[3] for the synthesis of lapachol.

[6] All melting points are corrected.

[7] Price and Robinson, *J. Chem. Soc.*, 1522 (1939).

of yellow leaves of IV, m. p. 149.4–150.2°. It does not dissolve immediately in dilute aqueous potassium hydroxide, but the suspension on standing slowly acquires a red color.

Anal.[8] Calcd. for $C_{15}H_{14}O_3$: C, 74.36; H, 5.82. Found: C, 74.29; H, 5.79.

This material (15 mg.) on standing in concentrated sulfuric acid solution for fifteen minutes yields, on dilution with water and crystallization from dilute alcohol, the isomer VI of β-lapachone described above (9 mg.), m. p. 118.5–119°, mixed melting point not depressed.

Condensation of Leucoisonaphthazarin with Dimethylvinylcarbinol. Lapachol (I).—Dimethylvinylcarbinol[10] (4 cc.) was condensed with 2.77 g. of leucoisonaphthazarin under approximately the conditions outlined above. The reaction mixture, filtered from 0.70 g. of isonaphthazarin, was made alkaline, aerated, extracted with ether and the acidic material taken into ether after acidification with glacial acetic acid. Further processing included extraction by dilute potassium carbonate and chromatographic adsorption on magnesium sulfate from benzene–hexane of the material recovered from the deep red carbonate solution by acidification. Elution of a homogeneous bright yellow band by absolute ether and concentration yielded a yellow residue of impure lapachol (I) (186 mg.) which readily solidified, m. p. 132–136°. One crystallization from petroleum ether raised its melting point to 139–140.5°. The material did not depress the melting point of an authentic sample of lapachol.

Condensation of Leucoisonaphthazarin with 2-Methylbutene-2-ol-1. 2-Hydroxy-3-(2′-methyl-2′-butenyl)-1,4-naphthoquinone (II).—2-Methylbutene-2-ol-1[11] (4 g.) was condensed with leucoisonaphthazarin (from 4 g. of isonaphthazarin) under approximately the conditions outlined above. A processing scheme similar to those described above yielded bright yellow platelets of II, 175 mg., m. p. 120–121°. Recrystallization from ether–petroleum ether gave 160 mg., m. p. 120.5–121.5°.

α-Methyl-α-ethyldihydrofurano-1,4-naphthoquinone (IV) was prepared by stirring the above substance (28 mg.) into a mixture of 8 cc. of glacial acetic acid and 1.5 cc. of concentrated hydrochloric acid and heating on the steam-bath for one hour. Dilution of the reaction mixture with 30 cc. of water at the end of this time resulted in the separation of bright yellow needles which, after recrystallization from alcohol, melted at 147.5–148°; yield 12 mg. The isomeric **α-methyl-α-ethyldihydrofurano-1,2-naphthoquinone (VI)** was prepared by stirring the above isomer of lapachol (29 mg.) into 2 cc. of concentrated sulfuric acid and diluting the orange-brown solution with 35 cc. of water. Recrystallization from alcohol of the precipitated red solid afforded 13 mg. of dark red needles, m. p. 113–114°.

Although a direct comparison was not made, the methods of preparation and the correspondence in melting points of the hydroxyquinones and of the derivatives of the α- and β-lapachone types make the identity of the above isomer of lapachol and that isolated from the isoprene reaction highly probable.

Attempted Condensation of Leucoisonaphthazarin and 2 Methylbutene-1-ol-3.—2-Methylbutene-1-ol-3[12] was treated with leucoisonaphthazarin (from 4 g. of isonaphthazarin) as described for earlier examples. On working up the reaction mixture by the same general scheme used above only isonaphthazarin was recovered. A similar reaction carried out at 65–80° over a period of nine days was also unsuccessful.

Lapachol Methyl Ether.—To 121 mg. of lapachol in a few cc. of ether at 0° was added 1.50 cc. of cold freshly prepared and standardized 0.334 *N* diazomethane solution. The resulting deep orange solution was allowed to stand for several hours during which time the color lightened to yellow. The solution was extracted several times with dilute carbonate solution (acidification of the crimson carbonate extracts gave 11 mg. of unchanged lapachol, m. p. 138–140.5°), washed with water and brine and then filtered and concentrated to dryness. The residual orange oil (116 mg.) solidified on manipulation and was crystallized several times from methanol, in which it is quite soluble, to give 50 mg., m. p. 51–51.8°, of beautiful bright yellow needles. A sample was crystallized once again for analysis and dried at 10^{-4} mm. for several hours, m. p. 52–52.4°.

Anal. Calcd. for $C_{16}H_{16}O_3$: C, 74.98; H, 6.29. Found: C, 74.51; H, 6.14.

The material is readily hydrolyzed to lapachol on warming with dilute potassium hydroxide in water and methanol.

Summary

Leucoisonaphthazarin has been shown to condense with isoprene, dimethylvinylcarbinol and 2-methylbutene-2-ol-1 in the presence of anhydrous oxalic acid to give low yields of 2-hydroxy-3-alkenyl-1,4-naphthoquinones. Dimethylvinylcarbinol gives rise to lapachol, 2-methylbutene-2-ol-1 gives 2-hydroxy-3-(2′-methyl-2′-butenyl)-1,4 naphthoquinone, and isoprene yields a mixture of these products.

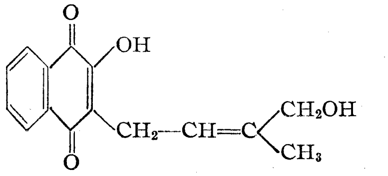
A Synthesis of Lomatiol

BY MARSHALL GATES

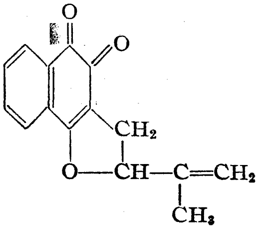
Lomatiol, the yellow coloring matter surrounding the seeds of several Australian species of *Lomatia*, was first investigated by Rennie[1] who, after demonstrating its close relationship to lapachol, left further investigation of the pigment to Samuel Cox Hooker. Hooker,[2] in a series of papers closely integrated with those describing his elegant work in the lapachol field, was able to show that the structure 2-hydroxy-3-(3′-hydroxymethyl-2′-butenyl)-1,4-naphthoquinone (I) is in complete harmony with the experimental facts. In the course of this work Hooker accomplished the conversion of lomatiol into lapachol.

We have now achieved the reverse transformation of lapachol into lomatiol, and, since lapachol has been prepared synthetically by several methods,[3,2b] this constitutes a synthesis of lomatiol. Our conversion made use of selenium dioxide oxidation of leucolapachol triacetate in the presence of acetic anhydride, essentially as described by Guillemonat,[4] to give a mixture containing both leucolomatiol tetraacetate and unchanged leucolapachol triacetate.[5] This crude product on saponification and air oxidation yielded a mixture from which lomatiol and lapachol were easily separated by chromatographic adsorption on magnesium sulfate. The lomatiol was fully identified by comparison with an authentic sample,[6] by conversion to its highly characteristic barium salts,[2b] and by conversion to dehydroiso-β-lapachone (II)[2b] which was compared with a sample prepared from authentic lomatiol.



I

Lomatiol



II

Dehydroiso-β-lapachone

Experimental Part[7]

Lomatiol.—Leucolapachol triacetate[8] (119 mg., m. p. 141–142.5°) dissolved in a mixture of 5 cc. of C. P. acetic anhydride and 3 cc. of glacial acetic acid (refluxed and distilled over chromium trioxide) was treated with 15 mg. of freshly sublimed selenium dioxide. There was no apparent action at room temperature, but on warming gradually to reflux during fifteen minutes the mixture darkened, the selenium dioxide began to go into solution and selenium, at first red, later black, began to separate. The mixture was held at reflux for twenty-five minutes, cooled and diluted with water. The precipitated oil was taken into peroxide-free ether, washed twice with water, twice with 2% sodium hydroxide, again with water, dried and concentrated. The residual clear pale-yellow very viscous oil (134 mg.) was dissolved in 5 cc. of methanol and treated with 5 cc. of water containing 2 g. of potassium hydroxide. The solution, which immediately became deep brown but quickly changed to deep red, was heated to reflux for ten minutes during which it was necessary to dilute with a small amount of water to redissolve some dark red oily sodium salt which had separated. After cooling the mixture was carefully acidified with 5% hydrochloric acid and the precipitated brown gummy solid was taken into peroxide-free ether, filtered from a small amount of insoluble material, washed twice with water, once with saturated brine, filtered through anhydrous sodium sulfate and concentrated. The residual brown very viscous oil (64 mg.) was taken into hot benzene (not entirely soluble), cooled and chromatographed on ignited magnesium sulfate. Development with benzene caused a broad yellow-tan band (1) followed by a thin, faint yellow band (2) to pass rapidly into the filtrate, and left three distinct bands on the column—toward the bottom a thin reddish band (3) overlain by a broad yellow band (4) and at the top a reddish-brown band (5)—which were sectioned out and eluted, (3) and (4) with ether, (5) with alcohol. Fractions 2 and 5 were discarded, fractions 1, 3 and 4 were concentrated and pumped out.

Fraction 1 (orange solid, 17 mg.) proved to be crude lapachol, and after three crystallizations from benzene–hexane, the final one with the aid of norite, yielded 5 mg. of beautiful bright yellow leaves, m. p. 139.2–139.8°, which did not depress the melting point of an authentic sample of lapachol of m. p. 139–140.3°.

Fraction 3 (yellow solid, 8 mg.) was sparingly soluble in benzene and gave no immediate red color with dilute aqueous potassium hydroxide, although on standing or fairly rapidly on heating a crimson color was produced with alkali. After boiling up twice with benzene the bright yellow material remaining insoluble melted with decomposition and the production of a blue-green color at 186–188°. It was not investigated further, although its properties indicate that it may be of the α-lapachone type.

Fraction 4 (orange solid, 21 mg.) was crystallized four times, once with the aid of norite, from benzene, in which it was rather sparingly soluble, to yield 11.5 mg. of beautiful bright yellow needles m. p. 127.3–128.5°, which did not

depress the melting point of an authentic sample[6] of lomatiol of m. p. 127.7–129°. It dissolved in dilute potassium hydroxide with a deep crimson color, and a drop of a solution of its barium salt, prepared as described by Hooker,[2b] allowed to evaporate on a microscope slide, exhibited the two characteristic forms and the highly characteristic behavior on rubbing described by him.

Dehydroiso-β-lapachone was prepared from a sample (7.1 mg.) of the synthetic lomatiol described above by the method of Hooker.[2b] After two crystallizations from dilute alcohol 3 mg. of orange-red needles were obtained which exhibited the following very characteristic melting point behavior. An initial melting point of 110–112° was observed (*cf.* refs. 1 and 2b) but if the capillary was held for some time at about 113° the material resolidified and then remelted at 115.2–116.2°. Likewise, if a freshly melted sample of the needles (m. p. 110–112°) was caused to solidify by brief removal from the bath it remelted at 115.2–116.2°. A precisely similar behavior was exhibited both by a sample of dehydroiso-β-lapachone prepared from an authentic sample[6] of lomatiol and by a mixture of the two. The lower of the two melting points corresponds to the metastable needles observed by Rennie,[1] whereas the higher corresponds to the stable prisms reported by Hooker. We have observed both forms, but have not had a sample composed exclusively of the prismatic form.

Summary

A conversion of lapachol to lomatiol has been accomplished.

Symmetrical Morpholinium Alkyl Sulfates

BY J. B. NIEDERL, H. W. SALZBERG AND J. J. SHATYNSKI[1]

Studies in the morpholinium type of "Invert Soaps"[2] have now been extended to those derived from symmetrical dialkyl sulfates and morpholines containing a long chain alkyl substituent on nitrogen.

Experimental

Dialkyl Sulfates.—Dimethyl and diethyl sulfates were commercial products; the others were prepared using the method of Barkenbus and Owen.[3]

N-Alkyl morpholines were prepared by refluxing equimolar quantities of morpholine and the appropriate alkyl bromide in absolute ethyl alcohol with anhydrous potassium carbonate for six hours. The solvent was distilled off, the residue washed with distilled water and the product distilled under reduced pressure.

Morpholinium sulfates were obtained by mixing equimolecular quantities of the alkyl morpholine and the dialkyl sulfate. With methyl sulfate the reaction was quantitative in the cold; with ethyl sulfate slight heating on a steam-bath was necessary; with *n*-butyl and *n*-hexyl sulfates prolonged heating in sealed ampules on a steam-bath was needed; and with hexadecyl sulfate prolonged refluxing of the reactants in toluene was required. The methyl sulfates were recrystallized from water in form of crystalline hydrates while the others were recrystallized from ethyl acetate.

Physiological.—In the phenol coefficient determinations using the U. S. Bureau of Standards technique toward *S. aureus*, the N-hexadecyl morpholinium series exhibited the maximum activity, reaching phenol coefficients of 500 to 600 depending on the *p*H of the solutions tested, with hardly any difference in the methyl, ethyl and *n*-butyl or *n*-hexyl sulfate series. Toward *E. typhosa*, the N-tetradecyl compounds showed the higher activity, the phenol coefficients being about 200. Equal activities toward both Gram-positive as well as Gram-negative microörganisms was reached with the hexyl sulfate compounds.

Synthetic Estrogens. Phenyl and Benzyl Hexestrols and Dienestrols[1,2]

BY J. B. NIEDERL AND R. M. SILVERSTEIN

Studies in the introduction of alkyl radicals into the benzene rings of synthetic estrogens, with subsequent enhancement of therapeutic properties in at least two cases,[3] have now been extended to include phenyl and benzyl substituted hexestrols and dienestrols.

3,4-bis-(*m*-Phenyl-*p*-hydroxyphenyl)-2,4-hexadiene and 3,4-(*m*-benzyl-*p*-hydroxyphenyl)-2,4-hexadiene were prepared from *o*-phenylphenol and *o*-benzylphenol, respectively, using the following method of synthesis.[4] The phenols were esterified with propionic anhydride. The resulting esters were subjected to a Fries rearrangement to yield the 3-phenyl-4-hydroxy- and the 3-benzyl-4-hydroxy-propiophenones which were then esterified. These ketones were reduced to the corresponding pinacols which in turn were dehydrated and saponified to the desired dienestrols. Catalytic hydrogenation yielded the corresponding hexestrols.

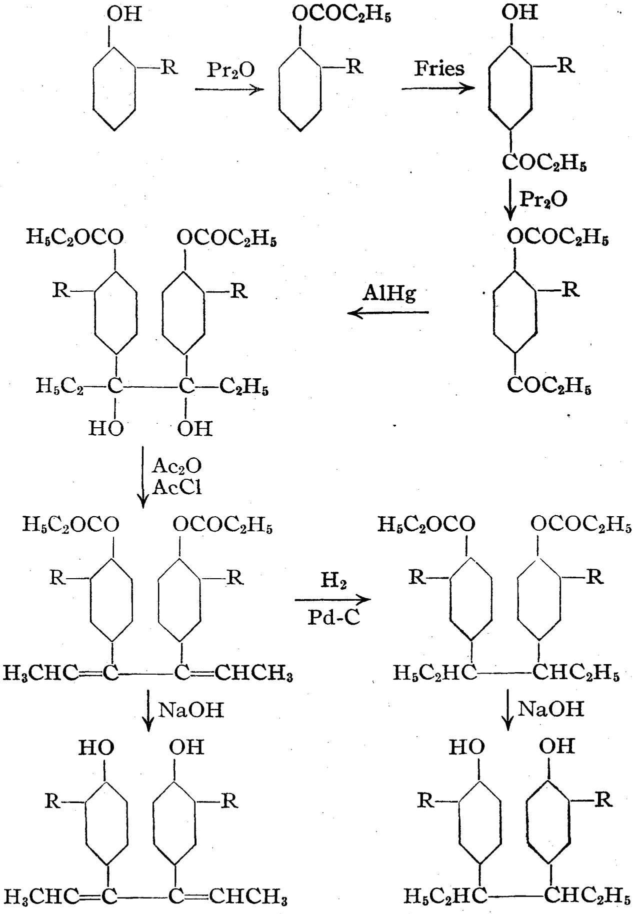
Experimental

***o*-Phenylphenylpropionate (I) and *o*-Benzylphenylpropionate (II).**—*o*-Phenylphenola nd *o*-benzylphenol were esterified with propionic anhydride. The propionic acid formed and the unreacted anhydride were removed under reduced pressure and the residue used without further purification.

3-Phenyl-4-hydroxypropiophenone (III) and 3-Benzyl-4-hydroxypropiophenone (IV).—These compounds were obtained by a Fries rearrangement[5] of (I) and (II). One and one-half moles of anhydrous aluminum chloride was dissolved in 400 ml. of nitrobenzene. When the solution cooled to room temperature one mole of the ester (I, II) was added dropwise with constant stirring at such a rate that the temperature did not rise above 30°. The flask was protected with a calcium chloride tube, allowed to stand overnight, then heated to 50° for three hours. The solution was poured into about three times its volume of an ice–water mixture and allowed to stand for several hours until the aluminum chloride complex was hydrolyzed. The aqueous layer was separated and extracted with ether which was then combined with the nitrobenzene layer. The ether–nitrobenzene mixture was extracted with 10% sodium hydroxide. After washing with several portions of ether to remove traces of nitrobenzene, the alkaline extract was acidified with dilute hydrochloric acid. The precipitate was filtered, washed, dried and used in the next step without further purification.

3-Phenyl-4-propionoxypropiophenone (V) and 3-Benzyl-4-propionoxypropiophenone (VI).—(III) and (IV) were esterified with propionic anhydride. After removing the propionic acid and anhydride and a forerun probably consisting of the ortho rearranged isomer, the esters distilled at 190–192° (3 mm.) and 208–209° (3 mm.), respectively, and crystallized on standing.

FLOW SHEET



R = phenyl, benzyl

3,4-bis-(*m*-Phenyl-*p*-propionoxyphenyl)-3,4-hexanediol (VII) and 3,4-bis-(*m*-Benzyl-*p*-propionoxyphenyl)-3,4-hexanediol (VIII).—Two moles of aluminum foil were cut into strips, crumpled loosely, amalgamated with mercuric chloride, washed rapidly with water, ethanol and ether, then covered with 500 ml. of ether in a 2-liter 3-necked flask. The flask was fitted with a sealed stirrer, a dropping funnel and a reflux condenser. One third of a mole of the ketone (V, VI) was added in one batch. Water was added dropwise through the dropping funnel at such a rate that a gentle reflux of ether was maintained. The reaction took about eight hours until the aluminum was exhausted. The mass was filtered and the residue extracted with ether which was then combined with the filtrate. The ether was removed and the viscous residue used in the next step. Neither of the reaction products could be crystallized.

3,4-bis-(*m*-Phenyl-*p*-propionoxyphenyl)-2,4-hexadiene (IX) and 3,4-bis-(*m*-Benzyl-*p*-propionoxyphenyl)-2,4-hexadiene (X).—Fifty grams of the hexanediol (VII, VIII)

was refluxed for twenty minutes with 150 ml. of acetic anhydride and 100 ml. of acetyl chloride. The solution was poured into a large volume of ice–water mixture in an Erlenmeyer flask, shaken vigorously and allowed to stand for several hours. The semi-solid mass which separated was shaken with several changes of water, then triturated with a small amount of cold methanol until solidification was effected. The flaky solid was filtered, washed with methanol and recrystallized from the same solvent.

3,4-bis-(*m*-Phenyl-*p*-hydroxyphenyl)-2,4-hexadiene (XI) and **3,4-bis(*m*-Benzyl-*p*-hydroxyphenyl)-2,4-hexadiene** (XII).—Saponification of (IX, X) was effected by heating at 60° for two hours with Claisen solution and allowing to stand overnight at room temperature. The solution was diluted with water, filtered, the filtrate acidified, and the precipitate filtered, washed and recrystallized from dilute ethanol.

3,4-bis-(*m*-Phenyl-*p*-hydroxyphenyl)-hexane (XIII), and 3,4-bis-(*m*-Benzyl-*p*-hydroxyphenyl)-hexane (XIV).—These compounds were obtained by hydrogenation of (IX, X) in acetone with palladium on carbon at 3 atmospheres and room temperature for one hour. The solvent was removed but in neither case could the viscous residue be crystallized. Saponification was effected as under (XI, XII) and the compounds were recrystallized from dilute ethanol.

Esters.—The diacetates of (XI, XII) and (XIII, XIV) and the propionates of (XIII, XIV) were prepared by refluxing with acetic and propionic anhydrides, respectively, and recrystallizing from dilute ethanol. The dibenzoates were prepared from (XI, XII) and (XIII, XIV) by the Schotten–Baumann method and recrystallized from an absolute ethanol–ethyl acetate mixture.

Physiological.—Assays were performed according to standard procedure by subcutaneous injection into rats of oil solutions of the compounds. At the 50 gamma dose level 3,4-bis-(*m*-benzyl-*p*-hydroxy)-hexane showed no estrogenic activity. At the same dose level 3,4-bis-(*m*-phenyl-*p*-hydroxy)-hexane elicited estrogenic response in 10% of the animals tested.

Acknowledgment.—The authors desire to express their appreciation to Dr. C. T. Van Meter of Reed and Carnrick, Jersey City, N. J., for the estrogenic assays.

Summary

In continuation of the work done in this Laboratory in the field of synthetic estrogens the phenyl and benzyl hexestrols and dienestrols have been prepared. The introduction of the phenyl or benzyl group resulted in considerable diminution of estrogenic activity.

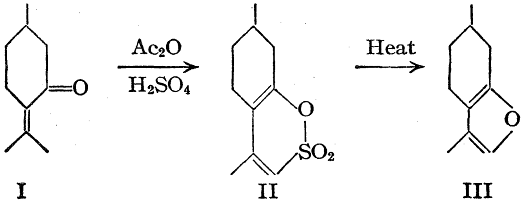
Occurrence of Menthofuran in Oil of Peppermint (Mentha piperita vulgaris S.)

BY PAUL Z. BEDOUKIAN

In 1904, Charabot[1] obtained from the flowering heads of the peppermint plant an oil which was found to have a rotation of +19° whereas the oil obtained from the whole plant was known to have a rotation of −19 to −22°. Further investigation of this oil by Carles[2] in 1929 showed that the positive rotation was due to the presence of an unidentified substance. This substance could not be isolated in the pure state but repeated distillations gave a fraction rich in the unknown substance with a rotation of +81°. Carles studied the properties of this substance and although he was unable to elucidate its structure his studies led him to believe it to be an oxide. The dextrorotatory substance was present in both French and Italian peppermint oils. It is noteworthy to mention a report of the occurrence of a dextrorotatory fraction in American peppermint oil which the investigator[3] attributed to the possible presence of *d*-menthone.

In 1934 Wienhaus and Dewein[4] deduced the structure of this dextro-rotatory compound to be tetrahydro-4,5,6,7-dimethyl-3,5-coumarane (menthofuran). Their deduction was based on experimental facts such as its complete reduction to *p*-menthane and oxidation to β-methyladipic acid. On hydrogenation it gave a product identical to the oxide derived from isopulegol which possessed an oxygen between the carbon atoms 3 and 9.

The syntheses of this unusual compound was successfully carried out by Treibs.[5] On treating pulegone (I) with cold acetic anhydride–sulfuric acid mixture by Reychler's method[6] Treibs obtained the cyclic ester of pulegenol sulfonic acid (II). When this compound was heated with an inert filler such as zinc oxide it lost one molecule of sulfur dioxide, giving a liquid of a composition $C_{10}H_{14}O$ (III).



I II III

The product was found to contain two double bonds which were conjugated, since the compound combined readily with maleic anhydride giving an addition product $C_{14}H_{16}O_4$. The conjugated double bonds were present in the furan ring because the vapor of menthofuran gave a deep red pine splinter reaction. Further evidence of the structure of synthetic menthofuran was obtained by degradation experiments.

The purpose of the present investigation was to establish conclusive proof of the presence of menthofuran in peppermint oil by direct comparison of the synthetic compound with the naturally occurring oxide.

In the examination of essential oils it is imperative to start with material of unquestionable purity. The peppermint oil investigated was obtained from plants grown in southern Ontario, the plants, *Mentha piperita vulgaris S.*, having been originally imported from Indiana. The writer was present during the harvesting and distillation period and acquired several drums of oil on the spot. The harvesting of the plant was begun as usual with the flowering of the plant and was continued for about two weeks. The fields were free from weeds and foreign plants. During the analysis of these oils which involved fractionation it was noted that a small fraction had a positive rotation, an unusual occurrence with peppermint oils. The properties of this oil were reported in a publication.[7] The dextro-rotatory fraction was separated and subjected to a study.[8] It was found impossible to obtain it in the pure state even after the removal by chemical means of menthone and menthol which have boiling points close to menthofuran. The purest fraction obtained had a rotation of +61° and exhibited properties similar to menthofuran as described in the literature. Its identity was established by the fact that its addition product with maleic anhydride did not give a depression in melting point when mixed with the addition product of synthetic menthofuran. The occurrence of menthofuran in oil of peppermint (*Mentha piperita vulgaris S.*) was thus definitely established.

Since menthofuran is present in relatively large quantities in the oil of flowering heads of *Mentha piperita vulgaris S.* and only in traces in oil of peppermint obtained from the whole plant, it is quite probable that the source of menthofuran in peppermint is the flower of the plant.

Menthofuran, in common with other furans, exhibits some interesting color reactions. On exposure to air both the natural and synthetic menthofuran turn purplish. This color, apparently due to the formation of an oxidation product, is completely removed by filtering the oil with magnesium carbonate powder. Menthofuran gives an intense blue–violet color on adding bro-

mine to its solution of carbon tetrachloride. This reaction recalls the behavior of azulenes. Similar color reactions of many essential oils may be due to the presence of such compounds of unknown structure.

Experimental

Separation of Natural Menthofuran.—The fraction of peppermint oil possessing a slight dextro-rotation was subjected to several fractionations and the fractions having a rotation of +15 to +20° were collected. The menthone present in these fractions was removed by means of semicarbazide hydrochloride. On fractionation the unreacted oil gave a product having a rotation of +61°, $d^{20}{}_{25}$ 0.930, $n^{25}{}_D$ 1.4657, b. p. (17 mm.) 92–94°. Carles[2] obtained a purer sample of natural menthofuran with the following constants: rot. +81°, b. p. (20 mm.) 95°, d^{15} 0.965, $n^{20}{}_D$ 1.4807.

Maleic Anhydride Addition Product of Natural Menthofuran.—The above impure menthofuran (5 g.) was added to 15 ml. of benzene containing 5 g. of maleic anhydride. There was a noticeable rise in temperature and the mixture was allowed to stand for two hours. The crystals obtained after several recrystallizations from benzene had a m. p. of 133–133.5°. The mixed m. p. with the synthetic product showed no depression (m. p. 133°).

Preparation of Pulegenol Sulfonic Ester.—Oil of pennyroyal (100 g.) was fractionated and the fraction having a b. p. of 100–101° (17 mm.), rot. +21.50, $d^{25}{}_{25}$ 0.939, $n^{20}{}_D$ 1.4850, was taken as pure pulegone. Forty grams of pulegone was treated with 80 g. of an ice cold mixture of 2 moles of acetic anhydride and 1 mole of sulfuric acid. The temperature rose to 25° and the mixture was allowed to stand for two hours. The crystals obtained were filtered, washed and recrystallized from methyl alcohol, m. p. 86°. Treibs reports m. p. 85° for pulegenol sulfonic acid cyclic ester.

Formation of Menthofuran.—The above product (20 g.) was mixed with 20 g. of zinc oxide and heated at atmospheric pressure. When the oil-bath reached 280–290° strong fumes of sulfur dioxide came off followed by an oil of bluish color. The oil (13 g.) was first washed with water, then with a 5% solution of sodium carbonate, redistilled and the fraction (8 g.) of b. p. 205–206°, rot. +92° $n^{20}{}_D$ 1.4855, $d^{25}{}_{25}$ 0.966, was taken as menthofuran. It was a colorless oil which turned purplish on exposure to air. Treibs gives the following constants for synthetic menthofuran: b. p. 80° (18 mm.), d^{15} 0.972, n_D 1.4890, rot. +92°.

Maleic Anhydride Addition Product.—The same procedure was followed as with natural menthofuran. The maleic anhydride addition product had a m. p. of 133–133.5°. Treibs reports 138° for the m. p. of the addition product of menthofuran. Both the natural and synthetic menthofuran exhibited a greenish coloration and fluorescence in benzene solution although the crystals themselves were colorless.

Summary

A dextro-rotatory substance occurring in oil of peppermint (*Mentha piperita vulgaris S.*) was shown to be menthofuran (tetrahydro-4,5,6,7-dimethyl-3,6-coumarane). Its identity was established by the fact that its maleic anhydride addition product did not give a depression in m. p. when mixed with the maleic anhydride addition product of synthetic menthofuran.

Monomers and Polymers. II. α-Methylstyrenes and the Steric Hindrance of *ortho*-Substituents[1]

BY G. BRYANT BACHMAN AND R. W. FINHOLT[2]

Although styrene (S) itself polymerizes readily in the presence of peroxides, α-methylstyrene (AMS) resists polymerization with peroxides and forms high polymers only in conjunction with other vinyl compounds.[2a] This is in part advantageous since the AMS may be stored even in the presence of air without loss (except by partial oxidation to acetophenone), and may be recovered from reaction mixtures with ease. The copolymers of AMS do not appear to differ markedly in physical properties from the analogous copolymers of S.

In undertaking a study of synthetic rubbers prepared by copolymerizing substituted α-methylstyrenes with butadiene we soon became aware of the importance of the relative positions of the substituent groups. Thus, 3,4-dichloro-AMS gave good rubbers with butadiene while 2,4-dichloro-AMS did not copolymerize. Construction of molecular models showed that the isopropenyl group is not free to rotate through 360° in the 2,4-isomer because of the hindering effect of the *ortho* chlorine atom. Such hindrance is not apparent in the S series, and there are numerous references in the literature to the polymerization of ortho substituted S's.[3] Models of the polymers of 2-chloro-AMS show that the phenyl groups are forced to lie at right angles to the direction of prop-

agation of the chain, like pennies strung on a wire through a small hole in their centers.

While the above-described steric hindrance is not great enough to preclude ordinary reactions of AMS's, it does effectively prevent polymerization reactions, probably because of the small free energy changes (about 8 cal./mole) involved in going from a monomer to a polymer. An *ortho* fluorine atom, which is about midway in size between a hydrogen and a chlorine atom, is apparently just small enough to permit copolymerizations. This is evident in the models and corresponds with our experience. On the other hand, an *o*-methoxy group prevents copolymerization of AMS. The CH_3O- group is larger than the F atom but may, through restricted rotation, assume a position that is not in interference with the isopropenyl group. It is apparent, however, that rotation of the methoxy group is not restricted sufficiently to permit copolymers to form.

2,3-Dimethoxy- and 3,4,5-trimethoxy-AMS's not only did not copolymerize but also inhibited the polymerization of butadiene. This is not the result of steric hindrance, but is probably associated with the well-known inhibiting action of *o*- and *p*-dihydroxy aromatic compounds in polymerizations catalyzed by peroxides. It is even possible that traces of these methoxy compounds were hydrolyzed to the corresponding hydroxy compounds during their purification or polymerization.

The substituted AMS's, like AMS itself, did not polymerize on standing alone or in the presence of peroxides.

In Table I are summarized the results obtained with eleven AMS's. The rubbers from the unhindered AMS's were about equal to GR-S in their properties except for those from 4-chloro- and 3,4-dichloro-A7S which were superior. Table II compares the properties of these rubbers with a GR-S control.

Acknowledgment.—The authors are indebted to the Purdue Research Foundation and the General Tire and Rubber Company for financial support in the form of a fellowship and to the latter for testing the synthetic rubbers prepared.

Experimental

Known Styrenes.—The following were prepared in the indicated yields by published procedures: 2-methoxy-AMS[4], 64% yield from methyl 2-methoxybenzoate; 2-fluoro-AMS[4] (d^{25}_{25} 1.004), 65% yield from methyl 2-fluorobenzoate; 4-methoxy-AMS,[5] 73% yield from 4-methoxyacetophenone; 4-ethoxy-AMS,[5] 65% yield from 4-ethoxyacetophenone; 3,4,5-trimethoxy-AMS.[6] (m. p. 34°), 66% yield from methyl 3,4,5-trimethoxybenzoate.

2,4-Dichloro-AMS.—A solution of 110 g. (0.5 mole) of ethyl 2,4-dichlorobenzoate in 300 ml. of ether was added slowly with cooling to 9.1 moles of methylmagnesium iodide in 750 ml. of ether. After refluxing for half an hour, the mixture was hydrolyzed with aqueous ammonium chloride and the ether extract was dried and evaporated. Without further treatment the residue was slowly distilled at 70 mm. pressure from 0.5 g. of phosphorus pentoxide and 6 g. of sodium acid sulfate. Rectification of the dried distillate gave 64 g. (68% yield) of the desired AMS, b.p. (15 mm.) 103–104°, d^{25}_{25} 1.182, n^{25}_D 1.5460.

Anal. Calcd. for $C_9H_8Cl_2$: Cl, 37.91. Found: Cl, 37.85, 37.72.

3,4-Dichloro-AMS.—Saturation of a solution of 382 g. of 3,4-dichlorobenzoic acid in 2 l. of ethanol with dry hydrogen chloride followed by neutralization and distillation gave 410 g. (95% yield) of the ester. Reaction of this with an excess of methylmagnesium iodide and conversion to the AMS as described in the preceding preparation gave 248 g. (70% yield) of product, b. p. (3 mm.) 94°, d^{25}_{25} 1.224, n^{25}_D 1.5732.

Anal. Calcd. for $C_9H_8Cl_2$: Cl, 37.91. Found: Cl, 37.69, 37.61.

2-Chloro-AMS.—From 313 g. of *o*-chlorobenzoic acid was obtained 317 g. (87% yield) of the ethyl ester. This was reacted with methylmagnesium iodide, the resulting crude alcohol was dehydrated and the styrene was obtained in 60% yield, b. p. (14 mm.) 75°, d^{25}_{25} 1.057, n^{25}_D 1.5329.

Anal. Calcd. for C_9H_9Cl: Cl, 23.23. Found: Cl, 22.92, 22.82.

4-Chloro-AMS.—A solution of 154.5 g. of *p*-chloroacetophenone in 700 ml. of ether was added slowly with cooling and stirring to 1.2 moles of methylmagnesium iodide in 1200 ml. of ether. The crude tertiary alcohol obtained as a product was dehydrated at 15 mm. pressure by heating with 2 g. of sodium acid sulfate. Rectification gave 110 g. (71% yield) of the desired AMS, b. p. (10 mm.) 86°, d^{25}_{25} 1.073, n^{25}_{D} 1.5540.

Anal. Calcd. for C_9H_9Cl: Cl, 23.23. Found: Cl, 23.09. 22.90.

2,3-Dimethoxy-AMS.—A solution of 77 g. (0.4 mole) of methyl 2,3-dimethoxybenzoate in 300 ml. of ether was reacted with 0.8 mole of methylmagnesium iodide in 700 ml. of ether to obtain the tertiary alcohol which was dehydrated by slow distillation at normal pressure from 5 g. of phosphorus pentoxide. The resulting AMS was obtained in 28.5 g. (42% yield); b. p. (3 mm.) 78°, d^{25}_{25} 1.026, n^{30}_{D} 1.5237.

Anal. Calcd. for $C_{11}H_{14}O_2$: C, 74.13; H, 7.92. Found: C, 73.89, 73,80; H, 7.89, 7.76.

3,5-Dibromo-AMS.—A solution of 200 g. of anthranilic acid in 2 l. of methanol was saturated with hydrogen chloride and refluxed for twenty hours. The ester solution was treated with 160 ml. of bromine in 400 ml. of concentrated aqueous potassium bromide maintaining the temperature at 25–30°. After three hours the dibromo ester (376 g., 83% yield) was precipitated in 25 liters of water. A solution of 154.5 g. of the ester in a mixture of 50 ml. of water, 50 ml. of acetic acid and 300 ml. of 95% ethanol was heated to boiling and treated with 85 g. of isopropyl nitrite added slowly over a period of three hours. The deaminated acid (88 g., 62% yield) was precipitated by pouring into 2 liters of water. It was esterified by saturating the solution in 1 l. of methanol with hydrogen chloride and refluxing for eight hours. The ester (86.5 g., 94% yield) separated on cooling as long white needles, m. p. 62–63°.

A solution of 99 g. (0.34 mole) of methyl 3,5-dibromobenzoate in 300 ml. of benzene was reacted with 0.7 mole of methylmagnesium bromide in 650 ml. of ether. Distillation of the resulting tertiary alcohol from 4 g. of phosphorus pentoxide at 20 mm. pressure and rectification of the product gave 65 g. (70.3%) yield of the desired AMS; b. p. (3 mm.) 98°, d^{25}_{25} 1.750, n^{30}_{D} 1.6097.

Anal. Calcd. for $C_9H_8Br_2$: C, 39.16; H, 2.92. Found: C, 39.33, 39.40; H, 2.78, 2.85.

Polymerization Experiments.—Each monomer was copolymerized with butadiene on a small scale (2.5 g. of AMS) to approximate the rate, then on a larger scale (50 g. or more of AMS) to compound, cure and test the rubber. The polymerization recipe was: butadiene 75 parts, AMS 25 parts, soap 5 parts, OEI (a mercaptan mixture from the Naugatuck Chemical Company) 0.6 part, a peroxide salt 0.3 part, water 175 parts by weight. The polymerizations were done in small sealed Pyrex tubes or quart size soda water bottles immersed and rotated in a thermostat bath. The conditions and results are summarized in Tables I and II.

Summary

The copolymerizations of eleven different nuclearly substituted α-methylstyrenes with butadiene have been studied. The effects of the natures and positions of the substituents on the rates of copolymerization have been discussed and the hindrance of *ortho* substituents has been indicated. Six new α-methylstyrenes have been prepared and characterized.

Some Properties of Phenanthrene Semiquinone

BY L. MICHAELIS AND S. GRANICK

It has been shown in previous papers[1,2,3,4] that phenanthrenequinone or its sulfonate on partial reduction establishes a compound intermediate between the quinone and the hydroquinone. This intermediate compound, when in the dissolved state, is in equilibrium with the two "parent substances" and furthermore exists in two modifications which also are in equilibrium with each other, namely, the free paramagnetic semiquinone radical and its diamagnetic, quinhydrone-like dimerization product. All of the equilibrium constants for an aqueous solution at 30° and at different acidities have been determined. The equilibrium between the free radical, the quinone and the hydroquinone is displaced in favor of the radical by increase of *p*H up to about 11, and remains constant at its maximum value on further increase of *p*H. The percentage of dimerization of the free radical is increased with increasing total concentration, as expected for a bimolecular reaction. Two more properties of that intermediate compound will be described in this paper.

(1) The dimerization of the free radical is counteracted by water-miscible organic solvents such as ethanol or pyridine. Even at a very high concentration of potassium phenanthrenequinone-3-sulfonate, 0.05 *M*, no noticeable dimerization of the free radical takes place if the solvent is 50% pyridine instead of pure water. Evidence for this statement is produced by the measurement of the change of magnetic susceptibility of the quinone in alkaline solution during the slow reduction by glucose using the method described previously.[5] In the three experiments plotted in Fig. 1 the alkalinity is always great enough to make the semiquinone formation constant maximal and independent of minor variations of *p*H. In a purely aqueous solution, at the very high concentration of the substance used in this experiment, the change of susceptibility in time is such as to indicate *in maximo* not more than about 16% (3) of the substance in the state of a free radical. Such

(4) L. Michaelis, R. K. Reber and J. A. Kuck, *ibid.*, **60**, 214 (1938).

(5) L. Michaelis, *ibid.*, **63**, 2446 (1941). (1) Calculated as shown in (5).

a value is compatible with results obtained previously with different initial concentrations of the substance. When the same experiment is carried out with 50% pyridine as a solvent, the change of susceptibility in time is much larger and indicates, at the maximum point, the presence of 64% of the substance as a free radical. There is no evidence, either spectrophotometrically or otherwise, for any appreciable, measurable amount of the dimer.

(2) The free radical disappears both for solutions in water and in 50% pyridine (or alcohol) on addition of a small amount of a salt of calcium (or strontium or barium, but not magnesium or zinc or nickel). Instead of the brown radical an intensely emerald-green calcium compound of it is formed which is diamagnetic. During the reduction of the quinone by glucose in the presence of calcium no change of susceptibility is observed but the color changes observed during the reduction go from light yellow through green to light yellow (Fig. 1).

It is desirable to confirm the existence of the three modifications of the intermediate reduction product spectrophotometrically. In fact, they can be distinguished. Figure 2 shows first of all that the absorption of the quinone and the hydroquinone above 400 mμ is almost negligible. It is worth while mentioning that in such an alkaline solution the yellow color of the hydroquinone is more intense than that of the quinone, as can also be inferred from the graph. Figure 2 shows the molar absorption curve of the free radical. The relative values are quite reliable although the absolute values may be in error by 10 or perhaps even 20% because of the uncertainties involved in the calculation of the concentration of the free radical, as described in the legend of Fig. 2. Anyhow, it is obvious that the molar absorption coefficient of the free radical is much smaller than that of a "good" dyestuff such as methylene blue. This seems to be true for most of the free semiquinone radicals.

Curve O—O shows, as well as possible, the molar absorption curve for the dimer as it arises in purely aqueous alkaline solution of high concentration of the quinone on partial reduction. The calculations may be much more in error than for curve ·—·, especially for the absolute values, but the fact that this spectrum represents a compound which is different from the free radical is established without doubt.

The absorption curve for the green calcium complex, curve ×—×, is quite reliable for the relative values although the absolute values may be somewhat in error.

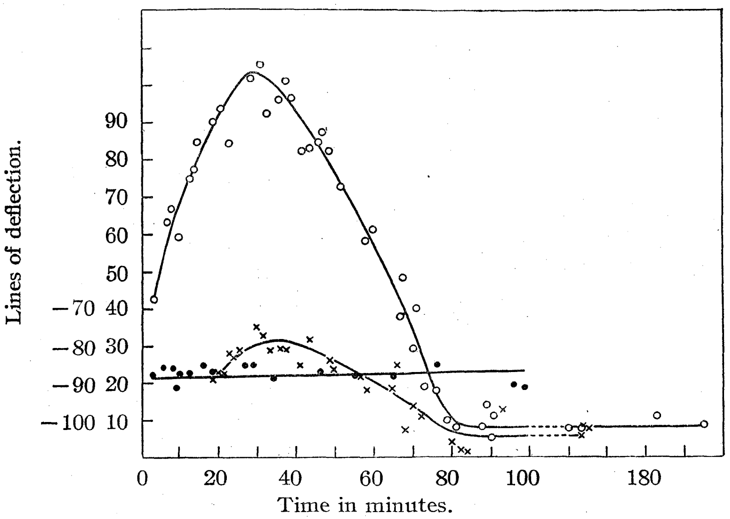

Fig. 1.—Change of magnetic susceptibility of potassium phenanthrenequinone-3-sulfonate during the reduction by glucose in an alkaline solution. The solution of the substance is contained in the upper compartment of the "double vessel" (or "compensation vessel"); the lower compartment is permanently filled with an agar gel. The ordinate is magnetic pull in terms of lines of deflection, measured always at an amperage close to 8.5 and recalculated for 10 amperes. One line of deflection corresponds to an increment of susceptibility 4.20×10^{-10} c. g. s. u. The solution is made up of 0.0407 g. of potassium phenanthrenequinone-3-sulfonate, 0.150 g. of glucose, and brought to a volume of 2.5 cc.: 1, for O—O by a solution made from 25 cc. of pyridine, 25 cc. of water and 1 cc. of 7.3 *N* NaOH; 2, for ×—× by a solution made from 50 cc. of water + 1 cc. of 7.3 *N* NaOH; 3, for ●—● by an aqueous solution of $Ca(OH)_2$, 0.047 *N*. At time "O" the reduction has started already. The intermediate color is: red-brown for O—O; brown for ×—×; green for ●—●.

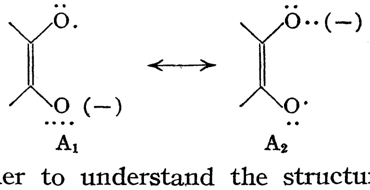
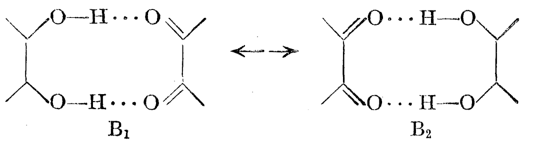
Discussion

The structure of the three molecular species, intermediate in oxidation between quinone and hydroquinone, may now be considered. It is easy to account for the structure of the free radical. It may be in analogy to the structure previously proposed for the semiquinone of duroquinone, symbolized by a structure resonating essentially between two equivalent "limiting structures," A_1 and A_2.



A_1 A_2

In order to understand the structure of the dimer one has to keep in mind the fact that the dimerization constant d/s^2, where d is the concentration of the dimer and s that of the free radical, was found (2) to be $= 2 \times 10^6$ at *p*H 4.6, but as low as 70 at *p*H 12. Such a high dependence on *p*H is compatible only with the assumption that the dimer does not consist of two negatively charged semiquinone ions as represented by the structure A_1, A_2, but that it consists of two uncharged molecules of the free radical with protons attached. So the dimer may be symbolized as B_1 in resonance with B_2. This formula is analogous to the one suggested for the diamagnetic benzoquinhydrone as it exists in the solid state, and to a minute extent also in solution[6] probably with the difference that for this ortho-quinoid compound both moieties lie in one plane, *i. e.*, the dimer is coplanar, whereas there was reason to assume that for the para-quinonoid compounds such as benzoquinhydrone in the dissolved state, the two rings lie stacked upon each other. The bond that holds together the two moieties may be classified among the "dimeric resonance bonds."[8] This resonance differs from most other cases of resonance in so far as it represents the only force holding together the two moieties, whereas usually resonance only increases the stability of a molecule which may be imagined to form a molecular unit even without that resonance.



B_1 B_2

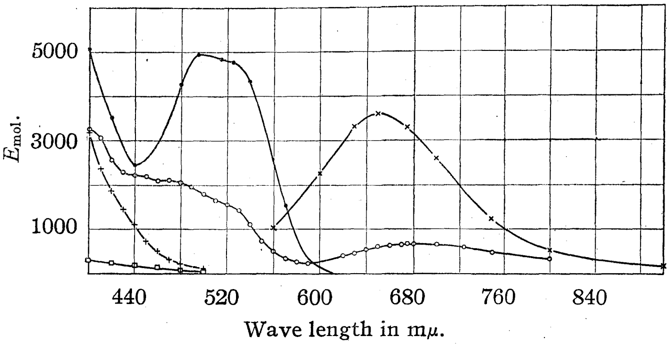


Fig. 2.—The ordinate is molar absorption coefficient, $1/(cd)$ log (I_0/I), where I_0 is light transmitted through blank, I that transmitted by the solution; c is concentration in gram moles per liter; d is light path through the absorption cell in centimeters. All solutions are 0.073 N in sodium hydroxide and 1.048×10^{-4} molar in potassium phenanthrene-quinone-3-sulfonate, unless otherwise stated. O—O Solution of the quinone itself in 50% pyridine in a 1-cm. absorption cell; x—x, same, after complete reduction by glucose to the hydroquinone; +, the free semiquinone radical. (The two maxima at 490 and at 525 mμ are distinctly visible also in the hand spectroscope.) This curve has been obtained as follows. The alkaline solution of the dye in 50% pyridine was completely reduced by $Na_2S_2O_4$, slightly reoxidized by air, transferred to the absorption cell and sealed with mineral oil to keep the level of oxidation constant for a sufficiently long time. Readings of optical density at various wave lengths were taken. These values were translated into molar absorption coefficients as follows. The alkaline solution of the quinone plus some glucose was transferred to the absorption cell and the optical density for one particular wave length was watched while the reduction proceeded. After a certain time the optical density passes through a maximum. It is known from previous potentiometric measurements that *in maximo* 64% of the dye exists in the form of the free radical. This is true for any solution of pH > 11. These data are sufficient to convert the optical densities observed into molar absorption coefficients. There may be an error of 10% or even 20% with respect to the absolute values, but there is no appreciable error in the relative values. Since the hydroquinone, at least at the left hand of this curve, also absorbs somewhat, the curve has been slightly corrected by subtracting the absorption due to the hydroquinone which at 50% reduction of the quinone was supposed to be present to the extent of 18% of the total dye. × is the diamagnetic dimer of the radical, or the "quinhydrone." The solvent contains no pyridine. A 0.0193 M solution of the dye in 0.05 M sodium hydroxide is prepared. This concentration of the dye in the alkaline, aqueous solution is high enough to have the intermediate form to a very large extent in the dimeric form. The absorption cell had a diameter of 0.00578 cm. as described previously.[7] In principle the curve was obtained in the same way as for +, so no corrections for the presence of some free radical and of the quinone and the hydroquinone were applied. The absolute values may be considered as reliable only as to the order of magnitude, the relative values somewhat better, but no accuracy is claimed. Nevertheless, it is obvious that the absorption is much more diffuse than that of the free radical. The essential result is that the difference between two forms, the free radical and its dimeric "quinhydrone," is substantiated also spectrophotometrically. × is the green calcium complex of the radical, measured in a 1-cm. cell: 1 cc. of 2.47×10^{-3} M stock solution of the dye in 0.05 N NaOH + 9 cc. of 0.05 N NaOH + 0.4 cc. of saturated solution of $Ca(OH)_2$. The curve is obtained in the same way as in +. (Since a slight cloud of colorless precipitate appears, a corresponding solution in the completely oxidized, practically colorless state, was chosen as a blank for the readings. The dye was completely reduced with $Na_2S_2O_4$, and during the reoxidation by air the maximum point of absorption at any one wave length was watched.) It is assumed that *in maximo* practically all of the dye exists as the calcium quinhydrone. This may involve an error perhaps up to 20% or even more in the absolute values, but no essential error as to the relative values of the extinction coefficients.

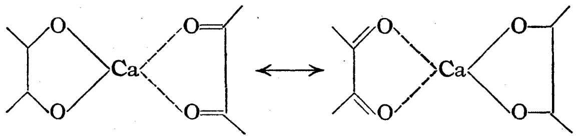
For the calcium complex we may imagine the two H atoms replaced by Ca:



C_1 C_2

The fact that a structure can hardly be imagined otherwise than in coplanar configuration is in favor of the coplanarity, also of the calcium-free

[8] L. Michaelis and S. Granick, *ibid.*, **65**, 1747 (1943).

dimer. It may be mentioned that a comparable effect of calcium was not observed with quinone, duroquinone, or 1,4-or 1,2-naphthoquinone.

The fact that organic solvents prevent the dimerization, at least in the absence of calcium, is not easy to explain. This effect is quite analogous to the effect of organic solvents on the dimerization of regular (quinonoid, not semiquinone) dyestuffs, such as methylene blue, recognizable by spectrophotometric methods. Here also alcohol prevents dimerization. In alcohol such dyestuffs obey Beer's law: in water they do not because there is an equilibrium established between the monomer and the dimer, depending on concentration and temperature. Furthermore, it may be added that according to preliminary experiments the dimerization of the free radicals of the "Wurster's dye" type, obtained by partial oxidation of aromatic *para*-diamines, is counteracted also by alcohol to a certain extent.

Summary

The semiquinone radical of phenanthrene-quinone-3-sulfonate is paramagnetic. In aqueous solution it is in equilibrium with its quinhydrone-like, diamagnetic dimer. The dimerization is prevented by pyridine or alcohol. In presence of calcium ion the radical forms a diamagnetic calcium complex of green color.

The Dipole Moments of Diazines

BY WILLIAM C. SCHNEIDER

During the course of an investigation of the dipole moments of some thiouracil derivatives,[1] it was deemed desirable to determine the dipole moments of some simpler pyrimidine derivatives and other similar heterocyclic nitrogen compounds in order to obtain a value for the carbon–nitrogen bond moment in this type of molecule which could be used in calculating the electric moments of the more complex thiouracils. Although these thiouracil derivatives later proved to be too complicated for a detailed analysis, the simpler heterocyclic compounds were found to be of sufficient interest in themselves to warrant discussion.

Experimental

The apparatus and measuring technique will be described in another article.[1] Dioxane used as solvent was purified as follows: Commercial dioxane was partially frozen, and the liquid portion discarded. The remaining solid after remelting was refluxed over sodium to remove water and finally distilled through an efficient fractionating column to remove any remaining impurities. The best dioxane obtained in this manner had the following properties: b. p. (uncor.), 100.5°, $d^{35}{}_4$ 1.01690, ϵ_{35} 2.1874, n^{35} 1.4150.

TABLE I

Compound	M. p., °C.
Pyridazine[a]	......
Pyrimidine[a]	18–20
Pyrazine[b]	52–53
4-Oxypyrimidine[b]	163–164
2,5-Dichloropyrimidine[c]	57–57.5
2-Mercapto-5-chloropyrimidine[c]	221–222
2-Methoxy-5-chloropyrimidine[c]	53–54

[a] Furnished by Dr. R. C. Lord, The Johns Hopkins University. [b] Furnished by Dr. I. F. Halverstadt, these Laboratories. [c] Furnished by Dr. J. P. English, these Laboratories.

The compounds investigated are listed in Table I. Table II gives the experimental values of ϵ, dielectric constant, d density and w, weight fraction for dioxane solutions at 35°. Dipole moments were calculated by a modified Hedestrand method similar to that introduced by Halverstadt and Kumler,[2] differing in that densities were used rather than specific volumes. The empirical equation used may be written as

$$ {}_{\infty}p_{\mathrm{T}} = \frac{\epsilon_0 - 1}{\epsilon_0 + 2} \times \frac{1}{d_0}\left[1 - \beta/d_0\right] + \frac{3\alpha}{(\epsilon_0 + 2)^2 d_0} \qquad (3) $$

where ϵ_0 = extrapolated dielectric constant of solvent
d_0 = extrapolated density of solvent
${}_{\infty}p_{\mathrm{T}}$ = specific polarization at infinite dilution
α = slope of dielectric constant *vs.* weight fraction curve
β = slope of density *vs.* weight fraction curve.

The total molar polarization at infinite dilution, ${}_{\infty}P_{\mathrm{T}}$, is obtained from the specific polarization by multiplying by the molecular weight. Atomic polarization was neglected, and molecular refractions were calculated from the atomic refractions listed in the "Landolt–Börnstein Tabellen." The values obtained from these calculations are listed in Table III, where P_{D} and P_0 refer to the distortion and orientation polarizations, respectively.

Discussion

To determine whether or not the carbon–nitrogen linkage can be adequately represented by a single constant in heterocyclic ring systems, its moment was calculated from the observed moment of pyridine, 2.3*D*,[3] assuming a value of 0.4*D* for the carbon–hydrogen link and a plane hexagonal structure for the pyridine ring. A value of 1.9*D*

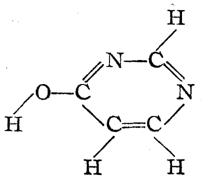
was obtained. Using this value, the dipole moments of pyridazine, pyrimidine and pyrazine were calculated, assuming again a plane hexagonal structure for the heterocyclic ring. Table IV lists these calculated values together with experimental values.

TABLE IV

Compound	$\mu_{\text{obs.}} \times 10^{18}$	$\mu_{\text{calcd.}} \times 10^{18}$
Pyridine (benzene)	2.3	...
Pyridazine (dioxane)	3.9	4.0
Pyrimidine (dioxane)	2.4	2.3
Pyrizine (dioxane)	0.6	0.0
(benzene)	.0	.0
Quinoline (benzene)	2.2	2.3

These data allow three important conclusions to be drawn: (1) the carbon–nitrogen electric moment apparently has a constant value in these heterocyclic compounds; (2) a heterocyclic ring of the pyridine type can be represented by a plane, regular hexagon; and (3) in the compounds investigated, all bonds between nitrogen and carbon seem to be electrically[4] equivalent.

To obtain an additional check upon the carbon–nitrogen bond moment obtained above, the dipole moment of 4-oxypyrimidine was calculated and compared with the experimental value. This compound may be represented as



where the hydrogen–oxygen linkage exhibits free rotation about the carbon–oxygen axis. Since the resultant moment of the ring acts at an angle to the direction of the carbon–oxygen moment, it is necessary to take into consideration the free ro-

---

(4) So far as dipolar characteristics are concerned.

tation of the hydrogen–oxygen linkage when calculating a moment for the molecule.

At any given instant the vector diagram for the resultant moment, μ, of the molecule may be represented by Fig. 1. Fuchs[5] has developed an expression for calculating the average value, $\bar{\mu}$, of the resultant moment which in the present case may be written as

$$\bar{\mu}^2 = \mu_1^2 + \mu_2^2 + 2\mu_1\mu_2 \cos \varphi \cos \theta \qquad (2)$$

Using equation (2) and the following assumptions: (1) $\mu_{H-O} = 1.7D$, (2) $\mu_{C-O} = 0.7D$, (3) $\mu_{C-N} = 1.9D$ and (4) an oxygen valency angle of 110°, the dipole moment of 4-oxypyrimidine is calculated to be $2.6D$, which gives satisfactory agreement with the experimental value, $2.7D$.

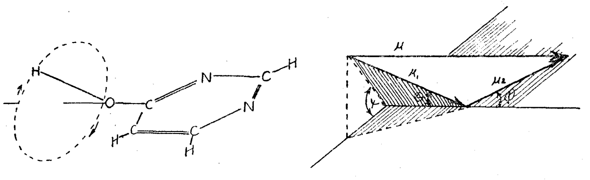


Fig. 1.—Vector representation of the resultant moment of a molecule which has a freely rotating group.

Several additional pyrimidine derivatives were investigated, yielding rather interesting results. Table V lists these compounds and their moments, together with the corresponding benzene derivatives. Presumably, the moment of 2,5-dichloropyrimidine is identical with the moment of the pyrimidine ring. The observed moment of pyrimidine, $2.4D$, supports this assumption. Since the moment of 2-methoxy-5-chloropyrimidine can be considered as the resultant of the ring moment and the moment of p-chloroanisole, and since these last two moments are essentially identical, the observed zero moment forces one to the conclusion that the resultant of the carbon–chlorine and methyl–oxygen moment exactly opposes the moment of the ring. A similar argument can be used to account for the moment of 2-mercapto-5-chloropyrimidine.

TABLE V

[a] Values taken from *Annual Tables of Constants and Numerical Data*, "Dielectric Constants and Dipole Moments," Vol. 11 Sect. 22 (1931–1934), Hermann and Co., Paris, 1937.

Unless resonance effects in all of the above compounds are identical or the agreement merely fortuitous, the two opposing moments must lie on the same straight line since neither pyrimidine derivative possesses a center of symmetry. The vector representation for the resultant moment of the carbon–chlorine and hydrogen–sulfur–carbon groups is given in Fig. 2. Initially, the hydrogen–sulfur bond is assumed to be in the plane of the paper; the dotted vectors indicate the situation after rotation through 180°. Since the resultant moment always intersects the axis of rotation at the constant angle φ regardless of the position of the freely rotating hydrogen–sulfur vector, it cannot exactly cancel the ring moment unless the valence angle is 180° for then φ will be zero.

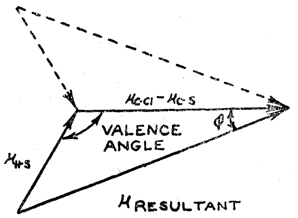

Fig. 2.—Vector representation of the resultant moment of a freely rotating group.

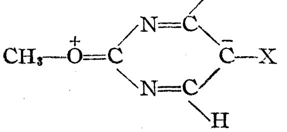
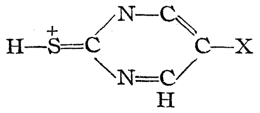
However, in any real molecule the distortion of the valency angle is probably much less than that predicted above for exact cancellation. In para substituted anisoles Bergmann and collaborators in Germany[6] and Hampson and Sutton in England[7] concluded that the oxygen valency angle is greater than 110°, the latter authors reporting a value of 142 ± 8°.[8] Opposing this point of view Bennett[9] concludes that induced moments in the molecule could introduce errors in the method used by the above investigators, and that it is more logical to assume a constant valency angle of 110° and calculate induced moments rather than assume constant bond moments and calculate deviations in the valency angle.

The data are perhaps best interpreted by assuming that an unknown but significant distortion in the valence angle combined with resonance effects causes the hydrogen–oxygen, hydrogen–sulfur or methyl–oxygen link moments to contribute as though they were acting at 180° to the para substituted ring moment. Resonance effects would tend to spread the valence angle slightly and reduce the link moment between the aromatic carbon and oxygen or sulfur atoms due to resonance structures of the type





Using this assumption satisfactory agreement can be obtained between calculated and observed

moments for all of the above mentioned compounds and for most of the para substituted anisoles whose moment values are in the literature. Table VI lists observed and calculated moments for several compounds of the type discussed above; Table VII gives the values used for the various bond moments.

The dipole moment of 4-methoxypyridine gives further evidence in support of an abnormal valency angle of oxygen in para substituted derivatives and a constant value of the carbon–nitrogen linkage. Curran and Leis[10] found this compound to have a moment of 2.94D in benzene solution. The calculated value obtained using the above assumptions is 3.0D.

It must be emphasized that the speculations concerning the valency angle of oxygen and the carbon–oxygen link moment are valid only in the case of *para* substituted derivatives. This fact is immediately obvious if one considers anisole where the observed moment is identical for all practical purposes with that of diethyl ether, thereby requiring a normal carbon–oxygen link moment and an oxygen valency angle of 110°. This viewpoint is further substantiated if one considers the meta substituted isomers. Table VIII compares observed and calculated values for various meta substituted derivatives. The calculated values were obtained by use of equation (2) assuming an oxygen valency angle of 110°, and a carbon–oxygen link moment of 0.7D and the link moments listed in Table VII. Here again, the agreement is satisfactory considering that the observed values were obtained from solution measurements by different workers.

Acknowledgment.—The author wishes to express here his indebtedness to Doctors I. F. Halverstadt and P. H. Bell for many helpful discussions and to the American Cyanamid Company for permission to publish these results.

Summary

1. The dipole moments in dioxane solution at 35° have been determined for the following compounds: pyridazine (3.94), pyrimidine (2.42), pyrazine (0.6), 2,5-dichloropyrimidine (2.27), 2-mercapto-5-chloropyrimidine (0), 2-methoxy-5-chloropyrimidine (0) and 4-oxypyrimidine (2.70).

2. The diazine rings may be represented as plane, regular hexagons.

3. In pyridine and the diazines the carbon–nitrogen linkage has a bond moment of 1.9D compared to 0.5D in aliphatic compounds.

4. The observed fact that 2-methoxy-5-chloropyrimidine and 2-mercapto-5-chloropyrimidine have zero electric moments is best interpreted by assuming that an unknown distortion in the valence angle combined with resonance effects reduces the link moment between the aromatic carbon and oxygen or sulfur atoms and causes the CH_3–O and H–S link moments to contribute as though they were acting at an angle of 180° to the para substituted ring moment.

5. An analogous situation is assumed to exist in several para substituted phenols and anisoles.

The Volatility and Vapor Pressure of Eight 2-Chloroethyl Alkyl (or Cycloalkyl) Sulfides[1]

BY C. ERNST REDEMANN,[2] SAUL W. CHAIKIN AND RALPH B. FEARING[3]

In conjunction with other studies in progress in this Laboratory it was necessary to determine the volatility[4] and vapor pressure of several 2-chloroethyl alkyl (or cycloalkyl) sulfides over the temperature range 0 to 60°. One of these compounds, bis-(2-chloroethyl) sulfide,[5] has been studied before, but other observations had indicated that there might be some considerable error in these data and that a re-evaluation of its volatility was desirable.

The static method of measuring the vapor pressure was unsatisfactory, since for some of these compounds the vapor pressure is only a few thousandths of a millimeter of mercury at 20° and its value needed to be known with considerable accuracy. Of the several dynamic methods the one known as the transpiration method, first described by Regnault[6] but frequently referred to as the method of Walker,[7] was chosen as most suitable. The direct measurement of volatility given by the Regnault procedure was especially desirable for the problem in hand. The apparatus used in these studies was patterned after that of Bent and Francel[8] and will not be described in this report except where important differences are present.

Experimental

Dried tank nitrogen was used as the entrainment gas for all compounds since it avoids possible oxidation of sensitive compounds and is less soluble in most organic compounds than is the oxygen of the air. Six sizes of bottles were used to meter this dry nitrogen before it was passed through the saturator. These bottles were of 1, 2.5, 4, 9, 20 and 50 liters capacity and their volume was determined to closer than ±0.1% by weighing the bottles empty and then filled with distilled water at a known temperature, from which the corrected volume of the bottle was computed.

The spiral condensation traps were cooled by a mixture of solid carbon dioxide and acetone rather than by liquid air as used by Bent and co-workers,[8] since computation indicated that even for a volatile liquid like water under equilibrium conditions at the temperature of solid carbon dioxide the amount of water vapor escaping uncondensed from the trap was far less than the error in weighing the trap when 100–200 mg. of water had been collected. A second cold trap was used in over-night runs, which might finish before the return of the operator, to avoid diffusion of moisture from the atmosphere back into the trap to be weighed.

The 20, 40 and 60° thermostats were of a conventional type with the necessary precautions observed for careful temperature regulation. The temperature was maintained constant to ±0.008° as measured at different points in the bath with a Beckmann thermometer over an extended interval of time. The 0° thermostat was a 1-gallon silvered Pyrex Dewar flask filled with crushed ice and distilled water. In some runs a small electrically driven stirrer was added to this bath, but since it was found to add nothing to the constancy of the temperature it was omitted in later runs.

Vaporizer.—The vaporizer shown in Fig. 1 was patterned after the one described by Bent.[8] It was modified to give more rapid saturation with less liquid[9] by using a coarse sintered glass disk at (A) and indentations at (B). For successful operation the inner spiral should be made from tubing having a bore of 3.5 to 4.0 mm. Both larger and smaller bore tubing are less satisfactory. The vaporizer required 6 to 8 ml. of compound for proper operation. When the vaporizer had been freshly filled with a compound, dry nitrogen was bubbled through the liquid for some hours to remove traces of moisture which may have been picked up during the filling operation. This also served to remove traces of lower boiling impurities in certain cases.

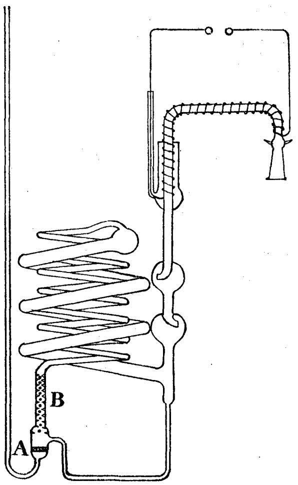

Fig. 1.—Vaporizer.

Presaturator.—In some runs it was considered desirable to approach saturation from both sides. The presaturator shown in Fig. 2 was used to accomplish this. It was connected to the inlet of a regular vaporizer just above the thermostated bath by means of a ground glass joint lightly lubricated on the outer 10 mm. of ground surface. The temperature of the presaturator was maintained about 20° higher than the thermostat bath surrounding the regular vaporizer by applying the proper voltage to the ends of the electrically heated coil by means of a variable transformer.

Results were the same when equilibrium was approached from both sides only if the rate of gas flow was sufficiently low when approaching equilibrium from the unsaturated side. This required rates of flow as low as 0.5 to 1.5 liters/hr. for those compounds which reached equilibrium most slowly. In general the compounds of low viscosity produced more rapid saturation of the nitrogen stream than was produced by the more viscous liquids.

Flow Regulator.—The needle valve used by Bent[8] to regulate the rate of flow of water from the reservoir into the metering bottle, displacing the contained nitrogen,

[9] A saturator requiring only a very small amount of liquid was necessary since for certain of the compounds studied only very small samples were submitted.

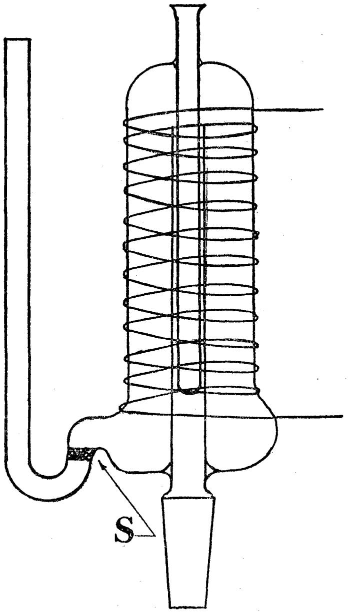

Fig. 2.—Presaturator: S, sintered glass disk.

was advantageously replaced by a calibrated flow regulator of the form shown in Fig. 3. The by-pass on the side of the regulator was opened when the water was forced back into the reservoir from the metering bottle. A series of these regulators was prepared having flow rates varying from 0.8 l./hr. to 6.0 l./hr. It was customary to use a different flow rate for each determination at a given temperature. If the results with different rates of flow checked, equilibrium was assumed to have been established; if the higher rate of flow gave a lower volatility than the slower rate of flow, it was assumed that the higher flow rate was too great and that saturation had not been secured. Only rates of flow slow enough to give concordant results were used.

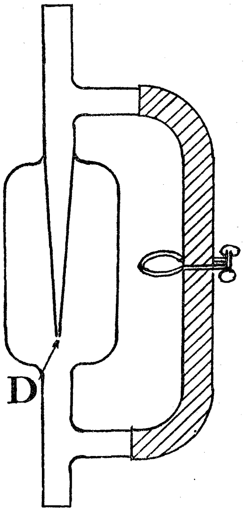

Fig. 3.—Flow regulator: D, diameter 0.5 to 0.1 mm.

Purification of Compounds.—As indicated in Table I all compounds studied were prepared in laboratories other than that of the authors. Samples were generally furnished in a purified form. Nevertheless, each sample was carefully fractionally distilled under reduced pressure from all-glass apparatus just prior to use. A fraction having an essentially constant boiling point was used for these measurements. The boiling range, refractive index and density of the fraction used are recorded in Table I. The refractive index of the material in the vaporizer was checked at the completion of a series of runs, in some cases, to make certain that no change in composition had occurred during the determination. Two samples of bis-(2-chloroethyl) sulfide, one made by the Levinstein[10] and one by the thiodiglycol[11] process, were each purified highly and run separately, thus giving an indication of the reproducibility of the method and the purity of the samples.

Treatment of Results

In the interest of economy of space the experimental points are not given, three to twelve measurements having been made at each temperature for each compound. Values agreeing within 1 to 3%, the lower limit for moderately volatile compounds and the upper limit for compounds of very low volatility, were used. The study of 2-chloroethyl 2-chlorocyclohexyl sulfide was made with somewhat less precision, but is included here for completeness. Exceptionally large values at the beginning of a run, due to traces of more volatile impurities, and points of obvious experimental error were discarded. Measurements were made for each compound at 20, 40 and 60° wherever possible, in some cases at 0, 20 and 40°, and in a few instances at 40 and 60° only because of the very low vapor pressure of the compound. The arithmetic mean of all points at any given temperature was taken for each compound. A smoothed curve was fitted to these mean points by the method of least squares.

The Clausius–Clapeyron equation was used in deriving appropriate relationships between the several variables since it was believed that over the small temperature range 0 to 60° these assumptions were justified: (1) the molal latent heat of vaporization remains essentially constant, (2) the vapor at these low partial pressures obeys the laws of ideal gases and (3) the volume of unit mass of the liquid phase is negligible in comparison with the volume of the same mass of the vapor at these temperatures and pressures. These assumptions allow the three equations used to be related quantitatively.

$$W = \frac{wT_1(p_2 - p)}{vT_2p_1} \qquad (1)$$

W = volatility expressed in mg./liter of nitrogen (or air) saturated with the compound.
w = increase in the weight of the trap in mg.
v = corrected volume, in liters, of the bottle metering out the dry nitrogen
T_1 = initial temperature of the gas in the metering bottle °K.
T_2 = temperature of the thermostat bath, °K.
p = vapor pressure of liquid under study, found by successive approximations, mm.
p_1 = barometric pressure when the bottle was closed after filling with dry nitrogen and equalizing to atmospheric pressure, mm.
p_2 = mean barometric pressure during the determination of mm.

$$\log p = A - B/T \qquad (2)$$

$$\log WT = A' - B/T \qquad (3)$$

in which $A' = A + \log M + 1.20520$. A, A', and B are constants and M is the molecular weight of the compound under study. In equations (2) and (3) pressure was expressed in mm., and temperature in ° K.

In Table II are shown the mean and the maxi-

[a] Supplied by Dr. R. C. Fuson. [b] Supplied by Edgewood Arsenal. [c] Supplied by Dr. R. Norris Shreve. [d] According to Mumford's equations (ref. 5c) the refractive index at 30° is 1.5226 and at 25° the density is 1.2693. [e] Kirner (THIS JOURNAL, **50**, 2446 (1928)) gives d^{20}_{20} 1.1245. [f] This compound behaved as if it were undergoing decomposition during the determination. Results may not be closer than ±10% for this compound. However, Kilmer and du Vigneaud (*J. Biol. Chem.*, **154**, 247 (1944)) report the b. p. as 105–108° (1.5 mm.). The value calculated from our equation is 106.6° (1.5 mm.). [g] Dawson (THIS JOURNAL, **55**, 2070 (1933)) gives d^{25}_4 1.0663 for the ethyl derivative and d^{25}_4 1.1479 for the benzyl compound. [h] Sherlin and Vasilevksii (*J. prakt. Chem.*, **121** 173 (1929)) report the boiling point as 67.5–69° (12 mm.) and the density as d^{20}_{20} 1.0768. [i] R. C. Fuson, *et al.*, *J. Org. Chem.*, **11**, 484–498 (1946).

mum percentage deviation from the smoothed curve of the experimental points. For all the compounds except the 2-chlorocyclohexyl 2-chloroethyl sulfide the mean deviation is less than 2%. The mean and the maximum deviation are also included for the points calculated, using the least squares equation, from the smoothed curve values. The small percentage deviations of these points indicates that the equation describes the curve accurately over the temperature range studied.

