[a] Ethyl alcohol as solvent. [b] Granules. [c] Plates.

Experimental

To 1 g. of the acid chloride in a 10-cm. test-tube was added 0.5 cc. of the liquid alcohol or 0.5 g. of the solid alcohol and the mixture gently heated over a micro burner until the evolution of hydrogen chloride ceased. This usually required about ten minutes. The molten mass was then poured into 20 cc. of an ice and water mixture. Most of the esters solidified instantly. Those that came down as oils usually changed to solids in a few minutes, but in a few instances it was necessary to wash the oil with a 20% solution of alcohol to obtain a solid. One recrystallization will usually give a pure compound, but the results in Table I are from compounds which were recrystallized twice, with the exception of the ethyl and the 3-pentanol esters which were recrystallized three times. Either methyl or 95% ethyl alcohol can be used as a recrystallizing solvent. Methyl alcohol was used for the compounds in the table unless otherwise indicated. They crystallized in needles, unless otherwise noted. The isoamyl ester when crystallized from 95% ethyl alcohol sometimes came down as needles with the melting point shown and sometimes as plates with a melting point of 40.4–40.8°. The plates after melting, solidification and remelting had a melting point of 72.3–72.9°. When recrystallized from methyl alcohol, it always had the melting point of 72.3–72.9°. The melting points were all taken by Anschütz thermometers, which were checked against a thermometer with a Bureau of Standards certificate.

The Potassium Permanganate Test for Detection of Unsaturation[1]

BY V. N. IPATIEFF, W. W. THOMPSON[2] AND HERMAN PINES

Many books suggest for the detection of unsaturation (particularly in compounds insoluble in water) a procedure comprising treatment of an acetone solution of the compound dropwise with a 2% potassium permanganate solution, until the purple color of the permanganate persists.

It was found that such procedure gave a negative test for unsaturation with several olefinic compounds. The results with the various hydrocarbons tested were not consistent. For example, β-pinene showed a negative test for unsaturation, while α-pinene showed a positive test. It was found, however, that when the olefins showing a positive test were redistilled, the unsaturation test for olefins was negative. These results indicate that the olefins on standing might have undergone some changes, which caused the discoloration of the permanganate solution.

Absolute or 96% ethanol is a more suitable solvent for the unsaturation test; in the presence of olefins the color of the permanganate solution is

(1) This work was made possible in part through the financial support of Universal Oil Products Company.

(2) American Chemical Society Predoctoral Fellow (1947–1948).

discolored instantaneously. When a mixture of ethanol and acetone is used as a solvent, the rate of discoloration of the permanganate solution increases with the increase of alcohol concentration. Ethanol *per se* in the absence of olefins does not discolor the permanganate solution even after five minutes of standing. Methanol and 2-propanol act in a similar fashion as ethanol.

It was found that the addition of only a small amount of water to acetone increases the rate of discoloration when tested for unsaturation. A 5% solution of water in acetone seems to be a suitable solvent for the unsaturation test.

The procedure used for testing the various compounds was essentially as follows: One drop of a 2% aqueous solution of potassium permanganate was added to 0.1 cc. (0.1 g. if solid) of the compound dissolved in 2 cc. of the investigated solvent. Test was indicated as positive (+) when the color of the potassium permanganate changed within five seconds after the addition of the permanganate. If the potassium permanganate color persisted for longer than five minutes, the test was reported to be negative (−). The length of time required to discolorize the permanganate is expressed in seconds.

The tables summarize the results obtained.

Hydrolytic Titrations of Lead with Potassium Cyanide

BY LOUIS MEITES

In the course of a study of hydrolytic titrations of various divalent cations with potassium cyanide, it was found that the atypical behavior of plumbous ion was of particular interest. It is well known that most such titrations are characterized by a continuous rise in *p*H on addition of cyanide, with sharp increases at points corresponding to quantitative formation of insoluble compounds, such as $M(CN)_2$, or complex ions, such as $M(CN)_4^=$.

Titration of an aqueous solution of lead nitrate, however, gives, after an ill-defined end-point at about 1.5 mole of cyanide per mole of lead, a sharp downward break in *p*H at a mole ratio of about 1.8. This break is of the order of 0.25 *p*H unit, and it is followed by a steady rise in *p*H as the titration is continued, with no clear indication of any further end-point to a mole ratio of at least eight.

In 50% ethanol a pronounced end-point (taken as the point of maximum slope) is observed at a mole ratio of 1.002 ± 0.004, and it is followed by, first, a downward break similar to that found in aqueous medium, and then, at a mole ratio of 1.50 ± 0.01, a second sharp end-point.

The insoluble products of the reactions in 50% ethanol were isolated by titrating 500-ml. portions of an 0.05 *M* solution of lead nitrate with standard potassium cyanide until the previously determined *p*H values at the respective end-points, as measured with a Beckman glass electrode *p*H meter, had been exactly reached. The products were filtered off, washed with 50% ethanol and ether, and air-dried. They were analyzed by decomposition in platinum over a very low flame, followed by ignition at a dull red heat, and both gave light yellow plumbous oxide apparently uncontaminated by any trace of a red higher oxide. The compound formed at the first end-point evolved much nitrogen dioxide during its decomposition. Found: PbO, 78.1, 78.2; calculated for Pb(OH)(NO_3), 77.99%. The other compound gave off only a faint odor of cyanogen. Found: PbO, 87.4, 87.3; calculated for $Pb(OH)(CN)\cdot Pb(CN)_2$, 87.62%. This substance has not previously been described in the literature.

The reactions taking place during this titration may, therefore, be represented by the equations

$$Pb^{++} + CN^- + H_2O + NO_3^- \longrightarrow Pb(OH)(NO_3) + HCN \quad (1)$$

and

$$2Pb(OH)(NO_3) + 2CN^- + HCN \longrightarrow Pb(OH)(CN)\cdot Pb(CN)_2 + H_2O + 2NO_3^- \quad (2)$$

The sudden decrease in *p*H between the two end-points is accounted for by the assumption that the concentration of cyanide ion must reach a certain value before reaction (2) is initiated, but that, once started, it progresses to a point at which most of the free cyanide ion has been removed.

The products formed during the titration in aqueous medium were prepared by adding known volumes of standard potassium cyanide to known volumes of standard lead nitrate solution, filtering, and air-drying. They were analyzed as described above. Addition of 1.50 mole of cyanide per mole of lead gave another new compound. Found: PbO, 81.8, 81.8; calculated for $Pb_2(OH)(NO_3)(CN)_2$, 81.85%. This compound evolved nitrogen dioxide during its decomposition. The substance formed at a mole ratio of 2.00 (*i.e.*, after the downward break) was again the hydroxytricyanide described above.

Consequently, the stoichiometry of the reactions in aqueous medium is described by the equations

$$2Pb^{++} + NO_3^- + H_2O + 3CN^- \longrightarrow Pb_2(OH)(NO_3)(CN)_2 + HCN \quad (3)$$

and

$$Pb_2(OH)(NO_3)(CN)_2 + CN^- \longrightarrow Pb(OH)(CN)\cdot Pb(CN)_2 + NO_3^- \quad (4)$$

The Structure of Uranium Hydride

BY LINUS PAULING AND FRED J. EWING

R. E. Rundle[1] has recently reported the results of an X-ray investigation of uranium hydride, UH_3. He found that there are eight molecules of this substance in the unit cube, with $a_0 = 6.631$ Å., and that the uranium atoms have the β-tungsten arrangement, with two UI at 000 and 1/2 1/2 1/2 and six UII at 1/2 1/4 0, etc. He suggested that each uranium I atom is surrounded by twelve hydrogen atoms, on the lines connecting the UI atom with the twelve surrounding UII atoms, and that there are half-bonds between hydrogen and each of the two uranium atoms ligated to it.

In this note we point out that consideration of the interatomic distances supports this proposal, and, moreover, leads to the conclusion that uranium hydride contains a new form of uranium, with small valence, similar to the low-valent forms of chromium and manganese previously reported.[2]

A hydrogen atom in a metallic hydride may be at the center of a tetrahedron of metal atoms, or of an octahedron of metal atoms.[3] In zirconium hydride, ZrH, for example, the zirconium atoms are in a cubic closest packed arrangement, and it seems likely from consideration of the interatomic distances that the hydrogen atoms occupy tetrahedral positions, corresponding to the sphalerite structure. The single-bond radius of hydrogen is then calculated from the zirconium–hydrogen distance 2.06 Å., with use of the zirconium single-bond radius 1.454 Å. and the correction 0.36 Å. for bond-number 1/4, to be 0.25 Å. In palladium hydride, PdH_x, the tetrahedral positions are too small for hydrogen atoms, which instead occupy octahedral positions; the palladium-hydrogen distance 2.03 Å., with palladium single-bond radius 1.28 Å. and correction 0.47 Å. for bond-number 1/6, then leads to 0.28 Å. for the hydrogen radius. This radius lies between 0.25 and 0.32 Å in most metallic hydrides, in good agreement with the range of values for non-metallic hydrides, 0.28 to 0.32 Å.[4]

In uranium hydride the U–H distance of 1.85 Å. (assuming the hydrogen to be midway between UI and UII) is approximately equal to that predicted, namely, the single-bond radius of uranium, 1.42, plus the radius of hydrogen, 0.27, plus the correction for bond number 1/2, 0.18, a total of 1.87 Å. There is no satisfactory position in the uranium hydride structure for hydrogen with coordination number larger than two. In UH_3 each UI atom forms twelve bonds with bond number 1/2 with the surrounding hydrogen atoms, corresponding to a valence of six for uranium I. Each UII forms four such bonds with four surrounding hydrogen atoms, and also forms two bonds with adjacent UII atoms, at 3.316 Å., the calculated bond-number for these bonds being 0.16. This leads for uranium II to the value 2.3 for the valence. No form of uranium metal or intermetallic compound of uranium has been reported so far in which uranium has this low valence, but a low-valent form of chromium and one of manganese have already been reported, so that a similar form for uranium is not entirely unexpected.

It is interesting to point out that the Brillouin-zone treatment of the β-tungsten structure provides some basis of understanding of the stability of this structure for both β-tungsten and uranium hydride. The first expected Brillouin zones correspond to the strong reflections {210} and {211}, which lead to about 16 electrons per unit cube. There then occurs another Brillouin polyhedron, bounded by the strong reflections {222}, {320}, and {400}. (A fourth strongly reflecting form, {321}, does not further truncate this polyhedron.) The content of this polyhedron is 53.5 electrons

(3) G. Hägg, *Z. physik. Chem.*, **B11**, 433 (1930); **B12**, 33 (1931). Hägg's assignment of the hydrogen atoms to these positions was based on the assumption that the effective radius of hydrogen in metallic hydrides is about the same as in non-metallic hydride molecules.
(4) L. Pauling, "The Nature of the Chemical Bond," Cornell University Press, Ithaca, New York, 1940, p. 168.

per unit cube. The brittleness of uranium hydride suggests that it has a filled-Brillouin-polyhedron structure. The number of electrons per unit calculated from the formula and the assumed valences 6 for UI, 2.3 for UII, and 1 for H is 49.8, which is slightly less than the theoretical value. It is possible that UII actually has valence 3 (like the low-valent form of its congener chromium), each atom forming four half-bonds with hydrogen and two (somewhat strained) half-bonds with its two UII neighbors; this valence would then lead to 54 valence electrons in the unit cube, in excellent agreement with the theoretical value.

The possibility that somewhat different effective radii, corresponding to difference in hybridization of the orbitals, should be used for metals in forming bonds with hydrogen than with other metal atoms may be mentioned. It has been pointed out before[5] that the very strong metal–metal bonds in gallium, β-tungsten, and α-uranium, for which bond numbers of about 1.3 are calculated from the metallic radii, may really be single bonds, the effective radii being a few hundredths of an ångström less than usual for these bonds and greater for the other bonds. Thus in ZrH each of the twelve bonds formed by a zirconium atom with its zirconium ligands is calculated with the usual radius 1.454 Å. to have bond number 0.17, which leads to the low valence 3.04 for zirconium. In order for the valence 4 of zirconium to be effective, the single-bond radius of the metal in its Zr–Zr bonds would have to be taken as 1.50 Å. Similarly the single-bond radius of palladium effective in the Pd–Pd bonds in PdH is required to be 1.33 Å. instead of 1.278 Å. to conform with the valence 5.78. An increase in effective single-bond radius of UII for the U–U bonds in UH_3 and a decrease for the H–UII bonds would permit UII to be exercising the valence 3, found for its congener chromium in the A3 modification of this element.

The electron number per unit cube in β-tungsten itself is 48 (for valence 6) or 46.24 (for valence 5.78, as assumed in Ref. 2), corresponding to a metallic structure with partial filling of a Brillouin zone.

Nitrogen-substituted Chloroalkylamines[1]

BY RICHARD F. PHILLIPS, CLIFFORD H. SHUNK AND KARL FOLKERS

Two nitrogen-substituted β,β′-dichlorodiethylamines were prepared by a procedure in which the Mannich reaction[2] is an essential step.

4-(β,β′-Dichlorodiethylamino)-2-butanone Perchlorate.—To 10 g. of β,β′-dichlorodiethylamine hydrochloride[3] dissolved in 40 ml. of absolute ethanol, 15 ml. of acetone and 3 g. of paraformaldehyde were added. After heating at reflux for ten minutes, an additional gram of paraformaldehyde was added; heating was continued for fifteen minutes. Evaporation at 40° under reduced pressure left an oil, which did not crystallize. The oil was dissolved in 75 ml. of water. After filtering, 10 g. of 70% perchloric acid was added to the filtrate. On cooling, 12.0 g. of crystalline material was deposited, m. p. 112–115°. On recrystallization from water, the melting point reached a constant value of 115–116°. A sample was dried at room temperature in a vacuum desiccator.

Anal. Calcd. for $C_8H_{16}O_5NCl_3$: C, 30.74; H, 5.16; N, 4.48; Cl, 34.03. Found: C, 31.19; H, 5.65; N, 5.00; Cl, 32.89 (Parr bomb).

Apparently some perchloric acid was lost by dissociation on crystallization from water.

4-(β,β-Dichlorodiethylamino)-2-butanone Hydrobromide.—To a suspension of 10 g. of the perchlorate in 50 ml. of water, a solution of 5 g. of sodium hydroxide in 10 ml. of water was added while cooling in ice. The colorless oil which separated was extracted with ether. The ether extract was dried over potassium carbonate, filtered, cooled in ice–salt mixture and saturated with dry hydrogen bromide. An oil was precipitated which crystallized on treatment with a small amount of acetone; wt. 9.2 g., m. p. 90–100°. Recrystallization of the salt from acetone raised the melting point to 108–111°; further recrystallization from absolute ethanol gave a constant melting point of 112–113°. The analytical sample was dried at room temperature in a vacuum desiccator.

Anal. Calcd. for $C_8H_{15}ONCl_2 \cdot HBr \cdot 0.5H_2O$: C, 31.80; H, 5.67; N, 4.64; Br^-, 26.45. Found: C, 31.65; H, 5.38; N, 4.75; Br^-, 26.52 (Volhard titration).

4-(β,β′-Dihydroxydiethylamino)-2-butanone Hydrochloride.—Ten grams of diethanolamine was converted to the hydrochloride by treatment with 9 ml. of concentrated hydrochloric acid. Water was removed by evaporation under reduced pressure. The residue was treated with absolute ethanol and evaporated again. After this treatment had been repeated once more, the residual viscous oil was dissolved in a mixture of 40 ml. of absolute ethanol and 16 ml. of acetone. Five grams of paraformaldehyde was added. After heating at reflux for twelve hours, evaporation of the clear solution at 60° under reduced pressure gave a viscous oil which crystallized from ethanol–acetone. The crystalline product was deliquescent. After storage in a vacuum desiccator it weighed 15 g. and melted at 75–80° in a sealed capillary tube. Two further recrystallizations of this product raised the melting point to a constant value of 83–85°. The substance appears to be unstable on heating. At 57° *in vacuo*, a sample lost 15% of its original weight in three hours.

Anal. Calcd. for $C_8H_{17}O_3N \cdot HCl$: Cl^-, 16.75. Found: Cl^-, 16.42 (Volhard titration, sample dried at room temperature in a vacuum desiccator).

4-(β,β′-Dihydroxydiethylamino)-2-butanol.—A solution of 10 g. of 4-(β,β′-dihydroxydiethylamino)-2-butanone hydrochloride in 125 ml. of methanol was shaken with 0.4 g. of platinum oxide catalyst and hydrogen at a pressure of 30–45 lb. per sq. in. The theoretical amount of hydrogen was absorbed within six hours. The catalyst was removed by filtration, and the filtrate was evaporated under reduced pressure. The residue was dissolved in 30 ml. of water. An excess of concentrated potassium hydroxide solution was added while cooling the flask in

(1) This paper is based in part on work done for the Office of Scientific Research and Development under Contract OEMsr-1124 with Merck & Co., Inc.

(2) "Organic Reactions," Vol. I, John Wiley and Sons, New York, N. Y., 1942, Chapter 10, p. 303.

ice. Saturation of the alkaline solution with potassium carbonate precipitated an oil. The mixture was extracted with chloroform. The chloroform extracts were dried over potassium carbonate and evaporated under reduced pressure. The residue on distillation gave 7.1 g. of material, b. p. 132–154°(0.23 mm.).

2,2′-Dichloro-N-(3-chlorobutyl)-diethylamine Hydrochloride and Picrate.—A solution of 3.5 g. of 4-(β,β′-dihydroxydiethylamino)-2-butanol in 5 ml. of chloroform was saturated with hydrogen chloride. After removal of the chloroform and the excess hydrogen chloride under reduced pressure, 5 ml. of benzene and 5.6 ml. of thionyl chloride were added. The mixture was heated at 55° until hydrogen chloride ceased to be evolved (about thirty minutes). The chloroform and excess thionyl chloride were removed under reduced pressure. Ten milliliters of absolute ethanol was added and removed under reduced pressure. The residual dark oil was cooled, seeded with crystalline material (obtained first through the picrate), and placed in a vacuum desiccator over sodium hydroxide at 0.5 mm. After a short time, the oil changed to a crystalline mass which was dissolved in acetone–ether and allowed to crystallize, wt. 3.7 g., m. p. 106–107°. On recrystallization from acetone–ether, the melting point reached a constant value of 106–108°.

Anal. Calcd. for $C_8H_{16}NCl_3 \cdot HCl$: C, 35.71; H, 6.37. Found: C, 36.05; H, 6.06.

The picrate was obtained from the oily hydrochloride as follows: One gram of the oil was dissolved in 10 ml. of 95% ethanol and added to 25 ml. of ethanol containing 0.85 g. of picric acid. The addition of water precipitated an oil. The solvent was decanted, and the oil crystallized after standing for a few days in an open flask. The crystals were washed with cold ethanol, m. p. 93–95°. On recrystallization from ethanol, the compound had a constant melting point at 95.5–96.5°.

Anal. Calcd. for $C_{14}H_{19}O_7N_4Cl_3$: C, 36.42; H, 4.15; N, 12.13. Found: C, 36.71; H, 4.24; N, 11.90.

The hydrochloride was obtained in crystalline form from the picrate as follows: One-half gram of the picrate was suspended in 25 ml. of cold water. A layer of ether and 5 ml. of 2.5 *N* sodium hydroxide were added. The mixture was shaken and filtered to remove sparingly soluble sodium picrate. The ether layer was separated and dried over Drierite. Dry hydrogen chloride was passed into the solution. A colorless oil was precipitated. The ether was decanted, and the oil became crystalline after standing in a vacuum desiccator over sodium hydroxide. The material was recrystallized from acetone–ether, m. p. 105–107°.

The Reaction of Ketene with 2-Nitro-4-chlorophenylsulfenyl Chloride and Other Organic Halogen Compounds

BY ARTHUR ROE AND J. W. MCGEEHEE

It is known that aryl sulfenyl chlorides will add to olefins forming aryl β-chloroethyl sulfides.[1-3] Aliphatic sulfenyl chlorides likewise add to olefins.[4] Ketene contains an olefinic linkage, and we have found that 2-nitro-4-chlorophenylsulfenyl chloride will react with ketene to form 2-nitro-4-chlorophenylmercaptoacetyl chloride in good yield. This acid chloride was not isolated as such but converted to 2-nitro-4-chlorophenylmercaptoacetic acid, which had previously been prepared by Pollack, Riesz and Kahane[5] by the reaction of sodium chloroacetate with the sodium salt of 2-nitro-4-chlorophenylmercaptan. The new synthesis here reported seems to offer an easy approach to the mercaptoacetic acids.

The ready reaction of ketene with 2-nitro-4-chlorophenylsulfenyl chloride made it advisable to see if ketene would also react with arylsulfinyl and arylsulfonyl chlorides. The results were negative; ketene did not react with benzenesulfinyl chloride or with benzenesulfonyl chloride (no solvent used).

In view of Staudinger's report[6] of a reaction between diphenylketene and acid chlorides, we attempted to bring about a reaction between ketene and certain acid chlorides (propionyl, *n*-butyryl, *i*-valeryl and benzoyl) at temperatures ranging from −70 to 100°, both without catalyst and in the presence of a variety of catalysts (aluminum chloride, stannic chloride and sulfuric acid); the only reaction observed was polymerization of the ketene. This work was done before the publication of the article by Blomquist, Holley and Sweeting[7] describing the reaction of ketene with various compounds containing active halogens.

Experimental

2-Nitro-4-chlorophenylmercaptoacetic Acid.—2-Nitro-4-chlorophenylsulfenyl chloride was prepared by the chlorination of bis-(2-nitro-4-chlorophenyl) disulfide.[3] Ketene from a lamp delivering about 0.5 mole of ketene per hour was bubbled through a solution of 30 g. (0.13 mole) of 2-nitro-4-chlorophenylsulfenyl chloride in 100 ml. of dry chloroform; the solution was cooled in an ice-bath. The reaction was stopped after an hour and the chloroform solution carefully poured on 250 ml. of ice in a beaker. When the ice had melted the beaker was warmed to evaporate the chloroform; a bright yellow precipitate formed as the evaporation proceeded. The crude acid was dissolved in dilute sodium carbonate solution, filtered, and precipitated by the addition of dilute sulfuric acid; recrystallization from ethanol produced 21 g. (61%) of long yellow needles of 2-nitro-4-chlorophenylmercaptoacetic acid, m. p. 209–210° (in agreement with the literature value[5]). Conversion of the acid to 2-nitro-4-chlorophenylsulfonylacetic acid (m. p. 157–158°), 3-hydroxy-6-chloro-1,4-benzothiazine (m. p. 204–205°), and 5,5′-dichloro-7,7′-dinitrothioindigo was carried out as described by Pollack[5]; the melting points obtained are in agreement with those he reported.

quantitative bromination of phenols and phenol alcohols. It is the aim of this note to describe the preparation of these new compounds, and to comment briefly on the reaction employed.

Hydroxymethyl derivatives of phenols are most conveniently prepared by the reaction due to Lederer[2] and Manasse,[3] according to which the phenol is treated with formaldehyde in the presence of an alkaline catalyst, at room or elevated temperature depending upon the strength of the catalyst. Since the reaction may proceed beyond the desired hydroxymethyl stage to produce condensed products such as dihydroxydiphenylmethanes[4,5,6] and higher polymers, it is not uncommon in preparing a derivative to obtain a crystalline dimer or an oil which cannot be crystallized. The present work indicates that the experimental conditions are more critical than one might infer from the literature, so that the reaction should be carried out under carefully controlled, and hence reproducible, conditions if undesirable condensation is to be avoided. In this way, a procedure which is satisfactory for one phenol may often be successfully applied to a large number of other phenols. Moreover, should analysis indicate that a large yield of dimer has been obtained, the conditions can be accurately modified (the temperature, reaction time or catalyst concentration decreased; the mole ratio of formaldehyde to phenol increased) so that the desired hydroxymethyl derivative is obtained. It has also been found that when an oil is obtained upon acidification of the alkaline solution, it is far better to proceed to crystallize the oil *in situ* by intense refrigeration than to extract the oil with ether and to attempt to crystallize the ether extract. The procedure described below has given good results not only for the new compounds reported, but for other phenol alcohols.

Experimental

General Procedure.—One-quarter of a mole of the phenol was dissolved in 100 g. (0.25 mole) of a 10% aqueous sodium hydroxide solution, and the solution was cooled to 25–30°. Forty-four and six-tenths grams (0.55 mole) of 37% formaldehyde was added, and the reaction mixture in a stoppered flask was placed in a constant temperature bath at 27° for twenty-four hours. When the solution was acidified with 5 *M* acetic acid, an oil separated out. Upon refrigeration of the mixture (oil plus watery layer) in a Dewar flask containing a freezing mixture of solid carbon dioxide and trichloroethylene, the oil crystallized. The solid mass was filtered off and dried *in vacuo*.

On the Distribution of Water in Cellulose and Other Materials*

BY ROBERT SIMHA AND JOHN W. ROWEN

The distribution of water molecules in cellulose and similar textile materials is of theoretical and industrial importance. However, the mechanism of their interaction is not completely understood. It is a well known fact that the water content of these systems increases in a characteristic way dependent upon the vapor pressure, as shown for the case of cellulose in Fig. 1. This familiar sigmoid curve is characteristic of a large variety of systems: *e. g.*, protein-water,[1] titanium dioxide–water[2] and sulfuric acid–water.[3] These systems differ in structure and chemical properties and it would therefore be surprising if the same mechanism of sorption were operating in each. The question then arises, does the distribution of water in cellulose lead to a system more akin to a solution or is it indeed a system more nearly like the one involved in the adsorption of water by titanium dioxide?

One might speculate that in the limit of low vapor pressure the combination of the polymer with water is more nearly an adsorption phenomenon. Actually the shape of the pertinent curves and the amounts involved correspond to what has been observed in adsorption. In the opposite limit of high vapor pressure the process might be more appropriately considered as a "solution" phenomenon.

* This material formed part of a paper presented at the 113th meeting of the American Chemical Society, held at Chicago, Illinois April, 1948.

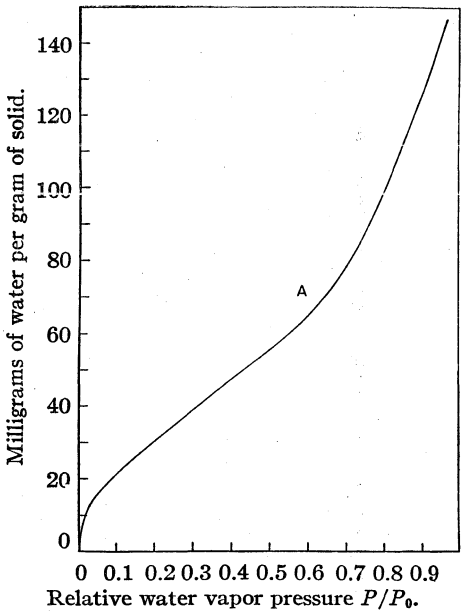

Fig. 1.—Sorption of water vapor by cellulose at 25°.

Such a concept has been advanced[4] in order to account for the upward curvature at higher pressures (beyond A in Fig. 1).

There is no complete theory at present of the mixing of a partially crystalline polymer such as cellulose with a liquid. Nevertheless it appears of interest to apply current statistical treatments[5,6,7] of polymer–liquid mixtures to the cellulose–water and similar systems. The results of such an analysis may then be compared with the results obtained from the application of modern adsorption theory[8] to the same system. In this note such a comparison is made based on experimental data obtained in this laboratory.[9]

Using the notation of references (5) and (6), we may write

$$\ln a_1 \doteq \ln (P/P_0) = \ln v_1 + v_2 + \mu(v_2)^2 \qquad (1)$$

where a_1 is the activity, P/P_0 the relative pressure, v_1 the volume fraction of water and v_2 the volume fraction of polymer. A term of the order of the reciprocal of the chain length has been omitted in (1). μ is the well-known semi-empirical interaction parameter appearing in these theories.

The relationship resulting from the Brunauer–Emmett–Teller treatment is

$$\frac{P}{V(P_0 - P)} = \frac{1}{V_m C} + \frac{C - 1}{V_m C}\frac{P}{P_0} \qquad (2)$$

where V is the volume of water adsorbed, V_m is the fixed volume of water adsorbed when a unimolecular layer completely covers the surface, and C is a constant which is related to the energy of binding between the gas molecules in the first layer and the absorbent. According to this theory, a plot of $P/V(P_0 - P)$ against P/P_0 should be a straight line with $1/V_m C$ as the intercept and $C - 1/V_m C$ as its slope.

(9) J. W. Rowen and R. L. Blaine, *Ind. Eng. Chem.*, **39** (1947).