TABLE II

PRECISION OF DATA

Alkyl group	Percentage deviation from the smoothed curve of Experimental points Mean	Maximum	Points calculated from least squares equation Mean	Maximum
Methyl	0.5	1.1	0.2	0.3
Ethyl	0.9	1.5	.02	.05
2-Chloroethyl	1.5	3.8	.3	.7
Allyl	0.6	0.9	.2	.4
Benzyl	1.8	2.2	.1	.3
2-Chlorocyclopentyl	1.9	2.9	.1	.2
2-Chlorocyclohexyl	3.5	6.1	1	.3
Bis-(2-chloroethyl) trisulfide	1.5	2.7	3	.8

A consideration of the known sources of error involved in these determinations would indicate a probable error of ±1 to 2%, depending upon the size of the sample collected in the weighing trap. However, since several of the systemic errors tend to cause low results, it is almost certain that the results herein reported will tend to be low, if in error.

The two samples of bis-(2-chloroethyl) sulfide, prepared by different methods, gave vapor pressure determinations which were in excellent agreement as shown by a percentage deviation from the mean of only 0.5% at both ends of the temperature range, and since the sign of the deviation was the same at both limits, the curves were parallel. This speaks well for the reproducibility of the method. Balson, Denbigh and Adams[12] have recently reported their study of the vapor pressure of bis-(2-chloroethyl) sulfide made concurrently with our study. Their results over the temperature range common to both studies are in quite good agreement with our own.

The equations reported are supposed to apply quite precisely between 0 and 60°, but they may be used over a much larger temperature range if somewhat larger errors can be permitted. It must also be borne in mind that these equations are for the liquid phase only.

Acknowledgment.—The authors gratefully acknowledge the kind assistance given by Professor H. E. Bent of the University of Missouri in permitting one of us (C. E. R.) to use his equipment and to become familiar with his technique prior to constructing our apparatus. Thanks are due Miss Drusilla Van Hoesen and Mr. Joseph Savit for their assistance in making some of the determinations.

Summary

1. The volatility of eight 2-chloroethyl alkyl (or cycloalkyl) sulfides has been measured between 0 and 60° by a transpiration method.

2. Vapor pressures have been calculated from the volatility measurements, and using these values logarithmic equations have been calculated for both the volatility and the vapor pressure of these compounds.

3. The mean molar latent heat of evaporation has been calculated from the derived vapor pressure equation for each compound.

4. The probable error of these determinations over the temperature range 0 to 60° is estimated to be ±1 to 2%. The equations may be used for extrapolating to temperatures outside these limits with somewhat larger errors.

The Vapor Pressure of "Mustard Gas" (β,β'-Dichloroethylsulfide), Diphenyl Ether and their Mixtures

BY H. E. BENT AND R. J. FRANCEL[1]

In 1940 when this work was begun, vapor pressure data on mustard gas showed poor agreement and data on solutions of mustard were almost lacking. Our object was to develop a physical method of measurement which would be suitable for not only mustard but also other compounds of similar characteristics. We attempted to keep each individual experimental error below 0.1%.[2]

The following corrections have not been applied. The true vapor pressure is less than that under one atmosphere pressure of air by about 0.5%. No correction has been applied for the solubility of air in mustard, which probably introduces an error of 0.1%. No correction has been made for deviations from the gas laws which may introduce an additional error of 0.1% to 0.2%.

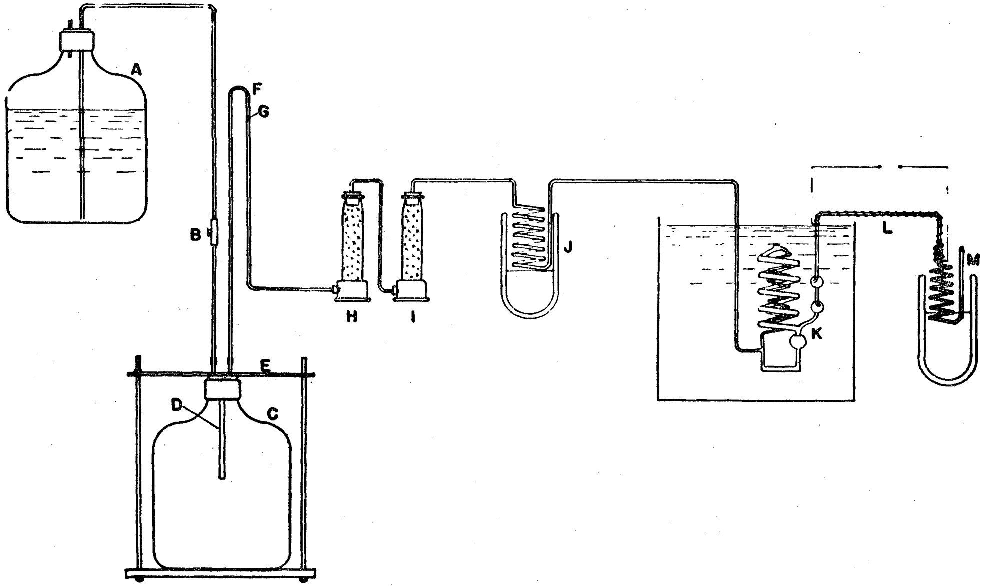

Fig. 1

The dynamic method is well known and perhaps needs little description aside from the information given in Fig. 1. Water in A displaces dry air in C which is in turn again dried by calcium chloride in H, phosphorus pentoxide in I and liquid air in J. The saturator at K is a spiral which exposes a continually fresh surface of liquid since the air stream circulates a small amount of liquid through the apparatus as shown in more detail in Fig. 2. Great care was taken to avoid the formation of spray in this saturator and to avoid fog in the collector at M. Each part of the apparatus was carefully checked and then the apparatus as a whole checked, first by carrying out runs with different rates of flow and second by measuring the vapor pressure of water. The accepted value at 30° is 31.842. We obtained as a result of ten runs 31.79 ± 0.05 mm.

Purity of Compounds.—Mustard was prepared by treating a 15-ml. portion of Union Carbide and Carbon "Kromfax" solvent (β,β'-dihydroxyethylsulfide) with excess of concentrated hydrochloric acid at 60° for thirty minutes. The mustard forms as a water insoluble layer thus

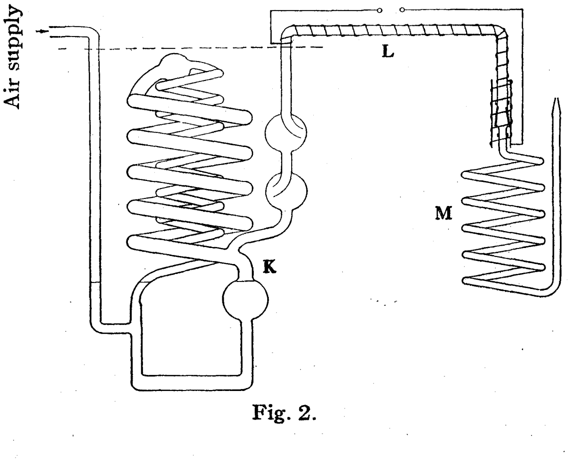

Fig. 2.

---

[2] For a detailed discussion of experimental errors the reader is referred to the original thesis of R. J. Francel, University of Missouri library.

separating it from water soluble impurities possibly present in the original material. No impurities insoluble in water were present in the "Kromfax" solvent. After allowing the reaction mixture to cool, the mustard was separated by decantation and then washed several times with small amounts of distilled water. Since the reaction is slow at 60° with hydrochloric acid, one may infer that at room temperature several rapid washings will not hydrolyze the mustard. The liquid was then distilled under reduced pressure at from 85 to 100° out of contact with rubber. Five fractions were collected, all of which agreed in refractive index to less than 0.0001, but only the middle three fractions were used. Substitution of nitrogen for air in the runs gave no indication of oxidation of mustard.

Diphenyl ether, Eastman Kodak Co. White Label, was distilled under reduced pressure at 95–110°. The two end fractions were discarded.

Solutions of diphenyl ether and mustard were prepared volumetrically and analyzed by determining the refractive index. A refractive index curve (unpublished) prepared by C. A. Krinbill was used. We are also indebted to C. A. Krinbill for assistance during the construction of the apparatus and testing of various designs.

The refractive index for the mustard we found to be 1.5227 at 30° which may be compared with the value calculated from the equation of Mumford, Phillips and Ball[3] of 1.5226. The error in the composition of the solution due to 0.0001 in the refractive index is 0.002 in the mole fraction.

Calculation of Results

Vapor Pressure.—The vapor pressure is obtained with the aid of the expression

$$p = \frac{RT_W}{M} \div \left[V \times \frac{T_2}{T_1} \times \frac{P_1}{P_2 - p}\right]$$

in which V is the volume of bottle C, the next term takes care of the difference in temperature between the bottle and the thermostat and the last takes care of the difference in pressure when the bottle was closed and during a run. "p" is a small correction factor, the vapor pressure of the liquid being studied, obtained by successive approximations.

Values of the vapor pressure are given in Table I and are represented graphically in Figs. 3 and 4. The equations for these curves are for mustard

$$\log_{10} p = 9.4819 - \frac{3117.2}{(t + 273.1)}$$

and for diphenyl ether

$$\log_{10} p = 9.5842 - \frac{3351.9}{(t + 273.1)}$$

which give with the aid of the Clapeyron equation 14,300 ± 50 calories for the heat of vaporization of mustard and 15,300 ± 500 calories for the heat of vaporization of diphenyl ether.

A comparison of our results, Table I, with previous investigators shows poor agreement with Mumford, *et al.*,[3] better agreement with Vedder[4] and still better agreement with the recently published work of Balson and co-workers.[5] The results of Holst and Melander[6] are approximately 100% higher than ours and are not included in the table.

TABLE I

THE VAPOR PRESSURE OF MUSTARD AND DIPHENYL ETHER

The observed values are averages of from three to eight determinations.

Mustard

Raoult's law may be expressed as

$$p_1 = p_1^0 N_1$$

Deviations from Raoult's law may be expressed by either of two expressions, one involving the mole fraction and the other involving the volume fraction. Hildebrand[7] has shown the latter is to be preferred when the molecular volumes of the two components differ appreciably. We may write this expression as

$$RT \ln p_1/p_1^0 N_1 = \beta v_1 V_2^2$$

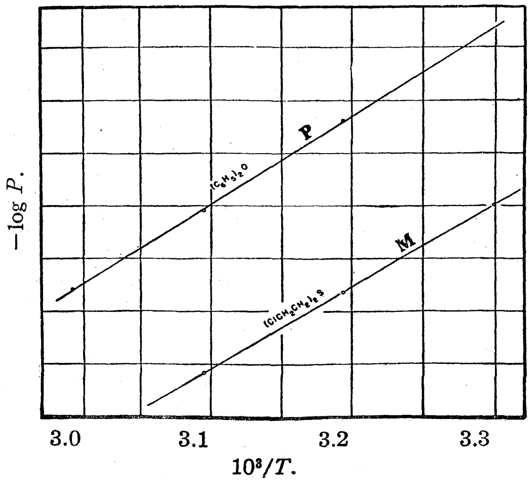

Fig. 3.—P, $(C_6H_5)_2O$; M, $(ClCH_2CH_2)_2S$.

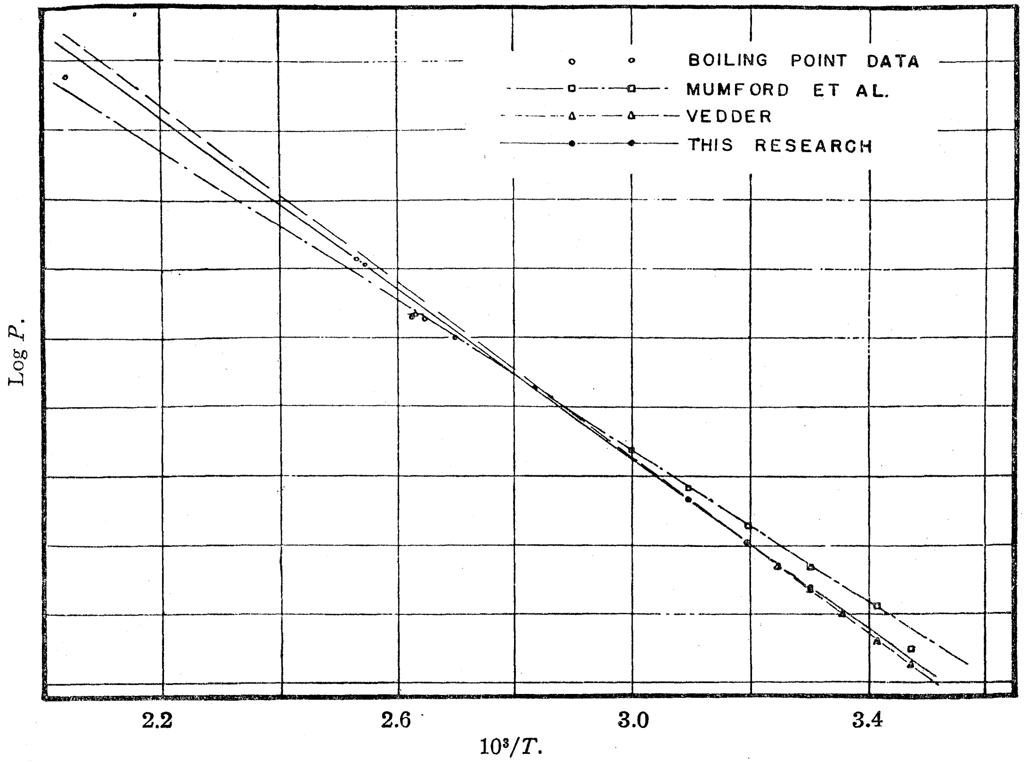

Fig. 4.

and the corresponding equation for the other component with subscripts interchanged. v_1 is the molar volume of the first component and V_2 the volume fraction of the second component. The molar volumes of the pure liquids were obtained using the equation of Wilkinson and Wernlund[8] for the density of mustard and that of Zhuravlev[9] for the density of diphenyl ether. For mustard gas $d = 1.2790 - 1.058 \times 10^{-3} (t - 15)$ and for diphenyl ether $d = 1.0880 - 8.6 \times 10^{-4}\, t$.

The values obtained for β at a mole fraction of 0.658 are 1.87 at 30°, 1.85 at 40°, 1.83 at 50° and, with a mole fraction of mustard of 0.330, 1.76 at 50°. This lack of constancy of β is not as significant as it might at first appear, as it determines the deviation from Raoult's law and not the part of the volatility to be expected from this law and is not much greater than our experimental error, as can be seen from Table II in which calculated volatilities are compared with the experimental values. In this table an average value of 1.83 is used.

Table II

Comparison of Calculated Values of the Volatility of Solutions of Mustard and Diphenyl Ether with Experimental Values. Volatility is Expressed as Mg./Liter

Temp., °C.	Mole fraction	Calcd. volatility with β = 1.83 Mustard	Ether	Total	Experimental
30	0.658	0.927	0.123	1.050	1.051 ± 2
40	.658	1.910	.268	2.178	2.179 ± 3
50	.658	3.756	.555	4.311	4.316 ± 8
50	.330	2.149	.952	3.101	5.083 ± 3

One objection to using volume fractions instead of mole fractions in calculating deviations from Raoult's law is the added labor in carrying out the calculations. This means having values for the densities of the liquids at various temperatures. In order to eliminate this labor for any one wishing to use our results we have given values for the activity coefficient in Table III.

Table III

Activity Coefficients of Mustard Gas[a]

Values of γ in the equation $p/p^0 = \gamma N$ in which N is the mole fraction.

Mole fraction of mustard gas	30°	40°	50°
0.0	1.466	1.453	1.441
.2	1.306	1.298	1.290
.4	1.179	1.174	1.170
.6	1.084	1.082	1.080
.8	1.022	1.022	1.021

[a] For a more complete table of activity coefficients, order Document 2484 from American Documentation Institute, 1719 N Street, N. W., Washington 6, D. C., remitting $0.50 for microfilms or $0.50 for photoprints.

We may use our average value of β to calculate the heat of vaporization from the relation given by Hildebrand

$$\beta = \left[\left(\frac{E_1}{v_1}\right)^{1/2} - \left(\frac{E_2}{v_2}\right)^{1/2}\right]^2$$

---

(8) Wilkinson and Wernlund, This Journal, **42**, 1382–1385 (1920).

(9) Zhuravlev, *J. Phys. Chem.* (*U. S. S. R.*), **9**, 875–882 (1937).

Since our data are better for mustard, we will use this equation to calculate the heat of vaporization of diphenyl ether, giving 13,800 which may be compared with 15,300 ± 500 by the slope of the vapor pressure curve. The discrepancy is somewhat more than might be expected. However, there is an uncertainty of 500 cal. in the heat of vaporization of diphenyl ether, perhaps 100 in the heat for mustard and another hundred in the value for β and of course departures in the behavior of these liquids from the assumptions of Hildebrand in deriving the above equation. Perhaps the most obvious such deviation would be that of association of the mustard. Considering all of these factors perhaps the agreement is as good as can be expected. Finally we may use the value of E/v to place these compounds in Hildebrand's series of internal pressure, the value for mustard being 114.0 and for diphenyl ether 95.9. This places mustard between bromoform and bromine and diphenyl ether with aniline.

As an independent check we have the composition of the vapor as determined by Krinbill[10] using a refractometer. The agreement between the calculated composition using the data from this paper and the observed composition determined with the aid of the refractometer is within the experimental error.

TABLE IV

MOLE FRACTION OF MUSTARD IN LIQUID AND VAPOR AT 50°

Liquid	Vapor Calculated	Vapor Observed
0.658	0.877	0.884
.330	.706	.708

We wish to acknowledge indebtedness to our colleagues, particularly to Professor L. B. Thomas, who tested an early form of the apparatus.

Summary

1. The vapor pressure of mustard (β,β-dichloroethylsulfide) is given by the expression

$$\log_{10} p = 9.4819 - 3117.2/(t + 273.1)$$

and for diphenyl ether by the expression

$$\log_{10} p = 9.5842 - 3351.9/(t + 273.1)$$

Results on mustard agree closely with those of Vedder and with Balson, *et al.*, but not with those of Mumford, Phillips and Ball.

2. Mixtures of these two liquids show small positive deviations from Raoult's law which can be expressed by the equation

$$RT \ln \frac{p_1}{p_1^0 N_1} = 1.83 v_1 V_2^2$$

in which v_1 is the molal volume and V_2 is the volume fraction. A table of activity coefficients is given in order to eliminate the labor involved in using the above equation.

The Volatility and Vapor Pressure of Nine Organic Arsines[1]

BY C. ERNST REDEMANN,[2] SAUL W. CHAIKIN, RALPH B. FEARING[3] AND DORA BENEDICT[4]

As part of a systematic study of the properties of certain toxic compounds the volatility and vapor pressure were determined between 0 and 60° for a series of nine organic arsines. The vapor pressure has been measured for some of these arsines previously; however, these measurements were made at temperatures above 60° in most instances and for lower temperatures values were obtained by extrapolation. To reduce the uncertainty of these values over the desired temperature interval the volatility[5] was measured directly by an air (or nitrogen) saturation method devised by Regnault.[6] The vapor pressure was in turn computed from the volatility by the method outlined in an earlier report.[7]

Gibson and Johnson[8] published data on the vapor pressure of methyldichloroarsine, ethyldichloroarsine and *n*-propyldichloroarsine obtained by measuring the boiling point under various pressures. Baxter and co-workers[9] reported equations for the vapor pressure of phenyldichloroarsine and methyldichloroarsine determined by a procedure very similar to that used by the present authors. Lewis and Perkins[10] cite unpublished data of Baxter on the vapor pressure of 2-chlorovinyldichloroarsine (Lewisite). Boiling point and density measurements as well as vapor pressure are given by Sartori[11] for methyldichloroarsine

[a] Submitted by Dr. C. S. Hamilton. [b] Seide and Gorski, *Ber.*, **62**, 2190 (1929), give the boiling point as 132–133° at atmospheric pressure. Zappi, *Anales soc. quim. Argentina*, **3**, 447 (1915), gives b. p. 132° (760 mm.). [c] Fries and West, ("Chemical Warfare," 1921, McGraw–Hill Book Co., New York), give d^{20} 1.838. [d] Baxter, Bezzenberger and Wilson (ref. 9) give 8.6944 and 2281.7 for dichloromethylarsine and 9.150 and 3164 for dichlorophenylarsine. [e] Submitted by Dr. M. S. Kharasch. [f] Gibson and Johnson (ref. 8) report the density as 1.6595 at 20°. [g] Supplied by Edgewood Arsenal. [h] This is for isomer I. (The method of preparation used gives almost pure isomer I. Careful distillation failed to reveal the presence of any isomer II.) [i] Baxter (see Lewis and Perkins, ref. 10) gave 9.123 and 2789.69, respectively, for these constants. Lewis and Perkins give d^{20} 1.888.

ethyldichloroarsine, 2-chlorovinyldichloroarsine and phenyldichloroarsine. The work reported in the present paper confirms certain of these values but disagrees with others.

Experimental

The apparatus employed in these determinations has been described in earlier reports.[7,12] Dry nitrogen was used as the entrainment gas to avoid any possible oxidation of the arsines. Measurements were made at 20, 40 and 60° for all compounds except dichloromethylarsine, where 0, 20 and 40° were necessary, and for dichlorophenylarsine, where 40 and 60° were used because of the very small volatility at lower temperatures. From three to eight measurements were made at each temperature and the arithmetic mean value was computed for each temperature from these points. Values of known error were discarded, as were high values sometimes obtained in the first measurements after filling the saturator. When there was any definite trend in a series of determinations it was repeated to ascertain whether the trend resulted from a change in composition of the material in the saturator or if it was fortuitous. In some cases the refractive index and the density before and after the run were compared to see if any change in composition had taken place during the run.

The arsines were all prepared in laboratories other than our own (see Table I). In most cases the samples were carefully purified before they were submitted to our laboratory. However, the samples were all fractionally distilled under reduced pressure from all-glass equipment prior to use. Only fractions having essentially a constant boiling point were used.[13] When a new compound was placed in the saturator dry nitrogen was passed through the apparatus to remove traces of more volatile impurities before starting a run. The observed values for the boiling point, refractive index and density of the samples used in the volatility measurements are recorded in Table I.

Discussion

An arithmetic mean of the acceptable points at each given temperature was taken. Curves of the form

$$\log p = A - B/T \qquad (1)$$

and

$$\log WT = A' - B/T \qquad (2)$$

were fitted by the method of least squares to the mean points for the several temperatures studied. The values for A, A' and B thus derived are recorded in Table I. These constants apply when the pressure, p, is in millimeters of mercury, the temperature, T, is in ° K. and the volatility, W, is in milligrams per liter of nitrogen (or air).

The mean and the maximum percentage deviation from the smoothed curve of the experimental points and of the points calculated from the least squares equation are recorded in Table II. The mean deviation for each of these compounds is less than 2%. The small values for the deviations of the mean points from the points calculated from the least squares equations indicate that these equations satisfactorily reproduce the experimentally determined points. An examination of the probable sources of error indicates that if the experimental points are in error the values are apt to be small rather than large.

TABLE II

PRECISION OF DATA

Arsine	Percentage deviation from smoothed curve of Experimental points Maximum	Mean	Points calculated from Least squares equation Maximum	Mean
Dichloromethyl	0.15	0.1	Identical	
Dichloroethyl	1.3	0.9	0.7	0.3
Dibromoethyl	2.5	0.8	0.4	0.2
Dichloro-*n*-propyl	1.6	1.1	0.6	0.4
Dibromo-*n*-amyl	7.5	1.9	2.8	1.7
Dichlorophenyl	2.3	1.6	0.9	0.6
Dichloro(2-chlorovinyl)	1.5	0.9	0.2	0.06
Bis(2-chlorovinyl)methyl	0.6	0.3	Identical	
Cyanoethyl-*n*-propyl	6.0	1.9	0.5	0.3

A brief comparison of vapor pressures at different temperatures as calculated from the equations of Baxter and co-workers[9] and from the present equations for two of the arsines is given in Table III. This comparison appears justified since the measurements were made in a similar manner over

---

[12] Bent and Francel, THIS JOURNAL, **70**, 634 (1948).

[13] Actually, some variation in boiling point was observed in some cases, probably due to the slight variations in pressure during the course of the distillation. A variation of 1° was tolerated in three cases, see Table I.

part of the same temperature interval by both authors.

TABLE III

COMPARATIVE DATA ON TWO SUBSTITUTED ARSINES

°C.	Pressure in millimeters Dichloromethylarsine Baxter	This Work	Dichlorophenylarsine Baxter	This Work
0	2.20	2.26	0.0037	0.0040
60	70.2	58.6	0.451	0.409
133[a]	1188	832	....	......
250[b]	.....	....	1259	855

[a] This is the value most frequently given in the literature as the boiling point at 760 mm. pressure for dichloromethylarsine. [b] This is an average value for the values quoted for the boiling point at 760 mm. of dichlorophenylarsine.

If we assume the two normal boiling points to be correct,[14] we then see that an error of about 10% is present in values calculated for the vapor pressure at temperatures considerably above the experimental range.

Summary

1. The volatility of nine substituted arsines has been measured between 0 and 60° by a transpiration method.

2. Vapor pressures have been calculated from the volatility measurements, and from these data logarithmic equations have been developed for both the volatility and the vapor pressure as a function of the temperature.

3. The mean molar latent heat of evaporation over the temperature range 0 to 60° has been computed from the vapor pressure equation for each compound.

4. The average precision of these measurements is better than ±2% over the specified temperature range. However, the equations may be used to extrapolate to other temperatures with somewhat less precision.

CHICAGO, ILLINOIS

RECEIVED JULY 19, 1947

[14] This seems unlikely since normal boiling points are quoted for dichlorophenylarsine ranging from 247 to 257°, with the value 250° appearing most frequently.

The Electrolyte Effects in the Hydration of Isobutene[1,2]

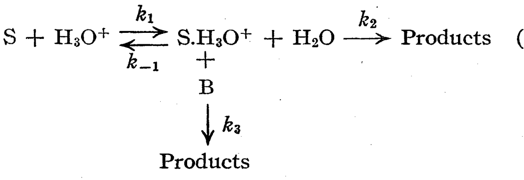
BY FRANK G. CIAPETTA[3] AND MARTIN KILPATRICK[4]

The problem of electrolyte effects of large magnitude in reactions involving an uncharged substrate and the hydrogen ion has been a subject of study in this Laboratory.[5,a,b,c,d] More recently Olson and Tong[6] have attempted to interpret these salt effects, and Sullivan and M. L. Kilpatrick,[7] and M. L. Kilpatrick[8] have advanced a different viewpoint which should be considered.

Whereas Leininger and Kilpatrick[5b] postulated the pre-equilibrium with k_2 the rate determining

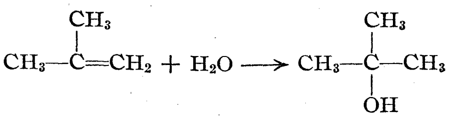
$$S + H_3O^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \{S\cdot H_3O\}^+ \xrightarrow{k_2} \text{Products} \quad (1)$$

step, M. L. Kilpatrick[8] for the hydrolysis of cyanamide, where the cation is formed in appreciable concentration, found the rate determining step to be the reaction of the solvated cation with the base water (k_2), and if additional bases are present the rate is higher than that anticipated on the basis of a hydrogen ion catalysis. This is due to the concurrent reaction (k_3) of the base B with the solvated cation.



$$\begin{array}{c} S + H_3O^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} S.H_3O^+ + H_2O \xrightarrow{k_2} \text{Products} \\ + \\ B \\ \downarrow k_3 \\ \text{Products} \end{array} \quad (2)$$

The present investigation deals with the effect of electrolyte concentration on the rate of hydration of isobutene in aqueous solutions of strong acids and the weaker chloroacetic acids. The reaction in nitric acid solution has been shown to be



$$CH_3-\underset{}{\overset{\displaystyle CH_3}{\overset{|}{C}}}=CH_2 + H_2O \longrightarrow CH_3-\underset{\displaystyle OH}{\underset{|}{\overset{\displaystyle CH_3}{\overset{|}{C}}}}-CH_3 \quad (3)$$

first order with respect to isobutene and its rate proportional to the acid concentration at constant ionic strength,[9] and this conclusion has been verified by G. R. Lucas and Hammett.[10]

Lucas and Eberz followed the course of the reaction analytically but the dilatometric method

was employed in the present investigation. The hydration of isobutene proceeds with a contraction in volume, but due to the low solubility of isobutene (*ca.* 0.005 mole per liter at 25°) the experimental volume change is so small that it was necessary to employ dilatometers of larger volume than usual to obtain the desired accuracy. In considering the design of the dilatometer, the problem of obtaining rapid thermal equilibrium with the constant temperature bath becomes important. It is also necessary to control the bath temperature within narrow limits.

Experimental Part

Apparatus.—One of the dilatometers is shown in Fig. 1 where F_1, F_2, F_3 and F_4 are four interconnecting cylinders each of approximately 80-ml. capacity giving a total reaction vessel volume of 465 ml. The reaction vessel is connected through stopcock A to the mixing chamber G with side arm C, and through stopcock B to a small mercury reservoir fitted with a steel plunger operating on a screw (not shown). A fritted glass disc H was sealed in the bottom of the reservoir through which the isobutene was introduced to saturate the water. The calibrated capillary of 2.28×10^{-3} sq. cm. cross section gave a maximum linear change during an experiment of 8–9 cm. corresponding to a volume change of 0.017–0.020 ml. The other dilatometer was of similar dimensions. The dilatometers were mounted on brass racks in well-stirred insulated water-baths whose temperature was controlled by large-capacity mercury–alcohol thermoregulators and F. G. 57 thyratron tubes.[11] Every effort was made to minimize temperature fluctuations in the bath by vigorous stirring, careful regulation of heating and cooling periods and clean mercury surfaces. The temperature was determined by means of a certified platinum resistance thermometer in conjunction with a Mueller bridge. Tests with the resistance thermometer showed only slight variations ($< \pm 0.001°$) with time and only negligible stratification throughout the bath when the room temperature was quite constant ($\pm 1°$) and not more than 2–3° below the bath temperature. The importance of temperature control is emphasized by the fact that a change of ± 0.001° corresponds to a difference in reading of 0.07–0.08 cm. on the capillary of the dilatometer. Investigation of the time necessary for the dilatometer to come to thermal equilibrium using water revealed that the half-time was 2.6 minutes.

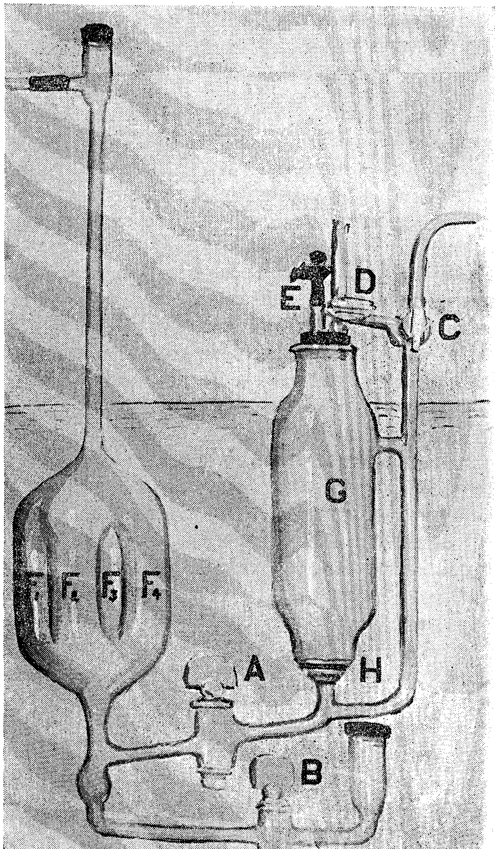

Fig. 1.—Dilatometer.

Determination of Rate.—The following procedure was adopted in the determination of the rate. With cocks D and B closed and tube E sealed off by means of a piece of rubber tubing with a screw clamp (Fig. 1), isobutene was introduced into the dilatometer through cocks C and A for fifteen minutes to purge the dilatometer of air. Cocks A and C were closed and 500 ml. of water placed in reservoir G. With cock D open, isobutene gas was introduced through cock C to the bottom of the reservoir where the gas was dispersed into small bubbles by the fritted disc before passing through the water. The isobutene was bubbled through the water for one and a half hours at a constant back pressure (*ca.* 5 cm.) of mercury. Cock C was closed and a 10-ml. pipet introduced below the surface of the solution through tube E and connected to it by a short piece of rubber tubing. By introducing isobutene gas through cock D a sample of the solution for the determination of the isobutene concentration could be obtained without loss of dissolved isobutene. The solution was stirred with a motor-driven glass stirrer for five minutes after which the required amount of acid was added and the stirring continued for five minutes longer. The solution was forced into the dilatometer by introducing isobutene through cock D (E closed) and opening cock A. Cock A was then sealed off with mercury using the procedure of Brönsted, Kilpatrick and Kilpatrick[12] and the readings started as soon as possible.

After the addition of the acid the time required to fill the dilatometer was approximately fifteen to twenty minutes. In experiments at temperatures of 30 and 35° the reaction mixture required ten to fifteen minutes after sealing in the dilatometer to come to thermal equilibrium. Hence no attempt was made to study reactions whose half-time was less than thirty to thirty-five minutes. No trouble was experienced from the formation of gas bubbles, except in the dichloroacetic acid–sodium dichloroacetate buffer experiment where the total electrolyte concentration was high. In this experiment small gas bubbles, probably isobutene, appeared during the filling of the dilatometer.

In all cases the progress of the reaction was followed by contraction of the solution as read from the graduated capillary of the dilatometer.

The observed velocity constants were evaluated by the method reported by Guggenheim.[13] In a few experiments the experimentally observed infinity reading was used for the second set of readings. In determining the best straight line through the experimental points observed values of ΔV which were less than one were not included since the errors due to temperature fluctuations were accentuated at these low values.

Isobutene.—Isobutene was prepared by the catalytic dehydration of tertiary butyl alcohol. Two different procedures were employed during the course of this investigation. In the first the alcohol was dehydrated over activated aluminum oxide pellets at a temperature of 370–

380°.[14] The catalyst was supported in a vertical reaction tube (2.8 cm. i.d. and 86 cm. in length) heated in an automatically controlled aluminum-bronze block furnace.[15] The alcohol was delivered at a constant rate of 3 ml. per minute to the top of the reaction chamber by a Tropsch-Mattox bellows pump.[16] After leaving the reaction chamber the products were cooled by a water condenser and the isobutene bubbled through two wash bottles in series containing water to remove entrained alcohol vapors. The scrubbed gas then passed through a drying tube and condensed in a high-pressure cylinder (200-ml. capacity) cooled in a Dry Ice-acetone-bath. Two samples of isobutene prepared by this procedure were analyzed by a Consolidated Mass Spectrometer.[16a] Both samples were found to contain 99.9% isobutene and 0.1% isobutane. The second procedure employed was similar to that described by Spence and Hurd.[17] The alcohol was dehydrated by refluxing with oxalic acid and the isobutene purified and collected in the same manner as described above. Consistent results were obtained using isobutene prepared by either procedure.

Determination of Concentrations.—The isobutene concentration was determined by a modification of the method employed by Lucas and Eberz.[9] The acid concentration was determined at the completion of an experiment by titration with carbonate-free sodium hydroxide standardized against benzoic acid. No change was found in the acid concentration, within the experimental error (0.10%) in those runs where both the initial and final acid concentrations were determined.

Experimental Results

Order of the Reaction.—Since Lucas and Liu[18] found some falling off in the velocity constant in the hydration of trimethylethylene, careful experiments were carried out to demonstrate that the reaction is first order. As the data cannot be shown graphically on a small scale the data and calculations for a typical run at 25° are tabulated in Table I. Column 2 gives the first set of readings taken over a period approximately two and a half times the half-time. Readings taken two and four hours later are given in columns 3 and 4. When the logarithms of ΔV, the differences between the readings in columns 2 and 3 and 2 and 4, are plotted against the time given in column 1 the slope of the best straight lines through the points is $-0.4343\ k_{obs}$. In this particular experiment the lines were exactly parallel. Columns 5 and 6 give $\Delta V_{obs.} - \Delta V_{calcd.}$, the deviations of any point from the line.

TABLE I

HYDRATION OF ISOBUTENE IN PERCHLORIC ACID SOLUTION AT 25.00°

$HClO_4$, 0.3974*M*; Isobutene, 0.00483*M*; $k_{obs.} = 13.22 \times 10^{-3}$; $t_{1/2} = 52$ min.

100	13.89	12.48	12.22	+ .01	− .01
105	13.79	12.47	12.21	+ .01	+ .01
110	13.68	12.46	12.21	.00	.00
115	13.58	12.44	12.20	.00	.00
120	13.50	12.43	12.20	.00	+ .01

The data shown in Table I are for the same experiment, the only difference being the time interval between the two sets of readings. The second set of readings was taken immediately after the completion of the first set, while the third set of readings was taken after an additional interval of two hours. By this procedure the reaction was followed to 99% completion. In both cases the deviations of the observed values of ΔV from those calculated, with the exception of the first value, are well within the experimental error. Thus the reaction is strictly first order with respect to the isobutene concentration over the entire range.

Results with Strong Acids.—The hydration of isobutene was studied in the presence of perchloric, hydrochloric, and *p*-toluenesulfonic acid to determine the electrolyte effect of these acids. The results are summarized in Tables II, III and IV. Column 1 gives the molarity of the acid, column 2 the observed velocity constant (in minutes) and column 3 the second order constant, $k_{H_3O^+}$, obtained by dividing the observed velocity constant by the acid concentration.

It is to be noted that at 25° the second order constant consistently increases with increasing electrolyte concentration. The results at 30 and 35° are somewhat erratic but show the same general increase in the second-order constant with increasing electrolyte concentration. The erraticalness is due to the fact that the isobutene is less soluble at higher temperatures and the smaller volume change combined with the poorer constancy of temperature (±0.003° compared to ±0.001°) means less accurate experiments. The initial concentration of isobutene ranged from 0.0052 to 0.0047 molar at 25°, 0.0046 to 0.0039 at 30° and 0.0037 to 0.0032 at 35°.

[a] In presence of ultraviolet light. [b] Solution 0.1 *M* in *t*-butyl alcohol. [c] Solution 0.2 *M* in *t*-butyl alcohol.

Several experiments were carried out in perchloric acid solutions in the presence of *t*-butyl alcohol to determine the effect, if any, of the reaction product on the velocity constant. At 25° for a solution 0.1 molar in the alcohol the first and second order constants were consistent with those found in the absence of the alcohol. However, at 35° for a solution 0.2 molar in the alcohol, the values were lower than was expected for the acid concentration employed.

The effect of ultraviolet light on the reaction velocity was investigated at 25°; the results indicated that the radiation had no effect on the rate of the reaction.

In order to compare the magnitude of the electrolyte effects of the acids at 25° the second-order constants obtained at 30 and 35° were converted to 25° by means of the energy of activation for the reaction. The energy of activation was computed by the equation employing the average values of the second-order constants at zero electrolyte concentration, $k^0_{\mathrm{H_3O^+}}$, for 25 and 35°. The values of $k^0_{\mathrm{H_3O^+}}$ for perchloric, hydrochloric, *p*-toluenesulfonic and nitric[9] acids at 25°, hydrochloric, *p*-toluenesulfonic and nitric[9] acids at 35°, and the average values of $k^0_{\mathrm{H_3O^+}}$ at these temperatures are given in Table V.

$$E_{\mathrm{A}} = \frac{2.303RT_1T_2}{T_1 - T_2} \log \frac{k_{\mathrm{T_1}}}{k_{\mathrm{T_2}}} \qquad (4)$$

With the exception of the value for nitric acid at 35°, the values of $k^0_{\mathrm{H_3O^+}}$ were obtained by plot-

TABLE V

VALUES OF THE SECOND ORDER CONSTANT AT ZERO ELECTROLYTE CONCENTRATION

Acid	$10^2 k^0_{\mathrm{H_3O}}$ 25°C.	$10^2 k^0_{\mathrm{H_3O}}$ 35°C.
$HClO_4$	2.134	...
HCl	2.211	8.030
p-$CH_3C_6H_4SO_3H$	2.291	8.007
HNO_3	2.190	7.887
	Av. 2.207	7.975

ting the logarithm of the second order constant at a function of the acid concentration and taking the intercept at zero electrolyte concentration from the best straight line (as found by the method of averages) through the experimental points for each acid. The value of $k^0_{\mathrm{H_3O^+}}$ for nitric acid at 35° was calculated from the value of $k^0_{\mathrm{H_3O^+}}$ for this acid at 25° and the energy of activation found by Lucas and Eberz.[9] The energy of activation for the hydration of isobutene obtained from the data given in Table V is 23.46 kcal. per mole which is in agreement with the value 23.39 kcal. given by Lucas and Eberz.[9]

In Fig. 2 the logarithms of the second order constants obtained at 25° and those calculated to 25° by the above procedure for perchloric, hydrochloric and p-toluenesulfonic acids are shown plotted as a function of the acid concentration. Using the logarithm of the average value of $k^0_{\mathrm{H_3O^+}}$ at 25° given in Table V as the intercept at zero electrolyte concentration the best straight line was drawn through the data for each of the acids. Also shown in Fig. 2 are the data of Lucas and Eberz[9] for nitric acid at 25°. Figure 2 shows that the logarithm of the second order constant for the acids investigated increases linearly with acid concentration over the range of acid concentration investigated and thus obeys an equation of the type where C is the concentration of the acid in

$$\log k_{\mathrm{H_3O}} = \log k^0_{\mathrm{H_3O^+}} + BC \qquad (5)$$

moles per liter and B is a constant depending on the acid employed. The following equations express the electrolyte effect of the various acids studied.

$$\log k_{\mathrm{H_3O^+}} = \bar{2}.3433 + 0.47C_{\mathrm{HClO_4}} \qquad (6)$$

$$\log k_{\mathrm{H_3O^+}} = \bar{2}.3433 + 0.44C_{\mathrm{HCl}} \qquad (7)$$

$$\log k_{\mathrm{H_3O^+}} = \bar{2}.3433 + 0.30C_{p\text{-}\mathrm{CH_3C_6H_4SO_3H}} \qquad (8)$$

The electrolyte effect of nitric acid on the second order constant at 25° calculated from the data of Lucas and Eberz[9] is given by the equation

$$\log k_{\mathrm{H_3O^+}} = \bar{2}.3405 + 0.21C_{\mathrm{HNO_3}} \qquad (9)$$

The values of the B term show that these acids have a large electrolyte effect on the rate of the reaction. The effect decreases in the order $HClO_4$ > HCl > p-$CH_3C_6H_4SO_3H$ > HNO_3 which is different from that found by Lucas and Liu[18] for the hydration of trimethylethylene; their data indicate the order of decreasing electrolyte effect to be HCl > $HClO_4$ > HNO_3 > p-$CH_3C_6H_4SO_3H$. However, with the exception of nitric acid this order of electrolyte effect on the rate of hydration of trimethylethylene is based on one experiment for each of the acids at a concentration of 0.1 M.

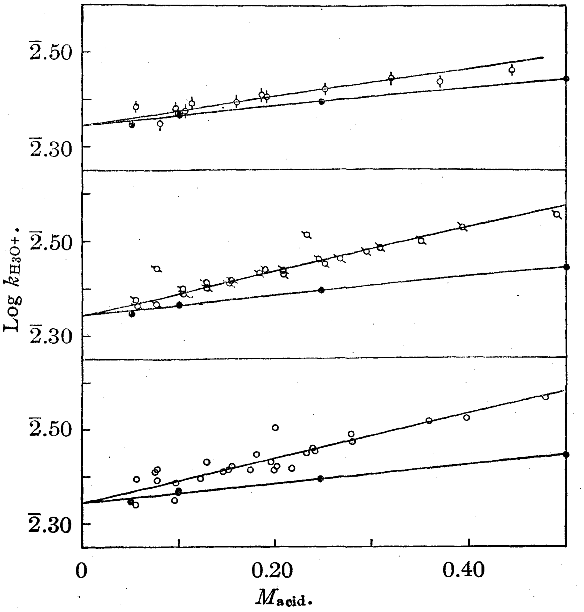

Fig. 2.—Hydration of isobutene: ○, $HClO_4$; ϕ, p-$CH_3C_6H_4SO_3H$; -○-, HCl; ●, HNO_3; temp. 25°.

Hantzsch and Weissberger[19] studied the effect of strong monobasic acids on the rate of inversion of sucrose at 25°. Their data for perchloric, hydrochloric, hydrobromic, benzenesulfonic and nitric acids are shown in Fig. 3, where the logarithms of the second-order velocity constants are plotted as a function of the acid concentration. Over the range of acid concentrations investigated the second-order constants increase linearly with acid concentration. The electrolyte effects of these acids on the second-order constants are given by the equations

$$\log k_{\mathrm{H_3O^+}} = \bar{3}.560 + 0.29C_{\mathrm{HClO_4}} \qquad (10)$$

$$\log k_{\mathrm{H_3O^+}} = \bar{3}.520 + 0.27C_{\mathrm{HBr}} \qquad (11)$$

$$\log k_{\mathrm{H_3O^+}} = \bar{3}.540 + 0.25C_{\mathrm{C_6H_5SO_3H}} \qquad (12)$$

$$\log k_{\mathrm{H_3O^+}} = \bar{3}.536 + 0.21C_{\mathrm{HCl}} \qquad (13)$$

$$\log k_{\mathrm{H_3O^+}} = \bar{3}.550 + 0.17C_{\mathrm{HNO_3}} \qquad (14)$$

The values of the B term for the various acids indicate that for the inversion of sucrose, as for the hydration of isobutene, perchloric acid has the largest electrolyte effect on the velocity constant and nitric acid the lowest. However, for perchloric and hydrochloric acids the magnitudes of the B term are much greater for the hydration of isobutene than for the inversion of sucrose.

Riesch and Kilpatrick[5a] also observed that the perchlorate ion had the largest electrolyte effect on the rate of hydrolysis of diethyl acetal at 0°. For this reaction the order of decreasing electrolyte effect for the anion of the sodium salts in-

---

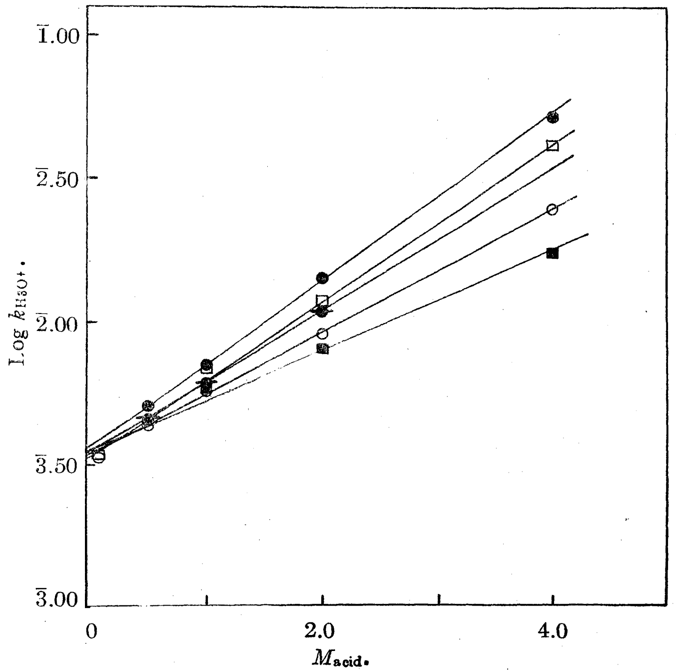

Fig. 3.—The inversion of sucrose at 25°: ●, $HClO_4$; -●-, $C_6H_5SO_3H$; ■, HNO_3; □, HBr; O, HCl.

vestigated was $ClO_4^- > Cl^- > NO_3^- > p\text{-}CH_3C_6H_4SO_3^- \eqsim C_6H_5SO_3^-$. The smaller electrolyte effect observed for the *p*-toluenesulfonate and benzenesulfonate ions than for the nitrate ion is not in agreement with the electrolyte effects of these ions on the rates of hydration of isobutene and the inversion of sucrose. The magnitudes of the *B* terms for sodium perchlorate and sodium chloride at a salt concentration of 0.5 *M* are similar to those found for perchloric and hydrochloric acids in the hydration of isobutene.

Results with chloro-substituted acetic acids.—In the hydrolysis of cyanamide[7] the observed velocity constant was in some cases found to be greater in solutions of trichloroacetic acid than in solutions of nitric acid of the same concentration. To compare the observed velocity constants for these two acids for the hydration of isobutene trichloroacetic acid was purified by recrystallization from benzene and hydration experiments carried out in the usual way. The reaction was first order and tests for chloride ion showed no decomposition of the acid during the reaction. The results are summarized in Table VI and the comparison of the observed velocity constants for the two acids presented graphically in Fig. 4. The data revealed that the observed velocity constants are higher for trichloroacetic acid below 0.4 *M* than for nitric acid, while the reverse is true at higher concentrations in spite of the fact that trichloroacetic acid is considered to be a weaker acid than nitric acid. The possibility that Scheme 2 is operative in the hydration of isobutene and we are not dealing with a specific hydrogen ion-catalyzed reaction was tested in the following way.

Dichloroacetic acid was purified by vacuum distillation and a middle fraction boiling from 95–96° (mainly at 95.5°) at 18 mm. mercury pressure was used to prepare a dichloroacetic acid–sodium dichloroacetate buffer solution with an acid to base ratio approximately unity. The observed velocity constant for the hydration was determined with a portion of this solution, and other portions of the original stock solution were diluted with water containing the required amount of sodium chloride to keep the ionic strength nearly constant and the velocity constant again determined. The last solution had approximately one fourth of the concentration of dichloroacetic acid and dichloroacetate of the first solution. The results are presented in Table VII.

The stoichiometric composition of the buffer solutions is given in columns 1 to 3, the observed velocity constant in column 4, the calculated hydrogen ion concentration based on a value of the dissociation constant of 7.05×10^{-2} calculated from the data of Harned and Hawkins[20] in column 5, and the value of the

second order constant $k_{H_3O^+}$ obtained by dividing the observed velocity constant by the calculated hydrogen ion concentration in column 6. The first solution gave no test for chloride ion after the completion of the run so that there was no detectable decomposition of the acid or its anion. The constancy of $k_{H_3O^+}$ (last column) indicates there is no detectable effect of dichloroacetic acid or dichloroacetate on the velocity constant and one must conclude that the rate is proportional to the hydrogen ion concentration for these experiments.

A further test was carried out in monochloroacetic acid–monochloroacetate buffers at the same ionic strength and the results are reported in Table VIII. Here the hydrogen ion concentration remains constant as there is very little change in acid–base ratio on dilution. Unfortunately the chloroacetate ion loses chloride[21] and the contraction in volume is offset by an expansion due to this unavoidable side reaction. However, the half-times of the reaction in the two buffer solutions were approximately the same, indicating no difference in rate in spite of the fourfold difference in concentration of the buffer constituents, and scheme 2 does not appear to apply to this reaction.

Discussion

If the reaction is an example of specific hydrogen ion catalysis with unusually large electrolyte effects it should be possible to calculate the dissociation constant of trichloroacetic and dichloroacetic acids and compare the results with values obtained by other methods. To make such a calculation a value for the electrolyte effect of the anion must be assumed. Since the observed velocity constants are in some cases lower for nitric acid the assumption that the primary kinetic electrolyte effect of trichloroacetate is equal to that of nitrate would lead to absurd answers. Hence, the assumption is made that the kinetic electrolyte effect of trichloroacetate is equal to that for perchlorate. If the electrolyte effect of the chloride ion were taken instead of perchlorate the calculated dissociation constant would be somewhat higher. The hydrogen ion concentration is determined by dividing the observed velocity constant for trichloroacetic acid by the second-order constant for the perchloric acid solution at the corresponding ionic strength, and the classical dissociation constant

$$K_c = [H_3O^+]^2/[CCl_3COOH] \qquad (15)$$

is computed and given in Table IX. Since these dissociation constants (column 5) are at different ionic strengths the activity coefficients are needed to obtain the thermodynamic dissociation constant, but as these are not known a fair approximation is to take those of acetic acid from the data of Harned and Hickey.[23] In other words, the K_c/K_a ratio for acetic acid is divided into the values of K_c in column 5 and the thermodynamic dissociation constant, K_a, obtained (column 6). The average value of K, 0.98, is in fair agreement with the value 1.2 reported by Ostwald[24] which was obtained from a value of the dissociation constant of dichloroacetic acid of 0.051 obtained from conductivity data and a determination of the ratio of the

[24] W. Ostwald, *Z. physik. Chem.*, **3**, 369 (1889).

dissociation constant of tri- and di-chloroacetic acids by a comparison of the rates of inversion of sucrose for the two acids. A calculation neglecting the effect of ionic atmosphere on the mobilities of the ions using the conductance data of Ostwald[24] gives a value of the dissociation constant which is almost a power of ten lower after correction for activity coefficients. Hall[25] reports a value of 2×10^{-1} and Baughan[26] rightly claims there is no reliable value of the dissociation constant of trichloroacetic acid in water. The conductance data are not accurate enough to attempt a calculation using the procedure of Onsager.[27] A calculation of the dissociation constant from the data of Hantzsch and Weissberger[19] making the same assumptions as used in handling the kinetic data for the hydration of isobutene yields an average value of K_a, 0.478, which is not in agreement with the other kinetic data. A similar calculation using the data reported by Taylor[28] for the hydrolysis of ethyl acetate in trichloroacetic acid solutions with and without the addition of potassium trichloroacetate gives an average value 0.98 in agreement with that calculated from the kinetic data of the hydration of isobutene.

In Table X are given the calculated values of the dissociation constant for dichloroacetic acid based on the kinetic data of Table VII and calculated on the same assumptions used in obtaining the dissociation constant of trichloroacetic acid. The average value of $K_a = 0.043$ is higher than the value 0.0332 reported by Harned and Hawkins[20] from kinetic measurements on the rate of hydrolysis of ethyl acetate, but lower than the value 0.0514 reported by Ostwald[24] from conductance data. A recalculation of part of the conductance data taking into account the change in mobility and activity coefficients with ion concentration yields a value 0.046 for the thermodynamic dissociation constant at 25°, but too much reliance cannot be placed on this value as Ostwald himself pointed out that the experimental data in dilute solutions are not too reliable.

TABLE X

DISSOCIATION CONSTANT FOR DICHLOROACETIC ACID AT 25°

Moles per liter					
Acid	Na salt	NaCl	$[H_3O^+]$	K_c	K_a
0.1285	0.1126	0.3732	0.0429	0.078	0.0415
.2506	.2395	.2114	.0571	.088	.0468
.3766	.3592	.0862	.0613	.082	.0436
.5276	.4623		.0648	.074	.0394

With our present incomplete knowledge of the dissociation constant of trichloroacetic acid at infinite dilution and at any electrolyte concentration, no reliable calculation of the possibility of acid molecule catalysis can be made. The results with dichloroacetate and monochloroacetate buffer solutions do not indicate any detectable catalytic effect of the molecules of these acids. These experiments also indicate that the mechanism proposed in scheme 2 where the anion might have a catalytic effect is not applicable and one is forced to consider that the hydration of isobutene is another reaction catalyzed solely by hydrogen ion and exhibiting an unusually large electrolyte effect.

Summary

1. The rate of hydration of isobutene in aqueous solutions of perchloric, *p*-toluenesulfonic, hydrochloric and trichloroacetic acids has been investigated by the dilatometric method.
2. The electrolyte effects of the strong acids on the rate of the reaction are larger than predicted by the Brönsted theory of primary salt effects.
3. In trichloroacetic acid solutions the observed velocity constants appear to be larger than would be expected on the basis that the reaction is catalyzed solely by hydrogen ion. However, the results obtained in dichloroacetate and monochloroacetate buffer solutions do not indicate any basic catalysis of the cation of isobutene or catalysis by the molecular acid.
4. The dissociation constants of trichloro- and dichloroacetic acids have been calculated from the kinetic measurements.

Some Properties of Lithium Dichromate

BY WINSLOW H. HARTFORD AND KEITH A. LANE

Lithium dichromate has been described[1,2] and the system Li_2O–CrO_3–H_2O has been investigated at 30°,[3] while Heydweiller[4] has investigated the density and equivalent conductance of dilute solutions at 18°. The black or brownish-black crystals of lithium dichromate dihydrate previously described were suspected of being impure in view of the characteristic red to orange color of the other alkali dichromates. The growing importance of lithium salts and of the dichromates has rendered the reevaluation of the properties of this salt desirable.

Experimental

Preparation of Lithium Dichromate Dihydrate.—Lithium carbonate of N. F. grade was employed as a source of lithium. This material assayed 99.60%, the principal impurities being other alkalies and sulfate.[5] Technical chromium trioxide, 99.7% pure, was used as the source of chromium, the principal impurities in this material being Cr(III), sulfate and moisture. The procedure for the preparation of a typical batch of lithium dichromate dihydrate was as follows:

Three and one-half kilograms of chromium trioxide was dissolved in water to give 7.5 liters of solution. Solid lithium carbonate was added, with agitation, until a *p*H of 3.5 was reached, about 1.3 kg. of lithium carbonate being employed. Cr (III) was converted to Cr (VI) by electrolysis of the solution at 4.5 volts, using lead electrodes. The oxidation of Cr (III) was judged complete when the solution became bright orange-red in color. The batch was filtered free of lead chromate, concentrated to a volume of 4.0 liters and allowed to cool with agitation, when a crop of crystals separated which were centrifuged and dried in a stream of warm air in a small rotating dryer. Additional yields may be obtained from reconcentration of the mother liquor. The crystals are bright red-orange in color, deliquescent, and consist of thin plates with crystal angles resembling those of sodium dichromate dihydrate. The black color reported by the original investigators[1,2] was evidently due to trivalent chromium present in the chromium trioxide used. Their identification of the salt as the dihydrate was confirmed by the following analyses: For $Li_2Cr_2O_7 \cdot 2H_2O$: calcd.: Li_2O, 11.24, CrO_3, 75.21; H_2O, 13.55. Found: Li_2O (as sulfate) 11.23, 11.31; CrO_3 (by electrometric titration with $FeSO_4$) 74.91, 74.91; H_2O (by weight loss), 13.54.

Existence of the Anhydrous Salt and Behavior on Heating.—The dihydrate is converted to the anhydrous salt on heating. All water is removed on heating four days at 110°; Schulerud[1] reports dehydration at 130°. On heating the crystalline dichromate slowly with saturated solution to the boiling point and then cooling with agitation, no evidence was obtained of any transition point on plotting a time–temperature curve. The anhydrous salt does not exist as a crystalline phase in contact with solution at temperatures below the boiling point of a saturated solution, 149°.

When the solid dihydrate is slowly heated with agitation in air, it melts with partial decomposition at 187°. Water and oxygen are evolved and the salt is partially decomposed to lithium chromate and chromic chromates.

Density of the Solid Dihydrate.—The density of the solid dihydrate was measured in a pycnometer at 30°, using light mineral oil as the immersion liquid, giving d^{30}_{4} 2.34.

Density of the Solution.—The salt dissolves congruently in water, and no difficulty was experienced in measuring the density of the solution in a pycnometer. The following values were obtained at 30°.

% $Li_2Cr_2O_7 \cdot 2H_2O$ by weight	d^{30}_{4}	% $Li_2Cr_2O_7 \cdot 2H_2O$ by weight	d^{30}_{4}
0.00	0.9957	36.64	1.2575
4.05	1.0195	38.79	1.2777
6.15	1.0320	41.48	1.3026
8.16	1.0455	44.64	1.3325
12.13	1.0705	46.10	1.3470
15.37	1.0930	50.72	1.3954
18.98	1.1178	52.67	1.4177
22.38	1.1427	56.44	1.4602
26.82	1.1767	61.96	1.5246
30.82	1.2082	65.11	1.567[a]

[a] Extrapolated to saturation concentration.

The data are plotted in Fig. 1, and may be shown to fit the empirical equation

$$d^{30}_{4} = 0.9957 + 0.00586C + 0.000233C^2 + 0.000000303C^3$$

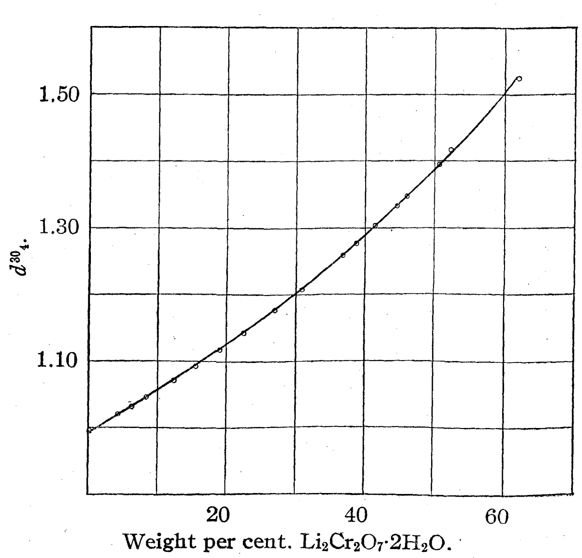

Fig. 1.—Density of lithium dichromate solutions at 30°.

where C is concentration in weight per cent. of $Li_2Cr_2O_7 \cdot 2H_2O$, with an average error of 0.0006 in the density. These data are in substantial agreement with those of Heydweiller,[4] which cover the range up to 23%, when the temperature difference is taken into consideration.

Solubility in Water.—This was determined by agitating about 2 liters of solution with an excess of the solid phase in a covered container at a constant temperature provided by an immersion heater and a vapor–mercury sensitive element. After reaching equilibrium (about six hours) a sample of the clear solution was removed by means of a sintered glass funnel and analyzed. The results given are the average of duplicate analyses for chromate on each of two samples, which checked with an average error of 0.04%. The value for 0.8° was obtained by surrounding the solution container with crushed ice, and represents an average of temperatures varying from 0.6 to 1.0°. The following data were obtained:

Temp., °C.	Soly., % by weight $Li_2Cr_2O_7 \cdot 2H_2O$	Temp., °C.	Soly., % by weight $Li_2Cr_2O_7 \cdot 2H_2O$
0.8	62.36	70.0	69.49
30.0	65.11[a]	80.0	70.76
40.0	66.08	90.0	72.26
50.0	67.28	100.0	73.55
60.0	68.39		

[a] Schreinemakers' data[3] at 30° give 65.4% $Li_2Cr_2O_7 \cdot 2H_2O$ for the solubility.

These data, when plotted, deviate an average of 0.06% from the empirical equation: $S = 62.18 + 0.0890t + 0.000243t^2$, where S is solubility in weight per cent. and t is temperature in degrees C. The maximum deviation is 0.12%.

Freezing Point of Solutions.—Five hundred milliliter portions of analyzed solutions were cooled in an insulated container by means of solid carbon dioxide and alcohol. Time–temperature heating and cooling curves were employed to determine the ice-point for each solution, and these data further checked by observation of the appearance and disappearance of ice-crystals. The following data were obtained:

% $Li_2Cr_2O_7 \cdot 2H_2O$ by weight	Ice point, °C.	% $Li\ Cr_2O_7 \cdot 2H_2O$ by weight	Ice point, °C.
0.0	0.0	41.10	−24.0
20.14	− 6.2	47.39	−35.4
29.97	−12.0	52.32	−49.8
34.82	−17.2	57.53	No crystallization at −60

A smooth curve may be drawn through these points with an average deviation of 0.4°.

Eutectic Point.—Facilities did not permit investigation of the system below −60°. Graphical analysis indicates the eutectic composition to be close to 56.5% $Li_2Cr_2O_7 \cdot 2H_2O$ and the eutectic temperature below −70°.

Solubility in Organic Liquids.—Lithium dichromate dihydrate is insoluble in ether, carbon tetrachloride and hydrocarbon solvents. It dissolves in ethyl alcohol to the extent of about 20 g. per 100 ml. of solvent at room temperature. No exact measurement is possible because of the rapid oxidation of the alcohol and reduction of the dichromate. In acetone solution occurs at first, then the dichromate decomposes with precipitation of yellow lithium chromate.

Summary

1. Lithium dichromate dihydrate has been prepared and shown to consist of red-orange crystalline plates when pure.

2. Its density, solubility and behavior on heating have been described.

3. Data have also been presented giving the density and freezing point of aqueous solutions, and the eutectic composition and temperature estimated.

4. The solubility in common organic liquids has been qualitatively examined.

Colorimetric Determination of Iron with 4-Hydroxybiphenyl-3-carboxylic Acid[1]

BY JOHN H. YOE AND AUBREY E. HARVEY, JR.[2]

As early as 1834,[3,4,5] the color reactions between ferric ions and phenolic derivatives were observed and used as a qualitative test for the aromatic hydroxyl group. Salicylic acid was the first phenol to be used for the detection of ferric ions,[6,7,8,9] and for its quantitative determination.[10–16] Derivatives of salicylic acid which have been used as quantitative colorimetric reagents for iron are: sulfosalicylic acid,[17,18,19] salicylaldoxime,[20] and β-resorcylic acid.[21]

This paper introduces 4-hydroxybiphenyl-3-carboxylic acid as a new colorimetric reagent for ferric iron. The reagent is very sensitive and is

practically specific, its only other color reaction being with the uranyl ion. The latter reaction will be studied in more detail. The colorless solution of the reagent in ethanol appears to be stable indefinitely. The iron complex is soluble in slightly acid 40% ethanol solution; its intense violet color is stable for at least fourteen hours. Iron may be determined without difficulty in the presence of titanium, and there is remarkably little interference from other cations. Anions such as phosphate, fluoride, oxalate, phthalate, and tartrate which form complexes with the ferric ion, either reduce the sensitivity of the reaction or prevent color formation altogether. The procedure for the determination of iron is simple and may be applied to a wide variety of materials with highly satisfactory results.

Apparatus and Solutions

Instruments.—Spectrophotometric measurements were made with a Beckman quartz spectrophotometer, Model D, using 10.0 mm. Corex glass transmission cells, at a spectral band width of 5 mμ.

Visual color matching was made in 50-ml. Nessler cylinders (220 mm.); also with a color comparator[22] using 100-ml. tubes (160 mm.).

Reagent Solution.—4-Hydroxybiphenyl-3-carboxylic acid, mol. wt. 214, was furnished by courtesy of E. I. du Pont de Nemours and Company. The compound is only slightly soluble in water, but is highly soluble in 70% ethanol. The melting point is 214–215° (cor.) as compared with 212–213° reported in the literature.[23] Solutions containing 0.1916 and 1.0000 g. of solute, respectively, in 100 ml. of 95% ethanol were used. One milliliter of the more dilute solution added to 50 ml. of a solution containing 10 p. p. m. iron furnished 1 mole of reagent to 1 gram-ion of ferric ions. Reagent solutions appear to be stable indefinitely.

Standard Iron Solution.—7.0224 g. of ferrous ammonium sulfate hexahydrate was dissolved in 100 ml. of distilled water, 5 ml. of concentrated sulfuric acid and 1 ml. of bromine were added, and the solution boiled to oxidize the iron and expel the excess bromine. The solution was diluted to 1 liter and the iron determined gravimetrically. The solution should contain 1.00 mg. of iron per ml. More dilute solutions may be prepared from this stock solution as needed.

Solutions of Diverse Ions.—Solutions of salts were prepared from reagent grade, iron-free chemicals, and contained 0.5 mg. of the desired ion per ml.

Spectrophotometric Study of the Color Reaction

Spectrophotometric measurements were made to determine the effect of reagent concentration on the color intensity in an effort to establish the empirical formula for the violet complex formed in 40% ethanol solution.[24] Two series of solutions were prepared in which the molar ratio of reagent to iron varied from 0.2:1 to 10:1. The *p*H of one series was adjusted to 2.8 and of the other to 3.0. All solutions contained 10 p. p. m. of iron and 40% ethanol. The absorbancy ($-\log T$) was measured for each solution at 575 mμ, the wave length of maximum absorption for the complex. The results are plotted in Fig. 1.

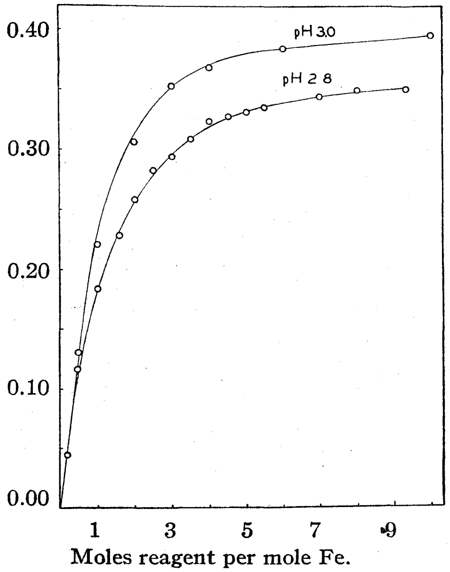

Fig. 1.—Effect of reagent concentration: 10 p. p. m. Fe; λ575 mμ.

These curves show no sharp break or leveling off to a constant maximum absorbancy. The absorbancy is still increasing slightly at a reagent–iron ratio of 10:1, indicating that the complex is appreciably dissociated in solution. The curves show, moreover, that a large excess of reagent (at least a 10:1 molar ratio) is necessary to insure full color development.

The method of "continuous variation" first proposed by Job[25] and extended by Vosburgh and co-workers[26,27] was applied to the determination of the ratio of reagent to iron in the complex studied in this investigation. A 1.79×10^{-4} M solution of ferric ions (10 p. p. m.) and a reagent solution of the same molarity were prepared in 40% ethanol. The *p*H of these solutions was adjusted to 3.0. Twelve solutions of the colored complex were obtained by mixing x ml. of the reagent solution and $(20 - x)$ ml. of the iron solution. The *p*H of each solution after mixing was checked with a glass electrode and found to be 3.0. The values of x were chosen so that the molar ratio varied from 0.25 to 9 moles of reagent for each mole of iron. In one experiment, ammonium sulfate was added to the reagent solution so that the concentration of sulfate ion remained constant in the whole series. This precaution did not affect the results in any way. The absorbancy was determined at 550, 575 and 600 mμ, respectively. In Fig. 2 the absorbancy values at 575 mμ are plotted against the volume of reagent solution [expressed x liters added to $(1-x)$ liters of iron solution].

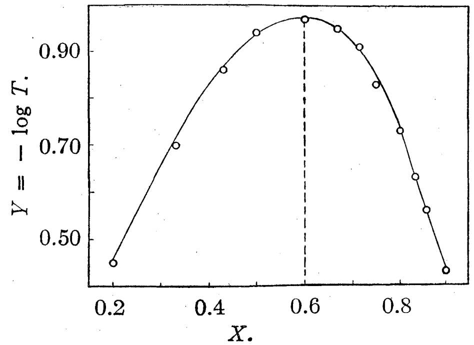

Fig. 2.—X liters of 1.79×10^{-4} M reagent solution added to $(1 - X)$ liters of 1.79×10^{-4} M Fe^{+++} solution: λ, 575 mμ, pH 3.0.

A Y function, first introduced by Job[25], may be defined as the difference between the observed absorbancy and the calculated absorbancy, assuming no reaction between the components of the colored complex.

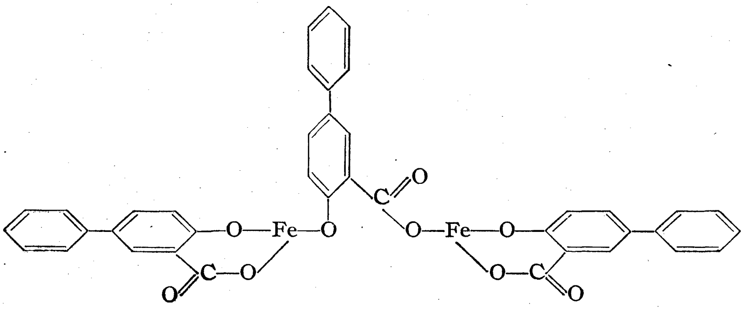
$$Y = E_{\text{obs.}} - d[\epsilon_1 M(1 - x) + \epsilon_2 Mx]$$

The symbols ϵ_1 and ϵ_2 represent, for a given wave length, the molecular extinction coefficients of ferric ion and the reagent, respectively; M the molarity of the solutions used; d the thickness of the ransmission cell; $(1 - x)$ and x the volumes in liters of the solutions mixed.

The new iron reagent is colorless and therefore ϵ_2 is zero at any wave length in the visible range. The term $\epsilon_1 M(1 - x)$ may be neglected because ferric ions show no appreciable absorption at the concentration used in this procedure. The Y function for this particular case is then simply the observed absorbancy (−log T). It has been shown[26] that if Y is plotted against x, the value of x for which the curve passes through a maximum or a minimum will give the value of n in the formula FeR_n by the relationship $n = x/(1 - x)$. The maximum in Fig. 2 indicates a formula of $FeR_{1.5}$ or Fe_2R_3 for the complex. The curve has a rather broad maximum which is to be expected when there is appreciable dissociation.

Vosburgh and Cooper[26] point out that for solutions in which only one complex is formed, the maximum or minimum in Y will occur at the same value of x for any wave length at which measurements are made. The absorbancy values at 10 mμ intervals from 520 to 620 mμ were determined for solutions containing 10 p. p. m. of iron with the following molar ratios of reagent to iron: 0.2:1, 0.5:1, 1:1, 2:1, 3:1 and 9:1. Plotting log E against wave length gave curves which were identical in shape and could be superimposed by adding a suitable constant to the ordinates of each curve. This shows that in the color system under consideration the reagent forms only one complex with ferric iron.

Various attempts have been made to establish the structures of complexes formed by the reaction between ferric ions and phenolic derivatives.[28,29,30,31,32,33,34] Wesp and Brode[35] found that the absorption curves for the water-soluble complexes of ferric ions with 44 phenols and 10 naphthols, as well as the curves for the ferric–salicylic acid color in 28 different solvents were identical in shape, though the wave length of maximum absorption depended on the particular phenolic derivative used and varied also with the solvent. The characteristic shape of these absorption curves is duplicated by that of the ferric thiocyanate complex. This similarity indicates that all the complexes have the same or very similar structures. Bent and French,[36] and also Edmonds and Birnbaum[37] independently, have reported that the color of the thiocyanate complex is due to the $Fe[CNS]^{+2}$ ion. Gould and Vosburgh[27] confirmed the presence of the $Fe[CNS]^{+2}$ ion using the method of continuous variation. Hence it would seem that the water-soluble iron complexes with phenolic derivatives have the formula FeR^{+2} in solution. Weinland and Binder[33] have assigned the formula $[Fe(OC_6H_4OCH_3)_4]H$ to the violet complex formed by ferric ions and guaicol in alcoholic solution. Wesp and Brode[35] point out that the structure of the guaicol compound may well differ from that of the other phenolic complexes of iron because the compound is insoluble in water. The same reasoning would apply in the present case since the complex under investigation is insoluble in water and the color is formed in ethanol solution. It is probable that a molecule rather than an ion is responsible for the color. Since the reagent has two replaceable hydrogens, it is reasonable to assume that the structure of the complex may be represented as



A Spectrophotometric Study of the Effect of pH on the Color Reaction.—Attempts to form the colored complex of ferric ions with 4-hydroxy-

biphenyl-3-carboxylic acid in aqueous solution were unsuccessful. The reagent precipitates immediately from solutions as dilute as 0.15 mg. per ml. if the *p*H is 3.3 or below. In higher concentrations the reagent precipitates at any *p*H below 4.4. At this latter *p*H the precipitation of ferric hydroxide from aqueous solution interferes with the color reaction.

The intensity of the color in 40% ethanol is extremely sensitive to changes in hydrogen-ion concentration. Visual observations indicated that maximum absorption is reached at a *p*H of about 3. In more acid solutions, the absorption is markedly diminished. Decreasing the acidity not only causes a decrease in color intensity, but also a change in hue from violet to reddish-violet at *p*H 4. This change in hue is thought to be due to the formation of colloidal, hydrated ferric oxide. Solutions containing 10 p. p. m. iron in 40% ethanol developed a red color without addition of the reagent when the *p*H was adjusted to 4.0 or above. Ferric hydroxide precipitated from these solutions on standing overnight.

Spectrophotometric measurements were made on a series of solutions containing 10 p. p. m. iron and varying in *p*H from 2.1 to 3.6. All solutions contained 4 moles of reagent to each mole of iron. Absorbancy measurements were made at 10 mμ intervals from 400 to 700 mμ. The absorbancy *vs.* wave length curves are shown in Fig. 3. The solutions of *p*H 2.1, 2.4 and 2.8 are deep violet in color and have absorption maxima at 575 mμ, the absorbancy being greatest at *p*H 2.8. The curve at *p*H 3.6 shows a slight shift of the maximum toward the shorter wave lengths, and increased absorption from 400 to 500 mμ. These variations are increasingly pronounced from *p*H 3.8 to 4.3 and correspond with a change in hue to reddish-violet. The increased absorption between 400 and 500 mμ could be explained by the formation of colloidal ferric oxide, which absorbs in this range. On standing twenty-four hours, the reddish-violet solutions of *p*H 3.6 and above became turbid, the color faded and a reddish-brown precipitate gradually settled out.

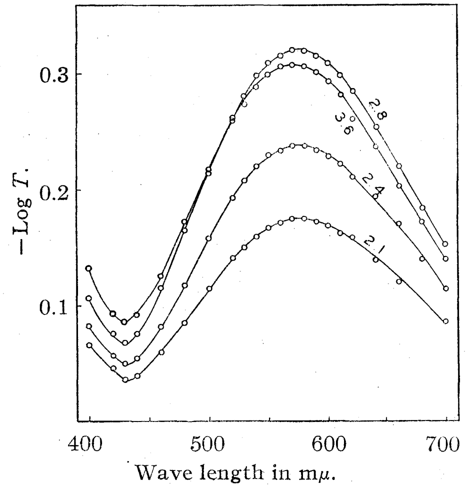

Fig. 3.—Effect of *p*H on extinction: moles reagent: moles Fe = 4:1; 10 p. p. m. Fe.

In order to determine more closely the optimum *p*H range, three solutions were used having *p*H values of 2.8, 3.0 and 3.2. These solutions differed from the first series in that each contained a 10:1 molar ratio of reagent to iron. Their extinction is plotted against wave length in Fig. 4. The upper curve of Fig. 3 is reproduced in Fig. 4. The curves for *p*H 3.0 and 3.2 coincide at all wave lengths. The difference in intensity of these solutions and of that at *p*H 2.8 cannot be detected visually. The optimum *p*H range may therefore be set at 2.8–3.2.

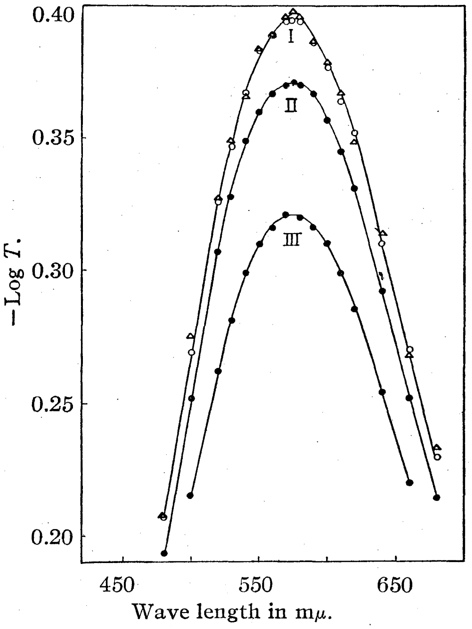

Fig. 4.—Effect of *p*H on extinction: moles reagent: moles Fe; I and II 10:1, III 4:1; △, *p*H 3.2, ○, *p*H 3.0, ●, *p*H 2.8.

It was found that the *p*H can be adjusted closely enough by adding 1 *N* sodium hydroxide until the solution is alkaline to congo red paper, and then 0.1 *N* hydrochloric acid until a drop of the solution turns the paper light blue. The use of a buffer was dispensed with in order not to decrease the sensitivity of the reaction.

Conformity to Beer's Law

The new iron complex was found to conform to Beer's law up to an iron concentration of 10 p. p. m. Solutions containing 15 and 20 p. p. m. iron showed increasing deviation from Beer's law, and on standing a short while gave a mixed blue-white precipitate of complex and reagent. Spectrophotometric measurements were made over a wave length range from 520 to 620 mμ.

Stability of the Colored Complex.—Solutions of the colored complex in the optimum *p*H range, containing a large enough excess of reagent for full color development, are stable from fourteen to sixteen hours in the diffuse light of the laboratory. A precipitate of reagent and complex separates from solutions containing 10 p. p. m. iron after thirty-six hours, and from solutions with 1 p. p. m. after a week. It is recommended that fresh standards be prepared daily.

Sensitivity of the Reaction.—The limit of sensitivity of the violet iron complex is 1 part of iron in 40 million parts of solution when observations are made either in 50-ml. tall-form Nessler cylinders or in a color comparator.[22] Solutions having a *p*H of 3.0 and containing 1 part of iron in 10, 20, 30, 40 and 50 million parts of solution, respectively, with 1 ml. of 1% reagent and 40 ml. of 95% ethanol per 100 ml. of solution were transferred to comparator tubes or Nessler cylinders. Three independent observers were able to arrange the four more concentrated solutions in the proper order and to distinguish from a reagent blank, the solution containing 1 part of iron in 40 million.

The optimum concentration range for comparison in the Nessler cylinders is 0.2 to 1 p. p. m. of iron. Over this range, increments of 1 part of iron in 30 million parts of solution may be detected. Solutions containing 5 p. p. m. of iron are too dark for comparison in Nessler cylinders, though solutions of this concentration differing by 1 part of iron in 20 million parts of solution may be distinguished in the color comparator.

The spot-plate sensitivity was determined by transferring 0.05 ml. (one drop) of iron solutions of varying concentrations to depressions of a white porcelain spot-plate and adding 0.05 ml. of a 1% reagent solution of *p*H 3. Two-tenths of a microgram of iron could thus be detected.

Effect of Diverse Ions

Reactions with Various Ions.—Spot-plate tests were made by adding a drop of 1% reagent solution to a drop of the solution containing 1 mg. per ml. of the respective ions. Tests were made in acid, neutral and alkaline media when the character of the ion permitted. No color or precipitate formation was observed with the following ions: Al^{+3}, Ag^{+1}, As^{+3}, AsO_4^{-3}, $AuCl_4^{-1}$, $B_4O_7^{-2}$, Ba^{+2}, Be^{+2}, Bi^{+3}, Br^{-1}, CO_3^{-2}, Ca^{+2}, CbO_4^{-3}, Cd^{+2}, Ce^{+3}, Cl^{-1}, Co^{+2}, Cr^{+3}, Cs^{+1}, Dy^{+3}, Er^{+3}, Eu^{+3}, F^{-1}, Fe^{+2}, Ga^{+3}, Gd^{+3}, Ge^{+4}, HfO^{+2}, Hg^{+1}, Hg^{+2}, I^{-1}, In^{+3}, Ir^{+4}, K^{+1}, La^{+3}, Li^{+1}, Mg^{+2}, Mn^{+2}, MoO_4^{-2}, NO_2^{-1}, NO_3^{-1}, Na^{+1}, Nd^{+3}, Ni^{+2}, OsO_5^{-2}, HPO_4^{-2}, Pb^{+2}, Pd^{+2}, Pr^{+3}, $PtCl_6^{-2}$, Rb^{+1}, ReO_4^{-1}, Rh^{+3}, Ru^{+3}, S^{-2}, SO_4^{-2}, Sb^{+3}, Sc^{+3}, SeO_3^{-2}, SiO_3^{-2}, Sm^{+3}, Sn^{+2}, Sn^{+4}, Sr^{+2}, TaO_4^{-3}, TeO_4^{-2}, Th^{+4}, Ti^{+4}, Tl^{+3}, Tm^{+3}, VO^{+2} WO_4^{-2}, Y^{+3}, Yb^{+3}, Zn^{+2}, ZrO^{+2}.

Key to symbols: M = matches 1 p. p. m., M+ = 1.05 p. p. m., M− = matches 0.95 p. p. m., NM = no match or matches 1.10 or 0.90 p. p. m., X = off-tint, D = intensity greatly decreased, B = color bleached.

Ferric ions produced a violet color and a blue precipitate; UO_2^{+2} an orange color. These are the only ions reacting with the reagent in acid solution; in ammoniacal solution, the cupric ion gives a green color.

Determination of Iron in the Presence of Other Ions.—In determining the interference of diverse ions, a measured volume of a standard solution of the diverse ion and 20 ml. of 95% ethanol were added to 5.0 ml. of standard iron solution (0.01 mg. per ml.) in a 50-ml. tall-form Nessler cylinder; the volume was made up to 45 ml. with distilled water and the *p*H adjusted to about 3 with congo red paper; 1 ml. of 1% reagent solution was added; the tube was filled to the mark and the solution mixed. These solutions containing 1 p. p. m. of iron with the diverse ion were compared with color standards containing 0.90, 0.95, 1.00, 1.05 and 1.10 p. p. m. of iron, respectively. The diverse ion was judged not to interfere if the solution was not off-tint, and the intensity could be matched with that of the 1 p. p. m. standard. If the solution matched the 0.95 or 1.05 p. p. m. standard, it is so indicated. If the color corresponded to the 1.10 or 0.90 p. p. m. standard, "no match" is reported. No concentration of diverse ions greater than 100 p. p. m. or less than 1 p. p. m. was used. The results of these tests are shown in Table I.

These data show that the most serious interference is encountered with anions such as fluoride, phosphate, and the anions of organic acids which are common constituents of buffer solutions. Fortunately, the acidity may be satisfactorily adjusted with the aid of congo red paper. Fluoride must be removed if its concentration is greater than that of the iron. Phosphate interferes at a concentration equal to that of the iron.

Of the metallic ions which interfere, only Cu^{+2} and Ti^{+4} are likely to exceed the limiting concentration in materials to which colorimetric methods for iron are commonly applied. Copper is easily separated from iron by precipitation as copper sulfide. An investigation showed that the interference of titanium is due to hydrolysis and that this can be avoided by decreasing the *p*H of the solution. A gray color results when the reagent is added to solutions containing 1 p. p. m. each of iron and titanium. These solutions give a brownish precipitate on standing a few hours. A similar precipitate was observed in 40% ethanol solution of *p*H 3.0 containing 1 p. p. m. of these metals without the reagent. If the *p*H of the solution and color standards is adjusted to 2.5, the solution containing titanium shows no off-tint, and a match may be made without difficulty.

Recommended Procedure

A procedure for the colorimetric determination of iron with 4-hydroxybiphenyl-3-carboxylic acid has been based on the foregoing study of the properties of the reagent. The color must be developed in 35–40% ethanol solution because of the small solubility of the reagent in water. A 10:1 molar ratio of reagent to iron is sufficient for full color development at the optimum *p*H of 3. If titanium is present adjust the *p*H to 2.5.

Weigh out a sample containing 1 mg. of iron or less. Dissolve the sample by alkali fusion, mineral acid treatment, or both as may be necessary. If interfering ions are present in excess of the limiting concentrations shown in Table I, remove them by standard methods. Dilute the solution in a volumetric flask to 100 ml. with distilled water. After thorough mixing, transfer 5 ml. (or an aliquot part that will give an iron concentration of 0.1 to 1 p. p. m. when diluted to 50 ml.) to a Nessler cylinder. Add 20 ml. of 95% ethanol and dilute to 40–45 ml. with distilled water. Add 1 *N* sodium hydroxide dropwise until a drop of the solution on a stirring rod does not change the color of congo red paper. Then add 0.1 *N* hydrochloric acid until the indicator paper just turns blue when tested with a drop of the solution. If the acid concentration in the aliquot is excessively high, the solution should be partially neutralized with a stronger solution of base before the 1 *N* sodium hydroxide is added. After the *p*H has been adjusted, add 1 ml. of 1% reagent solution, dilute to the mark with distilled water, mix thoroughly, and compare the color with a series of standard solutions similarly prepared.

If the sample contains titanium, the solution will develop a gray color on addition of the reagent. In this case, add 0. 1 *N* hydrochloric acid dropwise until the color becomes violet. Add the same amount of acid to the standards, before matching. The *p*H of standards and sample should be checked with the *p*H meter after matching and should agree within 0.1 of a *p*H unit. If the titanium is known to be present in high enough concentration to interfere, the *p*H may be adjusted to 2.5 before the reagent is added.

Determination of Iron in Various Materials.—The applicability of the reagent to the colorimetric determination of iron in various materials

TABLE II

DATA ON IRON DETERMINATIONS

Materials N. B. S.	Fe_2O_3 N. B. S. value, %	Fe_2O_3 found, %	Diff., %

[b] Sample contained 0.16% TiO_2. Matched at *p*H 2.5.
[c] Copper removed as CuS.

was established by analyzing a representative group of samples issued by the National Bureau of Standards. The results are recorded in Table II.

Discussion of Results

The data in Table II show that the reagent may be used successfully for the determination of small amounts of iron in various materials. All values determined with the new reagent are well within the range of values reported by the Bureau. The precision between individual analyses is excellent. Feldspar 70, dolomite 88, silica brick 102 and soda lime glass 128 contained, respectively, 0.012, 0.003, 0.025 and 0.01% of P_2O_5. No interference from phosphate was encountered with any of these samples. When no interfering ions are present, a sodium carbonate fusion of the sample may be taken up in dilute hydrochloric acid, filtered directly into a 100-ml. volumetric flask, diluted to the mark and mixed. An aliquot part of the solution is taken for analysis. Dehydration of the silica before filtration is not necessary.

Summary

A new, sensitive and practically specific reagent for the colorimetric determination of iron is presented. The nature of the reaction and the optimum conditions for color formation have been determined spectrophotometrically. The colored complex obeys Beer's law over the useful range of iron concentration.

The reagent is sensitive to 1 part of iron in 40 million parts of solution when observations are made in Nessler cylinders (50-ml. tall-form). An analytical procedure based on visual methods of color matching has been applied to a variety of materials with good accuracy. The number of interfering cations is small. Iron may be determined in the presence of titanium without interference.

The Effect of Fluorine Substitution on Chemotherapeutic Agents. I. Synthesis of Some Fluorine-Containing Medicinals[1]

BY H. LEON BRADLOW[2] AND CALVIN A. VANDERWERF

Because of the increasing interest in organic compounds containing fluorine we have undertaken a program involving the synthesis of a variety of fluorine substituted compounds, with the ultimate aim of determining the effect on the pharmacological properties of various medicinals produced by the substitution of fluorine atoms for other groups in the molecule. The present paper describes the synthesis of sample compounds of a number of types, the pharmacological and germicidal testing of which it is hoped will provide leads for future work. Previous investigations of this nature have been concerned mainly with the substitution of fluorine for other halogen atoms[3]; in view of the fact that a number of isosteres of important medicinal agents have proved to be as effective or better than the original drugs,[4] however, emphasis in the present work has been placed upon the substitution of fluorine atoms for the isosteric amino and hydroxy groups.[5] Representative fluorine-containing compounds related to medicinals of the following general types were prepared: (1) antimalarials, (2) arsenicals, (3) diphenylsulfones, (4) antiseptics derived from resorcinol and (5) sulfonanilides.

Experimental[6,7]

***p*-Nitrofluorobenzene.**—Direct nitration of fluorobenzene by dropwise addition, with vigorous stirring, of 3 moles to 600 cc. of a 2:1 (by volume) mixture of concentrated sulfuric acid and yellow fuming nitric acid (sp. g. 1.5) at −10°, followed by addition of ice, ether extraction and careful fractionation through a packed column of the residue after removal of the ether, gave 338 g. (80%) of *p*-nitrofluorobenzene, b. p. 109–109.5° at 36 mm., f. p. from cooling curve 26.0°, together with 40.0 g. (7.2%) of 2,4-dinitrofluorobenzene, b. p. 129–130° at 2.7 mm. In an alternate method *p*-nitrofluorobenzene was obtained from *p*-nitroaniline in 65% yield by diazotization followed by decomposition at 40° in anhydrous hydrogen fluoride.

***p*-Fluoroaniline.**—Reduction of *p*-nitrofluorobenzene in absolute alcohol using Raney nickel catalyst with a small amount of platinum tetrachloride as promoter repeatedly gave 92–95% yields of *p*-fluoroaniline, b. p. 98–99° at 33 mm. With Adams catalyst the reduction in either absolute alcohol or acetic acid gave only 65–70% yields of the amine together with 5% of *p*-fluoroacetanilide, m. p. 150.6–151.1°, when the latter solvent was used; this

last-named product was obtained in 77% yield when the reduction was carried out in acetic anhydride.

The low yields (30–35%) of *p*-fluoroaniline consistently obtained from *p*-aminoacetanilide by the Schiemann reaction, followed by hydrolysis of the resulting *p*-fluoroacetanilide, were not improved by the use of the modification[8] in which the borofluoride is added gradually to xylene at 140°.

2-Carboxy-5-chloro-4′-fluorodiphenylamine.—In a modification of the general method of Magidson[9] a mixture consisting of 16.7 g. (0.15 mole) of *p*-fluoraniline, 26.1 g. (0.13 mole) of 2,4-dichlorobenzoic acid, 24 g. of potassium carbonate, 10.1 g. of potassium acetate, 0.15 g. of copper powder and 180 ml. of *n*-butyl alcohol was refluxed for four hours, then steam distilled. The product was isolated in the usual manner[10] and 24–25 g. (90–94%) of reprecipitated material, m. p. 204–209°, was obtained. It crystallized from glacial acetic acid as long yellow needles, m. p. 212.0–213.1°.[11]

Anal. Calcd. for $C_{13}H_9O_2NClF$: N, 5.3; Cl, 13.4. Found: N, 5.4, 5.4; Cl, 13.8, 13.8.

The procedure of Price and Roberts[11] gave the desired product in very poor yield and that of Bachman[10] in 70–75% yields.

2-Fluoro-6,9-dichloroacridine.—Exactly 5.0 g. of 2-carboxy-5-chloro-4′-fluorodiphenylamine was refluxed for four hours with 35.0 g. of phosphorus oxychloride. The latter compound was then partially removed at the water pump and the residue poured into water and chloroform. The chloroform layer was washed with cold water, dried over drierite, and the solvent removed at the pump. After trituration of the black residue with acetone to remove the dark color 2.5 g. (50%) of the desired product was obtained. Because of its obvious instability it was not further characterized.

2-Fluoro-6-chloro-9-(1-methyl-4-diethylaminobutyl)-aminoacridine.—The total product obtained as described above was dissolved in 10 cc. of phenol and 1.5 g. of 1-diethylamino-4-aminopentane was added. After the mixture had been heated on the steam-bath for two hours with stirring the product was isolated in the usual manner as the dihydrochloride. One recrystallization from alcohol–ether gave 2.75 g. (63%) of fine yellow crystals, m. p. 225.0–226.5°, with darkening at 219°.

Anal. Calcd. for $C_{22}H_{29}N_3Cl_3F$: N, 9.1; Cl, 23.0. Found: N, 8.9, 8.9; Cl, 22.7, 22.6.

4-Fluoro-3-nitroaniline.—The procedure of Holleman[12] was modified as follows: 13.8 cc. of yellow fuming nitric acid (sp. g. 1.5) in 72 cc. of concentrated sulfuric acid was added dropwise with stirring at −5° (internal cooling with Dry Ice) to a solution of 33.3 g. (0.3 mole) of *p*-fluoroaniline in 175 cc. of concentrated sulfuric acid. After being stirred at −5° for one hour the mixture was allowed to come to 0° over the course of an additional hour, then poured onto ice, neutralized with sodium carbonate and filtered. Washed with water and dried, the product (36 g., 77%) was obtained as red plates, m. p., after one recrystallization from water, 97.0–98.2°.

4-Fluoro-3-nitrophenylarsonic Acid.—This product, obtained as yellow plates in 49% yield from 4-fluoro-3-nitroaniline by the general method of Doak,[13] darkened at 260° and melted at 279.2–281.3° after recrystallization from hot water.

An alternate sequence *via* the nitration of *p*-fluorophenylarsonic acid was abandoned because of our failure to obtain the acid by any of three plausible methods.[13,14]

3,3′-Diamino-4,4′-difluoroarsenobenzene.—Prepared by the general procedure of Ehrlich and Bertheim,[15] this compound was obtained in 73% yield. It was purified as the dihydrochloride, m. p. 195.2–196.4°, from methyl alcohol–ether. Both compounds are extremely sensitive to oxygen, and satisfactory analyses were not obtained.

3-Amino-4-fluorophenylarsonic Acid.—This compound was obtained in 53% yield by the general method of Stevinson and Hamilton.[16] The procedure of Jacobs[17] gave less satisfactory results.

Because of the extreme air-sensitiveness of the free amine, it was converted directly to the acetyl derivative by treatment of the water solution with acetic anhydride under the Schotten–Baumann conditions. The 3-acetylamino-4-fluorophenylarsonic acid was isolated as brown needles melting at 217.1–218.2° after recrystallization from ethyl alcohol–water.

Anal. Calcd. for $C_8H_9O_4NFAs$: N, 5.1. Found: N, 5.2, 5.0.

***p*-Amino-*p*′-fluorodiphenylsulfone.**[18]—To a solution of 13.8 g. of *p*-amino-*p*′-nitrodiphenylsulfone[19] in 35 cc. of concentrated hydrochloric acid and 60 cc. of water, 3.5 g. of sodium nitrite dissolved in 25 cc. of water was added rapidly. After the mixture had been stirred for twenty minutes 17.0 g. of sodium fluoborate in a minimum of water was added and stirring was continued for an additional forty-five minutes. A quantitative amount (18.4 g.) of the borofluoride was isolated in the usual manner.

In a typical decomposition, a small flask containing 8.1 g. of the borofluoride was immersed in an oil-bath heated to 145° until evolution of boron trifluoride ceased. The black product was extracted with benzene, the combined extracts filtered and the filtrate concentrated to give 4.1 g. (63%) of fine crystals. These were reduced[20] directly to yield 2.6 g. (70%) of *p*-amino-*p*′-fluorodiphenylsulfone, m. p., after recrystallization from alcohol–water, 200.4–201.6°.

Anal. Calcd. for $C_{12}H_{10}O_2NSF$: S, 12.8; N, 5.6. Found: S, 12.6, 12.7; N, 5.8, 5.9.

***p*-Fluorobenzenesulfonyl Chloride.**—The procedure of Huntress[21] was found to be satisfactory on a large scale if the reaction was conducted at −5 to 0° with vigorous stirring and the reaction mixture was then allowed to stand overnight. The product, purified by distillation at 105–110° at 5 mm., was isolated in 83% yield. The amount of sulfone formed was negligible.

***p*-Chloro-*p*′-fluorodiphenylsulfone.**—This compound was prepared in 69% yield by the procedure of Beckurts,[22] modified in that the reaction mixture after hydrolysis was steam distilled to remove excess chlorobenzene. Recrystallized from alcohol–water, it formed large prisms melting at 113.2–113.6°.

Anal. Calcd. for $C_{12}H_8O_2SClF$: S, 11.9. Found: S, 12.1, 12.1.

***p*-Fluoro-*p*′-hydroxydiphenylsulfone.**—The methoxy derivative was prepared in 90% yield by the method of Beckurts[22] with the modification described above. It melted at 88.5–90.1° after recrystallization from alcohol–water.

Anal. Calcd. for $C_{13}H_{11}O_3SF$: S, 12.1. Found: S, 12.2, 12.4.

The desired hydroxy compound was prepared by refluxing 10.0 g. of the methoxy derivative in a mixture of 100 cc. of acetic acid and 125 cc. of concentrated hydrobromic acid for sixty hours. The reaction mixture was diluted with water, made almost neutral with sodium hydroxide, and the product extracted with benzene which was then back-extracted with 20% sodium hydroxide solution. The latter solution was re-acidified and extracted with benzene. After washing with water and drying the solvent was evaporated leaving 7.0 g. (74%) of *p*-fluoro-*p*′-hydroxydiphenylsulfone, m. p. 111.8–113.1°, following recrystallization from alcohol–water.

Anal. Calcd. for $C_{12}H_9O_3SF$: S, 12.7. Found: S, 12.9, 12.9.

***p*,*p*′-Difluorodiphenylsulfone.**—Because of the facts that the application of the generalized Schiemann procedure in the case of *p*,*p*′-diaminodiphenylsulfone led only to the formation of tarry material and that the results of Huntress[21] could not be duplicated[23] the conventional method of Beckurts[22] was employed. The compound, m. p. 97.5–98.1°,[24] even after repeated recrystallization from alcohol, was obtained in 95% yield.

Anal. Calcd. for $C_{12}H_8O_2SF_2$: S, 12.6. Found: S, 12.5, 12.5.

m-Fluorophenol.—Approximately 580 g. (29 moles) of anhydrous hydrogen fluoride was added to 163 g. (1.5 moles) of *m*-aminophenol contained in a 1-liter copper beaker cooled in ice. To the stirred mixture 104 g. (1.5 moles) of sodium nitrite was added over the course of one hour; stirring was continued for two more hours. The reaction mixture was then allowed to stand for two days in an iron flask provided with an efficient hydrogen fluoride condenser, after which it was steam distilled and the distillate extracted with ether. After the ether extract had been washed with ammonium hydroxide and dried, the solvent was removed and the residue distilled to yield 58.2 g. (35%)[25] of *m*-fluorophenol, b. p. 97–103° at 46 mm.

An alternate method of synthesis using the Schiemann reaction was attempted unsuccessfully. Preparation of *m*-nitroanisole by the procedure of Vermeulen[26] was effected in quantitative yields provided that carefully purified *m*-nitrophenol was used. The *m*-nitroanisole was reduced to *m*-anisidine in 82% yield with Raney nickel catalyst in absolute alcohol. The borofluoride of the latter compound, however, decomposed spontaneously at room temperature.

2-Acetoxymercuri-5-fluorophenol.[27]—To a solution of 3.9 g. of *m*-fluorophenol in 60 cc. of water was added 10.8 g. of mercuric acetate in 30 cc. of water acidulated with acetic acid. After four days of standing the mixture was filtered and the precipitate washed with water, dried and recrystallized from acetic acid. The product (10.4 g., 80%) crystallized as colorless plates, decomposing over a wide range starting at 250°.

The *s*-Amyl-5-fluorophenols.—Application of the method of Klarman, *et al.*,[28] to *m*-fluorophenol gave two isomers, the first boiling at 88–91° at 1.5 mm., and the second at 93–95° at 0.4 mm. No attempt was made to determine the exact structure of these compounds, which are probably 2-*s*-amyl-5-fluorophenol and 4-*s*-amyl-5-fluorophenol.

Anal. Calcd. for $C_{11}H_{15}OF$: C, 72.5; H, 8.2. Found for first isomer: C, 72.3, 72.7; H, 8.0, 8.1. Found for second isomer: C, 72.1, 72.4; H, 8.1, 8.1.

3,3-bis-(4-Fluorophenyl)-phthalide.—To a mixture of 8.0 g. of phthaloyl chloride and 40 cc. of fluorobenzene kept at 60–70° anhydrous aluminum chloride (7.6 g.) was added in small portions with shaking. The mixture was warmed on a steam-bath for three hours and then allowed to stand at room temperature overnight. Following removal of the fluorobenzene at the water pump the residue was stirred with dilute sodium hydroxide solution for several hours and the mixture was then acidified to yield 12.0 g. (92%) of the phthalide, m. p., after recrystallization from alcohol–water, 125.1–126.2°.

Anal. Calcd. for $C_{20}H_{12}O_2F_2$: C, 74.5; H, 3.7. Found: C, 74.4, 74.4; H, 3.9, 3.8.

Attempted condensation of fluorobenzene and phthalic anhydride in the presence of sulfuric acid or anhydrous hydrogen fluoride under a variety of conditions was unsuccessful.

N^4-Acetyl-*p*′-fluorosulfanilanilide.—Exactly 13.0 g. of acetylsulfanilyl chloride was added gradually to a solution of 5.6 g. of *p*-fluoroaniline in 34 cc. of acetone and 5 cc. of pyridine. After standing overnight the mixture was filtered, the filtrate concentrated, 50 cc. of water added with stirring and the mixture filtered to yield 9.8 g. (63%) of colorless needles, m. p. 189.9–190.1°, after recrystallization from alcohol–water.

Anal. Calcd. for $C_{14}H_{13}O_3N_2SF$: N, 9.1; S, 10.4. Found: N, 9.1, 9.1; S, 10.6, 10.7.

Hydrolysis of the acetyl compound gave a 94% yield of *p*′-fluorosulfanilanilide, m. p. 163.2–164.1°[29] after recrystallization from alcohol–water.

N^4-Succinyl-*p*′-fluorosulfanilanilide.—Prepared in 92% yield by the general procedure of Miller, *et al.*,[30] this product melted at 141.3–142.9° after recrystallization from alcohol–water.

Anal. Calcd. for $C_{16}H_{15}O_5N_2SF$: S, 8.8; N, 7.7. Found: S, 8.3, 8.4; N, 7.9, 8.0.

4′-Fluoro-4-succinimido-benzenesulfonanilide.—This compound was prepared in 61% yield by the general method of Miller, *et al.*[30] It formed micro-crystals from hot water, m. p. 156.1–157.5°.

Anal. Calcd. for $C_{16}H_{13}O_4N_2SF$: S, 9.2; N, 8.1. Found: S, 9.2, 8.9; N, 8.0, 8.0.

Acknowledgment.—We wish to acknowledge the kindness of Dr. C. M. Suter of the Winthrop Research Institute for supplying the noval diamine and to Parke, Davis and Company for supplying the *p*,*p*′-diaminodiphenylsulfone used in this investigation.

Summary

As the preliminary step in a study designed to determine the effect of fluorine substitution on chemotherapeutic and germicidal agents a number of new fluorine-containing compounds related to medicinals of the following general types have been prepared and described: (1) antimalarials, (2) arsenicals, (3) diphenylsulfones, (4) antiseptics derived from resorcinol and (5) sulfonanilides. Specifically, synthesis of the following compounds has been described: 2-fluoro-6-chloro-9-(1-methyl-4-diethylaminobutyl)-aminoacridine as an

---

(23) Despite repeated attempts, the only product obtained by the direct action of chlorosulfonic acid on fluorobenzene, even when more drastic conditions were employed, was *p*-fluorobenzenesulfonyl chloride. The reported formation of *p*,*p*′-difluorodiphenylsulfone may, perhaps, be due to the unsuspected presence in the reaction mixture of small amounts of some catalytic agent.

(24) Huntress and Carten, ref. 21, reported 100°.

(25) Although the yield is low, this procedure has the advantages of simplicity and ready availability of the starting material, *m*-aminophenol.

(26) Vermeulen, *Rec. trav. chim.*, **25**, 12 (1906).

(27) Although the exact structure of the compound has not been proved, the assigned structure appears likely on the basis of the strong *para*-orienting effect of the fluorine atom.

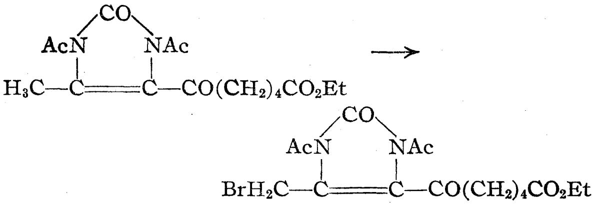
Synthesis of Imidazolones Structurally Related to Biotin by Means of N-Bromosuccinimide[1]

BY ROBERT DUSCHINSKY AND L. ALLEN DOLAN

The preparation of 1,3-diacetyl-4-bromomethyl-5-(δ-carbethoxyvaleryl)-2-imidazolone as illustrated



by application of Ziegler's[2] bromination method and the replacement of the bromine by oxygen-containing groups were essential steps in a recently reported synthesis of O-heterobiotin.[3]

The present paper demonstrates the versatility of the bromination and replacement reactions in the synthesis of a number of imidazolone derivatives. Some of them are structurally related to biotin since they possess its C,N skeleton and carry in the α-position of the side chains heteroatom-containing groups. The bromo compounds and substitution products are listed in Table I. Starting materials are the corresponding bromine-free compounds.

With the exception of 4-methyl-5-carbethoxy-2-imidazolone, which directly reacted with bromine to give I, diacylated imidazolones were used for the bromination by Ziegler's method.[4] The bromination was achieved by refluxing a carbon tetrachloride solution of such an imidazolone with one or, for the preparation of the dibromo compound IV, with two moles N-bromosuccinimide until the latter was completely converted into succinimide. The bromo compounds obtained in good yields are crystalline, not lachrymatory solids, which are sometimes inclined to undergo decomposition with release of hydrobromic and acetic acid. It is, therefore, advantageous to proceed at once with the desired replacement reaction. Depending on the reagent and reaction conditions, the replacement of the bromine may be accompanied by total or partial loss of the acetyl groups. Formation of mixtures of unacetylated, mono- and diacetylated products explains some of the low yields encountered in the substitution reactions.

Proof of the introduction of bromine into the methyl group has been established for the keto ester VI.[3] The same is true for compound I, because it was found to be identical with the product obtained from ethyl δ-ethoxy-β-ketobutyrate via 4 - ethoxymethyl - 5 - carbethoxy - 2 - imidazolone (IA).[5]

The structure of III was established by conversion into an acetyl-free substitution and hydrogenation product. Thus, application of a method described for the preparation of 5-allyl-5-isopropylbarbituric acid[6] gave the barbiturate IIIA in fair yield. Due to its "de-aromatization" by acetyl groups,[3] the compound could be hydrogenated with palladium charcoal catalyst at room temperature, whereby only one of the two possible diastereomers, undoubtedly the *cis* form, was obtained in excellent yield.[7] It was readily deacetylated by cold sodium hydroxide. The obtained 4-methyl-5-(5′-isopropyl-5′-barbiturylmethyl)-2-imidazolidone was microbiologically inactive. Attempts to cleave the barbiturylimidazolone and imidazolidone for the purpose of obtaining the desthiobiotin isomer VIII correspond-

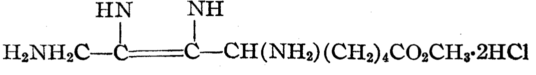
[a] The diacyl compounds are written as N,N-derivatives, although the possibility of N,O-acylation cannot be excluded. [b] One acetyl group only. [c] The dipropionyl derivative was also prepared. [d] Four moles at room temperature. [e] Five and one-half moles, refluxed in benzene.

ing in structure to Kögl's "α-biotin"[8] were abandoned when the accomplished synthesis of such desthiobiotin isomers by Brown and Ferger[9] became known to us.

Structures II, V and VII are assigned by analogy without direct proof. For the dibromo compound IV a symmetrical structure is assumed.

Treatment of the diacetyl bromo compounds with dibenzylamine, depending on the temperature and the excess of amine present, causes more or less stepwise removal of one acetyl group, replacement of the bromine and finally removal of the second acetyl group. 4-Dibenzylaminomethyl-5-(δ-carbomethoxyvaleryl)-2-imidazolone (VC), obtained from V in 70% yield, gave an oxime (84% yield) which upon palladium–charcoal catalyzed hydrogenation in presence of hydrochloric acid afforded 4-aminomethyl-5-(α-amino-ε-carbomethoxyamyl)-2-imidazolone dihydrochloride (IX) in 46% yield.



IX

The same sequence of reactions was performed with the ethyl ester VI.

Sulfur-containing substituents were introduced by treating bromoesters V and VI with thiourea and sodium sulfite, respectively. The isothiouronium bromide VB and the sodium sulfonate VIC resulted in fair to good yields.

It was previously reported that the keto group located in the α-position of *unacetylated* imidazolones undergoes easily hydrogenolysis and is converted into methylene.[5,10] In an analogous manner the keto esters VC and VIC lost the keto groups upon catalytic hydrogenation under mild conditions. Compound VC was also debenzylated. The ring double bond as well as the α-amino and α-sulfo groups remained intact, however. 4-Aminomethyl-5-(ε-carbomethoxyamyl)-2-imidazolone hydrochloride and the sodium salt of 4-sulfomethyl-5-(ε-carbethoxyamyl)-2-imidazolone were isolated in good yields.

1,3 - Diacetyl - 4 - methyl - 5 - (ε - carbethoxyamyl)-2-imidazolone[10] and 1,3-diacetyl-4,5-dipropyl-2-imidazolone reacted with two moles of bromosuccinimide whereby an amount of succinimide was recovered which indicated bromination in the α-methylene groups. However, no crystalline dibromo derivatives could be isolated.

Experimental[11]

4-Bromomethyl-5-carbethoxy-2-imidazolone (I).—To a stirred boiling suspension of 51 g. of 4-methyl-5-carbethoxy-2-imidazolone[5] in one liter of carbon tetrachloride 48 g. of bromine was added within one hour. Boiling and stirring were continued for five more hours. After cooling the bromo ester was filtered and washed with carbon tetrachloride; yield 73.5 g. (98.5%). The substance decomposed *in vacuo* at *ca.* 220°. No depression was observed in admixtures with material obtained by a previously described method.[5]

[8] Kögl and Borg, *Z. physiol. Chem.*, **281**, 65 (1944).

[9] Brown and Ferger, THIS JOURNAL, **68**, 1507 (1946). We are indebted to Dr. Vincent du Vigneaud for communicating to us the contents of this paper prior to its publication.

[10] Duschinsky and Dolan, *ibid.*, **67**, 2079 (1945).

[11] Melting points were determined with an uncalibrated set of Anschütz thermometers. For the microanalyses we are indebted to Dr. Al Steyermark and his staff, for the microbiological assays to Dr. S. H. Rubin and his staff.

4-Ethoxymethyl-5-carbethoxy-2-imidazolone (IA).—To a solution of 11.1 g. of the foregoing bromo ester in 220 cc. of ethanol (obtained by short boiling and subsequent cooling) 43.2 cc. of *N* sodium ethoxide solution was added until the mixture was slightly alkaline to methyl orange. Evaporation *in vacuo* and crystallization of the residue from 5 cc. of water yielded 6.2 g. (65%) of needles, melting at 178–180° and showing no depression in admixtures with material obtained previously.[5]

4-Acetoxymethyl-5-carbethoxy-2-imidazolone (IB).—To a solution of 4.98 g. of bromo ester I in 90 cc. of hot acetic acid 3.34 g. of silver acetate was added with stirring. After ten minutes the silver bromide was filtered and the solution evaporated *in vacuo*. The residue was crystallized from 10 cc. of ether; yield 2.75 g. (60%). The substance was recrystallized by dissolving in 100 cc. of boiling ethyl acetate and adding 100 cc. of petroleum ether; m. p. 154–155°.

Anal. Calcd. for $C_9H_{12}O_5N_2$: C, 47.37; H, 5.30; N, 12.28. Found: C, 47.51; H, 5.36; N, 12.33.

1,3-Diacetyl-4-bromomethyl-2-imidazolone (II).—A solution of 9.1 g. of 1,3-diacetyl-4-methyl-2-imidazolone[10] in 30 cc. of carbon tetrachloride was refluxed with 8.55 g. of bromosuccinimide for twenty minutes until the potassium iodide reaction was negative and the succinimide was visible as a layer covering the top of the liquid. After cooling, the imide was filtered off, the filtrate evaporated *in vacuo* and the residue crystallized from ether; yield, 9.14 g. (70%). It crystallized in needles, melting at 80–81°, which were inclined to turn pink. For the analysis a sample was sublimed at 0.3 mm. and 90° (bath).

Anal. Calcd. for $C_8H_9O_3N_2Br$: C, 36.80; H, 3.47; N, 10.73. Found: C, 36.52; H, 3.34; N, 10.40.

4-(β,β-Dicarboxyethyl)-2-imidazolone (IIA).—The carbon tetrachloride solution obtained in the above described manner by reaction of 3.64 g. of 1,3-diacetyl-4-methyl-2-imidazolone and 3.54 g. of bromosuccinimide and filtering the succinimide was added slowly to 20 cc. of a 1.1 *N* calcio diethyl malonate[12] solution in carbon tetrachloride. The mixture was refluxed with stirring for four and one-half hours, then washed in a separatory funnel with water until the washings were bromine-free. The carbon tetrachloride layer was dried over sodium sulfate and evaporated to a yellow oil. After removing excess malonic ester by heating *in vacuo* in a bath at 140°, a solution of 8 g. of sodium hydroxide in 55 cc. of water was mixed with the residue and let stand overnight. Some tar was filtered off, the solution was concentrated on a water-bath to 20 cc., neutralized with hydrochloric acid and evaporated to dryness. The residue was extracted three times with 25 cc. of boiling dioxane. The dioxane extract was evaporated to dryness and extracted three times with 10 cc. of ether. The ether insoluble residue was crystallized from 6 cc. of water; yield 610 mg. (15%) as needles which after recrystallization from 10 cc. of water melted in an evacuated capillary tube at 253–255°.

Anal. Calcd. for $C_7H_8O_2N$: C, 42.00; H, 4.03; N, 14.00. Found: C, 41.80; H, 3.89; N, 13.76.

Acetyl-4-dibenzylaminomethyl-2-imidazolone (IIB).—A solution of 1.64 g. of II in 25 cc. of benzene was mixed with a solution of 6.3 g. (5 moles) of dibenzylamine in 25 cc. of benzene. The mixture was refluxed with stirring for three hours. The crystallized dibenzylamine hydrobromide (1.62 g.) was sucked off, the filtrate evaporated and finally dried *in vacuo* at 100°. The resulting honey-like mass was twice extracted with 50 cc. of petroleum ether whereupon it became almost solid. Crystallization from 10 cc. of methanol and recrystallization from ethanol gave 190 mg. (9%) of needles melting at 174–176°. The analysis indicated the presence of some diacetyl compound.

Anal. Calcd. for $C_{20}H_{21}O_2N_3$: C, 71.62; H, 6.31; N, 12.53; CH_3CO, 12.83. Found: C, 71.47; H, 6.17; N, 11.77; CH_3CO, 14.30.

1,3-Diacetyl-4-bromomethyl-5-methyl-2-imidazolone (III).—A solution of 19.6 g. of 1,3-diacetyl-4,5-dimethyl-2-imidazolone[13] in 200 cc. of carbon tetrachloride was refluxed for fifteen minutes with 17.5 g. (1 mole) of bromosuccinimide and worked up as described above. Crystallization from 30 cc. of ether yielded 22.3 g. (81.5%) of colorless needles melting at 84–89°.

Anal. Calcd. for $C_9H_{11}O_3N_2Br$: C, 39.29; H, 4.03. Found: C, 39.41; H, 4.45.

1,3-Diacetyl-4-methyl-5-(5′-isopropyl-5′-barbiturylmethyl)-2-imidazolone (IIIA).—A solution of 21.96 g. of the foregoing freshly prepared bromo compound in 80 cc. of dioxane was added gradually to a cooled solution of 13.89 g. of 5-isopropyl-barbituric acid in 81 cc. of *N* sodium hydroxide which held 0.2 g. of copper–bronze powder in suspension. After shaking the mixture consisting of two layers for fourteen hours it was evaporated to a heavy oil which was dissolved in 70 cc. of methanol. Gradual addition of 70 cc. of water yielded crystals which were washed with 90 cc. of 50% methanol until they were bromine free; yield 13.93 g., m. p. 164–172°. Extraction with 100 cc. of dry ether left undissolved 10.89 g. material melting at 183–186° (37.4%). The product can be recrystallized from aqueous 40% ethanol. It melts then at 189–191°.

Anal. Calcd. for $C_{16}H_{20}O_6N_4$: C, 52.74; H, 5.53; N, 15.38. Found: C, 52.61; H, 5.37; N, 15.51.

1,3-Diacetyl-4-methyl-5-(5′-isopropyl-5′-barbiturylmethyl)-2-imidazolidone.—The foregoing ether-washed imidazolone (IIIA) (2.44 g.) was hydrogenated for three hours with 750 mg. of 10% palladium-charcoal catalyst in 25 cc. of acetic acid at room temperature and atmospheric pressure until 1 mole hydrogen was taken up and the reaction stopped. The filtered solution was evaporated and the well-dried residue became crystalline upon addition of 20 cc. of ether; yield 1.97 g. (83%), melting at 237–241°, and after recrystallization from 30 volumes of 50% ethanol at 243–244°.

Anal. Calcd. for $C_{16}H_{22}O_6N_2$: C, 52.45; H, 6.05. Found: C, 52.61; H, 6.39.

4-Methyl-5-(5′-isopropyl-5′-barbiturylmethyl)-2-imidazolidone.—The above diacetyl compound (760 mg.) was dissolved in 7.2 cc. of *N* sodium hydroxide. After five hours the solution was neutralized with 7.2 cc. of *N* hydrochloric acid. The separated crystals were filtered and washed with water; yield 490 mg. (84%), melting at 261–263°, and after recrystallization from water at 269–271° (*in vacuo*). The compound revealed neither biotin nor antibiotin activity for *Saccharomyces cerevisiae* No. 139 and *Lactobacillus casei*.

Anal. Calcd. for $C_{12}H_{18}O_4N_2$: C, 51.05; H, 6.43; N, 19.85. Found: C, 51.17; H, 6.50; N, 19.70.

1,3-Diacetyl-4,5-bis-(bromomethyl)-2-imidazolone (IV).—A solution of 3.92 g. of 1,3-diacetyl-4,5-dimethyl-2-imidazolone in 40 cc. of carbon tetrachloride was refluxed for thirty minutes under stirring with 7.08 g. (2 moles) of bromosuccinimide. The solution filtered from the succinimide was concentrated to a sirup which became crystalline upon addition of 10 cc. of dry ether. The crystals were washed with ether; yield 3.51 g. (49.6%), m. p. 108–110°. The product can be recrystallized from ether containing 4% dioxane.

Anal. Calcd. for $C_9H_{10}O_3N_2Br_2$: C, 30.53; H, 2.85; N, 7.91. Found: C, 30.97; H, 3.07; N, 7.97.

1,3-Diacetyl-4,5-bis-(acetoxymethyl)-2-imidazolone (IVA).—A mixture of 380 mg. of IV, 10 cc. of dry acetone and 1 g. of anhydrous potassium acetate was shaken for forty-eight hours. Addition of ether to the filtered solution produced 135 mg. (43%) of crystals melting at *ca.* 133°, which after sublimation at 0.4 mm. and 160° (bath) melted at 143–145°.

Anal. Calcd. for $C_{13}H_{16}O_7N_2$: C, 50.00; H, 5.16; N, 8.97. Found: C, 49.95; H, 5.18; N, 8.98.

(13) Biltz, *ibid.*, **40**, 4801 (1907).

1,3-Diacetyl-4-methyl-5-(δ-carbomethoxyvaleryl)-2-imidazolone.—A mixture of 37.9 g. of 4-methyl-5-(δ-carbomethoxyvaleryl)-2-imidazolone[5] and 165 cc. of acetic anhydride was refluxed for twenty minutes. The resulting solution was concentrated to a small volume first at atmospheric pressure, then *in vacuo*. The residue was taken up with 165 cc. of acetic anhydride. The refluxing and evaporating were repeated. The final residue was dried for one hour at 100° *in vacuo* and crystallized by addition of 40 cc. of methanol and cooling in an acetone–Dry Ice-bath; yield 44.2 g. (87%), melting at 68–69°, and after recrystallization from methanol at 69–70°.

Anal. Calcd. for $C_{15}H_{20}O_6N_2$: C, 55.55; H, 6.22. Found: C, 55.59; H, 6.16.

The **dipropionyl derivative** was obtained as described above in a yield of 84% by substituting propionic anhydride for acetic anhydride. It melted at 65–66°.

Anal. Calcd. for $C_{17}H_{24}O_6N_2$: C, 57.94; H, 6.86. Found: C, 57.74; H, 6.76.

1,3-Diacetyl-4-bromomethyl-5-(δ-carbomethoxyvaleryl)-2-imidazolone (V).—A solution of 16.2 g. of 1,3-diacetyl-4-methyl-5-(δ-carbomethoxyvaleryl)-2-imidazolone in 95 cc. of carbon tetrachloride was refluxed for one hour with 8.55 g. of bromosuccinimide. The solution filtered from the succinimide (4.44 g.) was evaporated and the residue crystallized from 50 cc. of cold ether; yield 18.5 g. (92%) colorless needles melting at 58–60°, and after recrystallization from 4 volumes of methanol at 59–61°.

Anal. Calcd. for $C_{15}H_{19}O_6N_2Br$: C, 44.68; H, 4.75. Found: C, 44.74; H, 4.54.

1,3-Dipropionyl-4-bromomethyl-5-(δ-carbomethoxyvaleryl)-2-imidazolone.—It was obtained in an analogous manner with a yield of 53%, m. p. 59–61°.

Anal. Calcd. for $C_{17}H_{23}O_6N_2Br$: C, 47.34; H, 5.37. Found: C, 47.38; H, 5.40.

1,3-Diacetyl-4-benzoxymethyl-5-(δ-carbomethoxyvaleryl)-2-imidazolone (VA).—A solution of 4.03 g. of crude bromo ester V in 50 cc. of dioxane was shaken for two days with 5 g. of silver benzoate. The filtered bromine-free solution was evaporated. The residue was extracted with ether which left some silver-containing material undissolved. The ether extract was evaporated to an oil which became crystalline upon addition of methanol; yield 2.34 g. (53%). The material melting at *ca.* 90° was recrystallized by dissolving in 40 cc. of ether, adding methanol and evaporating the ether *in vacuo;* yield 1.8 g. of crystals melting at 90–93°.

Anal. Calcd. for $C_{22}H_{24}O_8N_2$: C, 59.45; H, 5.44; N, 6.30. Found: C, 59.70; H, 4.90; N, 6.12.

1,3-Diacetyl-4-guanylthiomethyl-5-(δ-carbomethoxyvaleryl)-2-imidazolone Hydrobromide (VB).—To a solution of 0.76 g. of thiourea in 50 cc. of anhydrous dioxane 4.03 g. of bromo ester V was added. The mixture was refluxed for ten minutes, then cooled, whereupon the hydrobromide crystallized in fine leaflets. It was filtered and washed with dioxane and ether; yield 3.23 g. (68%). The substance melted at 161–162° and after recrystallization from 12 volumes of dioxane at 164–165°.

Anal. Calcd. for $C_{16}H_{23}O_6N_4SBr$: C, 40.09; H, 4.84; N, 11.69; S, 6.69. Found: C, 40.13; H, 4.90; N, 11.62; S, 6.24.

Acetyl-4-bromomethyl-5-(δ-carbomethoxyvaleryl)-2-imidazolone.—When a carbon tetrachloride solution of diacetyl bromo ester V was treated for fifteen minutes at room temperature with one mole of dibenzylamine a substantial amount (*ca.* 20%) of monoacetyl bromo ester crystallized out. It was recrystallized from benzene, m. p. 129–130°.

Anal. Calcd. for $C_{13}H_{17}O_5N_2Br$: C, 43.22; H, 4.75; N, 7.76; Br, 22.13. Found: C, 43.53; H, 4.73; N, 7.85; Br, 22.15.

4-Dibenzylaminomethyl-5-(δ-carbomethoxyvaleryl)-2-imidazolone (VC).—Solutions of 44 g. of crude bromo ester V in 700 cc. of benzene and of 120 g. (5.6 moles) of dibenzylamine in 100 cc. of benzene were mixed and refluxed with stirring for six and one-half hours. After cooling the crystallized 28.5 g. (94%) of dibenzylamine hydrobromide was filtered off. The filtrate was evaporated to a yellowish sirup which was washed by four extractions with a total of 1.5 liters of petroleum ether. The petroleum ether insoluble oil became crystalline when mixed with 250 cc. of ether. The still pasty crystals were filtered off and recrystallized from 200 cc. of methanol; yield 33.2 g. (70%), m. p. 134–135°. After a second recrystallization the substance melted at 135–136°.

Anal. Calcd. for $C_{25}H_{29}O_4N_3$: C, 68.49; H, 6.71; N, 9.65. Found: C, 68.92; H, 6.51; N, 9.66.

The **free acid** was prepared from the foregoing ester by heating on a water-bath for one hour with a mixture of 10 volumes of *N* sodium hydroxide and 5 volumes of methanol and neutralizing with hydrochloric acid. It was recrystallized from aqueous ethanol, m. p. 207–208°.

Anal. Calcd. for $C_{24}H_{27}O_4N_3$: C, 68.39; H, 6.46. Found: C, 68.26; H, 6.17.

Acetyl-4-dibenzylaminomethyl-5-(δ-carbethoxyvaleryl)-2-imidazolone (VIA).—To a solution of 835 mg. of bromo ethyl ester VI in 20 cc. of benzene 790 mg. of dibenzylamine (2 moles) in 20 cc. of benzene was added dropwise with stirring. Dibenzylamine hydrobromide was filtered off after letting the mixture stand for twenty hours. Since only 300 mg. of hydrobromide (59%) was recovered another 790 mg. of dibenzylamine was added. An additional crop of dibenzylamine hydrobromide (total 90%) was filtered off after letting the mixture stand overnight. The filtrate was concentrated to a sirup which was mixed with ethanol to produce 430 mg. (45%) of crystals melting at 98–100°, and after recrystallization from 5 cc. of ethanol at 101–102°.

Anal. Calcd. for $C_{28}H_{33}O_5N_3$: C, 68.41; H, 6.77; CH_3CO, 8.76. Found: C, 68.31; H, 7.27; CH_3CO, 9.18.

4-Dibenzylaminomethyl-5-(δ-carbethoxyvaleryl)-2-imidazolone (VIB).—The bromo ethyl ester VI (8.34 g.) after reaction with 21.5 g. (5.5 moles) of dibenzylamine in the manner described for the methyl ester V gave 6.93 g. (74%) of dibenzylamino compound melting at 103–106°. Several recrystallizations from 95% ethanol raised the melting point to 107–109°. The product was acetyl free and contained one molecule water of crystallization.

Anal. Calcd. for $C_{26}H_{31}O_4N_3 \cdot H_2O$: C, 66.79; H, 6.68; N, 8.99. Found: C, 67.16, 67.23; H, 6.67, 6.85; N, 9.01.

Upon drying *in vacuo* at 100° the substance melted to a yellowish resin and became anhydrous.

Anal. Calcd. for $C_{26}H_{31}O_4N_3$: C, 69.46; H, 6.94. Found: C, 69.43; H, 7.01.

4-Dibenzylaminomethyl-5-(α-oximino-ε-carbomethoxyamyl)-2-imidazolone.—A solution of 8.7 g. of crude methyl ester (VA) in 14 cc. of pyridine was mixed with 2.8 g. (2 moles) of finely powdered hydroxylamine hydrochloride and heated with occasional shaking for thirty-eight hours at 39°. After initial dissolution crystallization started. The reaction mixture was diluted with 120 cc. of water, the crystals were filtered and washed chlorine free with water, then with methanol and ether; yield 7.55 g. (84%), m. p. 188–190°. For the analysis the oxime was recrystallized from 12 volumes methanol. It melted at 191–192°.

Anal. Calcd. for $C_{25}H_{30}O_4N_4$: C, 66.64; H, 6.71; N, 12.44. Found: C, 66.40; H, 6.80; N, 12.76.

4-Dibenzylaminomethyl-5-(α-oximino-ε-carbethoxyamyl)-2-imidazolone was obtained in 65% yield from the crude ethyl ester (VIB) in the above described manner. It was recrystallized from 100 volumes of ethanol and melted at 184–185°.

Anal. Calcd. for $C_{26}H_{32}O_4N_4$: C, 67.22; H, 6.94. Found: C, 67.14; H, 6.84.

4-Aminomethyl-5-(α-amino-ε-carbomethoxyamyl)-2-imidazolone Dihydrochloride (IX).—A mixture of 13.16 g. of crude 4-dibenzylaminomethyl-5-(α-oximino-ε-carbomethoxyamyl)-2-imidazolone, 135 cc. of methanol, 5 cc. of concentrated hydrochloric acid and 7 g. of prehydrogenated palladium oxide catalyst (Baker and Co.) was hydrogenated for one hour at room temperature and four hours at 50° at a pressure of 900–1000 lb. The filtered solution was evaporated *in vacuo* below 40° to a sirup, which was mixed with 35 cc. of methanol and 60 cc. of ether. On standing in the cold 4.38 g. (46%) of thin plates was obtained which melted and decomposed at 173–175°, and after dissolving in 20 volumes of hot methanol and adding 5 volumes of ether at 176–178°. The product gave an intense red ferric chloride reaction indicating the presence of the imidazolone double bond.

Anal. Calcd. for $C_{11}H_{20}O_3N_4 \cdot 2HCl$: C, 40.13; H, 6.74; N, 17.02; Amino N, 8.51. Found: C, 39.82; H, 6.53; N, 17.03; Amino N, 8.78, 8.31.

4-Aminomethyl-5-(α-amino-ε-carbethoxyamyl)-2-imidazolone dihydrochloride was obtained in 56% yield by an analogous hydrogenation in ethanol of 1.75 g. of corresponding oximino ethyl ester. The substance was recrystallized from 85% ethanol and ether. It melted at 164–166° and gave an intense ferric chloride reaction.

Anal. Calcd. for $C_{12}H_{22}O_3N_4 \cdot 2HCl$: C, 41.99; H, 7.05; N, 16.32; Amino N, 8.16. Found: C, 41.97; H, 6.90; N, 16.26; Amino N, 8.41.

4-Aminomethyl-5-(ε-carbomethoxyamyl)-2-imidazolone Hydrochloride.—A suspension of 970 mg. of keto ester (VC) and of 1 g. of prehydrogenated palladium oxide catalyst in 20 cc. of methanol and 0.2 cc. of concentrated hydrochloric acid was hydrogenated at room temperature and atmospheric pressure. Two moles of hydrogen was absorbed in twenty minutes, two additional moles in three hours. The filtered solution was evaporated to a small volume until crystals separated, the amount of which was increased by addition of acetone; yield 410 mg. (70%), m. p. 181–182°. Two recrystallizations from a little methanol raised the melting point to 186–188°. The substance gives an intense red ferric chloride reaction.

Anal. Calcd. for $C_{11}H_{19}O_3N_3 \cdot HCl$: C, 47.56; H, 7.26; N, 15.13; Amino N, 5.04. Found: C, 47.70; H, 7.11; N, 14.92; Amino N, 5.34.

Sodium Salt of 4-Sulfomethyl-5-(δ-carbethoxyvaleryl)-2-imidazolone (VIC).—A mixture of 1.53 g. of bromo ester VIA, 0.93 g. of sodium sulfite (2 moles) and 5 cc. of water was refluxed until after fifteen minutes a clear solution was obtained. Considerable sulfur dioxide evolution was observed. The resulting slightly acidic solution gave upon evaporation *in vacuo* a crystalline cake. In order to decompose any remaining sulfite the product was dissolved in 5 cc. of hot 10% acetic acid and the resulting solution evaporated. The final residue was dissolved in 2 cc. of hot water. Upon addition of 8 cc. of ethanol and cooling, fine needles separated which were washed bromine free by 80% ethanol; yield 0.59 g. (45%). The substance melted under decomposition in an evacuated capillary tube at about 272° and after recrystallization by dissolving in 2 cc. of 10% warm acetic acid and adding 10 cc. of ethanol, whereby 0.52 g. was recovered, at 280–282°.

Anal. Calcd. for $C_{12}H_{17}O_7N_2SNa$: S, 9.00; Na, 6.45; C_2H_5O, 12.65. Found: S, 8.91; Na, 6.57; C_2H_5O, 12.10.

Sodium Salt of 4-Sulfomethyl-5-(ε-carboxyamyl)-2-imidazolone.—The foregoing keto compound (320 mg.) was hydrogenated at room temperature and atmospheric pressure with 300 mg. of prehydrogenated platinum oxide catalyst (Baker and Co.) in 10 cc. of acetic acid. Although in twenty minutes the hydrogen uptake (2 moles) had practically stopped, shaking was continued for fifty minutes. The filtered solution was evaporated *in vacuo* and the obtained residue dissolved in 5 cc. of methanol. Addition of 10 cc. of ether and scratching produced crystallization in microscopic rhombs; yield 230 mg. (76%). The substance was recrystallized with little loss by dissolving in 5 cc. of hot 90% methanol and adding 12 cc. of ether. It melted and decomposed *in vacuo* at about 252° and gave an intense red ferric chloride reaction indicating the presence of the imidazolone double bond.

Anal. Calcd. for $C_{12}H_{19}O_6N_2SNa$: C, 42.10; H, 5.59; S, 9.36; Na, 6.72. Found: C, 42.59; H, 6.11; S, 9.11; Na, 6.80.

1,3-Diacetyl-4-bromomethyl-5-benzoyl-2-imidazolone (VII).—A solution of 2.86 g. of 1,3-diacetyl-4-methyl-5-benzoyl-2-imidazolone[10] in 25 cc. of carbon tetrachloride was refluxed for twenty-five minutes with 1.77 g. of bromosuccinimide. The filtrate from the recovered succinimide (94%) was evaporated to a sirup which became crystalline upon addition of 25 cc. of ether; yield 3.25 g. (89%), m. p. 131–132°. Recrystallization from 20 volumes of ethanol did not change the melting point.

Anal. Calcd. for $C_{15}H_{13}O_4N_2Br$: C, 49.33; H, 3.59. Found: C, 49.44; H, 3.64.

Acetyl-4-dibenzylaminomethyl-5-benzoyl-2-imidazolone (VIIA).—Solutions of 3.13 g. of VII in 40 cc. of benzene and 3.38 g. (2 moles) of dibenzylamine in 20 cc. of benzene were mixed and stirred for two hours, then allowed to stand overnight. The filtrate from the dibenzylamine hydrobromide was evaporated to a volume of *ca.* 10 cc. and mixed with 10 cc. of petroleum ether. The formed crystals were filtered and washed with methanol. The mother liquor gave a second crop on evaporation and addition of 20 cc. of methanol: total yield 1.58 g. (42%) melting at about 195°. Recrystallization from 10 volumes of ethanol raised the melting point to 204–205°, without causing much loss of material.

Anal. Calcd. for $C_{27}H_{25}O_3N_3$: C, 73.78; H, 5.73; N, 9.56; CH_3CO, 9.80. Found: C, 74.32; H, 5.59; N, 9.75; CH_3CO, 10.14.

1,3-Diacetyl-4-nitromethyl-5-benzoyl-2-imidazolone[14] **(VIIB).**—A solution of 1.5 g. of VII in 25 cc. of anhydrous dioxane was shaken for fifteen hours with 2 g. of dry silver nitrite. The solution was rendered bromine free by addition of 1 g. more of silver nitrite and stirring for one hour at 50°. A small amount of sodium chloride was added to the filtrate in order to eliminate silver ions. Evaporation to a sirup and addition of 20 cc. of 50% ethanol yielded 440 mg. (30%) of crystals melting at 137–138° and after recrystallization from 20 cc. of ethanol at 139–140°. The substance contains apparently one molecule of water of crystallization which is not eliminated by drying *in vacuo* at 60°.

Anal. Calcd. for $C_{15}H_{13}O_6N_3 \cdot H_2O$: C, 51.58; H, 4.33; N, 12.03. Found: C, 52.02; H, 4.09; N, 11.80.

1,3-Diacetyl-4,5-dipropyl-2-imidazolone.—4,5-Dipropyl-2-imidazolone[15] (16.8 g.) was acetylated by twice refluxing and evaporating with 90 cc. of acetic anhydride. It was crystallized from ethanol at −30°; yield 18.88 g. (74%), m. p. 57–59°.

Summary

A number of 4- and 5-substituted 2-imidazolones were brominated in the α-position of the side chains by applying with one exception Ziegler's N-bromosuccinimide method to the diacyl derivatives. The bromo compounds were submitted to various replacement reactions (Table I).

Imidazolones were prepared which possess the C,N-skeleton of biotin and carry in the α-positions oxygen, nitrogen and sulfur-containing groups (VA, VB, VC, VIA, VIB, VIC, and IX).

Catalytic hydrogenation of the double bond in the diacetyl compound IIIA was possible under

---

(14) The alternative formulation as nitrous acid ester is less likely in view of the stability of the compound toward water and alcohol.

(15) Basse and Klinger, *Ber.*, **31**, 1221 (1898).

mild conditions. Catalytic hydrogenation of the unacetylated compounds VC and VIC caused reduction of the α-keto group to methylene whereas the double bond and the α-amino and α-sulfo group remained intact.

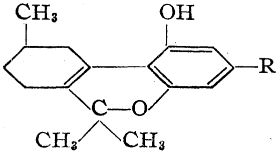
Tetrahydrocannabinol Homologs. XVII.[1]

BY ROGER ADAMS, BEN F. AYCOCK, JR., AND S. LOEWE

Modification of the 3-alkyl substituent of the synthetic tetrahydrocannabinol molecule (I) has resulted in the production of compounds of varying marihuana activity. Such compounds containing a 1′-methylalkyl side-chain have been shown to possess greatly enhanced activity compared to their *n*-alkyl analogs, and the most potent compound previously synthesized, the homolog with a 1′-methylheptyl group, has an activity greater than that of natural tetrahydrocannabinol.[1] Two additional members of the series, the 1′-methyloctyl and the 1′-methylnonyl, have now been synthesized.

The effect of distance from the aromatic ring of a substituent methyl in the 3-alkyl group has been investigated by the synthesis and testing of compounds with the 2′-, 3′- and 4′-methylpentyl groups in the 3-position. In Table I are included for comparison the pharmacological activities of these compounds, the 1′-methyloctyl and 1′-methylnonyl homologs and certain closely related compounds.



I

Inspection of Table I leads to several interesting conclusions. The 1′-methyloctyl homolog (no. 5) has an activity double that of the next lower member (no. 4) and over four times that of natural tetrahydrocannabinol (no. 14); thus it becomes the most potent substance ever tested. As a result of the unusual duration of action of the next higher homolog (no. 6) it is impossible to say where the peak of activity in this series occurs. The 1′-methylnonyl compound is only slightly soluble in propylene glycol and therefore was injected as an emulsion. This fact may account for the prolonged action exhibited by this substance.

It is also apparent that substitution of the alkyl group in the position in the side-chain next to the ring has a much greater effect than in a more distant position, the activity falling from 3.7 in the 1′-methylpentyl to 1.14 in the 4′-methylpentyl. Furthermore, the order of activity of the various isomeric hexyl side chains studied shows that all except the 1′-methylpentyl have a lower potency than the *n*-hexyl, the activities falling in the order: 1′-methylpentyl > *n*-hexyl > 1′-ethylbutyl > 2′-methylpentyl > 3′-methylpentyl > 4′-methylpentyl (isohexyl). It is significant that although the isohexyl homolog was reported to have negligible activity[7] by the Gayer test,[8] its potency, according to the dog ataxia test, is even greater than that of the standard.

The methods of preparation of these homologs are essentially those of Adams and Baker,[9] and

Adams, Chen and Loewe.[1] The method of reducing the 3,5-dimethoxyphenyl alkyl ketones to the corresponding methylene compounds by hydrogenation over copper chromite catalyst at 250° and 5000 pounds pressure was found prefer-

---

[10] These pyrones were prepared by the method of Adams and Baker.[8] The yield would unquestionably have been better if the procedure of Adams, Chen and Loewe had been followed as in the synthesis of the other pyrones.

[11] This pyrone was previously prepared[7] and reported to have a melting point of 177–180°, and the corresponding pyran b. p. 203° (1 mm.) (bath temperature).

able in many respects to the Wolff–Kishner procedure.

Experimental

All compounds prepared are described in Tables II–VII.

3,5-Dimethoxyphenyl Alkyl Ketones.—These ketones were prepared in the usual way[12] in ethyl ether without the addition of dibutyl ether.

3,5-Dimethoxyphenyl Olefins.—The olefins were prepared by the procedure of Adams, Chen and Loewe.[1]

3,5-Dimethoxyphenyl Alkanes.—The two 1′-methylalkyl derivatives were obtained by catalytic reduction of the ketones at high temperature and pressure in the presence of copper chromite as a catalyst. A typical conversion of a ketone to the correponding methylene compound is the preparation of $RCH_2CH_2CH(CH_3)CH_2CH_3$, where R = 3,5-dimethoxyphenyl. A mixture of 18.5 g. of $RCOCH_2CH(CH_3)CH_2CH_3$ and 3 g. of copper chromite catalyst was heated at 260° under an initial pressure of hydrogen (before heating was begun) of 3100 pounds. The hydrogen uptake reached the theoretical in seven hours. After cooling the bomb was opened, and the product rinsed out with ethanol, filtered and distilled. The yield of product was 13.5 g. (78%).

5-Alkylresorcinols.—The cleavage of the ethers was carried out as previously described.[1]

1-Hydroxy-3-alkyl-9-methyl-7,8,9,10-tetrahydro-6-dibenzopyrones.—The condensation of the resorcinols with 5-methyl-2-carbethoxycyclohexanone was effected according to the method of Adams, Chen and Loewe.[1]

1-Hydroxy-3-alkyl-6,6,9-trimethyl-7,8,9,10-tetrahydro-6-dibenzopyrans.—The conversion of the pyrones to pyrans utilized the conventional treatment with 12 moles of methylmagnesium iodide.[9]

Summary

1. Two new tetrahydrocannabinol homologs with the groups $—CH(CH_3)(CH_2)_6CH_3$ and $—CH(CH_3)(CH_2)_7CH_3$ in the 3- position have been synthesized.

2. The activity of the 1′-methyloctyl homolog is 32. This is the most potent substance ever tested, having an activity over four times that of natural tetrahydrocannabinol. The 1′-methylnonyl, presumably because of decreased solubility, has a potency of only 2.08 but the duration of peak effect is five times that of its congeners.

3. Three isomeric methylpentyl groups have also been introduced into the 3- position, namely, $—CH_2CH(CH_3)CH_2CH_2CH_3$, $—CH_2CH_2CH(CH_3)CH_2CH_3$ and $—CH_2CH_2CH_2CH(CH_3)_2$.

4. The activities of these isomers varies inversely as the distance of the methyl group from the ring.

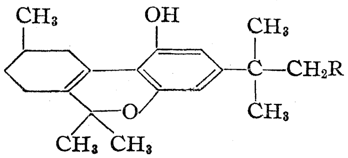
Tetrahydrocannabinol Homologs with Doubly Branched Alkyl Groups in the 3-Position. XVIII[1]

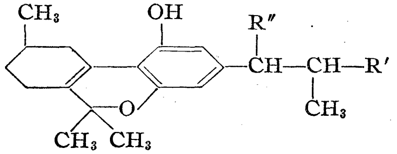
BY ROGER ADAMS, SCOTT MACKENZIE, JR., AND S. LOEWE

In synthetic tetrahydrocannabinols with *n*-alkyl groups or alkyl groups with a methyl substituent next to the ring in the 3-position the marihuana potency reaches a maximum of peak activity as the chain is lengthened. The significant increase in activity resulting from the introduction of a methyl group in the 1′-position of the 3-alkyl group stimulated a study of the activity of homologs having more highly branched side-chains in the 3-position.