The data[9] obtained on cellulose, silk and wool–water systems are plotted for comparison in Figs. 2, 3 and 4, according to equation (1) and equation (2), respectively. It is noted that for $P/P_0 < 0.5$, the data follow the straight line relationship called for by equation (2). Thereafter a more rapid increase is observed. The agreement over such a wide range is remarkable although unexpected on the basis of the assumptions underlying the derivation of equation (2). On the other hand it will be seen that the parameter μ starts out with a negative value, increases slowly and then assumes a fairly constant positive value of about 1.0–1.25 for $P/P_0 > 0.6$. In terms of the volume fraction v_1 of water the total range of measurements corresponds to $0.01 < v_1 < 0.26$. In the region of $0.10 < v_1 < 0.26$, equation (1) is obeyed by cellulose and silk. In wool μ varies approximately from 0.93 to 1.05 over the range $0.18 < v_1 < 0.26$. The various energy and entropy contributions to the quantity μ are different at high and low polymer concentrations.[10] These changes can lead to a variation of the "constant" μ. For rubber–benzene mixtures, the only system so far studied over the whole concentration range,[11,12] no significant change of μ was observed. In any case the deviations from equation (1) obtained by us over a relatively narrow range of volume fractions are too large to be caused by the above-mentioned effect. The limiting values obtainable from these data are $\mu = 1.25$, 1.15, and 1.05 for cellulose, silk and wool, respectively. If the polymer is regarded effectively as a network, allowance must be made for the free energy change accompanying elastic distortion during sorption. The model of a Hookean isotropic medium, subject to a deformation dependent on the concentration, leads merely to a slight reduction in the μ-values reported. These are larger than those usually found by means of solution or swelling measurements for other polymers.[13,14] Also, an examination of the temperature coefficients of μ leads to negative values of the heat term and reduced entropies which indicate that mixing is not a random process. In view of the nature of the systems considered here this is not surprising.

These results provide some support for the concept mentioned earlier. They suggest that the combination of water with these textile materials in the limit of low vapor pressures can be described in terms of adsorption theory. However, as one approaches the limit of high vapor pressures the system can be analyzed in terms of a theory of polymer–liquid mixtures. In the intermediate region between the two extremes a gradual transition occurs. It will be of interest to study the effect of variation in the nature of the liquid upon the properties of these systems.

p-Aminosalicylic Acid (4-Amino-2-hydroxybenzoic Acid)

BY JOHN T. SHEEHAN

When *m*-aminophenol and ammonium carbonate react under pressure an acid is obtained which melts at 148°.[1] In the original publication no identification is made beyond that of *m*-aminophenolcarboxylic acid. To determine whether the acid formed is *p*-aminosalicylic acid (4-amino-2-hydroxybenzoic acid) which is of current interest in the chemotherapy of tuberculosis,[2,3] the preparation was repeated in this Laboratory.

It was found that the acid could be isolated directly from the reaction mixture rather than as the hydrochloride as originally described. It could also be precipitated as the barium salt, from which the acid can be readily obtained in purer form. The identity of the acid was established as *p*-aminosalicylic acid by converting it through the diazonium salt into 4-chlorosalicylic acid and comparing this with a sample of the same compound prepared by reacting 2,4-dichlorobenzoic acid with barium hydroxide. Finally a comparison of antibacterial activity[4] disclosed no difference between the acid prepared by the present method and another sample of *p*-aminosalicylic acid.[5]

Experimental

p-Aminosalicylic Acid.—A mixture of 150 g. (1.37 moles) of *m*-aminophenol, 600 g. of ammonium carbonate (6.25 moles) and 750 ml. of water was heated in a rocker-type autoclave at 110° for twelve hours. The mixture was filtered and the filtrate concentrated *in vacuo* to a volume of 450 ml. The solution was then acidified to *p*H 5 and extracted with three 250-ml. portions of ether, from which 75 g. of *m*-aminophenol was recovered. The aqueous solution from the extraction was adjusted to *p*H 2–3 and the *p*-aminosalicylic acid filtered off and washed with water. The product weighed 47 g. and was crystallized from warm alcohol. Alternatively, it can be purified through the barium salt. A 22% yield of product melting at 146–147°[6] was obtained. *Anal.* Calcd. for $C_7H_7NO_3$: C, 54.90; H, 4.57; N, 9.15. Found: C, 55.03; H, 4.91; N, 9.13.

4-Chlorosalicylic Acid.—Fifteen and three-tenths grams (0.1 mole) of the above acid were diazotized and con-

(5) Supplied by Calco Chemical Division, American Cyanamid Co., Bound Brook, New Jersey.

(6) The reported melting point of *p*-aminosalicylic acid is 220° (dec.); Seidel, *Ber.*, **34**, 4351 (1901); Seidel and Bittner, *Monatsh.*, **23**, 415 (1902). Since the acid was prepared by reducing *p*-nitrosalicylic acid with tin and hydrochloric acid it seems likely that the melting point of the hydrochloride, which we found decomposes about this temperature, is recorded despite the fact that the empirical formula and analyses given are for the free acid.

verted to the chloride.[7] Nine grams of 4-chlorosalicylic acid was obtained, m. p. 211° after crystallization from water. No depression in m. p. was observed when this product was mixed with the substance prepared below. *Anal.* Calcd. for $C_7H_5O_3Cl$: C, 48.71; H, 2.92; Cl, 20.54. Found: C, 48.52; H, 3.04; Cl, 20.69.

A mixture of 6 g. of 2,4-dichlorobenzoic acid, 20 g. of barium hydroxide hydrate, 60 ml. of water and 0.5 g. of copper-bronze was heated in a sealed tube for six hours at 160–170°. The product was filtered and then suspended in water and decomposed with hydrochloric acid. Crystallized from hot water, the chlorosalicylic acid, 2.9 g, melted at 211–212°. 4-Chlorosalicyclic acid is reported to melt at 211°; 2-chloro-4-hydroxybenzoic acid at 159°.[8]

(7) The procedure described in "Org. Syn.," Coll. Vol. I, p. 163, 1st ed., was followed except that threefold volumes of acid were employed to facilitate the reaction of the insoluble acid hydrochloride and its insoluble diazonium salt. In addition, chlorobenzene was added during the decomposition of the diazonium salt, to extract the product as formed.

The Preparation of Phthalaldehyde

BY S. WAWZONEK AND R. E. KARLL[1]

Varying yields have been reported for the preparation of phthalaldehyde from *o*-xylene.[2] It has been found that, by using all-glass apparatus and the procedure described below, *o*-xylene and *o*-methylbenzyl bromide can be brominated in 64% yield to $\alpha,\alpha,\alpha',\alpha'$-tetrabromo-*o*-xylene. Under similar conditions *o*-methylbenzyl chloride gives the same yield of a mixture of $\alpha,\alpha,\alpha',\alpha'$-tetrabromo-*o*-xylene and $\alpha,\alpha,\alpha',\alpha'$-chlorotribromo-*o*-xylene. *o*-Methylbenzyl chloride is the most suitable starting material since the best commercially available *o*-xylene is only 90% pure while *o*-methylbenzyl bromide is a powerful lachrymator.

The tetrahalo-*o*-xylenes can be hydrolyzed to phthalaldehyde of melting point 55.5° in a 90% yield by the method of Thiele.[2a] The only modification made in this procedure was to saturate the aqueous solution of the aldehyde with sodium chloride instead of sodium sulfate.

Experimental[3]

$\alpha,\alpha,\alpha',\alpha'$-Tetrahalo-*o*-xylene.—*o*-Methylbenzyl chloride[4] was brominated according to the directions given in "Organic Syntheses"[5] with the following modifications. All-glass equipment was used together with a Trubore glass stirrer. From 132.6 g. of *o*-methylbenzyl chloride, 245 g. of product was obtained by taking up the reaction mixture in hot chloroform (300 ml.) and cooling; m. p., 106°. Repeated recrystallizations from ethanol gave a white crystalline compound melting at 110–111°. A mixture with tetrabromo-*o*-xylene (m. p., 115.5°) melted at 112°.

Anal. Calcd. for $C_8H_6ClBr_3$: Br, 63.6. Calcd. for $C_8H_6Br_4$: Br, 78.20. Found: Br, 72.89, 72.97.

Ethyl Acetamidoacetoacetate

BY RICHARD H. WILEY AND OLIN H. BORUM

The reduction of oximinoacetoacetic ester over palladium catalyst in acetic anhydride gives a product, m. p. 46–47.5°, which has been characterized as acetamidoacetoacetic ester, $CH_3CONHCH(COCH_3)CO_2C_2H_5$. The only known previous reference[1] to this compound describes a less convenient method of preparation and reports a melting point of 141°.

Experimental

Ethyl Oximinoacetoacetate.—This compound was prepared by the method of Adkins and Reeve.[2]

Ethyl Acetamidoacetoacetate.—Thirty-two grams of ethyl oximinoacetoacetate and 6.9 g. of palladium catalyst[3] were shaken in 50 ml. of acetic anhydride at room temperature under 30 lb. hydrogen pressure for ten hours. After separating from the catalyst and removing the excess acetic anhydride, 35 g. of acetamidoacetoacetic ester b. p. 128–140° (3–4 mm.) was obtained. Refractionation gave 25.7 g. b. p. 125–132° (3–4 mm.) which solidified on standing, m. p. 46–47.5°.

Anal. Calcd. for $C_8H_{13}O_4N$: C, 51.33; H, 7.0; N, 7.48. Found: C, 51.13; H, 7.0; N, 7.50.

This solid gave qualitative tests for carbonyl with 2,4-dinitrophenylhydrazine reagent and for enol with alcoholic ferric chloride. Reaction with phenylhydrazine in ether, according to the procedure of Michael[4] for the preparation of the phenylhydrazone of acetoacetic ester, gave a yellow precipitate of the phenylhydrazone, m. p. 131.5–132.5°.

The Decomposition of *o*-Methoxybenzene Diazonium Chloride

BY H. E. WOODWARD AND A. A. EBERT, JR.

M. L. Crossley and others[1] have reported that the decomposition of *o*-methoxybenzene diazonium chloride can be assumed to consist of two de-

(1) THIS JOURNAL, **69**, 1160 (1947).

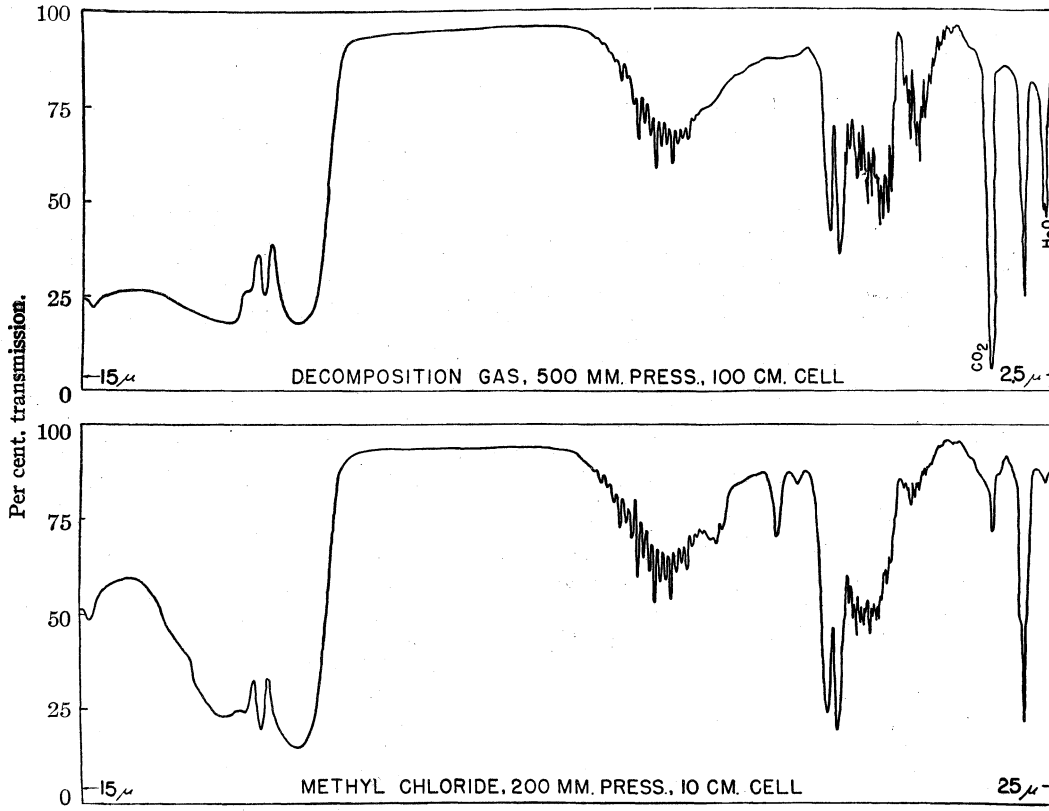

Fig. 1.—Comparison of spectra of methyl chloride and gas sample obtained from decomposition of *o*-methoxybenzene diazonium chloride.

composition reactions occurring simultaneously, one a slow single-step reaction to give guaiacol, and the other a pair of consecutive reactions to give catechol. They regretted that they did not find methyl chloride or methyl alcohol to substantiate their hypothesis.

We have obtained some evidence that their hypothesis is correct by infrared spectral analysis of the evolved nitrogen in the following manner: A solution of the diazonium salt was prepared from *o*-anisidine with 2.5 equivalents of hydrochloric acid and 1 equivalent of sodium nitrite. This solution was heated for about six hours at 90–95° and the evolved gas was passed through Drierite and soda-lime (to remove carbon dioxide used in sweeping air out of the apparatus) and collected over mercury. The gas was transferred to an infrared absorption cell which had an optical path length of one meter. With the gas at a pressure of 500 mm. the spectrum was recorded between 2.5 and 15 microns. The characteristic absorption spectrum of methyl chloride clearly was evident as shown in Fig. 1. A quantitative determination showed that the mole fraction of methyl chloride was 0.026. No other products were detected.

colorless crystals which melt, in most cases, with decomposition, have solubility properties reminiscent of α-amino acids, and show a tendency to revert to the original components on solution in polar solvents.

Experimental

The method of Schubert[2] was used in all cases, and the results obtained are listed in Table I.

2-(2′-Thienyl)-thiazolidine-4-carboxylic acid.—L(+)-Cysteine hydrochloride[6] (5 g., 0.028 mole) and 3 g. (0.035 mole) of potassium acetate were dissolved in 43 ml. of distilled water. To this solution was added 3.56 g. (0.0318 mole) of freshly distilled thiophene-2-aldehyde in 45 ml. of 95% ethanol. On shaking vigorously, precipitation occurred. After refrigeration overnight, the crystalline product was separated by filtration, washed with 20 ml. of cold ethanol, and recrystallized from the same solvent, giving a 94% yield of product melting at 145–146°.

NEW COMPOUNDS

6-β-Hydroxyethoxy-4-(3′-diethylaminomethyl-4′-hydroxyanilino)-quinoline

2-Diethylaminomethyl-4-aminophenol dihydrochloride[1] (13.3 g.) and 6-β-hydroxyethoxy-4-chloroquinoline[2] (11.2 g.) were refluxed in isopropyl alcohol (550 cc.) for twenty-four hours. The dihydrochloride of 6-β-hydroxyethoxy-4-(3′-diethylaminomethyl-4′-hydroxyanilino)-quinoline precipitated and was filtered from the hot reaction mixture. Suspending the precipitate in fresh, hot isopropyl alcohol, then filtering, gave 20 g. of dihydrochloride. This material (20 g.) was dissolved in water (150 cc.), ether (200 cc.) was added, and the mixture was made alkaline with potassium carbonate with shaking. The free base was filtered off, triturated in a mortar with water, and crystallized from acetone (16 volumes). When dried to a melting point of 144–145° the compound contained one-half mole of water; yield, 40%. The substance was a tan powder, soluble in acetone, slightly soluble in benzene or chloroform, and very slightly soluble in ether.

by these authors, it was found desirable to wash the benzene solution of the crude amide with several times the amount of 5% hydrochloric acid called for by them.

The crude amides were dissolved in hot ethyl or *n*-propyl alcohol, diluted in several instances with water. The solutions were filtered hot after the addition of activated carbon together with kieselguhr, and the filtrates chilled to obtain the recrystallized products. A substantial quantity of a second crop of satisfactory purity was obtained by concentration of the mother liquors from the recrystallization of the derivatives of *p*-bromoaniline and 3-bromo-4-aminotoluene. The melting points reported are the best values obtained after recrystallization from a variety of solvents.

The derivatives and their properties are listed in Table I. All melting points are corrected.

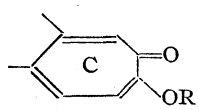
COMMUNICATIONS TO THE EDITOR

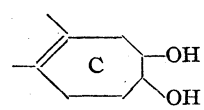
THE STRUCTURE OF RING C OF COLCHICINE[1]

Sir:

It has been suggested,[2] without experimental support, that ring C of colchicine is seven-membered (I, R = CH_3). We have obtained evidence which favors the Dewar and definitely excludes the Windaus[3] formulation.



I

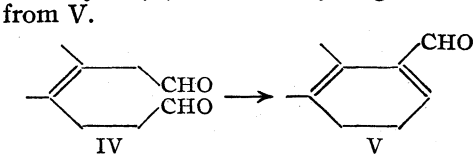


II

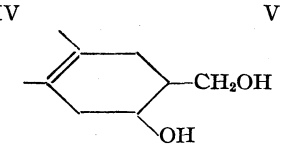
Colchiceine (I, R = H) (m. p. 175.5–176°; calcd. for $C_{21}H_{23}O_6N$: C, 65.45; H, 5.97; N, 3.66. Found: C, 65.65; H, 6.06; N, 3.45; benzoate, m. p. 207–209°, calcd. for $C_{28}H_{27}O_7N$: C, 68.70; H, 5.90; N, 2.86. Found: C, 68.87; H, 5.90; N, 2.78), prepared from purified colchicine,[4] was reduced with Raney nickel in methanol at room temperature and atmospheric pressure for one day, taking up three moles of hydrogen. The product was first crystallized from methanol, yielding about 26% of crude hexahydrocolchiceine[5] (II), m. p. 195.5–197°. Repeated crystallization from methanol–ether afforded the pure compound, m. p. 205.5–206° (calcd. for $C_{21}H_{29}O_6N$: C, 64.39; H, 7.47; N, 3.58. Found: C, 63.68; H, 7.39; N, 3.65; diacetate, m. p. 167°; calcd. for $C_{25}H_{33}O_8N$: C, 63.14; H, 6.99; N, 2.95. Found: C, 63.01; H, 6.83; N, 3.37).

Hexahydrocolchiceine was oxidized with periodic acid in 50% aqueous methanol at *p*H 4. At a lower *p*H side reactions appeared to take place. In a typical experiment hexahydrocolchiceine, m. p. 201–202°, $[\alpha]^{21.5}D$ −205 ± 1° (*c* = 1.544, methanol), $[\alpha]^{19}D$ −162 ± 1° (*c* = 1.436, 50% aqueous methanol) gave an uptake of 0.86 mole periodate after ten minutes, 0.92 mole after ninety minutes, unchanged after eighteen hours. At the end of the reaction, the rotation of the reaction mixture (50% aqueous methanol) had fallen to $[\alpha]^{19}D$ −109 ± 1° (*c* = 1.401). These results indicate the presence of one 1,2-glycol group in hexahydrocolchiceine.

A chloroform extract of the reaction mixture yielded a yellow mobile sirup (III), strong Schiff and Tollens reactions, and reduced Fehling solution. On standing, it slowly lost its aldehydic properties. Efforts to obtain a semicarbazone or dimedone derivative have been unsuccessful, but an alcoholic solution of III with 2,4-dinitrophenylhydrazine in 2 *N* hydrochloric acid gave amorphous mono-2,4-dinitrophenylhydrazone, m. p. 103–107° (dec.) (after chromatography on alumina) (calcd. for $C_{27}H_{29}O_8N_5$: C, 58.77; H, 5.30; N, 12.7. Found: C, 59.65; H, 5.39; N, 12.84). The oxidation of II presumably gives the dialdehyde (IV) which cyclises spontaneously to the monoaldehyde (V), or the dehydrogenation product from V.



IV V



VI

On the Windaus structure, hexahydrocolchiceine would be a 1,3-glycol (VI) and no oxidation should occur with periodate; the above results are in agreement with (I).

Work is continuing on this and other reduction products of colchicine and its derivatives.

RECOIL-ACTIVATED AND THERMAL EXCHANGE REACTIONS BETWEEN SULFUR-35 AND CARBON DISULFIDE

Sir:

Two interesting exchange reactions have been observed in research on the preparation of S^{35}-tagged CS_2 (CSS*). Each reaction presents an interesting chemical phenomenon, namely, the exchange of a free sulfur atom or ion with one bound in the CS_2 molecule, and each is applicable to the preparation of CSS*. Such *atomic* exchange reactions, involving energetic covalent bonds, have been found in the past to be much slower.

The activation energy in the first of these reactions is supplied by the specific nuclear process which results in formation of S^{35}. Two experiments have been performed to date, each utilizing the n,p reaction on Cl^{35} to make the 87-day S^{35}. In the first experiment, a solution of CS_2 in CCl_4 (10 volume per cent. CS_2) was placed in the stray neutron field near the Massachusetts Institute of Technology cyclotron for one month. The total S^{35} activity and that present as CS_2 were assayed by Carius analysis. For the CS_2 analysis, exhaustive extraction with Na_2CO_3 solution was followed by distillation of the mixture to remove the other S^{35}-containing compounds ($CSCl_2$ etc. No effort was made to separate CCl_4 and CS_2). About 50% of the S^{35} formed in compounds not volatile below room temperature was present as CSS*. In the second experiment, a solution of one gram of C_2Cl_6 in 1 ml. of CS_2 was sealed in a quartz vial for a thirty-day bombardment in the Oak Ridge pile, and assayed as described above, except that upon receipt, the sample was kept frozen until aliquoted for total S^{35} analysis to avoid loss of the more volatile compounds (of $BaCS_3$). In this case, 12% was recovered as CSS*. The lower value in the second experiment may be attributed (a) to the precaution taken to recover volatile compounds, and (b) to the greater variety and number of radiation-induced side reactions possible in the higher neutron flux of the pile. The specific activity of S^{35} as CSS* in the Oak Ridge sample attained a value of greater than one millicurie per gram.

The second reaction, now being studied, is the exchange of sulfide ion in aqueous solution with CS_2 as a separate phase. The reaction proceeds through sulfide exchange with thiocarbonate ion ($CS_3^=$), and like the electron transfer reactions of thallium[1] and iron[2] recently reported appears to be catalyzed by precipitation (of $BaCS_3$). On the other hand, when the $CS_3^=$ is decomposed with acid and the resulting CS_2 extracted with CCl_4 and analyzed, this exchange shows a half-time of about forty minutes (sulfide concentration about 0.5 M, thiocarbonate about 0.15 M, pH 9.5, 30°). Investigation of the kinetics of this reaction continues.

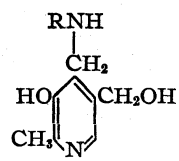
PYRIDOXYLAMINES

Sir:

Pyridoxal has been reductively coupled with certain amines, including several pressor amines, to give compounds of structure I. For example,



I

β-phenylethylamine, tyramine, tryptamine, isobutylamine, histamine (amines derived from naturally occurring amino acids), as well as benzylamine reacted with pyridoxal to give yellow Schiff bases, which were hydrogenated over a platinum catalyst to give pyridoxyl-β-phenylethylamine dihydrochloride, II (m. p. 227–228°, dec.), pyridoxyltyramine dihydrochloride, III (m. p. 238–239°, dec.), pyridoxyltryptamine hydrochloride, IV (m. p. 222–223°, dec.), pyridoxylisobutylamine hydrochloride, V (m. p. 204–205°, dec.), pyridoxylhistamine dihydrochloride, VI (m. p. 236–237°, dec.), and pyridoxylbenzylamine dihydrochloride, VII (m. p. 220–221°, dec.). These new compounds as well as the intermediary Schiff bases were also analytically characterized.

These pyridoxylamines, which are derivatives of both pyridoxine and the pressor amines, are being studied for vitamin B_6 activity and for pressor activity.

The tests of these compounds for vitamin B_6 activity in deficient rats were made by Dr. Gladys Emerson and Miss Elizabeth Wurtz of the Merck Institute for Therapeutic Research, who have found that compounds II, III, IV and VII show activities which range between 50 and 100% of the activity of a molar equivalent of pyridoxine. Such high biological activity for these new compounds is in contrast to the low activity which has been found for previous structural modifications of the vitamin B_6 group.[1]

EVIDENCE FOR THE INVOLVEMENT OF GLUTATHIONE IN THE MECHANISM OF PENICILLIN ACTION

Sir:

Several authors have suggested the involvement of —SH groups in the antibacterial action of penicillin (see review[1]). The similarity in the molecular structure of glutathione and of penicillin[2,3] suggests the possible involvement of glutathione in the antibiotic action of penicillin. The following experiments (supported partly by the Cutter Laboratories, Berkeley, California) bear on this question.

When standard penicillin assay plates are flooded with a 1% solution of 2,6-dichlorophenolindophenol in a saturated aqueous solution of sodium bicarbonate the inhibition zones promptly stain intensely blue, and are sharply delineated from the faintly bluish uninhibited background by a narrow colorless rim that locates the ring of enhanced growth that circumscribes each zone. Similar patterns obtain on plates pretreated for five minutes with acetone, which blocks —SH groups from cysteine but not those from glutathione.[4] However, if —SH groups of glutathione are blocked by flooding the plates for ten minutes with a 10% solution of formaldehyde in saturated sodium bicarbonate the 2,6-dichlorophenolindophenol is no longer reduced to the colorless form in the ring of enhanced growth, which now stains deep blue.

The reducing activity in the regions of enhanced growth may be strikingly revealed also by flooding plates with a 0.5% aqueous solution of 2,3,5-triphenyltetrazolium chloride, whereupon these regions become intensely red, while the zones of inhibition remain uncolored. Pretreatment of the plates with 10% formaldehyde blocks this reaction. When such plates are subsequently flooded with the tetrazolium reagent, the red color fails to develop, except at the extreme outer margin of the ring of enhanced growth where it is very faint.

Such simple experiments do not themselves afford unequivocal proof of the participation of glutathione in the mechanism of penicillin action. However, it is generally assumed that —SH groups are involved. Our results indicate that some of these —SH groups are less reactive than those of cysteine, and in view of the work on the role of glutamine revealed by Gale and Taylor[5,6,7] it seems reasonable to deduce the involvement of glutathione.

IMPROVED ION EXCHANGE METHOD FOR SEPARATING RARE EARTHS IN MACRO QUANTITIES[1]

Sir:

Previous communications from this laboratory[2] described ion exchange methods by which rare earths were separated from one another in kilogram quantities. The process consisted essentially of absorbing the mixed rare earths on the top of long columns of commercial IR-100 Amberlite resin, in the acid cycle, and then eluting by means of citric acid solutions whose *p*H had been adjusted to the required value by the addition of ammonium hydroxide. While these processes represented an enormous saving, in man-hours required per gram of pure rare earth produced, over the old processes of fractional crystallization, etc., they were not ideal in the sense that when a mixture of rare earths was present, shapes of the elutions bands were such that there was a slight trailing of the preceding rare earth across the main band of the following one. This cut down the amount of pure rare earth obtained from any one pass of the column and frequently resulted in the necessity of recycling considerable quantities of the material.

Considerable work has been done in this Laboratory concerning the nature of the separation process. Good spectroscopic evidence has been obtained that at least four complexes of the rare earths with citrate solution exist and that each of these in turn becomes important as the *p*H range and citric acid concentrations are changed. Recently, it has been found that separation of the rare earths in large amounts can be markedly increased by eluting with a 0.1% citric acid solution in the *p*H range between 5.0 and 5.5. Under these conditions both the front and rear edges of the elution band (amount of rare earth eluted per liter plotted against liters of the eluant passed through the column) are steep and the tops of the eluting bands are flat. Furthermore, the bands separate from each other until the front edge of the one rare earth band is riding on the rear edge of the preceding band. Increasing the length of the column beyond the limit necessary to do this does not separate the bands any further, so there is good evidence that the one rare earth is replacing the

(1) This document is based in part on work performed under Contract No. W-7405 eng-82 for the Atomic Energy Project.

other rare earth on the column as the material is eluted. It was also noted that in the cases tested the *p*H of the solution which comes from the column varies with the rare earth being eluted and differs by about 0.05 of a *p*H unit for adjacent rare earths. With binary mixtures of 50–50% neodymium–praseodymium and neodymium–samarium, it has been found possible to recover from 60 to 90% of each of the rare earths in such purity that the other rare earths could not be detected spectrophotometrically in these fractions.

Work is being continued and the details of this process will be presented in a paper soon to be submitted for publication.

LEAF XANTHOPHYLLS

Sir:

Recently, a violaxanthin-like xanthophyll called xanthophyll-epoxide has been reported as a new leaf pigment.[1] However, earlier observations indicate that this leaf xanthophyll is spectroscopically identical with violaxanthin, obtained originally from pansies (*Viola*).[2] Moreover, leaf violaxanthin and pansy violaxanthin are chromatographically identical in Tswett columns of magnesia or of sugar.[3]

Karrer and co-workers also claim that, in spite of other similarities, violaxanthin and leaf violaxanthin (their xanthophyll-epoxide) yield different pigments when treated with acids[1]

violaxanthin ⟶ auroxanthin
xanthophyll-epoxide ⟶ flavoxanthin.