Five pyrans have now been prepared, two of which, (I) and (II), have two methyl groups on the 1′-carbon of the side-chains in the 3-position. The other three, (III), (IV) and (V), have two alkyl groups, one on the 1′-carbon and the other on the 2′-carbon of the side-chain.



I R = C_2H_5
II R = C_5H_{11}



III R′ = C_2H_5; R″ = CH_3
IV R′ = CH_3; R″ = C_2H_5
V R′ = C_5H_{11}; R″ = CH_3

All products were tested by a procedure described previously. Activities of these compounds and certain isomers are listed for comparison in Table I.

Examination of Table I reveals the extreme variation in potency induced by changes in the structure of the 3-alkyl substituent. Branching of the side-chains not only increases activity but also requires larger groups to attain the maximum of peak effect (compare nos. 3 and 8). It is not surprising that the compound having the 1′,1′-dimethylbutyl side-chain in the 3-position is the most potent of the hexyl series of compounds. The substances with the 1′,1-dimethylalkyl substitution have activities comparable to the corresponding monomethyl derivatives, and the activity is much higher in the compound with a straight chain of seven carbon atoms than with

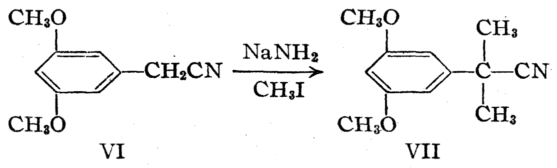
3	$-C_6H_{13}$-*n*[2]	7	1.82 ± 0.18 (max. in *n*-series)
4	$-CH(CH_3)C_4H_9$[4]	8	3.17 ± 0.33
5	$-CH(C_2H_5)CH(CH_3)CH_3$	6	3.40 ± 1.10
6	$-CH(CH_3)CH(CH_3)C_2H_5$	4	3.80 ± 0.32
7	$-C(CH_3)_2C_3H_7$	5	4.18 ± 0.34
Nonyl Isomers			
8	$-CH(CH_3)C_7H_{15}$[1]	19	32.6 ± 3.02 (max. in *s*-series)
9	$-CH(CH_3)CH(CH_3)C_5H_{11}$	18	512 ± 72.6
10	$-C(CH_3)_2C_6H_{13}$	5	21.8 ± 1.91

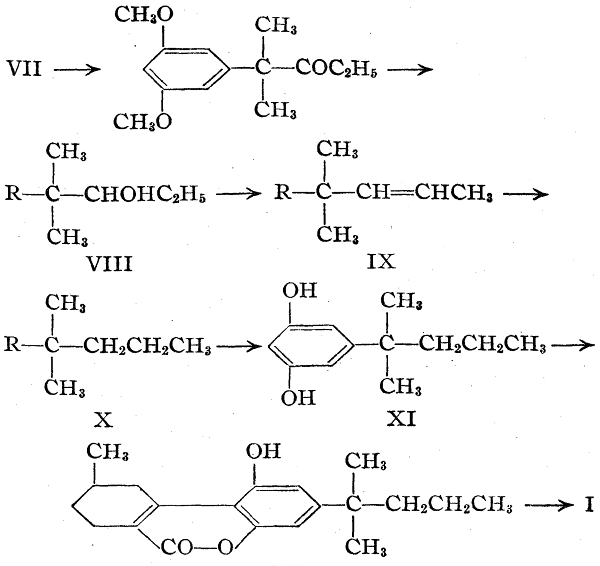
one of four carbon atoms. Although the 1′,2′-dimethylalkyl derivative with a total of six carbon atoms present in the side-chain is about equal in potency to the 1′,1′-dimethylalkyl derivative, the isomeric 1′,2′-dimethylalkyl analog with seven carbon atoms in the straight chain exceeds in activity the corresponding 1′,1′-isomer, and indeed has a value of 512. This is about sixteen times as potent as the most active homolog previously synthesized and seventy times the potency of natural tetrahydrocannabinol. The new order of the marihuana activity of the compound having the 1′,2′-dimethylheptyl side-chain makes generalization difficult at this time.

The 1′,1′-dimethylalkylpyrans were synthesized from 3,5-dimethoxybenzaldehyde. The aldehyde, first prepared by Mauthner[5] by the Rosenmund reduction, was obtained from the acid by the method described by McFadyen and Stevens[6] through 3,5-dimethoxybenzoyl-*p*-toluenesulfonylhydrazide. The aldehyde was hydrogenated in the presence of platinum oxide catalyst and the resulting benzyl alcohol was converted through the corresponding chloride and nitrile (VI) to 2-(3,5-dimethoxyphenyl)-2-methylpropionitrile (VII).



VI VII

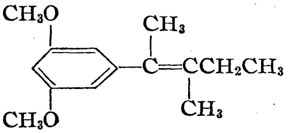
Both pyrans with two carbons on the 1′-carbon atom in the side-chains were prepared from this nitrile (VII) by the scheme shown below for the hexyl compound (VII–XII).



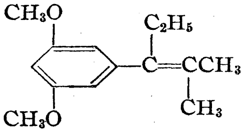
VIII IX X XI XII

The nitrile (VII) was converted by the action of ethylmagnesium bromide to the corresponding ketone which with hydrogen and copper chromite catalyst was reduced to the carbinol (VIII). Attempted dehydration of VIII by acidic reagents always resulted in rearrangement; the olefins thus formed were isolated, reduced and condensed to the pyrones, the structures of which were demonstrated by synthesis using unequivocal methods. The xanthate method of dehydration described by Tschugaeff[7] produced the unrearranged olefin (IX). This was reduced, demethylated, converted to the pyrone (XII), then to the pyran by the procedure previously described.[4,8]

Although Tschugaeff's assertion that no rearrangement occurs when alcohols are dehydrated by the xanthate method was further substantiated by Whitmore,[9] the structure of the tertiary olefin was more conclusively established. Dehydration of the pentanol (VIII) with acidic reagents would lead to the formation of either of two rearrangement products, (XIII) or (XIV). Both of these



XIII



XIV

olefins were synthesized from 3,5-dimethoxybenzamide[10] by conversion first to the ketone with the appropriate Grignard reagent, followed by the action of methyl- or ethyl-magnesium halide to form the carbinol. These were dehydrated, reduced and demethylated to the resorcinols which were converted to the pyrones.

Neither of the pyrones was identical with the pyrone (XII) prepared from the neopentyl type carbinol by the Tschugaeff method. The tertiary structure of the olefin (IX) obtained by the xanthate method is thus confirmed. The pyrones were converted to pyrans in the usual way.

Experimental

The procedures used for the conversion of a 5-alkylresorcinol dimethyl ether to the corresponding pyran have been described previously.[8]

Ethyl 3,5-Dimethoxybenzoate.—A mixture of 100 g. of 3,5-dimethoxybenzoic acid, 350 ml. of anhydrous benzene, 2 ml. of pyridine and 300 g. of purified thionyl chloride was refluxed for three hours. After removal of the solvent and excess thionyl chloride by distillation, 300 ml. of cold absolute ethanol was added to the cooled residue. The resulting solution was refluxed for four hours. The ethanol was removed by distillation and an ethereal solution of the residue was extracted with aqueous sodium bicarbonate. After removal of the ether the residue was distilled under reduced pressure. The product, collected at 120–125° (3 mm.), was a colorless liquid, n^{20}_D 1.5214. The yield was 100 g. (87%).

Anal. Calcd. for $C_{11}H_{14}O_4$: C, 62.86; H, 6.67. Found: C, 63.05; H, 6.79.

3,5-Dimethoxybenzhydrazide.—A mixture of 100 g. of ethyl 3,5-dimethoxybenzoate, 100 g. of 85% hydrazine hydrate and 110 ml. of absolute ethanol was refluxed for eight hours. The yield of brilliant white plates obtained by cooling the solution was 97 g. (83.5%). The product was purified from ethanol, m. p. 168–169° (cor.)

Anal. Calcd. for $C_9H_{12}N_2O_3$: C, 55.10; H, 6.12. Found: C, 55.17; H, 6.15.

3,5-Dimethoxybenzoyl-*p*-toluenesulfonylhydrazide.—A mixture of 100 g. of 3,5-dimethoxybenzhydrazide, 100 g. of *p*-toluenesulfonyl chloride and 100 ml. of pyridine was heated for one hour on a steam cone and then allowed to stand overnight. The solution was poured into 750 ml. of water and stirred until a granular, light brown solid was produced. The product was purified by recrystallization from aqueous ethanol. The total yield of large brilliant plates, m. p. 165–166°, was 117.5 g. (79%).

Anal. Calcd. for $C_{16}H_{18}N_2O_5S$: C, 54.86; H, 5.14. Found: C, 54.90; H, 5.34.

3,5-Dimethoxybenzaldehyde.—Into a one-liter Erlenmeyer flask heated by an oil-bath were placed 100 ml. of glycerol and 25 g. of 3,5-dimethoxybenzoyl-*p*-toluenesulfonylhydrazide. The mixture was stirred manually and heated to 125°. A hot (100°) solution of 20 g. of potassium carbonate in 100 ml. of glycerol was added all at once. The solution was heated rapidly to 135–140° and maintained at this temperature for about thirty seconds. After the evolution of gases partially subsided the solution was poured onto 300 g. of ice. The aqueous suspension was extracted three times with ether and the ether portions were combined and dried over anhydrous magnesium sulfate. After removal of the ether the liquid residue was distilled under reduced pressure. The fraction collected at 125–130° (1–2 mm.) was crude aldehyde and was purified by recrystallization from petroleum ether (b. p. 90–110°). The yield of fine lusterless needles, m. p. 45–46°, was 8 g. (68%). Mauthner[5] reported m.p. 45–46°.

3,5-Dimethoxybenzyl Alcohol.—The aldehyde was hydrogenated at room temperature and at 2–3 atm. pressure in the presence of platinum oxide catalyst. Ethanol was used as the solvent. The yield of fine white needles, m. p. 47–48°, from 16.6 g. of aldehyde was 16.0 g. (95%). The reported m. p. is 47–48°.[5]

3,5-Dimethoxybenzyl Chloride.—A solution of 22.5 g. of purified thionyl chloride in 100 ml. of anhydrous ether was added in 20-ml. portions with occasional shaking to a solution of 15 g. of 3,5-dimethoxybenzyl alcohol and 1 ml. of pyridine in 200 ml. of anhydrous ether. The mixture was allowed to stand for fifteen minutes and then was extracted twice with 100-ml. portions of cold water. The ether was allowed to evaporate *in vacuo* at low temperature. The crude chloride was purified by recrystallization from petroleum ether (b. p. 90–110°). The yield of fine needles, m. p. 46°, was 16.0 g. (96%).

Anal. Calcd. for $C_9H_{11}O_2Cl$: C, 57.91; H, 5.90. Found: C, 57.94; H, 6.09.

3,5-Dimethoxybenzyl Cyanide.—A mixture of 16 g. of 3,5-dimethoxybenzyl chloride, 300 ml. of ethanol, 30 g. of sodium cyanide and 75 ml. of water was refluxed for three hours. The solution was poured onto 400 g. of ice. The solid was collected on a filter and purified by recrystallization from petroleum ether (b. p. 90–110°). The yield of fine lusterless needles, m. p. 53°, was 14.5 g. (95%).

Anal. Calcd. for $C_{10}H_{11}NO_2$: C, 67.80; H, 6.21. Found: C, 67.81; H, 6.42.

2-(3,5-Dimethoxyphenyl)-2-methylpropionitrile.—3,5-Dimethoxybenzyl cyanide was methylated using a slight modification of the procedure described by Smith and Spillane[11] for the preparation of 2-(3,5-dimethylphenyl)-2-methylpropionitrile. The sodamide solution obtained from 3.5 g. of sodium, 200 ml. of liquid ammonia and a few crystals of ferric nitrate was allowed to evaporate to a volume of about 75 ml. The remaining ammonia was displaced by 200 ml. of anhydrous ether and a solution of 25 g. of 3,5-dimethoxybenzyl cyanide in 100 ml. of anhydrous ether was added all at once and the mixture refluxed for eighteen hours. Then 25 g. of methyl iodide was added to the cooled solution as rapidly as possible with stirring. The solution was refluxed for two hours, heating was discontinued and 50 ml. of ethanol was added with stirring. After washing and drying the reaction mixture was again subjected to methylation.

When reaction was complete the solvent was removed and the crude product obtained by distillation under reduced pressure was heated for one hour with 0.25 tablespoonful of Raney nickel and 200 ml. of absolute ethanol to remove any amide. Upon fractionation, a yield of 21.5 g. (72.5%) was obtained. The colorless product, b. p. 147–150°, n^{20}_D 1.5201, d^{20}_4 1.0813, became slightly yellow on standing.

Anal. Calcd. for $C_{12}H_{15}NO_2$: C, 70.24, H, 7.32. Found: C, 70.03; H, 7.53.

2-(3,5-Dimethoxyphenyl)-2-methylpropanoic Acid.—A mixture of 50 ml. of ethylene glycol, 1 g. of the propionitrile, 1 g. of potassium hydroxide and 1 ml. of water was refluxed for four hours. The solution was diluted with water, extracted with ether, acidified and extracted four times with ether. After removal of the solvent the crude acid was recrystallized from petroleum ether (b. p. 90–110°). The yield of colorless crystals, m. p. 99°, was 0.5 g. (46%).

Anal. Calcd. for $C_{12}H_{16}O_4$: C, 64.29; H, 7.14. Found: C, 64.45; H, 7.29.

2-Methyl-2-(3,5-dimethoxyphenyl)-3-pentanone.—A solution of 26 g. of 2-methyl-2-(3,5-dimethoxyphenyl)-propionitrile in 100 ml. of anhydrous ether was added to the Grignard reagent prepared from 41.2 g. of ethyl bromide, 5.9 g. of magnesium and 200 ml. of dry ether. The ether was replaced by 300 ml. of dry benzene and the solu-

tion was refluxed for forty-eight hours. The reaction mixture was decomposed with dilute sulfuric acid and the benzene was removed by distillation. The resulting mixture of acid and crude ketone was heated for an additional two hours on the steam cone. After cooling the mixture was extracted with ether, and the ether was removed. The crude product was distilled twice under reduced pressure to give a yield of 21 g. (70%) of colorless liquid (Table II).

2-Methyl-2-(3,5-dimethoxyphenyl)-3-pentanol.—The ketone was hydrogenated at a temperature of 150–170° under a pressure of hydrogen of 3000 pounds in the presence of copper chromite. The product was fractionated under reduced pressure, those fractions having $n^{20}D$ 1.5249 ± 0.0001 being combined.. The yield of colorless, viscous liquid, b. p. 129–130°(0.5 mm.), d^{20}_4 1.0980, was 15.2 g. (72.5%).

Anal. Calcd. for $C_{14}H_{22}O_3$: C, 70.59; H, 9.24. Found: C, 70.52; H, 9.44.

2-Methyl-2-(3,5-dimethoxyphenyl)-3-pentene.—A solution of 15.2 g. of the pentanol in 100 ml. of dry ether was allowed to react over a six-hour period with a suspension of 2.5 g. of metallic potassium (previously powdered in Stanolind) in 200 ml. of ether. An equimolar quantity of carbon disulfide was added and the mixture was stirred for one-half hour. To the thick white mass was added 9.0 g. of methyl iodide. The suspension was refluxed for six hours and allowed to stand overnight. The potassium iodide was removed by filtration. After removal of the ether the yellow residue was placed in a 50-ml. modified Claisen flask and distilled under reduced pressure. About one-half hour of careful heating was necessary before the actual distillation of light yellow product began. An alcoholic solution of the distillate was refluxed with Raney nickel and redistilled. The final product was a colorless liquid (Table III).

2-Methyl-2-(3,5-dimethoxyphenyl)-3-octanone.—A solution of 18.6 g. of 2-methyl-2-(3,5-dimethoxyphenyl)-propionitrile in 100 ml. of anhydrous ether was added to the Grignard reagent prepared from 42.1 g. of *n*-amyl bromide, 6.63 g. of magnesium and 150 ml. of anhydrous ether. After replacement of the ether with dry benzene the mixture was refluxed for forty-eight hours. The decomposition with dilute sulfuric acid and the purification of the product were carried out as described for the pentanone (Table II).

2-Methyl-2-(3,5-dimethoxyphenyl)-3-octanol.—The ketone was hydrogenated in the presence of copper chromite under conditions identical with those described above. After fractionation under reduced pressure, the yield of colorless liquid, b. p. 162° (0.5 mm.), n^{20}_D 1.5138, d^{20}_4 1.0262, was 15.5 g. (79%).

Anal. Calcd. for $C_{17}H_{28}O_3$: C, 72.86; H, 10.00. Found: C, 72.72; H, 10.19.

2-Methyl-2-(3,5-dimethoxyphenyl)-3-octene.—The preparation of the xanthate was carried out as described above. Gentle heating for three hours was necessary before the decomposition was complete (Table III).

Summary

1. Tetrahydrocannabinols have been prepared with the following alkyl groups in the 3-positions: $—C(CH_3)_2CH_2CH_2CH_3$, $—C(CH_3)_2CH_2(CH_2)_4CH_3$, $—CH(CH_3)CH(CH_3)CH_2CH_3$, $—CH(CH_3)CH(CH_3)CH_2(CH_2)_3CH_3$, $—CH(C_2H_5)CH(CH_3)_2$.

2. The resorcinols required for the first two were synthesized from 3,5-dimethoxybenzoic acid. This was converted to the resorcinol dimethyl ether derivatives by the following steps: $—COOH, \rightarrow —CHO \rightarrow —CH_2OH \rightarrow —CH_2Cl \rightarrow —CH_2CN \rightarrow —C(CH_3)_2CN \rightarrow —C(CH_3)_2COCH_2R \rightarrow —C(CH_3)_2CHOHCH_2R \rightarrow —C(CH_3)_2CH{=}CHR \rightarrow —C(CH_3)_2CH_2CH_2R$. Finally, demethylation yielded the resorcinols which were converted by previously described methods to the corresponding pyrans.

3. The resorcinols for the last three substances mentioned in (1) were made from 3,5-dimethoxybenzamide. This was converted as follows to the resorcinol dimethyl ether derivatives: $—CONH_2 \rightarrow —COCH(CH_3)R \rightarrow —C(R')(OH)CH(CH_3)R \rightarrow —C(R'){=}C(CH_3)R \rightarrow —CH(R')CH(CH_3)R$.

4. The substances with the 1',1-dimethylalkyl substitution have activities comparable to the corresponding monomethyl derivatives, and the activity is much higher in the compound with a straight chain of seven carbon atoms than with one of four carbon atoms. Although the 1',2'-dimethylalkyl derivative with a total of six carbon atoms present in the side-chain is about equal in potency to the 1',1'-dimethylalkyl derivative, the isomeric 1',2'-dimethylalkyl analog with seven carbon atoms in the straight chain exceeds in activity the corresponding 1',1'-isomer and indeed has a value of 512. This is about sixteen times as potent as the most active homolog previously synthesized and seventy times the potency of natural tetrahydrocannabinol.

URBANA, ILLINOIS RECEIVED JUNE 7, 1947

[CONTRIBUTION FROM STERLING-WINTHROP RESEARCH INSTITUTE]

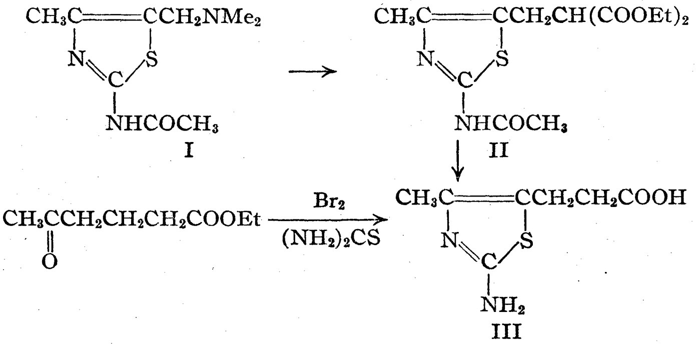
Alkylation with Non-ketonic Mannich Bases. Aminothiazoles and Pyrrole

BY NOEL F. ALBERTSON

Several years ago it was observed independently, both in this Laboratory and elsewhere, that gramine, 3-(dimethylaminomethyl)-indole, or one of its quaternary salts could be employed to alkylate malonic ester,[1,2] and this fact was used to develop a synthesis of tryptophan.[2,3] At that time the dialkylaminomethylindoles were the only reported examples of non-ketonic Mannich bases which can serve as alkylating agents for reactive methylene compounds. In fact, gramine was unique not only in its reaction but also in its preparation as compared with all of the other examples of Mannich bases compiled by Blicke.[4] The synthesis of gramine involves the introduction of a dialkylaminomethyl group directly onto a carbon atom in a ring which does not contain a ketonic or phenolic group.

It appeared unlikely that gramine should be so unique. On the contrary, it seemed probable that heterocyclic compounds of a phenolic nature, which contain a suitably activated hydrogen atom, would undergo the Mannich reaction to form "allylic" amines which could, in turn, serve as alkylating agents.

To test this supposition 2-acetamido-4-methylthiazole was treated with dimethylamine and formalin in acetic acid. From the reaction mixture a compound was obtained which, based on analysis, was the Mannich amine I. Sodioacetamidomalonic ester was readily alkylated by this base, in the form of its methyl sulfate, to give diethyl 5-(2-acetamido-4-methylthiazylmethyl)-acetamidomalonate. Since it has been pointed out by Bodendorf and Koralewski[5] that amides react with formalin and amines, an alternative structure for the Mannich base must be considered wherein the dimethylaminomethyl group is on the amide nitrogen. The fact that acetamide failed to react under the conditions under which 2-acetamido-4-methylthiazole reacted militated against this structure. Direct proof that the substitution actually took place on the ring rather than on the amide nitrogen was obtained by using the Mannich base (I) to alkylate malonic ester. The product obtained (II) was hydrolyzed and partially decarboxylated to yield III, a propionic acid which proved to be identical with that synthesized by interaction of ethyl γ-acetobutyrate, bromine and thiourea, and subsequent hydrolysis. The establishment of structure III for the propionic acid is indirect proof of the structure of the Mannich base (I).



When 2-acetamidothiazole was substituted for 2-acetamido-4-methylthiazole it also gave a Mannich base which served as an alkylating agent.

As one would expect, elimination of the 2-acetamido group greatly diminished the reactivity of the thiazole nucleus toward this type of reaction. 2,4-Dimethylthiazole gave a very minute yield of an unidentified product in the Mannich reaction. 2-Methyl-4-phenyloxazole gave only the acetate when treated with dimethylamine and formalin in acetic acid. A single attempt to use 2-(dimethylaminomethyl)-thiophene as an alkylating agent was unsuccessful.

The alkylation of acetamidomalonic ester with 2-(dimethylaminomethyl)-pyrrole has been reported recently.[6] Before the appearance of this work we had found that it is possible to replace not only the amino group of a monosubstituted pyrrole, but that both amino groups of a 2,5-bis-(aminomethyl)-pyrrole may be eliminated in an alkylation reaction. Thus, 2,5-bis-(piperidinomethyl)-pyrrole[7] reacted with acetamidomalonic ester to give ethyl pyrrole-2,5-bis-(2-acetamido-2-carbethoxypropionate), IV.

Experimental

2-Acetamido-4-methyl-5-(dimethylaminomethyl)-thiazole (I).[8]—A mixture of 15.6 g. of 2-acetamido-4-methylthiazole, 8 ml. of 37% formalin solution and 25 ml. of a solution of dimethylamine in glacial acetic acid (equivalent to 0.11 mole of amine) was warmed for seven hours on a steam-bath. Then 50 ml. of water was added, the solution made basic with potassium carbonate and extracted with five 50 ml. portions of chloroform. Removal of the solvent *in vacuo* left 25.9 g. of viscous residue. This was dissolved in alcohol and acidified with alcoholic hydrogen chloride. The crude hydrochloride was filtered and washed with alcohol; yield 23.0 g. (92%), m. p. 208–210°. This material was used for alkylation. A sample, recrystallized from aqueous acetone, melted at 223°.

Anal. Calcd. for $C_9H_{15}N_3OS \cdot HCl$: S, 12.84. Found: S, 12.64.

The free base, m. p. 138–139.5°, may be obtained by treating the hydrochloride with aqueous sodium carbonate. However, the hydrochloride is just as satisfactory for alkylation reactions as is the free base provided sufficient sodium ethylate is employed.

2-Acetamido-5-(dimethylaminomethyl)-thiazole.—This compound was prepared in the same manner as the analogous 4-methylthiazole; m. p. 248–249°.

Anal. Calcd. for $C_7H_{11}N_3OS \cdot HCl$: Cl, 15.04; S, 13.60. Found: Cl, 15.10; S, 13.51.

2-Acetamido-5-(piperidinomethyl)-thiazole.—This compound was prepared in the manner described above; m. p. 159–161.5° (free base).

Anal. Calcd. for $C_{11}H_{17}N_3OS$: C, 55.21; H, 7.16; N, 17.56. Found: C, 55.43; H, 7.13; N_k, 17.25.

Diethyl 5-(2-acetamido-4-methyl) thiazylmethylacetamidomalonate.—To a solution of 0.93 g. of sodium in 75 ml. of absolute alcohol was added 8.80 g. of acetamidomalonic ester, 7.2 g. of crude 2-acetamido-5-(dimethylaminomethyl)-4-methylthiazole (free base) and 6.3 ml. of dimethyl sulfate. It was necessary to cool the reaction flask in ice water occasionally. After four hours the reaction mixture was poured onto 200 g. of water–ice mixture containing 2.4 ml. of acetic acid. The white crystals (6.5 g.) were filtered, washed and dried; m. p. 183°. A sample for analysis, recrystallized from aqueous alcohol, melted at 183.5°.

Anal. Calcd. for $C_{16}H_{23}O_6N_3S$: C, 49.86; H, 6.01; N, 10.90. Found: C, 49.70; H, 6.09; N, 10.56.

Diethyl 5-(2-Acetamidothiazylmethyl)-acetamidomalonate.—This product was prepared in the same manner as the analogous 4-methylthiazole except that the hydrochloride rather than the free Mannich base was used. An additional amount of sodium ethylate (equivalent to the hydrochloride) was used in the reaction; m. p. 224–225°.

Anal. Calcd. for $C_{15}H_{21}N_3O_6S$: N, 11.31; S, 8.63. Found: N, 11.30; S, 8.80.

Diethyl 5-(2-Acetamidothiazylmethyl)-malonate.—This was prepared in the same manner as the above two compounds by substituting malonic ester for acetamidomalonic ester, m. p. 150.5–152°.

Anal. Calcd. for $C_{13}H_{18}N_2O_5S$: S, 10.20. Found: S, 10.29.

β-[5-(2-Amino-4-methylthiazyl)]-propionic Acid (A) from Mannich Base.—To 1.45 g. of sodium in 100 ml. of dry alcohol was added 15 ml. of malonic ester, 6.6 g. of 2-acetamido-5-dimethylaminomethyl-4-methylthiazole hydrochloride and 4.9 ml. of dimethyl sulfate. The reaction mixture was cooled by swirling in ice water. After four hours the reaction mixture was poured onto ice and water containing 3 ml. of acetic acid. The product was extracted with chloroform. The solvent and excess malonic ester were removed on a steam-bath under 2 mm. pressure and the residual 4.2 g. of oil hydrolyzed by refluxing for two hours with 20 ml. of hydrochloric acid (1:1). The solution was charcoaled, filtered and concentrated *in vacuo*. The viscous yellow residue was dissolved in 10 ml. of water and the *p*H brought to 7 with ammonium hydroxide. The solution slowly deposited crystals of the acid, m. p. 253–257° dec.

Anal. Calcd. for $C_7H_{10}N_2O_2S$: S, 17.22; N, 7.52. Found: S, 17.52; N, 7.30.

(B) **From Ethyl γ-Acetobutyrate.**—Ethyl γ-acetobutyrate was prepared as described below. To a suspension of 15.8 g. of ethyl γ-acetobutyrate and 15.2 g. of thiourea was added 15.9 g. of bromine with shaking.[9] After all of the bromine had been added the mixture was warmed for two and one-half hours on the steam-bath whereupon it became brown. A small amount of water was added, the mixture warmed and the clear solution treated with charcoal. Addition of ammonium hydroxide to a sample of the filtrate gave a black unpromising solution from which an oil slowly separated. Consequently, the main filtrate was warmed for forty minutes on the steam-bath to effect hydrolysis. The solution was filtered from sulfur and neutralized with ammonium hydroxide. The acid which precipitated was filtered, washed with water, alcohol and ether; yield 9.1 g. The product can be purified by reprecipitation from sodium hydroxide solution with acetic acid or from hydrochloric acid solution with ammonium hydroxide. The product melted at 254–256° and when mixed with the acid prepared by method A also melted at 254–256°.

γ-Acetobutyric Acid.—Condensation of methyl acrylate with a two-fold excess of acetoacetic ester in the presence of sodium ethylate gave a 73% yield of β-(carbomethoxyethyl)-acetoacetic ester as a pale yellow oil, b. p. 109–110° at 2 mm., $n^{25}D$ 1.4385.

Anal. Calcd. for $C_{10}H_{16}O_5$: C, 55.55; H, 7.46. Found: C, 55.24; H, 7.46.

Hydrolysis of β-(carbomethoxyethyl)-acetoacetic ester was effected by refluxing with concentrated hydrochloric acid (3 ml. per g.) until evolution of carbon dioxide ceased. Most of the water was then removed *in vacuo* until the monohydrate started to crystallize. Water of crystallization was removed by addition of benzene and azeotropic distillation. The γ-acetobutyric acid boiled at 107.5–109° (5 mm.); yield, 85%.[10]

Esterification[11] yielded the ethyl ester (67%), b. p. 52–59° (1 mm.), which was used without further purification.

Ethyl 2,5-Pyrrole-bis-(2-acetamido-2-carbethoxypropionate).—Sodium (3.3 g.) was dissolved in 200 ml. of dry ethanol. There was then added 31 g. of acetamidomalonic ester,[12] 7.8 g. of 2,5-bis-(N-piperidinomethyl)-pyrrole[7] and 11.0 ml. of dimethyl sulfate. After twelve hours the mixture was diluted with water and extracted with chloroform. Evaporation of the chloroform gave a crystalline residue in practically quantitative yield. Several recrystallizations from aqueous alcohol gave a product melting at 160–160.8° (cor.).

Anal. Calcd. for $C_{24}H_{35}N_3O_{10}$: C, 54.85; H, 6.71; N, 7.99. Found: C, 54.75; H, 6.60; N, 7.90.

Summary

2-Acetamidothiazoles, unsubstituted at position five, were found to react with formalin and dimethylamine to introduce a dimethylaminomethyl group directly onto the ring. These Mannich bases were used to alkylate malonic esters.

2,5-bis-(Piperidinomethyl)-pyrrole reacted with two moles of acetamidomalonic ester to give the symmetrically substituted pyrroledipropionate.

A Novel Synthesis of Substituted Phenylglyoxylic Acids[1]

BY I. MOYER HUNSBERGER[2] AND E. D. AMSTUTZ

Up to the present time there has not been available a general and convenient method for the synthesis of hydroxy-substituted phenylglyoxylic acids. Of the methods which have been used for the preparation of phenylglyoxylic acids only one[3] appears to be suited to the use of mono- and polyhydroxybenzenes. This procedure uses cyanogen and yields by-products formed by reaction of both nitrile groups.

In this paper is reported the synthesis of a series of new 2,4-dihydroxy-5-*n*-alkylphenylglyoxylic acids (I) and of 2,4-dihydroxy-3-ethyl-5-methylphenylglyoxylic acid (II) by condensation of alkylresorcinols with ethyl cyanoformate in the presence of anhydrous hydrogen chloride. These glyoxylic acids were desired in order to compare their antibacterial activity with that of the alkylresorcinols from which they are derived. Especial interest was taken in compound II because of the striking structural similarity of one of its quinonoidal forms (such as IIa and b) with that deduced[4] for the antibiotic citrinin (III). Further, it was felt that the cyanoformate condensation might have some value in synthetical work on citrinin.

The ethyl cyanoformate condensation first was applied to resorcinol and orcinol, 2,4-dihydroxyphenylglyoxylic acid and 2,4-dihydroxy-6-methylphenylglyoxylic acid lactone (IV), respectively, being obtained in agreement with Karrer and Ferla's[3] results using cyanogen. The general procedure then was extended to 4-ethyl-, 4-*n*-butyl-, 4-*n*-hexyl-, 4-*n*-octyl-, 4-*n*-nonyl-, 4-*n*-dodecyl- and 2-ethyl-4-methyl-resorcinol, the results of which are recorded in Table I. In all cases dry hydrogen chloride was introduced into a dry ethereal solution of ethyl cyanoformate and alkylresorcinol. After a length of time depending on the individual reaction the ketimine ethyl ester hydrochloride precipitated as highly-colored crystals which were hydrolyzed by hot water to the glyoxylic acid ethyl ester and thence by water or dilute alkali to the free glyoxylic acid (I).[5] In no case did the esters crystallize well so that purification was effected after saponification. Purification of the acids increased in difficulty with increase in weight of the 5-*n*-alkyl group.

TABLE I

PREPARATION OF HYDROXYPHENYLGLYOXYLIC ACIDS

Substituted 2,4-dihydroxyphenylglyoxylic acids	Crystallization solvent	Yield, %	M. p., °C.	Color	Analyses, % Calcd. C	H	Found C	H

[a] The insoluble reaction product was removed by filtration, washed with fresh ether and hydrolyzed directly to produce the lactone by thirty minutes heating in water near the boiling point. Extraction of the aqueous filtrate with ether followed by removal of the acid with sodium bicarbonate yielded additional (IV). [b] Karrer and Ferla (ref. 3) listed 212°. [c] Anhydrous zinc chloride was added. A suck-back of the concentrated sulfuric acid traps necessitated pouring contents of reaction flask and acid traps separately into ice. The solidified material thus obtained was saponified under nitrogen to the crude acid. [d] Since no crystallization had occurred, water and ice were added to the reaction mixture. After removing the ether the ethyl ester separated as a red oil which was extracted with ether and the ether with sodium bicarbonate. Upon heating the latter a cream-colored precipitate settled out and was filtered off. Its solubility in water indicated it to be the sodium salt, and acidification produced the crude acid. Evaporation of the ether produced the ethyl ester as a red oil, from which more crude acid was obtained as above. Fractionation was effected by successive dilutions with water. [e] Uncorrected. [f] The ethyl ester was obtained as brown-orange crystals, m. p. 74–77°, saponification of which produced crude II.

Although the position of the entering ketocarboxyl (COCOOH) group as *ortho* to one and *para* to the other phenolic hydroxyl group of the resorcinol nucleus was not proved rigorously in this investigation,[6] the general behavior of resor-

---

(4) Coyne, Raistrick and Robinson, *Phil. Trans. Roy. Soc.*, **220**, 297 (1931); Hetherington and Raistrick, *ibid.*, **220**, 269 (1931). Very recent evidence [*cf.* Sprenger and Ruoff, *J. Org. Chem.*, **11**, 189 (1946); Gore, Panse and Venkataraman, *Nature*, **157**, 333 (1946)] has cast doubt on the correctness of structure III.

(5) Only in the case of compounds derived from 4-*n*-octyl- and 4-*n*-nonyl-resorcinol did the ketimine salt fail to crystallize, a circumstance very probably the result of failure to introduce hydrogen chloride for a sufficient period. However, slight modification of the general procedure used in handling the reaction product permitted isolation of the corresponding glyoxylic acids in a pure state.

(6) Bulow and Wagner [*Ber.*, **36**, 1941 (1903)] established the position of the COCOOH group in 2,4-dihydroxylphenylglyoxylic acid by their preparation of this compound from 2-phenyl-7-hydroxy-1,4-benzopyranol-4-carboxylic acid.

IVb

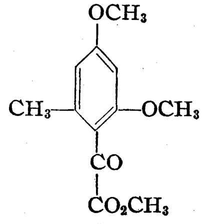
cinol lends strength to the proposed formulation. That the initial insoluble reaction products are ketimine hydrochlorides is indicated by their solubility in water and insolubility in ether. The condensation therefore is related closely to the familiar Gattermann and Houben–Hoesch syntheses.

Since neither the ketocarboxyl nor resorcyl fragment of the 2,4-dihydroxyphenylglyoxylic acid molecule is strongly chromophoric, the bright yellow color exhibited by such compounds is considered to be the result of a contribution of the *ortho* (such as IIb) or possibly the *para* (such as IIa) methylenequinone structure.[7] By supposing chelation to exert a color-deepening effect (resonance stabilization of the *ortho*-quinonoid form[8]), a rather satisfactory correlation between structure and the color of numerous hydroxy-substituted acetophenones, benzophenones, benzoquinones, naphthoquinones, anthraquinones and phenylglyoxylic acids, as compared to the respective unsubstituted compounds, can be drawn.

All 2,4-dihydroxy-5-alkylphenylglyoxylic acids prepared in this investigation gave dark red-brown colorations with ferric chloride and colors ranging from light yellow-brown to dark bluish-green with a mixture of thiophene–benzene and concentrated sulfuric acid.

An attempt to form a 2,4-dinitrophenylhydrazone of the hexyl acid failed. This result is in accord with Karrer and Ferla's[3] inability to form either an oxime or phenylhydrazone from 2,4-dihydroxyphenylglyoxylic acid and also bespeaks an interaction of the carbonyl and the ortho hydroxyl group. The many earlier reports of facile oxime, hydrazone, phenylhydrazone and bisulfite addition product formation[9] can be understood more readily when it is recalled that none of the early acids contained both *ortho* and *para* hydroxyl groups.

We have not been able to isolate any pure crystalline materials from the diazomethane methylation of the acids of series I. Whereas the relationship between IIa and b well may involve the phenomenon of resonance, we felt that with IVa and b the equilibrium should be rather of the tautomeric type; hence, the isomer IVb conceivably might have real and independent existence. Thus, methylation with diazomethane under essentially anhydrous conditions (avoiding lactone hydrolysis) could yield both colorless (from IVa) and colored (from IVb) methyl ethers. We were successful in isolating only the latter and in small yields. The material possessed a deep yellow color with analytical data corresponding to that calculated for a monomethyl ether of IV. Moist diazomethane yielded an orange–red crude product from which was isolated the colorless trimethylated derivative V, which corresponded in every detail to the product obtained by Karrer[3] with dimethyl sulfate and alkali. Both methylation and hydrolysis undoubtedly proceeded simultaneously during this wet methylation. We believe the orange–red color of the crude product was due to the presence of materials which first were methylated and then perhaps hydrolyzed and further methylated. However, we were unable to isolate any such products in a pure state.



V

Work along the general lines outlined in this paper is being continued.

All the compounds prepared were tested for antibacterial activity against *S. aureus*, *E. coli* and *B. subtilis* by both the broth serial dilution (BSD) and agar streak plate (ASP) techniques. The so-

---

[7] Chromophoric character is an attribute of such a structure not without precedent, for almost twenty years ago Robertson and Robinson [*J. Chem. Soc.*, 2196 (1927)] used a similar assumption to explain the bright yellow color of 2,6-dihydroxy-3,5-dimethylbenzaldehyde. Furthermore, it is expected that the two *ortho-para* orienting ring substituents would combine their influence with that of the carboxyl group on the methylene carbon atom to stabilize the methylenequinone structure [*cf.* Gomberg and West, This Journal, **34**, 1529 (1912)] in the case of 2,4-dihydroxyalkylphenylglyoxylic acids.

[8] *Cf.* J. R. Johnson, "Modern Electronic Concepts of Valence," Vol. II, chapter 25, of "Organic Chemistry," H. Gilman, editor-in-chief, second edition, John Wiley and Sons, Inc., New York, N. Y., 1943, p. 1870; Geissman, Schlatter, Webb and Roberts, *J. Org. Chem.*, **11**, 741 (1946).

[9] Schad, *Ber.*, **26**, 216 (1893); Tiemann, *ibid.*, **24**, 2877 (1891); Vorländer, *ibid.*, **44**, 2463 (1911); Bouveault, *Bull. soc. chim.*, [3] **15**, 1014 (1896).

dium salt of the 5-*n*-octyl-2,4-dihydroxyphenylglyoxylic acid was the most active, completely inhibiting the growth of *S. aureus* at 1:12,500 dilution (BSD) and *B. subtilis* at 1:25,000 dilution (ASP). None of the compounds had significant action against *E. coli*. The octyl compound was also active at 1:8,000 dilution against the fungi *Epidermophyton floccosum*, *Microsporon canis* and *Trichophyton rubrum*.

Acknowledgments.—The authors wish to express their appreciation to the Wm. S. Merrell Company for financial assistance and to Drs. M. G. Van Campen, Jr., and Milton Foter for arranging the antibacterial and antifungal tests. We also appreciate the assistance rendered by Sharp and Dohme who generously supplied us with hexylresorcinol, and Mr. V. Warren Fox, who prepared some of the glyoxylic acid from hexylresorcinol.

Experimental[10]

4-Alkylresorcinols.—All 4-alkylresorcinols used in this work were prepared by Clemmensen reduction of the ketone formed by condensation of resorcinol with the proper carboxylic acid in the presence of zinc chloride. Only in the purification of 4-n-dodecylylresorcinol was modification of the standard procedure[11] necessary.

2-Ethyl-4-methylresorcinol.—2,6-Dihydroxyacetophenone was prepared by alkaline cleavage of 4-methyl-7-hydroxy-8-acetylcoumarin[12] and reduced to 2-ethylresorcinol by a slight modification[13] of Clemmensen's method. The latter compound was transformed to 2,4-dihydroxy-3-ethylbenzaldehyde by a modification[14] of the Gattermann aldehyde synthesis. Another Clemmensen reduction then produced the desired 2-ethyl-4-methylresorcinol, which was purified according to Robinson and Shah.[15]

2,4-Dihydroxyphenylglyoxylic Acid.—The preparation of this acid illustrates the general procedure for all hydroxyphenylglyoxylic acids.

In a flask equipped with reflux condenser, stirrer and gas inlet tube were placed 11.0 g. (0.100 mole) of vacuum dried resorcinol, 10.8 g. (0.109 mole) of ethyl cyanoformate[16] and 100 ml. of absolute ether (dried over sodium). A rapid stream of dry hydrogen chloride was introduced for two hours, cold water being used at intervals to dissipate the heat generated. Hot water hydrolyzed the precipitated ketimine salt directly to a mixture of the crude keto acid (2.2 g.) and its ethyl ester (14.6 g.), the two being separated by extraction of an ethereal solution with sodium bicarbonate. The ester formed yellow–orange crystals, m. p. 65–68°, after recrystallization from water; it is soluble in benzene, ethanol, ether and chloroform, but insoluble in low-boiling petroleum ether.

Anal. Calcd. for $C_{10}H_{10}O_5$: C, 57.1; H, 4.80. Found. C, 57.6; H, 5.12.

Saponification of this ester with 10% potassium hydroxide produced more of the desired acid as mustard–yellow crystals, m. p. 161.5–163°,[17] after recrystallization from water.[18]

Anal. Calcd. for $C_8H_6O_5$: C, 52.8; H, 3.32. Found: C, 52.7; H, 3.32.

On standing six days the ethereal mother liquor from the original insoluble ketimine salt deposited a small quantity of light yellow crystals. The ether was decanted and the crystals covered with fresh ether which was neutralized with sodium bicarbonate. Evaporation of the ether produced orange crystals, presumably the ketimine ethyl ester, which did not melt below 330°. This product was slightly soluble in ether but quite insoluble in water; it gave no halogen test with silver nitrate but evolved ammonia when treated with 50% potassium hydroxide.

We found that satisfactory neutral equivalents of the acids prepared in this investigation could be determined by visual titration in water or aqueous alcohol using phenolphthalein as indicator (two acid hydrogens titrated per mole) when the end-point was not obscured by fluorescence.[19]

2,4-Dimethoxy-6-methylphenylglyoxylic Acid Methyl Ester (V).—An ethereal solution, not previously dried, containing about 2.8 g. (0.065 mole) of diazomethane was added gradually to a solution of 2.3 g. (0.013 mole) of pure 2,4-dihydroxy-6-methylphenylglyoxylic acid lactone (IV) in 60 ml. of ordinary ether at 0°. Evaporation of the ether produced an orange–red solid from which 0.4 g. (14%) of pure ester (V) was obtained as snow-white crystals, m. p. 73–74°, by repeated fractional crystallization from aqueous acetic acid. Saponification of the ester yielded the colorless free acid, m. p. 138.8–139.2°.[20]

Anal. Calcd. for $C_{11}H_{12}O_5$ (acid): C, 58.93; H, 5.40. Found: C, 59.12; H, 5.66.

Monomethyl Ether of 2,4-Dihydroxy-6-methylphenylglyoxylic Acid Lactone.—An ethereal solution containing *ca.* 2.1 g. (0.050 mole) of diazomethane (previously dried for three hours over potassium hydroxide and thirty minutes over sodium wire) gradually was added to 3.0 g. (0.017 mole) of 2,4-dihydroxy-6-methylphenylglyoxylic acid lactone (IV) dissolved in 70 ml. of absolute ether which had been dried over sodium. After six hours, the ether was evaporated to an oil which crystallized on standing overnight in a refrigerator. This solid was refluxed thirty minutes (nitrogen atmosphere) with excess 3% sodium hydroxide. The cold alkaline solution was filtered and acidified, whereupon 1.1 g. of crude product, m. p. 143–153°, separated.[21] This material was extracted twice with boiling water and the insoluble residue dissolved in hot 10% sodium bicarbonate solution and reprecipitated with acid. The yellow product thus obtained was extracted fractionally and crystallized with carbon tetrachloride to yield four fairly pure fractions (melting between the extremes of 163° and 171°), which after combination and retreatment with sodium bicarbonate and acid, as before, produced a small amount of pure monomethyl ether of IV as a bright yellow precipitate, m. p. 168–170.5°. There was no color with ferric chloride.

---

[10] All melting points are corrected for stem emergence unless specified otherwise.

[12] Russell and Frye, "Organic Syntheses," **21**, 22 (1941).

[13] Russell, Frye and Mauldin, THIS JOURNAL, **62**, 1441 (1940).

[14] Adams and Levine, *ibid.*, **45**, 2373 (1923).

[15] Robinson and Shah, *J. Chem. Soc.*, 1491 (1934). They found that the intermediate 2,4-dihydroxy-3-ethylbenzaldehyde melted at 115–118°; we found 119.5–121°. The higher value probably can be attributed to the superiority of water to benzene as recrystallization solvent.

[16] Gluud, Nussler and Keller, German Patent 592,539; *Chem. Zentr.*, **105**, II, 3437 (1934).

[17] Karrer and Ferla (ref. 3) listed 168° and stated that the value of 194° (ref. 6) was probably a typographical error.

[18] A few drops of concentrated hydrochloric acid added to an almost saturated solution hastened crystallization.

[19] Titrations performed with a Beckmann *p*H meter produced curves having well defined equivalence points corresponding to titration of one acid hydrogen ion. These equivalence points fell in a *p*H range of 5.12 to 5.80, indicating the strongly acidic nature of the compounds. However, the neutral equivalents calculated from such points were almost invariably 18 to 70 units too high. These results may be due to the presence of a phenolic group ortho to the ketocarboxyl side chain, since Anschütz [*Ann.*, **368**, 80 (1909)] found *o*-acetoxyphenylglyoxylic acid to behave normally on visual titration.

[20] Karrer and Ferla (ref. 3) reported 73–74° and 138–139° for the ester and acid, respectively.

[21] A considerable quantity of unreacted starting material (m. p. 206–209°) was recovered by ether extraction of the filtrate from the crude product. More starting material was recovered during later fractionations.

Anal. Calcd. for $C_{10}H_8O_4$: C, 62.49; H, 4.20. Found: C, 62.69; H, 4.64.

Summary

1. The condensation of ethyl cyanoformate with alkyl derivatives of resorcinol has been used to prepare a number of new 2,4-dihydroxyalkylphenylglyoxylic acids.

2. The use of ethyl cyanoformate is proposed as a general method for introducing the ketocarboxyl (COCOOH) group into activated positions on aromatic nuclei.

3. All hydroxyphenylglyoxylic acids prepared in this work have been subjected to antibacterial and antifungal testing but none showed exceptional activity.

Alkoxyaryloxyketones and their Condensation with Isatins

BY R. L. SUBLETT AND PAUL K. CALAWAY

To continue our work[1,2] on the preparation of keto ethers and their conversion into substituted quinoline acids we have prepared a series of ketones from alkoxyphenols by the procedure of Hurd and Perletz.[3] The resulting alkoxyaryloxyketones have been condensed with both isatin and 5-methylisatin, by the method of Pfitzinger,[4] to produce 3-alkoxyaryloxy-4-quinaldinecarboxylic acids.

The yields of the ketones prepared ranged from 47.6%, in the case of the 2-methoxy-4-methylphenoxyacetone, to 73% for the 4-propoxyphenoxyacetone. All of the ketones were obtained, after purification, as light yellow, low-melting solids, which darkened on standing.

The potassium salts of the quinaldinecarboxylic acids were salted out by high concentrations of potassium hydroxide. In every instance, decarboxylation of these acids was observed to start well below the melting point, hence melting point values changed with the rate of heating and are of little significance.

Experimental

Preparation of Alkoxyaryloxyacetones.—The procedure for the condensation of chloroacetone with the alkoxyphenols was based on the method of Hurd and Perletz.[3]

To a vigorously stirred and refluxing suspension of 0.4 mole of the alkoxyphenol and 57 g. (0.41 mole) of anhydrous potassium carbonate in 150 ml. of dry acetone was added over a period of thirty minutes a solution of 50 g. (0.54 mole) of chloroacetone and 3 g. of potassium iodide in 50 ml. of dry acetone. The chloroacetone mixture had been allowed to stand for twenty hours prior to addition. After refluxing for seven hours, stirring was continued for an additional twenty hours at room temperature. The mixture was filtered and the salt washed well with dry acetone. To obtain the ketone from the filtrate it was diluted with water and cooled with ice. The precipitate was recrystallized twice from methanol and water, and again from cyclohexane. The essential data on the ketones and derivatives are tabulated in Table I.

Preparation of 3-(4-Methoxyphenoxy)-4-quinaldinecarboxylic Acid.—Fourteen and seven-tenths grams (0.1 mole) of isatin was dissolved in 200 ml. of 33% aqueous potassium hydroxide solution and 17 g. (0.1 mole) of 4-methoxyphenoxyacetone was added. The resulting mixture was heated under reflux on the steam-bath for four hours, and upon cooling a solid cake of potassium 3-(4-methoxyphenoxy)-4-quinaldinecarboxylate separated in the reaction flask. The latter was disintegrated and dissolved in 800 ml. of hot water. The resulting solution was boiled with Nuchar, filtered, cooled in ice, and the quinoline acid precipitated by the addition of acetic acid (1:1). The product was separated by filtration, suspended in 600 ml. of hot water, and converted into the soluble potassium salt by the addition of 33% potassium hydroxide. The treatment with Nuchar was repeated, and 23 g. (74% yield) of the purified acid was obtained. The product was dried over phosphorus pentoxide in a vacuum desiccator.

The remaining 3-alkoxyaryloxy-4-quinaldinecarboxylic acids were formed in essential accordance with this general procedure. In each case a small sample was recrystallized from a large quantity of water and this material used for

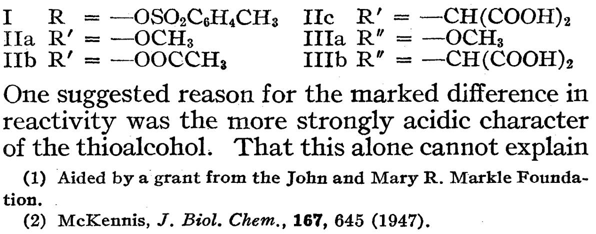
Some Reactions of Cholesteryl *p*-Toluenesulfonate[1]

BY HERBERT MCKENNIS, JR.

In a continuation of studies[2] on the relationship of the structure of cholesterol to its ability to promote growth of *Attagenus* larvae, a number of cholestene derivatives were desired. Cholesteryl *p* toluenesulfonate has been employed successfully in the preparation of 3-alkoxycholestenes,[3] 3-iodocholestene,[4] and a number of other derivatives.

The facile preparation of cholesteryl ethers by refluxing solutions of the *p*-toluenesulfonyl ester of cholesterol in an excess of various alcohols suggested the study of the possible reaction with corresponding mercaptans. This was of interest as a possible synthetic route to thioethers of cholesterol. Additional knowledge of the reactivity of cholesteryl *p*-toluenesulfonate was also desirable since we had planned to study the effect of this compound upon the growth of larvae.

Since *n*-propyl mercaptan has a boiling point quite close to that of methyl alcohol the former was selected for a preliminary study. Attempts to bring about the reaction of cholesteryl *p*-toluenesulfonate (I) with an excess of the mercaptan at reflux temperature for short periods were unsuccessful. After a three-hour period the ester was recovered in quantitative yield. Under similar conditions methanol reacts readily and cholesteryl methyl ether (IIIa) is easily obtained.



I II III

I R = —$OSO_2C_6H_4CH_3$ IIc R' = —$CH(COOH)_2$
IIa R' = —OCH_3 IIIa R'' = —OCH_3
IIb R' = —$OOCCH_3$ IIIb R'' = —$CH(COOH)_2$

One suggested reason for the marked difference in reactivity was the more strongly acidic character of the thioalcohol. That this alone cannot explain the results is clearly shown in experiments in which thiophenol and benzyl mercaptan were the alcohols employed. Thiophenol, kindly supplied by Dr. E. Emmett Reid, reacted readily with the tosyl ester to yield a bis-(phenylthio)-compound which is tentatively assigned the structure of 3,5-bis-(phenylthio)-cholestane. Benzyl mercaptan also reacted. The product in this instance was not, however, obtained in pure condition.

In view of the marked differences in reactivity observed it became desirable to know whether or not *n*-propyl alcohol itself would react under conditions drastic enough for the seemingly quantitative reaction with methanol, but not sufficiently drastic or prolonged for significant reaction with *n*-propyl mercaptan. The reaction with *n*-propanol under comparable conditions proceeded readily, and cholesteryl *n*-propyl ether was obtained in good yield.

In contrast to the marked reactivity of cholesteryl *p*-toluenesulfonate with methanol, propanol, thiophenol, and benzyl mercaptan at temperatures below 70°, the ester appeared not to react at all when heated with an excess of benzylamine at 70° for two hours. At reflux temperature (185°) reaction took place with the formation of an N-benzylamino compound which is assigned the quasi-committal name, N-benzylcholesterylamine, in accordance with the precedential designation, N-phenylcholesterylamine, for the product obtained by the analogous reaction of aniline and cholesteryl *p*-toluenesulfonate.[5] Under alkaline conditions cholesteryl *p*-toluenesulfonate reacts with methanol[3a] and other alcohols[3b] to give ethers, isomeric with the compounds obtained in the absence of alkali, for which structure IIa has been proposed.[6] Wagner-Jauregg and Werner[7] have found that a comparable situation obtains when cholesteryl chloride or bromide is heated with methanol. When the reaction was carried out in the presence of potassium acetate, *i*-cho-

[7] Wagner-Jauregg and Werner, *Z. physiol. Chem.*, **213**, 119 (1932).

lesteryl methyl ether (IIa) was obtained, the normal ether being formed when no potassium acetate was present. The further observation that the iso compound was transformed slowly when heated with methanol and one equivalent of hydrogen chloride at 130° to the normal ether (IIIa) led to the suggestion by them that the iso compound is first formed and then, if no base is present, it is converted under the influence of liberated acid to the normal ether.

We have found that *i*-cholesteryl methyl ether in methanol containing *p*-toluenesulfonic acid is converted to IIIa in good yield at reflux temperature within three hours. Since the conditions used here were similar to those ordinarily employed for the direct preparation of the normal compound from the tosyl ester, the comparatively rapid conversion in this instance affords additional support to the conception of Wagner-Jauregg and Werner. In view of this corroboration it would be interesting to study the possible catalytic action of acids on reactions of the tosyl ester with amino and sulfhydryl compounds.

It is interesting that under certain conditions derivatives of both cholesterol and *i*-cholesterol can be obtained from cholesteryl *p*-toluenesulfonate. Beynon, Heilbron and Spring[3a] isolated cholesteryl benzyl ether and *i*-cholesteryl benzyl ether from the mixture obtained by reaction of cholesteryl *p*-toluenesulfonate with benzyl alcohol in the presence of potassium acetate. Kaiser and Svarz[8] noted that the mixture from the reaction of cholesteryl *p*-toluenesulfonate with sodiomalonic ester contained a number of cholesterol derivatives. Two compounds obtained from the saponified reaction mixture were assigned tentatively structures IIIb, 3-cholesterylmalonic acid, and IIc, *i*-cholesterylmalonic acid.[9] The latter and its methyl ester were found to give a negative Liebermann–Burchard test while the former responded positively.[9]

Wallis, Fernholz and Gephart[6] have reported the conversion of *i*-cholesteryl acetate (IIb) to cholesteryl acetate by treatment with acid, and also have described the conversion of *i*-cholesterol, which gives a positive Liebermann–Burchard reaction,[10] to a normal cholesterol derivative. *i*-Cholesteryl methyl ether which in methanolic solution can be converted to the normal ether in the presence of acid catalyst, was found in our study to give a positive Liebermann–Burchard reaction.

The positive Liebermann–Burchard reactions of *i*-cholesterol and *i*-cholesteryl methyl ether can, in view of the demonstrated conversions of iso to normal compounds, be tentatively ascribed to formation of Δ^5-3-cholestenyl derivatives which take place under the acidic conditions of the Liebermann–Burchard test and precede the development of color. In contrast, since 3-cholesterylmalonic acid gives a positive test and *i*-cholesterylmalonic acid gives a negative test, it can be assumed that the latter yields no Δ^5-3-cholestenyl derivative under the test conditions. These interpretations appear to be consistent with the known limited specificity of the Liebermann–Burchard reaction.

Experimental[11]

3,5-bis-(Phenylthio)-cholestane.—A mixture of 4.50 g. of cholesteryl *p*-toluenesulfonate and 24 cc. of thiophenol was heated at 50° for two hours. The ester went into solution quickly and, in time, white crystals formed. These, presumably *p*-toluenesulfonic acid, were hygroscopic and insoluble in benzene. Excess thiophenol was removed by shaking the mixture or its ethereal solution exhaustively with 2 *N* potassium hydroxide. The oily product was dissolved in 40 cc. of hot alcohol containing enough chloroform to completely solubilize the product. The solution, on cooling to room temperature, deposited white prisms, m. p. 180–184°. A solution of the product in a minimal amount of hot chloroform was diluted to a volume of 125 cc. with 95% ethanol. The yield of glistening white product, m. p. 186–186.5°, was 2.34 g.

Anal. Calcd. for $C_{39}H_{56}S_2$: C, 79.51; H, 9.59; S, 10.89. Found: C, 79.58; H, 9.65; S, 11.30; $[\alpha]^{25}D$ $-127°$, *c* 1.71, carbon tetrachloride.

Benzyl mercaptan reacted with the ester under the above conditions. Crystals of alleged *p*-toluenesulfonic acid were formed. After removal of acid and excess benzyl mercaptan an oil remained. This gave strong qualitative tests for sulfur, but failed to crystallize from the usual solvents.

N-Propyl Cholesteryl Ether.—A solution of 0.500 g. of cholesteryl *p*-toluenesulfonate in 30 cc. of *n*-propyl alcohol was heated at 62–63° for three hours. The solution was cooled and 8 cc. of water was added. The crude ether, m. p. 99°, weighed 346 mg. (87% of the calculated amount). A small additional amount of ether was obtained by further dilution of the mother liquor. N-Propyl cholesteryl ether prepared by other methods has been reported to melt at 99.5–100°[12], 100°[13], and at 100–100.5°[14].

When the above components were heated at 50° for two hours, a product was obtained which melted over a wide range and contained unreacted ester.

N-Benzylcholesterylamine.—A solution of 1.00 g. of cholesteryl *p*-toluenesulfonate in 6 cc. of benzylamine, protected by a sodalime tube, was heated under reflux for three hours. The mixture was diluted with 100 cc. of ether and washed with water until no more benzylamine could be extracted. The ethereal solution was dried over anhydrous sodium sulfate and then concentrated to an oil. The oily residue was dissolved in a minimal amount of acetone and diluted with 95% ethanol until a faint turbidity was produced. The solution was cooled. The yield of crude product, m. p. 110–118°, was 0.500 g. After one recrystallization from acetone the compound melted at 118–119°. *Anal.* Calcd. for $C_{34}H_{53}N$: C, 85.82; H, 11.23; N, 2.94. Found: C, 86.06; H, 10.61; N, 3.12; $[\alpha]^{28}D$ $-25.1°$, *c* 2.15, chloroform.

N-Acetyl-N-benzylcholesterylamine.—A mixture of 1.00 g. of N-benzylcholesterylamine, 34 cc. of ether, and 1 cc. of acetic anhydride was heated under reflux for thirty minutes and then concentrated to a volume of 15 cc. The product, m. p. 152–153°, was obtained as clusters of needles. The yield was 0.91 g. (84% of calculated amount). An additional crop was obtained by concentrating the mother liquor. For analysis the derivative was recrystallized several times from ethyl acetate. The melting point was unchanged. *Anal.* Calcd. for $C_{36}H_{55}NO$: C, 83.50;

H, 10.71. Found: C, 83.63; H, 10.72; $[\alpha]^{25}_{D}$ −8.6°, *c* 0.934, carbon tetrachloride.

N-Benzylcholesterylamine Hydrochloride.—Dry hydrogen chloride was passed into a solution of 70 mg. of N-benzylcholesterylamine in 20 cc. of absolute ether until no more gelatinous precipitate formed. The salt was obtained in granular form by recrystallization from methanol containing a little hydrochloric acid. The hydrochloride melted with decomposition above 300°. *Anal.* Calcd. for $C_{34}H_{53}N \cdot HCl$: Cl, 6.92. Found: Cl, 6.59.

Cholesteryl Methyl Ether from *i*-Cholesteryl Methyl Ether.—To a solution of 100 mg. of *p*-toluenesulfonic acid monohydrate in 36 cc. of methanol was added 300 mg. of *i*-cholesteryl methyl ether. The mixture was heated under reflux for two hours and then concentrated under diminished pressure to a volume of approximately 25 cc. When the solution was chilled the product separated. It was collected and washed with a small volume of cold methanol. The yield was 279 mg. (93% of the calculated amount). The melting point, 84°, which is in agreement with reported values, was not depressed by admixture of authentic cholesteryl methyl ether.

Summary

1. The comparative reactivity of several mercaptans, alcohols, and benzylamine with cholesteryl *p*-toluenesulfonate has been studied in a qualitative manner. Under conditions favorable for the reaction of methanol and propanol with the formation of the corresponding cholesteryl ethers, *n*-propyl mercaptan, and benzylamine fail to react appreciably. Thiophenol and benzyl mercaptan react readily with cholesteryl *p*-toluenesulfonate.

2. The positive Liebermann–Burchard reaction of *i*-cholesterol and of *i*-cholesteryl methyl ether has been interpreted in the light of the known reactions of these compounds under acidic conditions, while the negative reaction of the analogous *i*-cholesterylmalonic acid has been tentatively ascribed to the inability of the latter to yield appreciable amounts of Δ^5-3-cholestenyl derivative under the Liebermann–Burchard test conditions.

3. The preparation of bis-(phenylthio)-cholestane, and of N-benzylcholesterylamine and derivatives have been described.

N,N-Dialkyl-β-hydroxyamides via the Reformatsky Reaction[1,2]

BY NATHAN L. DRAKE, CHARLES M. EAKER[3] AND WILBUR SHENK[4]

When it seemed desirable to prepare certain N,N-dialkyl-β-hydroxyamides for testing as potential insect repellents, the use of the Reformatsky reaction[9] involving N,N-dialkyl-α-haloamides suggested itself as a direct approach to the desired compounds. The present paper records the results of a study which demonstrated that N,N-dialkyl-α-haloamides can be substituted for α-bromoesters in the Reformatsky reaction with little loss in yield.

possible to obtain consistently yields above 65% of the calculated amount by adding an ether solution of the desired dialkylamine (2 moles) slowly to an ether solution of the desired bromoacyl halide (1 mole) cooled to −15°. The N,N-disubstituted-α-haloamides prepared in this way are listed in Table I; all of the bromoamides are strongly lachrymatory and sternutatory.

All of the amides listed in Table I were used successfully. It was noted, however, in the only two cases studied in which the disubstituted amides were related to high homologs of acetic acid, that yields obtained were considerably lower than those obtainable from corresponding acetamides. Thus, N,N-diethyl-α-bromocaproamide gave only a 43% yield of hydroxyamide when it reacted with 2-ethylbutyraldehyde; on the other hand, N,N-diamylbromoacetamide reacted with the same aldehyde and yielded 65% of the calculated amount of the expected hydroxyamide. A similar comparison can be made between yields obtained in the reaction of cyclohexanone with N,N-diethyl-α-bromopropionamide and N,N-diethyl-α-bromoacetamide, respectively. Branching of the alkyl groups attached to nitrogen appeared, from the very limited evidence available, to cause lower yields.

The reaction appears to be applicable to aliphatic or aromatic aldehydes and to most ketones. Worthy of note is the fact that we were unable to use furfural successfully as the carbonyl-bearing component. This finding is difficult to explain inasmuch as furfural participates normally in the usual form of the Reformatsky reaction. Nine ketones were investigated and all were converted to the expected hydroxyamide. Five aldehydes were studied; with the exception noted above, all participated in the reaction, but in the case of anisaldehyde the hydroxyamide underwent spontaneous dehydration.

The behavior of three alicyclic ketones, cyclohexanone, 4-methylcyclohexanone and cyclopentanone, was studied. The reaction proceeded satisfactorily with the first two but only poorly with the third. In four different attempts to bring about reaction between cyclopentanone and N,N-diethylbromoacetamide, the yield of desired product was never above 14%. Cyclic ketones in general appeared to form more insoluble zinc complexes than was the case with other carbonyl compounds investigated and vigorous stirring was necessary to prevent the separated zinc complex from coating the zinc alloy and stopping the reaction. It was found expedient to employ larger quantities of solvent in such cases to minimize this difficulty. In order to study steric effects in this reaction, methyl isopropyl ketone, diisopropyl ketone and pinacolone were used with N,N-diethylbromoacetamide in a series of similar reactions. All of the reactions occurred satisfactorily; the yields obtained were, respectively, 39, 69 and 55% of the calculated amounts. It is noteworthy that diisopropyl ketone, a substance which Conant and Blatt[10] found would react additively only with methylmagnesium iodide among various Grignard reagents studied, participates additively in the modified Reformatsky reaction to a considerable extent.

Several experiments in which attempts were made to substitute α-chloroamides for the corresponding α-bromoamides indicated that yields

[a] B = benzene; E = ether; T = toluene. Cl and Br refer to the halogen in the haloamide used. [b] Microanalyses by Miss E. Werble. [c] The hydroxyamide suffered dehydration during preparation.

obtainable from chloro compounds were considerably smaller than those from the corresponding bromoamides.

The dehydration of N,N-diethyl-β,β-diphenylhydracrylamide proceeds smoothly in the presence of 99% formic acid; it is probable that the other hydroxyamides described could be similarly converted to the corresponding unsaturated compounds.

Experimental

The aldehydes and ketones used were purified by usual methods.

Preparation of α-Haloamides.—An ether solution of the appropriate α-haloacyl halide was cooled to −15°, and an ether solution of 2 equivalents of the desired amine was added to the well-stirred solution at such a rate that the temperature of the mixture did not exceed −10°. After the reaction was complete, enough cold water was added to dissolve the precipitated amine hydrochloride. The organic layer was separated and washed successively with dilute phosphoric acid, dilute potassium carbonate and finally with saturated brine until neutral. After removal of the ether by distillation, the product was purified by distillation under diminished pressure, or by recrystallization.

The compounds prepared are found in Table I,

Preparation of N,N-Disubstituted-α-hydroxyamides.—The calculated quantity of turnings of zinc–copper alloy (8% copper) and a crystal of iodine were added to a 500 ml., three-necked flask for experiments in which 0.2 to 0.25 mole of reactants were employed. The flask was fitted with a reflux condenser, stirrer and dropping funnel and was protected from atmospheric moisture by drying tubes; before use the apparatus was flamed until dry while a stream of dry air was drawn through it. A small quantity (*ca.* 15 ml.) of a solution of the α-haloamide and the aldehyde or ketone in 100–150 ml. of the solvent listed in Table II was added, stirring was begun and the mixture was heated under reflux until the reaction started (usually within 15 min.). After the initial reaction had subsided, the remainder of the solution of reactants was added at such a rate that gentle refluxing occurred (*ca.* one hour). The mixture was then heated under reflux for one hour, cooled and poured onto 200 ml. of cold 10% sulfuric acid. Copper and unused zinc were removed by filtration, whereupon the organic layer was washed in turn with 5% solutions of sulfuric acid and potassium carbonate and finally with saturated brine until neutral. After the solution had been dried, the solvent was removed by distillation, and the product was purified by distillation or crystallization.

The compounds prepared and certain pertinent data are listed in Table II.

Dehydration of N,N-Diethyl-β,β-diphenylhydracrylamide.—The method used was similar to one already described.[11] The amide (3 g.) in 20 ml. of 99% formic acid was heated on a steam-bath for fifteen minutes. The cooled reaction mixture was poured into water, the product was extracted with benzene and the benzene solution was washed with 5% potassium carbonate and then with water until neutral. Evaporation of the benzene yielded a solid which was purified by recrystallization from petroleum ether (60–80°). Purified for analysis the compound melted at 83.6–84.3°. *Anal.* Calcd. for $C_{19}H_{21}NO$: C, 81.72; H, 7.53. Found: C, 81.87, 81.99.; H, 7.46, 7.47.

α,β-Dibromo-N,N-diethyl-β-anisylacrylamide.—Prepared from a solution of N,N-diethyl-β-anisylacrylamide in carbon tetrachloride by the addition of a 5% solution of bromine in the same solvent, and recrystallized from benzene–petroleum ether (1:1), the analytical sample melted at 122–122.8°. To obtain reproducible melting points, it was found necessary to heat the melting-point bath to 115° before inserting the capillary. *Anal.* Calcd. for $C_{14}H_{19}Br_2NO_2$: C, 42.75; H, 4.84. Found: C, 43.16, 42.86; H, 5.03, 5.23.

α,β-Dibromo-N,N-diisopropyl-β-anisylacrylamide.—Prepared as above, the analytical sample melted at 139–140°. *Anal.* Calcd. for $C_{16}H_{23}Br_2NO_2$: Br, 38.01. Found: Br, 37.70, 38.05.

Summary

1. The substitution of N,N-disubstituted-α-halomides for α-haloesters in the Reformatsky reaction has been studied and shown to be practical.

2. Sixteen different hydroxyamides prepared by this method are described.

3. Anisaldehyde reacted with two α-haloamides to yield the unsaturated relative of the expected hydroxyamide.

4. It was found impossible to isolate the expected product when furfural was one of the reactants.

Certain N-Alkyl, N-Carboxyalkyl and N-Hydroxyalkyl Derivatives of 4,4′-Diaminodiphenyl Sulfone

By Ernest L. Jackson

Numerous derivatives of 4,4′-diaminodiphenyl sulfone (I) have been reported[1] since the observation of the antibacterial activity of this sulfone by Buttle, *et al.*,[2] and by Fourneau, *et al.*[3] Among the amino substituted derivatives the results of biological studies[4] indicate the desirability of the presence of one free amino group and suggest the superiority of the alkyl type of substituent. The present paper reports the synthesis of a number of derivatives having an alkyl, carboxyalkyl or hydroxyethyl group substituted in one of the amino groups. Several similar derivatives of 4-amino-4′-nitrodiphenyl sulfone (II) were prepared both for use as intermediates in the synthesis of some of the derivatives of I and also for tests of their antibacterial activity, since compound II is known to show considerable bacteriostatic activity.

Two methods were employed in the preparation of the crystalline derivatives of I shown in the table: (1) direct alkylation or carboxyalkylation of I, an excess of I being used to minimize substitution in the second amino group of the molecule; (2) alkylation or hydroxyethylation of II and subsequent reduction of the nitro group of the product by iron and 1.5% hydrochloric acid in ethanol solution. The first method, the success of which depends on efficient separability of the product from I, was applied to the preparation of compounds IV and X–XIV. As alkylation and carboxyalkylation agents, ethyl iodide was used for the preparation of IV, the appropriate *n*-alkyl bromide for XII–XIV, bromoacetic acid for X and β-bromopropionic acid for XI. In the case of the glycine and β-alanine derivatives, separation from excess I was effected by removal of the carboxyl compounds as the water-soluble sodium salts. The acids required further purification, which was accomplished readily through the crystalline pyridine salts. The ethyl derivative crystallized from the ethylation solution at the end of the reaction. The difference in solubility of the *n*-butyl, *n*-amyl and *n*-tetradecyl derivatives in 2.5–5% hydrochloric acid as compared with I provides a convenient method of separation. Compounds IV and XIV were prepared also by the second method, which was the way the β-hydroxyethyl (VII) and benzyl (XVII) derivatives were obtained. The yields of amino derivatives in the reduction of the nitro compounds were excellent, 90% in one case.

The hydroxyethylation of II by reaction with 2-bromoethanol proceeds at a slow rate in boiling cellosolve solution to produce compound VI in a yield of 30–35%. Prolonged duration of the reaction results in a secondary reaction involving the hydroxyethyl group of the initial product (VI), as shown by the formation of both the β-hydroxyethyl (VII) and ethyl (IV) derivatives in the reduction of the mixture resulting from the hydroxyethylation reaction under certain conditions. Although the mechanism of the formation of IV in the two-step process has not been established, it seems possible that the compound might result from the reduction of 4-nitro-4′-β-bromoethylaminodiphenyl sulfone, which could be produced by the reaction of VI with the hydrobromic acid accumulated in the hot hydroxyethylation reaction solution. The direct hydroxyethylation of I by the reaction of 2-bromoethanol and I in equimolecular proportions at 100° produced a mixture from which only crystalline 4,4′-bis-(β-hydroxyethylamino)-diphenyl sulfone (VIII) was isolated. During the progress of this investigation Heymann and Heidelberger[1] reported the preparation of VIII, in low yield, through a pressure reaction of ethylene oxide with I followed by isolation of the product as the crystalline N,N′-dinitroso derivative. 2-Bromoethanol possesses advantages over ethylene oxide for the preparation of VIII, since

[a] Data supplied by Dr. M. I. Smith and Dr. J. M. Junge on qualitative tests against Type I pneumococcal infections in white mice. The slight activity or inactivity of several of the compounds may be due to poor absorption. Mice tolerate much larger doses of the derivatives than of diaminodiphenyl sulfone. For tests on compounds X and XI in experimental tuberculosis see ref. 4a and Smith, *N. Y. State J. Med.*, 45, 1665 (1945). In tests by Dr. E. W. Emmart marked inhibition of the growth of tubercle bacilli (human strain A27) was shown by compound VII in Kirchner's medium at a concentration of 4 mg.% and by compound IX in horse meat bouillon at a concentration of 25 mg. %. [b] Microcombustions and nitrogen analyses by Mr. C. A. Kinser, Mrs. Betty Mount and Mrs. Margaret M. Ledyard. [c] Corrected. Compound XI contained combined solvent. [d] Neut. equiv. calcd., 306; found, 305. [e] Neut. equiv. calcd., 320; found, 325.

the reaction of the former with I is carried out at atmospheric pressure and apparently the product is isolated more readily in crystalline condition.

The reaction of benzyl chloride and II in approximately equimolecular proportions afforded principally the monobenzyl (XVI) derivative and a smaller amount of 4-nitro-4′-dibenzylaminodiphenyl sulfone. The latter compound was not isolated, but its formation is evident since reduction of the benzylation mixture yielded both XVII and XVIII. Mingoia and Berti[5] obtained 4-nitro-4′-dibenzylaminodiphenyl sulfone through reaction of benzyl chloride with II; the monobenzyl derivative apparently was formed also, but the compound was not isolated in pure condition. Benzyl chloride and I in the molecular proportions of 3.5 to 1.0 yielded the tetrabenzyl (XIX) derivative, which has been described by Buttle, *et al.*[6]

Experimental

4-Nitro-4′-ethylaminodiphenyl Sulfone (III).—A solution of 20 g. of II and 12.3 g. of ethyl iodide in 150 cc. of 95% ethanol was refluxed for twenty-two hours and then cooled to room temperature. After the addition of 25 cc. of water and 7 g. of sodium bicarbonate, which produced crystallization, the refluxing was continued for an additional twenty-nine hours. The yellow crystals were separated from the hot mixture by filtration, washed first with cold 80% ethanol and finally with cold water. The nearly pure III weighed 5.8 g. and melted at 219–220°. The filtrate deposited at room temperature 11.3 g. of crystals melting at 155–160°, and upon concentration yielded more crystals showing a similar melting point. Additional III was obtained by recrystallization of the lower-melting material from ethanol. The compound is difficultly soluble in absolute ethanol, from which it crystallizes as elongated plates.

4-Amino-4′-ethylaminodiphenyl Sulfone (IV).—To a solution of 4 g. of pure III in 600 cc. of hot 95% ethanol was added 25 cc. of 38% hydrochloric acid. After the addition of 12 g. of 40-mesh, degreased iron filings in several portions to the hot solution, the mixture was refluxed for three hours, then filtered hot to remove excess iron, which was washed with hot ethanol. The hot filtrate was made slightly alkaline by the addition of concentrated aqueous sodium hydroxide solution, the precipitate filtered off and washed thoroughly with hot ethanol. The colorless filtrate, neutralized by hydrochloric acid, was concentrated *in vacuo* to dryness. The residue was extracted with 40 cc. of cold water in two portions to remove sodium chloride. The undissolved crystals were taken up in 70 cc. of hot absolute ethanol, from which a first crop of 2.7 g. of virtually pure IV crystallized. Additional crystals, isolated from the mother liquor, increased the yield to 3.3 g. or 91%. The compound usually crystallized from ethanol as slightly yellow, rod-shaped prisms, but sometimes was observed to crystallize as blades or thick plates. It showed diazotization and coupling according to the Bratton and Marshall[7] technique.

Compound IV was prepared also by direct ethylation of I. A mixture of 100 g. of I (2.0 molecular equivalents), 31.4 g. of ethyl iodide (1.0 molecular equivalent), 17 g. of sodium bicarbonate, 500 cc. of 95% ethanol and 100 cc. of water was refluxed for forty-eight hours. The solution deposited at room temperature 16.1 g. of slightly impure IV, which was collected, washed first with 80% ethanol and finally with water. These crystals were purified readily by recrystallization from absolute ethanol. The mother liquor from the crude IV yielded about 80 g. of crystals from which was separated by fractional recrystallization from ethanol about 1 g. of IV. The remainder of the material consisted principally of I.

Benzoylation of IV.—To a solution of 0.4 g. of pure IV in 12 cc. of anhydrous pyridine at 0° was added 0.4 g. of benzoyl chloride. After being kept at room temperature for twenty-two hours, the solution was mixed with ice water which precipitated a sirup that soon crystallized. The crystals were collected and washed with cold water. In order to remove benzoic acid, the substance was extracted with 75 cc. of cold absolute diethyl ether. The undissolved crystals of crude monobenzoyl derivative (V) weighed 0.5 g. It was purified by recrystallization from acetone, from which it crystallized as colorless, rod-shaped prisms melting at 226–227° (uncor.). The compound possesses no free primary amino group, as indicated by its failure to show diazotization and coupling in aqueous acetone solution by the Bratton and Marshall[7] method.

4-Nitro-4′-(β-hydroxyethylamino)-diphenyl Sulfone (VI).—A solution of 50 g. of II and 23 g. of 2-bromoethanol in a mixture of 250 cc. of 2-ethoxyethanol and 30 cc. of water was refluxed for fifty-eight hours. The filtered solution was neutralized by sodium hydroxide solution and then concentrated *in vacuo*, with the bath at 65–75°, virtually to dryness. The solid residue was mixed thoroughly with 250 cc. of water, then filtered and washed with cold water. It was taken up in hot absolute ethanol, in which it is difficultly soluble, some Norit added and filtered off. The solution deposited yellow, boat-shaped prisms of VI. The mother liquor upon concentration yielded several crops of impure crystals, from which was isolated more VI by fractional recrystallization from ethanol; yield, 17.5 g. or 30%. The analytical sample was obtained by further recrystallization from ethanol.

In a modified experiment evidence was obtained to show that a secondary reaction, involving the hydroxyethyl group, occurs during prolonged refluxing of the reaction solution. A solution similar in composition to that described was refluxed for eighty hours, cooled and stirred with a glass rod to induce crystallization. After twenty-four hours a crop of impure crystalline product was separated. The filtrate, neutralized with sodium hydroxide solution and concentrated *in vacuo* to about one-half the original volume, deposited additional product which was filtered off. The solvent was then removed by distillation *in vacuo*, the residual sirup mixed with water, finally separated and extracted with 70 cc. of hot ethanol. After filtration of the undissolved crystalline product, more material was isolated from the filtrate to make the yield of crystals melting at 200–206° about 46%, calculated as VI. These crystals proved to be a mixture. In an extraction with three parts of hot acetone, about 80% of the crystals melting at 206–209° was undissolved. This material upon reduction by iron and 1.5% hydrochloric acid in hot ethanol solution yielded a mixture consisting principally of VII and about 10% of IV. The two compounds were separated by fractional recrystallization from absolute ethanol. The crystals of IV were identified by the melting point of 199–200° (uncor.) alone or mixed with authentic IV; also by benzoylation according to the previously described procedure to yield the crystalline monobenzoyl derivative melting at 226–227° (uncor.), not depressed by crystals of the authentic compound.

4-Amino-4′-(β-hydroxyethylamino)-diphenyl Sulfone (VII).—Recrystallized VI (8.9 g.), melting at 207–210°, was reduced by iron (27 g.) and 1.5% hydrochloric acid in hot ethanol solution (555 cc.) according to the procedure described for the preparation of IV. The crude product (VII), after being washed with cold water, was recrystallized from absolute ethanol as thick, virtually colorless plates; yield, 6.1 g. or 76%. It is readily soluble in acetone, soluble in ethanol and dioxane, also soluble in cold 1% hydrochloric acid, somewhat soluble in hot water, and only slightly soluble in cold water. The presence of a primary amino group in the molecule was demonstrated by diazotization.[7]

4,4′-bis-(β-Hydroxyethylamino)-diphenyl Sulfone (VIII).—Seventy-five grams of I (1.0 molecular equivalent) and 37.8 g. of 2-bromoethanol (1.0 molecular equivalent) were mixed thoroughly while being heated on the steam-bath. The mixture was kept at 100° under a reflux condenser for thirteen hours and then dissolved, apparently as the hydrobromides, in 200 cc. of warm water. The addition of 30 g. of sodium bicarbonate precipitated a sirup, which changed to a gum upon being cooled in ice water. The gum, after separation from the aqueous layer by decantation, was taken up in 50 cc. of methanol. The solution, upon being left for several days in an open flask at room temperature with occasional stirring, deposited 9.4 g. of somewhat impure crystals of VIII. The mother liquor, kept in an open beaker with occasional addition of methanol and stirring, yielded 7.7 g. of crystalline VIII. The remainder of the material was a sirup, which probably consisted of a mixture of I, VII and VIII. The crude VIII was purified by recrystallization from methanol as virtually colorless, rod-shaped prisms.

N-[p-(p-Nitrophenylsulfonyl)-phenyl]-glycine (IX).—A mixture of 50 g. of II, 23.9 g. of monobromoacetic acid, 16.7 g. of sodium bicarbonate and 280 cc. of water was shaken until effervescence ceased. After the addition of 420 cc. of 2-ethoxyethanol, the mixture was kept at 100° under a reflux condenser for thirty hours. The red solution was neutralized by sodium bicarbonate, the solvent removed by distillation *in vacuo* with the bath at 50°, some water added and evaporated *in vacuo*. The sodium salt of IX was separated from water-insoluble material by extraction of the residue with 900 cc. of cold water in several portions, the final portion showing no precipitate upon addition of hydrochloric acid. The undissolved solid weighed 39.1 g. and melted at 148–151°. The addition of hydrochloric acid to the sodium salt solution precipitated IX as a sirup which crystallized overnight. To an efficiently stirred suspension of the crude acid in water was added sodium hydroxide solution until the mixture was neutral to phenolphthalein. After filtration to remove some undissolved solid, the acid was precipitated by the addition of hydrochloric acid; air-dried; yield of virtually pure IX, 11.8 g. The analytical sample was obtained by recrystallization of the compound as yellow, spear-shaped prisms from a mixture of acetone and water.

N-[p-(p-Aminophenylsulfonyl)-phenyl]-glycine (X).—A solution of 100 g. of I (2.0 molecular equivalents), 28 g. of monobromoacetic acid (1.0 molecular equivalent) and 19 g. of sodium bicarbonate in a mixture of 500 cc. of water and 250 cc. of 2-ethoxyethanol was kept at 100° under a reflux condenser for thirty-two hours. The crude solid was isolated and preliminary purification accomplished by a procedure similar to that described for IX; air-dried; yield, 39 g. melting at 185–193°. About 62 g. of impure I was recovered. Although the acid could be recrystallized from methanol, its purification is facilitated by the preparation of the pyridine salt.

A solution of 37 g. of the acid in about 175 cc. of hot pyridine, upon being filtered and kept overnight at room temperature, deposited elongated, well-formed prisms of the pyridine salt which were filtered, washed first with cold pyridine and finally with methanol. Crystals obtained from the mother liquor, after concentration *in vacuo*, increased the yield to 38 g., most of which was nearly pure. After being recrystallized to constant melting point from pyridine and dried in an evacuated desiccator over calcium chloride, the pure salt melted at 167–168° (uncor.).

To a suspension of 10 g. of pure pyridine salt in 100 cc. of water was added 27.3 cc. of *N* sodium hydroxide solution. In order to remove pyridine, the filtered solution was concentrated to dryness *in vacuo* with the bath at 55–60°, the residual sirup taken up in water and the concentration repeated. After some absolute ethanol had been added and distilled off *in vacuo*, the sodium salt was dissolved in 35 cc. of water, the solution filtered and the acid precipitated by the addition of 27.3 cc. of *N* hydrochloric acid. The virtually colorless pure X was filtered off, washed with cold water and dried in the air at room temperature; yield, 7.5 g. The presence of a primary amino group in the molecule was demonstrated by a test with p-dimethylaminobenzaldehyde, also by diazotization and coupling.[7]

N-[*p*-(*p*-Aminophenylsulfonyl)-phenyl]-β-alanine (XI).—A mixture of 163 g. of I, 50 g. of β-bromopropionic acid, 30 g. of sodium bicarbonate, 500 cc. of water and 250 cc. of 2-ethoxyethanol was kept at 100° under a reflux condenser for forty-six hours. The solution, after being neutralized by sodium bicarbonate, deposited at room temperature 102 g. of I melting at 168–172°. Crude XI was isolated as a sirup in a similar way as described for IX. A solution of the sirup in a mixture of 65 cc. of methanol and 85 cc. of pyridine deposited at 5° crystals of the pyridine salt of XI. After the crystals had been filtered and washed with diethyl ether, the filtrate was concentrated *in vacuo* to a thin sirup which, upon being mixed with 15 cc. of pyridine, gave at 5° a second crop of crystals to make the yield 63 g. The pyridine salt is readily soluble in cold pyridine and in cold methanol, soluble in ethanol and only slightly soluble in diethyl ether. It crystallizes from a mixture of pyridine and absolute ethanol as colorless needles or elongated plates. After being dried in an evacuated desiccator over calcium chloride, the pure salt melts at 134–135° (cor.).

The acid was prepared as a nearly colorless sirup from 33 g. of the pyridine salt as described for X, 84 cc. of *N* sodium hydroxide solution and 84 cc. of *N* hydrochloric acid being used in the operation. The sirupy acid was separated from the aqueous layer at 0–5° by decantation and washed with a little water. The acid crystallized from a solution of the sirup in 23 cc. of methanol saturated with benzene; air-dried; weight, 24 g.; m. p. 119–120°. After being recrystallized further as spear-shaped prisms from a mixture of methanol and benzene and dried in an evacuated desiccator over calcium chloride, the virtually colorless pure XI melted at 127–128° (cor.). These crystals lost no weight at 65° *in vacuo*. Calcd. for $C_{15}H_{16}N_2O_4S + 0.5\ C_6H_6$: C, 60.1; H, 5.3. Found: C, 60.1; H, 5.5. The solvent-free analytical sample was obtained by evaporation of a solution of the crystals in acetone followed by drying the residual sirup at 100° *in vacuo*. The compound reacts with *p*-dimethylaminobenzaldehyde and shows diazotization and coupling,[7] results which demonstrate the presence of a primary amino group in the molecule.

4-Amino-4′-*n*-butylaminodiphenyl Sulfone (XII).—A solution of 85 g. of I (2.5 molecular equivalents) and 18.7 g. of *n*-butyl bromide (1.0 molecular equivalent) in a mixture of 495 cc. of 95% ethanol and 26 cc. of water was refluxed for twenty-five hours. The solution deposited at room temperature 19.3 g. of somewhat impure XII. The mother liquor was neutralized by sodium hydroxide solution, then treated hot with Norit and freed from solvent. The solid residue was extracted thoroughly with cold 2.5% hydrochloric acid. Neutralization of the hydrochloric acid solution by sodium hydroxide precipitated 50 g. of nearly pure I melting at 172–173°. The solid, which was undissolved by the hydrochloric acid, was washed with water and recrystallized from ethanol, yielding colorless plates of XII. The total yield was 27.5 g. or 66%. The compound showed diazotization and coupling.[7]

4-Amino-4′-*n*-amylaminodiphenyl Sulfone (XIII).—A yield of 72 g. or 70% of XIII was obtained from 200 g. of I and 49 g. of *n*-amyl bromide by a procedure similar to that described under XII. The compound crystallized from ethanol as almost colorless, spear-shaped prisms, which are readily soluble in acetone and virtually insoluble in water. It showed diazotization and coupling.[7]

4-Amino-4′-*n*-tetradecylaminodiphenyl Sulfone (XIV).—A solution of 10 g. of I and 4.5 g. of myristyl bromide in a mixture of 55 cc. of ethanol and 6 cc. of water was refluxed for thirty hours. The product was isolated and purified in a similar way as described for XII. It crystallized from absolute ethanol as colorless, thin blades; m. p. 174–174.5° (cor.).

Compound XIV was prepared also by the reaction of I and myristyl bromide in the molecular proportions of 1.25 to 1.00.

Reduction of 1.2 g. of the pure nitro derivative (XV) by iron filings (4 g.) and 1.5% hydrochloric acid in ethanol solution (84 cc.) yielded crystals of XIV. Identity with the crystals prepared from I was established by the melting point of 174–174.5° (cor.), not depressed by crystals prepared from I; also by resemblance in crystal form and solubility. Samples prepared by both methods showed diazotization and coupling.[7]

4-Nitro-4′-*n*-tetradecylaminodiphenyl Sulfone (XV).—A solution of 20 g. of II and 19.9 g. of myristyl bromide in a mixture of 100 cc. of 2-ethoxyethanol and 12 cc. of water was kept at 100° under a reflux condenser for fifty-four hours. The solid material was recovered and neutralized in aqueous suspension. Fractional recrystallization from absolute ethanol afforded a partial separation of XV from unreacted II. Crystals of pure XV were obtained by recrystallization of selected fractions of the mixture from acetone, from which the compound crystallized as yellow blades. The analytical sample was dried at 65° *in vacuo*.

4-Nitro-4′-benzylaminodiphenyl Sulfone (XVI).—A mixture of 200 g. of II, 96 g. of benzyl chloride, 480 cc. of 95% ethanol and 720 cc. of water was refluxed for fifty hours. After the reaction mixture had been kept overnight at 25°, the supernatant liquid was decanted from a sirup, which was washed thrice with cold water and then dissolved in 200 cc. of hot dioxane. The filtered solution deposited at room temperature 168 g. of crystals, the yield of crude product being increased to about 225 g. by the isolation of more crystals from the mother liquor. Purification was completed by recrystallization from dioxane as thick, yellow plates which, in the air-dried condition, retained combined solvent. The analytical sample was dried to constant weight at 100° *in vacuo;* it then melted at 149–150° (uncor.).

Some 4-nitro-4′-dibenzylaminodiphenyl sulfone is formed in the benzylation reaction, as shown below by the isolation of crystals of XVIII from the products of the reduction of some impure XVI.

4-Amino-4′-benzylaminodiphenyl Sulfone (XVII) and 4-Amino-4′-dibenzylaminodiphenyl Sulfone (XVIII).—A solution of 15 g. of XVI, which had been dried at 100° *in vacuo*, in 460 cc. of hot 95% ethanol was treated with 18 cc. of 38% hydrochloric acid and 45 g. of iron filings by the procedure described for the preparation of IV, with the exception that methanol was substituted for ethanol in washing the excess iron and iron compounds. The solution, neutralized by hydrochloric acid, deposited at room temperature 6.7 g. of crystals, melting at 178–180°, which proved to be a mixture of XVII and XVIII. The mother liquor was decolorized with carbon and concentrated virtually to dryness. The residue was stirred with 100 cc. of water, the undissolved crystals collected and washed with water. Extraction of the 6.7 g. of crystals with 100 cc. of hot methanol left undissolved 1.7 g. which, upon recrystallization from a mixture of acetone and methanol, yielded about 1 g. of difficultly soluble, rod-shaped prisms of XVIII. Fractional recrystallization of the remainder of the material from methanol, with the use of decolorizing carbon when necessary, afforded 7.6 g. or 55% of virtually pure, colorless blades of XVII. The crystals of XVII showed diazotization and coupling.[7] Crystals of pure XVIII in aqueous acetone solution gave a diazotization[7] value of 28% as compared with I; calculated, 29%.

4,4′-*bis*-(Dibenzylamino)-diphenyl Sulfone (XIX).—A mixture of 10 g. of I (1.0 molecular equivalent), 17.8 g. of benzyl chloride (3.5 molecular equivalents), 36 cc. of water and 24 cc. of 95% ethanol was refluxed for forty-seven hours. The crude product was isolated as a sirup, which crystallized from a mixture of acetone and ethanol. Purified by recrystallization first from a mixture of acetone and ethanol and finally from acetone, the colorless rod-shaped prisms melted at 199–200° (uncor.). Buttle, *et al.*,[6] reported a melting point of 200° (cor.).

Summary

A number of new derivatives of 4,4′-diaminodiphenyl sulfone having an alkyl, carboxyalkyl or

hydroxyethyl group substituted in one of the amino groups have been synthesized. Several similar derivatives of 4-amino-4′-nitrodiphenyl sulfone were prepared. The preparation and the properties of the compounds are described.

The antipneumococcal and antitubercular activities of certain of the compounds are recorded.

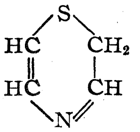
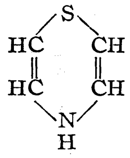
The Preparation of 1,4-Thiazine

BY CHARLES BARKENBUS AND PHILLIP S. LANDIS[1]

Compounds containing the uncondensed heterocyclic 1,4-thiazine ring have never been thoroughly investigated although, condensed with the benzene ring, this heterocyclic structure occurs in the important thiazine dyes. 1,4-Thiazine, which can theoretically exist in two forms (I) and (II), has never been described in the literature.



I



II

It has been found possible to synthesize 1,4-thiazine by making the imide of thiodiglycolic acid and reducing this imide with aluminum powder at an elevated temperature.

Thioglycolic acid, the starting point in the synthesis of 1,4-thiazine can be made easily by the usual method of the reaction of monochloroacetic acid with sodium sulfide. By extracting the acid from the reaction mixture with ether yields of 90% can be obtained.

The imide of thiodiglycolic acid was mentioned by Schulze in 1865 but no further reference to this interesting imide could be found. It was found that thiodiglycolimide could be made in excellent yields by heating the dry ammonium salt of thiodiglycolic acid in a partial vacuum.

The reduction of thiodiglycolimide to 1,4-thiazine is comparable to the preparation of pyrrole from succinimide. A literature search easily reveals that the reduction of succinimide, in spite of the large amount of space devoted to it by standard texts, is of very little preparative value and no one recommends this reduction as a means of making pyrrole or pyrrolidine. The most encouraging reduction method appeared to be that of Ray and Dutt,[2] who heated succinimide at an elevated temperature with aluminum powder instead of the customary zinc dust and obtained a 15% yield of pyrrole. The high temperature recommended, namely, dull red heat, placed some doubt as to whether the sulfur of the ring would survive such treatment. After many modifications of the original method, however, yields of 13% of 1,4-thiazine were finally obtained.

1,4-Thiazine, the mother substance of this interesting type of ring structure, is a colorless liquid boiling at 76.5–77°, miscible with water in all proportions, and is a weak base, $K = 4.0 \times 10^{-9}$. It has an ammoniacal odor combined with a faint but detectable odor of sauerkraut. It does not form a sulfonamide by the Hinsberg method and appears to be a tertiary amine having the structure corresponding to formula (I).

In investigating the many methods of reduction that have been tried on imides the reduction of chloro substituted imides appeared to offer some possibilities. Succinimide when treated with phosphorus pentachloride can be chlorinated to dichlorosuccinimide[3] which on further treatment gives tetrachloropyrrole. Prolonged treatment of thiodiglycolimide with phosphorus pentachloride completely destroyed the imide but careful heating of the imide with small amounts of phosphorus pentachloride gave a white crystalline compound having only one chlorine in the molecule. At first it was thought that this compound, because of the ease of hydrolysis of the chlorine, was an iminochloride. Mild treatment with alkali, however, did not regenerate the imide but produced instead thioglycolic acid, glyoxalic acid and ammonia. This would indicate that the chlorine had entered the α-position and that on hydrolysis a cyclic hemithioacetal was produced which on further hydrolysis gave the above products.

Experimental

Thiodiglycolic Acid.—Nine hundred and forty-five grams (10 moles) of monochloroacetic acid was placed in a 5 liter round-bottomed flask and dissolved in 1500 ml. of water. To this solution was added slowly with stirring 840 g. (10 moles) of solid sodium bicarbonate until the solution was neutral to litmus. The flask was placed in an ice-bath and 1320 g. (5.1 moles) of hydrated sodium sulfide dissolved in 1850 ml. of water was added slowly with stirring keeping the temperature between 25–30°. The solution was allowed to stand in the ice-bath for one hour and then 750 ml. of concentrated sulfuric acid was added with stirring, keeping the temperature between 25–30°.

The resulting solution was placed in a continuous extractor and ether passed through the solution at the rate of about 6 ml. per minute for twelve hours. At the end of each twelve-hour period fresh ether was placed in the extractor and the extraction continued for a total of thirty-

six hours. Since thiodiglycolic acid is as soluble in water as it is in ether, an efficient extractor had to be designed which would also be capable of accommodating the large volume of solution to be extracted. The extractor was made by connecting two 2-liter round-bottom flasks and one 1-liter round-bottom flask to a 40-mm. diameter glass tube so that the over-all height was 2200 mm. The ether was conducted to the bottom of the apparatus by a 5 mm. tube to which was sealed a sintered glass filter stick. The combined ether extracts were evaporated to dryness and the crude acid dissolved in 2 liters of hot water, decolorized with charcoal and, after filtering, concentrated to a volume of 750 ml. After cooling with ice the crystals were filtered off and washed with three small portions of ice water. In order to remove such a small amount of liquid from the large mass of crystals a high vacuum was necessary. The acid on air-drying weighed 580 g., had a m. p. 129° and neut. equiv., 75.5. The filtrate was concentrated to 250 ml. and the acid obtained was recrystallized from 150 ml. of water. Seventy-two grams of acid of the same purity was obtained. The combined filtrates were concentrated to 100 ml. and this crop of acid recrystallized from 20 ml. of water. Eleven grams more of the same purity was obtained; total yield, 663 g. (88% yield).

Thiodiglycolimide.—One hundred and fifty grams of pure thiodiglycolic acid was placed in a 500-ml. three-necked round-bottom flask fitted with ground glass joints. A capillary tube was fitted into one of the openings and a short wide adapter connected the flask by a ground joint to a liter three-necked round-bottom flask. This was cooled with water and connected to a water pump. To the acid was added 150 ml. of concentrated ammonium hydroxide and the contents heated first to 100° in an oil-bath using a slight vacuum and then to 190° for one hour. Toward the end a vacuum was used to remove last traces of water. After substituting a clean flask for the receiver, the oil-bath was raised to 215–220° and a vacuum of about 10 mm. applied. The imide was slowly formed and distilled into the flask. It was necessary to heat the connecting tube to prevent the imide from blocking the opening. A total of two hours was necessary to complete the distillation.

The crude imide was dissolved in 400 ml. of 95% alcohol and, after decolorizing with charcoal, the solution was concentrated to 150 ml. On cooling and filtering 100 g. of the imide was obtained melting at 128°. On concentrating the filtrate 5.7 g. of imide of like purity was obtained; total yield 105.5 g. (82%).

The yields in this preparation are dependent on the purity of the acid. A quantity of acid from one run gave an excellent yield of the imide while that from another identical preparation gave practically no yield. This was rather remarkable since both samples of the acid had the same melting point and neutralization equivalent. One crystallization of this impure acid gave a product that produced an excellent yield of the imide. The nature of this interfering impurity was not determined but apparently only traces are necessary to interfere with the synthesis.

1,4-Thiazine.—Ten grams of thiodiglycolimide was placed in a six-inch test-tube fitted with a sealed inlet tube which extended to the bottom of the test-tube and an outlet tube fitted with a ground joint. The test-tube was connected to a glass tube 100 cm. long and 2 cm. in diameter packed to three-fourths of its length with pumice which had been coated with aluminum powder. A 500-ml. flask surrounded with ice was attached to this tube and the latter attached to a glass spiral cooled with ice and salt. The end of the spiral was allowed to dip into 300 ml. of 10% potassium hydroxide solution. The long glass tube was heated for three-fourths of its length to 450° in an electric furnace and a rapid stream of carbon dioxide was passed through the test-tube containing the imide which had been melted and heated to 180–190° by an oil-bath. In this manner the imide was slowly volatilized through the long tube. After the imide had been volatilized the receiving apparatus was washed well with water and the washings combined with the potassium hydroxide solution.

The water solution from five such runs was combined and saturated with potassium carbonate. One-half of this solution was distilled and the distillate treated in the same manner. This was continued until a volume of 20–25 ml. was obtained. On saturating this solution with potassium carbonate the upper layer was separated, allowed to stand over powdered potassium hydroxide and then distilled. On redistillation the 1,4-thiazine boiled at 76–76.5°; yield 5.5 g. (13.4%), n^{25}_{D} 1.5975, d^{25}_{4} 0.8465. *Anal.* Calcd for C_4H_5NS: S, 32.30. Found: S, 32.40.

This base gave no derivative when boiled with benzenesulfonyl chloride in pyridine for one hour. A water solution on warming reduced potassium permanganate and only oily products were obtained when the base was allowed to react with methyl iodide or methyl *p*-toluenesulfonate. A picrate formed readily which had m. p. 158–159°. It also formed a very insoluble chloroplatinate which, after washing well with alcohol and drying, melted at 236–238°. *Anal.* Calcd. for $(C_4H_5NS)_2 \cdot H_2PtCl_6$: Pt, 32.1. Found: Pt, 31.9. On passing dry hydrochloric acid gas through an anhydrous ether solution of the base a white precipitate of 1,4-thiazine hydrochloride was formed. This salt is very hygroscopic but after drying in a vacuum desiccator over phosphorus pentoxide melted at 74–75°.

α-Monochlorothiodiglycolimide.—In a 200-ml. round-bottom flask was placed 5 g. of thiodiglycolimide, 8 g. of phosphorus pentachloride and 10 ml. of toluene. On heating in a water-bath the solids dissolved and after one-half hour a yellowish white solid separated from the black solution. The reaction mixture was cooled and the black liquid decanted from the solid. The solid was dissolved in 200 ml. of boiling toluene, decolorized with charcoal and concentrated to 100 ml. On cooling, light yellow crystals separated which were filtered off and dried in a vacuum desiccator. The crystals had a m. p. of 135°. Repeated crystallization raised the m. p. to 135.5°. *Anal.* Calcd. for $C_4H_4O_2NSCl$: Cl, 21.4; S, 19.4. Found: Cl, 21.5; S, 19.8.

The α-monochlorothiodiglycolimide when treated in the cold with dilute sodium hydroxide solution readily lost the chlorine but on acidification the original imide was not obtained and the odor of thioglycolic acid was detected. On warming the alkaline solution, ammonia was evolved showing that a profound decomposition of the compound had taken place.

Summary

1,4-Thiazine, the mother substance of the 1,4-thiazine series, has been prepared for the first time by the reduction of thiodiglycolimide and some of its properties have been described.

Methods of preparation of thiodiglycolic acid and thiodiglycolimide have been investigated and a satisfactory method giving excellent yields has been worked out for each. Thiodiglycolimide has been chlorinated to α-monochlorothiodiglycolimide by means of phosphorus pentachloride.

Studies in the Anthracene Series. III. Amino Ketones Derived from 9-Acetylanthracene

BY EVERETTE L. MAY AND ERICH MOSETTIG

This investigation was undertaken with the purpose of preparing anthracene-9-alkamines of the types —$CHOHCH_2NR_2$ and —$CHOHCH_2CH_2NR_2$ which could be expected to show antimalarial activity in view of the marked action of analogous 9-derivatives in the phenanthrene series.[1]

By the bromination of 9-acetylanthracene (V), 9-ω-bromoacetylanthracene (III), the desired intermediate for the preparation of the ethanolamine derivatives, was obtained in a yield of 50%. The bromo ketone III, however, failed under a variety of conditions to react normally with secondary amines.[2] The inertness of the bromine atom made its location in the side-chain appear somewhat doubtful, but eventually III could be obtained also by the Friedel–Crafts reaction of anthracene with bromoacetyl bromide, although only in yields of 2–3%. Aluminum isopropoxide reduction of III did not give the expected bromohydrin. In one instance, a 25% yield of a bromine-free compound, tentatively designated 9-(β-hydroxyethyl)-anthracene (IV),[3,4] was isolated, but usually only amorphous products were obtained. The product IV was shown by direct comparison to be different from 9-(α-hydroxyethyl)-anthracene.[5] Hydrogenation of the bromo ketone III with palladium–charcoal catalyst yielded readily 9-acetylanthracene.

By condensing, according to Mannich, 9-acetylanthracene, paraformaldehyde, and morpholine, 9-(3-morpholino-1-oxopropyl)-anthracene (VI) was obtained in a yield of 50%. The amino ketone VI, as hydrochloride, absorbed approximately two moles of hydrogen (platinum oxide), and 9-(3-morpholino-1-oxopropyl)-1,2,3,4-tetrahydroanthracene (VIII)[6] was obtained as the main product. As a by-product was isolated a small quantity of 9-propionyl-1,2,3,4-tetrahydroanthracene (IX) which increased in amount as the hydrogen absorption was allowed to proceed beyond two moles. When VI was reduced as base, three moles of hydrogen was absorbed and IX was isolated in a yield of 74%. Finally, amino ketone VIII slowly absorbed one mole of hydrogen, yielding ketone IX.

In the hydrogenation of 9-propionylanthracene, two moles of hydrogen was absorbed, and the resulting product was found to be identical with the ketone IX obtained in the reductive fission of the amino ketones VI and VIII. Moreover, we were able to prepare VIII by subjecting 9-acetyl-1,2,3,-4-tetrahydroanthracene (VII) (formed by catalytic reduction of V) to the Mannich condensation with paraformaldehyde and morpholine. Chromic acid oxidation of the ketones VII and IX gave 1,2,3,4-tetrahydro-9,10-anthraquinone (X).

The outlined series of reactions establishes the structure of the amino ketone VIII and the alkyl ketones VII and IX.[7] Obviously, owing to steric hindrance, the carbonyl group attached to the *meso* position of anthracene is resistant to catalytic hydrogenation, and one of the terminal benzene rings is attacked. This observation corroborates the failure of V and II to form, under standard conditions, semicarbazones, the failure of the bromo ketone III to react with secondary amines, and the resistance of 9-anthramide to hydrolysis.[8]

Recently Horeau and Jacques[9] found that the hydrogenation (Raney Nickel) of 9-benzoylanthracene yields in a ratio of about 1:5, 9,10-dihydroanthryl-9-phenylcarbinol and a product to which they assign the structure of 9-benzoyl-1,2,-3,4-tetrahydroanthracene. Our study appears to support the conclusions of these authors.

Acknowledgment.—We are indebted to H. George Latham, Jr., of this Laboratory for the preparation of 9-acetyl- and 9-propionylanthracenes. The microanalyses were carried out by C. A. Kinser and Betty Mount of this Institute.

Experimental[10]

9-Acetylanthracene (V) was prepared by the method of Lüttringhaus and Kačer[11] who quote the melting point *ca.* 80°. Our material melted at 74–76°.

9-Propionylanthracene (II).—It was found necessary to modify slightly[12] the directions of Lüttringhaus and Kačer[11] in the preparation of II. To a mixture of 50 g. of anthracene, 132 g. of propionyl chloride and 320 cc. of benzene, cooled to −5°, was added, with stirring, 75 g. of aluminum chloride at such a rate that the temperature did not rise above 0°. The temperature was maintained

at 0° for one and one-half hours, and allowed to rise to 10° during an additional hour (stirring). The complex was filtered, washed with cold benzene and decomposed in ice–hydrochloric acid. The resulting solid was extracted with ether, the ether was washed with 2 *N* sodium carbonate, dried over sodium sulfate and evaporated to give an oil which was digested with methanol. Insoluble material was filtered, the filtrate was evaporated to dryness, and the residue distilled in a high vacuum. The distillate was recrystallized from methanol to give 7.0 g. of II, m. p. 71–75°. A second crop weighed 8.3 g. and melted at 69–73°.

9-ω-Bromoacetylanthracene (III). (a) By Bromination of V.—To an ice-cooled solution of 5 g. of V in 50 cc. of dry ether was added 1.1 cc. of bromine during one hour. After stirring for an additional hour, 2.5 g. of solid was collected. The ethereal filtrate was concentrated and diluted with ligroin (b. p. 30–60°) to give a second fraction of 1.5 g. The two fractions were combined and recrystallized from benzene–ligroin; yield 3.2 g. (50%), m. p. 104.5–107°. The analytical sample melted at 107–108.5°; pale yellow prisms.

Anal. Calcd. for $C_{16}H_{11}BrO$: C, 64.2; H, 3.7. Found: C, 63.8; H, 3.8.

(b) By the Friedel–Crafts Reaction.—A mixture of 10 g. of anthracene, 65 cc. of benzene and 27 cc. of bromoacetyl bromide, stirred and cooled to −25°, was treated with 15 g. of aluminum chloride during ten minutes. The mixture was allowed to warm to 0° during one hour and decomposed in ice–hydrochloric acid. The benzene layer was diluted with ether and washed with dilute potassium hydroxide. It was dried over sodium sulfate and concentrated to a small volume to give, after cooling, 4.5–6.5 g. of anthracene. The filtrate was diluted to 200 cc. with ligroin (b. p. 30–60°), kept in the ice-box overnight, and decanted from some oil and crystals. On further dilution of the decantate to 300 cc., seeding, and cooling in the ice-box for forty hours, 0.2–0.4 g. (3–4% based on used anthracene) of prisms, m. p. 104.5–107°, separated. Mixed with the III from (a), they melted at 105–107.5°.

Debromohydrogenation of III.—A mixture of 1.0 g. of III, from either (a) or (b), 0.4 g. of palladium charcoal (5% Pd), and 50 cc. of absolute ethanol absorbed one mole of hydrogen in about one hour. After removal of catalyst, the filtrate was concentrated to 10 cc. to give, after ice-cooling, 0.5 g. (65%) of V, m. p. 74–76°.

Aluminum Isopropoxide Reduction of III.—One gram of III was reduced for four hours with 5 cc. of 1 *M* aluminum isopropoxide. The mixture was evaporated to dryness and the residue partitioned between benzene and dilute hydrochloric acid. The benzene layer was dried and concentrated to 4–6 cc. After addition of ligroin (b. p. 30–60°), 0.2 g. (25%) of leaflets (IV?), m. p. 105–107°, separated.

Anal. Calcd. for $C_{16}H_{14}O$: C, 86.5; H, 6.4. Found: C, 86.5; H, 6.3.

In subsequent experiments, attempts to isolate this compound failed.

9-(3-Morpholino-1-oxopropyl)-anthracene (VI).—A mixture of 25 g. of V, 15 g. of morpholine hydrochloride, 10 g. of paraformaldehyde and 125 cc. of absolute ethanol was refluxed for about twenty hours. After evaporation of solvent *in vacuo*, the residue was triturated with acetone to give 6 g. of morpholine hydrochloride. From the filtrate 12.5 g. of the hydrochloride of VI, m. p. 140–143°, was obtained. Upon recrystallization from absolute ethanol–ether it was converted to another crystalline form of m. p. 167–168.5°. Either form gave, with dilute ammonium hydroxide, VI which crystallized from methanol in prisms, m. p. 116–117.5°. Ten grams of V was recovered.

Anal. Calcd. for $C_{21}H_{21}NO_2$: C, 79.0; H, 6.6. Found: C, 78.9; H, 6.6.

9-(3-Morpholino-1-oxopropyl)-1,2,3,4-tetrahydroanthracene (VIII).—A mixture of 3.0 g. of VI hydrochloride (m. p. 167–168.5°), 0.1 g. of platinum oxide, and 40 cc. of methanol absorbed two moles of hydrogen during 6.5 hours. Absorption was then constant at about 20 cc. per hour. The mixture was warmed to solution, filtered, concentrated *in vacuo*, and diluted with ether to give 1.9 g. (62%) of hydrochloride. Dilute ammonium hydroxide–alcohol converted it to the base which crystallized from alcohol–water in cubes, m. p. 103–104°.

Anal. Calcd. for $C_{21}H_{25}NO_2$: C, 78.0; H, 7.8. Found: C, 77.8; H, 7.6.

The hydrochloride crystallized from 95% ethanol in prisms of m. p. 202.5–203°.

Anal. Calcd. for $C_{21}H_{26}ClNO_2$: C, 70.1; H, 7.3. Found: C, 70.1; H, 7.6.

9-Propionyl-1,2,3,4-tetrahydroanthracene (IX). (a). From the Reduction of VI Hydrochloride.—The filtrate from the 1.9 g. of VIII hydrochloride above was evaporated to dryness and the residue partitioned between water and ether. The ether-soluble material was dried and evaporatively distilled in a high vacuum to give a small amount of oil which crystallized from methanol in plates of m. p. 58.5–59.5°.

Anal. Calcd. for $C_{16}H_{16}O$: C, 85.7; H, 7.6. Found: C, 85.4; H, 7.6.

(b) **From VI (base).**—A mixture of 1.1 g. of VI (m. p. 115–117°), 0.05 g. of platinum oxide, and 25 cc. of methanol absorbed three moles of hydrogen in twenty-five hours. After filtration of catalyst and evaporation of solvent, the residue was recrystallized from methanol to give 0.6 g. (74%) of IX, m. p. 56–58°.

(c) **From VIII.**—The base VIII (0.2 g.) absorbed one mole of hydrogen (platinum oxide) to give 0.1 g. of IX, m. p. 56.5–58°.

(d) **By Hydrogenation of 9-Propionylanthracene.**—A mixture of 1.0 g. of II (m. p. 72–75°), 0.04 g. of platinum oxide, and 20 cc. of methanol absorbed two moles of hydrogen during fifteen to twenty-five hours. After filtration, concentration of the filtrate and ice-cooling, 0.6 g. (60%) of IX, m. p. 57.5–59° was obtained. It gave no depression when mixed with any of the samples of IX obtained as described above.

The semicarbazone of IX could not be obtained (boiling ethanol). Ketone IX was recovered.

9-Acetyl-1,2,3,4-tetrahydroanthracene (VII).—As described under (d) above, VII was obtained in a yield of 74%. It crystallized from methanol in prisms, m. p. 74.5–75.5°.

Anal. Calcd. for $C_{16}H_{16}O$: C, 85.7; H, 7.2. Found: C, 85.2; H, 7.2.

In an attempt to prepare the semicarbazone (four hours in refluxing ethanol) VII was recovered quantitatively.

Preparation of VIII from VII.—The Mannich reaction using 0.7 g. of VII, 0.5 g. of morpholine hydrochloride, 0.3 g. of paraformaldehyde, and 7 cc. of absolute ethanol yielded as described for the preparation of VI, 0.2 g. (21%) of VIII, m. p. 102.5–103°. The m. p. was not depressed by mixture with VIII described above. Two-tenths gram of VII was recovered.

1,2,3,4-Tetrahydro-9,10-anthraquinone (X). (a) **From VII.**—To a stirred mixture of 1.0 g. of VII and 10 cc. of acetic acid was added during one-half hour, 2.0 g. of chromic acid in 1 cc. of water and 5 cc. of acetic acid. After three and one-half hours stirring, water was added and the mixture was cooled in ice; yield of X, 0.25 g. (27%), m. p. 145–153°. After one recrystallization from alcohol it melted at 152–154°, m. p. not depressed by authentic material.

(b) **From IX.**—One gram of IX in 20 cc. of acetic acid gave, as above, 0.2 g. (22%) of X.

Summary

Attempts failed to prepare, by standard methods, the alkamines —$CHOHCH_2NR_2$ and —$CHOHCH_2CH_2NR_2$ derived from anthracene and carrying the side chain in position 9. 9-ω-Bromoacetylanthracene does not react with secondary amines. In the catalytic reduction of 9-(3-morpholino-1-oxopropyl), 9-acetyl and 9-propionyl-anthracenes the carbonyl group is not attacked while one of the terminal benzene rings adds two moles of hydrogen.

Studies in the Anthracene Series. IV. *Meso*-Substituted 9,10-Dihydroanthracene Derivatives

BY EVERETTE L. MAY AND ERICH MOSETTIG

In the foregoing communication[1] we have shown that the catalytic hydrogenation of 9-(3-morpholino-1-oxopropyl)-anthracene hydrochloride (VIII), with the absorption of two moles of hydrogen, yields chiefly 9-(3-morpholino-1-oxopropyl)-1,2,3,4-tetrahydroanthracene. Originally, we had assumed this reduction product to be 9-(3-morpholino-1-hydroxypropyl)-9,10-dihydroanthracene (XIII). Analogously, alkyl 9-anthryl ketones gave the corresponding alkyl 9-tetrahydroanthryl ketones and not the expected alkyldihydroanthrylcarbinols. In order to study the chemistry and some biological aspects of the 9-substituted 9,10-dihydroanthracene derivatives, we elaborated their synthesis together with structural proofs.

9-Acetyl-9,10-dihydroanthracene (VI) was first prepared by Nenitzescu and co-workers[2] through the Friedel–Crafts reaction on 9,10-dihydroanthracene with acetyl chloride. On repeating this remarkable reaction,[3] we obtained, in modifying the isolation procedure, the oily ketone VI and small but varying amounts of 2-acetylanthracene. In a similar manner we prepared 9-propionyl-9,10-dihydroanthracene (II). The dihydro ketones could also be obtained in satisfactory yields in the hydriodic acid–phosphorus reduction[4] of 9-acetyl- and 9-propionylanthracenes. Moreover, VI was synthesized from 9,10-dihydro-9-anthroic acid (IX) via the diazo and bromo ketones. Acid IX was obtained in a yield of 27% in the Beckmann rearrangement of the stereochemically heterogeneous oxime of 9-benzoyl-9,10-dihydroanthracene, along with anthracene (26%) and a nitrogen-containing compound (17%) to which we assign tentatively formula XII. Anthracene has been formed, very likely, from the intermediate 9-amino-9,10-dihydroanthracene, unstable under the conditions of hydrolysis following rearrangement.[5]

The Mannich condensation on ketone VI, employing morpholine as the base, gave the morpholino ketone X which was readily hydrogenated (platinum oxide) to 9-(3-morpholino-1-hydroxypropyl)-9,10-dihydroanthracene (XIII). The

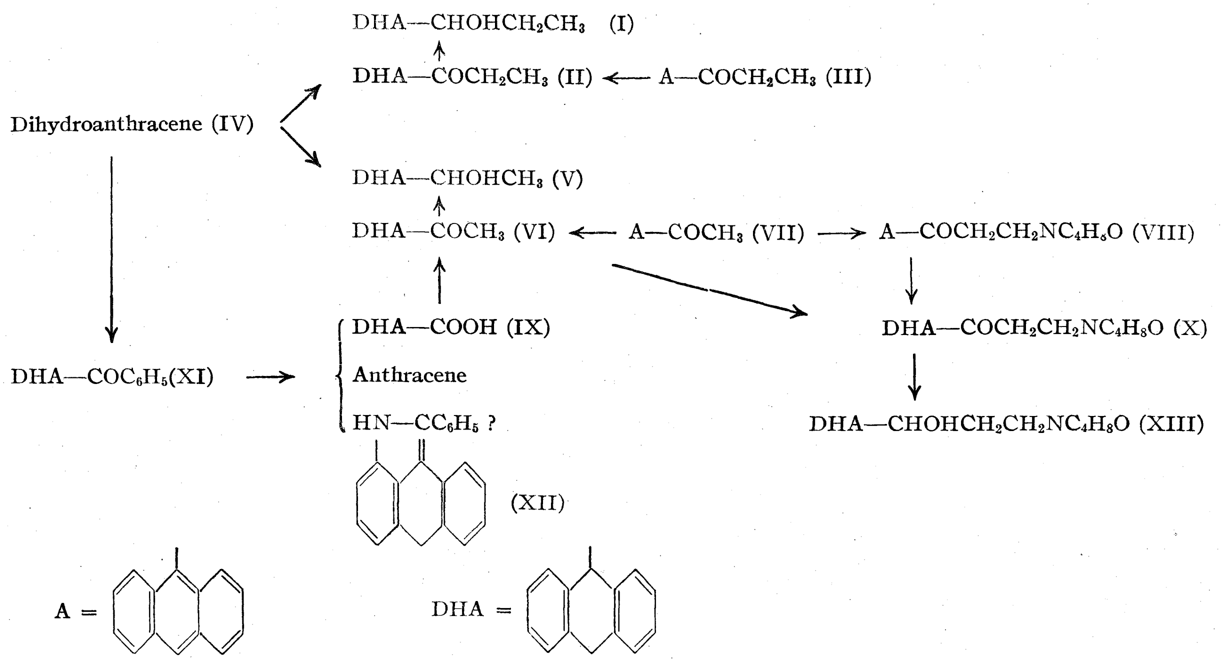
(4) This reductive method was employed by Cook, *J. Chem. Soc.*, 1677 (1926), in the preparation of 9-benzoyldihydroanthracene.

(5) Goldmann, *Ber.*, **23**, 2522 (1890).



structure of compound X was ascertained through its formation in the hydriodic acid–phosphorus reduction of amino ketone VIII.[1] Finally, the dihydroanthrylcarbinols V and I were prepared by aluminum isopropoxide reduction of ketones VI and II respectively, in order to show their non-identity with the corresponding, isomeric 9-acetyl- and 9-propionyltetrahydroanthracenes.[1]

Most of the 9-substituted-9,10-dihydroanthracene derivatives are rather unstable, and gradually become colored on standing. This was especially true of the oily ketone VI which, after a few days, yielded anthracene and occasionally some higher-melting material.[6]

Acknowledgment.—The microanalyses were carried out by C. A. Kinser and Betty Mount of this Institute. We are indebted to H. George Latham, Jr., for technical assistance.

Experimental[7]

Beckmann Rearrangement of the Oxime of XI.—A mixture of 6 g. of XI[2], 4.5 g. of hydroxylamine hydrochloride, 25 cc. of absolute alcohol and 8 cc. of pyridine was refluxed for four hours, concentrated *in vacuo* and diluted with water to give a rapidly-crystallizing oil. It crystallized from aqueous ethanol in a yield of 5.5 g., m. p. *ca.* 160–170°.[4] It was dissolved in 23 cc. of acetic acid and 16 cc. of acetic anhydride. Dry hydrogen chloride was bubbled into the solution until crystallization began (thirty to forty-five minutes). After standing for five hours at room temperature followed by ice-cooling, the amide mixture (3.3 g.), 25 cc. of acetic acid and 12 cc. of concentrated hydrochloric acid were refluxed together for thirty hours. The mixture was cooled in ice, filtered and the precipitate digested with hot, dilute sodium carbonate to give 1 g. of undissolved anthracene and 1.3 g. of IX,[8] m. p. 200–202°, on acidification of the filtrate.

The filtrate from the 3.3 g. of the amide mixture above was evaporated to dryness and the residue was refluxed with acetic acid–hydrochloric acid. Cooling and filtration gave a small amount of anthracene. The filtrate was evaporated to dryness, the residue treated with dilute sodium carbonate, and the insoluble material collected and sublimed. Recrystallization of the sublimate from aqueous ethanol gave 1.0 g. of light, yellow prisms of m. p. 145–150° (XII). The analytical sample melted at 152–153°.

Anal. Calcd. for $C_{21}H_{15}N$: C, 89.7; H, 5.4. Found: C, 89.7; H, 5.5.

The hydrochloride of XII crystallized from absolute ethanol–ether in orange prisms of m. p. 287–292° (dec.).

Anal. Calcd. for $C_{21}H_{16}ClN$: C, 79.4; H, 5.1. Found: C, 79.5; H, 5.3.

The acetyl derivative of XII, prepared in acetic anhydride–pyridine, crystallized from ethanol in long prisms, m. p. 183–183.5°.

Anal. Calcd. for $C_{23}H_{17}NO$: C, 85.4; H, 5.3. Found: C, 85.5; H, 5.5.

9,10-Dihydro-9-anthroyl Chloride.—A mixture of 3.8 g. of IX, 5 cc. of dry benzene and 4 cc. of thionyl chloride was refluxed for one hour and evaporated to dryness *in vacuo*. The residue crystallized from ligroin (b. p. 30–60°) in prisms; yield 3.7 g. (90%), m. p. 57–58°. The analytical sample melted at 57–58.5°.

Anal. Calcd. for $C_{15}H_{11}ClO$: C, 74.2; H, 4.6. Found: C, 74.2; H, 4.8.

9-(2-Bromo-1-oxoethyl)-9,10-dihydroanthracene.—The foregoing chloride (3.5 g.) in 25 cc. of dry ether was added during thirty minutes to 70 cc. of a stirred ether solution of diazomethane (from 7 g. of nitrosomethylurea) maintained at 3 to 5°. After one-half hour of stirring at 3 to 5° and one hour at room temperature, most of the ether was evaporated to remove excess diazomethane, 50 cc. of ether was added, and the stirred solution treated dropwise with 3.5 cc. of 48% hydrobromic acid in 3.5 cc. of ether (temperature 15–20°). After fifteen minutes at room temperature, the mixture was shaken with dilute sodium carbonate, dried, and evaporated to 10–15 cc. Addition of an equal volume of ligroin (b. p. 30–60°) gave, after cooling, 3.1 g. (73%) of bromo ketone, m. p. 104–105°; needles from ether–ligroin or methanol, m. p. 107–108° (strong gas evolution).

Anal. Calcd. for $C_{16}H_{13}BrO$: Br, 26.5. Found: Br, 26.8.

Analyses for carbon–hydrogen gave consistently high values.

9-Acetyl-9,10-dihydroanthracene (VI) Semicarbazone. (a) From 9-(2-Bromo-1-oxoethyl)-9,10-dihydroanthracene.—A mixture of 1.0 g. of the above bromo ketone, 0.2 g.of palladium–charcoal (10% Pd) and 25 cc. of absolute ethanol absorbed one mole of hydrogen in one hour. After removal of catalyst, the filtrate was treated with a slight excess of alcoholic ammonia and concentrated *in vacuo*. Semicarbazide hydrochloride (0.9 g.), 1.3 g. of sodium acetate and some water were added. The mixture was refluxed for one hour. The prisms (0.7 g. (77%), m. p. 223–225°) which separated overnight were recrystallized from dioxane–water and then from alcohol; m. p. 224–226° (gas evolution).

Anal. Calcd. for $C_{17}H_{17}N_3O$: C, 73.1; H, 6.1. Found: C, 73.0; H, 6.4.

(b) By the Friedel–Crafts Reaction.—To an ice-cooled, stirred mixture of 10 g. of dihydroanthracene,[9] 6 cc. of acetyl chloride and 100 cc. of carbon disulfide was added during ten minutes, 8 g. of aluminum chloride. After stirring for six hours without cooling, the solvent was decanted and the residue was partitioned between ice–hydrochloric acid and ether. The ether was washed with dilute sodium carbonate, dried and evaporated *in vacuo* to give 7.8 g. of a light-colored oil. Instead of purifying this oil by distillation (Nenitzescu and co-workers[2]), it was dissolved in 30–40 cc. of 95% ethanol to give, on cooling in the ice-box overnight, 0.2–0.5 g. of 2-acetylanthracene. The filtrate was refluxed for one hour with 5 g. of semicarbazide hydrochloride, 3.5 g. of fused sodium acetate, an additional 25 cc. of ethanol and 15–20 cc. of water. After cooling, the precipitate was recrystallized from dioxane–water. The yield of semicarbazone, identical with that described above, was 4.5–6 g. (30–40%), m. p. 224–226°.

(c) From 9-Acetylanthracene.[4]—A mixture of 10 g. of VII,[10] 2.8 g. of red phosphorus, 5 cc. of 55% hydriodic acid, and 100 cc. of acetic acid was refluxed for two and one-half hours, filtered and the filtrate evaporated *in vacuo*. The residue was partitioned between ether and an excess of 5–10% sodium hydroxide. The ether was washed with water, dried and evaporated. The semisolid residue was triturated with 20–25 cc. of 95% ethanol and cooled in ice to give 3.1 g. of IV, m. p. 103–107°. The filtrate, refluxed with 5 g. of semicarbazide hydrochloride, 3 g. of sodium acetate and some water, yielded 5.5 g. (43%) of the semicarbazone of VI, m. p. 220–224°.

Oxime of VI.—The semicarbazone of VI (0.5 g.), and 5 cc. of 10% hydrochloric acid were refluxed together for two hours. The resulting oil (0.4 g. after drying in ether), 0.3 g. of hydroxylamine hydrochloride, 3 cc. of absolute ethanol and 1 cc. of pyridine, refluxed for one hour yielded, on dilution with water and cooling, an oxime which crystallized from 95% ethanol in a yield of 0.25 g., m. p. 165–166°; prisms.

Anal. Calcd. for $C_{16}H_{15}NO$: C, 81.0; H, 6.4. Found: C, 80.8; H, 6.4.

Nenitzescu and co-workers,[2] who prepared the oxime in alcohol, quote the melting point 148–149°.

9-Propionyl-9,10-dihydroanthracene (II). (a) By the Friedel–Crafts Reaction.—To a stirred mixture of 10 g. of IV, 7 g. of propionyl chloride and 100 cc. of carbon disulfide, cooled in ice, was added 8 g. of aluminum chloride during ten minutes. The mixture was stirred for six hours without cooling, ice–hydrochloric acid was added, and the carbon disulfide washed with dilute sodium carbonate, dried and evaporated. The residual oil was dissolved in 90 cc. of 95% ethanol, 10 g. of semicarbazide hydrochloride, 7.5 g. of fused sodium acetate and about 30 cc. of water were added and the whole refluxed for two and one-half hours. Addition of water and cooling gave a crude solid which was fractionally crystallized from dioxane–water to yield 4.4 g. (28%) of prisms, m. p. 200–202°. A mixture of 2.5 g. of this semicarbazone and 20 cc. of 10% hydrochloric acid was refluxed for one hour. The resulting oily II was dried in ether and crystallized from methanol; white crusts, m. p. 62.5–63°.

Anal. Calcd. for $C_{17}H_{16}O$: C, 86.4; H, 6.8. Found: C, 86.4; H, 7.1.

The semicarbazone crystallized from 95% ethanol in prisms, m. p. 198–200° (bubbling).

Anal. Calcd. for $C_{18}H_{19}N_3O$: C, 73.7; H, 6.5. Found: C, 73.7; H, 6.6.

(b) From 9-Propionylanthracene.—As described for VI under method (c), 10 g. of III[1,10] yielded 4.1 g. of IV and 3.4 g. of II semicarbazone, m. p. 192–197°.

9-(1-Hydroxyethyl)-9,10-dihydroanthracene (V).—The semicarbazone of VI (1 g.) and 10 cc. of 10% hydrochloric acid were refluxed together for two hours. The resulting oil, dried in ether, was reduced with 6 cc. of 1 *M* aluminum isopropoxide for one-half hour. The solvent was distilled *in vacuo* and the residue partitioned between ether and dilute hydrochloric acid. Drying and evaporation of the ether left an oil which crystallized from methanol–water; yield 0.5 g. (63%), m. p. 88–89.5°. Recrystallized from ethanol–water and finally from 95% ethanol, it melted at 89.5–90.5°; prisms.

Anal. Calcd. for $C_{16}H_{16}O$: C, 85.7; H, 7.2. Found: C, 85.7; H, 7.4.

9-(1-Hydroxypropyl)-9,10-dihydroanthracene (I).—As described in the previous experiment, 1.0 g. of II (m. p. 62–63°) (reaction time one to two hours) yielded, from ligroin (b. p. 30–60°), 0.6 g. of I, m. p. 68–72°. After two recrystallizations from ligroin, the melting point was constant at 75.5–76.5°; prisms.

Anal. Calcd. for $C_{17}H_{18}O$: C, 85.7; H, 7.6. Found: C, 86.0; H, 7.9.

9-(3-Morpholino-1-oxopropyl)-9,10-dihydroanthracene Hydrochloride (X). (a) From VIII.—A mixture of 2.0 g. of VIII,[1] 2 cc. of 55% hydriodic acid, 0.5 g. of red phosphorus and 20 cc. of acetic acid was refluxed for two and one-half hours, cooled and filtered. The filtrate was evaporated to dryness *in vacuo* and the residue partitioned between ether and 5% sodium hydroxide. The ether was dried and acidified with ethereal hydrogen chloride to give an oil which crystallized from acetone–ether in a yield of 0.6 g., m. p. 168–170°. The analytical sample melted at 169–171°; long needles.

Anal. Calcd. for $C_{21}H_{24}ClNO_2$: C, 70.5; H, 6.8. Found: C, 70.1; H, 6.9.

(b) From VI.—The semicarbazone of VI (1.3 g.) was hydrolyzed as described above. The resulting oily VI, 0.6 g. of morpholine hydrochloride, 0.2 g. of paraformaldehyde and 5 cc. of absolute ethanol were refluxed for four hours. An additional 0.2 g. of paraformaldehyde was added and the refluxing continued overnight. Evaporation of the alcohol *in vacuo* and trituration of the residue with acetone gave a small amount of morpholine hydrochloride. Ether dilution of the filtrate yielded an oil which crystallized on cooling in ice. It crystallized from absolute ethanol–ether in a yield of 0.5 g. (30%), m. p. 169–171°, and did not depress the m. p. of X prepared as described by procedure (a).

9-(3-Morpholino-1-hydroxypropyl)-9,10-dihydroanthracene Hydrochloride (XIII).—The hydrochloride of X (0.8 g.) was converted to the base (dilute aqueous ammonia) which was dried in ether, dissolved in 10 cc. of methanol, and the solution hydrogenated with 0.05 g. of platinum oxide. One mole of hydrogen was absorbed during two to three hours. The catalyst was removed and the filtrate evaporated to dryness *in vacuo*. The residue was dissolved in acetone and acidified with ethereal hydrogen chloride to give 0.5 g. of the hydrochloride of XIII, m. p. 200–202°. It crystallized from absolute ethanol–ether in plates of m. p. 202–203° (dec.).

Anal. Calcd. for $C_{21}H_{26}ClNO_2$: C, 70.1; H, 7.3. Found: C, 69.7; H, 7.5.

The hydrobromide of XIII crystallized from absolute ethanol–ether in plates, m. p. 184–186° (dec.).

Anal. Calcd. for $C_{21}H_{26}BrNO_2$: C, 62.4; H, 6.5. Found: C, 62.3; H, 6.7.

The hydrochloride of X could also be hydrogenated to XIII.

Summary

The preparation of 9-acetyl- and 9-propionyl-9,10-dihydroanthracenes is described.

9-Acetyl-9,10-dihydroanthracene was subjected to the Mannich condensation (morpholine as base), and the resulting amino ketone was hydrogenated to the corresponding amino carbinol.

Phosphorus–hydriodic acid reduction provides an excellent means of converting 9-acyl and 9-aminoacyl derivatives of anthracene to the corresponding 9,10-dihydroanthracene derivatives.

The Papilionaceous Alkaloids. II. *Baptisia australis* (L.) R. Br.[1]

BY LÉO MARION AND JACQUES OUELLET

Few of the species belonging to the genus *Baptisia* have been investigated for alkaloids and none of these investigations has been at all thorough. Cytisine is the only alkaloid reported so far in these plants. It has been isolated from *Baptisia tinctoria* R.Br.[2] and detected by means of a microchemical test in *Baptisia australis* (L.) R.Br., *B. exaltata*, Sweet and *B. leucantha*, T. & G.[3] It seemed improbable that these plants should contain only one alkaloid, and, indeed, a thorough investigation of *Baptisia australis* has now revealed the presence in it of several other alkaloids.

B. australis (L.) R.Br. used in this investigation was grown at the Experimental Farm, Dominion Department of Agriculture, Ottawa, through the kindness of Dr. H. A. Senn, to whom the authors acknowledge their indebtedness. The aerial part of the plant and the root were examined separately, but were found to contain the same alkaloids. Four alkaloids have been isolated. The two main bases are N-methylcytisine and *d*-sparteine. The third in importance is cytisine while the fourth, alkaloid P_2, was present in such small quantity that it could not fully be characterized. With the possible exception of alkaloid P_2, all the alkaloids found in the plant are known and have been isolated previously from other sources. It is of interest to note that the four alkaloids reported in *Anagyris foetida*[4] differ from those of *B. australis* only in that anagyrine is substituted for alkaloid P_2 of the latter.

B. australis also contains a non-nitrogenous substance A which can be hydrolyzed by acids to a new substance B. Both substances A and B are soluble in aqueous sodium hydroxide.

Experimental

The dried and ground aerial part of *B. australis* (2620 g.) was extracted in Soxhlet extractors with methanol and the solvent, largely distilled from the combined extract which was then diluted with water, made acid to congo red by the addition of hydrochloric acid and kept on the steam-bath for nine hours. The mixture was cooled, filtered and the insoluble cake warmed again with dilute acid, cooled and filtered. The combined aqueous acid filtrate was repeatedly extracted with ether and the extract distilled to dryness. It left a residue consisting of a mixture of crystals and a thick oil which were separated by filtration through a fritted glass funnel. The crystalline substance A was purified by repeated crystallization from boiling methanol from which it separated as colorless needles, m. p. 261°.[5]

Anal. Found: C, 71.91, 72.14; H, 4.90, 4.82. Calcd. for $(C_{25}H_{20}O_6)_n$: C, 72.11; H, 4.81.

Substance A dissolved in aqueous sodium hydroxide to give an intensely yellow solution from which it was recovered by acidification. Refluxing for two hours with 10% sulfuric acid converted substance A into a new substance, B, which after repeated crystallization from boiling methanol was obtained as clusters of small crystals which in bulk had a slightly brownish-yellow color. It softened at 331° and melted at 334°.

Anal. Found: C, 61.28, 61.15; H, 3.89, 3.92. Calcd. for $(C_{14}H_{10}O_6)_n$: C, 61.31; H, 3.57.

The aqueous acid solution which had been extracted with ether was alkalized with strong potassium hydroxide and extracted repeatedly with chloroform. The combined extract was distilled to dryness and the residual amorphous base (6 g.) dissolved in warm dilute hydrochloric acid, the cooled solution filtered through charcoal and extracted with ether (discarded). The aqueous solution was alkalized with ammonia and repeatedly extracted first with ether (extract A) and then with chloroform (extract B). Extract A was evaporated to dryness and the residual oily base distilled *in vacuo*. It yielded the following: fraction I, b. p. 95–115° (0.4 mm.), a colorless oil, wt. 0.182 g.; fraction II, b. p. 130–155° (0.4 mm.), a yellowish oil, part of which crystallized on standing, wt. 0.163 g.; fraction III, b. p. 175–195° (0.4 mm.), a yellowish oil which crystallized on standing, wt. 0.61 g.; fraction IV, b. p. 200–215° (0.4 mm.), a thick, brownish oil, wt. 0.324 g.; fraction V, b. p. 215–220° (0.4 mm.), a thick brown oil, wt. 0.107 g., and an appreciable residue.

Isolation of *d*-Sparteine.—The colorless fraction I was dissolved in methanol and the solution added to a methanolic solution of picric acid. On cooling, a picrate sepa-

[5] All melting points are corrected.

rated which after two recrystallizations from boiling methanol was obtained as lemon-yellow prismatic needles, m.p. 208°.

Anal. Found: C, 46.68; H, 4.71; N, 16.19. Calcd. for $C_{15}H_{26}N_2 \cdot 2C_6H_3O_7N_3$: C, 46.81; H, 4.62; N, 16.18.

The melting point and analytical figures are in good agreement with those of *l*-sparteine dipicrate but the melting point was depressed by admixture with an authentic sample. The base was therefore recovered from some of the pure picrate, redistilled twice (b.p. 95–105° (0.3 mm.)) and used for the determination of the optical activity: $[\alpha]^{24}D$ +17.1° (c = 2.16 in absolute ethanol). The value $[\alpha]_D$ +16.3° (alcohol) is recorded in the literature.[6] The base recovered from the ethanol solution was divided into two portions. One portion was dissolved in methanol, the solution neutralized to congo red with 65% perchloric acid and diluted with ether to the point of incipient turbidity. On standing, the perchlorate separated in colorless needles forming feathery aggregates, m. p. 173°, which is almost identical with the melting point (171–172°) recorded for *d*-sparteine monoperchlorate. Furthermore, the salt can be extracted with chloroform from an ammoniacal aqueous solution, a property characteristic of sparteine monoperchlorate.[4]

Anal. Found: C, 53.70, 53.75; H, 8.32, 8.31; N, 8.58, 8.64. Calcd. for $C_{15}H_{26}N_2 \cdot HClO_4$: C, 53.83; H, 8.07, N, 8.37.

The second portion of the base employed for determining the optical rotation was dissolved in a little 10% hydrochloric acid and a slight excess of a 5% aqueous platinic chloride solution added. After concentration, the chloroplatinate separated as clusters of small flat orange needles which darkened at 253° and melted at 261° (dec.). This is in agreement with the behavior of *l*-sparteine chloroplatinate. In admixture with *l*-sparteine chloroplatinate the melting point was depressed.

Anal. Found: Pt, 29.08. Calcd. for $C_{15}H_{26}N_2 \cdot H_2PtCl_6 \cdot 2H_2O$: Pt, 28.69.

Isolation of N-Methylcytisine.—Fraction II was dissolved in methanol and converted to picrate. It yielded mostly *d*-sparteine dipicrate. Fraction III was also converted to picrate in methanol and added to the mother-liquor obtained from fraction II. The resulting solution when concentrated yielded a picrate which after two recrystallizations from boiling methanol was obtained as pale yellow needles melting at 192–193°, but after three more recrystallizations from the same solvent it melted at 234°. A sample of N-methylcytisine picrate reported by Manske and Marion[7] as melting at 193° was recrystallized several times from boiling methanol and found also to melt at 234° either alone or in admixture with the above picrate. The highest melting point recorded[8] so far for N-methylcytisine picrate is 229–230° (uncor.).

Anal. Found: N, 16.22, 16.27. Calcd. for $C_{12}H_{16}ON_2 \cdot C_6H_3O_7N_3$: N, 16.16.

The base recovered from the picrate was redistilled. It consisted of a thick straw-colored oil, b.p. 160–168° (0.6 mm.), which crystallized on standing. Recrystallized from ether–petroleum ether, it separated as colorless prismatic needles, m. p. 138°, either alone or in admixture with N-methylcytisine.

Anal. Found: C, 70.65; H, 7.95; N, 13.51. Calcd. for $C_{12}H_{16}ON_2$: C, 70.59; H, 7.84; N, 13.41.

A small quantity of the base was dissolved in methanol and the solution made just acid to congo red by the cautious addition of 65% perchloric acid. A perchlorate separated on standing which after recrystallization from methanol consisted of brilliant, colorless needles, m. p. 282°, either alone or in admixture with N-methylcytisine perchlorate.

Anal. Found: C, 47.15; H, 5.69. Calcd. for $C_{12}H_{16}ON_2 \cdot HClO_4$: C, 47.30; H, 5.58.

Isolation of Cytisine.—Fraction IV was combined with fraction V, dissolved in methanol and added to a methanolic solution of picric acid. A very small quantity of a picrate first separated which was filtered and, after several recrystallizations from methanol, consisted of small yellow platelets, m. p. 238°. This is further dealt with under alkaloid P_2. The mother-liquor from the above picrate deposited after some time a second crop of crystals. This second picrate was difficult to purify and after repeated recrystallization still consisted of a mixture. It was decomposed and the recovered base when distilled *in vacuo* yielded first a thick, colorless oil, b.p. 175–190° (0.35 mm.) which crystallized on cooling and then a crystalline fraction subliming at 190–200° (0.35 mm.). The first crystalline base melted at 154° and in admixture with cytisine at 155°.

Anal. Found: C, 69.52, 69.65; H, 7.24, 7.30. Calcd. for $C_{11}H_{14}ON_2$: C, 69.47; H, 7.37.

A small quantity of this base was converted to picrate in methanolic solution. After several recrystallizations the picrate was obtained as small, pale-yellow needles, m. p. 289.5°, either alone or after admixture with cytisine picrate.

Anal. Found: C, 48.64, 48.48; H, 4.30, 4.15; N, 16.71, 16.88. Calcd. for $C_{11}H_{14}ON_2 \cdot C_6H_3O_7N_3$: C, 48.68; H, 4.06, N, 16.70.

A small quantity of the base was converted to perchlorate. After recrystallization from boiling methanol, the salt melted at 298° either alone or after admixture with cytisine perchlorate.

Isolation of Alkaloid P_2.—The crystalline sublimate obtained in the course of the purification of cytisine melted at 293° and after two recrystallizations from methanol–ether melted at 300°. The quantity of base was so small that it was converted to perchlorate in order to increase the weight of product. The base perchlorate, after recrystallization from methanol, consisted of colorless needles, m. p. 198°.