By contrast, I have found violaxanthin from the two sources to react with acids in the following way

pansy violaxanthin ⟶ flavoxanthins ⟶ auroxanthin
leaf violaxantin ⟶ flavoxanthins ⟶ auroxanthin

Obviously, pansy violaxanthin and leaf violaxanthin are identical with respect to their reaction with acids. This xanthophyll, whether obtained from pansies or from leaves, should, therefore, be called violaxanthin, not xanthophyll-epoxide.

In spite of Karrer's assertions to the contrary,[1] numerous experiments confirm the complexity of the leaf pigment mixture. The leaves of some fifty plants, ranging from ferns to angiosperms, have yielded the following pigments: chlorophylls a and b (with traces of chlorophylls a′ and b′), neoxanthin, zeaxanthin, violaxanthin, lutein, cryptoxanthin-like pigments and β-carotene ± α-carotene. In leaves of eleven species of cycads representing six genera, taraxanthin, identical with taraxanthin from dandelions, accompanies the pigments just enumerated. In most of these plants, lutein is the principal xanthophyll, violaxanthin is slightly less abundant, neoxanthin occurs in small amounts, and zeaxanthin and the cryptoxanthin-like pigments are present in very small proportions. Traces of flavoxanthins are sometimes found in the leaf extracts.

When the pigments of fresh leaves are extracted with methanol or acetone, transferred to petroleum ether, adsorbed in columns of powdered sugar, and washed with petroleum ether containing 0.5% propanol, the following sequence of adsorbed pigments is obtained: neoxanthin, violaxanthin, (flavoxanthins), chlorophyll b, (taraxanthin), lutein plus zeaxanthin[4] plus chlorophyll b′, chlorophyll a, chlorophyll a′, crytpoxanthin-like pigments and the non-adsorbed carotenes.

1,2-Dichloroethane, formerly employed for the resolution of leaf xanthophylls by adsorption,[5] decomposes easily, especially in the presence of moisture, yielding hydrochloric acid. Unless special precautions are observed, the action of this acid on the leaf xanthophylls dissolved in dichloroethane may decrease the amount of violaxanthin and increase the amounts of flavoxanthins and isolutein.[5]

All these facts confirm the identity of violaxanthin from leaves and from pansies. They indicate that flavoxanthins can be converted into auroxanthin. They illustrate the complexity and the lability of the leaf xanthophylls. They point to precautions to be observed in the handling of leaf xanthophylls, and they illustrate problems in nomenclature arising from the use of different names for a single substance.

resultant streptamine sulfate[2-4] was characterized by its X-ray powder diffraction diagram, which was identical with that of an authentic specimen obtained from streptomycin. Streptamine sulfate was treated with the stoichiometric amount of barium hydroxide and the resultant aqueous solution of the free base was heated at 70–80° for forty-eight hours with an equivalent amount (added in portions) of S-methylthiopseudourea sulfate.[5] A crystalline reaction product was obtained which, when triturated with dilute ammonium hydroxide, yielded streptidine sulfate monohydrate,[2,3,6,7] identified by its X-ray powder diffraction diagram,[8] nitrogen analysis (calcd., 22.2%; found, 22.1) and octaacetyl derivative[7] (m. p. 259–261°, unchanged on admixture with an authentic specimen prepared from streptomycin).

NEW BOOKS

Quantitative Organische Mikroanalyse. Fifth Austrian Edition. By F. PREGL and H. ROTH. Springer-Verlag, Vienna, 1947. 317 pp. 80 Figs. 16 × 23.5 cm. Price $7.40 (Swiss Francs 32.--).

F. Pregl's "Die quantitative organische Mikroanalyse" has had three original editions (1st, 1916, 2nd, 1922, and 3rd, 1929). Since Pregl's death on Dec. 13, 1930, two revisions by H. Roth have appeared: the first in 1935 and the second, or present fifth edition, in 1947.

Since neither the fourth nor the present fifth edition have been previously discussed in THIS JOURNAL, it was thought expedient to not only examine these two revisions but also compare them with the third and last original Pregl edition. This is being done in the table given herewith.

TABLE I

Chapters	Number of pages 3rd edition	4th edition	5th edition
Balances	14	16	14
Methods of elementary analysis	175	164	175
Carbon and hydrogen	69	66	59
Oxygen	...	...	11
Nitrogen (Dumas)	30	20	20
Nitrogen (Kjeldahl)	11	8	7
Halogen	21	28	25
Sulfur	15	12	19
Miscellaneous	28	26	28
Methods of structure analysis	29	86	78
Molecular weight determinations	15	24	16
Determ. of physical constants	2	25	20
Total	256	328	317

As can be seen from the table, the two revisions differ from the last and original Pregl edition chiefly by an enlargement in the structure analytical section. Thus, in this field, there have been added the well-known iodometric determination of O-, S- and N-alkyls by F. Vieboeck and C. Brecher and three methods by R. Kuhn and co-workers, such as a gasometric determination of active hydrogen, an oxidation procedure (acetic acid) and a method of ozonolysis (acetone). In the field of elementary analysis the additions involve iodometric methods for the determination of oxygen (J. Unterzaucher) and of sulfur (W. Zimmermann), a hydrogenation method for nitrogen (A. Lacourt) and an alkalimetric determination for chlorine and bromine (M. K. Zacherl).

The fifth edition differs from the fourth by the iodometric methods for the determination of oxygen (1940) and sulfur (1943) and the determination of nitrogen by hydrogenation (1940) cited above. On the other hand, the chapter on molecular weight determinations has been weakened by the omission of any and all ebullioscopic methods. The literature references are incomplete and none goes beyond 1943. There is no author index, nor does the book contain any log or nitrogen reduction tables. Use of ordinary balances in quantitative organic microanalysis is not mentioned.

In view of the foregoing, which at the same time might also be regarded as an indication of the progress of organic microchemistry in Central Europe for the last twelve years, the present edition appears to be rather a "Second Printing" of the fourth edition, or first revision. The bypassing of Pregl's original and still active laboratory at the University of Graz, Austria, his successor and original co-workers as co-authors appears inexcusable and is most unfortunate.

JOSEPH B. NIEDERL

Violin Varnish. A Plausible Re-creation of the Varnish Used by the Italian Violin Makers between the Years 1550 and 1750, A. D. By JOSEPH MICHELMAN. Published by Joseph Michelman, 5050 Oberlin Boulevard, Cincinnati, Ohio, 1946. 185 pp. 14 × 21 cm. Price, $3.75.

The question of the varnishes used by the great Italian violin makers of the mid-sixteenth to the mid-eighteenth centuries has always provoked great curiosity and specula-

tion. Violin makers and scientists still disagree about the actual contribution of varnish to the tonal qualities of the violin, but most consider that it is an important one. Unfortunately, the varnish formulas used by the master violin makers were shop secrets and little opportunity has been found to analyze, even on a micro scale, the varnish on the very few instruments that have come down to us. In this brief volume the author, who apparently is well versed in modern varnish technology, has attempted to reconstruct the work-shop receipts of the famous violin artisans from a study of the materials then available, and to analyze the properties of the finishes produced thereby.

After carefully surveying the existing literature on violin varnish, the author discusses the materials used in its manufacture by the master Italian violin makers, which included Venetian turpentine (oleoresin from the European larch), potash, alum, copperas, linseed oil, alcohol, and red dye obtained from the madder root and the different mordant salts used to fix it. Next follow several chapters describing in detail numerous experiments with these materials to establish the old formulas, without the aid of modern laboratory devices, and possible receipts that the violin makers might have used. In these experiments small batches, comprising often only a few grams or cubic centimeters of the principal ingredients, were employed. One wonders whether proper conditions for varnish making can be established on such a small scale. Many of the experiments involve the preparation of metal rosinates which, combined with linseed oil, the author believes were used for under-coats or sub-varnishes. Combinations of aluminum and iron rosinates made from potassium rosinate could have been used to produce the brown undertone so frequently seen. The color of top varnishes could have been obtained by combining various natural dyes with metal rosinates and linseed oil; among them the extract from madder root or modern alizarin gives best results. The author then lists a series of simple formulas for violin varnishes for the use of the amateur, followed by a discussion of materials and methods which the modern varnish technologist might employ.

The collector of old violins and the modern amateur violin maker will find this volume of much interests The subject matter is well organized and the book i. attractively printed.

A Quantitative Study of Reversible Boundary Spreading in the Electrophoresis of Proteins[1]

BY ROBERT A. ALBERTY

Introduction

The usual criterion for the electrophoretic homogeneity of a protein is that it migrates as a single boundary in an electric field in buffers of various hydrogen ion concentrations and ionic strengths. However, this alone is not sufficient evidence that all the protein molecules have the same electrophoretic mobility, and further evidence regarding the electrophoretic homogeneity may be obtained by studying the rate with which the protein gradient spreads in the electrical field. If the molecules in a protein "family" vary with respect to electrophoretic mobility because of differences in net charge or size or shape, the protein gradient will spread faster in the electrical field than expected for diffusion alone but will become sharper upon reversal of the field.[2] While in the case of a heterogeneous protein spreading is observed at both boundaries in the U-tube, in the case of spreading caused by conductivity[3] or pH[4] gradients in the moving protein gradient, spreading at one boundary is accompanied by sharpening at the other. Spreading and sharpening caused by these superimposed gradients may be minimized by performing the electrophoresis experiment at the average isoelectric point of the protein.[5] Convection caused by the temperature gradient set up in the electrophoresis cell by electrical heating or caused by electroosmosis along the cell wall may also spread the protein boundary. Such convection effects would not be reversed by reversing the electric field because they are a result of turbulence, and so it is possible to test electrophoresis experiments for their presence.

Reversible electrophoresis spreading has been cited as evidence for the electrophoretic heterogeneity of *Helix pomatia* and *Helix nemoralis* hemocyanins,[6,7] ovomucoid,[5] alfalfa mosaic virus,[8] horse pseudoglobulin GI,[9,10] pectin[11] and bovine γ_1- and γ_2-globulins.[12]

Two quantitative methods for representing boundary spreading have been proposed,[6,13] but neither of these has been used to calculate the actual distribution in mobility among the protein molecules. The purpose of this paper is to present a quantitative method for the determination of the mobility distribution in certain cases.

Theory

If the electrophoresis of a heterogeneous protein with a mobility distribution $g(u)$ is carried out under conditions such that no convection is caused by temperature gradients or electroosmosis in the electrophoresis cell and there are no conductivity or pH gradients through the boundary between protein solution and buffer, the refractive index gradient, $\partial n/\partial x$, as a function of height in the electrophoresis cell, x, at time t_D after the formation of the boundary and time t_E after application of the electric field, is given by equation

(1).[14] D is the diffusion constant which is assumed to be the same for all the protein molecules, u is electrophoretic mobility, E is the electric field strength, and $(n_1 - n_2)$ is the difference in refractive index of the protein solution and buffer. The boundary will spread faster than expected for diffusion alone because of the difference in rates of migration of the protein ions.

$$\frac{\partial n}{\partial x} = \frac{(n_1 - n_2)}{2\sqrt{\pi D t_D}} \int_{-\infty}^{+\infty} g(u) e^{\frac{-(x - uEt_E)^2}{4Dt_D}} du \quad (1)$$

If diffusion is negligible during the electrophoresis experiment, Sharp, *et al.*,[10] point out that equation (1) assumes a simple form, and a heterogeneity constant, H, may be defined by

$$H = \Delta\sigma / \Delta t E \quad (2)$$

where $\Delta\sigma/\Delta t$ is the time rate of change of the standard deviation, σ, of the refractive index gradient. For this case, H characterizes the mobility heterogeneity of the protein and the mobility distribution may be determined directly from the gradient curves.

If diffusion is not negligible during the electrophoresis experiment, it is theoretically possible to obtain the mobility distribution $g(u)$ from the experimental refractive index gradient curves by using equation (1), but this is not a practical method for studying the distribution in mobilities because of the difficulties in computation. However, a suitable function for $g(u)$ with parameters to be evaluated from the experimental curves may be introduced in equation (1). In the case of a protein at its "average" isoelectric point so that the most frequent molecule has a mobility of zero, it is convenient to try a Gaussian distribution function with h, the heterogeneity constant, the parameter to be evaluated.

$$g(u) = \frac{1}{h\sqrt{2\pi}} e^{-u^2/2h^2} \quad (3)$$

h has the dimensions of mobility and is the standard deviation for the mobility distribution which has been normalized to unity. Substituting this form of $g(u)$ in (1) and integrating, we obtain the equation giving the refractive index gradient as a function of height in the cell for such a protein during electrophoresis.

$$\frac{\partial n}{\partial x} = \frac{(n_1 - n_2)}{\sqrt{2\pi}\sqrt{E^2h^2t_E^2 + 2Dt_D}} e^{-x^2/2(E^2h^2t_E^2 + 2Dt_D)} \quad (4)$$

This equation shows that if there is a Gaussian distribution of mobilities, the electrophoresis gradient curves should be Gaussian, as is closely realized for the systems studied.

The heterogeneity constant, h, may be evaluated by noting that the standard deviation, σ, of the experimental curve should be

$$\sigma = \sqrt{E^2h^2t_E^2 + 2Dt_E + 2D\Delta t} \quad (5)$$

if the electrophoresis is started after the boundary has been diffusing Δt seconds. $2D\Delta t$ is the square of the standard deviation of the gradient curve at the moment the electric field was applied, σ_0^2. Rearranging

$$D^* = \frac{\sigma^2 - \sigma^2}{2t_E} = D + \frac{E^2h^2}{2} t_E \quad (6)$$

D^* is the "apparent diffusion constant" calculated from the experimental gradient curves during the electrophoresis.[15] According to this equation, the apparent diffusion constant should plot as a straight line against time of electrophoresis and extrapolate back to the normal diffusion constant at zero time. If the protein is heterogeneous and has a Gaussian distribution of mobilities, the straight line will have a slope $E^2h^2/2$ from which the heterogeneity constant h may be calculated. Since the heterogeneity constant is the standard deviation for the mobility distribution, the actual mobility distribution curves may be constructed using a table of values for the Gaussian probability function.

Equation (5) for the standard deviation of the electrophoresis curves in terms of the heterogeneity constant h may be used to show the relationship between the heterogeneity constant, H, introduced by Sharp, Taylor, Beard and Beard[13] and h. For the case in which electrophoresis and diffusion start simultaneously

$$H = \frac{\sigma}{tE} = \sqrt{\left(\frac{2D}{E^2}\right)\frac{1}{t} + h^2} \quad (7)$$

This shows that if diffusion is negligible, $H = h$. If diffusion is not negligible, H will decrease with time approaching h asymptotically.

As a check on irreversible spreading during electrophoresis, the direction of the electric field may be reversed for an equal period of time. The manner in which the apparent diffusion constant varies with time during the reversal period may be shown by using equation (5). If t_E is the total time the current has been flowing in both direc-

(14) This equation has been but slightly modified from that given by Sharp, Hebb, Taylor and Beard.[10] The times in the equation have been given subscripts to indicate whether they are the time of diffusion or electrophoresis so that the more general case in which these are not equal may be treated. Sharp, *et al.*, prefer to use a modified diffusion constant D_1 which may not be the same as D since they state variations in mobility of individual particles with time may affect the rate of diffusion under the influence of an electric field. If, however, as assumed by Tiselius (ref. 2, p. 26) diffusion is simply superimposed on the electrophoretic migration, it should not be necessary to distinguish between two diffusion constants provided convection can be eliminated, and no distinction is made in this paper.

(15) The apparent diffusion constant may be calculated from the gradient curves by any of the standard methods which will all give the same result provided the refractive index gradient is Gaussian in form. In this paper the apparent diffusion constants have been calculated from enlarged tracings of the photographs by using the half width x, of the gradient curves at the inflection point $\frac{Y}{\sqrt{e}}$, or from the area, A, and maximum height, Y,

$$D_\sigma^* = \frac{x^2 - x_0^2}{2t_E G^2} \qquad D_A^* = \frac{\left(\frac{A}{Y}\right)^2 - \left(\frac{A}{Y}\right)_0^2}{4\pi t_E G^2}$$

If x, A and Y are measured in centimeters on a tracing of the photograph, G is the number of cm. on the tracing paper corresponding to one cm. in the electrophoresis cell.

tion, and t_1 is the time after which the current was reversed, for $t_E > t_1$

$$D^* = D + \frac{E^2h^2}{2}\frac{(2t_1 - t_E)^2}{t_E} \qquad (8)$$

Thus the apparent diffusion constant decreases with time and becomes equal to the diffusion constant at $t_E = 2t_1$. The slope of the D^* *vs.* t_E plot immediately after reversing the current ($t_E = t_1$) is $-\frac{3}{2}E^2h^2$, and when $t_E = 2t_1$ the slope is zero showing that an error of a few minutes in the time of reversing the current will generally not cause D^* to differ significantly from D.

More general distribution functions with as many constants as justified by the precision of the experimental data may be used in place of the error function.[16] In cases in which the gradient curves are symmmetrical but not Gaussian, the sum of two or more Gaussian distribution functions may be used to represent the mobility distribution $g(u)$. Such a distribution function may be integrated conveniently when substituted in equation (1), and the parameters may be evaluated from the successive moments of a single gradient curve by the same method used in determining the diffusion constants and relative amounts of two or more independently diffusing molecules in a polydisperse system.[17]

Experimental

The optical system used in this work was the cylindrical lens schlieren optical system with a schlieren lens on each side of the thermostat arranged so that light from the horizontal slit passed through the cell in a parallel beam.[18] A diagonal slit (0.50 mm. wide) was used in the optical system, and the photographs were taken on Eastman Kodak Co. CTC plates and enlarged and traced. The gradient curves were obtained by averaging the ordinates of the two edges of the band of light and constructing the corresponding mean curve. It was found that the diffusion constants determined by this method did not vary with the exposure time as did those determined by the diagonal knife edge method.

It was found that when diffusion boundaries were formed in the standard Tiselius electrophoresis cell by the usual method and compensated into the optical system at the rate of 2–3 cm. per hour using a mechanically driven syringe, thirty to ninety minutes had to be added to the diffusion times in order to obtain a constant diffusion constant for short time diffusions (less than ten hours).[19] The quality of the initial boundary is very important in an electrophoresis spreading experiment since it must be carried out in a short period compared to the usual 3–4 day diffusion experiment. As shown by equation (6), the apparent diffusion constant may be calculated even when the initial gradient is diffuse, provided it is Gaussian, by using the method of differences, and this is satisfactory if the electrophoresis spreading is large. However, in the case of a homogeneous protein the spreading of the gradient during the experiment is not large and D^* calculated by the method of differences is subject to rather large experimental errors. In order to avoid the correction for the width of the initial boundary, the sharpening technique of Kahn and Polson[20] may be applied. In forming these so-called "sharpened" boundaries for some of the electrophoresis spreading experiments, a capillary was lowered into the protein boundary after it had been compensated into the cell, which was set up with both sides open to the atmosphere, and the diffuse portion of the boundary was drawn off by suction at a rate of about 0.4 cc. per minute. The sharpening of the boundary was followed with the schlieren optical system, and when the boundary became no sharper, the suction was practically stopped while the capillary was carefully withdrawn, and this time was taken as the starting time for the diffusion. Figure 1 shows the results of a short diffusion of crystallized bovine albumin[23] using a sharpened boundary. The zero time correction was negligible after one hour, and the agreement between the diffusion constants calculated by two methods indicates the precision obtained with the schlieren optical system. The average diffusion constant, 3.1×10^{-7} cm.^{2} sec.$^{-1}$ at 1.5°, is in agreement with earlier values.[21]

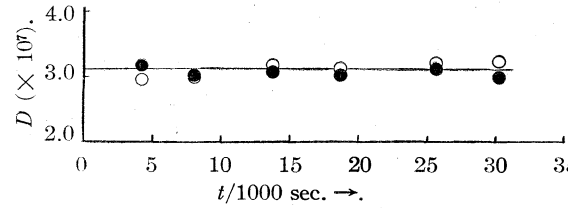

Fig. 1.—Diffusion constant for crystallized bovine albumin, $\Gamma/2 = 0.1$, pH 4.6, 0.6% protein, at 1.5°. ●, calculated from the half width at the inflection point; O, calculated from the height and area.

The disadvantage of applying the sharpening technique in electrophoresis spreading experiments is the difficulty of sharpening both boundaries simultaneously. When only one of the boundaries is sharpened and conclusions are drawn from its behavior alone, sharpening or broadening of the peak caused by the field and pH gradients may go undetected, and an erroneous conslusion as to the homogeneity of the protein may be drawn.

More than the usual care to avoid thermal convection must be taken in electrophoresis spreading experiments. In electrophoresis load tests with alternating current Tiselius[22] found that power dissipations of 0.5 to 1 watt/cc. could be used in flattened electrophoresis cells near the temperature of maximum density of water. Loads of about 0.15 watt/cc. are used routinely in this Laboratory with the standard 11-cc. cells, but for spreading experiments the loads were kept below 0.015 watt/cc. It has been found that loads which do not cause convection in short experiments (two hours) may cause convection in prolonged spreading experiments as the density gradient becomes progressively less.

In order to reduce the difference in buffer salt concentration in the protein solution and equilibrium buffer caused by the Donnan effect and to reduce optical errors inherent in measuring high refractive index gradients, protein concentrations of 0.5 to 0.8% were used in all experiments. The electrophoresis samples were dialyzed two days in the cold before electrophoresis. The conductivity of the equilibrium buffer measured at the temperature of the thermostat (1°) was used in calculating the potential gradient, and the pH of the buffers was measured at 25° using a glass electrode.

Results

Bovine Albumin.—The isoelectric point of crystallized bovine albumin was found to be *p*H 4.6 at 0.10 ionic strength in acetate buffers. A number of spreading experiments carried out at this *p*H showed that although there was partial resolution of about 5% of another protein constituent, the same rate of boundary spreading was observed in both limbs of the U-tube. The additional protein component would not appear to be α- or β-globulin.[23] In these experiments the boundaries were compensated into the electrophoresis cell at a rate of about 1 cm. per hour, and after they had diffused until the maximum gradient was recorded by the optical system, a photograph was taken to determine σ_0 and the electric field applied. In the experiment shown in Fig. 2 one boundary was sharpened and the electric field applied immediately. The vertical arrows indicate the reversal time and the end of the experiment. The fact that the apparent diffusion constant at the end of the experiment is in agreement with the diffusion constant obtained from free diffusion (3.1×10^{-7} cm.^{2} sec.$^{-1}$, Fig. 1) is evidence that thermal and electroosmotic effects of the current did not disturb the boundaries appreciably. This is in agreement with the observation of Longsworth[24] that the correct diffusion constant for a raffinose boundary in 0.1 *N* lithium chloride was obtained in an electric field provided the power dissipation was not too great and is contrary to the conclusion of Janssen[25] that boundaries of non-electrolytes spread more rapidly in an electric field than expected from diffusion alone. A small amount of reversible spreading is evident in the case of bovine albumin, and although this amount of electrical spreading is not much greater than the experimental error, the electrical heterogeneity of bovine serum albumin at its isoelectric point has been confirmed by spreading experiments at 0.01 ionic strength where higher field strengths may be used.[26]

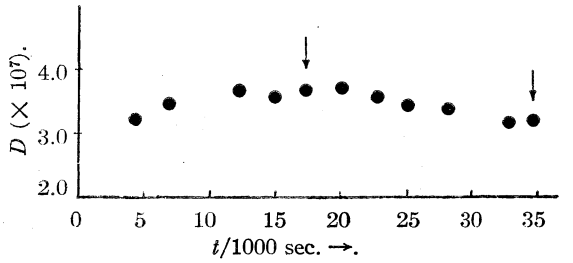

Fig. 2.—Electrophoretic spreading experiment with crystallized bovine albumin at $\Gamma/2 = 0.10$, *p*H 4.61 at 1.59 volts/cm. and 0.0135 watt/cc. using a sharpened boundary. The apparent diffusion constants were calculated by the inflection point method.

Human γ_2-Globulin.—Human γ_2-globulin[27] was studied by electrophoresis spreading experiments at several ionic strengths. The sample of protein used contained less than 2% of γ_1- and β-globulins and albumin as judged by electrophoresis at *p*H 8.6, $\Gamma/2 = 0.10$. Some of the refractive index gradient curves obtained during the electrophoresis of human γ_2-globulin at its average isoelectric point at 0.10 ionic strength are given in Fig. 3. The experimental refractive index gradient curves in solid lines are plotted with their bisecting ordinates located at the time at which the photograph was taken. The superimposed dashed curves give the patterns which would have been obtained if the spreading had been caused by diffusion alone (calculated using $D_0^0 = 2.0 \times 10^{-7}$). Note that after the direction of the electric field was reversed at 300 minutes, the experimental gradient curves became sharper and that after the electric field had been applied for equal times in the two directions, the experimental gradient was just that expected from diffusion alone. Figure 4 shows a comparison of a refractive index gradient curve obtained in the electrophoresis of human γ_2-globulin with the Gaussian probability curve in normal coördinates.[28] This gradient is nearly enough Gaussian

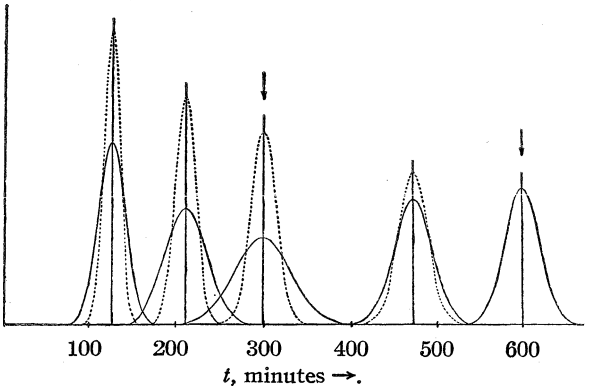

Fig. 3.—Refractive index gradient curves (solid lines) from the electrophoresis of human γ_2-globulin at $\Gamma/2 = 0.1$, *p*H 7.27, at 1.70 volts/cm. and 0.0131 watt/cc. using a sharpened boundary. The superimposed dashed curves give the patterns which would have been obtained if the spreading had been caused by diffusion alone. The field was reversed after 300 minutes.

(23) The crystallized bovine albumin was from Lot 46 prepared by Armour Laboratories, Chicago, Illinois. Electrophoresis experiments in *p*H 8.6, 0.1 ionic strength diethyl barbiturate buffer indicate no appreciable content of globulin impurities, while immunological tests carried out as described by Cohn, Hughes and Weare, THIS JOURNAL, **69**, 1755 (1947), indicate that less than 0.01% α-globulin is present. Thus the immunological tests would indicate that any impurity could not be the same protein as that which constitutes most of the alpha globulin component of plasma. They do not eliminate the possibility that another protein component similar to albumin in its antigenic behavior may be present. Private communication from Dr. J. B. Lesh.

that the mobility distribution may be represented by the error function. Figure 5, which shows the variation in apparent diffusion constant during the sharpened electrophoresis experiments represented in Fig. 3, indicates that D^* plots as a straight line *vs.* t_E during the period before the current was reversed as predicted by equation (6) for a Gaussian distribution of mobilities. The apparent diffusion constants calculated by the height and area method were somewhat higher than those calculated by the inflection point method in the case of the gradients spread both by diffusion and electrical heterogeneity, as would be expected because of the deviation of the gradients from perfect Gaussian form (Fig. 4). Since the apparent diffusion constant calculated from the half width at the inflection point is less affected by the resolution of small amounts of γ_1- and β-globulin from the main peak, the heterogeneity constant was calculated from the slope of the straight line through these points. The initial straight line extrapolates back to the diffusion constant for γ_2-globulin at zero time, and the heterogeneity constant, h, calculated from the slope is 0.52×10^{-5} cm.^{2} volt^{-1} sec.$^{-1}$. When the direction of the current was reversed for an equal period of time, the correct diffusion constant was obtained, and this indicates that irreversible spreading caused by thermal convection and electroosmosis were negligible in this experiment. The values expected for the apparent diffusion constant during the reversal period were calculated using equation (8) and $h = 0.52 \times 10^{-5}$. The calculated values are represented by the solid curve in Fig. 5, and the agreement with the experimental points is further evidence that the electrical heterogeneity of human γ_2-globulin may be represented by a Gaussian mobility distribution.

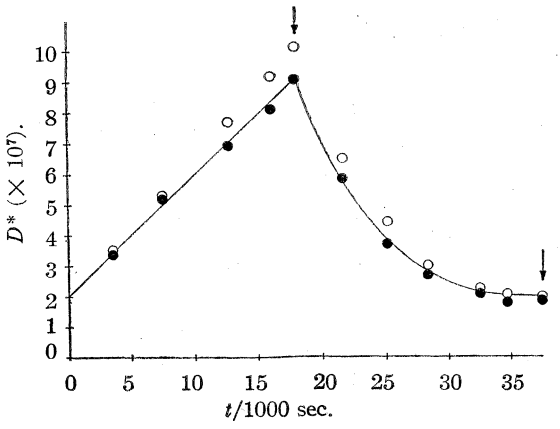

Fig. 5.—Plot of apparent diffusion constant *vs.* time of electrophoresis for the electrophoresis experiment with human γ_2-globulin given in Fig. 3: ●, calculated from half width at inflection point; ○, calculated from height and area.