Anal. Found: C, 46.05; H, 6.55; N, 9.67. Calcd. for $C_{11}H_{18}ON_2 \cdot HClO_4$: C, 44.83; H, 6.45; N, 9.51.

Insufficient material was available for a better characterization of alkaloid P_2. The picrate, m. p. 238°, isolated in the course of the purification of cytisine picrate could not be characterized fully owing to the small quantity of material on hand and a complete analysis was not possible. The incomplete analytical figures indicate that the picrate might be that of alkaloid P_2.

Anal. Found: C, 50.35, 50.20; H, 5.18, 5.12. Calcd. for $C_{11}H_{18}ON_2 \cdot C_6H_3O_7N_3$: C, 48.22; H, 4.96.

The chloroform extract B of the crude base was distilled to dryness, the residue distilled *in vacuo* and the various fractions (total wt. 1.0 g.) treated exactly as the similar fractions obtained from the ether extract A. It yielded further quantities of the bases already described.

Acknowledgment.—The authors wish to express their grateful indebtedness to the National Research Council of Canada for a Studentship awarded to one of them (J. O.) and to Professor Lionel Lemay, University of Montreal, who rendered the collaboration possible.

Summary

1. *Baptisia australis* (L.) R.Br. has been shown to contain four alkaloids, *i. e.*, N-methylcytisine, *d*-sparteine, cytisine and alkaloid P_2.

2. The first three of these alkaloids are already known. Alkaloid P_2, which could not fully be characterized, may be new.

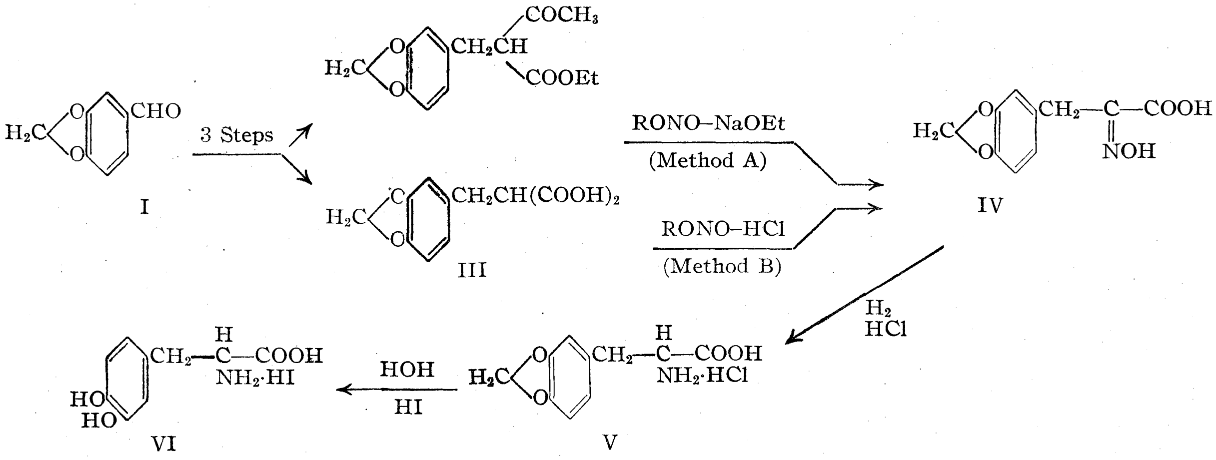
A New Synthesis of 3,4-Dihydroxyphenylalanine (Dopa)[1a]

BY RICHARD H. BARRY,[1b] ALBERT M. MATTOCKS[1c] AND WALTER H. HARTUNG

3,4-Dihydroxyphenylalanine (dopa) has been postulated as an intermediate in the biological synthesis of melanin[2] and epinephrine.[3,4] The *levo*-isomer may be isolated from the velvet bean[5] or prepared synthetically from *l*-tyrosine.[6] Many of the syntheses of *dl*-dopa and its derivatives[3,7a–c] are tedious and often give an impure product. Improvements in the azlactone synthesis from vanillin have been made by Harington and McCartney[7c] but the method is not entirely suitable for large scale preparations.

Previous work in this Laboratory has shown that α-amino acids can be conveniently prepared by the reduction of α-oximino acids.[8] The preparation of α-oximino acids from substituted acetoacetic and malonic esters and from substituted malonic acids[9] offered methods for preparing intermediates leading to the synthesis of dopa. It has been shown[9] that 3,4-substituted benzylacetoacetic esters, *e. g.*, 3,4-methylenedioxybenzylacetoacetic ester, are sensitive to a high concentration of acids and therefore cannot be nitrosated by the usual acid-catalyzed procedure.[8] When the nitrosation of 3,4-methylenedioxybenzylacetoacetic ester II was carried out in ethanolic sodium ethoxide with alkyl nitrite, a 60% yield of α-oximino β-(3,4-methylenedioxyphenyl)-propionic acid IV was obtained (Method A). A more satisfactory method for the preparation of IV is the nitrosation of 3,4-methylenedioxybenzylmalonic acid III with alkyl nitrite in the presence of hydrogen chloride (Method B). Yields from 85 to 90% were obtained consistently. Catalytic reduction of IV produced 3,4-methylenedioxyphenylalanine V, which was hydrolyzed with hydriodic acid to dopa-HI, VI. Slight discoloration of the dopa salt was noted after five or six days. 3,4-Methylenedioxyphenylalanine V, on the other hand, is quite stable over long periods and it is suggested that this intermediate amino acid be kept and converted into dopa as needed. Equations for the synthesis of dopa-HI, starting with piperonal[10] are shown



Experimental

3,4-Methylenedioxybenzylacetoacetic Ester (II).—This ester, b. p. 160–161 (4 mm.), was prepared in 61% yield in the usual manner from sodioacetoacetic ester and piperonyl chloride.[11]

3,4-Methylenedioxybenzylidenmalonic Ester.—Prepared according to the directions of Knoevenagel,[12] the ester distilled at 215–225 (8–10 mm.). The yield was 50%; if allowance was made for recovered piperonal, the yield was 87%.

3,4-Methylenedioxybenzylmalonic Acid (III).—A solution of 73 g. (0.25 mole) of 3,4-methylenedioxybenzylidenmalonic ester in 250 ml. of ethanol was shaken with 3 g. of 10% palladium–charcoal catalyst[13] in an atmosphere of hydrogen for three hours, when the theoretical quantity of hydrogen was taken up. The catalyst was removed by filtration, the 3,4-methylenedioxybenzylmalonic ester was not isolated but was converted into the acid by adding to the clear alcoholic filtrate 56 g. (1 mole) of potassium

hydroxide, refluxing and stirring for one hour. Distilled water (100 ml.) was then added, and the alcohol was removed by distillation. The resulting aqueous solution of the potasium salt was cooled to 0° by means of crushed ice, and dilute hydrochloric acid was added until the mixture was acid to congo red. The malonic acid was extracted with ether, the ether solution dried over anhydrous sodium sulfate, and 100 ml. of dry toluene was added. The ether was removed over a steam-bath and the residual toluene solution was cooled overnight. Fifty-three grams (89.5% yield) of 3,4-methylenedioxybenzylmalonic acid was removed by filtration. The colorless product melted[14] with evolution of gas at 143°. The previously reported melting point is 142–143°.[15]

α-Oximino-β-(3,4-methylenedioxyphenyl)-propionic Acid (IV): Method A.—In a 250-ml. 3-neck flask fitted with mechanical stirrer, reflux condenser and dropping funnel was placed 60 ml. of absolute ethanol in which was dissolved 2.3 g. of sodium. To the cooled and stirred solution was added 20.4 g. (0.1 mole) of 3,4-methylenedioxybenzylacetoacetic ester. To the flask, surrounded by a cold (10°) water-bath was added, with rapid stirring, 9.8 g. (0.11 mole) of isopropyl nitrite over a period of fifteen minutes. Stirring was continued for thirty minutes after addition of the nitrite, then the ethanol and isopropanol were removed under reduced pressure at 50°. Crushed ice (35 g.) was added to the residue and the mixture carefully acidified with 6 *N* sulfuric acid, then extracted with ether. The ether solution was then thoroughly extracted with cold 10% sodium hydroxide solution. The alkaline extract was warmed on the steam-bath for fifteen minutes, then chilled and carefully acidified with dilute hydrochloric acid. The α-oximino acid was filtered off, decolorized in hot 30% ethanol with Nuchar and recrystallized from dilute ethanol. The colorless crystalline product melted at 160°. The yield was 62%.

Anal. Calcd. for $C_{10}H_9O_5N$: N, 6.2. Found: N, 6.3 (Kjeldahl).

Method B.—In a beaker surrounded by an ice–salt mixture was placed a solution of 5.6 g. (0.024 mole) of piperonylmalonic acid in 100 ml. of ether, and to it was added 2.2 g. (0.025 mole) of isopropyl nitrite. Dry hydrogen chloride was passed into the stirred mixture at the rate of two to three bubbles per second for about one hour. The reaction mixture, now yellow in color, was allowed to stand at room temperature for four hours, then warmed on the steam-bath until the solvents had evaporated. The residue was dissolved in hot toluene, and the solution was allowed to cool in the ice-box. The colorless crystals of the oxime were collected and dried over sulfuric acid *in vacuo*. A yield of 4.7 g. (89%) of product melting at 160° was obtained.

3,4-Methylenedioxyphenylalanine Hydrochloride (V).—To 7 g. (0.031 mole) of the oxime IV, dissolved in 100 ml. of absolute alcohol containing 2 g. of hydrogen chloride, was added 3 g. of 10% palladium catalyst. The mixture was hydrogenated at atmospheric pressure, the theoretical quantity of hydrogen being taken up in two and one-half hours. The catalyst was removed, the filtrate was concentrated to about 50 ml. under reduced pressure, and 200 ml. of dry ether was added with stirring. Cooling of the ether–alcohol solution produced 6.4 g. (92%) of colorless crystals of 3,4-methylenedioxyphenylalanine hydrochloride which melted at 284° with decomposition.

Anal. Calcd. for $C_{10}H_{11}O_4N{\cdot}HCl$: N, 5.38. Found: N, 5.30 (Kjeldahl).

3,4-Dihydroxyphenylalanine Hydriodide (VI).—In fifty milliliters of hydriodic acid (sp. gr. 1.49) was dissolved 7.4 g. (0.03 mole) of 3,4-methylenedioxyphenylalanine hydrochloride, and the mixture was refluxed for two hours. Toluene (200 ml.) was then added, a Dean–Stark trap equipped with stopcock outlet for removal of the water was inserted between the flask and reflux condenser and the mixture refluxed until no more water collected in the trap (three to four hours). The toluene solution of the dopa-hydriodide was allowed to cool overnight in the ice-box and the amino acid filtered off. The crystals were colorless and did not darken while being dried *in vacuo* over sulfuric acid. The acid melted at 201° (d.)[16] and gave a dark green color with ferric chloride. The yield of dopa-hydriodide was 4.1 g. (88%).

Anal. Calcd. for $C_9H_{11}O_4N{\cdot}HI$: N, 4.32. Found: N, 4.27 (Kjeldahl).

Summary

1. A practical synthesis of *dl*-3,4-dihydroxyphenylalanine (dopa) has been developed.

2. 3,4-Methylenedioxybenzylacetoacetic ester and 3,4-methylenedioxybenzylmalonic acid were nitrosated to give α-oximino β-(3,4-methylenedioxyphenyl)-propionic acid, which was reduced catalytically to give 3,4-methylenedioxyphenylalanine in good yield. The latter was converted into *dl*-dopa by hydrolysis with hydriodic acid.

BALTIMORE, MARYLAND RECEIVED AUGUST 20, 1947

The Preparation of Raney Nickel Catalysts and their Use Under Conditions Comparable with Those for Platinum and Palladium Catalysts

BY HOMER ADKINS AND HARRY R. BILLICA[1]

It has been the practice in this and many other laboratories to use a platinum or palladium catalyst if a hydrogenation was to be carried out in glass apparatus at room temperatures. However, improvements in the procedure for the preparation of a catalyst from the Raney nickel–aluminum alloy now makes available a catalyst which appears to be approximately as effective as platinum or palladium for catalysis of hydrogenation at pressures of 45 p. s. i. or lower. It is not implied that any of the three metals is lacking in characteristics which make it uniquely useful. For example, the inactivity of palladium against benzenoid nuclei and nitriles and its relative inactivity toward aldehydes make this catalyst particularly useful in certain selective hydrogenations. Platinum and nickel are more alike in activity in that both, under suitable conditions, are effective against almost all types of carbon-to-carbon double bonds, aldehydes, ketones, nitriles, nitro compounds and oximes. Each of them is preferred to the other for certain situations.

The activity of Raney nickel catalysts under mild conditions has been recognized for some time. In our first publication,[2] its effectiveness at low pressure and room temperature was illustrated with results obtained with styrene, acetone, mesityl oxide and acetoacetic ester among other compounds. G. B. L. Smith and his associates[3] have reported on the effectiveness of Raney nickel with and without a platinum promoter particularly for the hydrogenation of nitro compounds. However, it seemed that the Raney nickel catalysts available were not particularly useful at room temperature, except in the hydrogenation of alkene linkages.

The most active nickel catalyst now known to us is one to which we refer as "W-6 Raney nickel,"[4] It is made by a procedure given later in this paper. The modifications of earlier procedures consist in rapidly carrying out the removal of aluminum from the Raney alloy at a lower temperature and in washing the catalyst under pressure of hydrogen. The use of hydrogen under pressure in the washing process may be advantageous in that it protects the catalyst from contact with air and the loss of the rather large quantity of hydrogen which is adsorbed on the catalyst.

There is summarized in the table the results of applying the W-6 Raney nickel catalyst to the hydrogenation of a variety of organic compounds. The hydrogenations were carried out in glass under the conditions normally used with platinum and palladium catalysts. The absorption of hydrogen was in every experiment within ±4% of that required for the formation of the compounds reported in the last column of the table. Except as noted under the table the hydrogenations went quantitatively to a single product.

Compounds containing a carbon–carbon double bond such as cinnamic acid, ethyl cinnamate and diethyl isopropylidenemalonate, were very rapidly hydrogenated in three to ten minutes to the corresponding saturated compound. Stearolic acid was converted into elaidic acid within less than two minutes. The elaidic acid was then much more slowly converted to stearic acid. Thus it is possible with the W-6 catalyst to selectively hydrogenate an alkyne to an alkene linkage.

Representative aldehydes and ketones were rapidly hydrogenated to the corresponding alcohols. It was found that the addition of a little triethylamine to the reaction mixture approximately cut in half the time required for the hydrogenation of an aldehyde or ketone. Thus through the use of W-6 catalyst with triethylamine all of the aldehydes and ketones tested were hydrogenated to the corresponding alcohol within less than forty minutes, while some of them reacted much more rapidly. The presence of triethylamine retards the hydrogenation of a benzenoid nucleus so that even with a naphthyl ketone there is no danger of hydrogenating the nucleus.

The W-6 catalyst is not only effective against alkene, alkyne and carbonyl linkages, but will also bring about the hydrogenation of benzenoid and pyridinoid nuclei. Diphenyl, hydroquinone, β-naphthol, methyl β-naphthylcarbinol and β-phenylethanol were hydrogenated although more slowly than the types of compounds referred to just above. However, as is shown in the case of hydroquinone, the rate of hydrogenation can be greatly increased through the use of higher ratio of catalyst to compound undergoing hydrogenation. The hydrogenation of the pyridinoid ring in quinoline went rapidly. The hydrogenation of the compounds containing two unsaturated rings was selective, in that under the conditions used only one ring was hydrogenated. The W-6 catalyst was also effective in bringing about a hydrogenolysis of benzhydrol, but not without hydrogenation.

The W-6 catalyst was effective in catalyzing the hydrogenation of nitriles such as benzyl cyanide and stearonitrile. The proportion of primary and secondary amine produced from benzyl cyanide was similar to that observed in a high

pressure hydrogenation in the absence of ammonia. However, there was no secondary amine formation in the hydrogenation of stearonitrile.

p-Nitrotoluene was converted smoothly and rapidly into *p*-toluidine of excellent quality. The reduction of a nitro group is so exothermic a reaction that precautions must be taken to keep the reaction under control. This is particularly important when a catalyst so active as W-6 is used. As indicated below, there is danger in the use of W-6 Raney nickel under certain circumstances.

The oximino groups in a simple oxime, in an oximinoketone and in an oximinoketo ester were smoothly and rather rapidly hydrogenated to the primary amine group. The keto groups were also hydrogenated to alcohol groups, but the carboethoxy group was stable at the low pressure. Under higher pressure, as will be described in a later paper, the W-6 catalyst catalyzes the conversion of carboethoxy to carbinol.

An alkaline catalyst, referred to as W-7 Raney nickel, has given good results in hydrogenating

7.4 Cinnamic acid	0	10	β-Phenylpropionic acid
7.0 Stearolic acid	2	0	Stearic acid, m. p. 67–70°, b. p. 188–190° (1 mm.)
7.0 Stearolic acid	0	2	Elaidic acid, m. p. 42–45°, b. p. 185–187° (1 mm.)
10.0 Diethyl isopropylidene malonate	0	8	Diethyl isopropylmalonate, b. p. 74–76° (3 mm.), $n^{22}\mathrm{D}$ 1.4186; acid, m. p. 86.5–87.5°
5.2 Diphenyl[c]	6	0	Phenylcyclohexane, b. p. 125–128° (30 mm.), $n^{25}\mathrm{D}$ 1.5210
5.5 Hydroquinone	36	0	1,4-Cyclohexanediol, needles, m. p. 98.5–101°[d]
5.5 Hydroquinone[c]	8	0	1,4-Cyclohexanediol
6.1 β-Phenylethanol[c]	96	0	β-Cyclohexylethanol, b. p. 118–120° (36 mm.), $n^{25}\mathrm{D}$ 1.4700; phenylurethan, m. p. 119.5–120.5°
7.2 β-Naphthol	4	0	1,2,3,4-Tetrahydro-2-naphthol (27%), b. p. 118–120° (3 mm.), insoluble in alkali. 5,6,7,8-Tetrahydro-2-naphthol (55%), b. p. 114–116° (3 mm.), soluble in alkali
9.2 Diphenylcarbinol	27	0	$\left\{\begin{array}{l}\text{Diphenylmethane}\\ \text{Benzylcyclohexane}\end{array}\right\}$ b. p. 90–100° (3 mm.), $n^{25}\mathrm{D}$, 1.5600[e]
8.5 β-Acetylnaphthalene	45	0	Methyl-β-tetrahydronaphthylcarbinol[f]
5.9 Benzyl cyanide	1	6	β-Phenethylamine (72%), b. p. 106–107° (37 mm.), $n^{25}\mathrm{D}$ 1.5306; picrate, m. p. 173–174° Di-(β-phenethyl) amine (15%), b. p. 215–220° (38 mm.), $n^{25}\mathrm{D}$ 1.5521; picrate, m. p. 150–151.5°
6.7 Stearonitrile	5	0	*n*-Octadecylamine, b. p. 146–154° (2 mm.), m. p. 51.5–53°; picrate, m. p. 116°; hydrochloride, m. p. 159–161°
6.9 *p*-Nitrotoluene	0	13	*p*-Toluidine, b. p. 107–109° (33 mm.), m. p. 43–44°; picrate, m. p. 179.5–180.5° (dec.)
5.7 Cyclohexanone oxime	0	45	Cyclohexylamine (90%), b. p. 48–52° (30 mm.), $n^{25}\mathrm{D}$ 1.4569; hydrochloride, m. p. 204–206°
8.2 α-Oximinopropiophenone	3	30	2-Amino-1-phenyl-1-propanol, m. p. 99–103°; hydrochloride, m. p. 189–191°; oxalate, m. p. 243–244.5°[g]
8.0 Ethyl α-oximinoacetoacetate	1	20	Ethyl α-amino-β-hydroxybutyrate, b. p. 82–84° (2 mm.), $n^{25}\mathrm{D}$ 1.4495[h]
6.5 Quinoline	0	50	1,2,3,4-Tetrahydroquinoline, b. p. 85–86° (2 mm.), $n^{25}\mathrm{D}$ 1.5910; hydrochloride, m. p. 179–181°

[a] The hydrogenations were carried out at room temperature (25–30°) under a pressure of 15 to 45 p. s. i. in a 250-ml. glass centrifuge bottle shaken at 172 r. p. m. The reaction mixture was made up to a volume of 100 ml. with dry ethanol and contained 2 g. of W-6 Raney nickel, except as noted below. [b] The reaction mixture contained 2 ml. of triethylamine. [c] Nine grams of W-6 Raney nickel was used. [d] Other work has shown the product to be a mixture of the *cis* and *trans* isomers in approximately equal proportions. [e] This value indicates approximately three parts of diphenylmethane and one part benzylcyclohexane. [f] The compound is an alcohol, b. p. 119–119.5° (2 mm.), $n^{25}\mathrm{D}$ 1.5484, $d^{25°}$ 1.0408, M_{R} calcd. 53.33, found 53.3. Phenylurethan, m. p. 230–231.5°. *Anal.* Calcd. for $C_{12}H_{16}O$: C, 81.8; H, 9.14. Found: C, 81.6; H, 9.08. The position of the hydrogens added is not known. [g] A mixture of stereoisomers. [h] The yield of a mixture of stereoisomers was low, probably because of the formation of a piperazine during distillation of product.

ketones, phenols and nitriles, for which alkali in the reaction mixture is beneficial.[5,6] The catalyst is attractive because of the simplicity of the procedure used in washing it. It was somewhat less active than W-6 toward diphenyl and benzyl cyanide, but the proportion of primary to secondary amine was increased. The W-7 catalyst was somewhat more active toward acetophenone than W-6 without triethylamine. The catalyst was remarkably active toward hydroquinone, giving complete hydrogenation within fifteen minutes instead of in eight hours as with W-6.

Preparation of W-6 Raney Nickel Catalyst

WARNING.—The Raney nickel catalysts described below have given reactions proceeding with violence. In one case a hydrogenation proceeding at 125° at 5000 p. s. i. showed a pressure rise to considerably more than 10,000 p. s. i. before the reaction could be stopped or the pressure released. Several instances of sudden increases in pressure have been noted when quantities of catalyst of the order of 10 to 15 g. were being used in the temperature range of 100 to 150° under 5,000 p. s. i. The high activity of the catalysts and the presence of aluminum and rather large amounts of adsorbed hydrogen make it advisable to be *very cautious in their use.* No difficulty has been encountered at temperatures below 100°. Hydrogenations may be carried out safely above 100° if the ratio of catalyst to possible reactants is kept low, *e. g.*, 5% as much nickel as weight of hydrogen acceptor.

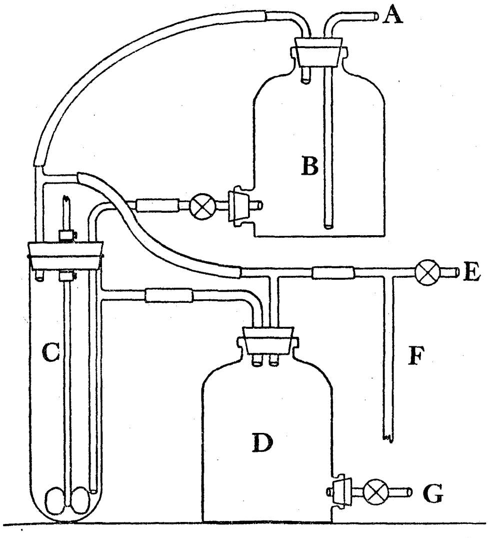

Fig. 1.—Apparatus for washing catalyst: A, distilled water inlet; B, reservoir for distilled water; C, chamber for washing catalyst; D, overflow bottle; E, hydrogen inlet; F, manometer; G, water outlet. It is more convenient to have the inlet tube for wash water sealed into the bottom of the chamber rather than introduced through the stopper as shown.

Procedure.—In a two-liter Erlenmeyer flask equipped with a thermometer and a stainless steel stirrer, is placed 160 g. of sodium hydroxide in 600 ml. of distilled water. The rapidly stirred solution is allowed to cool to 50° in an ice-bath equipped with an overflow siphon. Then 125 g. of Raney nickel–aluminum alloy is added in small portions over a period of twenty-five to thirty minutes. The temperature is maintained at 50 ± 2° by controlling the rate of addition of alloy to the sodium hydroxide and of ice to the cooling bath. When all the alloy has been added, the suspension is digested at 50° for fifty minutes with gentle stirring. It is usually necessary to remove the ice-bath and replace with a hot water-bath. The catalyst, after digestion, is washed three times by decantation and then transferred immediately to the washing tube for further washing.

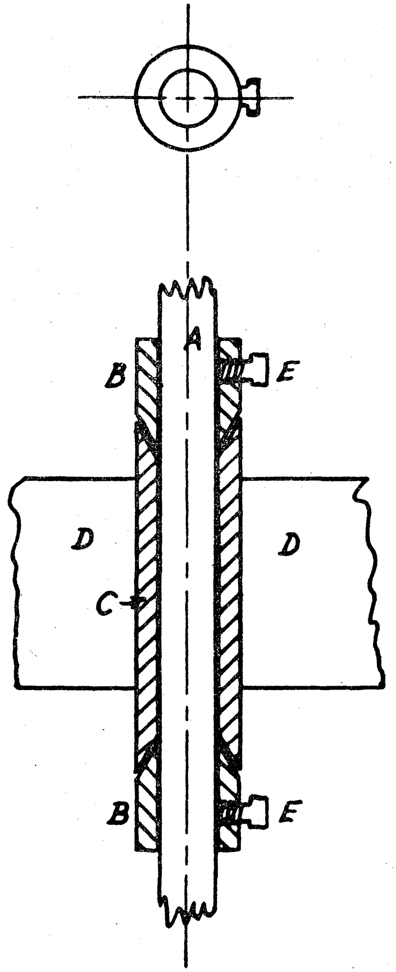

Fig. 2.—Gas tight bushing: The gas tight bushing for the shaft of the stirrer consists of three parts; two cones (B) which fit the shaft snugly and are attached to it by set screws (E); and a bushing (C) so cut that the cones fit into it at top and bottom. The two cones are placed on the 0.25 inch shaft (A) of the stirrer, above and below the bushing and attached to the shaft so that they fit snugly against the bushing. A gas-tight seal is obtained by placing a drop or two of heavy lubricating oil between each cone and the bushing. The over-all dimensions of the bushing are approximately 13 × 65 mm. and it is held in a rubber stopper (D).

[6] Fluchaire and Chambert, *Bull. soc. chim.*, **11**, 22 (1944).

A glass test-tube, approximately 5.1 cm. in diameter and 38 cm. in length, with a side arm 6 cm. from the top, is used as the container in washing the catalyst. The tube is equipped with a snugly fitting rubber stopper which is held in place by a suitable device. The stopper carries a gas tight bushing (Fig. 2) through which the 0.25-inch shaft of a stainless steel stirrer projects to the bottom of the washing tube. A 5-liter reservoir for distilled water is so placed that water will flow from it through a stopcock down a glass tube, 8 mm. in diameter, which passes through the stopper and down the side of the washing tube to its bottom. The side arm of the test-tube is connected by rubber tubing to a 5-liter overflow bottle from which the water may be allowed to flow through a stopcock to the drain. A connection from a source of distilled water is made to the reservoir. All connections of rubber and glass tubes should be so fastened that they will withstand the pressures used. The general arrangement of the apparatus is shown in Fig. 1, while certain details of construction are given in Fig. 2.

The catalyst sludge is immediately transferred to the washing tube after the third decantation. The last portions are rinsed from the flask into the tube with distilled water and the tube and reservoir nearly filled with distilled water. The apparatus is then rapidly assembled, and hydrogen introduced so that the water in the reservoir, washing tube and overflow bottle is under a pressure about 0.5 atm. above that of the outside atmosphere. The stirrer is operated at such a speed that the catalyst is suspended to a height of 18–20 cm. Distilled water from the reservoir is allowed to flow through the suspended catalyst at a rate of about 250 ml. per minute. When the reservoir is nearly empty and the overflow bottle full, the drain cock and distilled water inlet are simultaneously opened to an equal rate of flow such that, as the overflow bottle empties, the reservoir is filled, while the pressure in the system remains constant.

After about 15 liters of water has passed through the catalyst, the stirrer and the water are stopped, the pressure released and the apparatus disassembled. The water is decanted from the settled sludge, which is then transferred to a 250 ml. centrifuge bottle with 95% ethanol. The catalyst is washed three times by stirring, not shaking, with 150 ml. of 95% ethanol, centrifuging after each addition. In the same manner, the catalyst is washed three times with absolute ethanol. One to two minutes centrifugation at 1500–2000 r. p. m. is sufficient to separate the catalyst. All operations should be carried out as rapidly as possible if a catalyst of the maximum activity is desired. The catalyst should be stored in a refrigerator in a closed bottle filled with absolute ethanol. The total elapsed time from the beginning of the addition of the alloy to the completion of the preparation, with the catalyst in the refrigerator, should be not more than about three hours.

The volume of the settled catalyst in ethanol is about 75–80 ml. containing about 62 g. of nickel and 7–8 g. of aluminum. It amounts to about twenty-eight "half teaspoonsful" if it is so measured. The catalyst loses some of its special activity upon standing, but seems to be quite active for about two weeks when stored in a refrigerator. After this period it is similar in activity to the Raney nickel made by earlier procedures. The W-3 to W-7 catalysts all lose their special activity rather rapidly when stored under water.

The procedure for the preparation of W-5 Raney nickel, a somewhat less active, but nevertheless excellent catalyst, is the same as that for W-6, except that it is washed at atmospheric pressure without the addition of hydrogen to the system. The W-5 catalyst is similar in method of preparation and activity to the W-4 Raney nickel catalyst as prepared by Pavlic.[4,7] The procedure in the preparation of W-7 Raney nickel, after the digestion and the three decantations, is to transfer the catalyst to a 250 ml. centrifuge bottle with 95% alcohol. It is then washed three times by stirring, not shaking, with 150 ml. of 95% ethanol, centrifuging after each addition. In the same manner, the catalyst is washed three times with absolute ethanol.

Summary

A procedure has been described for the preparation of Raney nickel catalysts, which are useful at room temperatures and low pressures, for the catalysis of the hydrogenation of alkyne and alkene linkages, aldehydes, ketones, nitro compounds, nitriles, oximes and benzenoid and pyridinoid nuclei. While the amount of catalyst required for a given rate of hydrogenation is higher than for platinum and palladium catalysts, it appears that a properly prepared Raney nickel catalyst is effective under as mild conditions of temperature and pressure as are the noble metals. It appears that, under the conditions normally used for the platinum and palladium catalysts, the W-6 Raney nickel catalyst is more selective in action than at higher pressures and temperatures. For example, stearolic acid was converted within two minutes to elaidic without significant reduction of the latter to stearic acid. It has been found that the addition of a small amount of triethylamine to a reaction mixture markedly increases the rate of hydrogenation of aldehydes and ketones over Raney nickel.

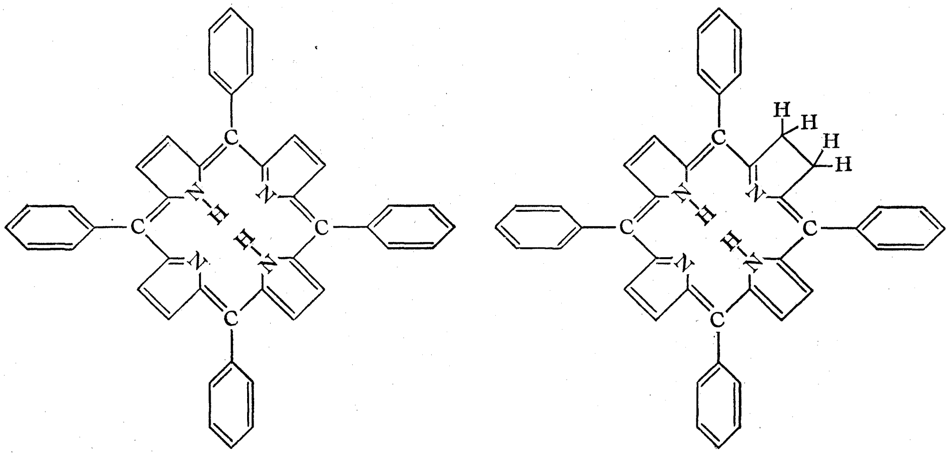
The Possibility of a Triplet State Intermediate in the Photo-oxidation of a Chlorin

BY M. CALVIN AND G. D. DOROUGH[1]

As part of a rather routine examination of the spectra of a number of tetraphenyl porphin and chlorin compounds (see Fig. 1), the zinc salt of tetraphenyl chlorin was prepared and dissolved in benzene. The solution at first was green in color and showed an intense red fluorescence, but upon standing a few hours this fluorescence died out, and the color of the solution changed from green to yellow. The cause of this curious phenomenon was attributed to a light induced oxidation by molecular oxygen, since it was found that benzene solutions of zinc tetraphenyl chlorin were quite stable if either light or air were excluded, or if the air were replaced by carbon dioxide.



a. Tetraphenyl porphin b. Tetraphenyl chlorin

Fig. 1.

The spectrum of such a degraded zinc chlorin solution is given in Fig. 2. This spectrum, upon reference to the spectra of the zinc complexes of porphin and chlorin (Fig. 3), indicates that some of the zinc chlorin still remains, as evidenced by the remnants of a band at about 6200 Å., that some zinc porphin has been formed, as evidenced by a band at 5500 Å. and that some new substance or substances have been formed, as shown by the high absorption in the region 4650 Å., a region where neither porphin nor chlorin have any appreciable absorption. These conclusions were substantiated by removing the zinc from a sample of the photoöxidation product upon which the spectrum had been run, and chromatographing the resulting free base. Found were tetraphenyl porphin and tetraphenyl chlorin and two substances which appeared as dark blue layers on the talc. No attempt was made to identify these blue materials.

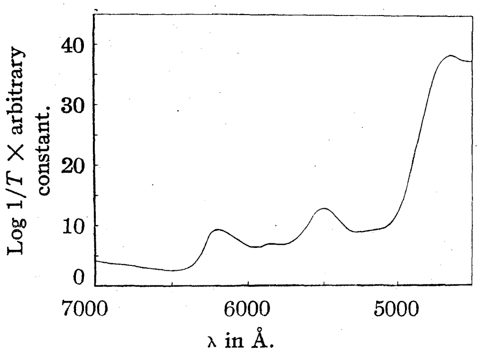


Fig. 2.—Oxygen-degraded zinc chlorin (in benzene).

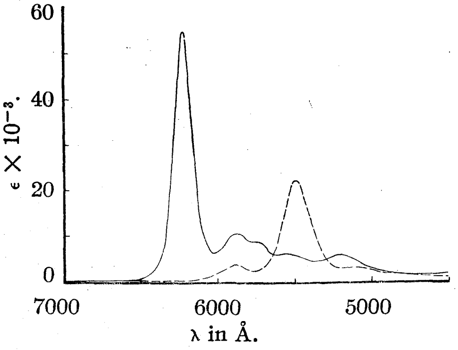

Fig. 3.—Absorption spectra of zinc complexes in benzene: — — — — —, tetraphenylporphin; ————, tetraphenyl chlorin.

The establishment of a photochemical conversion of chlorin to porphin by molecular oxygen prompted similar experiments with other oxidizing agents. In contrast to the oxygen reaction which gave several products, it was found that a

---

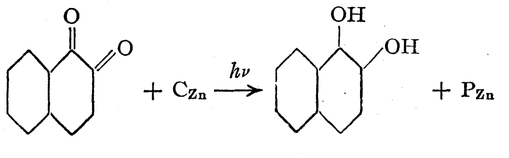
number of ortho and para quinones (*p*-benzo, 1,2-naphtho, 1,4-naphtho, and 9,10-phenanthro) in a deoxygenated benzene solution of zinc tetraphenyl chlorin gave quantitatively with light a single product—zinc tetraphenyl porphin. This latter reaction was thus considered to be of the following type where C_{Zn} and P_{Zn} represent zinc tetraphenyl chlorin and porphin, respectively. It was observed further that para quinones as a class seemed to react more slowly than the ortho quinones. Such a result is not unreasonable, for one might very well expect from spatial considerations alone that an ortho quinone might react in a simple bimolecular manner with the simultaneous removal of both hydrogens from the chlorin, while a para quinone could not sterically do so.

(Illustrating with
β-naphthoquinone):



The cleanness of the oxidation of zinc chlorin by the quinones led to a very detailed study of the reaction with one of them, β-naphthoquinone. The reaction was followed by measuring the simultaneous decrease and increase in absorption at 6212 Å. and 5500 Å., respectively, due to the disappearance of chlorin and the formation of porphin as the reaction proceeds (see Fig. 3). By modifying a Beckman spectrophotometer to permit thermostating, it was possible to run the reaction right in this instrument, using the tungsten light of the Beckman both for illumination of the solution and for the measurement of absorption. From rate studies carried out in this manner and other related experiments, it was possible to establish the following facts (see experimental section for details): (1) β-naphthoquinone reacts with zinc tetraphenyl chlorin to give zinc tetraphenyl porphin and β-naphthohydroquinone. (2) Light is required for the reaction—more particularly, only light that is absorbed by the chlorin is required, for illumination was always carried out at 6212 Å. where the naphthoquinone and the zinc porphin have no appreciable absorption. (3) Traces of oxygen inhibit the reaction, *i. e.*, cause the rate to be slower without reacting with the chlorin. (4) The rate of the reaction is independent of the naphthoquinone concentration down to a value of 1.8×10^{-6} *M;* the quantum yield corresponding to this rate is about 0.02. (5) The function of chlorin concentration, $(C_{Zn}) + \log A/\Sigma d$, gives a straight line when plotted against time. (6) The reaction rate increases with decreasing temperature. (7) The reaction rate is directly proportional to the light intensity. (8) There is no evidence for complex formation between the quinone and the chlorin. (9) An ortho quinone of lower oxidation–reduction potential, phenanthro, behaves in a manner identical to the above, but with a rate a factor of three smaller.

The primary step in this reaction must be the absorption of a 6212 Å. photon to give a chlorin molecule excited to the first electronic state. Furthermore, it would appear that the quinone does not react with this excited state, for if it did the rate would be proportional to the quinone concentration. This is due to the fact that the quantum yield is only 2%, and thus 98% of the excited chlorin molecules must be deactivated by a number of processes, fluorescence, solvent and wall deactivation, etc., and it is apparent that if the reaction with quinone were competing with these processes, then the probability of a reaction and thus the rate would increase with increasing quinone concentration. But this is not so; the reaction is independent of the quinone concentration down to a very small value. Thus, if the quinone does not react with the ground state, and does not react with the excited state, then one is forced to the conclusion that it reacts with some intermediate state which is only obtainable from the excited state.

We have considered this intermediate state to be the phosphorescent state, partly because of the ease with which such an assumption will explain the known facts. Figure 4 shows an energy level diagram of this state in relation to the ground and excited states. Now the ground state is a singlet state, that is, there are no unpaired electrons. Since transitions between states of different multiplicity are of low probability, the excited state must also be a singlet, for this transition is obviously of high probability (the extinction coefficient is high). G. N. Lewis[2,3,4] has considered the phosphorescent state to be of a different multiplicity, namely, a triplet state, and accounts for the slow emission of light to the ground state, *i. e.*, phosphorescence, by the low transition probability between these two states. The S′-T transition (dotted line) is a non-radiative transfer, which not being bound by the usual selection rules permits the transition to occur during the very short life time of the S′ state, about 10^{-9} seconds.

Experiments established that zinc tetraphenyl chlorin had a phosphorescence at about 8000 Å. (see Fig. 5) and an intrinsic lifetime of the triplet state of about 8×10^{-3} seconds. If one assumes that every molecule which gets into the triplet state reacts with quinone, then the rate would be independent of the quinone concentration down to the point where the time between collisions became so large as to allow other deactivating processes to occur. Collision number calculations based on the gas laws showed that a triplet state chlorin would, on the average, make an effective collision with quinone in about 10^{-5} second if the quinone concentration were at the point where

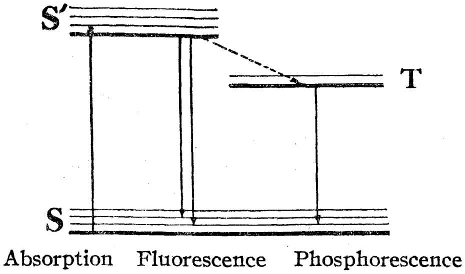

Fig. 4.—Energy level diagram.

quinone independence was experimentally observed to break down. That a triplet state molecule with an intrinsic lifetime of nearly a hundredth of a second could last more than 10^{-5} second in a media where solvent deactivation is inefficient is indeed reasonable.

The inhibitory effect of the oxygen could be accounted for by its paramagnetism. If an excited molecule such as a triplet state chlorin is placed in an inhomogeneous magnetic field, it will radiate due in effect to the breakdown of the selection rules forbidding the transition. Thus a triplet state chlorin approached closely by an oxygen would have a very large probability of being deactivated by radiation to the ground state, due to the magnetic field associated with the oxygen molecule. Thus an observed decrease in the rate of the reaction in the presence of small amounts of oxygen is explained.

The increase in the rate of the reaction with decreasing temperature is not in disagreement with a triplet state mechanism, but neither can it be said that it supports it. What the observation means is that the probability of the S′–T non-radiative transition is increased with decreasing temperature. The direction of change of this probability with temperature depends upon the relative positions of the two states and shapes of their representative potential energy curves, especially at their crossing point. The change may be in either direction.

A mechanism for this reaction may be summarized as

$$C_{Zn} + h\nu \xrightarrow[k_1]{} C^{S'}{}_{Zn} \qquad (1)$$

$$C^{S'}{}_{Zn} \xrightarrow[k_4]{} C_{Zn} + (h\nu \text{ or } kT) \qquad (4)$$

$$C^{S'}{}_{Zn} \xrightarrow[k_2]{} C^{T}{}_{Zn} \qquad (2)$$

$$C^{T}{}_{Zn} + Q \xrightarrow[k_3]{} P_{Zn} + H_2Q \qquad (3)$$

$$C^{T}{}_{Zn} + Q \xrightarrow[k_5]{} C_{Zn} + Q + kT \qquad (5)$$ [5]

k_1 is the primary absorption act

k_2 is the transition from excited singlet to the triplet state

k_3 is the reaction of triplet state molecules with quinone leading to oxidation to porphin

k_4 is the deactivation of excited singlet states by all processes leading to the ground state (fluorescence and thermal deactivation by solvent)

k_5 is the thermal deactivation of triplet state molecules by quinone leading back to ground state chlorin molecules.

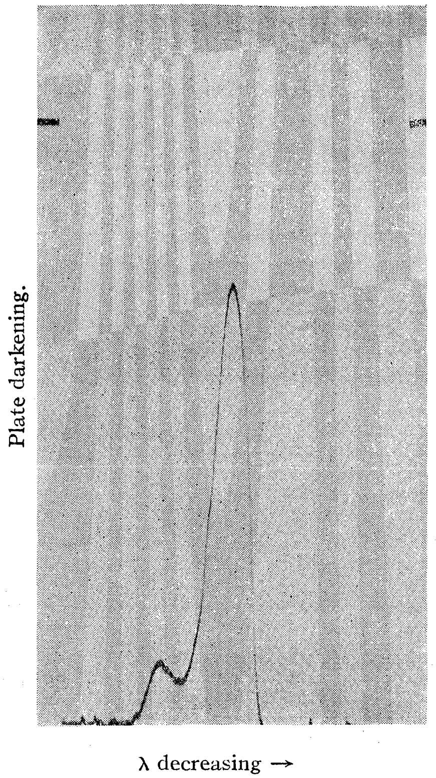

Fig. 5.—Tracing of spectrographic plate showing phosphorescence of zinc tetraphenylchlorin. Peak positions are at approximately 8000 Å. for the tall peak and 9000 Å. for the second peak.

The net rate of disappearance of Zn chlorin is given by

$$-\mathrm{d}(C_{Zn})/\mathrm{d}t = k_3(C^{T}{}_{Zn})(Q) \qquad (6)$$

The steady state expression for $C^{S'}{}_{Zn}$ molecules is

$$K_a I_{\text{absorbed}} = (k_2 + k_4)(C^{S'}{}_{Zn}) \qquad (7)$$

where K_a is a unit conversion factor involving the volume of solution and Avogadro's number to convert photons absorbed per second into moles of photons per liter absorbed per second. And the steady state expression for $C^{T}{}_{Zn}$ molecules is

$$k_2(C^{S'}{}_{Zn}) = k_3(C^{T}{}_{Zn})(Q) + k_5(C^{T}{}_{Zn})(Q) \qquad (8)$$

Combining (7) and (8) for $(C^{T}{}_{Zn})$ and substituting in (6), we have

$$\frac{-\mathrm{d}(C_{Zn})}{\mathrm{d}t} = \frac{k_2}{k_2 + k_4} \times \frac{k_3}{k_3 + k_5} \times K_a I_{\text{abs}} \qquad (9)$$

I_{abs} may be expressed in terms of Beer's and Lambert's law

$$I_{\text{abs}} = I_0 A = I_0(1 - 10^{-\Sigma C_{Zn} d})$$

where I_0 is the impinging light intensity, A is the fraction of the impinging light absorbed, Σ is the molar extinction coefficient for the wave length band used in these experiments, and Σ is the thickness of the solution through which the light passes.

Now it is also readily seen that $k_2/(k_2 + k_4)$ represents the quantum yield of the triplet state,

---

(5) This step was suggested to us by Prof. G. Rollefson and Mr. F. Hueunekens.

and that $k_3/(k_3 + k_5)$ represents the fraction of the triplet state molecules going to porphin. Thus

$$\frac{k_2}{k_2 + k_4} \times \frac{k_3}{k_3 + k_5} = \gamma$$

the quantum yield for the over-all reaction. Using these substitutions in (9) we have

$$-\mathrm{d}(C_{Zn})/\mathrm{d}t = \gamma K_a I_0(1 - 10^{-\Sigma C_{Zn} d})$$

which upon integration gives

$$(C_{Zn}) + \frac{1}{\Sigma d} \log A = \gamma K_a I_0 t + \pi \text{ (integration constant)} \qquad (10)$$

All of our runs showed excellent straight line agreement when the left side of equation (10) was plotted against time.

Another piece of evidence supporting this mechanism was provided by experiments with the copper salt. It was predicted that the copper salt of tetraphenyl chlorin would have a very short lived triplet state due to the magnetic field resulting from the odd electron in the copper orbitals. As a result, it was predicted that copper chlorin, if it reacted with quinone at all, should react very slowly. Experiments were run to test these predictions. It was found that the phosphorescence was so short lived as to be beyond the scope of the phosphoroscope used, which means a life of less than 10^{-5} second. A rate run with copper chlorin and β-naphthoquinone showed the rate to be considerably less than one hundredth that of zinc chlorin. In view of the close chemical similarity between copper and zinc chlorin, and the ease with which the copper chlorin is oxidized by other reagents, we feel this is supporting evidence for the triplet state mechanism.

From equation (9) it is apparent that although the rate of the reaction is independent of the quinone concentration, it is not independent of which quinone is used. The ratio $k_3/(k_3 + k_5)$ will be a characteristic of the quinone used, and increases with the oxidation potential of the quinone and is larger for the ortho quinones than it is for the para quinones. It is interesting to point out the parallelism of these results with those reported by Aronoff[6] on the production of oxygen by illuminated grana using a series of quinones as hydrogen acceptors.

If this reaction of zinc tetraphenyl chlorin is characteristic of the chlorin ring in general, then it may be that the knowledge gained from this reaction may find application in the study of photosynthesis. Using a sample of what we believed to be a pure mixture of chlorophylls *a* and *b*, we found[7] a phosphorescence of fair intensity at about 8000 Å. Whether this phosphorescence was due to chlorophyll is now open to question, for when we extended the work to the separated components of chlorophyll using samples the high purity of which we were absolutely certain, we found that the *b* component phosphoresced weakly at about 8600 Å. with a life of 0.03 second, while no phosphorescence could be detected for chlorophyll *a* below 8600 Å. Nevertheless, the possibility that chlorophyll could act in such a role is not yet excluded, for the S′–T transition under the conditions of the living plant could well be such as to give a high yield of chlorophyll in the metastable state.

It should be pointed out that this photoreduction of quinone by zinc chlorin is in all probability not a conversion of light energy into chemical energy since whatever estimates can be made of its free energy[8] indicate that its value is negative, at least with β-naphthoquinone. However, the reduction by chlorophyll of the pyridine enzymes (TPN or DPN) with the simultaneous formation of the corresponding porphyrin, might be expected to be somewhat endergonic to the extent of about 10 kcal. It could thus be part of the primary photo-chemical transformation.

Experimental

Part I. Apparatus and Materials

The Beckman Spectrophotometer.—The basic unit about which the apparatus was built was a Beckman Quartz Spectrophotometer Model DU. Illumination of the sample was always carried out at a slit width of 0.8 mm. and a wave length setting of 6212 Å., under which conditions the width of the spectral segment was about 300 Å. Absorption measurements which must be run with spectral segments of only a few Ångströms were made at slit width settings around 0.02, where the light intensity was only about 1/1600 of that used for illumination. This light intensity was so low that the reaction was virtually stopped, allowing as many absorption readings to be made as desired with no appreciable light reaction occurring.

Light Source.—The light source for the Beckman is 6–8 v. tungsten filament Mazda 2331 automobile headlight, ordinarily operated at 6 volts. In this work it was run at 9.0 volts, for the intensity from such a lamp is about tripled when the voltage is raised from 6 to 9, thus permitting the use of smaller slit widths and correspondingly narrower spectral ranges for illumination.

Thermostating.—Water from a large reservoir thermostated by conventional means was circulated through a specially designed cell compartment to maintain the temperature within 0.1°. Due to the fact that room temperature was usually below 25°, the benzene in the evacuated cell had the tendency to distil to the upper part of the cell when runs were made at this temperature. To prevent this, the upper part of the cell compartment was heated by a warm stream of air from a heated copper coil (see Fig. 6).

The Reaction Cell.—Figure 6 shows the details of the reaction cell and stirrer. The section in the optical path was constructed from 1-cm. Pyrex square mandrel tubing with one pair of opposite faces ground optically flat. The blank cell for the solvent was a twin to the reaction cell. The reaction cell had to be evacuated in order to exclude oxygen. The solution in the cell had to be stirred since the reaction took place only in the light beam, and thermal diffusion was not fast enough to keep the solution mixed. These two conflicting requirements, evacuation and stirring, were satisfied by the use of an all glass enclosed magnetic stirrer. Since there was no direct mechanical connection between the motor and the reaction cell, this type of stirrer also allowed the blank cell to be placed in the light beam for the balancing of the instrument when taking absorption readings.

(8) Fischer–Orth, "Die Chemie des Pyrroles," Vol. II, Akademische Verlagesellschaft (1937).

Filter Slide.—In addition to the very extensive modifications made on the cell compartment of the Beckman, a minor change was made on the filter slide. This slide has three openings which may be placed in front of the light path. For this work, the first opening was left blank, the second was replaced by a wire screen transmitting 38.0% of the light, and the third was filled with a piece of black cardboard. The filter slide was thus capable of use as a shutter, and as a means of varying the light intensity without varying the special composition of the light.

Preparation of Solutions. Zinc Chlorin.—The preparation was carried out in as dim a light as possible. About 2 mg. of free base chlorin was dissolved in 10 cc. of dioxane and boiled for several minutes with solid zinc acetate. The resulting zinc chlorin was then transferred to benzene, washed and dried, and made up to a volume of 100 cc. This gave a volume of roughly 3×10^{-5} *M*. The exact concentration was determined from the log $1/T$ value of the peak at 6212 Å.

$$C = \frac{\log 1/T}{\epsilon} = \frac{\log 1/T}{5.49 \times 10^4} \quad \text{for a 1 cm. cell}$$

Such solutions were found to be quite stable if stored in the dark and sampled in only the minimum of light.

Preparation of Solutions. β-Naphthoquinone.—Stock aminonaphthol was recrystallized and oxidized by ferric chloride according to "Organic Syntheses."[9] A number of stock benzene solutions were made up with the pure β-naphthoquinone in concentrations varying from 1.89×10^{-5} to 4.72×10^{-3} *M*.

Preparation of Samples for Rate Experiments.—Small aliquots of the order of 1 or 2 cc. of the chlorin and quinone solutions that would give the desired final concentrations were mixed in a small flask. This solution was then used to fill a small delivery cup equipped with an overflow spout. The delivery cup when filled delivered 2.56 cc. of solution, as shown by standardizations with benzene. During the evacuation of the cells, however, a little benzene was usually lost by distillation even though the solutions were frozen during pumping. A correction for this was made by the simple equation

$$V_0 = 2.56\ (C_M/C_O)$$

Where V_0 is corrected volume, C_M is concentration of chlorin when measured into the cell, and C_O is initial value of the chlorin concentration after pumping (determined spectrally). These sampling operations for the reaction mixture were also carried out in the very minimum of light. Solutions for the spectral blank were made with identical quinone concentrations, but without the chlorin.

Evacuation of Samples.—After the sample had been transferred to the reaction cell, the stirrer assembly was attached and the whole unit connected to a vacuum line. The solution was frozen in liquid nitrogen, and the system evacuated. The stopcock on the reaction cell was then closed and the solution thawed out and shaken. The cell was then refrozen, repumped and rethawed in an identical manner. The cell was now filled with hydrogen at nearly atmospheric pressure, and again frozen, pumped and thawed as before. Hydrogen was then twice more admitted. The cell was not thawed the last time; it was taken directly to the Beckman and placed in the thermostated cell compartment.

These operations, too, were carried out in a very minimum of light. As an added precaution, the reaction cell was kept covered by a small "skirt" of black cloth.

Method of Taking Rate Measurements.—After the reaction cell had attained temperature equilibrium, the rate experiments were conducted by illuminating the solution with stirring for intervals of five to fifteen minutes, and recording absorption readings at 6212 Å., 5500 Å., and 4640 Å. before and after each illumination period. The intensity of illumination was determined with a standardized thermopile–galvanometer circuit.

Absorption Spectra.—All absorption spectra were measured on a Beckman Quartz Spectrophotometer Model DU. Points were taken every 50 Å. by even fifties. The curves given represent smooth curves drawn through all points.

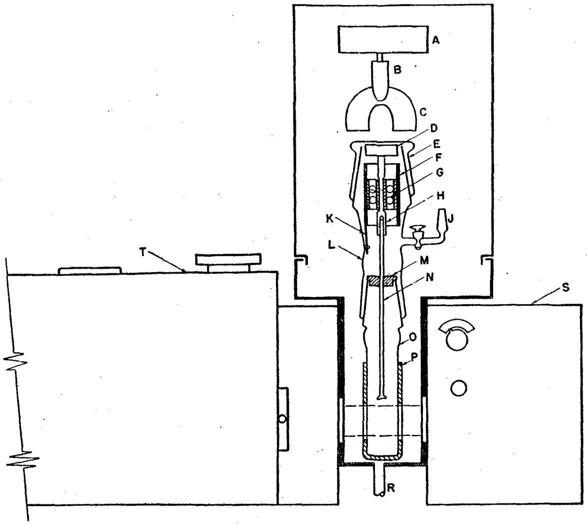

Fig. 6.—Reaction cell and stirrer assembly: A, motor; B, chuck; C, magnet; D, iron bar; E, 29/42 standard taper joint; F, brass column; G, double row ball bearing; H, chuck for stirrer; J, 10/30 standard taper inner joint; K, spring clip to hold column (F); L, Pyrex glass to standard taper 19/38 joint; M, brass bearing; N, glass stirrer; O, Pyrex cell (1 cm. square mandrel tubing); P, cell holder; R, thermostated water inlet; S, photocell compartment of Beckman; T, monochromator case of Beckman.

Phosphorescent Spectra.—The methods and apparatus used to determine spectra were identical to those described by Lewis and Kasha[4]; in fact, it was the same apparatus. The lifetime of the phosphorescences were measured on a photo-electric phosphoroscope.[10] Light from the phosphorescing sample is allowed to impinge on an infrared sensitive photo-multiplier tube, the signal from which is imposed on the vertical plates of an oscillograph. From the resulting decay curve trace and a knowledge of the sweep time, the life time can be calculated.

Part 2. Calculations

Determination of Concentrations During a Run.—In any region of light absorption where the absorption is due to only chlorin and porphin, Beer's law may be used to derive an expression for the chlorin concentration (for a 1.0-cm. cell)

$$C_c = \frac{\log 1/T - \epsilon_p C_T}{\epsilon_c - \epsilon_p}$$

where C_c is the concentration of the chlorin in moles/l, C_T is the total concentration of pigment, $C_c + C_p$; T is the fraction of light transmitted; and ϵ_p and ϵ_c are the molar absorption coefficients for phorphin and chlorin. Two wave lengths could be used

$$\text{at 6212 Å.} \quad C_c = \frac{\log 1/T(\text{obs.}) - 180C_T}{54700}$$

$$\text{at 5500 Å.} \quad C_c = \frac{22200C_T - \log 1/T\ (\text{obs.})}{16{,}300}$$

---

[9] "Org. Syntheses," Vol. XVII, p. 11, paragraph 1, p. 68.

[10] D. M. McClure, to be published.

Since the porphin has practically no absorption at 6212 Å., this wave length was used in most of the calculations. The values from measurements at 5500 Å. were used only for an occasional check.

Determination of Quantum Yield.—From the previously derived rate law (equation 10) it is seen that the quantum yield is easily calculated from the slope of the straight line obtained by plotting the left side of the equation against time

$$\gamma = \text{slope}/K_a I_0 \qquad (11)$$

Now K_a is merely a unit conversion factor, being equal to the reciprocal of the product of Avogadro's number and the volume of the solution in liters. The quantity I_0 is derived from the intensity of the light leaving the Beckman as measured by a standardized thermopile–galvanometer unit (sensitivity of 91.3×10^{-6} watt/sq. cm./cm. of deflection), the area of the light beam at the point of measurement (1.77 sq. cm.), the magnitude of the correction for the amount of light reflected, scattered, and absorbed before reaching the solution (1.6%), and the assumption that the average energy of the photons of the illuminating beam were that of a 6212 Å. photon. Substituting these quantities into equation (11)

$$\gamma = 2.0 \times 10^4 \times \frac{\text{slope} \times V}{D} \qquad (12)$$

V is the volume of the solution in ml., and D is the galvanometer deflection in cm.

It may seem curious that the final rate law should be used for the calculation of the quantum yield, since the quantum yield is an obvious factor in the determination of the rate law. As it turns out, however, the form of the rate law of equation (10) is rather general in character, and will be given by a number of other mechanisms, as well as the one from which it was derived here. In these other cases, however, the quantum yield would be a function of the quinone concentration such that the slope of the line represented by the equation would vary with the quinone. The fact that it does not tells us that these mechanisms are incorrect, but the fact that the equation gives a straight line plot indicates the form of the equation is right, and that we can use the simple equation (12) for calculating quantum yield rather than the more involved and laborious direct calculation which makes no assumption as to mechanism. Comparison of the two methods for a number of runs gave exactly identical results.

Part 3. Experimental Results

Effect of Oxygen and Quinone Concentration.—The first runs that were made (see Table I) were not swept out with hydrogen as is described in the section on the evacuation of samples, but were merely alternately pumped and thawed three times. Now all of these runs individually gave good straight line plots for the function $(C_{Zn}) + (\log Z/\Sigma d)$ against time, and all of the runs showed no trace of an oxygen reaction (no increase in absorption at 4640 Å.). But it is evident from the table that the runs reproduce each other very poorly, and that the rather large variation in quinone concentration has had little effect on the rate (quantum yield). In fact, the data seemed to indicate that the reaction was independent of the quinone concentration, with the quantum yields grouping around 0.015. If one assumed that this were so, then the variance among the different runs might be accounted for by an inhibition of the reaction by oxygen, since the oxygen content of the solutions is the only thing which might logically vary from one run to another. This hypothesis was tested by reducing the oxygen content of the solutions to a very low level, and noting whether or not the rate of the reaction increased. Control experiments were first made to get some sort of measure of the amount of oxygen in the solutions. Table II shows the results of two blank runs which were made in every respect like other runs except that the quinone was left out. Thus the only thing that could occur was the oxygen reaction. Experiment 8 was pumped in a manner identical to those experiments listed in Table I; experiment 9 was swept with hydrogen as described in the section on the evacuation of the reaction cell. Whereas experiment 8 showed a percentage change in the 6212 Å. band of 12.5% in thirty minutes, experiment 9 showed only a change of 13.3% in 105 minutes.

TABLE I

RUNS NOT SWEPT WITH HYDROGEN

Temperature, 25°; chlorine concn. $\cong 10^{-5} M$

Run	Concn. of quinone, M	Quantum yield
1	3.15×10^{-4}	0.019
2	3.15×10^{-4}	.015
3	9.44×10^{-4}	.012
4	9.44×10^{-4}	.010
5	9.44×10^{-4}	.016
6	3.15×10^{-3}	016
7	3.15×10^{-3}	.014

TABLE II

EFFECT OF HYDROGEN SWEEPING

Time, min.	log 1/T 6212 Å.	log 1/T 4640 Å.	% change 6212 Å.
Run 8. No hydrogen sweeping			
0	0.865	0.050	
5	.840	.063	2.9
10	.820	.078	5.2
20	.785	.103	9.2
30	.757	.121	12.5
Run 9. With hydrogen sweeping			
0	0.905	0.050	
10	.880	.068	2.7
35	.855	.090	5.5
60	.830	.106	8.3
105	.785	.136	13.3

Knowing now that the oxygen content could be reduced by sweeping with hydrogen, a new series of experiments were conducted with hydrogen sweeping incorporated into the procedure. Table III summarizes the results of these experiments. It is seen that the reduction in the amount of oxygen has indeed caused a marked increase in the quantum yield, and that over a very wide range in concentration of quinone, the quantum yield remains virtually constant. Undoubtedly these values do not represent the limiting value of the quantum yield, since a trace of oxygen is still present, but they are probably quite close to it.

TABLE III

RUNS SWEPT WITH HYDROGEN AT 25°

Run	Concentration of chlorin, M	Concentration of quinone, M	Quantum yield
10	1.10×10^{-5}	6.65×10^{-6}	0.0204
11	1.2×10^{-5}	1.81×10^{-5}	.0191
12	1.12×10^{-5}	3.99×10^{-4}	.0219
13	1.08×10^{-5}	1.63×10^{-3}	.0215

Run 10 is an extremely interesting one, for the quinone is present in smaller amounts than the chlorin. Yet the rate remained at the same high level until the quinone had fallen to only 1.8×10^{-6} M, and even at that low concentration the rate broke only slightly (see Fig. 7). It was not until the quinone was nearly gone that a reaction with the trace of oxygen present began to occur.

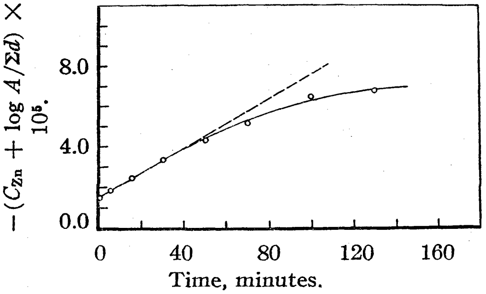

Fig. 7.—Run 10, slope: 5.97×10^{-7}.

Quinone–Chlorin Complex Formation.—An attempt was made to observe complex formation between zinc chlorin and β-naphthoquinone. This was done by running the spectrum of the zinc chlorin in the presence and absence of quinone. Absolutely no deviation was found in the two spectra in the region 6500 to 3000 Å., thus indicating that such complex formation does not exist.

Effect of Temperature.—The effect of temperature was studied by lowering the constant temperature bath from 25 to 10°. The results of two such runs are summarized in Table IV. Although the agreement between the runs is not exceptional, there is no doubt that the rather remarkable result of increasing rate with decreasing temperature has been found.

TABLE IV

RUNS SWEPT WITH HYDROGEN

Temperature, 10°; chlorin concn. $\cong 10^{-5}M$

Run	Quinone concn., M	Quantum yield
14	3.36×10^{-4}	0.0254
15	1.67×10^{-3}	0.0224

Effect of Light Intensity, Run 16.—The variation of the rate with light intensity was measured by the use of the screen described in the section on the filter slide. This screen transmitted 38.0% of light hitting it. A run was started with the screen in the light path, and then about half way through the run, the screen was removed and the run continued. The ratio of the slope of the rate curve for the second part of the run to the first part (see Fig. 8) was 2.65. The ratio of the light intensities for the second part of the run to the first part is

$$\frac{(I_0)_2}{(I_0)_1} = \frac{1}{0.38} = 2.63$$

Thus, the rate is proportional to the light intensity.

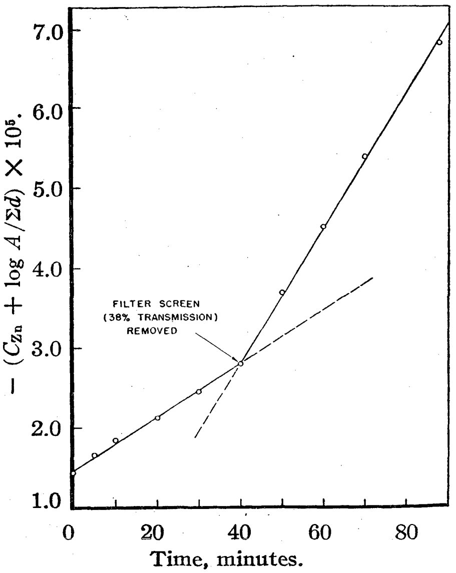

Fig. 8.—Run 16, slopes: 0–40 minutes, 3.2×10^{-7}; 40–88 minutes, 8.52×10^{-7}.

TABLE V

RUN 16

40	.404	.137	.027	0.735×10^{-5}	.251	-2.75×10^{-5}
38% screen filter out						
50	0.298	0.168	0.027	0.542×10^{-5}	0.291	-3.69×10^{-5}
60	.222	.188	.025	$.440 \times 10^{-5}$	.146	-4.52×10^{-5}
70	.162	.206	.025	$.295 \times 10^{-5}$	.108	-5.39×10^{-5}
88	.094	.223	.025	$.171 \times 10^{-5}$	.065	-6.80×10^{-5}

Details of Rate Data.—Complete experimental and calculated data for all the completed runs would consume far too much space to serve any useful purpose. To make completely clear our methods, however, Table V has been prepared summarizing the calculations for run number 16 (see also Fig. 8). The data of all completed runs were entirely consistent.

Acknowledgment.—The authors wish to acknowledge the many helpful suggestions and assistance of Prof. G. K. Rollefson, Drs. M. Kasha and R. V. Nauman, and Messrs. F. M. Huennekens and D. M. McClure. The junior author also wishes to express his appreciation for the assistance of the National Research Council.

Summary

1. The photochemical oxidation of a simple chlorin molecule to the corresponding porphin by oxygen and a number of ortho and para quinones is described.

2. From evidence based on rate experiments, a mechanism for the photochemical oxidation of tetraphenyl chlorin by β-naphthoquinone is derived involving the triplet state of the chlorin molecule as an intermediate.

3. A possible significance of the triple state of chlorophyll is indicated.

Properties of Electrolytic Solutions. XXXI. Conductance of Some Electrolytes in Pyridine at 25°[1]

BY DAVID S. BURGESS[2] AND CHARLES A. KRAUS

I. Introduction

In the last paper of this series,[3] it was shown that various quaternary onium salts are normal electrolytes in pyridine. Silver picrate and perchlorate, however, proved to have much larger dissociation constants than was to have been expected. Certain unreported results for sodium and potassium salts were erratic, indicating sources of error that had not been brought under control.

In view of these circumstances a comprehensive study of solutions in pyridine seemed worth-while.

It was suspected that inconsistencies in the results obtained with the alkali metal salts may have been due to the presence of small amounts of alcohol even though the conductance of the solvent was very low. On treating the pyridine with aluminum chloride, solvent was obtained that yielded consistent results with all salts. The marked effect of alcohol and, perhaps, other impurities that were eliminated by aluminum chloride, led to a study of the effect of the addition of small polar molecules, such as water, ammonia and methanol, on the characteristic constants of electrolytes dissolved in pyridine.

An investigation was made of several lithium, sodium and potassium salts and, in view of the unusual behavior of silver salts, silver picrate was included among the salts studied.

Certain quaternary ammonium salts which have been investigated in ethylene chloride and nitrobenzene, were measured for purposes of comparison. These salts were: tetra-*n*-butylammonium nitrate and acetate, tetramethylammonium picrate, ethyltrimethyl-, hydroxyethyltrimethyl-, bromoethyltrimethyl-, bromomethyltrimethyl-, and phenyldimethylhydroxy-ammonium picrate.

Measurements with pyridonium and piperidonium nitrates, as well as with phenylpyridonium picrate, are of obvious interest in view of the strong proton affinity of the solvent.

Measurements were also carried out with ammonium picrate, iodide and nitrate. The nitrate yielded inconsistent values for the conductance of the ammonium ion; publication of results for this salt is withheld pending further investigation.

In order to evaluate ion conductances, measurements have been made with tetrabutylammonium triphenylborofluoride and a value for the conductance of the tetrabutylammonium ion has thus been obtained according to Fowler's[4] method.

II. Experimental

Materials.—Pyridine prepared by the method of Luder[3] failed to yield consistent results; the procedure was, accordingly, modified so as to provide for elimination of residual traces of alcohol. This was accomplished by distillation from aluminum chloride. The distillate was then fractionally distilled, refluxed over aluminum oxide and finally fractionated. Pyridine obtained in this manner had a specific conductance below 1×10^{-9} and reproducible conductance values were obtained with salts which had previously yielded inconsistent results.

Methanol was refluxed over aluminum amalgam and finally distilled. Its specific conductance was 5×10^{-8}; a 0.275 *M*, solution in pyridine showed a specific conductance of 2×10^{-9}.

Ammonia was dried by distillation from sodium amide. A 0.0733 *M* solution of ammonia in pyridine had a specific conductance of 6×10^{-9}.

[3] Luder and Kraus, THIS JOURNAL, **69**, 2481 (1947).

[4] Fowler and Kraus, *ibid.*, **62**, 2237 (1940).

Sodium and potassium iodides of reagent grade were recrystallized from water and from alcohol.

Lithium, sodium and potassium picrates were prepared from the corresponding bases and recrystallized picric acid. Potassium picrate was recrystallized from water and from ethyl alcohol. The sodium salt was recrystallized from water and from methyl alcohol. It was necessary to heat this salt to 85° in a vacuum before a constant weight was obtained. Lithium picrate was recrystallized from pure ethanol and was dried in the same manner as the sodium salt.

Tetrabutylammonium nitrate was prepared by the method described by Cox,[5] m. p. 118°.

Tetrabutylammonium acetate was prepared by the metathesis of the pure iodide with recrystallized silver acetate in aqueous solution. The solution was filtered off from the silver iodide, concentrated, and pumped to dryness. The residue was dissolved in benzene, the solution filtered and the filtrate pumped to dryness. The salt residue was kept over phosphorus pentoxide in an evacuated tube for several weeks and then used directly in a series of measurements; m. p. 118°. Another sample of the acetate which had been recrystallized from butyl chloride was furnished by Dr. W. E. Thompson.[6]

Pyridinium nitrate was recrystallized from alcohol; m. p. 117.5–118°. Piperidonium nitrate was recrystallized from ethanol–benzene mixtures and was precipitated from ethylene chloride with anhydrous ethyl acetate. It decomposed without melting at 100°.

Phenylpyridonium chloride was prepared by the method of Zincke[7]; m. p. 106°. Metathesis of this salt with silver picrate in alcohol solution yielded phenylpyridonium picrate. This salt was recrystallized from alcohol; m. p 121–122°. An analysis for nitrogen, using catalytic hydrogenation at 350°, gave nitrogen 14.3%; calculated 14.6%.

The remaining salts had been prepared and purified in this laboratory. All were subjected to a final recrystallization from alcohol before use in conductance measurements.

Apparatus and Procedure.—Except for a few details, these were the same as described in earlier papers of this series. Buoyancy corrections (of about 0.1%) were applied in calculating the concentration of solutions of heavier salts.

Ammonia was introduced into the pyridine by attaching the pyridine reservoir (by means of a flexible tube) to a four-liter flask containing air and ammonia in proper proportions at atmospheric pressure. The partial pressure of ammonia was maintained equal to that at which the pyridine was to be saturated. As the ammonia was absorbed by the pyridine, more ammonia was admitted from the tank of purified ammonia, keeping the total pressure in the system constant. The ammoniated pyridine was forced into the conductance cell each time by means of a pressure of air and ammonia over the liquid in the stock flask, thus avoiding change in the composition of the solvent medium.

In order to minimize vapor corrections when working with ammoniated pyridine, the cell used was of small capacity (about 60 ml.) and the side arm leading to the electrode chamber was wide enough to permit mixing when the liquid level in the cell was high. Only a small free volume was allowed above the solution, and diffusion losses were kept low by having a long, narrow neck fitted to the cell. Water and alcohol were added to pyridine in a 500-ml. flask from a micropipet fitted with a drawnout capillary.

III. Results

The experimental data are summarized in Tables I and II in which are given the equivalent conductance Λ and the concentration C of the solution in moles per liter of solution, whose density was taken to be 0.97792.[8] Data for solutions in pure pyridine are given in Table I, while those for solutions containing added dipolar substances are given in Table II. The result of only one series of measurements is reported for each salt although at least two concordant series were carried out. All measurements were carried out at 25±0.01°.