The heterogeneity constant, H, of Sharp, *et al.*,[13] calculated from the data of this experiment using equation (2) has been plotted against time in Fig. 6. As expected H drifts downward because diffusion is not negligible, and H approaches the value of the heterogeneity constant, h, calculated from Fig. 5, asymptotically. In Fig. 6 the solid curve through the experimental points has been calculated from equation (7) using $h = 0.52 \times 10^{-5}$, $D = 2.0 \times 10^{-7}$, and adequately represents the experimental points.

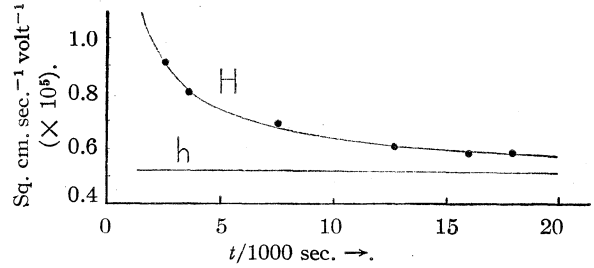

Fig. 6.—Plot of H *vs.* time of electrophoresis for human γ_2-globulin during the initial period of the experiment given in Fig. 3.

In order to study the variation of h for human γ_2-globulin with ionic strength, electrophoresis spreading experiments were also performed at 0.15 and 0.010 ionic strengths close to the isoelectric points under these conditions. The data on these experiments are given in Table I, and the

[a] V = diethyl barbiturate, Cac = cacodylate. [b] The heterogeneity constant (in cm.^{2} sec.$^{-1}$ volt^{-1}) obtained on the ascending side is placed below that obtained on the descending side.

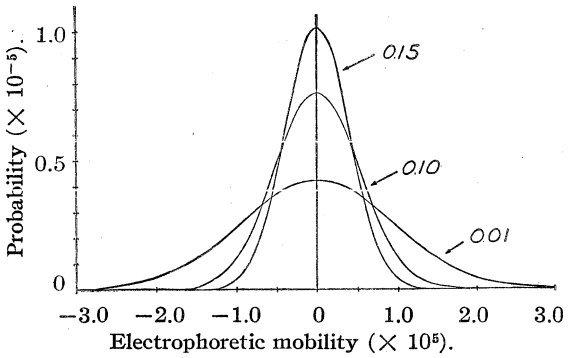

Fig. 7.—Mobility distributions for human γ_2-globulin at several ionic strengths.

mobility distributions are plotted in Fig. 7. The agreement between the heterogeneity constants obtained on the ascending and descending sides is evidence that electrical sharpening and spreading effects are of negligible importance. However, it should be pointed out that agreement between the heterogeneity constants determined from ascending and descending boundaries is not sufficient evidence that sharpening and spreading caused by conductivity and *p*H gradients is negligible in the case of a heterogeneous protein at a *p*H away from the isoelectric point. For example, in the case of human γ_2-globulin at *p*H 8.6, $\Gamma/2 = 0.10$, veronal buffer, the ascending peak has very nearly the same shape as the descending peak,[29] in spite of the tendency to sharpen on the ascending side because of the conductivity effect. This is probably not a result of the *p*H effect or a reversal of the conductivity effect because $(1/u)(du/dp\mathrm{H})$ and u are quite small.[4] The ascending boundary is more diffuse than expected from a superposition of the conductivity effect and diffusion in this case probably because the protein boundary velocity is greater on the ascending side, and this causes the actual separation of two molecules of different mobility in the heterogeneous protein to be greater on the ascending side after a given time than on the descending. Consequently too great a value for the heterogeneity constant would be obtained from both boundaries. In the experiments described here, the mobilities of the center of the boundaries were very low (less than 0.3×10^{-5} cm.^{2} sec.$^{-1}$ volt^{-1} uncorrected for electrode volume changes), and the difference in mobility on the ascending and descending sides was no larger than the usual experimental error.

Discussion

Variation of Heterogeneity with Ionic Strength.—The variation in mobility heterogeneity with ionic strength is a combination of a number of factors. In the case of human γ_2-globulin some euglobulin is not soluble at the average isoelectric point at 0.01 ionic strength so that the protein studied at this ionic strength is not identical with that studied at 0.10 and 0.15 ionic strength. The valence of a protein molecule a given number of *p*H units away from the isoelectric point generally decreases with decreasing ionic strength.[30] However, in spite of this decrease in valence, the electrophoretic mobility a given number of *p*H units from the isoelectric point generally increases with decreasing ionic strength[31] because of the decrease in the screening effect of the ionic atmosphere[32] and the modification of the viscous flow of solvent past the moving particle.[33] Assuming to a first approximation that the γ_2-globulin molecule may be represented by a sphere of 55 Å. radius (calculated from $D_0^0 = 2.0 \times 10^{-7}$), the effect of ionic strength on mobility may be estimated from electrophoretic theory.[31,33,34] The mobility resulting from a given net charge should be proportional to $\phi(\kappa a)/(1 + \kappa a)$ where κ is the reciprocal of the "thickness" of the ion atmosphere, a is the radius of the protein molecule, and $\phi(\kappa a)$ is Henry's function. Assuming that the net charge distribution in γ_2-globulin at the isoelectric point is independent of ionic strength, the standard deviation of the mobility heterogeneity should be proportional to $\phi(\kappa a)/(1 + \kappa a)$. Since the values of this function at 0.01, 0.10, and 0.15 ionic strengths at 0° are 0.379, 0.178, and 0.153, the heterogeneity constants expected at 0.01, 0.10, and 0.15 ionic strength are 1.11×10^{-5}, (0.52×10^{-5} assumed) and 0.45×10^{-5}. Although this is not an exact calculation it is seen that the direction and magnitude of the variation in h observed experimentally (Table I) is in agreement with that expected from electrophoretic theory.

Northrop[35] and Rothen[36] have concluded that the reversible electrophoresis spreading shown by crystalline diphtheria antitoxin of constant solubility can not be attributed to a heterogeneous preparation but is connected with electroösmosis because the spreading was diminished by the addition of calcium chloride to their buffer to a concentration of 0.05 *M*. In order to test for this possibility with human γ_2-globulin, a similar experiment was performed. It was not found possible to prepare the 0.067 *M*, *p*H 7.2, veronal buffer mentioned by Rothen because of the insolubility of the diethylbarbituric acid at this *p*H and 1°, and so the experiment was performed by using the 0.01 ionic strength veronal buffer indicated in Table I. Some of the buffer used for the spreading experiment at 0.01 ionic strength was made 0.05 *M* in calcium chloride by the addition of solid calcium chloride. Although a smaller potential gra-

dient had to be used in the case of the buffer containing calcium chloride, reversible spreading was observed, and the slope of the graph of D^* *vs.* time of electrophoresis yielded a heterogeneity constant of 0.42×10^{-5} (average of two limbs). Although this value for the heterogeneity constant is smaller than that obtained in the 0.01 ionic strength buffer ($h = 0.93 \times 10^{-5}$) before the addition of calcium chloride, it is about what should be expected at the higher ionic strength of the calcium chloride buffer ($\Gamma/2 = 0.16$) for reasons outlined in the preceding paragraph. The heterogeneity constant obtained with the calcium chloride buffer is in good agreement with that obtained at 0.15 ionic strength (0.02 *N* NaCac, 0.13 *N* NaCl) and does not indicate that the reversible spreading of human γ_2-globulin is caused by electroosmosis.

Sensitivity.—Spreading experiments at lower ionic strengths are a more sensitive test of electrophoretic homogeneity because higher electric field strengths may be employed without causing thermal convection and the standard deviation of the mobility distribution of a heterogeneous protein is greater at lower ionic strengths as illustrated in Fig. 7. As electrophoresis spreading experiments are carried out at present, the smallest heterogeneity constant which may be determined is limited by the conductivity of the buffer and the sensitivity of the schlieren optical system. Assuming an increase of 1×10^{-7} in the apparent diffusion constant during five hours electrophoresis is the minimum increase which may be measured and 0.015 watt/cc. is the maximum permissible heat dissipation in an electrophoresis cell of 0.77 cm.^{2} cross section, the smallest heterogeneity constant which could be determined in a buffer of 50×10^{-4} ohm^{-1} cm.$^{-1}$ conductivity at 0° is 0.2×10^{-5} while in a buffer of 1×10^{-4} ohm^{-1} cm.$^{-1}$ conductivity, 0.03×10^{-5} would be detected.

Interpretation.—Several of the possible interpretations of the reversible electrophoresis spreading of γ_2-globulin may be eliminated. Since this protein is apparently homogeneous with respect to sedimentation and diffusion, the variation in mobility cannot be attributed to a difference in the frictional coefficients of the molecules. Also the spreading cannot be attributed to the existence of different charged forms of identical protein molecules which are in equilibrium in a solution of given *p*H and ionic strength because any individual molecule in the system is constantly giving up and taking on protons, so that the time average of its net charge, considered over an appreciable time interval in which many proton exchanges take place, is identical with the mean net charge of all the molecules in the system.[37] Therefore, on the basis of electrophoresis spreading experiments it may be concluded that human γ_2-globulin consists of a mixture of molecules differing with respect to their average net charge.

The actual variation in net charge among the molecules in human γ_2-globulin as indicated by reversible electrophoresis spreading is not large. Calculation of the proportionality constant between valence of the protein ion and electrophoretic mobility by the method of Abramson, Moyer and Gorin[38] at 0.10 ionic strength (assuming a cylindrical molecule with an axial ratio of 7 and a molecular weight of 160,000) indicates that a molecule with a mobility equal to the standard deviation of the mobility distribution (0.52×10^{-5}cm.^{2} sec.$^{-1}$ volt^{-1}) has a net charge of approximately 3 electrons. This variation in net charge among the molecules would indicate a small variation in their contents of the ionizable amino acids, a variation in arrangement resulting in different end groups or perhaps only a variation in steric effects of groups neighboring ionizable amino acids residues which affects the dissociation constants. Human γ_2-globulin prepared from plasma pools contains antibodies to many different antigens,[39] and therefore according to present theories of antibody structure the molecules have a variety of different configurations. It might be expected therefore, that the molecules would not be identical with respect to net charge at a given *p*H and ionic strength even if they were identical with respect to amino acid composition.

Acknowledgments.—The author wishes to express his appreciation to Dr. J. W. Williams for his interest and helpful suggestions. He is also indebted to Dr. J. O. Hirschfelder for helpful suggestions, to Mr. E. A. Anderson for assistance in the laboratory, and to Dr. G. Kegeles for his review of the manuscript. Financial support which was received from the National Institute of Health is gratefully acknowledged.

Summary

1. A method for the determination of the electrophoretic mobility distribution in a heterogeneous protein having a Gaussian distribution of mobilities has been developed for the case in which diffusion during the electrophoresis experiment is not negligible. In this case the apparent diffusion constant is a linear function of time of electrophoresis and the heterogeneity constant, *h*, which is the standard deviation of the mobility distribution, may be calculated from the slope.

2. It has been shown that electrophoresis spreading experiments may be carried out under conditions such that spreading caused by the conductivity and *p*H effects, thermal convection, and electroösmosis are negligible.

3. Crystallized bovine serum albumin has been found to show a small amount of reversible spreading at its isoelectric point at 0.10 ionic

strength. Human γ_2-globulin shows a large amount of reversible spreading and the standard deviation for the mobility distribution has been found to vary with ionic strength in the direction expected from electrolytic solution theory.

Photochemistry of Tryptophan, *p*-Dimethylaminobenzaldehyde and Reaction Products in Sulfuric Acid Solution[1]

BY JOSEPH R. SPIES AND DORRIS C. CHAMBERS

During a previously reported study[2] of the color-forming reactions between tryptophan, *p*-dimethylaminobenzaldehyde (DAB) and sodium nitrite in sulfuric acid solution, it became necessary to study the effects of light on the reactants and reactions involved. This paper describes a method for studying the effects of illumination (the term "illumination" refers to exposure to light by a procedure described below), the effect of light on the stability of tryptophan, the effects of light on reactions I and II,[3] and a photochemical "after effect" produced by illumination of DAB in acid solution. The reactions were carried out in 19 *N* sulfuric acid because this concentration was found suitable for the determination of tryptophan in proteins by a procedure to be described in later papers.

Photochemical development of color from the colorless condensation product of tryptophan and DAB was first reported by Boyd[4] who attributed this effect to the ultraviolet rays of sunlight.[5]

The effect of illumination on the stability of tryptophan in 19 *N* acid at 25° is shown in Table I. Light accelerates the decomposition of tryptophan as losses of 3, 11 and 34% occurred on illumination for one-half, one and three hours, respectively, compared with a loss of only 8% on standing in the dark for forty-eight hours.

The effects of illumination during reaction I under conditions such that reactions I and II were proceeding simultaneously are shown in Table II. Illumination for the first ten seconds of reaction I caused no increase in pre-nitrite color[6] nor any loss of tryptophan. But illumination for thirty seconds caused an increase in pre-nitrite color and destruction of 6% of the tryptophan. The pre-nitrite color increased with time of illumination until after 180 minutes it amounted to 76% of the total. The loss of tryptophan, caused by illumination, increased to 25% of the total during the first five minutes of reaction I and then remained constant. Reaction I is 87% completed in five minutes (Table VI).[2] Therefore the destructive effects of illumination occur chiefly during the condensation of tryptophan and DAB.

TABLE I

EFFECT OF LIGHT ON THE STABILITY OF FREE TRYPTOPHAN IN 19 *N* SULFURIC ACID AT 25°[a]

[a] Procedure: nine ml. of 21.4 *N* acid at 25° was placed in tube A, Fig. 2, and 100 γ of tryptophan in 1.0 ml. of water was added. The solution was mixed and tube A was placed at once in holder B through which water at 25 ± 0.1° was circulating. Illumination was started twenty seconds after adding the tryptophan to the acid solution. After the desired interval of illumination the solution was poured onto 30 mg. of DAB in a 25-ml. glass-stoppered Erlenmeyer flask. Tryptophan was then determined by procedure C, Paper I.[2] [b] Results taken from Table VII, Paper I[2].

Rate of reaction II caused photochemically is rapid at first and then becomes quite slow as 70, 88 and 93% of the color was developed by five, twenty, and 120 minutes illumination, respectively.[7] After five minutes of illumination only 94% of the potentially available color could be obtained by subsequent oxidation with sodium nitrite. This destructive effect, however, was not progres-

(1) Paper II in a series entitled, "Chemical Determination of Tryptophan." Presented at the 111th meeting of the American Chemical Society held at Atlantic City, New Jersey, April, 1947. Not subject to copyright.

(2) Spies and Chambers, *Anal. Chem.*, **20**, 30 (1948).

(3) The condensation of tryptophan and DAB to form the leuco base is called reaction I and the oxidative development of the blue color, either photochemically or with sodium nitrite, is designated reaction II.

(4) Boyd, *Biochem. J.*, **23**, 78 (1929).

(5) Ruemele, *Z. Untersuch. Lebensm.*, **79**, 453 (1940), observed that light effected the formaldehyde–tryptophan colorimetric reaction but no detailed study was made.

(6) The term pre-nitrite color will refer to that color which develops in a test solution either spontaneously or as a result of exposure to light. The term post-nitrite color refers to that color which develops in a test solution after addition of sodium nitrite.

(7) Procedure: To 1.607 mg. of tryptophan and 482 mg. of DAB in a glass-stoppered Erlenmeyer flask was added 160.7 ml. of 19 *N* acid. The solution was kept in the dark at 25° for twenty-two hours. After illumination of 10 ml. aliquots of this solution pre-nitrite transmittancies were read and expressed as per cent. of the maximum color obtainable under ideal conditions of the test (procedure E, Paper I[2]).

TABLE II

EFFECT OF ILLUMINATION ON REACTION I[a]

Time illuminated	% Total color formed[b] Pre-nitrite	Post-nitrite	Loss
0	13	100	0
1 sec.	15	100	0
10 sec.	13	100	0
30 sec.	19	94	6
1 min.	29	89	11
5 min.	65	75	25
15 min.	68	72	28
30 min.	70	72	28
1 hr.	72	75	25
3 hr.	76	76	24

[a] Procedure: Eight ml. of 23.8 *N* acid and 1.0 ml. of 2 *N* acid containing 30 mg. of DAB were mixed and cooled to 25°. To this solution was added 100 γ of tryptophan in 1.0 ml. of water. Immediately after mixing, the solution was placed in tube A, Fig. 2, which was then placed in B, Fig. 2, through which water at 25 ± 0.1° was circulating. Illumination was started twenty seconds after adding the tryptophan. After the desired interval of illumination the solution was poured into a 25-ml. glass-stoppered Erlenmeyer flask which was stored in the dark at 25° for twenty to twenty-four hours. Pre-nitrite transmittancies were then read. Color was then developed by adding 0.1 ml. of 0.04% sodium nitrite solution. Post-nitrite transmittancies were read after the solutions had stood for thirty minutes in the dark. [b] Transmittancies were converted to weight of tryptophan then expressed as the per cent. of the maximum color obtainable with an equal quantity of tryptophan under ideal conditions of the test.[2]

sive because whether the illumination was for five or 120 minutes the same amount of color could subsequently be obtained with sodium nitrite.

Illumination of test solutions, in which the color had already been fully developed with sodium nitrite, for ninety minutes caused no loss in color intensity thus showing the stability of the blue colored substance to light.

The color formed photochemically has an absorption curve similar to that formed by sodium nitrite as shown in Fig. 1. The wave length of maximum density was 590 to 600 mu in both curves B and G and a characteristic absorption peak occurred at 425 mu.

Illumination of DAB in 21.4 *N* acid before the addition of tryptophan to the test solution produced considerable pre-nitrite color as "after effect."[8] The effect of time of illumination on the intensity of the pre-nitrite and post-nitrite colors is shown in Table III. The pre-nitrite colors of all non-illuminated control solutions of DAB represented from 2.5 to 4.5% of the total color. But when DAB was illuminated for five seconds, one, five, fifteen and sixty minutes, prior to addition of the tryptophan, the pre-nitrite color represented 5.1, 20, 45, 55 and 58% of the total color, respectively. Losses of tryptophan from 1.5 to 5.4%

(8) The photochemical "after effect" is discussed in some detail by Kistiakowsky, "Photochemical Processes," The Chemical Catalog Co., Inc., New York, N. Y., 1928, and Dhar, "The Chemical Action of Light," Blackie and Son, Limited, London and Glasgow, 1931. In general, this term refers to those photochemical reactions which occur after cessation of illumination.

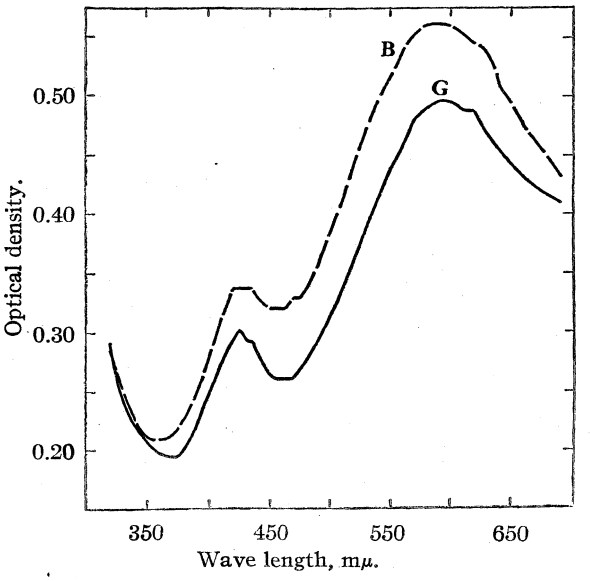

Fig. 1.—Absorption curves of tryptophan-DAB color developed with sodium nitrite (Curve B, taken from Fig. 1, Paper I) and light (Curve G, illuminated for 20 minutes). 100 γ of tryptophan was used for each test. Transmittancies were determined with a Beckman spectrophotometer with 10-mm. cuvettes.

TABLE III

EFFECT OF TIME OF ILLUMINATION ON THE PHOTOCHEMICAL AFTER EFFECT OF DAB IN 21.4 *N* ACID AT 25°[a]

Time illuminated	% Total color formed[b] Pre-nitrite Illuminated	Pre-nitrite Control	Post-nitrite Illuminated	Post-nitrite Control	Loss by illuminated
5 sec.	5.1	4.5	98.5	100	1.5
1 min.	20	3.2	96.8	100	3.2
5 min.	45	3.2	96.4	100	3.6
15 min.	55	2.5	94.6	100	5.4
60 min.	58	3.2	94.6	100	5.4

[a] Procedure for all tests was standardized so that the only variable was the interval of illumination. For each illumination test a control test was run in the same way except that the test was kept in the dark for a period of time equal to the illumination interval of the corresponding test. Following is an example of the test illuminated for five minutes and the control. Thirty mg. of DAB, in Tube A, was dissolved in 9.0 ml. of 21.4 *N* acid, and Tube A was placed in B through which water at 25 ± 0.1° was circulating. Two minutes after adding the acid the tube was illuminated for five minutes. Tube A was left in B for one minute after stopping the illumination and then 100 γ of tryptophan in 1.0 ml. of water was added to the test. The solution was mixed and poured into a 25-ml. glass-stoppered Erlenmeyer flask. The solution was cooled in the water-bath at 25° for two minutes and then placed in a dark chamber at 25° for four hours. Pre-nitrite transmittancy was then read using a control containing 30 mg. of DAB in 10 ml. of 19 *N* acid. To the solution was added 0.1 ml. of 0.04% sodium nitrite. Post-nitrite transmittancy was read after the test had stood thirty minutes in the dark. The control test was similar except that the solution was allowed to stand in Tube A in B in the dark for eight minutes before adding the tryptophan solution. [b] Transmittancy readings were converted to micrograms of tryptophan and then expressed as the per cent. of the maximum color obtainable with an equal quantity of tryptophan under ideal conditions of the test.[2]

resulted from using illuminated DAB solutions. These losses are attributed to the oxidative action of illuminated DAB on tryptophan before completion of reaction I a time when tryptophan is very sensitive to oxidative destruction as previously shown.

The rate of pre-nitrite development of color which resulted when tryptophan was added to previously illuminated solutions of DAB in 21.4 *N* acid is shown in Table IV. The pre-nitrite color of control tests ranged from 2.4 to 13% in four to seventy-one hours while the pre-nitrite color in tests in which DAB had been illuminated increased from 19% in fifteen minutes to a maximum of 71% in forty-seven hours. Eight to 10% of the tryptophan originally present was destroyed by the illuminated DAB solutions.

TABLE IV

RATE OF COLOR DEVELOPMENT RESULTING FROM PHOTOCHEMICAL AFTER EFFECT CAUSED BY ILLUMINATION OF DAB IN 21.4 *N* ACID AT 25°[a]

Time after addition of tryptophan to reading of pre-nitrite transmittancy, hours	% Total color formed[b] Pre-nitrite Illuminated	Pre-nitrite Control	Post-nitrite Illuminated	Post-nitrite Control	Loss by illumination, %

24	71	6.6	92	100	8
47	71	11			
71	69	13	86	96	10

[a] Procedure for all tests was standardized so that the only variable was the interval between addition of the tryptophan to the illuminated solution of DAB and reading the pre-nitrite transmittancy. For illumination experiments in which the time was four, twenty-four, forty-seven and seventy-one hours control tests were run in the same way except that illumination of DAB was omitted. Following is an example of the twenty-four-hour test: 30 mg. of DAB was placed in Tube A, Fig. 2, and dissolved in 9.0 ml. of 21.4 *N* acid. Tube A was then placed in B at 25° for two minutes. The solution was then illuminated for fifteen minutes and after standing one minute more 100 γ of tryptophan in 1.0 ml. of water was added. The solution was mixed and poured into a 25-ml. glass-stoppered Erlenmeyer flask which was then cooled in the water-bath at 25° for two minutes. The flask was placed in a dark chamber at 25° for twenty-four hours. Pre-nitrite transmittancy was then read. A blank solution containing 10 ml. of 19 *N* acid was used for all tests. To the solution was then added 0.1 ml. of 0.04% sodium nitrite solution and after standing in the dark for thirty minutes post-nitrite transmittancy was determined. [b] Transmittancy readings were converted to micrograms of tryptophan and then expressed as the per cent. of the maximum color obtainable with an equal quantity of tryptophan under ideal conditions of the test.[2]

In another series of experiments it was shown that pre-nitrite color of the same intensity was obtained whether the tryptophan was added five seconds or twenty hours after stopping the illumination of DAB. Therefore, once a solution of DAB has been exposed to light it appears to retain its oxidative capacity indefinitely.

Discussion

The mechanism of the photochemical development of color from the tryptophan–DAB condensation product probably involves oxidation by dissolved oxygen through the medium of DAB in the role of oxygen acceptor. The primary process is probably the formation of the peracid of DAB which then oxidizes the tryptophan–DAB complex to form the blue-colored compound. Cole[9] noted that color slowly developed without addition of an oxidizing agent when an acid solution of benzaldehyde and tryptophan stood a few days. Cole did not mention the possible effect of light in this reaction but believed that oxidation resulted from benzoyl peroxide formed by atmospheric oxygen. Bäckström,[10] who studied the photochemical oxidation of benzaldehyde and heptanal, postulated a chain mechanism for the photochemical formation of the peracids because the quantum yield was very large. According to Bäckström the quantum yield of benzoic acid was nearly constant in the region of 2536 to 3660 Å. Boyd[4] believed the photochemical effect observed by him was caused by ultraviolet light. The present experiments indicate that photochemical oxidation is caused by visible light, because most of the ultraviolet light would have been absorbed by the double thickness of Pyrex glass in the illumination apparatus shown in Fig. 2. Furthermore, when a test solution in a quartz flask was exposed to the radiations of a mercury vapor ultraviolet light, with visible light filter, no marked photochemical development of color occurred. It is recognized, however, that the destructive effects of illumination may have been caused by low-intensity ultraviolet light which may pass through Pyrex glass and water.

Whether DAB was illuminated fifteen or sixty minutes, the photochemical after effect, in four hours, produced pre-nitrite color equivalent to 55 to 58% of the total potentially available color. This proportion of the color was probably not determined by the availability of dissolved oxygen because in a test in which oxygen was bubbled into the solution during the fifteen minute illumination period the same amount of pre-nitrite color developed as when illumination was conducted in a closed tube. These results suggested the possibility that the after effect might be caused by a trace of contaminant in the DAB which was the limiting factor in determination of the magnitude of the after effect. To test this hypothesis, tests containing 10, 30, 60 and 100 mg. of DAB per test were illuminated fifteen minutes each and the after effect produced in twenty-four hours was determined. Pre-nitrite colors representing 58, 72, 72 and 72% of the total, respectively, were obtained. If the after effect were dependent on a contaminant in the DAB the proportion of pre-ni-

(9) Cole, *J. Physiol.*, **30**, 311 (1903–1904).

(10) Bäckström's work has been discussed in detail by Kistiakowsky and Dhar, ref. 8.

trite color should have increased in proportion to the quantity of DAB used per test. This did not occur. Therefore it was concluded that the after effect was caused by DAB and not by a contaminant.

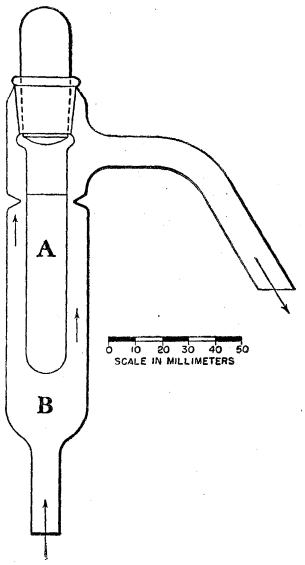
Illumination during the first five minutes of reaction I caused a loss of 25% of the tryptophan, but illumination of free tryptophan for thirty minutes and illumination of the final condensation product of tryptophan and DAB for 120 minutes caused only 3 and 6% losses, respectively. These observations indicate that an intermediate compound in the condensation of tryptophan and DAB is more susceptible to destruction by light than is either free tryptophan or the condensation product. The importance of protecting test solutions in analytical procedures from light particularly during the first five minutes of reaction I is therefore obvious. It is also important to protect acid solutions of DAB from light because loss of as much as 10% of the tryptophan may result from using illuminated DAB solutions.

Experimental

General procedure, apparatus and materials used in this study have been described in detail in a previous paper.[2] Transmittancies were determined with a Coleman spectrophotometer, Model 11, excepting the curves in Fig. 1 which were obtained with a Beckman quartz spectrophotometer. New procedures or variations from procedures previously described[2] are given in footnotes in the tables.

Reagent grade sulfuric acid was distilled using all glass joints. The first 8% of the distillate was discarded and a fraction representing about 85% boiling at 327 to 332° (uncor.) was collected in a receiver closed with a calcium chloride tube. This acid was used to prepare the sulfuric acid solutions used for experiments described in Tables III and IV as well as for some of the other tests.

Light Source and Illumination Procedure.—The light source was a 115-volt, No. 2 Photoflood, Mazda lamp made by General Electric Co. Lamps were mounted in a nine-inch aluminum coated reflector. The procedure for illumination was standardized as follows. The solution to be illuminated was placed in Tube A, Fig. 2. Tube A was placed in the glass holder B through which water at 25 + 0.1° was circulated at a rate of 5 liters per minute. Under these conditions the rise in temperature of the solution in Tube A was no more than 0.1 to 0.2° regardless of the length of time of illumination. The solution was illuminated with the outer tip of the light bulb 9 inches from the center of B so that the rays of light fell perpendicularly on the side of Tube A. The intensity of Photoflood lamps gradually declines with use. To minimize this effect fresh lights were used for short periods and used bulbs for longer periods of illumination.



Water at 25 ± 0.1°.

Fig. 2.—Illumination apparatus.

Summary

The photochemistry of tryptophan, *p*-dimethylaminobenzaldehyde and their reaction products in sulfuric acid has been studied. Evidence indicates that an intermediate compound formed in the condensation of tryptophan and *p*-dimethylaminobenzaldehyde is more susceptible to destruction by light than is either free tryptophan or the final condensation product. The photochemical development of color is caused by a visible portion of the spectrum and not by ultraviolet light. Previously illuminated acid solutions of *p*-dimethylaminobenzaldehyde cause the development of color and also some destruction of tryptophan as after effect when tryptophan is subsequently added to such solutions. Probable mechanism of the photochemical reactions is discussed.

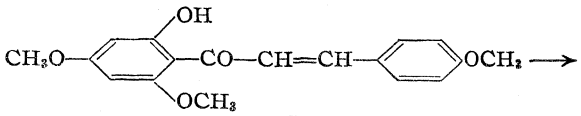
Flavonones and Related Compounds. V. The Oxidation of 2'-Hydroxychalcones with Alkaline Hydrogen Peroxide

BY T. A. GEISSMAN AND DAVID K. FUKUSHIMA

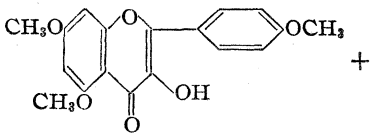
The oxidation by means of alkaline hydrogen peroxide of 2'-hydroxychalcones (and the corresponding flavanones) to 3-hydroxyflavones was first described by Algar and Flynn[1] and Oyamada,[2] and later studied in more detail by Murakami and Irie[3] and by Reichel and Steudel.[4] The results of these studies led to the conclusion[1,4] that the reaction was a general one, and could be applied to 2'-hydroxychalcones having methoxyl groups in a variety of positions in the two aromatic nuclei.

This method was chosen for the preparation of a sample of kampferol (3,4',5,7-tetrahydroxyflavone) which was required for comparison with some of this material isolated from carnation flower petals in the course of studies on the inheritance of color variation in this species.[5,6]

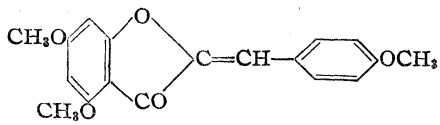
The oxidation of 2'-hydroxy-4',6',4-trimethoxychalcone (I) with alkaline hydrogen peroxide did yield a small amount of the desired flavonol (II), but the predominant product of the reaction was 4',4,6-trimethoxybenzalcoumaranone (III)



I



II



III

The formation of benzalcoumaranones in this reaction has not been encountered in previous studies,[1-4,7] and it is significant to note that in none of the earlier work were chalcones used which were derivatives of 2,4,6-trihydroxyacetophenone. Oxidation to the flavonol has been the only course observed when the chalcone is the benzal, anisal, veratral or piperonal derivative of 2-hydroxy-, 2-hydroxy-4-methoxy-, 2-hydroxy-3,4-dimethoxy-, or 2-hydroxy-3,4,5-trimethoxyacetophenone.[7]

It appeared likely that the presence of the 6'-methoxy group in I was responsible for the unexpected course of its reaction with alkaline hydrogen peroxide. Further studies showed that 2'-hydroxy-4',6'-dimethoxychalcone (IV), 2'-hydroxy-4',6',3,4-tetramethoxychalcone (V), and 2'-hydroxy-6'-methoxy-3,4-methylenedioxychalcone (VI) yielded the corresponding benzalcoumaranones, a trace of the flavonol (quercetin-3',4',5,7-tetramethyl ether) accompanying the benzalcoumaranone in the case of V only.

These new observations afford a further insight into the course of this reaction, substantiating in part certain of the conclusions of some of the earlier investigators and invalidating others. Oyamada[2] assumed that the reaction proceeded through the flavanone in each case, but the ease with which flavanones are opened in alkali to the salts of the corresponding 2'-hydroxychalcones renders this interpretation difficult to test,[4] and it is probable that the chalcone (as the salt) is the reactive species whether the chalcone or the flavanone is used as the starting material. Algar and Flynn concluded that an ethylene peroxide or a glycol was the intermediate since an oxido intermediate would be expected to lead to a flavone or a benzalcoumaranone.[1] It is apparent that this reasoning is somewhat contradictory, since an oxide and a glycol are at equivalent oxidation levels and at a different level from an ethylene peroxide. Murakami and Irie[3] attempted to show that the first step in the reaction is the formation of the oxido compound but were unable to prepare the latter from 2'-hydroxychalcone. They did succeed in showing that under mild conditions of treatment with alkaline hydrogen peroxide, 3-hydroxyflavanone was formed, and Reichel and Steudel[4] demonstrated that this compound is readily oxidized in alkaline solution to flavonol.

In the course of the present work numerous attempts were made to prepare the oxides of 2'-hydroxy-, 2'-acetoxy- and 2'-benzoyloxychalcone, but these attempts were unsuccessful. In the case of the acyl derivatives the extraordinarily facile removal of the acyl groups was the first reaction that occurred even under mildly alkaline conditions. Baker and Robinson[8] have also attempted without success to prepare 2'-hydroxychalcone oxide.

Reichel and Steudel[4] have offered an electronic interpretation of the reaction, using 2'-hydroxychalcone as the example, in which the successive steps were considered to be the addition of the hydroperoxide ion to the chalcone (ion), the rearrangement of the addition product to yield the

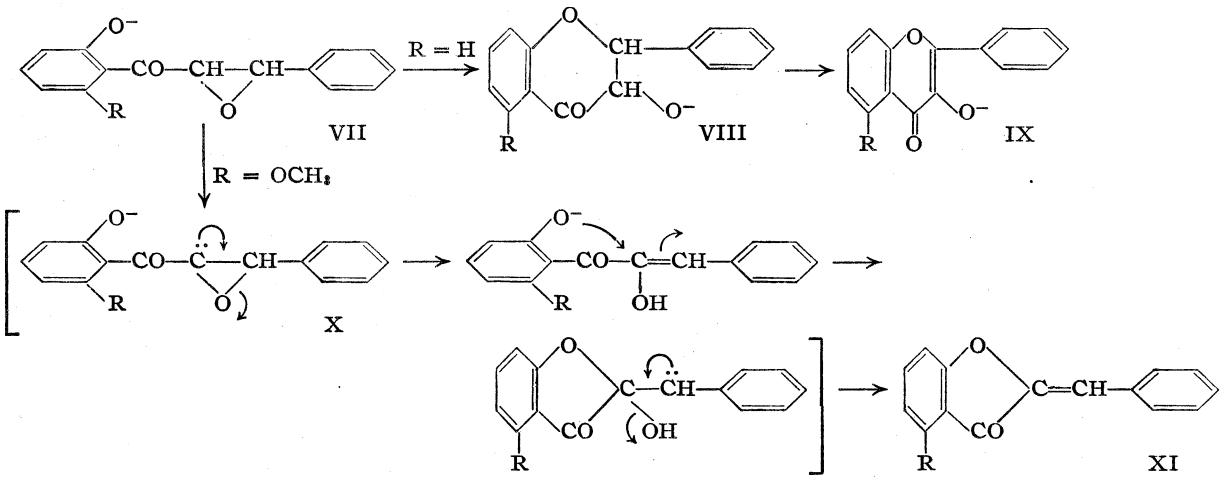
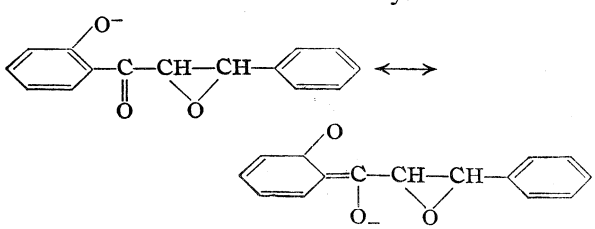
glycol (*o*-hydroxyphenyl-α,β-dihydroxyphenethyl ketone) and the displacement of the β-hydroxy group by the attack of the 2′-, anionic, oxygen atom to close the ring to 3-hydroxyflavanone.

A simpler and more satisfactory picture of the course of the reaction, and one which includes a consideration of the new observations described here, is that the first intermediate is indeed the oxide (VII). This reacts further to yield the flavanone (VIII) probably by a direct nucleophilic attack by the anionic oxygen atom upon the β-carbon atom, followed by oxidation to the flavonol (IX). When a substituent is present in the 6′-position of the chalcone, this course is not (exclusively) followed. It is probable that when R is a group which can offer substantial inhibition to the resonance in the system involving the anionic oxygen atom and the ortho carbonyl group, the result is an increase in the effective acidity of the α-hydrogen atom. Attack of a base upon this hydrogen atom gives rise to X, in which the oxide ring is opened by the attack of the electron pair on the adjacent (α-) carbon atom, leading through the changes formulated below to the benzalcoumaranone (XI)



This mechanism does not exclude the possibility that a mixture of the two possible products will be formed, since it does not suggest, and there is no reason to expect, that when R = OCH_3, the course VII → VIII → IX is excluded. The effect of the 6′-substituent is seen to be one of favoring the course leading to the benzalcoumaranone, since when resonance in VII of the system



is possible the series VII → X → XI would be less likely.

An alternative explanation for the effect of a 6′-substituent in directing ring closure to the benzalcoumaranone is that a direct steric effect favors the formation of a 5-membered rather than a 6-membered ring. Arnold and Rondestvedt[9] have shown that a 6-membered ring offers more steric hindrance to the position ortho to its point of juncture with another ring than does a 5-membered ring. In the present case, the more favorable bond angles in XI would allow less hindrance between R and the carbonyl group peri to it than in the case of IX, and might offer a plausible reason for a faster reaction in the ring closure to the benzalcoumaranone.

Results obtained in related studies indicate, however, that this explanation is not an adequate one. There appears to be a close analogy between the alkaline hydrogen peroxide oxidation of 2′-hydroxychalcones and the ring closure of 2′-hydroxy-α,β-dibromodihydrochalcones with alkali.[10-12] In the latter reaction, too, the number and position of the alkoxyl groups in the two aromatic rings influences the course of the reaction and determines whether a flavone or a benzalcoumaranone is formed. When the original chalcone is derived from 2,4,6-trihydroxyacetophenone, benzalcoumaranone formation is favored; but it is important to note that in this reaction the direction of ring closure is influenced also by the nature of the substituents in the benzal ring, and to some degree by the conditions of the reaction. Consequently, it appears that here simple steric effects are not the most important directing influences. It is with these observations in mind that the suggestion is made that benzalcoumaranone and flavonol formation are the result of two different kinds of attack upon a common intermediate, and that the course of the reaction is determined pri-

marily by the effects of substituents upon the reactivity of the α- and β-carbon atoms in the chalcone derivative.

Experimental[13]

Oxidation of 2'-Hydroxy-4',6',4-trimethoxychalcone.—To an ice-cold solution of 2.06 g. of 2'-hydroxy-4',6',4-trimethoxychalcone in a mixture of 14 ml. of 16% aqueous sodium hydroxide and 40 ml. of methanol was added 5.3 ml. of 15% hydrogen peroxide (analyzed before use). The mixture was kept at 5° overnight and the yellow solid which separated was collected, washed with methanol (A, see below) and recrystallized from acetone. The pure product formed canary yellow needles, m. p. 166.5–167.5°. It gave a deep crimson color with concentrated sulfuric acid, and no color with ferric chloride nor with magnesium–hydrochloric acid in alcoholic solution.

Anal. Calcd. for $C_{18}H_{16}O_6$: C, 69.23; H, 5.12; OCH_3, 29.81. Found: C, 68.99; H, 5.11; OCH_3, 29.42.

The compound showed no depression of melting point when mixed with a sample of 4',4,6-trimethoxybenzalcoumaranone prepared by treatment of 2-hydroxy-4,6-dimethoxyphenyl-α,β-dibromo-β-anisylethyl ketone with alcoholic alkali.

From the methanol washings (A) of the crude benzalcoumaranone was obtained 0.29 of crude, crystalline material which upon repeated recrystallization from methanol yielded 0.05 g. of 5,7,4'-trimethoxyflavonol, m. p. 150–153° (reported,[14] 150–151°). This compound gave in concentrated sulfuric acid a yellow solution with a green fluorescence, and a pink solution when treated with magnesium and concentrated hydrochloric acid in alcoholic solution. Demethylation with hydriodic acid and acetylation of the product yielded kampferol tetraacetate,[14] m. p. 182–184°.

Oxidation of 2'-Hydroxy-4',6',3,4-tetramethoxychalcone.—To a cold solution of 0.70 g. of 2'-hydroxy-4',6',-3,4-tetramethoxychalcone in a mixture of 30 ml. of methanol and 6 ml. of 16% aqueous sodium hydroxide was added 3 ml. of 15% hydrogen peroxide. The yellow solid which separated upon standing overnight at 5° was collected. The crude material melted at about 165° and recrystallization effected only a partial purification. After a short treatment with sodium acetate–acetic anhydride, followed by decomposition of the excess acetic anhydride with ice water and recrystallization of the product from dilute alcohol, afforded tiny, canary-yellow needles of the benzalcoumaranone, m. p. 173–174°, reported[15] 175°). The compound gave the characteristic deep crimson-magenta color in concentrated sulfuric acid.

The alkaline filtrate was diluted with water, acidified and extracted with ether. After washing the ether solution with sodium bicarbonate solution the solvent was removed, yielding 0.12 g. of a crude solid. Crystallization from alcohol yielded 0.07 g. of 5,7,3',4'-tetramethoxyflavonol, m. p. 193–194° (reported,[16] 197–198°). Its alcoholic solution gave a bluish-red coloration with magnesium and hydrochloric acid and a brownish-green color with ferric chloride.

Oxidation of 2'-Hydroxy-4',6'-dimethoxychalcone.—A cold solution of 0.48 g. of 2'-hydroxy-4',6'-dimethoxychalcone, 20 ml. of methanol, 5 ml. of 16% aqueous sodium hydroxide and 2.5 ml. of 15% hydrogen peroxide was kept at 5° overnight. The yellow precipitate weighed 0.30 g., and after recrystallization from alcohol melted at 152–153°. The melting point of 2-benzal-4,6-dimethoxycoumaranone-3 has been reported as 150–151°.[17] With concentrated sulfuric acid the compound gave a deep yellow-orange color.

From the alkaline filtrate was isolated only a small amount of 2-hydroxy-4,6-dimethoxybenzoic acid (neut. equiv. calcd., 198.1; neut. equiv. found, 197.4).

Oxidation of 2'-Hydroxychalcone. Method of Oyamada.—The oxidation of 1.0 g. of 2'-hydroxychalcone was carried out as described by Oyamada.[2] The yield of flavonol was 0.57 g.

Method of Murakami and Irie.—Two grams of 2'-hydroxychalcone, oxidized according to the procedure of Murakami and Irie,[3] yielded 1.0 g. of 3-hydroxyflavanone along with a small amount of flavonol. The flavanone melted at 177–180° (reported,[3] 174–177°).

Anal. Calcd. for $C_{15}H_{12}O_3$: C, 74.97; H, 5.04. Found: C, 74.53; H, 5.03.

Oxidation of 2'-Hydroxy-4'-methoxychalcone.—To a cold suspension of 1.0 g. of 2'-hydroxy-4'-methoxychalcone in 7 ml. of 15% aqueous sodium hydroxide was added 3 ml. of 13% hydrogen peroxide. After standing at 5° overnight, the mixture was filtered, yielding 0.84 g. of the sodium salt of 7-methoxyflavonol. The flavonol was obtained by treatment of the sodium salt with acid; it melted at 174.5–175.5° after recrystallization from alcohol. Kostanecki and Stoppani reported a m. p. of 180° for this compound.[18] It gave a yellow, blue-green fluorescing solution in concentrated sulfuric acid and an olive-green color with ferric chloride.

Anal. Calcd. for $C_{16}H_{12}O_4$: C, 71.39; H, 4.50. Found: C, 71.60; H, 4.47.

It formed a colorless **acetate**, m. p. 176–177°.

Anal. Calcd. for $C_{18}H_{14}O_5$: C, 69.67; H, 4.51. Found: C, 69.25; H, 4.53.

2'-Hydroxy-6'-methoxy-3,4-methylenedioxychalcone

Two grams of 2-hydroxy-6-methoxyacetophenone was moistened with 2 ml. of methanol, and 5 ml. of 60% aqueous potassium hydroxide was added. To the pasty, greenish solid resulting was added 2.0 g. of piperonal, and the mixture shaken vigorously. The mixture grew warm, a deep red-brown color developed and a thick, oily phase separated. After fifteen minutes, during which time the mixture was shaken frequently, enough methanol was added to produce a clear solution (*ca.* 5 ml.) and the solution was poured into iced, dilute hydrochloric acid. The red-orange gum which separated crystallized when ether was added. After recrystallization from chloroform–petroleum ether the product (3.4 g.) formed brilliant orange needles, m. p. 137–138°.

Anal. Calcd. for $C_{17}H_{14}O_5$: C, 68.43; H, 4.70. Found: C, 68.49; H, 5.15.

Oxidation of 2'-Hydroxy-6'-methoxy-3,4-methylenedioxychalcone: 4-Methoxy-3',4'-methylenedioxybenzalcoumaranone.—To a suspension of 1.0 g. of the chalcone in 5 ml. of methanol was added 5 ml. of 20% aqueous sodium hydroxide, followed by 2.0 ml. of 30% hydrogen peroxide. The mixture was shaken; after about fifteen seconds it grew warm and suddenly set almost to a paste with the appearance of a yellow solid. After standing for an hour at 0° the semi-solid mixture was stirred with water and ether, and filtered. The solid weighed 0.50 g. It was not a salt; it gave a brilliant magenta color with concentrated sulfuric acid and no color with magnesium–alcoholic hydrochloric acid. It was soluble in pyridine, chloroform and hot, glacial acetic acid, and crystallized from the latter solvent as small, bright yellow needles, m. p. 222–223.5°, resolidifying upon cooling.

Anal. Calcd. for $C_{17}H_{12}O_5$: C, 68.89; H, 4.09. Found: C, 68.79; H, 4.48.

The alkaline filtrate contained no material having the properties of a flavonol.

Summary

1. The oxidation of 2'-hydroxychalcones with alkaline hydrogen peroxide yields flavonols when the chalcones are unsubstituted in the 6'-position.

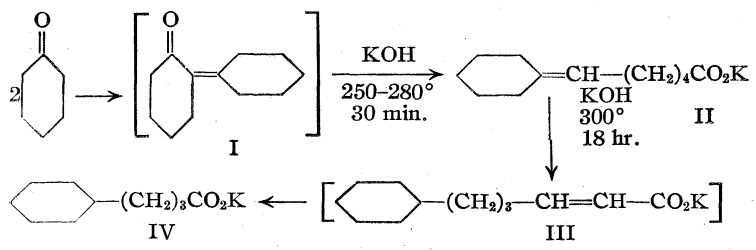
The Action of Alkali on Cyclohexanones

BY THEODORE L. CAIRNS, ROBERT M. JOYCE AND RICHARD S. SCHREIBER

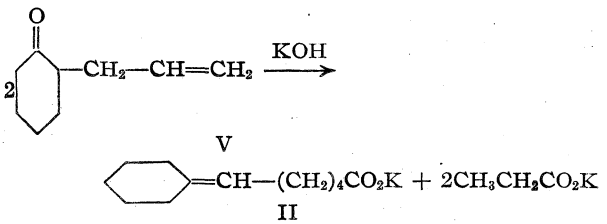
The cleavage of certain ketones by alkali with the formation of acids is well known for aromatic,[1] aralkyl,[2] and activated ketones such as β-keto acids. Relatively little work has been done with simple aliphatic ketones. This paper reports the results of an investigation of the nature of the products formed when cyclohexanone and one of its 2-substituted derivatives are treated with molten alkali. Other workers have shown that acids of unknown structure along with large amounts of neutral condensation products resulted when cyclohexanone was heated with potassium hydroxide at 180–190° for twenty-four hours.[3]

Three distinct types of reactions between cyclohexanone and potassium hydroxide have now been found, depending on the temperature used. The results can best be explained on the basis of the series of changes involving (1) formation of cyclohexylidenecyclohexanone (I), (2) cleavage of the ketone ring to a cyclohexylidenecaproic acid (II) and (3) migration of the double bond and degradation of the intermediate α,β-unsaturated acid to cyclohexanebutyric acid (IV). These transformations are shown in the accompanying equations and are discussed below.

At temperatures up to 220° the addition of cyclohexanone to molten potassium hydroxide resulted in the formation of a white crystalline solid which yielded only neutral products when treated with water. In the temperature range 250–280° a similar white precipitate formed momentarily but was very rapidly converted by an exothermic reaction to a yellow oil (II). When cooled, this yellow oil solidified and, after solution in water and acidification, a 12-carbon unsaturated acid was obtained. The position of the double bond in the acid from II was not established but no doubt exists concerning the carbon skeleton since this product yielded cyclohexanecaproic acid when hydrogenated. Prolonged treatment of II with molten alkali resulted eventually in a *saturated* 10-carbon acid identified as cyclohexanebutyric acid (IV). This transformation may involve the migration of the double bond of II into the α,β-position (III) followed by a retrograde aldol reaction to give cyclohexanebutyraldehyde which in turn would be converted by the alkali to IV. Support for the mechanism as pictured above is found in the fact that cyclohexylidenecyclohexanone yielded II when heated with molten potassium hydroxide.



In the case of 2-allylcyclohexanone (V) an unusual cleavage took place with the formation of the potassium salts of propionic acid and the acid II, derived from cyclohexanone, in accordance with the equation



The fact that propionic acid, and not acrylic acid, was isolated indicates that this change may involve the migration of the double bond in the allyl side chain into conjugation with the carbonyl group and hydrolytic removal of this residue with the formation first of propionaldehyde and then of propionic acid.

Experimental[4]

Action of Potassium Hydroxide on Cyclohexanone (280°—thirty minutes).—Two hundred twenty-five (225) grams of solid potassium hydroxide was fused in a heavy-walled glass tube in an atmosphere of nitrogen. To this was added, with vigorous agitation, 43.6 g. of cyclohexanone over a period of thirty minutes while the temperature was maintained between 260 and 280°. The mixture was cooled and dissolved in water to form a clear solution with

(1) Bachmann, THIS JOURNAL, **57**, 737 (1935).

(3) Wallach and Behnke, *Ann.*, **369**, 99 (1909).

(4) We are indebted to Dr. J. W. Stillman of these laboratories, under whose supervision the microanalyses reported here were carried out.

no evidence of any alkali-insoluble material. After acidification with concentrated hydrochloric acid and cooling, the solution was extracted with two portions of diethyl ether. The ether extract was then dried over anhydrous sodium sulfate, filtered, and the ether removed by distillation. The resulting residue, on distillation, yielded 14.7 g. of an acid (corresponding to II) boiling at 145–153° (2–3 mm.), $n^{20}D$ 1.4385.

Anal. Calcd. for $C_{12}H_{20}O_2$: neut. equiv., 196. Found: neut. equiv., 205.3.

This acid was found to be soluble in aqueous sodium bicarbonate, giving a solution which reduced potassium permanganate. It rapidly absorbed bromine with the evolution of hydrogen bromide and the formation of an oily derivative.

The ethyl ester prepared from this unsaturated 12-carbon acid had the properties: b. p. 131° (5 mm.); $n^{25}D$ 1.4642; d^{25}_4 0.9365.

Anal. Calcd. for $C_{14}H_{24}O_2$: C, 74.96; H, 10.78; sap. equiv., 224.3; M_R, 65.87 (from atomic refractivity constants given in Lange, "Handbook of Chemistry," 3rd Edition, 1939, p. 855). Found: C, 75.22, 75.59; H, 10.52, 10.97; sap. equiv., 223.9; M_R, 66.12 (R. Lorentz and H. Lorenz formula).

Hydrogenation of the acid in the presence of Raney nickel catalyst at 125° and 120 atm. hydrogen pressure for three hours yielded cyclohexanecaproic acid, from which was obtained a solid *p*-bromophenacyl ester identical with the *p*-bromophenacyl ester of an authentic sample of cyclohexanecaproic acid.[5]

Action of Potassium Hydroxide on Cyclohexanone (300°—eighteen hours).—A stainless steel bomb was charged with 125 g. of cyclohexanone and 250 g. of potassium hydroxide, the air was flushed out with nitrogen, and the mixture heated with agitation at 300° for eighteen hours. At the end of this time, the mixture was cooled and the grayish solid which separated was removed and discarded. The remaining oily product was extracted with water and the aqueous extract acidified with hydrochloric acid to yield an oily, water-insoluble acid. This acid on distillation gave a fraction amounting to 25 g. boiling at 160–180° (10 mm.). Redistillation of this product yielded cyclohexanebutyric acid boiling at 136–139° (4 mm.), m. p. 26.5–28.5°.

Anal. Calcd. for $C_{10}H_{18}O_2$: C, 70.55; H, 10.65; neut. equiv., 170.2. Found: C, 70.52; H, 10.34; neut. equiv., 178.5.

The *p*-bromophenacyl ester of this acid was found to melt at 76–77° and showed no depression in melting point when mixed with a sample of the *p*-bromophenacyl ester of an authentic sample of cyclohexanebutyric acid.

2-Allylcyclohexanone.—This was prepared by the method of Cornubert[6] using allyl chloride instead of allyl iodide, b. p. 80–87° (13–15 mm.), $n^{25}D$ 1.4662 to 1.4669.[6,7]

Action of Potassium Hydroxide on 2-Allylcyclohexanone.—In an atmosphere of nitrogen 20 g. of 2-allylcyclohexanone was added with stirring to 75 g. of potassium hydroxide at 240–250°. After twenty minutes the mixture was cooled, and the upper layer of yellowish solid was separated mechanically from the lower layer of potassium hydroxide and dissolved in water. Neutral products were removed from the aqueous layer by extraction with ether, and the aqueous layer was then acidified with the formation of a yellow oil. After separation and drying of the oil, it yielded, upon distillation, two fractions, the first (2 g.), boiling at 33–34° (5 mm.), and the second (4 g.) boiling at 157–170° (5 mm.).

The first fraction was demonstrated to be propionic acid: neut. equiv. Calcd. for $C_3H_6O_2$: 74.1. Found: 75.5, 75.6.

The *p*-bromophenacyl ester, m. p. 57.5–59°, showed no depression in melting point when mixed with the ester of an authentic specimen of propionic acid. The *p*-bromophenacyl ester of acrylic acid melted at 67.5–68° and mixtures of this ester with that of the ester in question melted at 53.5–56.5°.

The second, high-boiling fraction was shown to yield cyclohexanecaproic acid when hydrogenated.

Summary

1. Treatment of cyclohexanone with molten potassium hydroxide at 250–280° yields a 12-carbon unsaturated acid, and at 300° cyclohexanebutyric acid.

2. 2-Allylcyclohexanone is converted by molten potassium hydroxide at 250° to the same 12-carbon unsaturated acid; the allyl side chain appears as propionic acid.

p-Toluenesulfonates of 20-Hydroxypregnanes

BY LEWIS HASTINGS SARETT

The conversion of pregnane-3(α),20-diol 3-acetate 20-tosylate to Δ^{17}-pregnene-3(α)-ol by treatment with pyridine has been described.[1] The present work reports some additional applications of this useful procedure for the preparation of substituted ethylenes from secondary alcohols.[2]

Pregnane-3(α),12(α),20-triol 3,12-diacetate[3] (I), was prepared by catalytic reduction of pregnane-3(α),12(α)-diol-20-one diacetate.[4] With *p*-toluenesulfonyl chloride I yielded a diacetate tosylate, which on refluxing with collidine gave a crystalline mixture of Δ^{17}- and Δ^{20}-pregnene-3(α),12(α)-diol diacetate (IIa and IIb). From the mixture obtained by hydroxylation of II, a readily crystalline 3(α),12(α),17,20-tetrol (III) could be separated. Periodate cleavage then yielded *etio*-cholane-3(α),12(α)-diol-17-one, isolated as the diacetate (IV).[5] Oxidation of the amorphous glycol mixture which remained gave some *etio*-desoxycholic acid (V).