IV. Discussion

A. Solutions in Pure Pyridine.—The experimental data have been analyzed by the method of Fuoss[9] so as to obtain values for the limiting conductance and dissociation constant of the electrolytes under consideration. The dielectric constant and viscosity of pyridine were taken as 12.01[10] and 0.008824.[8] Plots were made of F/Λ against $C\Lambda f^2/F$ and values of Λ_0 and K were determined therefrom. These values are given in Table III and plots for some of the salts are shown in Fig. 1. All plots are linear at low concentrations but deviations become apparent a little below the critical concentration, 5×10^{-4}. The strongest electrolytes deviate toward too high a conductance and weaker electrolytes toward too low a conductance.

TABLE III

CONSTANTS FOR SOME SALTS IN PYRIDINE AT 25°

Salt	Λ_0	Λ_0^+	Λ_0^-	$K \times 10^4$
$(C_4H_9)_4NFB(C_6H_5)_3$	48.0	(24.0)	(24.0)	13.2

Ion Conductances.—In order to obtain the ion conductances given in columns three and four of Table III, we have assumed, as did Fowler[4] for ethylene chloride, that the conductance of the tetrabutylammonium ion is equal to that of the triphenylborofluoride ion. This gives a value of 24.0 for the conductance of the tetrabutylammonium ion. Using Luder's value for the limiting conductance of tetrabutylammonium picrate,[3] we arrive at a value of 33.7 for the conductance of the picrate ion. The remaining ion conductances are easily evaluated on the basis of these values. It may be noted here that tetrabutylammonium picrate has been reinvestigated and no appreciable error has been found in Luder's data, although traces of alcohol may have been present in his pyridine.

(10) Le Fèvre, *J. Chem. Soc.*, 776 (1935).

Several salt pairs permit intercomparison of ion conductance as derived from different combinations. Thus the conductance of the silver ion, as derived from its picrate, is 34.3; from Luder's value for the conductance of silver nitrate, the same value is obtained for the silver ion. Evaluating the conductance of the sodium, potassium and ammonium ions from the conductance of their picrates, the conductance of the iodide ion may be found from the conductance of the corresponding iodides. The value found is 48.4 for the three salts. This value is not in agreement with Luder's value of 49.1 as found from the conductance of tetrabutylammonium iodide.

The conductance of the simpler negative ions is markedly greater than that of corresponding positive ions. For the perchlorate and bromide ions Luder found conductance values of 47.6 and 51.3, respectively; for the nitrate ion, we have found the value 52.6. In contrast, the conductance of the tetramethylammonium ion is only 43.0, while that of the ammonium ion is 46.8.

The conductance of the pyridonium ion is 49.6, the highest for any cation thus far measured. It seems not unlikely that this high value, considering the size of the ion, is due to proton transfer from one solvent molecule to another, as with the the hydrogen ion in water.

The conductance of the alkali metal ions decreases markedly with decreasing dimensions of the unsolvated ion. Thus, the conductance of the lithium ion is little greater than that of the tetrabutylammonium ion. Obviously, there is strong interaction between the free ion and the solvent molecules as a result of which the mobility of the ion is greatly reduced. There is evidence (to be presented in another paper) that small negative ions likewise have a low conductance. The sodium and potassium ions, also, have low conductances. It will be noted that the conductance of the silver ion is greater than that of the potassium ion.

The introduction of negative elements or groups into the cation results in a marked decrease of conductance. Thus, the conductance of the ethyltrimethylammonium ion is 41.8 while that of the bromomethyltrimethylammonium ion is 37.8 and that of the bromoethyltrimethylammonium ion is 33.4. These effects are significant and indicate increased interaction with the solvent molecules as a result of the presence of the negative atoms or groups in the cations. The conductance of the phenyldimethylhydroxyammonium ion is lower than that of the phenylpyridonium ion. There is reason for believing that the hydrogen of the hydroxyl group interacts strongly with the basic pyridine molecules.

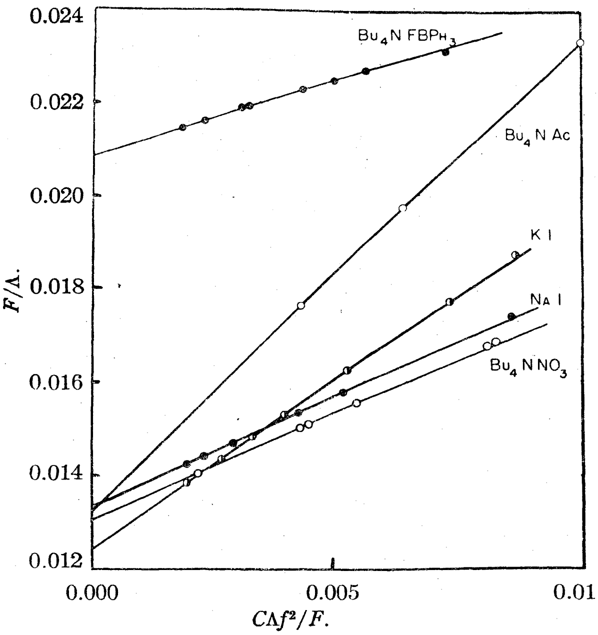

Fig. 1.—Fuoss plots for salts in pyridine at 25°.

Dissociation Constants.—The value of the dissociation constants of normal quaternary ammonium salts are such as might be expected for a solvent whose dielectric constant is 12. It is to be noted, however, that the dissociation constant does not change greatly with increasing dimension of the quaternary ammonium ion. Thus, the constant for tetrabutylammonium picrate[3] is only twice that of tetramethylammonium picrate. The constants of tetrabutylammonium salts of different negative ions follow the order of ion dimensions fairly well, the constants following the order $I^- > NO_3^- > Br^- > Ac^-$. The low value of the constant for the acetate is noteworthy.

The introduction of negative atoms or groups into the quaternary cation structure has a marked effect on the dissociation constant. Substitution of the hydroxyl group in the ethyl group of the ethyltrimethylammonium ion decreases the dissociation constant of the picrate fivefold, while introduction of a bromine atom decreases the constant 25%. Bromomethyltrimethylammonium picrate is a markedly weaker salt than tetramethylammonium picrate. Negative atoms or groups in the positive ions intensify the interaction of such ions with negative ions.

The dissociation constant of an electrolyte is determined by the distance of closest approach of the ions in the ion-pairs. We should, therefore, expect salts of larger ions to have larger dissociation constants, which ions should also have lower conductances. This simple relation usually fails in most solvents that are not of the hydroxylic type. Due to interaction with solvent molecules, ions may have a low conductance, but in their interaction with oppositely charged ions these molecules are not retained in the ion-pairs. This is well illustrated by the salts of lithium, sodium and potassium. The tetramethylammonium ion has a conductance of 43.0, and its picrate has a dissociation constant of 6.7×10^{-4}. On the other hand, lithium, sodium, and potassium ions have conductances of 24.9, 26.8 and 32.0, respectively, while their dissociation constants are, respectively, 0.83×10^{-4}, 0.43×10^{-4} and 1.0×10^{-4}. The picrate of the ammonium ion, whose conductance is 46.8, has a constant of 2.8×10^{-4}. In the case of sodium and potassium iodides, the constants increase in the order of decreasing ion conductance. It is of interest to point out that the dissociation constant of tetrabutylammonium iodide is 4.1×10^{-4}, only one-fourth that of the picrate (12.8×10^{-4})[3]. In the iodide, the sodium ion behaves like a large ion having a constant of 3.3×10^{-4}, but little smaller than that of the tetrabutylammonium salt. It will be recalled that the conductance of the two cations is 26.9 and 24.0, respectively.

An interesting case is that of the phenyldimethylhydroxyammonium ion, whose conductance is 28.6. The dissociation constant of the picrate of this ion is 12.3×10^{-4}, practically the same as that of tetrabutylammonium picrate. The hydrogen of the hydroxyl group evidently interacts strongly with the basic pyridine molecules and these molecules must be, in large measure, retained in the ion-pairs. However we may interpret the result, this ion in its interaction with other ions is effectively nearly as large as the tetrabutylammonium ion.

Pyridonium nitrate is a weak salt with a constant of 0.5×10^{-4}; piperidonium nitrate is an even weaker salt with a constant of 0.18×10^{-4}. Apparently, the additional hydrogen atom attached to nitrogen in the latter cation leads to interaction with the negative ion to yield the lower constant. It is of interest to note that phenylpyridonium picrate has a constant of 11.5×10^{-4} which is practically the same as that of tetrabutylammonium picrate. The geometrical configuration of an ion is an important factor in determining the properties of its salts.

An unexpected and exceptional result of this and the preceding investigation[3] is the high value of the dissociation constant for silver salts. For the nitrate, perchlorate and picrate, the constants are, respectively, 9.3×10^{-4}, 19.1×10^{-4} and 30.6×10^{-4}. Considering that the conductance of the silver ion is 34.4, which corresponds to that of only a moderately large ion, it is surprising to find a constant for silver picrate more than twice that of tetrabutylammonium picrate. If the distance between centers of charge in the ion-pairs is calculated according to the method of Fuoss,[11] the values "*a*" for the above mentioned silver salts are 6.6 Å., 10.6 Å. and 13.2 Å., respectively. The silver ion is exceptional in its interaction with other ions.

B. Solutions Containing Added Polar Molecules.—The results presented in Table II for solutions containing ammonia, water and methanol in small amount have been analyzed by the usual graphical method. Values of Λ_0 and of K for several salts are given in Table IV.

TABLE IV

EFFECT OF ADDED POLAR MOLECULES ON THE CONDUCTANCE OF SALTS IN PYRIDINE

Salt	Concn. added compound	Λ_0	$\Delta\Lambda_0$	$K \times 10^4$
$(C_4H_9)_4NPi$	0.000	57.68	..	12.2
	.073 NH_3	58.12	0.44	12.2
	.146 NH_3	58.58	.90	12.2
NaPi	0.000	60.5	..	0.44
	.007 H_2O	60.5	0.0	.49
KPi	0.000	65.27	..	1.00
	0.275 CH_3OH	64.10	−1.17	1.32
NaPi	0.000	59.98	..	0.44
	.733 NH_3	80	20	.66

As may be seen from the table, the addition of ammonia to a solution of tetrabutylammonium picrate in pyridine causes a small increase in the value of Λ_0 while the dissociation constant remains unchanged. The addition of 0.007 *M* of water to a solution of sodium picrate causes a 10% increase in the dissociation constant while the limiting conductance remains unchanged. The addition of 0.275 *M* methanol to a solution of potassium picrate increases the dissociation constant 32% while it decreases the limiting conductance 1.8%.

A striking result was obtained on the addition of ammonia to a solution of sodium picrate. For an ammonia concentration of 0.733 *M*, the conductance was increased approximately 20 units, or 33%. Since ammonia has but little influence on the conductance of the picrate ion, as shown by the results with tetrabutylammonium picrate, the observed conductance increase of sodium picrate must be due to an increase of approximately 50% in the conductance of the sodium ion.

While the present measurements are preliminary, there is no question as to their authenticity. Subsequent investigations, the results of which will be reported later, have confirmed the present results and have disclosed similar effects for other salts.[12] A comparison of conductance values in Table I, b, and Table II, e, will show that the conductance of sodium picrate in the presence of ammonia is much higher than it is in pure pyridine at all concentrations. This is due to the fact that while the dissociation constant of sodium picrate is not increased greatly (50%) on addition of ammonia, the conductance of the sodium ion is greatly increased. The low conductance of the sodium ion in pyridine is due to its interaction with pyridine molecules; more than one pyridine molecule must be associated with the sodium ion in order to account for its low conductance. The replacement of pyridine by smaller ammonia molecules results in a smaller ion of higher conductance. In the ion-pair equilibrium, however, the ammoniated ion is effectively somewhat larger than is the normal sodium ion in pure pyridine.

---

V. Summary

1. The conductance of the following salts has been measured in pyridine at 25°: tetrabutylammonium nitrate, acetate and triphenylborofluoride; tetramethylammonium, ethyltrimethylammonium, hydroxyethyltrimethylammonium, bromoethyltrimethylammonium, bromomethyltrimethylammonium, phenyldimethylhydroxyammonium, ammonium, lithium, sodium, potassium and silver picrate; ammonium, sodium and potassium iodide; and pyridonium and piperidonium nitrate.

2. The conductance has also been determined for solutions of tetrabutylammonium picrate in the presence of ammonia; sodium picrate in the presence of ammonia and of water and potassium picrate in the presence of methanol.

3. The experimental results have been analyzed by the usual graphical methods and values of Λ_0 and of the dissociation constant K have been obtained for all the systems investigated. Ion conductances have been evaluated by the method of Fowler.

4. The effect of various interactions on ion conductances and dissociation constants are discussed.

5. It has been shown that the addition of polar molecules to the solvent medium usually causes little change in ion conductance of salts having large ions. With salts of smaller ions, the dissociation constant is often increased. In the case of sodium picrate, the addition of ammonia causes a very large change in Λ_0, up to as much as 33%, with only a small increase in the dissociation constant.

Thallous Sulfoxylate Isomerism[1]

BY J. FENTRESS AND P. W. SELWOOD

The fact that thallous sulfide, Tl_2S, is easily oxidized when exposed to air was first pointed out by Lamy.[1a] At that time it was postulated that the final product of this oxidation was thallous sulfate, Tl_2SO_4. More recent investigation of the oxidation by Iskoldsky[2] has served to confirm much of Lamy's work. It is found that at 720° in air, thallous sulfide is oxidized 90% to thallous sulfate in two and a half hours. Further, the oxidation of the sulfide proceeds step-wise with the intermediate compounds, Tl_2SO_2 and Tl_2SO_3, being identified. Although one might expect to find a compound with the formula Tl_2SO, Iskoldsky was unable to prepare such a compound.

With Case's[3] discovery of the photo-sensitivity of oxidized thallous sulfide, and the more recent improvements on "Thalofide" photo-cells by Cashman[4] and several others,[5–9] new interest has developed in the actual oxidation of thallous sulfide, and the products formed.

The percentage of oxygen in various photosensitive cells[10] varies up to as much as a nearly 1:1 mole ratio of $Tl_2:O_2$, corresponding to the formula Tl_2SO_2. Thus, our interest in thallous sulfide oxidation products, from the point of view of identifying the composition of the photo-sensitive material, only extends as far as Tl_2SO_2 and is not concerned with the complete oxidation to thallous sulfate.

This present study is concerned with the two forms of thallous sulfoxylate[11] that we were able to obtain.

Preparation of Thallous Sulfide.—Thallous sulfide may be prepared either by precipitation at ordinary temperatures, or by direct reaction of thallium metal and sulfur at high temperatures. We selected the former method because early experiments indicated that oxidation proceeds more rapidly with thallous sulfide prepared by precipitation methods.

All the thallous sulfide used in our experiments was prepared by precipitation from alkaline thallous sulfate solution. The thallous sulfate starting material was originally 99% pure commercial material, which was purified by three recrystallizations from aqueous solution. This procedure yielded thallous sulfate which when analyzed by the standard chromate method gave results of satisfactorily high purity, *i. e.*, more than 99.9% of the theoretical thallium content.

A dilute solution of thallous sulfate, under nitrogen atmosphere, was made alkaline with ammonium hydroxide and the thallous sulfide precipitated at 50° with hydrogen sulfide in the pre-

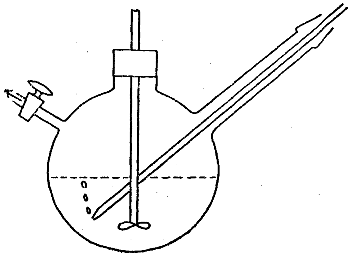

Fig. 1.

cipitation flask (Fig. 1) The filter tube (Fig. 2) was then attached and the thallous sulfide filtered under nitrogen atmosphere. The filter tube was then connected to the sample tube (Fig. 3) which was in place in the vacuum apparatus. While the filter tube was being put in place, a stream of nitrogen was passed through the sample tube to insure that no oxygen was present. The sample tube was evacuated and the sample pumped out until it appeared to be completely dry, two to three days, and then several taps on the side of the filter tube served to dislodge the sample causing it to fall into the sample tube. The sample was evacuated and pumped to a high vacuum, 10^{-3} mm., as measured by a McLeod gage incorporated in the vacuum system. The pumping was continued until the sample was brought to constant weight.

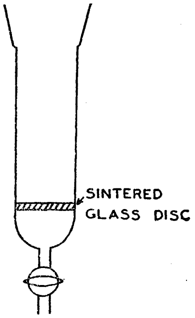

Fig. 2.

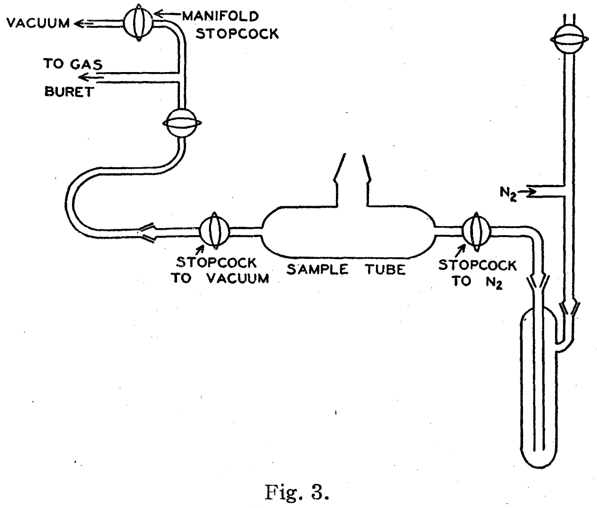

Fig. 3.

In order to carry out an analysis of the thallous sulfide without exposing the sample to the air the sampler (Fig. 4) was attached. The sample was taken by rotating the sample tube 180°, allowing some thallous sulfide to enter the sampler. Then the sample tube was rotated back to its original position leaving a small sample, 0.25–0.50 g., in the sampler. The end of the sampler containing the small sample of thallous sulfide was then sealed off. Once the weight was determined the sealed tube containing the sample was placed in a beaker of sulfuric acid and the tube broken, allowing the thallous sulfide to dissolve. This solution was boiled to remove all the hydrogen sulfide, then made alkaline with ammonium hydroxide, and the thallium determined by precipitation as the chromate. The results of the analyses on a series of thallous sulfide samples gave values from 99.5 to 99.75% pure thallous sulfide. The impurity in these samples was small amounts of water vapor that are not removed by evacuating the sample at room temperature. However, since the reaction between thallous sulfide and oxygen must be catalyzed by water vapor, or some other common catalyst, no attempt was made to remove these last traces of water.

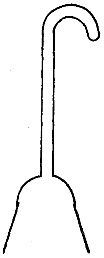

Fig. 4.

Oxidation of Thallous Sulfide.—The bulk of the thallous sulfide which was left in the sample tube was thoroughly pumped out at room temperature and its weight determined. After replacement of the sample tube in the vacuum line the whole system was completely evacuated and the stopcocks to the manifold and nitrogen lines closed. Pure oxygen gas was then introduced into the closed system from a gas buret and the rate at which the oxygen reacted with the thallous sulfide was measured.

In preliminary experiments the oxygen was generated by heating a mixture of potassium chlorate with small amounts of manganese dioxide. Any dust particles of manganese dioxide were filtered out by a sintered glass disc and the gas was stored in a reservoir bulb until it was drawn into the buret. In later experiments the oxygen was generated by direct heating of potassium permanganate. This change in procedure was made because it was felt that small amounts of chlorine gas might be present in the oxygen prepared by the first method.

The nitrogen gas used in these experiments was standard tank nitrogen which was passed over reduced copper at 300°, through soda lime and phosphorus pentoxide before being brought into contact with the thallous sulfide.

The thallous sulfide, with small amounts of water vapor as a catalyst, reacts moderately rapidly with oxygen until a mole ratio of $1:1/Tl_2S:O_2$ is reached. At this point the black thallous sulfide phase has completely disappeared and an olive-brown compound with the formula Tl_2SO_2 is formed. This compound will be designated as *alpha* thallous sulfoxylate, α-Tl_2SO_2. This compound is stable in air at room temperature and thus may be removed from the vacuum system without any decomposition.

The oxidation curves showed no break when a composition corresponding to the formula Tl_2SO was reached, which is in agreement with the observation of Iskoldsky.[2] In order to characterize the *alpha* thallous sulfoxylate the X-ray powder pattern was obtained, and the basic chemistry of the compound was investigated.

Conversion of Alpha Thallous Sulfoxylate to the Beta Form.—Since the *alpha* form of thallous sulfoxylate did not correspond to the greenish yellow compound reported by Iskoldsky,[2] nor to the yellow compound reported by von Hippel[10] as Tl_2SO_2, experiments were undertaken to prepare this yellow form. Since both workers had obtained their compound by oxidation of thallous sulfide at elevated temperatures small samples of the *alpha* form were heated in vacuum in hopes of obtaining the *beta* form. Approximately 1 g. of the *alpha* form in a sample tube was thoroughly evacuated at room temperature. An open-end manometer was included in the system to measure any pressure changes. After the sample was evacuated the stopcock to the vacuum line was closed and the sample was slowly heated in an oil-bath to 250°. In order to get good results the heating must be done slowly and a temperature of 250° must not be exceeded. If the heating is carried out too fast, or if too high a temperature is reached, a grayish powder results which is a mixture of the sulfoxylate with thallous sulfide. If the conversion is carried out as indicated the greenish-yellow form is obtained as a single phase. The small pressure changes noted on the manometer may be satisfactorily explained on the basis of the small amounts of water vapor impurity. This greenish-yellow compound, which also has the formula Tl_2SO_2, will be designated as *beta* thallous sulfoxylate, β-Tl_2SO_2. This compound is also stable in air at room temperatures, and under ordinary conditions shows no tendency to revert back to the *alpha* form. The X-ray powder pattern and basic chemistry of this compound were also investigated.

X-Ray Study of the Two Forms of Thallous Sulfoxylate.—The X-ray patterns of the two forms of thallous sulfoxylate, thallous sulfide and patterns of mixtures of these compounds were taken. These patterns were obtained using the North American Philips Company X-Ray Spectrometer Type No. 12021. In this instrument the conventional camera is replaced by a Geiger counter. A Brown recorder was used in connection with the counting unit to make the machine self-recording. For all the data given a copper target was used, thus all calculations are based on the CuKα line.

A series of patterns of thallous sulfide samples were taken and found to agree closely with the structure of thallous sulfide as proposed by Ketelaar and Gorter.[12] In Fig. 5 a diagram giving the positions and relative intensities of diffraction lines from samples of Tl_2S, α-Tl_2SO_2 and β-Tl_2SO_2 are given. In Table I are given the exact positions of the diffraction lines for *alpha* and *beta* thallous sulfoxylate as determined from the X-ray patterns. Values of d corresponding to measured values of the angle θ are calculated from the expression

$$d = 0.77/\sin\theta$$

for CuKα radiation. It should be noted that the angles given in Table I are equal to 2θ.

TABLE I

X-RAY POWDER DIFFRACTION DATA ON THALLOUS SULFOXYLATE

	Alpha Thallous Sulfoxylate			Beta Thallous Sulfoxylate

[a] The positions of these two lines were found by manually moving the Geiger tube until a maximum counting rate was obtained, and thus may be considered accurate to ±0.05°.

The patterns of the two forms of thallous sulfoxylate clearly show that we are dealing with two different structural forms. Further, comparison with the powder pattern of thallous sulfide indicates that both forms are significantly different from thallous sulfide itself.

The data given for *beta* thallous sulfoxylate, although not in exact agreement with the pattern given by von Hippel[10] for the yellow phase that he obtained in oxidized cells, is certainly in satisfactory enough accord to warrant the assumption that *beta* thallous sulfoxylate and von Hippel's yellow phase are one and the same compound. The pattern of the *beta* form was checked by comparison of three samples of β-Tl_2SO_2 prepared from three separate samples of α-Tl_2SO_2. Attempts to change the pattern by further heating of the *beta* form gave negative results. This heating only resulted in decomposition of the compound and the appearance of characteristic Tl_2S lines. Von Hippel[10] has proposed a face-centered cubic structure for the *beta* form. It appears that

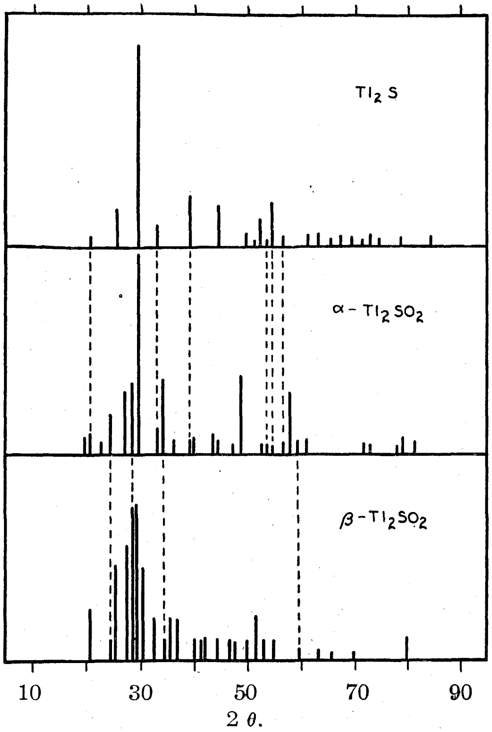

Fig. 5.

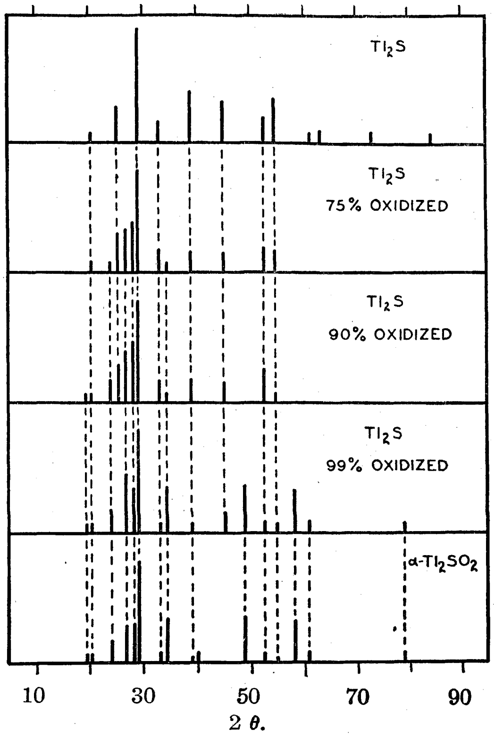

Fig. 6.

the *alpha* form may retain the layer lattice structure of thallous sulfide, but as yet we have failed to obtain sufficient data definitely to give the complete structure of this form, as all attempts to obtain crystals have been unsuccessful.

In Fig. 6 patterns showing different stages of oxidation in the preparation of the *alpha* form are given. These patterns indicate that partially oxidized samples of thallous sulfide do not represent mixtures of Tl_2S and α-Tl_2SO_2. Although some of the characteristic lines of α-Tl_2SO_2 are present in the 75% oxidized samples, at least two of the most intense lines given by the *alpha* form, 48.81° and 57.95°, do not appear until the oxidation is practically complete. This datum is in agreement with our observation that the characteristic brown phase of the *alpha* form does not appear until the reaction is nearly finished These patterns serve to give further evidence for the nonexistence of Tl_2SO at room temperature.

Our inability to obtain evidence of a Tl_2SO phase seems to cast some doubt on the theory advanced by von Hippel and Rittner[13] as to the position of the oxygen atoms in the photo-sensitive phase. These authors state that the most likely sites for the oxygen atoms are in spaces interleaving the Tl–Tl layers in the normal Tl_2S structure. Since the unit cell in the thallous sulfide structure contains twenty-seven Tl_2S units, and the number of possible oxygen positions is equal to the number of sulfur positions, based on the sites proposed by Von Hippel and Rittner, there will be twenty-seven possible locations for the oxygen atoms. If the oxygen atoms actually occupied these proposed sites the saturated structure would be Tl_2SO. The fact that Tl_2SO is so difficult to prepare may indicate that these sites are not as easily available as would at first appear. Calculations indicate that there are fifty-four equivalent positions in the Tl_2S unit cell available to oxygen atoms. Occupation of these would lead to the Tl_2SO_2 arrangement. However, the exact positions of the oxygen atoms cannot be determined without a more detailed X-ray study.

Basic Chemistry of the Thallous Sulfoxylates.—In attempting to elucidate the basic chemistry of the two forms of thallous sulfoxylate two early experiments led us to assign both forms as univalent thallium salts of sulfoxylic acid. Firstly, all evidence indicated that the oxidation of thallous sulfide had not served to oxidize either thallous ion to the thallic valence state. Secondly, all attempts to demonstrate the existence of sulfide ion in either form gave negative results.

Although sulfoxylic acid, H_2SO_2, is not known as the free acid, several inorganic salts have been prepared. The zinc salt $ZnSO_2$ may be prepared either by the action of sulfuryl chloride on zinc dust in absolute ether solution,[14] or by the reaction of

$$SO_2Cl_2 + 2Zn \longrightarrow ZnCl_2 + ZnSO_2$$

zinc metal with sulfur dioxide in absolute alcohol

$$SO_2 + Zn \longrightarrow ZnSO_2$$

---

[13] A. von Hippel and E. S. Rittner, *J. Chem. Phys.*, **14**, 370 (1946).

[14] E. Fromm and J. de S. Palma, *Ber.*, **39**, 3317 (1906).

The cobalt salt, $CoSO_2$, has been prepared by Scholder and Denk[15] by treating cobalt chloride with sodium hyposulfite in ammoniacal solution. Finally, Vogel and Partington[16] have prepared sodium sulfoxylate, Na_2SO_2, by treating sodium ethyl sulfoxylate with sodium hydroxide. In addition to these inorganic derivatives many organic compounds are known which may be considered as organic sulfoxylates.

Modifications of the above methods were attempted to prepare thallous sulfoxylate. Thallium metal turnings were added to a solution of pure sulfuryl chloride in absolute ether. But after prolonged stirring no reaction was observed. The speed with which thallium metal forms a protective oxide film may have been responsible for the failure to obtain any results.

The reaction between several different thallous salts and sodium hyposulfite was attempted under varying conditions. By adding thallous sulfate slowly to a solution of sodium hyposulfite an immediate white precipitate began to form which, however, could not be removed from the solution before it had turned dark gray. Repeated attempts to obtain the white compound which was believed to be $Tl_2S_2O_4$ failed and only Tl_2S and Tl_2SO_4 could be identified in the end-product.

The most satisfactory reaction was that between thallium metal shavings and sulfur dioxide in absolute alcohol. The reaction proceeded slowly yielding a white precipitate. This compound which was rather insoluble in alcohol could be obtained from the solution, and was found on analysis to be $Tl_2S_2O_4$. This compound appeared fairly stable in air, and was found to be rather highly soluble in water. Repeated attempts to convert this salt to thallous sulfoxylate failed to give any results.

However, it was found that *alpha* thallous sulfoxylate prepared from thallous sulfide, readily reacted with sulfur dioxide in alcoholic suspension to give a compound with the formula $Tl_2S_2O_4$ which seemed to be identical with the compound obtained above. It should be noted that *beta* thallous sulfoxylate would not react with sulfur dioxide under the same conditions.

Both forms of the sulfoxylate are only slightly soluble in water, but are quite soluble in dilute sulfuric acid. In the presence of concentrated acids both compounds appear to be decomposed, but concentrated bases have little effect on either compound. Solutions of both compounds containing 10 g. per liter of thallous ion were prepared and subjected to the standard tests for thallous ion. In all cases both compounds reacted as expected yielding both thallium ions immediately in the thallous state. Some difficulty was encountered in oxidizing these solutions to trivalent thallium with mild oxidizing agents, which suggested the presence of some reducing action in the solution.

In more dilute solution, less than 1 g. per liter of thallium, significant differences from normal thallous ion reactions may be noted. Attempts to precipitate the insoluble thallous halides from dilute acid solution gave precipitates only after several minutes, while attempts to precipitate the chromate from ammoniacal solution resulted in failure in most cases. However, it can be stated that there is very little difference in the two forms of the sulfoxylate as regard to the availability of the metal ions.

It was mentioned above that solutions of both forms appear to have a certain degree of reducing action. This fact coupled with the observation that both compounds on treatment with 5 *N* sulfuric acid gave precipitation of sulfur led us to postulate the existence of the thiosulfate ion as an intermediate product of the hydrolysis of sulfoxylic acid. This idea has already been suggested by Foerster[17] who considers sulfoxylic acid as an intermediate product in the formation of polythionates. He suggested that sulfoxylic acid is hydrolyzed according to the equation

$$2H_2SO_2 \longrightarrow H_2S_2O_3 + H_2O$$

The fact that we were able to demonstrate the presence of thiosulfate ion in aqueous solution of both forms lends support to the reaction as given above.

The thiosulfate ion was detected as an intermediate in the hydrolysis of both forms of thallous sulfoxylate by the characteristic reaction given with silver and mercuric ion. In the case of the *alpha* form 5 ml. of 10% solution of silver nitrate added to a saturated aqueous solution of the sulfoxylate gave the expected formation of a series of bright colored precipitates finally going to black silver sulfide. In the case of the *beta* form the reaction did not proceed as far as silver sulfide, but stopped with the formation of an intermediate brown precipitate, which was in part silver sulfite.

The following reactions were carried out in order to more fully investigate any difference in the course of hydrolysis of the two compounds. An aqueous solution containing 10 mg. of β-Tl_2SO_2 was made slightly acid with 2 *N* sulfuric acid. Before any sulfur began to appear this solution was treated with 0.5 ml. of potassium cyanide solution and 5 drops of ferric sulfate solution. The appearance of the familiar red color of the ferric thiocyanate complex indicated the presence of thiocyanate ion. A similar test with α-Tl_2SO_2 gave no color.

This formation of the thiocyanate ion is indicative of the presence of tetra- and pentathionic acid which may react with potassium cyanide according to the reaction

$$S_4O_6^{=} + 3CN^- + H_2O \longrightarrow SO_4^{=} + 2CN^- + S_2O_3^{=} + SCN^- + 2H^+$$

---

[15] R. Scholder and G. Denk, *Z. anorg. allgem. Chem.*, **222**, 17 (1935).

[16] I. Vogel and J. R. Partington, *J. Chem. Soc.*, **127**, 1514 (1925).

[17] F. Foerster, F. Lange, O. Drossbach and W. Seidel, *Z. anorg. allgem. Chem.*, **128**, 268 (1923).

$$S_5O_6^{=} + 4CN^- + H_2O \longrightarrow SO_4^{=} + 2CN^- + S_2O_3^{=} + 2SCN^- + 2H^+$$

Direct treatment of the two forms of thallous sulfoxylate with highly concentrated sulfuric acid gave different results in the two cases. When treated with 18 *N* acid the *beta* form gave off hydrogen sulfide as a decomposition product, and the solution remained clear, *i. e.*, no precipitation of sulfur. As opposed to this the *alpha* form gave no hydrogen sulfide, and sulfur began to precipitate immediately.

The formation of hydrogen sulfide may have been due to direct decomposition of the β-Tl_2SO_2, or may be a result of the hydrolysis of thiosulfate ion in strong acid according to the equation

$$2H_2S_2O_3 \longrightarrow H_2S + H_2S_3O_6$$

Bassett and Durrant[18] suggested the above reaction as one of three possible hydrolysis reactions of thiosulfate. These authors state that the above reaction would be favored in very strong acid.

In view of these results it should be mentioned that our inability to obtain thallous chromate precipitates from dilute solutions of the sulfoxylates in ammonium hydroxide may have been due to the formation of stable thiosulfate complexes in alkaline solution. Strongly complexed salts of this type are well known.

Goehring[19] has proposed that sulfoxylic acid may exist in two isomeric forms: the normal or sulfoxylic form reacting as if it were $S(OH)_2$, while the sulfinic form seems to react as HS(:O)OH. It is proposed by Goehring that the sulfoxylic form may react with thiosulfate ion according to the reaction

$$S(OH)_2 + 2S_2O_3^{=} + 2H^+ \longrightarrow S_5O_6^{=} + 2H_2O$$

and react with the bisulfite ion

$$S(OH)_2 + 2HSO_3^- \longrightarrow S_3O_6^{=} + 2H_2O$$

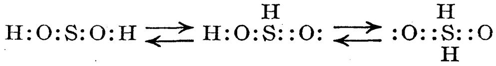
while the sulfinic form does not undergo reactions of this type.

To the present authors such marked differences seem difficult to understand when one realizes that if the sulfoxylate ion is involved the two forms given by Goehring are merely two possible resonance forms and thus could not be distinguished.

$$^{-}O{:}S{:}O^{-} \rightleftarrows {}^{-}O{:}\underset{-}{S}{::}O$$

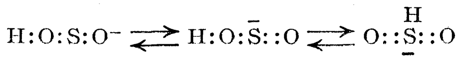
While if the postulated reactions involve the undissociated acid or bisulfoxylate ion it seems highly probable that a labile equilibrium between the two forms will exist.

Such an equilibrium between the two forms proposed by Goehring plus a third possible form could be represented by the equation



$$H{:}O{:}S{:}O{:}H \rightleftarrows H{:}O{:}\overset{H}{S}{::}O{:} \rightleftarrows {:}O{::}\underset{H}{\overset{H}{S}}{::}O{:}$$

for the undissociated acid and



$$H{:}O{:}S{:}O^{-} \rightleftarrows H{:}O{:}\overset{-}{S}{::}O \rightleftarrows O{::}\underset{-}{\overset{H}{S}}{::}O$$

for the bisulfoxylate ion.

From the data obtained it is evident that the primary step in the hydrolysis of both forms of thallous sulfoxylate proceeds according to the equation

$$2Tl_2SO_2 + H_2O \longrightarrow Tl_2S_2O_3 + 2TlOH$$

The noted differences in the end-products of the hydrolysis in each case would then most probably be due to the reaction of the thiosulfate ion, or some further hydrolysis product, with undissociated thallous sulfoxylate.

Summary

Two different forms of thallous sulfoxylate have been prepared and X-ray diffraction patterns of the two forms obtained. The pattern of *beta* thallous sulfoxylate indicates that this compound is identical with a compound obtained by von Hippel and independently by Iskoldsky. No previous reference has been found concerning the *alpha* thallous sulfoxylate.

Conditions are given for converting the *alpha* form into the *beta* form by careful heating *in vacuo* to 250°.

The chemistry of both forms has been investigated and both compounds have been shown to be thallous salts of the hypothetical sulfoxylic acid.

The Kinetics of Activation–Diffusion Controlled Reactions in Solution. The Temperature Dependence of the Quenching of Fluorescence[1,2]

BY BYRON WILLIAMSON[3] AND VICTOR K. LA MER

The quenching of fluorescence in solution is generally considered today to be a diffusion controlled reaction. The most conclusive evidence for this view is the dependence of the empirical rate constant upon the viscosity of the medium. By developing an equation with which they calculated the encounter frequency of ions in solution, and by measuring the quenching constant corrected for various interfering phenomena, Umberger and La Mer[4] showed that only about one encounter in four results in quenching for the reaction involving the quenching of the fluorescence of uranin (the basic form of fluorescein) by iodide ion. Hence the rate of diffusion of the reactants toward each other is the primary, but not the sole factor governing the rate of this and presumably other quenching reactions. It seemed probable that a chemical energy of activation might also be involved in the quenching process and an investigation of this aspect of the problem is the principal objective of this research.

Theory

The development of a rate equation which includes both the energy of activation and the collision frequency is not as simple for liquids as it is for gases. Rabinowitch[5] has shown that collisions in liquids occur in sets, called co-ordinations or encounters. Each encounter consists of many collisions, and the duration of an encounter depends upon the viscosity and the temperature of the liquid under consideration. This concept of diffusion in liquids will be used with the further general provision, namely, that collisions between two reactants, A and B, with each other and with the solvent molecules are not different kinetically when A and B are in an encounter together than when each is alone in an "encounter" with only solvent molecules. The presence of A and B in an encounter thus places no restriction upon either their electronic or thermal activation.

The molar rate constant, k, of a bimolecular reaction in solution can accordingly be represented as the product of the encounter frequency or the rate of diffusion of the reactants together, k_D, times the probability of reaction per *encounter*, p.

$$k = pk_D \qquad (1)$$

The Rate of Diffusion.—An exact and general expression for the encounter rate of molecular solute particles in solution, analogous to gaseous collison frequencies, is not derivable because of the limitations of our knowledge of the nature of liquids. Two different approaches to this problem have been used. Rabinowitch[5] and Fowler and Slater[6] have derived equivalent expressions by considering liquids to have a quasi-crystalline structure, and calculating the probability that two solute particles will occupy adjacent lattice points. Their expressions are especially approximate when the sizes of the solute and solvent molecules differ.

The second approach, and the one that has been used by Sveshnikoff and Wawilow[7] and by Umberger and La Mer[4] in their work with the quenching of fluorescence in solution is the application of Smoluchowski's theory[8] for the coagulation of colloids. Although there are objections to the derivation and to the use of Smoluchowski's expressions in the calculation of encounter frequencies, ample experimental agreement between the rapid coagulation of colloids and Smoluchowski's stationary state solution has been obtained. The stationary state solution, $4\pi DR$, gives very nearly the same numerical values as are obtained from the quasi-crystalline formula and will be used in this paper, *i. e.*

$$k_D = 4\pi DRN/1000f \qquad (2)$$

Sveshnikoff and Wawilow included the transient state term, $R/\sqrt{\tau_0 D}$, of Smoluchowski's theory in their theoretical treatment, substituting τ_0, the mean life of the excited state of the fluorescent molecule for Smoluchowski's general parameter, t. Umberger and La Mer also included the transient state term in their recent work, as has Montroll.[9] The full physical significance of this term needs further clarification. Smoluchowski's boundary conditions are not realized in physical processes, even in the case of colloidal coagulations, for very small or for very large values of t.

The equality of the quenching and diffusion radii also means that static quenching, as discussed by Frank and Wawilow,[10,11,12] will be absent. Static quenching also results from the electronic excitation of a fluorescent molecule while in an encounter with a quencher molecule. This effect is compensated, however, by fluorescence during an

encounter. As static quenching is a function of the concentration of quencher, it is eliminated beyond doubt in this work by the necessary extrapolation of the quenching constants to zero concentration quencher.

There remains the problem of the proper values of the diffusion constant to be used in the calculation of k_D. If the Stokes–Einstein expression, $D = kT/6\pi\eta r$, is used the question reduces to that of the proper radius to use. This difficulty has been minimized by Hodges and La Mer[13] who have measured the diffusion constants of the reactants involved using the diaphragm cell method.

The Probability of Reaction per Encounter.—Because collisions in liquids occur in sets, the probability of reaction depends not only upon an energy or an entropy of activation, but also upon the distribution of the collisions, for if a reaction occurs early in an encounter the subsequent collisions of that encounter will be wasted, *i. e.*, they will not be reflected in the reaction rate. To consider these circumstances, let w be the probability of reaction upon collision of reactants A and B, and let x be the probability of the encounter being broken by diffusion between collisions of A and B. If one assumes that an encounter begins with a collision of A and B, the probability of reaction per encounter, p, may be expressed as

$$p = w + (1 - w)(1 - x)p \qquad (3)$$

which, if $xw \ll x$ or w, reduces to

$$p = w/(x + w) \qquad (4)$$

If instead one assumes that diffusion away may occur before the first collision of A and B, equation (4) is derivable directly without the approximation that $xw \ll x$ or w.

The general equation for k, the reaction rate constant in solution, or in media where collisions occur in sets, is then

$$k = (w/x + w)k_{\mathrm{D}} \qquad (5)$$

i. e., the rate of reaction is equal to the rate of formation of encounters times the probability that reaction will occur before the encounter is broken by diffusion away.

Equation (5) is a more general form of equations that have been developed by Rabinowitch[5] and by Fowler and Slater[6] from considerations of the quasi-crystalline structure of liquids.

The probability of reaction per collision may be represented as

$$w = Pe^{-E_{\mathrm{a}}/RT} \qquad (6)$$

where P is an orientation or entropy factor, and E_a is the usual chemical energy of activation.

The probability of a molecule escaping by diffusion between collisions of A and B may also be represented by an exponential term

$$x = Ce^{-E_{\mathrm{d}}/RT} \qquad (7)$$

where E_d is an energy of activation of diffusion, and C consists of an orientation factor together with other small numerical factors to be discussed later.

The relative influence of the chemical energy of activation and the diffusional energy of activation is also shown by rearranging Eq. (4) to the form

$$(1/p) - 1 = x/w \qquad (8)$$

Substituting equations (6) and (7) into the logarithmic form of equation (8) gives

$$\log (1/p - 1) = \log C/P + (E_{\mathrm{a}} - E_{\mathrm{d}})/2.3RT \qquad (9)$$

A plot of $\log(1/p - 1)$ against $1/T$ will have a positive slope if $E_a > E_d$, a negative slope if $E_a < E_d$, and a zero slope if $E_a = E_d$. The intercept of the curve will be a measure of the relative magnitude of the steric factors of diffusion and reaction, and if one is known, the other may be determined.

An expression for the probability, x, of the termination of an encounter between collisions of A and B may be developed and E_a identified with the experimental energy of activation of diffusion. Let x' be the probability that any single attempt at diffusion will be successful, *i. e.*, a collision of a molecule with its cage wall will result in displacement to a new equilibrium position. Diffusion by either of the reactants to a new equilibrium position not adjacent to that occupied by the other reactant will break the encounter so that

$$x = (2n\gamma)x' \qquad (10)$$

where x is the probability that the new equilibrium position will not be adjacent to the other reactant, and $2n$ is the number of attempts at diffusion by the two reactants between collisions with themselves (assuming $n_a = n_b = n/2$).

The number of diffusive collisions per second is $x'Z_1 = 1/\theta$, Z_1 being the collision frequency in liquids and θ is the average time between diffusive collisions. From the Einstein[14] expression for the diffusion constant, the number of diffusive collisions per second in terms of the distance between equilibrium positions in the liquid, λ, is

$$1/t = 2D/\lambda^2 \qquad (11)$$

The relationship between x' and the diffusion constant is then given by equation (12)

$$x' = 2D/\lambda^2 Z_1 \qquad (12)$$

The probability, x', may now be expressed in terms of the experimental energy of activation of diffusion by substituting into Eq. (12) Eyring's[15] expression for D (Eq. 13) and Fowler's[6] expression for Z_1 (Eq. 14)

$$D = (\lambda^2/v_{\mathrm{f}}^{1/3})(k_{\mathrm{B}}T/2\pi m)^{1/2}\, e^{-E_{\mathrm{d}}/RT} \qquad (13)$$

$$Z_1 = 3(2k_{\mathrm{B}}T/\pi m)/a \qquad (14)$$

The factor a is defined as the diameter of the cage, *i. e.*, the diameter of the free volume allowed to any particle, so that a is approximately equal to $v_{\mathrm{f}}^{1/3}$, and Eq. (12) reduces to

$$x' = 1/6e^{-E_{\mathrm{d}}/RT} \qquad (15)$$

---

[13] K. C. Hodges and V. K. La Mer, THIS JOURNAL, **70**, 722 (1948).

[14] A. Einstein, *Ann. Physik*, **17**, 549 (1905).

[15] A. E. Stearn, E. M. Irish and H. Eyring, *J. Phys. Chem.*, **44**, 981 (1940).

Equation (10) now becomes

$$x = (2n\gamma/6)e^{-E_d/RT} \tag{16}$$

The factor n will vary from unity in the case of vibrations of A and B restricted to one coördinate to 11 for random movement in a hexagonal lattice, and γ is of the order of magnitude of $^1/_2$. Orientation or steric factors influencing the diffusion of a molecule from one equilibrium position to the next have not been considered above, and a probability factor, α, which will be unity for spherical molecules should be included in Eq. 16. The constant of Eq. (7) is now seen to be

$$C = \alpha\gamma m/3 \tag{17}$$

and is a small number approximately equal to unity for near spherical molecules. This means that for proper geometrical cases, log C/P, the intercept of equation (9) plotted against $1/T$, will give the order of magnitude of the reaction orientation factor P.

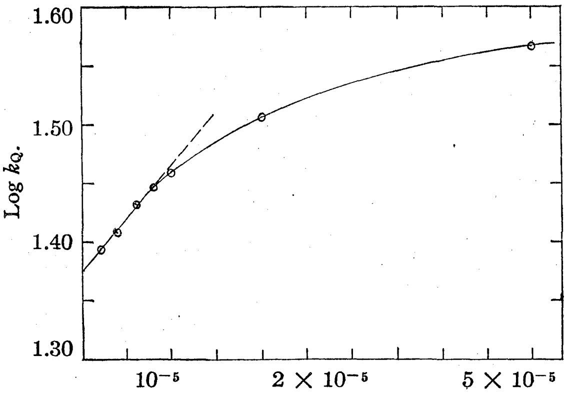

Fig. 1.—The molar quenching constant as a function of the concentration of uranin.

The probability, x', may also be derived as a function of temperature and viscosity, η, by substituting into Eq. (12) another form of Eyring's formula for D,[16] namely

$$D = \frac{\lambda_1}{\lambda_2\lambda_3}\frac{kT}{\eta} \tag{18}$$

The resulting expression for x is

$$x = C_1\sqrt{T/\eta} \tag{19}$$

where C_1 is of the order of magnitude of 10^{-6} to 10^{-5}, depending for the most part upon the mass of the solute particle. Equation (19) is useful because if C_1 can be determined, it will predict more accurately the dependence of x upon T and η than will Equation (7).

The Uranin–Aniline Quenching Reaction.—The quenching of the fluorescence of uranin, $Fl^=$, by aniline, An, has been measured as a function of the concentration of both uranin and aniline, as well as temperature, in order to obtain rate constant values free from absorption effects. The apparatus and procedure used is very similar to that of Umberger and La Mer. The photocells and cuvettes were enclosed in water jacketed housings for temperature control. The Stern–Volmer equation[17] was employed in the initial calculation of the quenching constants.

The decomposition of aniline in basic solution is serious in this work and the solutions, kept in blackened flasks, must be basic no longer than one hour at room temperature before intensity readings are obtained. The decomposition rate increases with temperature, and limits the temperature range employable.

The reabsorption of its own fluorescence by uranin in the presence of 0.01 M aniline at 27° is shown in Table I and Fig. 1, and is in good agreement with the theory and data of Umberger and La Mer.[4]

TABLE I

THE EXPERIMENTAL QUENCHING CONSTANT AS A FUNCTION OF THE CONCENTRATION OF URANIN

Concentration of uranin, m./l.	k_Q	log k_Q
1×10^{-4}	40.5	1.608
2×10^{-5}	32.0	1.505
1×10^{-5}	28.8	1.459
8×10^{-6}	28.0	1.447
6×10^{-6}	27.0	1.431
4×10^{-6}	25.6	1.408
2×10^{-6}	24.8	1.394
zero	(23.7)	(1.375)

At concentrations of aniline above 0.005 M, the quenching constant was found to increase with increasing concentration, Table II and Fig. 2. This

has been predicted by Sveshnikoff,[10,18] and constitutes the so-called deviations from the Stern–Volmer equation. Some absorption by aniline of the incident and fluorescent light also contribute. The increase is not due to a salt effect on the reaction as evidenced by no change in the quenching constant in the presence of 0.1 *M* NaOH or 0.1 *M* NaCl.

The quenching constant extrapolated to zero concentration of both uranin and aniline is 23.2 ± 0.3 at 27.0 ± 0.5°. The rate of quenching is hence 23.2 times as great as the rate of fluorescence on a molar basis. Using Equation (2), with

$$D = \frac{k_B T\,(1/r_{Fl^-} + 1/r_{An})}{6\pi\eta}$$

the number of encounters between uranin and aniline molecules in the time τ_0 is found to be 43.5 at 27.0°.[20] The probability of quenching per encounter is therefore 0.53 and approximately one out of every two encounters results in quenching.

The Temperature Dependence of the Uranin–Aniline Reaction.—Although much work has been done on the quenching of fluorescence in solution, the temperature dependence of a quenching reaction independent of viscous and other effects has not been determined. Stoughton and Rollefson[19] have been the most recent investigators of the temperature dependence of quenching, but since they did not employ an equation predicting the dependence of the quenching constant upon viscosity they were unable to treat the effect of temperature independently.

In this work the quenching constant of the uranin–aniline reaction has been measured at temperature intervals of five degrees from 7° to 54° using 0.01 *M* aniline and 10^{-5} *M* uranin. The results are given in Table III and Fig. 3. In order to obtain molar quenching constants from the experimental values, the per cent. correction, 19.5%, determined from the two necessary extrapolations at 27° was used at all temperatures. The validity of this procedure was established by measuring the effects of the aniline and uranin concentrations at 40°. The correction was found to be the same per cent. of the experimental value as at 27°.

The intensity of the fluorescence of a uranin solution in the absence of a quencher was found to decrease between 1–2% per 10° increase in temperature. From the work of Lewschin,[20] Jenness[21] and Speas[22] this effect may be shown to be due to a decrease in the extinction coefficient of the dye with increasing temperature. The fluorescence intensity is shown to be a linear function of the extinction coefficient, and the mirror symmetry of the fluorescence and absorption spectra is also maintained over this range of temperature. The average life of uranin in water has been shown to be independent of temperature by Perrin,[23] using polarization measurements. These considerations also show why the correction due to the re-

absorption of fluorescence is independent of temperature.

Although the radii of these reactants have not been measured as a function of temperature it is expected that they will be constant. The radius of mannitol has been measured as a function of temperature in aqueous solution by Scheffer and Scheffer[24] and discussed by Stearn, Irish and Eyring.[15] Their data show the radius to be independent of temperature to within a few tenths of an Ångström unit. Variations of this order of magnitude are not significant in this work as the value of k_D is not sensitive to small changes in the radii.

Discussion of Temperature Results

The quenching constant measured over a temperature range is a function of two variables, the temperature, T, and the viscosity, η. Equation (2) in terms of these parameters with the constants evaluated for the uranin–aniline reaction is given below

$$k_D = 0.00125T/\eta \tag{22}$$

The usual procedure of determining the energy of activation of a chemical reaction from measurements of the rate constant as a function of temperature is to plot log k *vs.* $1/T$. Such a procedure in this case cannot be used because of the dependence of the encounter frequency upon the temperature and the viscosity.

If Equation (9) is plotted against $1/T$ using the experimental values of p from Table III, the slope will be a measure of the difference in E_a and E_d. This plot is shown as Fig. 4. In accordance with Eq. (9) the slope of the curve shows that the energy of activation of the reaction is of the same order of magnitude as the energy of activation of diffusion, but is about 1000 calories per mole less, or approximately 3000 cal./mole.

The intercept of Fig. 4 is approximately 0.2, which means that $C = 1.5P$. Since C is approximately unity, P is also approximately unity, and hence the orientation and entropy requirements for the formation of an activated complex which will result in quenching are very slight.

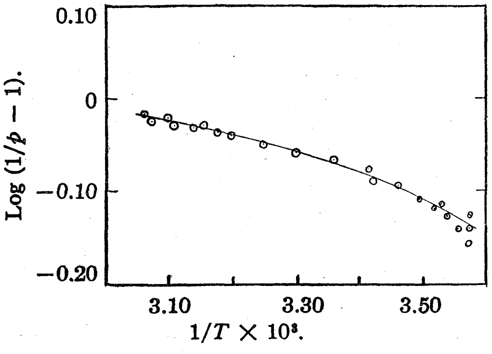

Fig. 4.—The probability of quenching per encounter as a function of temperature.

The average number of collisions per encounter, n, is the reciprocal of x, the probability per collision of an encounter terminating by diffusion of the reactants. The influence of the temperature, and the accompanying viscosity changes, upon the number of collisions per encounter may be calculated from Eq. (7) or Eq. (19). The viscous effect is predominant with the result that while n is nearly 1000 at 0°, it decreases to about 100 at 100°.

A survey of the literature shows that of all the many quenching reactions investigated only a very few are as efficient as the aniline–uranin reaction. The self-quenching of dyes as reported by Umberger and La Mer[4] is the only other type of quenching efficient enough to be a possible exception to the argument being presented. The diffusion constants of all common quenching reactants in solution will be of the same order of magnitude, and it is thus reasonable to expect that the large majority of quenching reactions will require a chemical energy of activation equal to, and in most cases exceeding, that required by uranin–aniline reaction. The quenching of fluorescence in solution in general therefore may be expected to be activation as well as diffusion controlled.

Acknowledgments.—The authors wish to express their appreciation for the suggestions made by Professor G. E. Kimball and by Dr. J. Q. Umberger.

Summary

1. The kinetics of the quenching of the fluorescence of uranin by aniline has been investigated using a precision photoelectric fluorimeter. Molar quenching constants, corrected for reabsorption and other effects, have been measured as a function of temperature.

2. A general equation, utilizing the concept that collisions in liquids occur in sets and introducing an energy of activation term into Smoluchowski's diffusion equation, is presented for reactions in solution whose rates are governed by both an energy of activation and by the interdiffusion of the reactants.

3. Experimental quenching constants for the uranin–aniline reaction, measured as a function of temperature (and necessarily of viscosity also), are interpreted using this equation. Quenching occurs in approximately one out of every two encounters (one out of every 1000 collisions) and hence diffusion alone is not sufficient to explain the observed rate of quenching. An energy of activation of the same order of magnitude as the energy of activation of diffusion suffices for agreement between theory and experiment. In general, the quenching of fluorescence in solution should be expected to be activation as well as diffusion controlled.

Solvent Effects on the Quenching of the Fluorescence of Uranin by Aniline[1,2]

BY KENNETH C. HODGES[3] AND VICTOR K. LA MER

The effects on the quenching of fluorescence produced by changes in viscosity, through the use of different solvents, were noticed early in experimental investigations of this subject.[4,5,6] The theoretical and experimental investigations of Umberger and La Mer[7] showed, however, that it was necessary to apply a number of corrections to the direct measurements of fluorescence quenching in order to convert these data to rate constants. Unfortunately, the necessity of making these corrections was not recognized in the early investigations so that none of the data on solvent effects in the literature can be interpreted unambiguously.

It is the primary purpose of this investigation to interpret rate constants for the quenching of the fluorescence of uranin (basic fluorescein ion) by aniline as a function of the viscosity of the medium. The presently accepted theoretical equations for the calculation of encounter frequencies involve the diffusion coefficients of the reactants. In order to compare the encounter frequencies in liquids with the rate constants, it was necessary to measure these diffusion coefficients. It will be shown that the elementary view that quenching constants will be linear functions of the solvent fluidity is inadequate.

Theory

The application of the cage-model theory of liquids to the study of reaction rates, and the development of rate equations, have been discussed in the previous paper[8] and will not be repeated.

One method of approach to the calculation of encounter frequencies in liquids has been from a model which considers liquids as possessing a lattice structure. Calculations of this type have been made by Rabinowitch,[9] Fowler and Slater,[10] and very recently by Kimball.[11] The molar encounter frequency derived by Kimball is

$$k_{\mathrm{D}} = 4\,\pi R^2 D\,\frac{1}{a}\,\frac{(\mathrm{N})}{1000}\ \text{liters moles}^{-1}\ \text{sec.}^{-1} \qquad (1)$$

where "a" is the distance between lattice points, and all other symbols have their usual values. Rewriting equation (1) as

$$k_{\mathrm{D}} = \frac{4\pi DR(\mathrm{N})}{1000}\,\frac{R}{a}$$

it is evident that k_{D} will be larger than the value given by the stationary state term of Smoluchowski's equation (ref. 8, eq. 2) since in general R will be larger than "a." The dependence of the encounter rate on the viscosity of the medium, eta, is evident if the relation

$$D = \frac{kT}{6\pi\eta}\left(\frac{1}{r_{\mathrm{d}}} + \frac{1}{r_{\mathrm{q}}}\right)$$

is substituted into either equation.

Equation 1 predicts a dependence of k_{D} on the solvent structure through the inclusion of the factor "a" which will be roughly proportional to the size of the solvent molecules. However, an exact value of "a" is not known. It is equivalent to λ, the distance between equilibrium positions of the molecules involved in viscous flow, as defined by Eyring.[12]

The results in this investigation are interpreted in terms of eq. 1. The effects of different solvents on the rate of fluorescence quenching reactions will be discussed on the basis of the relation presented for the probability of reaction per encounter by Williamson and La Mer.[8]

Experimental

Quenching Constants.—Quenching constants have been measured with the sensitive photoelectric fluorimeter developed by Umberger and La Mer,[7] and the experimental techniques described therein. The volume-molar quenching constants for the quenching of the fluorescence of uranin by aniline have been measured in the following solutions: water and glycerol, water and sucrose, water and methanol, and methanol, ethanol and isopropanol.

Uranin was chosen as the fluorescent material since its average life in the excited state, τ, was constant within the solvent ranges chosen.[13,14] Aniline was chosen as the quencher since its electrical neutrality in alkaline solution reduced very greatly primary kinetic salt effects. These have been shown to be zero by Williamson and La Mer.[8]

All quenching measurements were made within the temperature range 24.5–26.5°, with most falling between 24.5 and 25.5°. However, the actual temperature in the cell was recorded at the time of the measurement to $\pm 0.2°$, and the viscosity of the solution experimentally determined at this temperature with an Ostwald viscometer. The concentration of quencher used was 0.0100 molar, and the concentration of uranin 10^{-5} molar, with the pH of all solutions approximately 12. The results are given in Table I, and are plotted in Fig. 1 as a function of the solvent fluidity.

To correct for the reabsorption of the fluorescent light,[7] it was necessary to obtain the value of the quenching con-

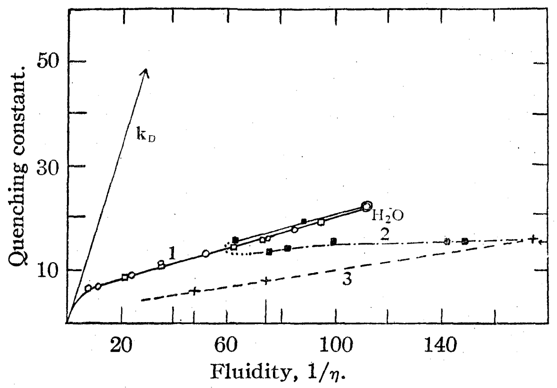

Fig. 1.—Quenching constants as a function of solvent fluidity: O, glycerol–H_2O; □, sucrose–H_2O; ■, methanol–H_2O.

stant extrapolated to zero uranin concentration. A plot of log k_Q against the concentration of dye shows a linear relation between 10^{-5} and 2×10^{-6} molar uranin. Extrapolation to the zero concentration intercept gives the quenching constant corrected for reabsorption. The slope of this line for the quenching reactions uranin and aniline and uranin and potassium iodide was determined in water at 25° as 8500 ± 500 l./m. In the glycerol–water and sucrose–water mixtures the slopes were found to be less than that in water; for example, 5600 ± 500 for 36.8% glycerol, and 6400 ± 600 for 18.6% sucrose, respectively. This decrease is probably due to a difference in the amount of overlap of the fluorescence and absorption spectra as the solvents are changed. Hence the correction to be applied to the 10^{-5} molar quenching constant decreased as the concentration of the glycerol and the sucrose increased. The slopes in the alcohols were the same as in water.

Isopropanol	20.8	48.1	8.0	6.2

A small correction was also necessary for the absorption of the incident light by the aniline, as reported by Williamson and La Mer.[8] Their experiments were repeated in various solvents and the absorption remained constant. Hence, as the k_Q decreased, the correction became relatively greater. Quenching independent of diffusion, known as static quenching, may occur when the uranin is excited while in an encounter.[15] This complication is removed by extrapolation to zero concentration of quencher.

Since the addition of sodium hydroxide to aniline hydrochloride produced a precipitate of sodium chloride in the alcoholic solvents, it was necessary to use freshly distilled aniline as quencher in these solvents. In 10^{-5} molar uranin, and 0.01 molar sodium hydroxide in excess of the aniline hydrochloride concentration, the same value of the quenching constant was obtained whether aniline or aniline hydrochloride was used as the quencher.

Diffusion Coefficients.—In order to calculate the molar encounter frequencies for the reaction, values of the diffusion coefficients D, of both dye and quencher are required. A search of the literature revealed that no values were recorded for uranin and aniline at 25°, in the solvents used. Hence, it was necessary to determine the diffusion coefficients in systems closely approximating those occurring during quenching measurements. The "diaphragm cell" method of measurement was employed,[16] using as a standard that value proposed by Gordon, $D = 1.838 \times 10^{-5}$ sq. cm./sec. for 0.10 molar potassium chloride for which $\Delta c_f/\Delta c_0$ is almost unity.

Analysis of the solutions in the upper and lower compartments was carried out as follows:

Potassium Chloride and Hydrochloric Acid.—Volumetric titration using standard procedures ("Elementary Quantitative Analysis" by Willard and Furman).

Uranin.—The uranin concentrations were measured in the fluorimeter after appropriate dilutions with solvent, until upper and lower intensities were comparable and in a range where reabsorption effects did not interfere.

Aniline.—Because of the decomposition which occurs in basic aniline with time, and the consequent shifting of absorption bands, it was necessary to do considerable trial work with basic aniline solutions, making periodic analyses at different wave lengths in the Beckman Ultraviolet Spectrophotometer. The absorption of aniline over a seventy-two hour period at wave lengths between 240 and 300 mμ was found to be sufficiently constant if the diffusion cells were painted black and the solutions protected as well as possible from the light.

The results for uranin and aniline in different solvents are given in Table II. The diffusion coefficients of 10^{-5} molar uranin in glycerol–water and sucrose–water solutions are plotted in Fig. 2 as a function of the weight percentage and mole fraction of glycerol or sucrose.

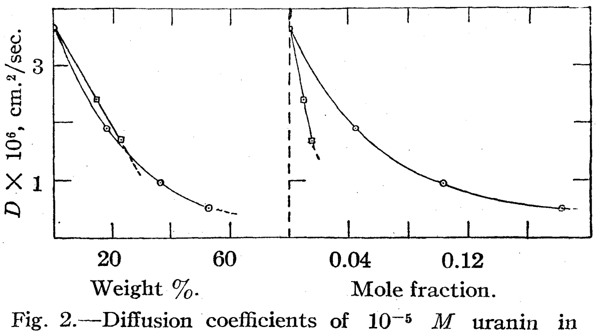

Fig. 2.—Diffusion coefficients of 10^{-5} M uranin in glycerol–water, ⊙, and in sucrose–water, ⊡, solution.

Discussion of Results

Diffusion Coefficients.—Kinetic theory when applied to suspended particles in a medium yields,[17] $D = RT/NaF$. Here *R*, *T*, and *Na*, have their usual meanings and *F* is the frictional resistance, to movement of a particle. According to Stokes' law the frictional resistance for spherical particles, large compared to the molecules of solvent, is $F = 6\pi\eta r$, where "*r*" is the radius of the particle, and eta is the viscosity of the medium. Combining the equations yields

$$D = \frac{RT}{Na} \times \frac{1}{6\pi\eta r} \qquad (2)$$

The methods of testing the reliability of this equation have been to observe the constancy of the products $D\eta$, and Dr, as the other variables are changed. Excellent constancy is obtained when the viscosity is varied by changing the temperature in a fixed solvent. On the other hand, less quantitative agreement is obtained when the viscosity is varied by changing the solvent at a given temperature. The explanation, very likely, is that the frictional resistance given above is less applicable when the solute molecules approach the size of the solvent molecules. In the limit, for very small solute molecules, Sutherland[18] expressed the frictional resistance as $4\pi\eta r$. The radius for uranin is consequently more reliable than that for the smaller aniline molecule.

The effective diffusion radius of the uranin and the aniline, calculated from the Stokes–Einstein relation(2), are reported in Table II. In the glycerol–water mixtures the values of "*r*" for uranin increase slightly with increasing glycerol content. Solvation of the uranin by the glycerol could account for this increase. It is believed that the smaller values of the radii obtained in the alcohols may be due to the inadequacies of the Stokes–Einstein relation rather than to an actual radius decrease. Hence, in calculating encounter frequencies in the alcohols, the values of the radii obtained in water have been used for the reaction radius, *R*.

The radius value obtained for uranin in water, 6.6 Å. (*p*H 12), checks well with the value, 6.8 Å., reported by Marenesco[19] for neutral fluorescein, but differs somewhat from his value, 5.5 Å., for uranin in 0.75 molar sodium hydroxide. Both of Marenesco's values were obtained from viscosity measurements.

Marenesco measured the diffusion coefficients for other dyes—Rhodamine B, Eosin—(see Table III) which are similar in structure to uranin, in solutions of *p*H 6.2–7. In this range of *p*H these dyes are not appreciably ionized. There is disagreement between the results of Marenesco and the authors in respect to the trend in radii resulting from the change of solvent from water to alcohols. This divergence probably results from the fact that the two sets of measurements involve substances of different electric charge type, namely, Marenesco's are on a molecule, and these upon ion. Likewise, all of the present measurements were carried out in solutions of 0.01 *M* sodium hydroxide concentration, and the dye was several hundred-fold more dilute. In addition, the differences of the dielectric constants in the solvents used may effect the diffusion in the case of the uranin.

TABLE III

COMPARISON OF DIFFUSION COEFFICIENTS IN DIFFERENT SOLVENTS

	2.1	Eosin	8.6			
Isopropanol				2.18	Uranin	4.7

Quenching Constants.—It may be seen from Table I and Fig. 1 that the results for the dependence of k_Q on η for the different types of solvents do not coincide with each other. The results show a decided dependence on the type of solvent used to obtain the macroscopic viscosity. Sveshnikoff[14] measured I_0/I values for the same reaction in a series of alcohols at various temperatures and reported no specific solvent effects.

---

(17) A. Einstein, *Z. Electrochem.*, **14**, 235 (1908).

(18) W. Sutherland, *Phil. Mag.*, [6] **9**, 781 (1905).

(19) N. S. Marenesco, *J. Chim. Phys.*, **24**, 593 (1927).

Unfortunately, it is impossible to correct his measurements for the various interfering effects mentioned previously. Hence, we are unable to report properly corrected quenching constants from his data.

The present results follow three general paths. Starting with water and increasing the viscosity by additions of either glycerol or sucrose, the quenching constants decrease along what has been labelled—path 1—in Fig. 1. The results in methanol, ethanol and isopropanol fall in a series by themselves—path 3—running more or less parallel to the water–glycerol series. However, in changing solvent from methanol to water through a series of methanol–water mixtures, the quenching constants follow path 2. The essentially different nature of methanol-rich mixtures and water-rich mixtures of the same macroscopic viscosity accounts for the effect of these solutions on the quenching constants.

The effect of solvent on the quenching constant, other than that caused by the macroscopic viscosity, may be partially interpreted by the effect of the solvent changes on the lattice distance "*a*." The larger value of "*a*" which one would expect in alcohols over that value in water will reduce k_D, the encounter frequency. For example, if the lattice distance be assumed equal to the cube root of the volume per molecule in the following solvents, the decreases in k_D are evident:

Solvent	Molar vol.	"*a*" in Å.	k_D ("*a*" const.)	k_D ("*a*" from column 3)
Water	18	3.1	122 (a = 3.1)	122
Methanol	40	4.1	226 (a = 3.1)	171
Ethanol	58	4.6	120 (a = 3.1)	81
Isopropanol	77	5.0	79 (a = 3.1)	50

Part of the specific solvents effects on the quenching of fluorescence may not have been recognized in the calculation of k_D, the encounter frequency, because the method of measurement of the diffusion coefficients in the various solvents involves the determination of large concentration differences. The true driving force of diffusion is not concentration gradient, but rather gradient of chemical potential or its index, the activity. This may necessitate corrections in k_D which cannot be made easily and it has been necessary to ignore them when treating the data.

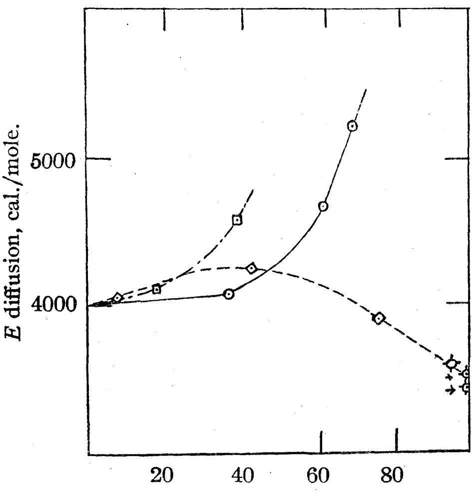

Fig. 3.—Energy of activation of diffusion as a function of solvent: —, ⊙, glycerol–water; – – –, ⊡, sucrose–water; — — —, ◇, methanol–water.

The probability of reaction per encounter, "p"[8] may change with changing solvent. This probability may be equated to the ratio of the probability of reaction per collision to the sum of the probabilities of reaction per collision plus the probability of diffusion out of the encounter by either reactant between collisions

$$p = \frac{P \exp.\ (-E\ \text{act.}/RT)}{P \exp.\ (-E\ \text{act.}/RT) + C \exp.\ (-E_{\text{diff.}}/RT)} \qquad (3)$$

It seems reasonable to assume that the solvent forming the cage will have only a small effect on the chemical energy of activation. However, it is well known that the energy of activation of diffusion, $E_{\text{diff.}}$, varies considerably in different solvents. It is at once apparent that the lower the value of the energy of activation of diffusion, the more likely an encounter is to be broken by diffusion between collisions. Thus the probability of reaction per encounter must diminish.