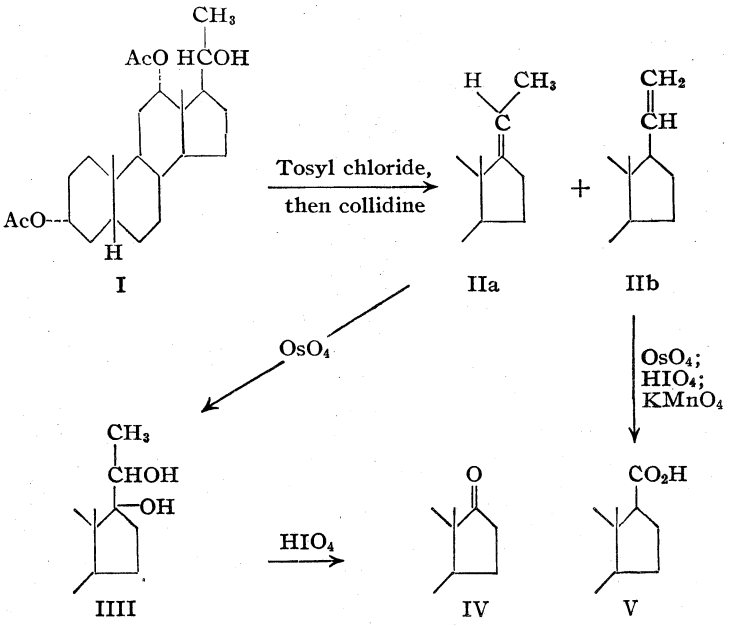
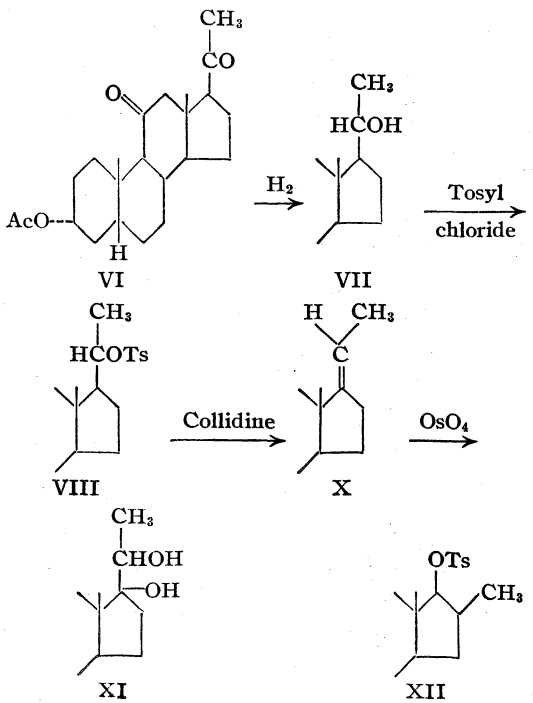
(5) We are indebted to Dr. L. F. Fieser of Harvard University for an authentic sample of this compound for comparison.



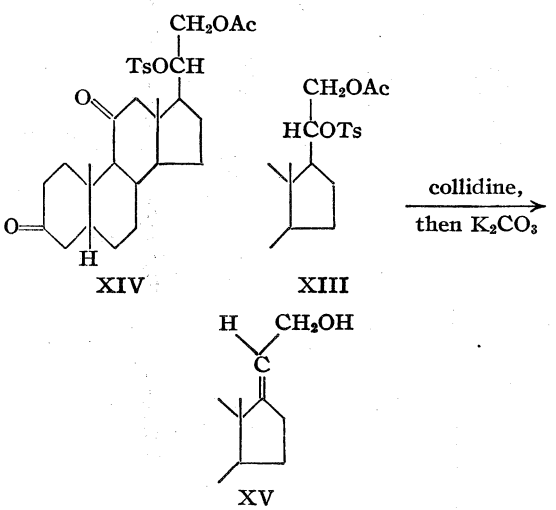
A more thorough investigation of the 11-keto series was facilitated by the ready crystallizability of the intermediates; in addition the reactions appeared to proceed more smoothly. The reduction of pregnane-3(α)-ol-11,20-dione acetate (VI) afforded one of the possible pregnane-3(α),20-diol-11-one 3-acetate epimers (VII) in an 85% yield. The other was present only to the extent of a few per cent. With *p*-toluenesulfonyl chloride VII gave the acetate tosylate VIII, which occurred in several crystalline modifications.

After treatment of the tosylate with collidine, a crystalline mixture of the Δ^{17} and Δ^{20} derivatives was obtained in which the Δ^{17} isomer (or isomers) preponderated. Ozonolysis of this mixture of acetates gave *etio*-cholane-3(α)-ol-11,17-dione acetate together with some 3(α)-acetoxy-11-keto-*etio*-cholanic acid. A pure Δ^{17}-pregnene-3(α)-ol-11-one (X) could be isolated by saponification of the mixture of acetates and repeated recrystallization of the product. Hydroxylation of X gave a triolone (XI), which with chromic acid was oxidized to *etio*-cholane-3,11,17-trione.

An additional product of the reaction of pregnane-3(α),20-diol-11-one 3-acetate 20-tosylate (VIII) with collidine was an isomeric acetate tosylate. Reductive hydrolysis of this material with sodium amalgam gave a ketodihydroxy derivative isomeric with pregnanediolones. Evidently a fundamental rearrangement occurred, probably to a D-homo derivative such as XII.



The applicability of the tosylate-collidine method for introducing the 17,20 double bond was tested also in the 21-acetoxy series. Partial acetylation of pregnane-20(β),21-diol-3,11-dione[6] and the epimeric glycol[6] gave the respective 21-monoacetates from which the corresponding acetate tosylates (XIII and XIV) were prepared. Only one of these mixed esters—that derived from the arbitrarily designated 20(β) series—reacted readily with collidine at the boiling point. It gave a non-crystalline acetate which was very easily hydrolyzed to a derivative of the empirical formula $C_{21}H_{30}O_3$; m. p. 128°; $[\alpha]^{25}D$ +63°. This substance upon hydroxylation with osmium tetroxide, followed by acetylation of the resulting triol, gave the same pregnane-17(α),20,21-triol-3,11-dione diacetate previously obtained by hydroxylation of a Δ^{17}-pregnene-21-ol-3,11-dione.



(6) Sarett, THIS JOURNAL, 68, 2478 (1946).

This latter compound melted erratically at about 150° and had $[\alpha]_D$ +56° but was not obtained analytically pure. Both the 128° and the 150° pregnenes gave amorphous acetates. An attempt to repeat the preparation of the higher melting pregnene gave only the lower melting product. Although, unfortunately, none of the former has been available for direct comparison, the data suggest that the two Δ^{17}-pregnene-21-ol-3,11-dione compounds are merely crystal modifications.

Experimental[7]

Δ^{17}- and Δ^{20}-Pregnene-3(α),12(α)-diol Diacetate (IIa and IIb).—A solution of 1.02 g. of pregnane-3(α),12(α)-diol-20-one diacetate in 50 cc. of acetic acid was shaken with 0.5 g. of platinum oxide under hydrogen until the theoretical quantity of hydrogen was taken up. The solution was then filtered, concentrated *in vacuo* and dissolved in ether. The ethereal solution was washed with aqueous carbonate, then with water, and concentrated to dryness. A sample of the crude pregnane-3(α),12(α),20-triol 3,12-diacetate was chromatographed but could not be obtained crystalline. The diacetate (1.02 g.) was then dissolved in 2 cc. of pyridine and treated with 850 mg. of *p*-toluenesulfonyl chloride. After standing at room temperature for sixteen hours, the solution was diluted with water and extracted with ether. The ethereal solution was washed with aqueous carbonate, dilute hydrochloric acid and with water and concentrated to dryness. The amorphous diacetate tosylate weighed 1.262 g. It was next refluxed with 20 cc. of collidine for twenty-five minutes, the solution cooled, diluted with ether, washed with dilute sulfuric acid and with water. The ethereal solution was concentrated to dryness and the residue was crystallized twice from methanol. The product (580 mg.) consisted of a mixture of Δ^{17}- and Δ^{20}-pregnene-3(α),12(α)-diol diacetate, m. p. 155–159°.

Anal. Calcd. for $C_{25}H_{38}O_4$: C, 74.59; H, 9.52. Found: C, 74.74; H, 9.78.

Hydroxylation of Δ^{17}- and Δ^{20}-Pregnene-3(α),12(α)-diol Diacetate.—A solution of 560 mg. of pregnene mixture (m. p. 155–159°) in 10 cc. of absolute ether was treated with 500 mg. of osmium tetroxide and 350 mg. of dry pyridine. After ten minutes the ether was removed *in vacuo*, the residue dissolved in 30 cc. of alcohol and the solution treated with 1.0 g. of sodium sulfite dissolved in 20 cc. of water. The mixture was refluxed for three hours and then filtered. To the filtrate was added 10 cc. of 1 *N* aqueous potassium hydroxide and the whole refluxed an additional half hour. The alcohol was removed *in vacuo* and the residual suspension extracted with chloroform. Concentration of the washed chloroform solution, followed by crystallization of the residue from acetone gave 80 mg. of a crude pregnane-3(α),12(α),17,20-tetrol (III), m. p. 253–259°. This material was not purified further but was suspended in 5 cc. of methanol to which was added 1.11 cc. of water containing 55 mg. of periodic acid. The suspension was swirled from time to time and after forty-five minutes the tetrol had dissolved. The solution was permitted to stand for an additional half hour and then concentrated to a small volume *in vacuo*. The aqueous suspension was extracted with ethyl acetate. Concentration of the ethyl acetate to a small volume gave a crystalline precipitate consisting of starting material. This was removed and the material in the mother liquors (67 mg.) heated in the steam-bath with a small volume of pyridine and acetic anhydride for thirty minutes. The acetylation mixture was then diluted with water and worked up in the usual manner. Crystallization of the product from ether–petroleum ether gave 45 mg. of *etio*-cholane-3(α),12(α)-diol-17-one diacetate, m. p. and mixed m. p. 157–158°.

(7) All rotations were taken in acetone; c~1.0. All melting points are corrected.

Anal. Calcd. for $C_{23}H_{34}O_5$: C, 70.73; H, 8.78. Found: C, 70.76; H, 8.89.

The mother liquors of the tetrol III were concentrated to dryness *in vacuo* and weighed 320 mg. They were similarly oxidized with periodic acid and then acetylated with pyridine–acetic anhydride as before. The crude diacetoxy-*etio*-cholanic aldehyde was then dissolved in 7 cc. of acetone and treated with 2.5 cc. of 5% aqueous potassium permanganate. After standing at room temperature for forty-five minutes, the mixture was concentrated to a small volume in a stream of air at 15°, then acidified with dilute sulfurous acid and extracted with ether. The ethereal solution was extracted with 1 *N* aqueous potassium hydroxide solution and the latter was then heated on the steam-bath for one hour. The alkaline solution was cooled, acidified with dilute hydrochloric acid and the precipitate washed and dried. Crystallization of the amorphous powder (60 mg.) from acetone gave 46 mg. of *etio*-desoxycholic acid, m. p. and mixed melting point, 290–294°.

Pregnane-3(α),20-diol-11-one 3-Acetate (VII).—A solution of 6.15 g. of pregnane-3(α)-ol-11,20-dione acetate in 125 cc. of acetic acid was shaken under hydrogen with 1.0 g. of platinum oxide. After six hours the theoretical amount of hydrogen had been taken up and the reaction had stopped. The solution was filtered and a large volume of water was added to the filtrate. The crystalline precipitate was washed with water and dried. It weighed 6.10 g. and melted at 182–199°. After recrystallization from benzene–petroleum ether and from dilute acetone, the product melted at 205–206°: $[\alpha]^{25}_D$ +66°; yield, 83%.

Anal. Calcd. for $C_{23}H_{36}O_4$: C, 73.36; H, 9.65. Found: C, 73.07; H, 9.98.

A sample of the combined mother liquors of the monoacetate was heated with pyridine–acetic anhydride and then chromatographed over alumina. The crystalline fractions melting above 200° were combined and after several recrystallizations from alcohol and from ether pure pregnane-3(α),20(*epi*)-diol-11-one diacetate, m. p. 234–235°, was obtained. The yield was 1.5% based on the 20-ketone (VI).

Anal. Calcd. for $C_{25}H_{38}O_5$: C, 71.74; H, 9.15. Found: C, 71.95; H, 9.24.

Pregnane-3(α),20-diol-11-one Diacetate.—A sample of pregnane-3(α),20-diol-11-one 3-acetate (m. p. 205–206°) was heated with acetic anhydride-pyridine on the steam-bath for fifteen minutes. The addition of water gave the crystalline diacetate, m. p. 160.5–161.0°; $[\alpha]^{25}_D$ +81°.

Anal. Calcd. for $C_{25}H_{38}O_5$: C, 71.74; H, 9.15. Found: C, 71.88; H, 9.18.

Pregnane-3(α),20-diol-one-11.—A sample of pregnane-3(α),20-diol-11-one 3-acetate (m. p. 205–206°) was refluxed for fifteen minutes with 1 *N* methanolic potassium hydroxide. The crystalline diol was precipitated with water and recrystallized from acetone. It melted at 236–238°.

Anal. Calcd. for $C_{21}H_{34}O_3$: C, 75.40; H, 10.25. Found: C, 75.47; H, 10.20.

Pregnane-3(α),20(*epi*)-diol-11-one.—A sample of pregnane-3(α),20(*epi*)-diol-11-one diacetate (m. p. 234–235°) was saponified similarly. The diol melted at 219°.

Anal. Calcd. for $C_{21}H_{34}O_3$: C, 75.40; H, 10.25. Found: C, 75.29; H, 10.29.

Pregnane-3(α),20-diol-11-one 3-Acetate 20-Tosylate (VIII).—To a solution of 4.75 g. of pregnane-3(α),20-diol-11-one 3-acetate in 9 cc. of pyridine was added 4.0 g. of recrystallized *p*-toluenesulfonyl chloride. The solution was permitted to stand at room temperature overnight and was then treated with sufficient water to destroy the excess acid chloride. After further dilution with water, extraction with chloroform, and successive washings with dilute hydrochloric acid, dilute sodium carbonate and water, the solution was concentrated to

dryness *in vacuo*. Crystallization from ether–petroleum ether gave 6.80 g. of solvated product, melting at 100°, resolidifying and melting again at 141–143°. Recrystallization from dilute methanol gave a non-solvated product, m. p. 144–145°; $[\alpha]^{25}D$ +57.5°.

Anal. Calcd. for $C_{30}H_{42}O_6S$: C, 67.89; H 7.97. Found: C, 67.92; H, 7.86.

After standing at room temperature for a month, the sample melted at 173°. In subsequent preparations only this higher melting form was obtained.

Δ^{17}-Pregnene-3(α)-ol-11-one (X).—A solution of 6.50 g. of pregnane-3(α),20-diol-11-one 3-acetate 20-tosylate in 50 cc. of redistilled collidine was refluxed for twenty-five minutes. The solution was cooled, diluted with petroleum ether, washed with dilute hydrochloric acid and with water and concentrated to a small volume. Crystals (200 mg.) of the isomeric acetate tosylate XII (?) separated and were filtered and set aside. The mother liquors were concentrated to dryness and the residue crystallized from methanol at 0°. The crude pregnenes weighed 3.61 g. and melted at 60–82°. The mixture was refluxed for thirty minutes with 30 cc. of 1.1 *N* methanolic potassium hydroxide, then diluted with water and permitted to crystallize. After a number of recrystallizations from methanol 1.4 g. of pure Δ^{17}-pregnene-3(α)-ol-11-one was obtained. It melted at 191–192° and had $[\alpha]^{25}D$ +55°. Refluxing the tosylate with 2 *N* methanolic potassium hydroxide gave smaller yields of this unsaturated compound.

Anal. Calcd. for $C_{21}H_{32}O_2$: C, 79.68; H, 10.12. Found: C, 79.57; H, 10.10.

A sample was converted to the acetate (IX) with pyridine–acetic anhydride. After recrystallization from methanol it melted at 125°.

Anal. Calcd. for $C_{23}H_{34}O_3$: C, 77.07; H, 9.56. Found: C, 77.03; H, 9.54.

Isomeric Tosylate (XII) (?).—The 200 mg. of crystals which separated from the collidine reaction product described above was recrystallized from methanol and melted at 197–200°, $[\alpha]^{25}D$ +46.5°. It was almost entirely stable to further treatment with collidine.

Anal. Calcd. for $C_{30}H_{42}O_6S$: C, 68.81; H, 8.24. Found: C, 68.70; H, 8.36.

Isomeric Diol from XII (?).—A suspension of 300 mg. of the tosylate XII (?) m. p. 197–200°, in 12 cc. of methanol and 3 cc. of water was stirred with 25 g. of 4% sodium amalgam overnight. The suspension was decanted from mercury and filtered. Recrystallization from a large volume of methanol gave a product which melted at 294–297°, and was isomeric with pregnanediolone.

Anal. Calcd. for $C_{21}H_{34}O_3$: C, 75.40; H, 10.25. Found: C, 75.70; H, 10.25.

Similar reduction of a sample of VIII (m. p. 173°) gave pregnane-3(α),20-diol-11-one, m. p. and mixed m. p. 236–238°.

Diacetate of Isomeric Diol.—A sample of isomeric diol (m. p. 294–297°) was heated with pyridine–acetic anhydride on the steam-bath for one hour. The addition of water gave crystals, m. p. 183°.

Anal. Calcd. for $C_{25}H_{38}O_5$: C, 71.74; H, 9.15. Found: C, 71.99; H, 9.02.

Ozonolysis of Crude Δ^{17}-Pregnene-3(α)-ol-11-one Acetate (IX).—Twenty-five grams of crude pregnene-17-ol-3(α)-one-11 acetate (an amorphous product direct from the detosylation with collidine was used) was ozonized and the product treated according to a previously described procedure.[8] A total of 8.43 g. of acidic material was obtained which was saponified and gave upon crystallization from ethyl acetate 2.13 g. of 3(α)-hydroxy-11-keto-*etio*-cholanic acid, m. p. and mixed m. p. 296–298°. The neutral fraction (16.5 g.) gave 10.2 g. of ketones from which 7.2 g. of pure *etio*-cholanol-3(α)-11,17-dione was obtained.

Pregnane-3(α),17,20-triol-11-one (XI).—A sample (100 mg.) of Δ^{17}-pregnene-3(α)-ol-11-one (X) in 20 cc. of absolute ether was treated with 100 mg. of osmium tetroxide and two drops of pyridine. After one hour the mixture was concentrated to dryness *in vacuo*, dissolved in 5 cc. of alcohol and treated with a solution of 300 mg. of sodium sulfite in 5 cc. of water. The mixture was refluxed for two hours, filtered, concentrated to a small volume, diluted with water and extracted with chloroform. The chloroform extract was concentrated to dryness and the residue crystallized from ether. The triol melted at 189–191°. A second crystalline form, m. p. 210–212°, was obtained by crystallization from benzene. The compound showed a strong tendency to separate as a gel from non-polar solvents and could not be obtained free of solvents. Prolonged heating appeared merely to lead to decomposition.

The diacetate was prepared with pyridine–acetic anhydride in the usual manner. It melted at 227–228°, $[\alpha]^{25}D$ +24°.

Anal. Calcd. for $C_{25}H_{38}O_6$: C, 69.10; H, 8.82. Found: C, 69.06; H, 8.65.

***etio*-Cholane-3,11,17-trione from XI.**—A solution of 450 mg. of pregnane-3(α),17,20-triol-11-one (XI) (purified through the diacetate) in 5.5 cc. of 90% acetic acid was treated with 10 cc. of 90% acetic acid containing 500 mg. of chromic acid. After fifty minutes at room temperature, the solution was diluted with water and extracted twice with chloroform. The washed chloroform solution was concentrated to dryness and the residue was chromatographed over 10 g. of acid washed alumina. The fractions from 9:1 ether–chloroform to 1:9 ether–chloroform contained the *etio*-cholanetrione, m. p. and mixed m. p. 134–135°. Subsequent fractions gave a product, m. p. 177–182°, the amount of which was too small to permit complete purification.

Pregnane-20(α),21-diol-3,11-dione 21-Acetate 20-Tosylate (XIV).—To a solution of 378 mg. of pregnane-20(α),21-diol-3,11-dione (m. p. 182–183°) in 1.05 cc. of absolute dioxane was added 576 mg. of a dioxane solution containing 161 mg. of acetic anhydride and 138 mg. of pyridine. After standing at room temperature for sixty hours, the solution was evaporated *in vacuo* and the residue chromatographed. Ether–chloroform mixtures eluted crystals of 21-monoacetate which after several recrystallizations from ether melted at 166–170° and weighed 97 mg. A total of 186 mg. of this partially purified monoacetate was treated with 125 mg. of tosyl chloride in 0.2 cc. of pyridine. After standing at room temperature overnight, the solution was diluted with water and taken up in ether. The washed ethereal solution was concentrated to dryness. The amorphous tosylate (254 mg.) was sparingly soluble in dry ether.

Pregnane-20(β),21-diol-3,11-dione 21-Acetate 20-Tosylate (XIII).—A sample (362 mg.) of pregnanediol-20(α),21-dione-3,11 (m. p. 168°) was similarly converted to the monoacetate. The crude product was chromatographed and gave 227 mg. of crude monoacetate together with some diacetate and starting material. The amorphous monoacetate with tosyl chloride gave 212 mg. of tosylate, m. p. 176–180°. After two recrystallizations from acetone a sample melted at 193–194°.

Anal. Calcd. for $C_{30}H_{40}O_7S$: C, 66.15; H, 7.40. Found: C, 66.26; H, 7.23.

A sample (250 mg.) of the 20(α)-tosylate (XIV) was refluxed for twenty-five minutes with collidine. Only 20% of the theoretical amount of collidine *p*-toluenesulfonate was formed. Chromatography of the product gave a small amount of oily reaction product, the remainder consisting of starting material or a rearrangement product thereof. Saponification of the detosylated material gave a non-crystalline product.

Δ^{17}-Pregnene-21-ol-3,11-dione (XV).—A solution of 166 mg. of crystalline 20(β)-tosylate (XIII) in 4 cc. of collidine was refluxed for twenty-five minutes. The solution was cooled and diluted with petroleum ether; 86 mg. (82%) of collidine *p*-toluenesulfonate separated. The solution was then diluted with ether, washed with dilute hydrochloric acid and concentrated to dryness,

The residue (130 mg.) was chromatographed over 3.5 g. of alumina. The eluates obtained with 10-cc. portions of 3:7, 2:8 and 1:9 petroleum ether–ether, with 10 cc. of ether and with 10 cc. of 9:1 ether–chloroform were combined and gave 69 mg. of amorphous Δ^{17}-pregnene-21-ol-3,11-dione acetate. This was dissolved in 3.5 cc. of methanol and treated with a solution of 2 cc. of water containing 60 mg. of potassium carbonate and 60 mg. of potassium bicarbonate. After two hours at room temperature, the solution was acidified with 2 drops of acetic acid and concentrated to a small volume *in vacuo*. The oily precipitate was dissolved in chloroform, washed and the solution concentrated to dryness. The residue (54 mg.) was chromatographed over 2 g. of alumina. The fraction eluted with 1:1 ether–chloroform and mixtures with an increasing proportion of chloroform could be crystallized from a small volume of ether. The combined crystals weighed 30 mg. and melted at 127.5–128°. Recrystallization from ether raised the melting point to 128–128.5°.

Anal. Calcd. for $C_{21}H_{30}O_3$: C, 76.33; H, 9.15. Found: C, 76.63; H, 9.38.

A 5-mg. sample was permitted to stand at room temperature with acetic anhydride–pyridine for two hours. The product was an oil, from which the original alcohol could be obtained by saponification.

Δ^{17}-Pregnene-21-ol-3,11-dione from Δ^{17}-Pregnene-3(α),21-diol-11-one 21-Hemisuccinate.—A sample of 159 mg. of the 21-hemisuccinate of Δ^{17}-pregnene-3(α),21-diol-11-one was oxidized and then saponified as previously described[8]. Crystallization of the product gave 70 mg. of Δ^{17}-pregnene-21-ol-3,11-dione, m. p. 128°. It did not depress the melting point of XV.

Pregnene-17(α),20,21-triol-3,11-dione Diacetate from XV.—A sample (82 mg.) of Δ^{17}-pregnene-21-ol-3,11-dione, (XV), m. p. 128°, was treated with osmium tetroxide, hydrolyzed and acetylated as previously described.[8] The crystalline diacetate weighed 72 mg., melted at 212–213°, and had $[\alpha]^{25}D$ +95°. A mixed melting point with the original sample showed no depression.

Acknowledgment.—For valuable suggestions concerning this work the author is indebted to Dr. K. Folkers and Dr. R. T. Major of these laboratories, and to Dr. E. S. Wallis of Princeton University. For the microanalyses reported herein acknowledgment is made to Messrs. R. Boos, W. H. Humphrey, E. Thornton, J. McGregor and R. Funk.

Summary

The application of the *p*-toluenesulfonate-tertiary amine reaction to certain 20-hydroxypregnenes is described. In the case of pregnane-20(β),21-diol-3,11-dione 21-acetate 20-tosylate, Δ^{17}-pregnene-21-ol-3,11-dione was obtained.

The Preparation of 2-Alkylbutadienes[1]

BY C. S. MARVEL, R. L. MYERS[2] AND J. H. SAUNDERS[3]

The observation[4] that emulsion copolymers of isoprene with styrene contain more diene units joined in the 1,4-manner than do the corresponding butadiene–styrene copolymers suggested the importance of investigating other 2-alkylbutadienes. The literature on the synthesis of this class of dienes is very limited. 2-Ethyl-1,3-butadiene has been reported as a product of dehydrohalogenation of 3-methyl-3,4-dibromopentane,[5] but no evidence of structure was presented. 2-Isopropyl-1,3-butadiene has been prepared by von Braun and Keller[6] by the Hofmann degradation of 2-isopropyl-1,4-diaminobutane. While this method gave a well-characterized product, the starting materials needed for the synthesis are not readily available. This communication describes the synthesis of 2-isopropyl-1,3-butadiene[7] by various routes, one of which appears to be a good general method for making 2-alkylbutadienes.

2-Isopropylbutadiene was first obtained by dehydration of 2-isopropyl-1,4-butanediol through acetylation and pyrolysis. The diol was synthesized by the method of Adkins and Wojcik.[8] The final yield of diene based on diethyl isopropylidenesuccinate was about 4%. An attempt to find an improved preparation of diethyl isopropylsuccinate through the addition of isopropyl-metal halides to diethyl maleate or fumarate did give the ester in 30% yields but the over-all reaction was still not a satisfactory one for preparative work.

A second series of reactions was then investigated. The starting material was isovaleraldehyde (I). It was converted either to isopropylacrolein (III) or to 2-isopropyl-3-hydroxypropionaldehyde (II) and then by the Grignard reaction and subsequent dehydration to the desired diene. Different sequences of reactions were tried and these are indicated in the chart.

The final choice of steps is that indicated by the heavy arrows. The Mannich intermediate[9] (VI) was not isolated but was converted directly to isopropylacrolein (VII). The unsaturated carbinol

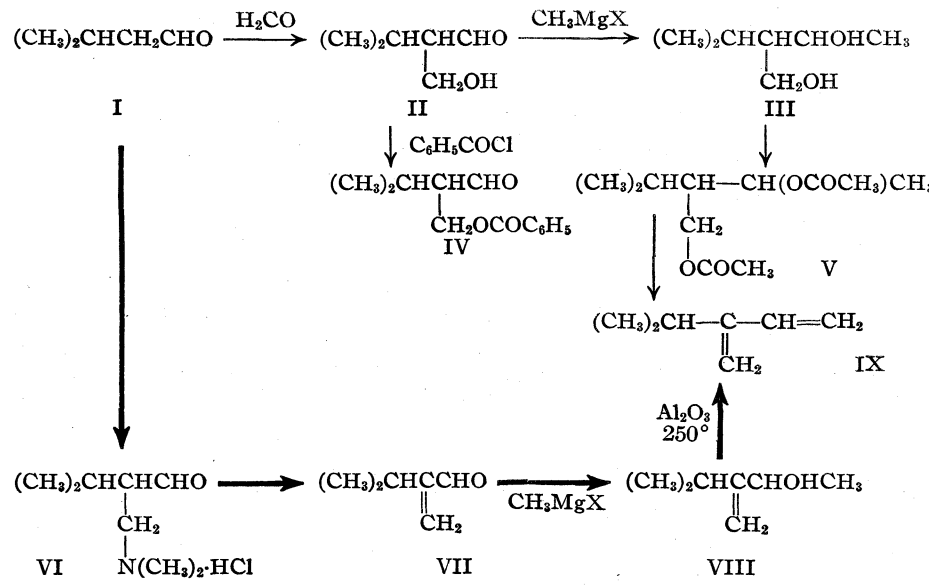
(7) The desirability of synthesizing this diene was first brought to our attention by Drs. W. E. Messer and V. C. Neklutin of the United States Rubber Company.

(8) Adkins and Wojcik, THIS JOURNAL, **55**, 4939 (1933); **56**, 2424 (1934).

(9) Mannich, Lesser and Silten, *Ber.*, **65**, 378 (1932).



(VIII) was also dehydrated by converting to the acetate and pyrolyzing this ester. This method may be useful in large scale work to effect dehydration. The over-all yield of diene from isovaleraldehyde is about 11%. The reactions are relatively simple to carry out in the laboratory on a fairly large scale.

By use of the preferred scheme outlined above *n*-butyraldehyde was converted to 2-ethylbutadiene and *n*-heptaldehyde was converted to 2-*n*-amylbutadiene.

Experimental

Diethyl Isopropylidenesuccinate.—Diethyl isopropylidenesuccinate was prepared according to the procedure of Adkins and Wojcik[8] with slight modifications. Sodium ethoxide was prepared in ether suspension by the method of Brühl[10] and used without isolation. The reaction was run for four hours at 0° after the addition of the acetone and diethyl succinate mixture to the sodium ethoxide suspension. The reaction mixture was then permitted to warm to room temperature and stand for sixteen hours prior to hydrolysis. Longer reaction times did not increase the yield. From 136 g. (2.0 moles) of sodium ethoxide in 1500 ml. of ether, 217.5 g. (1.25 moles) of diethyl succinate, and 116 g. (2.0 moles) of acetone there was obtained 120 g. (45%) of diethyl isopropylidenesuccinate, b. p. 91–96° (1 mm.), $n^{20}D$ 1.4521. When 2.0 moles of sodium ethoxide, 1.5 moles of ester, and 2.4 moles of acetone were used the yield was 53%. Other variations in the concentrations of reactants did not increase the yield.

The product was redistilled through a 12-in., helix-packed column to obtain pure diethyl isopropylidenesuccinate which boiled at 100–102° (2 mm.), $n^{20}D$ 1.4550, d^{20}_4 1.0304.

Adkins and Wojcik[8] reported the b. p. 115–122° (7 mm.).

Diethyl Isopropylsuccinate by Reduction of Diethyl Isopropylidenesuccinate.—A total of 815 g. (3.81 moles) of diethyl isopropylidenesuccinate was reduced over Raney nickel in a high pressure bomb without solvent. With an initial pressure of 1700 p. s. i. at 25° only one-third of the theoretical amount of hydrogen was taken up. The pressure was raised to 2150 p. s. i., the temperature to 100°, and the reduction was completed. The nickel was removed by filtration and the diethyl isopropylsuccinate was reduced to the glycol without purification.

Diethyl Isopropylsuccinate from Diethyl Fumarate and Isopropylmagnesium Bromide.—In a 1-liter, three-necked, round-bottomed flask equipped with a reflux condenser and a dropping funnel with calcium chloride tubes, and a Hershberg stirrer were placed 50 g. (0.3 mole) of diethyl fumarate and 250 ml. of dry ether. A Grignard reagent prepared in the usual manner from 7.07 g. (0.3 mole) of magnesium, 35.8 g. (0.3 mole) of isopropyl bromide and 300 ml. of ether was added dropwise to the reaction flask with vigorous stirring. The reaction mixture was stirred for an additional fifteen minutes after all of the Grignard reagent had been added.

The reaction mixture was worked up in the usual manner and the residual oil was distilled through a 12-in., helix-packed column. The yield of diethyl isopropylsuccinate was 18.8 g. (29.8%), b. p. 65° (0.5 mm.) or 82° (1 mm.), $n^{20}D$ 1.4261. A sample which was redistilled for analysis boiled at 123–125° (20 mm.), $n^{20}D$ 1.4284, d^{20}_4 0.9925.

Anal.[11] Calcd. for $C_{11}H_{20}O_4$: C, 61.09; H, 9.32. Found: C, 60.82; H, 9.10.

Adkins and Wojcik[8] who prepared this compound by the reduction of diethyl isopropylidenesuccinate reported the b. p. 110–112° (8 mm.). Neklutin[12] who prepared this compound in a manner similar to that of Adkins and Wojcik,[8] reported b. p. 71–78° (0.8 mm.), $n^{29}D$ 1.4288.

The use of 50% mole excess of diethyl fumarate did not increase the yield. When diethyl maleate was substituted for diethyl fumarate, the results were essentially the same (30.2% yield).

Five grams of diethyl isopropylsuccinate was hydrolyzed by refluxing for six hours with 40 ml. of 25% sodium hydroxide solution. The solution was cooled, extracted with ether and acidified. The white solid thus obtained was recrystallized from acetone and water, m. p. 115.5–116.5°. Roser[13] reported a melting point of 114° for *dl*-isopropylsuccinic acid. Henry and Paget[14] reported a melting point of 117° for this compound.

Diethyl Isopropylsuccinate from Diethyl Maleate and Isopropyl-cadmium Halide.—A Grignard reagent was prepared in the usual way, using 28.6 g. (1.18 moles) of magnesium, 143 g. (1.16 moles) of isopropyl bromide,

(11) We are indebted to Mr. H. S. Clark, Illinois State Geological Survey, for all microanalyses reported in this communication.

(12) Neklutin, private communication.

(13) Roser, *Ann.*, **220**, 271 (1883).

(14) Henry and Paget, *J. Chem. Soc.*, 70 (1928).

and 1000 ml. of dry ether in a 3-liter, three-necked, round-bottomed flask. The reaction mixture was stirred for fifteen minutes after the addition of the halide had been completed, and then was cooled to 0° by means of an ice–salt bath and was maintained at that temperature. During one and one-quarter hours 212 g. (1.16 moles) of anhydrous cadmium chloride was added in small portions to the reaction flask. The suspension was stirred for three-quarters of an hour and a solution of 200 g. (1.16 moles) of diethyl maleate in 500 ml. of ether was added dropwise to the reaction mixture during a period of three and one-half hours. During the addition of the ester the reaction mixture became very gummy and hard to stir. A less vigorous glass stirring shaft was substituted for the Hershberg stirrer and the reaction was continued. Stirring at 0° was continued for five hours.

The reaction mixture was worked up in the usual way and the residual oil was distilled through a 6-in., helix-packed column. The recovery of diethyl maleate was 69.5 g. (34.8%). The yield of diethyl isopropylsuccinate was 48 g. (29.3%), b. p. 118–126° (20 mm.), $n^{20}D$ 1.4311.

A similar experiment which involved longer reaction times between the isopropyl bromide and magnesium and between the isopropylmagnesium bromide and cadmium chloride did not give an increased yield.

2-Isopropyl-1,4-butanediol.—The diethyl isopropylsuccinate obtained from the reduction of the diethyl isopropylidenesuccinate was reduced over copper chromite at 260°, with an initial pressure of 6000 p. s. i.[8] Only about two-thirds of the theoretical amount of hydrogen was taken up.

The reduction mixture was filtered through a fluted filter paper to remove most of the catalyst, and the filtrate was distilled through a 12-in., helix-packed column. The recovery of diethyl isopropylsuccinate was 76.5 g. (9.4%). The yield of 2-isopropyl-1,4-butanediol was 72.5 g. (15.8%), b. p. 145–146° (18 mm.), $n^{20}D$ 1.4535, d^{20}_4 0.9672.

Adkins and Wojcik reported b. p. 119–122° (3 mm.), $n^{25}D$ 1.4535.

Diacetate of 2-Isopropyl-1,4-butanediol.—In a 200-ml., round-bottomed flask were placed 22 g. (0.167 mole) of 2-isopropyl-1,4-butanediol, 75 g. (0.73 mole) of acetic anhydride, and 1 g. of pyridine. The flask and its contents were set aside for three days. At the end of that time the acetic acid was removed by distillation through a 12-in., helix-packed column at atmospheric pressure, and the acetic anhydride was distilled at 100 mm. The residue was carefully fractionated. The yield of diacetate was 28.7 g. (80%), b. p. 105° (3 mm.), $n^{20}D$ 1.4346. A sample was redistilled for analysis, b. p. 96° (1.5 mm.), $n^{20}D$ 1.4349, d^{20}_4 1.0055.

Anal. Calcd. for $C_{11}H_{20}O_4$: C, 61.09; H, 9.32. Found: C, 61.32; H, 9.19.

2-Isopropyl-1,3-butadiene.—A 20-mm. Pyrex tube was packed for a distance of 12 in. with glass beads and heated in a furnace to 575 ± 10°. Twenty-eight grams (0.13 mole) of the diacetate of 2-isopropyl-1,4-butanediol was dropped through the hot tube at a rate of one drop every second. The pyrolysate was dissolved in 25 ml. of ether and washed twice with 50 ml. of water. The washings were combined and extracted with two 20-ml. portions of ether. All three ether solutions were combined and dried over 1 g. of anhydrous magnesium sulfate. The drying agent was removed and the ether solution was fractionated through a 4-in., helix-packed column. The fraction boiling at 82–84° was collected, $n^{20}D$ 1.4280. Since this fraction contained a trace of acetic acid it was dried over 0.25 g. of anhydrous potassium carbonate. The yield of 2-isopropylbutadiene thus obtained was 4 g. (32%), $n^{20}D$ 1.4339. von Braun and Keller[6] reported b. p. 86–87°, $n^{23}D$ 1.4321, $d^{24.5}_4$ 0.7276.

Maleic Anhydride Adduct of 2-Isopropylbutadiene.—In a 2-oz., screw-cap bottle were placed 5 ml. of dry benzene, 1 ml. (0.73 g., 0.0076 mole) of 2-isopropylbutadiene and 0.49 g. (0.005 mole) of maleic anhydride. The bottle was capped and rotated in a water-bath at 50° for twenty-two hours. The adduct was precipitated from the benzene solution by the addition of 5 ml. of low petroleum ether. After recrystallization from benzene and low petroleum ether the adduct melted at 86–86.5°.

The various maleic anhydride adducts obtained from 2-isopropylbutadiene produced by the different methods described in this paper had the same melting points, and mixed melting points showed no depression. A sample of this adduct was submitted for analysis.

Anal. Calcd. for $C_{11}H_{14}O_3$: C, 68.02; H, 7.26. Found: C, 68.21; H, 7.21.

α-Isopropylacrolein by the Mannich Method.—In a 5-liter, three-necked, round-bottomed flask fitted with a reflux condenser, a mechanical stirrer, and a thermometer were placed 975 g. (12.0 moles) of dimethylamine hydrochloride, 900 g. (12 moles) of a 40% solution of formalin, and 860 g. (10 moles) of isovaleraldehyde. The flask was heated by an oil-bath maintained electrically at 70° and stirred for twenty-four hours. The flask was then fitted for steam distillation, and the contents steam-distilled until organic material no longer separated from the distillate. The water layer was removed, and the organic material was dried over anhydrous magnesium sulfate. Distillation through an 18-in., electrically heated, helix-packed column yielded 113.5 g. of recovered isovaleraldehyde (13.1%), b. p. 92–95°, an intermediate fraction, 117 g., b. p. 95–105°, $n^{20}D$ 1.4115–1.4170, and 453 g. of α-isopropylacrolein, b. p. 105–108°, $n^{20}D$ 1.4223, d^{20}_4 0.8389, a yield of 52.6% (based on unrecovered isovaleraldehyde). Because of the unstable nature of the compound a good analysis was difficult to obtain, but a sample which was freshly distilled gave fair results.

Anal. Calcd. for $C_6H_{10}O$: C, 73.43; H, 10.27; *MR*, 29.79. Found: C, 72.92; H, 10.15; *MR*, 29.74.

A 2,4-dinitrophenylhydrazone, prepared according to a standard procedure,[15] melted at 164.5–165°.

Anal. Calcd. for $C_{12}H_{14}O_4N_4$: C, 51.79; H, 5.07. Found: C, 51.92; H, 5.10.

2-Isopropyl-3-hydroxypropionaldehyde.—In a 5-liter, three-necked, round-bottomed flask fitted with a mechanical stirrer, a dropping funnel, and condenser were placed 430 g. (5 moles) of isovaleraldehyde, 1200 g. (16 moles) of a 40% solution of formalin, and 1000 ml. of ethyl ether. Stirring was begun, and 1 liter of a 10% solution of potassium carbonate was added dropwise. After the addition of the alkali (four hours) stirring was continued an additional twenty-hours at room temperature. The organic layer was then separated and the aqueous layer was extracted three times with 300-ml. portions of ethyl ether. The extracts were combined with the original organic layer and the solution dried over anhydrous magnesium sulfate. After removal of the drying agent by filtration and flash distillation of the ether, the residual liquid was distilled through a 6-in., helix-packed column. There was obtained 215 g. of unreacted isovaleraldehyde, and 150 g. (52%) of 2-isopropyl-3-hydroxypropionaldehyde, b. p. 83.5° (9.5 mm.), $n^{20}D$ 1.4603, d^{20}_4 1.0517. A sample of the material was redistilled for analysis.

Anal. Calcd. for $C_6H_{12}O_2$: C, 62.04; H, 10.42; *MR*, 30.45. Found: C, 61.48; H, 10.60; *MR*, 30.05.

An attempt to prepare a 2,4-dinitrophenylhydrazone[15] resulted in yellow plates, m. p. 123–126°, which on recrystallization from ethanol turned red and melted at 158–159°. This melting point is almost that of the derivative for α-isopropylacrolein and a mixture of this product with that known derivative melted at 161–164°. The lack of depression indicated that the present compound had dehydrated on recrystallization.

Benzoate of 2-Isopropyl-3-hydroxypropionaldehyde.—In a 3-liter, three-necked, round-bottomed flask fitted with a mechanical stirrer, a dropping funnel and reflux condenser were placed 214 g. (1.85 moles) of 2-isopropyl-

(15) Shriner and Fuson, "The Systematic Identification of Organic Compounds," 2nd ed., J. Wiley and Sons, Inc., New York, N. Y., 1940, p. 143.

3-hydroxypropionaldehyde and 584 g. (4 moles) of benzoyl chloride. The flask was cooled by means of an ice-bath. To the stirred and cooled mixture was added 1000 ml. of a 10% solution of sodium hydroxide at a rate such that the temperature of the reaction did not exceed 35°. Following the addition of the alkali, stirring was continued for one-half hour. The semi-solid reaction mixture was dissolved in 600 ml. of benzene, and the solution was washed with 10% sodium carbonate solution until the washings were alkaline. The benzene was removed, and the residue was distilled through a 6-in., helix-packed column. The yield of the benzoate was 55 g. (13.5%), b. p. 103° (0.3 mm.), $n^{20}D$ 1.4820. A 2,4-dinitrophenylhydrazone of the material was prepared,[15] m. p. 130.5°.

Anal. Calcd. for $C_{19}H_{20}O_6N_4$: C, 56.99; H, 5.03. Found: C, 56.87; H, 5.06.

α-Isopropylacrolein by Pyrolysis of the Benzoate.—Fifty-five grams (0.25 mole) of the benzoate of 2-isopropyl-3-hydroxypropionaldehyde was passed dropwise through a 19-mm. outside diameter Pyrex tube packed for a distance of 12 in. with 4-mm. glass beads and heated to 575° by means of a combustion furnace. Distillation of the pyrolysate yielded 12 g. (50%) of α-isopropylacrolein, b. p. 108.5°, $n^{20}D$ 1.4223.

α-Isopropylacrolein by Dehydration of the Aldol.—After several preliminary attempts resulted in only polymeric material, a solution of 29 g. (0.25 mole) of 2-isopropyl-3-hydroxypropionaldehyde in 40 ml. of benzene was refluxed with 1.0 g. of iodine. Distillation of the material yielded 4.5 g. of α-isopropylacrolein, b. p. 108.5°, $n^{20}D$ 1.4230 (18%). Attempts to dehydrate the aldol by passing over activated alumina at 350° in a Pyrex tube, and by dropping on fused potassium acid sulfate at 225° produced only polymeric material.

2-Isopropyl-3-hydroxy-1-butene.—In a 5-liter, three-necked, round-bottomed flask fitted with a dropping funnel, a reflux condenser (both connected to calcium chloride drying towers) and a mechanical stirrer were placed 116.5 g. (4.84 moles) of magnesium turnings and 500 ml. of dry ether. A solution of 675 g. (4.84 moles) of methyl iodide in 1200 ml. of absolute ether was added with stirring as rapidly as control of the reaction would permit. After formation of the Grignard complex, a solution of 379 g. (3.87 moles) of α-isopropylacrolein in 1000 ml. of dry ether was added dropwise. After completion of the reaction the mixture was poured onto about 3 kg. of crushed ice. The complex was decomposed with dilute hydrochloric acid, and the ether layer was separated. The aqueous layer was extracted three times with 300-ml. portions of ethyl ether and combined with the original ether layer. After drying the ether solution over anhydrous magnesium sulfate, the drying agent was removed, and the ether was removed by distillation through a 6-in., helix-packed column. Distillation of the residual material through an 18-in., helix-packed column yielded 330.9 g. (75%) of 2-isopropyl-3-hydroxy-1-butene, b. p. 84° (75 mm.), $n^{20}D$ 1.4361, d^{20}_4 0.8473.

Anal. Calcd. for $C_7H_{14}O$: C, 73.63; H, 12.36; *MR*, 35.59. Found: C, 73.60; H, 12.27; *MR*, 34.82.

2-Isopropyl-1,3-butadiene by the Alumina Dehydration of 2-Isopropyl-3-hydroxy-1-butene.—One hundred grams of 2-isopropyl-3-hydroxy-1-butene was passed dropwise through an 18-mm. outside diameter Pyrex tube packed for a distance of 18 in. with 6–8 mesh activated alumina and heated to 250° by means of an electrically heated jacket. The pyrolysate was collected in a 500-ml. suction flask cooled in a Dry Ice–ethanol bath. The product was dried and distilled to yield 25.8 g. (30.4%) of 2-isopropyl-1,3-butadiene, b. p. 85–86°, $n^{20}D$ 1.4340, d^{23}_4 0.723. von Braun and Keller[6] reported b. p. 86–87°, $n^{23}D$ 1.4321, $d^{24.5}_4$ 0.7276. A higher-boiling fraction was also obtained, b. p. 75° (90 mm.), $n^{20}D$ 1.4130. This material is presumably 3,4-dimethylpentanone-2, b. p. 136–138°, which van Romburgh[16] reported b. p. 135–136°, d^{20}_4 0.815.

(16) van Romburgh, *Rec. trav. chim.*, **5**, 228 (1886).

An analogous rearrangement was observed with the corresponding ethyl derivative reported later.

2-Isopropyl-3-acetoxy-1-butene.—In a 125-ml. Erlenmeyer flask was placed a mixture of 28.8 g. (0.25 mole) of 2-isopropyl-3-hydroxy-1-butene, 36 g. (0.35 mole) of acetic anhydride and a few drops of pyridine. The mixture was allowed to stand overnight, washed with three 25-ml. portions of distilled water and distilled through a 6-in., helix-packed column to yield 31.1 g. (0.196 mole) of 2-isopropyl-3-acetoxy-1-butene, b. p. 89° (66 mm.), $n^{20}D$ 1.4256, d^{20}_4 0.8857, a yield of 79%. A sample of this material was redistilled for analysis.

Anal. Calcd. for $C_9H_{16}O_2$: C, 69.19; H, 10.32; *MR*, 44.96. Found: C, 69.09; H, 10.31; *MR*, 45.20.

2-Isopropyl-1,3-butadiene from the Pyrolysis of 2-Isopropyl-3-acetoxy-1-butene.—Pyrolysis of 82.7 g. (0.53 mole) of 2-isopropyl-3-acetoxy-1-butene was accomplished by passing the material dropwise through a 19-mm. Pyrex tube packed for a distance of 12 in. with 4-mm. glass beads and heated to 500° by means of a combustion furnace. Distillation of the washed and dried pyrolysate yielded 11.7 g. (23%) of 2-isopropyl-1,3-butadiene, b. p. 85–87°, $n^{20}D$ 1.4345.

2-Isopropyl-1,3-butanediol.—By the usual Grignard procedure, a solution of methylmagnesium iodide was prepared from 59 g. (0.42 mole) of methyl iodide, 10.0 g. (0.42 atom) of magnesium turnings and 200 ml. of anhydrous ethyl ether. To this solution was added 24 g. (0.21 mole) of 2-isopropyl-3-hydroxypropionaldehyde in 200 ml. of dry ethyl ether. The reaction was fairly violent, presumably because of the consumption of one-half of the Grignard reagent by the hydroxyl group. The complex was decomposed by pouring over ice and acidifying with dilute hydrochloric acid. After extraction of the aqueous layer with three 75-ml. portions of ethyl ether the combined ether extracts were dried over anhydrous magnesium sulfate, the ether was removed and the residue distilled through a 12-in., helix-packed column. There was obtained 20.0 g. (0.151 mole) of 2-isopropyl-1,3-butanediol, b. p. 106° (4 mm.), $n^{20}D$ 1.4528, a yield of 72%. A sample of the diol was redistilled for analysis.

Anal. Calcd. for $C_7H_{16}O_2$: C, 63.59; H, 12.20. Found: C, 63.34; H, 12.37.

2-Isopropyl-1,3-diacetoxybutane.—A mixture of 20.0 g. (0.15 mole) of 2-isopropyl-1,3-butanediol, 45 g. (0.45 mole) of acetic anhydride, and a few drops of pyridine was placed in a 125-ml. Erlenmeyer flask and allowed to stand overnight. The resulting solution was washed with three 10-ml. portions of distilled water, separated and the organic solution was distilled through a 6-in., helix-packed column. There was obtained 25.0 g. (0.116 mole) of 2-isopropyl-1,3-diacetoxybutane, b. p. 127° (24 mm.), $n^{20}D$ 1.4330, d^{20}_4 1.0026, a yield of 77%. A sample of the material was redistilled for analysis.

Anal. Calcd. for $C_{11}H_{20}O_4$: C, 61.08; H, 9.32; *MR*, 56.51. Found: C, 61.21; H, 9.24; *MR*, 56.06.

Pyrolysis of this material in a manner described above for the 2-isopropyl-3-acetoxy-1-butene yielded only 0.5 g. (4.5%) of 2-isopropyl-1,3-butadiene in addition to some higher boiling materials that were not characterized.

α-Ethylacrolein.—In a 5-liter, three-necked, round-bottomed flask fitted with an efficient stirrer, a reflux condenser, and a thermometer were placed 405 g. (5.0 moles) of dimethylamine hydrochloride, 324 g. (4.5 moles) of *n*-butyraldehyde, and 375 g. (5 moles) of 40% formalin. The flask and its contents were heated to 60°, maintained by an electrically heated oil-bath, and stirred for six hours. The condenser was arranged for distillation and the mixture was subjected to steam distillation until organic material no longer separated in the distillate. The organic layer was separated, dried and distilled through an 18-in., helix-packed column. Distillation yielded 280 g. of α-ethylacrolein, b. p. 91–92°, $n^{20}D$ 1.4205, a yield of 73.5%. α-Ethylacrolein has been previously

prepared by Sommelet[17] who heated over oxalic acid the 1,3-diethyl ether of 2-ethylglycerol. It has also been prepared by passing 2-ethylallyl alcohol over zinc oxide at 350°, but again no physical constants were given.[18] A semicarbazone of the material was prepared, m. p. 185.5–186°. Sommelet reported[17] 192.5°. A 2,4-dinitrophenylhydrazone was prepared according to the method of Shriner and Fuson,[15] m. p. 166.5–167°.

Anal. Calcd. for $C_{11}H_{12}O_4N_4$: C, 50.00; H, 4.58. Found: C, 50.06; H, 4.41.

2-Ethyl-3-hydroxy-1-butene.—In a 5-liter, round-bottomed, three-necked flask fitted with a dropping funnel, a reflux condenser (protected from the atmosphere by calcium chloride towers) and a mechanical stirrer, was placed 1000 ml. of a 4 molar solution of methylmagnesium bromide in ether (Arapahoe Chemicals Company). To this was added with stirring a solution of 280 g. (3.3 moles) of α-ethylacrolein in 1500 ml. of absolute ether. An ice collar around the top of the flask permitted relatively rapid addition of the ether solution. The reaction was stirred an additional hour and then poured onto crushed ice. The Grignard complex was decomposed by adding dilute hydrochloric acid until complete solution had been effected. The ether layer was separated and the aqueous layer extracted with two 300-ml. portions of ether. The ether extracts were combined with the original organic layer and dried over anhydrous magnesium sulfate. After removal of the drying agent by filtration, the ether was removed through a 6-in., helix-packed column and the residual liquid distilled through an 18-in., helix-packed, electrically heated column equipped with a total reflux partial take-off head. A total of 282 g. of 2-ethyl-3-hydroxy-1-butene was collected, b. p. 83° (100 mm.), $n^{20}D$ 1.4350, d^{20}_4 0.8491, a yield of 85.5%.

Anal. Calcd. for $C_6H_{12}O$: C, 71.92; H, 12.08; *MR*, 30.97. Found: C, 72.04; H, 11.99; *MR*, 30.77.

2-Ethyl-1,3-butadiene.—Dehydration of 2-ethyl-3-hydroxy-1-butene was accomplished by passing 50.0 g. (0.5 mole) dropwise through a 19-mm. outside diameter Pyrex tube packed for a distance of 18 in. with crystalline potassium acid sulfate and heated to 190–200° by means of an electrically heated jacket. The pyrolysate was collected in a 500-ml. filter flask immersed in a Dry Ice–methanol bath. The product was washed with water, and dried over anhydrous magnesium sulfate and distilled. Distillation yielded 17.5 g. of 2-ethyl-1,3-butadiene, b. p. 72–74°, $n^{20}D$ 1.4488, d^{20}_4 0.7173, a yield of 42.8%.

Anal. Calcd. for C_6H_{10}: C, 87.73; H, 12.27. Found: C, 87.87; H, 12.27.

There was also obtained an 8.0 g. sample of material which did not have the physical constants of the original carbinol. A sample of this material, b. p. 60° (95 mm.), $n^{20}D$ 1.4012, d^{20}_4 0.8130, was redistilled for analysis.

Anal. Calcd. for $C_6H_{12}O$: C, 71.92; H, 12.08. Found: C, 71.36; H, 11.77.

This material discharged bromine in carbon tetrachloride but with much evolution of hydrogen bromide. It reduced potassium permanganate and reacted with the 2,4-dinitrophenylhydrazine reagent. This indicated that it was not the original 2-ethyl-3-hydroxy-1-butene. A 2,4-dinitrophenylhydrazone derivative prepared according to the directions of Shriner and Fuson[15] had a constant melting point of 70–71° after three recrystallizations from 95% ethanol. This corresponds to the 71.2° reported by Drake and Veitch[19] for the derivative of methyl *s*-butyl ketone. A comparison of the physical properties of the unknown with those of this ketone further confirms their identity.

	Unknown	Methyl *s*-butyl ketone
B. p.	60° (95 mm.)	117° (760 mm.)
$n^{20}D$	1.4012	$n^{18}D$ 1.4002
d^{20}_4	0.8130	0.815

α-*n*-Amylacrolein.—In a 5-liter, three-necked, round-bottomed flask fitted with a mechanical stirrer, a thermometer, and a reflux condenser were placed 800 g. (9.9 moles) of dimethylamine hydrochloride, 740 g. (9.9 moles) of 40% formalin, and 855 g. (7.5 moles) of *n*-heptaldehyde. The flask and its contents were heated to 70° and maintained at that temperature by means of an electrically heated oil-bath. Stirring was continued for eighteen hours. The flask was then equipped for steam distillation and the contents were steam-distilled until organic material no longer separated from the distillate. The organic material was separated from the water layer and distilled through an 18-in., helix-packed, electrically heated column. There was obtained 650.5 g. of α-*n*-amylacrolein, b. p. 72° (30 mm.), $n^{20}D$ 1.4373, a yield of 69%. A sample of the material was redistilled for analysis.

Anal. Calcd. for $C_8H_{14}O$: C, 76.14; H, 11.18. Found: C, 76.15; H, 10.90.

A 2,4-dinitrophenylhydrazone prepared according to the directions of Shriner and Fuson[15] had a constant melting point of 134–134.5° after three recrystallizations from 95% ethanol.

Anal. Calcd. for $C_{14}H_{20}O_4N_4$: C, 54.89; H, 5.92. Found: C, 55.20; H, 6.43.

2-*n*-Amyl-3-hydroxy-1-butene.—In a 3-liter, three-necked, round-bottomed flask fitted with a mechanical stirrer, a reflux condenser and a dropping funnel both fitted with calcium chloride towers to exclude moisture, was placed 53 g. (2.2 atoms) of magnesium turnings, and 300 ml. of dry ether. To this was added with stirring a solution of 312 g. (2.2 moles) of methyl iodide in 750 ml. of dry ether. An ice collar around the top of the flask permitted very rapid addition of the methyl iodide solution. The mixture was permitted to stir an additional half-hour after the methyl iodide had been added. To this was then added a solution of 252.4 g. (2.0 moles) of α-*n*-amylacrolein in 700 ml. of dry ether. The mixture was allowed to stir an additional half-hour and was then poured onto about 2 kg. of crushed ice. The complex was decomposed with dilute hydrochloric acid, the ether layer separated, and the aqueous layer extracted three times with 300-ml. portions of ether. The ether extracts were combined with the original ether layer and dried over anhydrous magnesium sulfate. The drying agent was removed by filtration and the ether was removed by distillation through a 12-in., helix-packed column and the residual liquid distilled through an 18-in., helix-packed, electrically heated column. A total of 203.0 g. (71.5%) of 2-*n*-amyl-3-hydroxy-1-butene was collected, b. p. 68° (3 mm.), $n^{20}D$ 1.4448. A sample of the material was redistilled for analysis.