From the "p" values obtained from comparison of measured quenching constants with the calculated encounter frequencies, the energies of activation of diffusion have been calculated. The chemical energy of activation has been calculated to be 3900 cal./mole by the method of Williamson and La Mer[8] with k_D from equation 1. The energy of activation of diffusion in water was chosen as 4000 cal./mole at 25°. The ratio C/P (equation 3) equals 5, and for the $E_{\text{diff.}}$ calculations the steric factor P has been assumed unity. Selected $E_{\text{diff.}}$ values are given in Table IV. The energies of activation of diffusion of the solvents used are plotted as a function of solvent composition in Fig. 3.

The glycerol–water and sucrose–water solutions yield values of the energy of activation of diffusion of 4000 cal./mole or more in all cases. The solvents methanol, ethanol and isopropanol give values around 3500 cal./mole. The energies of activation of diffusion pass through a maximum in the methanol–water mixtures.

The literature gives the following information on energies of activation of diffusion. Quantitative data on energies of activation of diffusion are relatively scarce due to the difficulties of measurement. Scheffer and Scheffer's[20] data on the diffusion of mannitol in water yield an $E_{\text{diff.}}$ of 4460 cal./mole in the temperature range 20–30°. Other data calculated from the "International Critical Tables" for the solvent water gives $E_{\text{diff.}}$

---

(20) J. Scheffer and F. Scheffer, *Proc. Acad. Sci. Amsterdam*, **19**, 148 (1916).

at 15° as about 5000, while for iodine in methanol at 15° $E_{\text{diff.}}$ is 4100, and iodine in ethanol in the range 8–18° is 3700 cal./mole. In general when the solute molecules are large, $E_{\text{diff.}}$ is a function of the solvent rather than the solute.

Eyring[21] states that the energy of activation of diffusion is related to the energy of evaporation by a factor ranging between 3 and 4. For water and the alcohols these values have been calculated and are given in Table IV, assuming a constant factor of 3. The energy of activation of viscosity has been calculated from the temperature dependence of measured viscosities.

TABLE IV

OBSERVED AND CALCULATED VALUES OF THE ENERGY OF ACTIVATION OF DIFFUSION

Solvent	k_D (calcd.)	k_Q (meas.)	p	E_D (obs.) (cal./mole)	$E_{\text{visc.}}$ (calcd.) (cal./mole)	
36.8 Wt. % glyc.	55.9	11.4	0.20	4070	20%	4620
61.5 Wt. % glyc.	16.8	6.9	.41	4670	40%	5570
69 Wt. % glyc.	10.9	6.8	.63	5210	60%	7110
18.6 Wt. % sucrose	67.8	14.4	.21	4110	20%	4620
39.2 Wt. % sucrose	23.6	8.7	.37	4590	40%	6110
8.1 Wt. % methanol	98	19.6	.20	4070	47.4%	4560
43 Wt. % methanol	62.4	15.8	.25	4260	71.6%	3700
76 Wt. % methanol	87.0	14.2	.16	3910		
Methanol	171	15.9	.09	3540	2430	
Ethanol	81	8.1	.10	3580	$E_{\text{vap.}}/3$-3140	
Isopropanol	79	6.2	.08	3440	$E_{\text{vap.}}/3$-3170	
Water	122	22.0	.18	4000	$E_{\text{vap.}}/3$-3520	
					$E_{\text{visc.}}$	3700

The trends shown are all in agreement with the experimental results. Better quantitative agreement would be fortuitous, considering the original assumptions. Note that in Table IV, when p is small, the $E_{\text{diff.}}$ is small. This means that the probability of reaction during an encounter will be less the more easily the reactants can diffuse out of the encounter between collisions.

The dependence of quenching constants on the viscosity of the solvent will vary depending on the choice of solvent, and the chemical energy of activation for the particular fluorescent material and quencher. A linear relationship between quenching constant and fluidity will be the exception.

The data of this investigation have been recalculated on the basis of the normalized mole fraction concentration scale.[22] No advantage has been gained by such a change in this reaction.

Acknowledgments.—The authors wish to express their appreciation for the suggestions made by Professor G. E. Kimball and Dr. J. Q. Umberger.

The award of a National Research Council Predoctoral Fellowship to one of us (K.C.H.) made possible the completion of this work.

Summary

1. The kinetics of the quenching of the fluorescence of uranin by aniline has been investigated as a function of the viscosity of the solvent in which the reaction is carried out.

2. The diffusion coefficients, D of uranin and aniline have been measured using the diaphragm-cell method in the solvents water, methanol, ethanol, isopropanol, water–glycerol and water–sucrose. They are reported and discussed in terms of the theories pertaining to diffusion.

3. The molar quenching constants are dependent on properties other than the macroscopic viscosity of the solvent. Hence, the previously expected linear relationship between quenching constants and the reciprocal of viscosity need not hold. The data are interpreted in terms of both the diffusion of the reactants together and the probability of reaction when the two are in an encounter. This latter quantity is controlled by an energy of activation of diffusion. The functional dependence of quenching constants on viscosity will depend on the choice of solvent used to vary the viscosity.

Some Catalytic Hydrogen Exchange Reactions of Hydrocarbons

BY J. AMAN, L. FARKAS AND A. FARKAS[1a]

The catalytic exchange reaction of hydrocarbons with molecular hydrogen has been the subject of a large number of investigations.[1b-8] Two different mechanisms have been proposed for the reaction: (a) the dissociative and (b) the associative mechanism. The dissociative mechanism may be formulated as

$$RH_2 \xrightarrow[-H]{+K} RH - K \xrightarrow[+D]{-K} RHD \qquad (1)$$

On the other hand Polanyi and Horiuti have suggested the following associative mechanism for the exchange reaction

$$RH_2 \xrightarrow[+D]{+K} RH_2D - K \xrightarrow[-H]{-K} RHD \qquad (2)$$

(K = catalyst)

The half-hydrogenated compound which is formed by the first step in (2) is according to these authors responsible for the connection between the hydrogenation and exchange reaction, since it is an intermediate compound for both processes.

While all experiments on the exchange of saturated hydrocarbons indicate that in these cases the dissociative mechanism is operative[4,5,9,10] the exact mechanism of the exchange reactions of unsaturated hydrocarbons has not yet been definitely settled.

The present paper reports some results on the exchange of the following pairs of compounds: ethylene and water, *n*-butene and water, *n*-butane and water, *n*-butene and ethylene, and *n*-butane and ethylene. The mechanism of the catalytic exchange reactions is discussed in the light of these findings.

Experimental

Material

Ethylene was obtained either from a cylinder from the Ohio Chemical Co. or by dehydration of ethyl alcohol in the presence of alumina at 400°.

***n*-Butene** was prepared by the dehydration of *n*-butyl alcohol by means of alumina at 400°. The two isomers butene-1 and butene-2 thus obtained were used without separation.

***n*-Butane** was prepared by the hydrogenation of *n*-butene with an excess of hydrogen on a nickel or palladium catalyst.

Heavy *n*-butane was prepared by hydrogenating *n*-butene with deuterium in the presence of either nickel or palladium.

All the above mentioned hydrocarbons were purified by fractional distillation under low pressure.

Palladium Catalyst.—This was prepared by passing hydrogen through a suspension of 5 g. of activated charcoal (lumps) in a concentrated solution of 1 g. of palladium chloride at 50–60° until the solution was completely decolorized. The lumps of catalyst were washed with distilled water, neutralized with a dilute solution of sodium hydroxide, and again washed with distilled water until free of chloride ions. The catalyst was then dried at 100° in vacuum. The catalyst thus obtained contained about 10% palladium by weight.

Nickel Catalyst.—Raney nickel in the form of either powder or lumps was used. It was prepared in the usual way by dissolving out the aluminum with a concentrated solution of sodium hydroxide. The catalyst was protected from contact with air prior to use (for method of handling, see below).

Apparatus and Procedure

Two methods were used: (1) a static method in which the apparatus consisted essentially of a large reaction bulb, and (2) a circulating method in which the reacting gases were circulated over the catalyst by means of a pump.

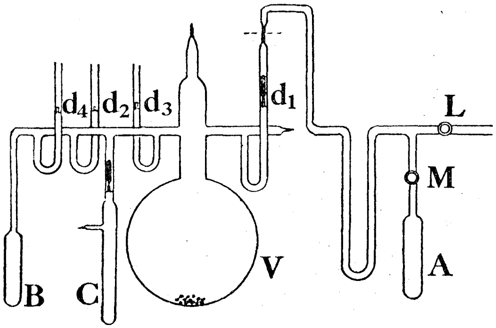

Fig. 1.—Reaction vessel (static method).

(1) In the static method (Fig. 1) reaction vessels 1 to 5 l. capacity were used. They were fitted with one or more break-seals, *d*, for the introduction or withdrawal of samples. The side-arm, B, served for the condensation of the reactants. If water was one of the reactants, it was previously degassed in a small glass tube and sealed off under vacuum. This tube, C, was connected to the reaction vessel via a break-seal. The palladium catalyst was introduced directly into the reaction vessel. When a nickel catalyst was used the following procedure was adopted: the nickel powder or lumps were washed by decantation with distilled water until free of alkali and transferred, while still wet, to a thin-walled glass tube. This tube was then connected via a trap cooled in an acetone–Dry Ice slush to a high vacuum system and the water distilled off. The catalyst was then degassed by heating to 200° for several hours, sealed off, and introduced carefully into the reaction vessel which was then evacuated. Grease and mercury vapors were excluded during this operation by a Dry Ice trap. Known amounts of the gaseous reactants were then distilled into the side-arm, B, by cooling it with liquid air, and the reaction vessel was sealed off. Water, if one of the reactants,

was then admitted into the reaction vessel by breaking the appropriate break-seal. If nickel was used as a catalyst, the reaction vessel was shaken vigorously at this stage, until the thin-walled tube containing the catalyst was broken. The reaction vessel was then heated in an electric furnace at a constant temperature for a definite time, after which it was connected through one of its break-seals to the evacuating system, thus enabling a sample of the contents to be withdrawn into A and analysed.

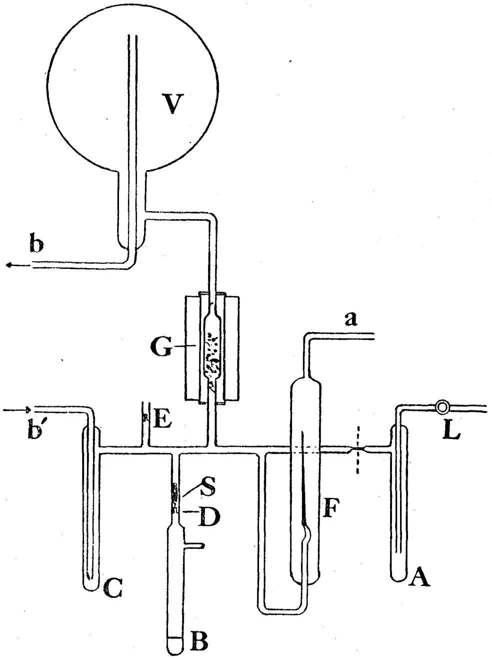

Fig. 2.—Reaction apparatus (circulating method).

(2) In the circulating method (Fig. 2) an all glass electromagnetic pump was used for circulating the reactants over a palladium catalyst heated to the desired temperature in an electric furnace, G. At the start of an experiment, the reaction system was evacuated and the catalyst outgassed at 150°. The reacting gas was then introduced through a trap, A, cooled in an acetone–Dry Ice slush into the tube, C, which was cooled in liquid air. After sealing off from the evacuating system, the break-seal D was broken, so that the water in B distilled over into C; the circulating pump was then started. The temperature of the catalyst was fixed at the desired value and the gas allowed to evaporate and bubble through the water in C which was kept at a constant temperature. After a certain time the reacting gas and water were withdrawn through the break-seal E and analysed. An all glass Bourdon type gage, F, was used to measure the change of pressure in the apparatus.

The electromagnetic pump (Fig. 3) differed in the following details from those described previously.[11,12]

(a) Only one electromagnet E was used for lifting the piston (consisting of an iron rod 25 mm. in diameter and 300 mm. long enclosed in a glass tube) and (b) a mercury switch M instead of an electric motor was used for interrupting the current. The pump works as follows: when a direct current from a 220 v. source is switched on, the electromagnet E lifts the piston; at the same time two small electromagnets, D, connected in parallel with E work against the spring, L, and tip the mercury switch, M, so that the current is interrupted. The piston then falls down freely while the spring L brings the switch M back to its initial position. The cycle is then repeated. With a current of 0.3 ampere the pump could circulate 1.1 l., of gas per minute against a back pressure of 110 mm. When only gaseous reactants were used the pump could work for several hundred hours without interruption. When water vapors were circulated, the piston stuck to the glass wall after about fifty hours and had to be cleaned.

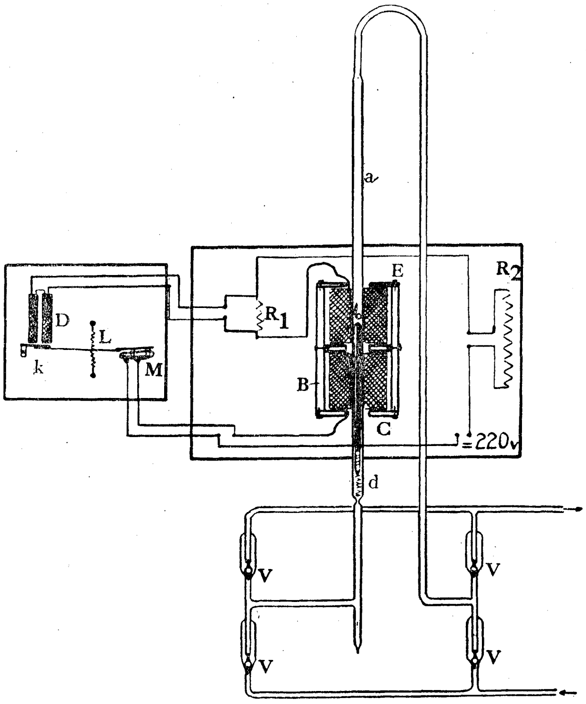

Fig. 3.—All glass electromagnetic circulating pump.

Analytical

The water was separated from the hydrocarbon by distillation in vacuum. It was further purified by the addition of anhydrous sodium carbonate and potassium permanganate and redistilling in vacuum. It was then analyzed for its deuterium content by the float method with an accuracy of 1 part of D_2O in 5×10^4 parts of H_2O. If 0.5 to 1 g. of the hydrocarbon were available, it was burnt over platinized asbestos and the water obtained after purification was analyzed by the float method. If only small samples of the hydrocarbon (3–5 mg.) were available, the analysis was carried out by a method described previously[13] consisting of burning the hydrocarbon to water over copper oxide and bringing this water into equilibrium with a minute amount of hydrogen by means of a glowing platinum filament. The deuterium content of the hydrogen was then analyzed by the microconductivity method.

Experimental Results

Exchange between Ethylene and Water.—The results of these experiments are given in Table I. Experiments 1, 2, 3, 15 and 16 were performed by the circulating method, and 4 and 5 by the static method. In Expt. 16 both the water and the ethylene were analyzed, in the others the deuterium content of the ethylene was calculated from the change in the deuterium content of the water. The last column of Table I shows the values of the partition

$$K = (D/H)\text{ ethylene}/(D/H)\text{ water}$$

TABLE I

EXCHANGE BETWEEN ETHYLENE AND WATER

				Water				Ethylene				
Expt.	Catalyst	Temp., °C.	Reac. time, hours	Moles	Partial pressure, mm.	% D-content initial	% D-content final	Moles	Partial pressure, mm.	% D-content initial	% D-content final	Partition, *K*
15	Pd (0.5 g.)	110	190	0.047	300	9.8	9.6	...	...	..	..	..
3	Pd (2 g.)	80	30	.10	17.5	1.00	0.99	0.076	500	0.00	0.00	0.00
1	Pd (2 g.)	120	20	.11	17.5	1.22	1.21	.069	400	.00	.00	.00
16	Pd (1 g.)	110	45	.31	17.5	9.9	9.5	.090	600	.00	.11	.01
2	Pd (2 g.)	170	21	.11	17.5	1.24	1.14	.070	500	.00	.07	.06
4	Pd (1.5 g.)	110	118	.083	350	1.05	0.44	.062	260	.00	.41	.93
5	Ni (5 g.)	110	140	.083	350	4.43	1.69	.088	370	.00	1.29	.76

It is seen from Table I that no exchange, or at most only a very slow one, occurred when the circulating method was used, even at a temperature of 170°. On the other hand, equilibrium was almost reached in the static method experiments. The longer reaction time in Expts. 4 and 5 cannot explain the higher deuterium values observed in the ethylene, and we have to assume that the much higher partial pressure of water (350 mm.) as compared with that in the circulating method experiments (17.5 mm.) is responsible for the higher rate of exchange. The dependence of the rate of exchange on the partial pressure of water and ethylene has not yet been investigated further.

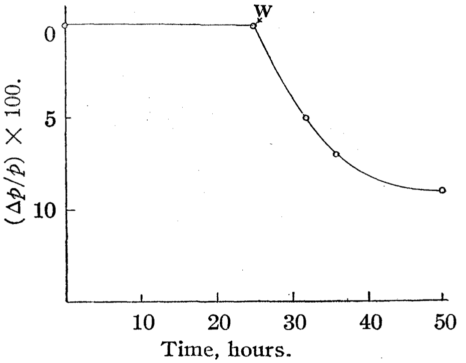

Fig. 4.—Polymerization of ethylene in the presence of water.

It was noticed that, in those experiments in which there was no appreciable exchange, a decrease of the pressure in the reaction system occurred due to polymerization. In Fig. 4 the change of pressure in Expt. 16 is given. It will be seen that the pressure change occurred only in the presence of water but not in the absence of water during the first twenty-five hours. After a certain reaction time, the catalyst becomes poisoned by traces of a high polymer and its activity considerably reduced. By determining the vapor pressure of the polymerization product at eight different temperatures between −60 and −25°, it was found to be butene-2. In Expts. 4 and 5 with high partial pressure of water no polymerization was observed. Besides the polymerization two side reactions also occurred in the presence of the palladium catalyst: the formation of small amounts of ethyl alcohol and acetic acid.

Exchange between Butene and Water.—The experimental results are given in Table II. In Column 13 the equilibrium values of the deuterium content of the butene are given. They were calculated on the assumption that all the eight hydrogen atoms are exchangeable and that the partition coefficient for this reaction is 0.8 (*i. e.*, the same as in the case of the ethylene and water). Column 14 gives the first order velocity constant

$$k = \frac{1}{t} \ln \frac{D_e}{D_e - D_t}$$

where D_e and D_t denote the deuterium content at equilibrium and at time t, respectively. It can be seen that in all cases an exchange between the hydrogen atoms of the water and the hydrogen atoms of the butene took place. Figure 5 shows the course of the exchange in Expt. 21. It can be seen that here also the catalyst gradually lost its activity.

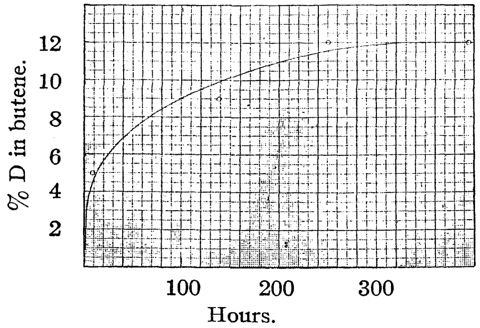

Fig. 5.—Exchange between butene and water at 120°.

The water recovered after exchange in the presence of the palladium catalyst contained an unidentified acid and also a solid polymer which remained behind on evaporating off the water.

Exchange between Butane and Water.—No exchange between butane and water was observed under conditions under which the exchange between butene and water took place readily (catalyst: 2 g. palladium; temperature, 120°; reaction time, 160 hours; p_{H_2O} = 220 mm.; $p_{C_4H_{10}}$ = 20 mm.). This negative result was not due to (accidental) inactivity of the catalyst, since the same catalyst was used in a subsequent experiment (Expt. 20, Table II) for the reaction between butene and water in which an exchange was observed.

TABLE II

EXCHANGE BETWEEN BUTENE AND WATER

				Water				Butene

Exchange between Butene and Ethylene.—The results are given in Table III. In all these experiments, except in Expt. 6, "heavy" butene was used in order to exclude the possibility of an apparent exchange reaction due to dimerization of "heavy" ethylene. Column 13 gives the equilibrium values of the deuterium content of the two hydrocarbons assuming a partition coefficient of 1. All the hydrogen atoms in the butene were assumed to be exchangeable. Column 14 gives the first order velocity constant. In all cases only the deuterium content of the ethylene was determined. Ethylene was chosen rather than butene, since the change in its deuterium content is relatively higher. In Expt. 18, a series of measurements on the progress of the exchange reaction was also made (see Fig. 6). During the reaction no change of pressure occurred.

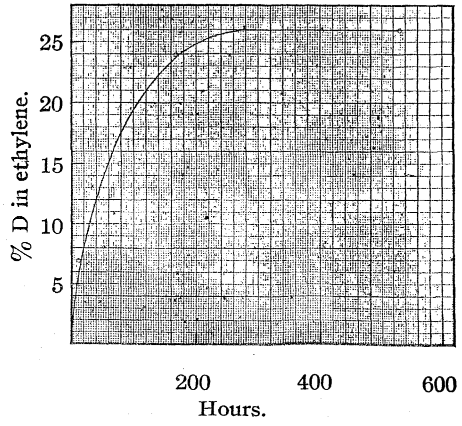

Fig. 6.—Exchange between butene and ethylene.

Exchange between Butane and Ethylene.—The exchange between butane and ethylene was tested by the same procedure as used in Expt. 18 of Table III: 0.0052 mole of butane (D-content 45%) and 0.0021 mole of "light" ethylene were allowed to interact on the palladium catalyst for one-hundred fifteen hours at 120°. After this treatment the deuterium content of the ethylene was found to be 1%. This increase was within the limits of experimental error. After this period, a small amount of "light" butene (0.0002 mole) was introduced into the reaction vessel in order to test whether the exchange between butane and ethylene proceeds via butene. After a period of one-hundred thirteen hours, the deuterium content of the ethylene rose to 1.5%. The possibility that these negative results were due to an accidental inactivation of the catalyst was excluded by using the same catalyst for the exchange of butene and ethylene in Expt. 23 of Table III.

The activity of the same catalyst was also tested for the exchange reaction of butane with deuterium. The catalyst which was used in the butane–ethylene exchange (one-hundred fifteen hours), butane–ethylene–butene exchange (one-hundred thirteen hours) and butene-ethylene (ninety hours; Expt. 23) was brought into contact with 0.0043 mole of "light" butane and 0.0028 mole of deuterium (99.6% D_2) in the same reaction vessel at 120°. The deuterium content in the butane was found to be 6 and 9% after thirteen and one-half and thirty-five and one-half hours, respectively.

Discussion

The exchange of water with ethylene has been observed by Horiuti and Polanyi,[3] and the present experiments are in qualitative agreement with their results. In the experiments of these authors, the ratio $p_{H_2O}/p_{C_2H_4}$ was 2.6. In the present experiments this ratio was about 1 when the static method was used and only 0.029 to 0.044 in the circulating method. These experiments show a strong dependence of the rate of exchange on the ratio of the partial pressures of water and ethylene and the simplest assumption is that water is displaced from the surface of the catalyst by ethylene if the ratio $p_{H_2O}/p_{C_2H_4}$ is low. On the other hand, the absence of dimerization of ethylene in the presence of a high partial pressure of water would suggest that under these conditions the ethylene concentration on the surface layer is low, so that ethylene–ethylene interaction becomes slow. At low partial pressures of water, the dimerization of ethylene could be explained by the well-known mechanism of carbonium ion formation

$$C_2H_4 + H_2O \longrightarrow C_2H_5^+ + OH^- \qquad (3)$$

$$C_2H_5^+ + C_2H_4 \longrightarrow C_4H_8 + H^+ \qquad (4)$$

If the first step goes only in a forward direction and the second step in this scheme is rapid, it would explain the absence (or relatively slow rate) of exchange of ethylene with water under these conditions. According to this mechanism the deuterium content of the dimer (butene) should have the value of 12.5% (one deuterium atom out of eight hydrogen atoms) if the dimerization were catalyzed by deuterons from pure deuterium oxide. In Expt. 16 of Table I, in which the content decreased from 9.86–9.6% a butene with 1.14% D-content should be obtained. The D-content of the butene formed by dimerization was not determined.

In the case of the exchange reaction between ethylene and water, the possibility that the reaction $C_2H_4 + H_2O \rightleftarrows C_2H_5OH$ contributes substantially to the exchange must be considered. However, a quantitative consideration shows that this is improbable. The equilibrium constant of this reaction is at 110° about 0.068,[14,15] so that at the equilibrium in Expts. 4 and 5 about 1.5% of ethyl alcohol should be formed. In fact only in Expt. 4 in the presence of palladium catalyst was the formation of ethyl alcohol detectable. Nevertheless the exchange also takes place on a nickel catalyst at a similar rate, and in this case there is no evidence that ethyl alcohol is formed.

This observation, together with the fact that ethyl alcohol and water on a platinum catalyst[16] exchange only the hydrogen atom of the hydroxyl group, show that the above reaction is a slow one and does not play an important role in the exchange process under our experimental conditions.

The general features of the butene–water exchange are similar to those of the ethylene–water exchange. In these experiments the $p_{H_2O}/p_{C_2H_4}$ ratio was between 0.9 and 10. These extreme values of the ratio do not influence the rate of exchange to a great extent. On the basis of the present experiments it is not possible to decide whether those hydrogen atoms attached to the double bonded carbon atoms exchange more readily than the remainder. Of particular significance is the absence of exchange between butane and water under conditions under which the exchange between butene and water takes place readily.

Horrex, Greenhalgh and Polanyi[17,18] found that the rate of exchange of benzene with water is about the same as that of cyclohexane and isopentane with water, and inferred that in general the exchange rate of saturated and unsaturated hydrocarbons with water is the same. Our observations indicate that this generalisation is not permissible, and that the similarity in the rates of exchange in the cases investigated by Horrex, Greenhalgh and Polanyi is accidental and dependent upon certain particular experimental conditions (partial pressures and temperature). The experiments on the exchange of ethylene with water show clearly that the ratio of partial pressures has a decisive influence on the rate of exchange of this pair, and it is probable that a more or less pronounced dependence on the ratio of partial pressures of the reactants may also occur in other cases. The comparison of the rate of exchange of butene and butane with water on the same catalyst under identical conditions suggests that in the case of the butane–water pair the absence of exchange is due to a complete displacement of butane by water from the catalyst. This mutual displacement strongly influences the rate of interaction on the catalyst, and it has already been emphasized in previous publications that this effect has to be taken into account.

The same authors also discussed the two possible mechanisms of exchange in the light of their findings that the rate of exchange between water and saturated hydrocarbons was similar to the rate of exchange between hydrogen and saturated hydrocarbons and came to the conclusion that the dissociative mechanism can be operative only if the first step in the scheme

$$RH_4 \underset{-H}{\overset{+K}{\longrightarrow}} RH_3 - K \underset{+H}{\overset{-K}{\longrightarrow}} RH_4$$

is the rate determining step. It was assumed that the chemisorbed hydrogen atoms on the catalyst arising from the presence of molecular hydrogen must be greater than that arising from the presence of water and therefore the second step should be much faster in the former case than in the latter. Actually we have found this to be the case in our exchange experiments with butane and water and butane and hydrogen so that the above conclusion that the second step cannot be the rate determining step can be upheld in its general form.

The experiments on the exchange of hydrogen atoms between ethylene and butene are of particular interest, in connection with the question as to whether or not unsaturated hydrocarbons undergo dissociation on the surface of the catalyst. Conn and Twigg[8] investigated the interaction of C_2H_4 and C_2D_4 on a nickel catalyst at 76° and 330–360°, but found that no ethylene molecules containing both hydrogen and deuterium atoms were formed, even if the time of interaction was much longer than the half life time of the exchange of ethylene with deuterium on the same catalyst. They considered these experiments as a direct proof that no dissociation of unsaturated compounds takes place to any appreciable extent, and concluded that the exchange of ethylene and deuterium must follow the associative mechanism.

It has been pointed out,[19] however, that this negative result might be due to the fact that under the experimental conditions of these authors the stationary concentration of hydrogen atoms on the surface of the catalyst was so low that the mutual exchange of C_2H_4 with C_2D_4 was inappreciable. The hydrogen concentration on the catalyst might be very low if the atoms formed by dissociation are removed from the catalyst by reaction with ethylene.

The present observations on the exchange of butene with ethylene show directly that unsaturated hydrocarbons can exchange their hydrogen atoms and although the observed rates were not very great (the same order of magnitude as the exchange rates with water) they show that there is only a quantitative difference in the behavior of unsaturated and saturated hydrocarbons. The negative result of the exchange experiment with ethylene and butane is presumably due to the displacement of the butane from the surface of the catalyst by ethylene.

Summary

The following exchange reactions of hydrogen atoms on palladium and nickel catalysts at pressures of 20–700 mm. and in the temperature range of 80–170° were investigated: water and ethylene, water and butene, water and butane, butene and ethylene and butane and ethylene.

It was found that exchange of hydrogen atoms between ethylene and water, butene and water and butene and ethylene does occur while under the same experimental conditions no exchange between butane and water or butane and ethylene was observed.

The experimental results are discussed and the importance of the mutual displacement of the reactants on the catalyst surface is emphasized. The two possible mechanisms for the exchange reactions are discussed in the light of the new experimental evidence.

The Effect of Substituents upon the Rate of Fading of Some Sulfonphthalein Indicators in Alkaline Solutions

BY ELIZABETH E. SAGER, ARTHUR A. MARYOTT AND MARJORIE R. SCHOOLEY

I. Introduction

The usefulness of an indicator in the measurement of *p*H depends, in part, on its chemical stability. Phenolphthalein and some of the substituted phenolphthaleins show a pronounced tendency to fade, particularly in alkaline solutions. Replacement of the carboxyl group in the phenolphthaleins by the sulfonic acid group to form the phenolsulfonphthaleins greatly increases the stability. Sulfonphthaleins covering practically the entire useful *p*H range are available commercially and form one of the most satisfactory series of indicators for colorimetric and spectrophotometric measurements. In the course of a program concerning the application of precise spectrophotometric methods in the determination of ionization constants of indicators, it seemed desirable to examine quantitatively the alkaline stability of a rather complete series. Although the fading rates of certain of the sulfonphthaleins have been the subject of a number of investigations,[1-6] data are lacking in some cases and have been obtained under varied experimental conditions in others, so that an extensive intercomparison of the effect of substituents upon the fading rates cannot be made.

The mechanism of the fading reaction has been established.[3] A study of the Brønsted primary salt effect showed that the bivalent, alkaline form of the indicator, $[\mathrm{R}^{=}]$, adds a hydroxyl ion to form the colorless carbinol, $[\mathrm{ROH}^{=}]$. As the reaction is reversible, the extent of fading depends on the alkali concentration. The equilibrium between the colored and faded forms is illustrated for phenolsulfonphthalein in Fig. 1. The bimolecular rate constants, k_1 and k_2, represent the fading and color-regenerating reactions, respectively.

In the present work, phenolsulfonphthalein and nine of its derivatives which have various substituents in the two chromophoric rings were studied.

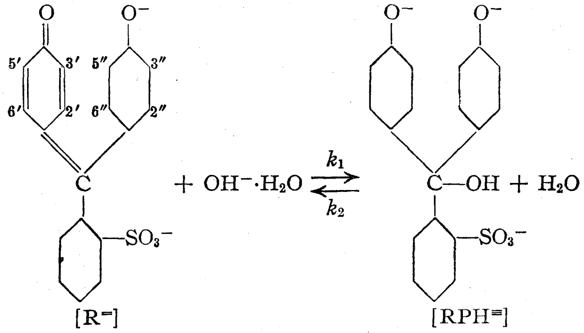

Fig. 1.—Alkaline fading of the phenolsulfonphthaleins.

II. Experimental

Brom phenol red was obtained from Hynson, Westcott and Dunning and the other indicators were obtained from W. A. Taylor and Company. Preliminary experiments were first made to determine the limiting spectral curves which represent the neutral yellow form and the reddish purple to blue alkaline form of each indicator. The molar absorbancy index, a_{M}, is calculated for any given wave length according to the equation

$$a_{\mathrm{M}} = -\log_{10} T_{\mathrm{s}}/(b \times M) \qquad (1)$$

in which T_{s} is the transmittancy of the solution, b is the length of the absorbing path between the boundary layers of the solution (cell-length in cm.), and M is the molar concentration of the indicator.

The maximum values of a_{M} were found for the alkaline forms of the indicators and vary from about 36,000 for thymol blue to 73,000 for brom cresol purple. As two-cm. absorption cells were used for the experiments, odd concentrations of each indicator were used to give an initial transmittancy value of 25 to 30% at the wave length of maximum absorption.

All of the fading reactions were conducted in relatively strong alkali, 1.12 *M*. At lower concentrations of alkali, the time required to follow some of the fading reactions is prohibitively long. The spectral transmittancies at the wave length of maximum absorption were observed throughout the course of the reactions at various intervals of time depending upon the rates of fading. The duration of the reactions ranged from less than an hour for brom phenol blue to a month and more for the more stable indicators. The transmittancies were measured with a Beckman quartz photoelectric spectrophotometer after revision of the cell compartment as described in a previous publication.[7] The temperature of the room containing the spectrophotometer and the solutions was maintained at 25° to within ±1°. In several instances the fading reaction continued to completion, but in a majority of cases a finite equilibrium between colored and colorless forms was reached. When there was no further change in the transmittancy at the wave length of maximum absorption, the spectral curve was taken at 5 mμ intervals from 220 to 750 mμ. These curves represented either the colorless carbinol form in cases of complete fading or an equilibrium mixture of colored and colorless forms. The solutions were again examined later to determine whether any changes in the spectral curves had occurred which might indicate irreversible decomposition.

III. Calculation of Rate Constants

Where the fading continues only until some definite equilibrium is established between the colored and the colorless forms of the indicator, the rate of disappearance of the colored form is given by

$$-\mathrm{d}[\mathrm{R}^{=}]/\mathrm{d}t = k_1[\mathrm{R}^{=}][\mathrm{OH}^{-}] - k_2[\mathrm{ROH}^{=}] \qquad (2)$$

As the alkali concentration is much greater than that of the indicator and does not change much during the reaction, the bimolecular rate constant, k_1, may be replaced by the first-order rate constant, $k_1' = k_1[\mathrm{OH}^{-}]$. The integrated rate equation is then

$$k_1' + k_2 = 2.303/t \log [x_{\mathrm{e}}/(x_{\mathrm{e}} - x_{\mathrm{t}})] \qquad (3)$$

where x_{t} is the fraction of $[\mathrm{R}^{=}]$ which has reacted at time, t, and x_{e} is the fraction reacted at equilibrium. From the relationship between the concentration and spectral transmittancy in accordance with Beer's law

$$x_{\mathrm{e}} = \frac{\log T_{\mathrm{s,o}} - \log T_{\mathrm{s,e}}}{\log T_{\mathrm{s,o}}}$$

and

$$x_{\mathrm{t}} = \frac{\log T_{\mathrm{s,o}} - \log T_{\mathrm{s,t}}}{\log T_{\mathrm{s,o}}}$$

where $T_{\mathrm{s,o}}$, $T_{\mathrm{s,t}}$, and $T_{\mathrm{s,e}}$ are the transmittancies at zero time, at time t, and at equilibrium, respectively. Equation 3 then becomes

$$k_1' + k_2 = \frac{2.303}{t} \log \frac{\log T_{\mathrm{s,o}} - \log T_{\mathrm{s,e}}}{\log T_{\mathrm{s,t}} - \log T_{\mathrm{s,e}}} \qquad (4)$$

From the transmittancies measured at intervals during the course of the fading and the observed equilibrium transmittancy, the forward and reverse rate constants and the equilibrium constant were evaluated in the following manner. The composite rate constant, $k_1' + k_2$, was determined from the slope of the straight line obtained by

plotting log (log $T_{s,e}$ − log $T_{s,t}$) as a function of time according to equation 4. The equilibrium constant was evaluated from

$$K = \frac{[ROH^=]}{[R^=][OH^-]} = \frac{\log T_{s,o} - \log T_{s,e}}{\log T_{s,e}\,[OH^-]} \qquad (5)$$

In general $T_{s,o}$ could not be obtained directly because measurable fading occurred during the time interval between the start of the reaction and the first experimental observations. It was obtained from the intercept of the above plot corresponding to zero time. The separate rate constants were then obtained from the equations

$$k_1 = \frac{k_1' + k_2}{[OH^-] + 1/K} \text{ and } k_2 = k_1/K$$

In cases where fading goes practically to completion, equation 4 assumes the simplified form

$$k_1' = \frac{2.303}{t} \log (\log T_{s,o}/\log T_{s,t}) \qquad (6)$$

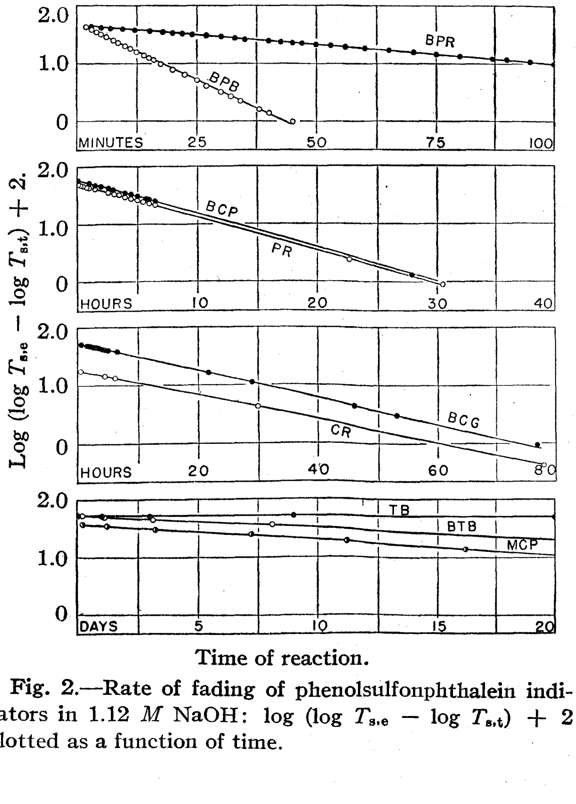

Fig. 2.—Rate of fading of phenolsulfonphthalein indicators in 1.12 M NaOH: log (log $T_{s,e}$ − log $T_{s,t}$) + 2 plotted as a function of time.

IV. Experimental Results

The ten sulfonphthaleins are listed in Table I and their common names as indicators, substituent groups, fading rates, effect of substituents upon the fading rates, as well as their equilibrium and ionization constants are also given. The indicators are given in the order of their fading rate constants, k_1, and the reverse rate constants, k_2, are calculated for the cases where they could be obtained. The substituent effects are defined and discussed in the next section. The experimental data plotted in accordance with equation 4 or equation 6 are shown in Fig. 2. The plots are linear over the entire range of fading. Additional data for TB, BTB, and MCP extended well beyond the twenty days given in the figure. TB fades extremely slowly and only an approximate value of k_1 could be obtained. Data for CPR are not shown. In this case the plot was linear only up to about 50% faded. Beyond this region the points fell above the straight line in a manner suggesting a small amount of colored impurity, presumably some other sulfonphthalein, having similar absorption but greater alkaline stability. In this case k_1 was evaluated from the initial, linear portion of the curve.

In addition to reversible fading similar to the sulfonphthaleins, the phenolphthaleins undergo gradual irreversible decomposition which has been attributed to oxidation by the air.[8] No definite evidence of irreversible decomposition, however, was found for any of the sulfonphthaleins during the course of the present observations. Any substantial irreversible change should be apparent as a gradual change in the transmittancy curves after fading had become complete or had reached an equilibrium. Figure 3 shows the spectral curves for BCG during various stages of the fading. In this case the fading goes to completion. Curves numbered 4 and 5 were taken after five and thirteen days, respectively, and indicate that no detectable change in spectral absorption of the colorless carbinol had occurred during this interval. Corresponding data for PR, which does not fade completely, are shown in Fig. 4.

---

[8] E. S. Amis and R. G. Overman, THIS JOURNAL, **66**, 941 (1944).

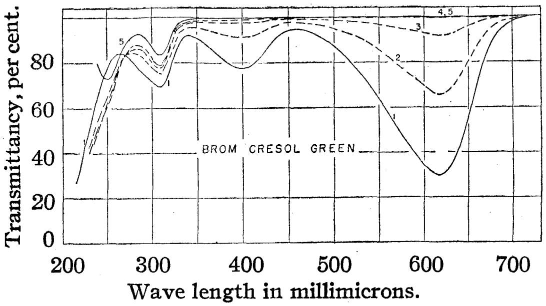

Fig. 3.—Per cent. transmittancy of brom cresol green in alkaline solutions plotted as a function of wave length: curve 1, unfaded at pH 8.2; curves 2, 3, 4 and 5, fading in 1.12 M NaOH after one, five, seven and thirteen days, respectively.

V. Discussion of Results

Substituents introduced into the rings of the parent substance, PR, have pronounced effects upon both the forward and the reverse rate constants, as shown in Table I. Qualitatively, the variations in k_1 are in accord with the general inductive influences of these substituents. Replacement of a hydrogen atom by the more electronegative halogen makes the effective charge on the reactive central carbon atom more positive, and thus increases its rate of reaction with the negative hydroxyl ion. The opposite inductive effect of a methyl or other alkyl group leads to a decrease in the rate of reaction, compared to PR. The inductive influence of a given substituent should have opposite effects upon the forward and reverse rate constants. An increase in effective positive charge on the reacting carbon atom should make more difficult the removal of the hydroxyl ion from the carbinol and thus decrease k_2. For substituents sufficiently removed from the point of reaction, that is, in the meta position with respect to the central carbon atom, such is the case. For example, CR, with a meta methyl group in each of the chromophoric rings, has a lower value of k_1 and a higher value of k_2 than PR. On the other hand, MCP, with a methyl group in the ortho position, has lower values for both k_1 and k_2, indicating that some other factor predominates over the inductive effect. In terms of the collision theory, this behavior would be attributed to a steric effect associated with the proximity of the substituent to the reacting center of the molecule, which would play a similar role in lowering both k_1 and k_2.

In the cases of the indicators which have more than one substituent in the chromophoric rings, it is of interest to ascertain whether they act more or less independently of each other in influencing the rate constants. According to the method of Hammett,[9] the effect of a substituent upon a given type of reaction may be defined by $A_x = \log k_x - \log k_0$, where k_0 is the rate for the unsubstituted compound, and k_x is the corresponding rate constant when a given substituent is introduced. On the basis of the transition state theory, A_x is related to the change in free energy of activation, ΔF, by $A_x = \Delta F/(2.3RT)$ and consequently reflects a change in either the energy of activation or the entropy of activation, which is characteristic of the nature and location of the substituent introduced. It has been found that, in general, substituents relatively far removed from the reacting center affect primarily the energy of activation, whereas neighboring groups influence both the energy and the entropy of activation. For example, from a thermodynamic study of the alkaline fading of several sulfonphthaleins Hochberg and LaMer[4] found that meta substituents influenced the energy of activation while ortho substituents influenced both the energy and the entropy of activation.

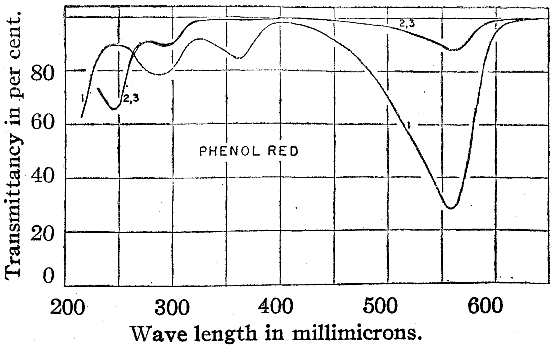

Fig. 4.—Per cent. transmittancy of phenol red in alkaline solutions plotted as a function of wave length: curve 1, unfaded at pH 11.8; curves 2 and 3, partially faded in 1.12 M NaOH after seven and twelve days, respectively.

Only three substituents need be considered for the present comparisons. These are a bromine in the meta position, an alkyl group (methyl or isopropyl) in the meta position, and a methyl group in the ortho position. No distinction is made between a methyl and an isopropyl group in the meta position, because their inductive effects should be practically the same and they are sufficiently removed from the reacting center to minimize any differences due to size. Only the fading rates will be considered in detail since the values of k_2 are more approximate and could not be obtained in some instances.

From the values of k_1 for BCP, CR, MCP, and PR the separate substituent effects are given by $A_{m\text{-Br}} = +0.89$, $A_{m\text{-alkyl}} = -0.86$, and $A_{o\text{-CH}_3} = -1.82$. These values represent the effect of two identical substituents, one in each of the chromophoric rings. For the five remaining cases which have two or three substitutents in each ring, the observed values of A_x should be the same as the values calculated by summation of the individual substituent effects provided these groups exert independent effects on the reaction. The seventh and eighth columns of Table I show a comparison of the observed and calculated values of A_x. The

---

[9] Louis P. Hammett, "Physical Organic Chemistry," McGraw-Hill Book Co., Inc., New York, N. Y., 1940.

agreement is exact for BCP and BTB, both of which have two groups of opposite inductive effect, bromine and alkyl, in the meta positions. For BPB and BCG with two bromines in the meta positions, the observed values of A_x are lower than the calculated values by 0.09 and 0.24, respectively, and suggest a tendency toward saturation when both meta substituents have inductive influences in the same direction. As the fading of TB was extremely slow it is conceivable that some mechanism other than the formation of the carbinol, which might be too slow to be observable in the other cases, might be the controlling factor. That the mechanism is the same, is supported by the agreement between the observed and calculated values of A_x. The reasonably good agreement between the two values of A_x for the five cases listed shows that the total change in the free energy of activation is nearly an additive function of the contributions of the separate substituents. It should be possible to make satisfactory estimates of the alkaline stability of other poly-substituted sulfonphthaleins from a knowledge of the individual substituent effects.

It is of interest to note that the accelerating effect of a *m*-halogen on the fading rate of a sulfonphthalein is practically the same as the retarding effect of a *m*-alkyl group. On the basis of the generally observed inductive influences of these groups, a much larger effect might be expected from the *m*-halogen atom. Hammett correlated substituent effects quantitatively for a wide variety of aromatic reactions where the substituent is in the meta or para position, so that the entropy of activation remains substantially independent of the nature of the substituent for a given type of reaction. A_x may then be regarded as the product of two factors, $A_x = \rho\sigma_x$, where ρ is characteristic only of the type of reaction and σ_x depends only on the nature of the substituent. If the reaction under consideration conformed to this general rule, the observed values of A_x, $A_{m\text{-Br}} = +0.89$, $A_{m\text{-Cl}} = +0.86$, and $A_{m\text{-alkyl}} = -0.86$ should be proportional to the substituent constants listed by Hammett which are $\sigma_{m\text{-Br}} = +0.39$, $\sigma_{m\text{-Cl}} = +0.37$, and $\sigma_{m\text{-alkyl}} = -0.07$. Although the relative values for the two halogen atoms are normal with bromine having a slightly larger effect, the proportionality does not hold when the halogen and alkyl groups are compared. That Hammett's rule does not apply is not surprising in view of the high degree of benzenoidal–quinoidal resonance in the indicator ion. This resonance affects and may largely determine the effective charge on the central carbon atom. A given substituent, consequently, may influence this effective charge not only by exerting its normal inductive effect but also by modifying the resonance. Since the possibilities for this sort of resonance do not exist in the carbinol, the individual effects of the meta substituents in the case of k_2 might be expected to follow the order observed by Hammett. From the reverse rate constants, $A'_{m\text{-Br}} = -1.0$, $A'_{m\text{-alkyl}} = +0.3$, and $A'_{o\text{-methyl}} = -1.5$. Although the agreement is none too good, possibly because of the greater experimental uncertainties in determining k_2, a meta bromine has a definitely greater effect than a meta alkyl group in accordance with the general inductive influences of these groups.

The rate studies may be used to make a rough estimate of the maximum amount of reversible alkaline fading which might be encountered during the normal use of these indicators in the measurement of *p*H. The upper limit of the interval of color transformation may be taken as a *p*H three units higher than the pK^* of the indicator corresponding to 99.9% of the colored alkaline form. The values for pK^*, representing the ionization constants for each indicator, are given in Table I, column 10. The ninth column lists the values of K for the equilibrium eventually established between the colored alkaline form and the colorless carbinol form. The values in parentheses could not be determined directly from the experimental data but are approximate values obtained from the known values of k_1 and values of k_2 estimated from the substituent constants listed in the preceding paragraph. The eleventh column shows the ratio of carbinol to colored form of each indicator, $[\text{ROH}^=]/[\text{R}^=]$, which would be reached at the above limit of *p*H after sufficient time had elapsed for the equilibrium to be established. The extent of reversible fading is of the same order for all of the indicators and does not exceed 1% in any case although the fading rate constants vary by a factor greater than 10^4. It is evident that the indicators which fade the most rapidly and have the largest equilibrium constants have a compensating factor in that their color transformations occur at lower values of *p*H.

Summary

A quantitative examination by precise spectrophotometric methods of the stability in 1 *M* alkali of phenolsulfonphthalein and nine of its derivatives with alkyl and halogen substituents in the ortho and meta positions has been made. Some of the indicators faded completely, but in general the reaction continued only until some finite equilibrium was established between the colorless carbinol and the colored quinoid forms. The fading rate constants k_1, and, where possible, approximate values of the color regenerating rate constants, k_2, were calculated. The substituents were found to exert nearly independent effects upon the fading rate constants in cases where more than one substituent was present in the two chromophoric rings.

Tetraphenylphosphonium and Tetraphenylstibonium Chloride

BY HOBART H. WILLARD, L. R. PERKINS[1] AND F. F. BLICKE

Tetraphenylarsonium chloride[2,3] has been found to have unique and very valuable analytical applications[4] inasmuch as it can be used satisfactorily for the determination of perchlorate, periodate, perrhenate, mercury, cadmium, tin and zinc.

In the hope that a substance might be found which would be equally useful as an analytical reagent, but available at a lower cost, we have studied the preparation and properties of tetraphenylphosphonium and tetraphenylstibonium chloride.

Tetraphenylphosphonium chloride had been prepared by Dodonov and Medox[5] by interaction of triphenylphosphine, phenylmagnesium bromide and oxygen, conversion of the tetraphenylphosphonium bromide produced into the phosphonium hydroxide, and treatment of the latter substance with hydrochloric acid. We found that tetraphenylphosphonium chloride could be obtained by successive recrystallizations of the corresponding bromide from saturated sodium chloride solutions. However, a far more advantageous process was elution of the bromide through a chloride-charged resin; Amberlite IR-4-B[6] proved to be satisfactory for this purpose.

In order to obtain the required tetraphenylphosphonium bromide it is not necessary to prepare and isolate triphenylphosphine since the phosphonium bromide can be obtained in one operation, and in good yield, from phosphorus trichloride merely by allowing the latter substance to react with phenylmagnesium bromide, and then passing oxygen into the mixture.[7]

The only tetraphenylstibonium salt known hitherto is the stibonium bromide which had been synthesized by Chatt and Mann[8] from triphenylstibine, bromobenzene and aluminum chloride. We prepared the bromide by interaction of triphenylstibine dichloride with phenylmagnesium bromide. The stibonium bromide was converted into the chloride by elution through chloride-charged Amberlite resin.

Experimental Part

Tetraphenylphosphonium Chloride.—In order to obtain tetraphenylphosphonium bromide, a solution of phenylmagnesium bromide was prepared from 160 g. (1.02 moles) of bromobenzene, 20.9 g. (0.86 mole) of magnesium and 600 ml. of ether in an atmosphere of nitrogen. The solution was cooled with ice, stirred rapidly, and 18 g. (0.13 mole) of phosphorus trichloride, dissolved in 50 ml. of ether, was added slowly. The material was stirred and refluxed for one hour. Dry oxygen, at the rate of about 250 ml. per minute, was then passed into the mixture while it was stirred and cooled; the gas was passed through a sintered glass disc in order to obtain fine bubbles. After the mixture had been treated with 250 g. of ice and 80 ml. of concentrated hydrochloric acid, the ether layer was separated and discarded. To the product, which had separated as an oil, and the aqueous layer, water was added until the total volume was 1 liter; the mixture was then heated until practically all of the oil had dissolved. After treatment with Norite, the mixture was filtered, and 250 g. of sodium chloride was added to the hot filtrate. The solution was cooled with ice, the precipitated crystalline bromide filtered, dried and washed with ether. The crude bromide weighed 50.0 g. (91%).

Fifty grams of the crude bromide was dissolved in 2 liters of boiling water, the solution cooled to room temperature, and then passed, successively, through two tubes; each tube was 25 mm. in diameter and 120 cm. long, and each contained 250 g. of the chloride-charged anion-exchange resin (Amberlite IR-4-B). The effluent solution was concentrated to a volume of 500 ml., 150 g. of sodium chloride was added, the precipitated phosphonium chloride filtered and dried. It was then dissolved in 50 ml. of hot ethanol, the mixture filtered, and the filtrate concentrated to a volume of 15 ml. The product was precipitated by addition of 500 ml. of dry ether; yield 39 g. or 79% based on the phosphorus trichloride used; m. p. 265–267°.[9]

Tetraphenylstibonium Chloride.—Crude triphenylstibine[10] (23.0 g.), dissolved in 35 ml. of carbon tetrachloride, was treated with chlorine until the solution became yellow; most of the solvent and excess chlorine were then removed on a steam-bath. The triphenylstibine dichloride (40.3 g., 94%), which separated from the cold, concentrated solution, melted at 142–144°.[11]

Phenylmagnesium bromide was prepared from 30.0 g. (0.19 mole) of bromobenzene, 4.4 g. (0.18 mole) of magnesium and 200 ml. of ether in a flask provided with a stirrer. After the addition of 25.4 g. (0.06 mole) of triphenylstibine dichloride, dissolved in a mixture of 30 ml. of dry benzene and 270 ml. of dry ether, the material was stirred occasionally, and allowed to remain at room temperature for at least three days. The mixture was treated with 30 g. of ice and 20 ml. of 48% hydrobromic acid, the ether–benzene layer separated, and the aqueous layer extracted four times with 100 ml. portions of ether. The combined ether–benzene layer and the extracts were heated on a steam-bath until the solvents had been removed; the viscous, brown, oily residue solidified when cooled. It was dissolved in 1 liter of boiling water, the solution filtered through glass wool, the filtrate concentrated to a volume of 250 ml., and 25 g. of sodium bromide was added to the hot solution. The stibonium bromide, which pre-

[8] Chatt and Mann, *J. Chem. Soc.*, 1192 (1940).

[9] The reported m. p. is 165° (ref. 5).

[10] The stibine was obtained by the method described by Morgan and Mickelthwaite (*J. Chem. Soc.*, **99**, 2290 (1911)). For our purpose it was merely necessary to remove the ether from the solution of the crude product.

[11] Pfeiffer (*Ber.*, **37**, 4621 (1904)) reported 141.5°.

cipitated from the cold solution, was washed with 5 ml. of water; yield 28.0 g.; m. p. 210–215°[12].

Anal. Calcd. for $C_{24}H_{20}SbBr$: Br^-, 15.7. Found: Br^-, 15.6.

The bromide (50 g.) was converted into the chloride by one passage through the anion-exchange resin in the manner which has been described; yield 40 g. (87%); m. p. 202–205°.

Anal. Calcd. for $C_{24}H_{20}SbCl$: Cl^-, 7.62. Found: Cl^-, 7.65.

The stibonium chloride can be recrystallized from water or ethyl acetate. It is only slightly soluble in ether or benzene.

Summary

New procedures have been developed for the preparation of tetraphenylphosphonium and tetraphenylstibonium chloride and bromide. The analytical applications of tetraphenylphosphonium chloride will be described in an early publication.

Hydroxyalkylamides of 4-Arsonophenoxy- and 4-Arsonoanilinoacetic Acids

By C. K. Banks, D. F. Walker, John Controulis, E. W. Tillitson[1] and L. A. Sweet

Study of the derivatives of 4-amino- and 4-hydroxybenzenearsonic acid has indicated that certain of them are of greater interest for therapeutic purposes than the parent arsenicals. 4-Arsonophenylurea (carbarsone-U.S.P.),[2] 4-arsonophenylglycineamide (tryparsamide-U.S.P.)[3] and others have become accepted therapeutic agents. Investigations of two types of derivatives, the carbamylmethyl[3,4] and the hydroxyalkyl,[5,6] have led to a number of interesting compounds. In order to determine the effect of incorporating both the hydroxyalkyl and carbamido functions in the same molecule, the hydroxyalkylamides of 4-arsonophenoxyacetic and 4-arsonophenylglycine were prepared.

4-Arsonophenoxyacetic acid[7] and 4-arsonophenylglycine[8] were converted to their methyl esters.[3,4] Reaction of these esters with hydroxyalkylamines yielded the desired amides. The substituted arsonic acids were reduced to the corresponding arsonous acids.

[a] All compounds are colorless. [b] Determined by the method of Banks and Sultzaberger, THIS JOURNAL, 69, 1 (1947). [c] The same compound was also obtained from methyl 4-arsonosophenoxyacetate and ethanolamine, yield 92%.

methylol group was formed on the amide nitrogen and one on the arylamino nitrogen in the last two instances. The position of the methylol group on nitrogen rather than on the benzene ring was proved by hydrolysis to 4-arsonophenoxyacetic acid and N-4-arsonophenylglycine.

4-Aminobenzenearsonous acid reacted with sodium formaldehyde bisulfite to yield a sulfomethyl derivative. 4-Cyano- and 4-hydrazinobenzenearsonous acid[9,10] were obtained by reduction of the corresponding arsonic acids.

Experimental

Acetamides.—The methyl ester of 4-arsonophenoxyacetic acid or 4-arsonophenylglycine (0.1 mole) was dissolved in an excess of the amine (100 ml.) and heated to 80° for two hours. On adding the reaction mixture to an excess of alcohol (2 l.), the amine salt of the hydroxyalkylacetamide crystallized. It was filtered off and dried *in vacuo*. The free arsonic acids were liberated when the amine salts were dissolved in a small amount of water and made strongly acid to congo red paper with hydrochloric acid. The arsonic acids were recrystallized from water.

Arsonous Acids.—The arsonous acids were prepared from the corresponding arsonic acids by previously published methods.[11]

Methylol Amides.—The arsono-substituted acetamide (0.1 mole) or urea was dissolved in water (25 ml.) by the addition of sodium hydroxide to pH 7, or the sodium salt was dissolved in water, and 37% aqueous formaldehyde (1 ml. per gram) added. The mixture was heated to 80° for two hours, then concentrated *in vacuo* to a solid. The residue was dissolved in a minimum of water, filtered and the sodium salt crystallized upon the addition of alcohol and ether. The free arsonic acids could be obtained by carefully acidifying cold aqueous solutions of the salts.

Acetone 4-Arsonophenylhydrazone.—4-Hydrazinobenzenearsonic acid[10] (5.8 g.) was warmed with 25 ml. of acetone and 5 ml. of water until solution occurred. On chilling, a mass of pale red crystals was obtained. After two recrystallizations from water–acetone (1:2), a nearly white crystalline product was obtained. Unlike the initial material, the product did not give a silver mirror test with ammoniacal silver nitrate.

Summary

1. Four new N-hydroxyalkyl derivatives of 4-arsonoanilinoacetic acid and five corresponding derivatives of 4-arsonophenoxyacetic acid are reported. Representative salts are described.

2. The arsonic acids were reduced to the corresponding arsonous acids.

3. Several miscellaneous related arsenicals are also reported.

C-Alkylation and O-Alkylation in the Synthesis of Substituted Furoic Acids

BY CHARLES D. HURD AND KENNETH WILKINSON

In the alkylation of ethyl sodio-oxaloacetate with ethyl bromopyruvate Sutter[1] claimed to have prepared 2,3,5-furantricarboxylic acid. That is to say, he assumed that C-alkylation had occurred followed by ring closure and the elimination of water. However, Reichstein[2] prepared the same tricarboxylic acid by partially decarboxylating furantetracarboxylic acid, and since pyrolysis of such acids causes preferential decarboxylation in the *alpha* position he contended that Sutter had experienced O-alkylation and had obtained 2,3,4-furantricarboxylic acid. Archer and Pratt[3] demonstrated that O-alkylation was the course followed in the analogous condensation between ethyl bromopyruvate and ethyl sodio-β-ketosuberate, since subsequent ring closure yielded 5-(3,4-dicarboxyfuryl)-valeric acid.

Similar interaction of acetoacetic ester and chloroacetone should produce 2,5-dimethyl-3-furoic acid (I) by C-alkylation, and 2,4-dimethyl-3-furoic acid (II) by O-alkylation. On the basis of

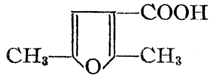
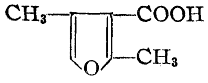
[3] Archer and Pratt, THIS JOURNAL, **66**, 1656 (1944).



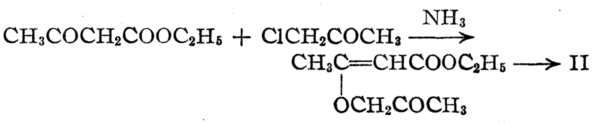
I



II

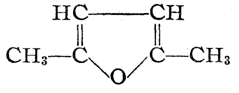
Archer and Pratt's work one might guess that chloroacetone and ethyl sodio-acetoacetate, followed by ring-closure, would yield II. Actually, this experiment was performed by Paal.[4] His acid, m. p. 136°, has been assigned structure I rather than II, but it must be said that the evidence regarding structure may be questioned.

A few years later, Feist[5] carried out a similar reaction between chloroacetone and acetoacetic ester, the base being ammonia instead of sodium ethoxide. His product melted at 122°. He suggested structure II, again without adequate proof. These steps would apply if O-alkylation occurred

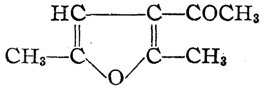


$$CH_3COCH_2COOC_2H_5 + ClCH_2COCH_3 \xrightarrow{NH_3} \underset{\displaystyle OCH_2COCH_3}{\underset{|}{CH_3C}}{=}CHCOOC_2H_5 \longrightarrow \mathrm{II}$$

We have repeated and confirmed both Paal's and Feist's observations. To establish conclusively the structures of the acids formed, we have synthesized I by an unequivocal method. For this work, 2,5-dimethylfuran (III) was chosen as a source material of unquestioned structure. It was converted into 3-acetyl-2,5-dimethylfuran (IV) by means of acetic anhydride and stannic chloride. Since the only previous synthesis[6] of IV involved autoclaving a mixture of succinic acid, acetic anhydride, sodium acetate and zinc chloride at 200°, the present synthesis of IV places the structure on a secure basis. Oxidation of this ketone by sodium hypoiodite yielded an acid melting at 135° and obviously of structure I.



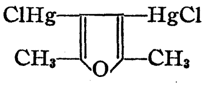
III



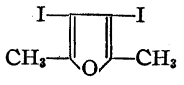
IV

This proof of structure I fixes structure II as well, and establishes the fact that C-alkylation is involved in the reaction of chloroacetone with acetoacetic ester and sodium ethoxide, whereas O-alkylation occurs if ammonia is used as the base. That the initial products of C- and O-alkylation were different was evident also in the reactions of cyclization. The former, $CH_3COCH(CH_2COCH_3)COOC_2H_5$, which is a 1,4-diketone, undergoes ring closure promptly on treatment with concentrated sulfuric acid. The latter, $CH_3C(OCH_2COCH_3){=}CHCOOC_2H_5$, undergoes practically no cyclization under these conditions. The method of cyclizing this material is to saponify, then acidify, a method not applicable to the C-alkylated compound since it promotes decarboxylation instead.

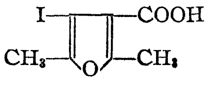
Other reactions of dimethylfuran were developed during this work. Both mono- and dimercuration (V) products were obtained by reaction with mercuric chloride. Both of these compounds reacted readily with iodine to yield 3-iodo-2,5-dimethylfuran and 3,4-diiodo-2,5-dimethylfuran (VI), respectively. Compound VI could not be brought into reaction with magnesium even by using butyl ether and temperatures[7] up to 140° or by employing a special magnesium alloy.[8] It was inert also toward potassium cyanide when an attempt was made to form the nitrile. A small amount of Grignard exchange was observed between methylmagnesium iodide and VI, since the product yielded 2,5-dimethyl-4-iodo-3-furoic acid (VII) on carbonation. On the other hand, methylmagnesium iodide did not cause substitution of magnesium into the nucleus of 2,5-dimethylfuran. Instead, a coördination compound precipitated.



V



VI



VII

Experimental

3-Acetyl-2,5-dimethylfuran.—A mixture of 46 g. of 2,5-dimethylfuran, 64 g. of acetic anhydride, and 0.2 ml. of stannic chloride was refluxed for four hours and then distilled. The yield of product boiling at 196° was 53.3 g. or 77%. The oxime[6] melted at 77°.

2,5-Dimethyl-3-furoic Acid.—A solution of iodine in aqueous potassium iodide was added to 1 g. of 3-acetyl-2,5-dimethylfuran and 4 ml. of 50% sodium hydroxide until there was an excess of iodine. The reaction was maintained at 60° for one-half hour, then the iodoform which formed in the reaction was extracted with ether. After warming off the ether, acidification and use of a small amount of bisulfite to remove the excess iodine yielded 2,5-dimethyl-3-furoic acid which was recrystallized from water, m. p. 135.4°. The neutral equivalent of this acid was found to be 139.8 (calcd., 140).

2,5-Dimethyl-3-furylmercuric Chloride.—A mixture of 10 g. of 2,5-dimethylfuran, 27 g. of mercuric chloride, 13 g. of sodium acetate trihydrate and 300 g. of water was warmed to 50° and shaken occasionally for three hours. The 14 g. of yellow cream solid which separated was dissolved in 50–60 ml. of hot acetone, filtered and precipitated by pouring into three volumes of water. This process was repeated before analysis.

Anal. Calcd. for C_6H_7ClHgO: Hg, 60.60. Found: Hg, 60.64.

A product analyzing 64.0% mercury was obtained by using relatively more sodium acetate. From a mixture of 5 ml. of 2,5-dimethylfuran, 13.6 g. of mercuric chloride, 10 g. of anhydrous sodium acetate and 50 g. of water, kept at 40–50° for thirty minutes, was obtained 5.4 g. of a cream-colored product after filtration and rinsing with water till free of mercuric chloride. It still analyzed 64.0% after dissolving nine-tenths of it in 80 ml. of hot acetone, filtering, and precipitating with 150 ml. of water.

The mercury analysis is satisfactory for a compound

of the structure C_6H_7O-Hg-C_6H_6O-HgCl (calcd. 64.1% Hg). At least, it appeared that both monomercurated and dimercurated furan nuclei were produced since iodination (I_2–KI reagent) yielded an oily mixture containing a substantial amount of solid 3,4-diiodo-2,5-dimethylfuran, m. p. 60.5°. Also, this mercurated product was much more soluble in hot acetone than compound (V), described below.

3-Iodo-2,5-dimethylfuran.—A mixture of 6.6 g. of 2,5-dimethyl-3-furylmercuric chloride (containing 60.6% Hg) and 50 g. of 2,5-dimethyl-3-furylmercuric chloride (containing 60.6% Hg) and 50 g. of water was shaken with an aqueous solution of iodine and potassium iodide until there was an excess of iodine. This was decolorized with sodium bisulfite. The mixture was treated with 0.5 g. of sodium bicarbonate and the oily product was steam distilled, ether extracted, dried over sodium sulfate and distilled; yield, 2.6 g. (62%) of b. p. 85.5–86° (20 mm.); $n^{22.6}_{D}$ 1.5388; d^{20}_{4} 1.699. The compound decomposes in two weeks if exposed to light.

Anal. (by J. Anderson): Calcd. for C_6H_7IO: C, 32.45; H, 3.16. Found: C, 32.56; H, 3.20.

2,5-Dimethyl-3,4-furan-bis-(mercuric chloride) (V).—By heating 18.4 g. (0.19 mole) of 2,5-dimethylfuran and 108.4 g. (0.4 mole) of mercuric chloride in 150 ml. of water at 70° with intermittent shaking for one hour, 2,5-dimethyl-3,4-furan-bis-(mercuric chloride), a white solid, was formed. It was filtered and dried at 50° since temperatures above 80° caused extensive decomposition. This material is only slightly soluble in hot acetone.

Anal. Calcd. for $C_6H_6Cl_2Hg_2O$: Hg, 70.87. Found: Hg, 70.6.

3,4-Diiodo-2,5-dimethylfuran.—An aqueous solution of iodine and potassium iodide was added to 33.1 g. of 2,5-dimethyl-3,4-furan-bis-(mercuric chloride) suspended in 100 ml. of water until there was an excess of iodine which persisted after an hour of intermittent shaking. Thiosulfate was then added to remove the excess of iodine. Any acids in the solution were neutralized by treatment with excess bicarbonate, after which the solution was steam distilled. The bicarbonate treatment removes traces of hydrodic acid which would promote resinification of the product. The oily distillate was extracted with ether, dried over anhydrous sodium sulfate, and the ether evaporated. The yield was 13 g. (41%) of white crystalline 3,4-diiodo-2,5-dimethylfuran, m. p. 60.8°. Its odor is similar to iodoform. It is stable in alcoholic solution, but in a crystalline state it completely decomposes in less than two months.

Anal. (by P. Craig): Calcd. for $C_6H_6I_2O$: C, 20.70; H, 1.72. Found: C, 20.93; H, 1.62.

2,5-Dimethyl-4-iodo-3-furoic Acid.—To a solution of 0.1 mole of methylmagnesium iodide in 25 ml. of ether was added 2.2 g. of 3,4-diiodo-2,5-dimethylfuran in 10 ml. of ether. The mixture was refluxed for one hour and then carbonated by pouring over solid carbon dioxide. The mixture was acidified with 30% sulfuric acid and extracted with ether, then the ether was extracted with 5% potassium hydroxide. Evaporation of the ether yielded 1.9 g. or 87% of the starting material. Acidification of the alkaline solution and extraction with ether gave 0.2 g. of 2,5-dimethyl-3-iodo-4-furoic acid which was recrystallized from 50% methanol: m. p. 208.8°.

Anal. (by P. Craig): Calcd. for $C_7H_7IO_3$: C, 31.59; H, 2.63; neut. equiv., 266. Found: C, 31.43; H, 2.48; neut. equiv., 265.

2,4-Dimethyl-3-furoic Acid *via* O-Alkylation.—A stream of ammonia gas was passed through a flask containing 100 ml. of ether, 28 g. of chloroacetone and 39 g. of ethyl acetoacetate. After thirty minutes the reaction was stopped, the ammonium chloride which had formed was filtered off, and the ether evaporated. The residual oil was fractionated under reduced pressure yielding 15 g. (27%) of a fraction boiling at 95–98° at 14 mm.; n^{25}_{D} 1.482. This alkylation product was saponified by warming with a slight excess of 5% sodium hydroxide for thirty minutes. Acidification of the hot solution yielded upon cooling pure 2,4-dimethyl-3-furoic acid, m. p. 123°; reported[5] 122°.

2,5-Dimethyl-3-furoic Acid *via* C-Alkylation.—After dissolving 7 g. of sodium in 100 ml. of absolute alcohol, 40 g. of ethyl acetoacetate was added and the solution was brought to refluxing temperature. To it was added 28 g. of chloroacetone over a period of two hours. After refluxing for an additional hour, the mixture was cooled, the sodium chloride filtered off and washed with alcohol, and the alcohol distilled away from the high boiling product. Fractionation under reduced pressure yielded 29 g. (43%) of a liquid boiling at 126–128° at 14 mm.; n^{25}_{D} 1.4385. This boiling point is considerably higher and the refractive index significantly lower than the analogous constants from the ammonia reaction.

Three grams of this alkylation product was poured into 10 ml. of concentrated sulfuric acid. After five minutes it was poured over cracked ice. The mixture was extracted with ether, the ether evaporated, and the oil remaining saponified with 5% sodium hydroxide solution on a steam-bath for ten minutes. Acidification yielded 0.4 g. (18%) of 2,5-dimethyl-3-furoic acid, m. p. 135.4°. A mixed melting point with an authentic sample prepared from the acetylation of 2,5-dimethylfuran followed by a hypoiodite oxidation showed no depression.

Summary

The synthesis of 2,5-dimethyl-3-furoic acid from 2,5-dimethylfuran is described by a method which proves its structure. The same acid is made starting with chloroacetone and ethyl sodio-acetoacetate, a process involving C-alkylation of the acetoacetic ester. A different acid, 2,4-dimethyl-3-furoic acid, results from reaction of chloroacetone and ethylacetoacetate in the presence of ammonia. This involves O-alkylation of the acetoacetic ester.

Mercuration studies on 2,5-dimethylfuran are reported.

3,4-Diiodo-2,5-dimethylfuran was inactive toward magnesium, but did undergo an exchange reaction with methylmagnesium iodide to yield upon carbonation, 2,5-dimethyl-4-iodo-3-furoic acid.

2,5-Dimethylfuran did not undergo a Grignard exchange with methylmagnesium iodide.

Hydroxylated Stearic Acids. II. The Periodate Oxidation of the 9,10-Dihydroxystearic Acids and the 1,9,10-Trihydroxyoctadecanes[1a]

BY HAROLD WITTCOFF, OWEN A. MOE AND MARJORIE H. IWEN

The quantitative oxidative cleavage of vicinal hydroxyl groups by the action of periodic acid to yield two carbonyl compounds was first demonstrated by Malaprade,[1b] and it was later postulated by Criegee[2] and co-workers that the reaction proceeded through an acidic cyclic ester which decomposed with water to yield the observed products.