Anal. Calcd. for $C_9H_{18}O$: C, 76.00; H, 12.75. Found: C, 76.14; H, 12.25.

2-*n*-Amyl-1,3-butadiene.—Dehydration of 536.6 g. (3.78 moles) of 2-*n*-amyl-3-hydroxy-1-butene was accomplished by passing the material dropwise over activated alumina in a 19-mm. outside diameter Pyrex tube packed for a distance of 18 in. and heated to 240–250° by means of an electrically heated jacket. The dehydration products were collected in a 500-ml. suction flask cooled in a Dry Ice–methanol-bath. The water layer was separated and the organic material distilled through an 18-in., helix packed column. There was obtained 103 g. (22%) of 2-*n*-amyl-1,3-butadiene, b. p. 148–149°, $n^{20}D$ 1.4510, d^{20}_4 0.7578.

Anal. Calcd. for C_9H_{16}: C, 87.02; H, 12.98. Found: C, 86.94; H, 13.04.

A higher-boiling fraction was obtained which was believed to be 3-methyloctanone-2, by analogy to the reaction that produced methyl *s*-butyl ketone from 2-ethyl-3-hydroxy-1-butene. This compound has been prepared by Powell, Murray and Baldwin[20] who reported b. p. 64–65° (18 mm.), $n^{27}D$ 1.424, d^{27}_4 0.832. The frac-

tion obtained in this work had the constants, b. p. 109° (65 mm.), $n^{20}D$ 1.4269. A 2,4-dinitrophenylhydrazone was prepared which had a constant melting point of 111–112° after two recrystallizations from ethanol.

Anal. Calcd. for $C_{15}H_{22}O_4N_4$: C, 55.88; H, 6.88. Found: C, 55.80; H, 6.90.

Summary

2-Ethyl-, 2-isopropyl- and 2-*n*-amyl-1,3-butadiene have been prepared by a general procedure which can presumably be applied to other 2-alkylbutadienes.

Experiments covering alternate routes to various of the intermediates and final products have been recorded.

The Synthesis of Unsaturated Fatty Acids[1]

BY KAMALLUDIN AHMAD AND F. M. STRONG

Despite the large number of unsaturated fatty acids which occur in the most diverse types of living organisms and their great technical and biological importance, only a very few have been synthesized to date by methods which could be expected to lead to pure products of unequivocal structure.[2] Recent improvements in methods for selectively hydrogenating acetylenes to olefins[3,4,5] and the ease of building up relatively long aliphatic chains by condensing alkyl halides with acetylene or alkyl acetylenes[6] suggested the possibility of obtaining unsaturated fatty acids from acetylenic alkyl halides *via* the nitrile or Grignard reagent:

$$R{-}C{\equiv}C{-}(CH_2)_nX \longrightarrow R{-}C{\equiv}C(CH_2)_n{-}COOH \longrightarrow R{-}CH{=}CH{-}(CH_2)_n{-}COOH$$

It was expected that acetylenic halides of the required type would be formed by reaction of alkyl acetylenes with, for example, bromo- or iodochlorides since acetylene itself readily yields analogous products.[7]

$$RC{\equiv}CH + I(CH_2)_n{-}Cl \xrightarrow{NaNH_2} RC{\equiv}C{-}(CH_2)_nCl$$

The feasibility of this method of synthesis has been tested by the preparation of 6-hendecenoic acid from 1-hexyne and 1-chloro-4-iodobutane according to the scheme

$$CH_3(CH_2)_3{-}C{\equiv}CH + I(CH_2)_4Cl \xrightarrow{NaNH_2} CH_3(CH_2)_3C{\equiv}C{-}(CH_2)_4Cl \xrightarrow[NaOH]{NaCN} CH_3(CH_2)_3C{\equiv}C{-}(CH_2)_4COOH \xrightarrow[Ni]{(H)} CH_3(CH_2)_3CH{=}CH(CH_2)_4COOH$$

The desired product was obtained with no particular difficulty, and the olefinic bond was found by oxidative degradation to be present in the expected position.

Experimental

1-Chloro-4-iodobutane.—Sodium iodide was refluxed in acetone solution with a three-molar proportion of 1,4-dichlorobutane[8] until less than 3% of the iodine remained in the inorganic form (five to six hours). Fractional distillation gave a 71% yield (based on the sodium iodide) of 1-chloro-4-iodobutane, b. p. 93–94.5° (17 mm.), of 94% purity.

Anal. Calcd. for C_4H_8ClI: I, 58.1. Found: I, 54.4.

Since the impurity was most probably unreacted dichlorobutane, the product was used without further purification.

1-Chloro-5-decyne.—A three-liter, three-neck round-bottom flask was fitted with a stirrer, dropping funnel, gas inlet tube, and block tin condenser cooled with a chloroform–Dry Ice mixture. Fifteen-hundred ml. of liquid ammonia was placed in the flask, the stirrer was started, and 0.3 g. of ferric nitrate and 1 g. of sodium were added. Dry air was bubbled through the solution for a few minutes until the blue color was discharged, after which an additional amount of 14.6 g. (0.68 g. atom, total) of sodium was added slowly in small portions. After the reaction had been in progress for thirty minutes, 1 g. of sodium peroxide was added. After two and one-half hours the mixture assumed a dull gray color, and the conversion of the sodium to sodamide was judged to be complete.[9]

An amount of 41 g. (0.50 mole) of 1-hexyne[10] was then introduced dropwise with stirring over a period of two hours, and after an additional interval of three hours, 117 g. (0.54 mole) of 1-chloro-4-iodobutane was added during four hours. Stirring was continued four hours longer, and the mixture was then allowed to stand at room temperature until the ammonia had evaporated. About 150 ml. of water was cautiously added, the mixture filtered, and the organic layer collected in ether. The ether solution was washed free from inorganic halides with water, and fractionally distilled. The main fraction, 45.4 g. (53%), b. p. 143–145° (51 mm.), contained 2.5% of iodine. Redistillation gave 31 g. of iodine-free product, b. p. 110–112° (15 mm.); $n^{25}D$ 1.4592, d^{25}_4 0.9238, *MR* (calcd.) 51.4, *MR* (found) 51.1. The yield of pure product thus amounted to 36%.

Anal. Calcd. for $C_{10}H_{17}Cl$: Cl, 20.53. Found: Cl, 19.6, 20.6.

6-Hendecynoic Acid.—To a solution of 16 g. (0.33 mole) of sodium cyanide in 25 ml. of water were added 115 ml. of 95% ethanol and 25.7 g. (0.15 mole) of 1-chloro-5-decyne. The mixture was refluxed until the bulk of the chloride had been converted to the inorganic

form (fifteen hours), after which 20 g. of sodium hydroxide was added and the refluxing continued overnight. Most of the alcohol was then distilled off, water added, and the alkaline solution extracted with ether. Acidification of the aqueous solution caused the separation of an oily liquid which was collected in ether, and fractionated to give 19 g. of material b. p. 126–150° (0.5 mm.). Since the neutral equivalent was high, the entire fraction was again dissolved in aqueous alkali and extracted with ether to remove neutral impurities. Isolation of the acid fraction as before, followed by distillation gave 10.4 g. (38%), b. p. 124–125° (0.17 mm.); $n^{25}D$ 1.4566, d^{25}_4 0.9537, *MR* (calcd.) 52.5, *MR* (found) 52.1.

Anal. Calcd. for $C_{11}H_{18}O_2$: C, 72.47; H, 9.96; neutral equivalent, 182.3. Found: C, 72.1; H, 9.98; neutral equivalent, 181.5, 182.0.

Quantitative microhydrogenation showed an uptake of 1.98 moles of hydrogen per mole of compound. Calculated, 2.00 moles. The *p*-phenyl phenacyl ester was prepared according to the directions given by Price and Griffith,[11] and after recrystallization from 65% ethanol melted at 58°.

Anal. Calcd. for $C_{25}H_{28}O_3$: C, 79.75; H, 7.49. Found: C, 79.78; H, 7.00.

Hendecanoic Acid.—An amount of 0.9774 g. of the above 6-hendecynoic acid was dissolved in 15 ml. of alcohol, and shaken at room temperature in an atmosphere of hydrogen with 59.8 mg. of platinum oxide catalyst. Absorption of the theoretical amount of hydrogen was complete in fifteen minutes. The catalyst and solvent were removed, and the product crystallized from a small volume of acetone. Colorless crystals, m. p. 28°, were obtained. The m. p. of hendecanoic acid has been reported to be 28.8–29.2°.[12]

Anal. Calcd. for $C_{11}H_{22}O_2$: neutral equivalent, 186.3. Found: neutral equivalent, 186.2, 186.0.

A small sample was converted to the *p*-phenyl phenacyl ester, which was recrystallized from 65% alcohol, and melted at 79.5°. The literature value is 79.5–80°.[11]

6-Hendecenoic Acid.—An alcoholic solution of 4.8 g. of 6-hendecynoic acid was shaken under approximately 3 atmospheres pressure of hydrogen in the presence of Raney W6 nickel catalyst.[13] One molar equivalent of hydrogen was absorbed in a few minutes, and the reduction was then immediately stopped. After removing the catalyst and solvent the product was distilled, and yielded 3.00 g. (62%) of a colorless liquid, b. p. 130–134° (0.15 mm.); $n^{25}D$ 1.4492, d^{25}_4 0.9208, *MR* (calcd.) 54.1, *MR* (found) 53.7.

Anal. Calcd. for $C_{11}H_{20}O_2$: C, 71.68; H, 10.91; neutral equivalent, 184.3. Found: C, 71.3; H, 10.69; neutral equivalent, 185.0.

Quantitative microhydrogenation resulted in the absorption of 0.97 mole of hydrogen per mole of the compound; calculated, 1.00 mole.

The *p*-phenyl phenacyl ester was prepared in the usual way and melted at 41°.

Anal. Calcd. for $C_{25}H_{30}O_3$: C, 79.33; H, 8.04. Found: C, 79.2; H, 8.10.

Oxidative Degradation of 6-Hendecenoic Acid.—One gram of 6-hendecenoic acid was oxidized with dilute alkaline permanganate by the procedure of Lapworth and Mottram.[14] Since the expected dihydroxy acid did not precipitate on acidification of the reaction mixture, the acidic solution was thoroughly extracted with ether. Removal of the ether followed by extraction of the residue with petroleum ether and drying gave 0.31 g. of the crude dihydroxy acid, which was not further purified.

The acidic aqueous solution and petroleum ether washings were combined, evaporated to dryness under reduced pressure, and the residue taken up in absolute alcohol. The solution was neutralized with sodium hydroxide, and the acid present converted to the *p*-phenyl phenacyl ester in the usual way. The recrystallized product melted at 146°. The *bis*-*p*-phenyl phenacyl ester of adipic acid is reported to melt at 148°.[15] A mixed melting point with an authentic specimen showed no depression.

The crude dihydroxy acid (0.31 g.) was dissolved in 5 ml. of anhydrous acetic acid and treated with 0.45 g. of lead tetraacetate. After shaking for twenty minutes at room temperature and five minutes at 45°, the mixture was cooled, diluted with 5 ml. of water, and 0.3 g. of hydroxylamine hydrochloride, 0.3 g. of sodium acetate, and 3–4 drops of methanol were added. The crystals which separated on standing overnight at 7° were filtered, washed with cold, dilute sodium hydroxide solution, then with water and dried. The product melted at 51°. *n*-Valeraldehyde oxime melts at 52°.[16] A mixed melting point with an authentic specimen showed no depression.

Discussion

Suitable selection of the intermediate halides should permit extension of the present synthesis to a wide variety of saturated, olefinic and acetylenic straight and branched chain acids, while reaction of the intermediate acetylenes with aldehydes, ketones or acid halides should result in hydroxy or keto derivatives. A series of straight chain, mono-unsaturated acids is being prepared in this Laboratory.

No effort was made to isolate the two geometrical isomers of 6-hendecenic acid. However, the present synthesis should offer opportunities for obtaining such isomers, since the partial hydrogenation of the acetylenic bond can be stereochemically controlled.[17]

Summary

A convenient and practical synthesis of mono-unsaturated fatty acids has been suggested. Alkyl acetylenes react with iodochlorides to form acetylenic chlorides which in turn, *via* the nitrile or Grignard reaction and subsequent selective hydrogenation of the triple bond, are converted to the mono-unsaturated fatty acids. The method promises to be of general utility for synthesizing a variety of fatty acids and related long chain aliphatic substances.

Quinazolines. V. The Synthesis of 2-(and 3)-*o*-Aminobenzyl-4-quinazolones[1]

BY A. TOMISEK AND BERT E. CHRISTENSEN

During an investigation of the acid hydrolysis of 3-(4′-quinazolyl)-4-quinazolone it became necessary to synthesize both the 2- and 3-*o*-aminobenzylquinazolones.

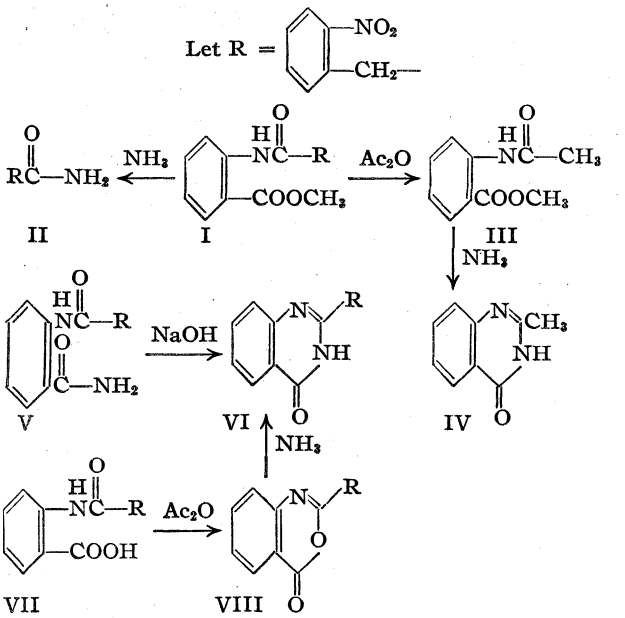
Methyl N-(*o*-nitrophenylacetyl)-anthranilate (I) was prepared as a possible intermediate for the synthesis of the 2-(*o*-aminobenzyl)-4-quinazolone. Weddige,[2] Zacharias,[3] and Thieme[4] had successfully cyclized similar compounds (I) (R = methyl) using ammonia. However, Thieme[4] had reported amide ammonolysis as a side reaction. In this instance (R = nitrobenzyl) (I) the ammonolysis product (*o*-nitrophenylacetamide) (II) was obtained in good yield with no trace of the quinazolone.

Methyl N-(*o*-nitrophenylacetyl)-anthranilate (I) was then refluxed with acetic anhydride in an attempt to prepare the anthranil. The un-isolated product of this reaction was in turn converted to the quinazolone by the use of concentrated ammonia. However, 2-methyl-4-quinazolone (IV) was obtained instead of the desired product, which indicated that transacylation to the methyl acetylanthranilate (III) had preceded the cyclization. Since both mono and diacetyl methyl anthranilate instead of acetanthranil are obtained by the action of acetic anhydride on methyl anthranilate,[5] the course of the above reaction was probably *via* methyl acetylanthranilate (III) and acetylanthranilamide.

The synthesis of the 2-(*o*-nitrobenzyl)-4-quinazolone (VI) was finally accomplished by two methods. N-(*o*-Nitrophenylacetyl)-anthranilamide (V) was prepared by the condensation of anthranilamide with *o*-nitrophenylacetyl chloride and then converted to 2-(*o*-nitrobenzyl)-4-quinazolone (VI) by aqueous base.

N-(*o*-Nitrophenylacetyl)-anthranilic acid (VII) was readily dehydrated to 2-(*o*-nitrobenzyl)-4-keto-3,1,4-benzoxazine (VIII), which in turn was also converted to the desired quinazolone in good yield. This last reaction probably proceeds *via* the anthranilamide (V) since this intermediate has been isolated in certain analogous cases.[6]

The synthesis of 3-(*o*-nitrobenzyl)-4-quinazolone was based upon the work of Bogert and Geiger,[7] in which it was shown that the N-alkylation of sodium 4-quinazolonate could be carried out with benzyl chloride. The extent of O-alkylation involved in the benzylation has been determined, but the precaution was taken to destroy by acid hydrolysis any O-ether which may have formed.



Experimental[8]

Methyl N-(*o*-Nitrophenylacetyl)-anthranilate (I).—A benzene solution of O-nitrophenylacetyl chloride, prepared with thionyl chloride from 5 g. of the acid,[9] was added to a dry benzene solution containing 4 ml. of methyl anthranilate. To this mixture was added gradually with stirring 40 ml. of 25% potassium hydroxide.

After washing the *warm* benzene solution with acid and then removing the solvent, the residue was dissolved in hot acetone, decolorized with charcoal, cooled and crystallized. The yield was 6.0 g. (69%), m. p. 131–133°. Recrystallization from alcohol or acetone gave white crystals, m. p. 133.5–134°.

Anal. Calcd. for $C_{16}H_{14}N_2O_5$: C, 61.1; H, 4.49; N, 8.92. Found: C, 61.3; H, 4.64; N, 8.92.

Methyl N-(*o*-nitrophenylacetyl)-anthranilate (I) was heated in a bomb with absolute alcoholic ammonia for eight hours at 180°. A good yield of *o*-nitrophenylacetamide (II) was obtained in place of a cyclized product.

One gram of methyl N-(*o*-nitrophenylacetyl)-anthranilate (I) was refluxed for fifteen hours in 4 ml. of acetic anhydride. The reaction mixture was added cautiously to an excess of hot 14% ammonia, containing a few drops of 10% potassium hydroxide. The mixture was heated on the steam-bath for one hour, and then refluxed with an excess of potassium hydroxide to destroy the acetamide. The cooled, filtered solution was brought to neutrality with hydrochloric acid. After standing two days, 0.14 g. of crude 2-methyl-4-quinazolone (IV) crystallized. This material was recrystallized from alcohol and identified by a mixed melting point test.

N-(*o*-Nitrophenylacetyl)-anthranilamide (V).—A dioxane solution of *o*-nitrophenylacetyl chloride prepared from 5 g. of the acid was added to 50 ml. of a dioxane solution, containing 7.6 g. of anthranilamide.[10]

After several hours the precipitate was removed, triturated with water, refiltered and thoroughly dried. Additional product was obtained by concentrating the dioxane solution. The combined fractions were decolorized and recrystallized from hot pyridine–benzene solution, yield, 6.06 g. (73%), m. p. 167–170°. Recrystallization from pyridine–benzene and pyridine–water gave product with m. p. 172–173°.

Anal. Calcd. for $C_{15}H_{13}N_3O_4$: C, 60.2; H, 4.38; N, 14.04. Found: C, 59.9; H, 4.64; N, 14.24.

2-(*o*-Nitrobenzyl-4-quinazolone (VI) from Nitrophenylacetylanthranilamide.—A mixture consisting of 3.46 g. of N-(*o*-nitrophenylacetyl)-anthranilamide (V), 12 ml. of pyridine, 12 ml. of water and 1 ml. of 10% sodium hydroxide after standing for one day at room temperature was made more basic by the addition of 75 ml. of 10% sodium hydroxide. The solution was then filtered and the crude product isolated by neutralizing the filtrate. The precipitate was extracted with boiling glacial acetic acid from which it crystallized on cooling; yield 2.85 g. (88%) of 2-(*o*-nitrobenzyl)-4-quinazolone, (VI). The product recrystallized from glacial acetic acid and pyridine–water for analytical purposes was white granular crystals, m. p. (dec.) 254.5°.

Anal. Calcd. for $C_{15}H_{11}N_3O_3$: C, 64.05; H, 3.94; N, 14.94. Found: C, 64.15; H, 3.73; N, 14.76.

N-(*o*-Nitrophenylacetyl)-anthranilic Acid (VII).—A dioxane solution of *o*-nitrophenylacetyl chloride prepared from 5 g. of the acid was mixed with 50 ml. of dioxane solution containing 20 g. of anthranilic acid. After several hours the crude N-(*o*-nitrophenylacetyl)-anthranilic acid (VII) was removed by filtration, triturated with water and then recrystallized from glacial acetic acid. A second fraction was obtained by dissolving the residue left after evaporation of the mother liquor in dilute sodium hydroxide and then reprecipitating the product with hydrochloric acid, recrystallizing it from glacial acetic acid and dioxane–water. The yield was 82% (4.9 and 1.9 g.). This combined yield, recrystallized again, melted with slow evolution of gas, m. p. 224–225°.

Anal. Calcd. for $C_{15}H_{12}N_2O_5$: C, 60.0; H, 4.03; N, 9.33. Found: C, 60.1; H, 4.02; N, 9.03.

2-(*o*-Nitrobenzyl-4-keto-3,1,4-benzoxazine (VIII).—Five grams of N-(*o*-nitrophenylacetyl)-anthranilic acid (VII) was refluxed for thirty minutes in 20 ml. of pure acetic anhydride. Four and four-tenths grams of 2-(*o*-nitrobenzyl)-4-keto-3,1,4-benzoxazine (VIII) crystallized from the cooled and seeded solution, m. p. 162–164°. This product when recrystallized from pyridine–water, alcohol, then pyridine–alcohol gave white plates, m. p. 165–166°.

Anal. Calcd. for $C_{15}H_{10}N_2O_4$: C, 63.8; H, 3.57; N, 9.92. Found: C, 63.6; H, 3.85; N, 10.10.

2-(*o*-Nitrobenzyl-4-quinazolone (VI) from Nitrobenzylbenzoxazone.—A suspension of 5 g. of 2-(*o*-nitrobenzyl)-4-keto-3,1,4-benzoxazine (VIII) in 25 ml. of 50% pyridine was saturated with ammonia and allowed to stand with occasional stirring for six hours. One milliliter of 10% sodium hydroxide was then added and the mixture was set aside for an additional twenty-four hours. Isolation procedure was the same as for the synthesis from the anthranilamide; yield 3.6 g. (72%).

2-(*o*-Aminobenzyl)-4-quinazolone.—To a suspension of 5 g. of 2-(*o*-nitrobenzyl)-4-quinazolone in 300 ml. of dilute sodium hydroxide was added a solution containing 33 g. (10% excess) of hydrated ferrous sulfate in 100 ml. of water. The reaction mixture was maintained at 80° for seven hours. The ferrous–ferric hydroxides were separated by centrifuging and washed repeatedly with dilute sodium hydroxide until the wash liquors gave no further precipitate upon neutralization. Combined precipitates obtained by the neutralization of the washings and the mother liquor were decolorized with charcoal and recrystallized from pyridine–water. The yield of 2-(*o*-aminobenzyl)-4-quinazolone was 3.68 g. (80%). It was recrystallized for analysis from dioxane and dioxane–water; the white, voluminous powder melted (decomposition) over a wide range, starting at about 250°.

Anal. Calcd. for $C_{15}H_{13}N_3O$: C, 71.7; H, 5.21; N, 16.72. Found: C, 71.4; H, 5.32; N, 16.58.

2-(*o*-Acetaminobenzyl)-4-quinazolone.—The corresponding amino compound (1.0 g.) was acylated in the usual manner. The product was recrystallized from pyridine–water, and acetic acid–water, to yield white needles of m. p. 258°.

Anal. Calcd. for $C_{17}H_{15}N_3O_2$: N, 14.33; Found: N, 14.52.

3-(*o*-Nitrobenzyl)-4-quinazolone.—To an aqueous solution containing ten grams of *o*-nitrobenzyl chloride, prepared according to the directions of Haeussermann and Beck[11] was added 13 g. of 4-hydroxyquinazolone and 5.9 g. of 85% potassium hydroxide pellets and 200 ml. of alcohol.

After refluxing for six hours the alcoholic solvent was removed and replaced with a mixture of dilute hydrochloric acid and benzene. This mixture was refluxed for fifteen minutes to hydrolyze any benzyl quinazolyl ether. The benzene layer was then separated and thoroughly extracted with 3 *N* hydrochloric acid. The combined fractions were treated with an excess of sodium hydroxide and the crude product (3 g.) separated by filtration. After decolorizing with charcoal the product was recrystallized from benzene, pyridine–water and acetic acid–water to yield a pure white product m. p. 169–170°.

Anal. Calcd. for $C_{15}H_{11}N_3O_3$: C, 64.1; H, 3.94; N, 14.94. Found: C, 64.3; H, 4.12; N, 14.96.

3-(*o*-Aminobenzyl)-4-quinazolone.—A uniform suspension of 2.83 g. of 3-(*o*-nitrobenzyl)-4-quinazolone and 7.27 g. of stannous chloride dihydrate in 30 ml. of glacial acetic acid was prepared. The mixture was saturated with dry hydrogen chloride and allowed to stand for ten hours. The gummy precipitate which formed was dispersed by two or three minutes of gentle heating and the mixture was then poured into water. The aqueous suspension was made strongly basic with sodium hydroxide and filtered. The precipitate was extracted with boiling pyridine, and water was added to complete a crystallization from pyridine–water. The 1.62 g. (64%) of crude, white plates were decolorized with charcoal and recrystallized from alcohol, dioxane–water and pyridine, m. p. 178°.

Anal. Calcd. for $C_{15}H_{13}N_3O$: C, 71.7; H, 5.21; N, 16.72. Found: C, 71.5; H, 5.39; N, 16.69.

Summary

2-(*o*-Nitrobenzyl)-4-quinazolone was prepared by (1) the cyclization of N-(*o*-nitrophenylacetyl)-anthranilamide and (2) by ammonolysis of 2-(*o*-nitrobenzyl-4-keto-3,1,4-benzoxazine.

3-(*o*-Nitrobenzyl)-4-quinazolone was prepared by the reaction of *o*-nitrobenzyl chloride and sodium 4-quinazolonate.

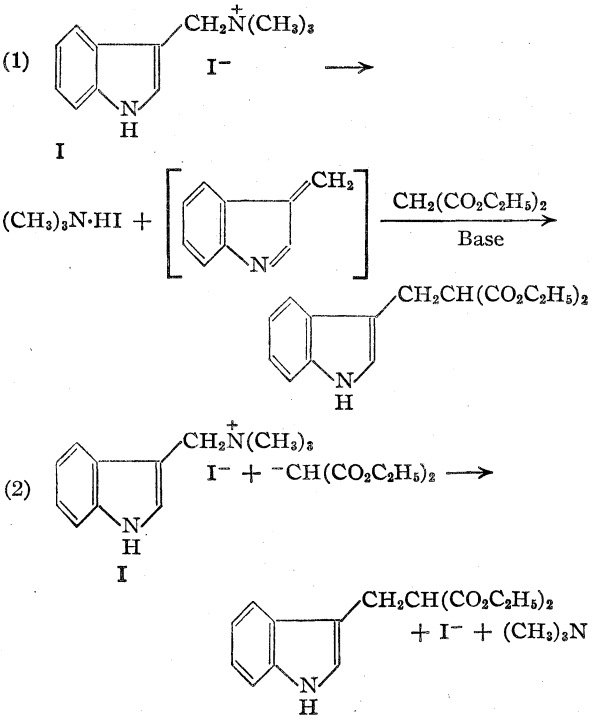
An Alkylation with the Methiodide of 1-Methyl-3-dimethylaminomethylindole (1-Methylgramine)[1]

BY H. R. SNYDER AND ERNEST L. ELIEL

Alkylations with gramine[1,2] and its quaternary salts[3] proceed with such ease as to suggest that the mechanisms of the reactions differ from those of alkylations with simple amines and quaternary salts containing a radical of the benzyl type. Two possible mechanisms for reactions with gramine methiodide are shown in equations 1 and 2. The first, consisting in the elimination of trimethylamine hydriodide and a Michael-type addition, is patterned after that suggested by Mannich[4] for alkylations with salts from ketonic Mannich bases.



In the second mechanism it is assumed that the trimethylamine molecule is displaced from the quaternary ammonium ion by the anion of the substance being alkylated. Mechanisms similar to 1 and 2 can be written for reactions of the tertiary amine, gramine.

A consideration of the two mechanisms suggested that reactions of 1-methylgramine (III) and its quaternary salt (IV) be examined. This paper reports the preparation of these two substances and the reaction of the quaternary salt (IV) with aqueous sodium cyanide.

Application of the Mannich reaction to 1-methylindole[5] (II) gave the methylgramine (III) in about 80% yield. The methiodide (IV), obtained in nearly quantitative yield from the base and methyl iodide in ethanol, reacted readily with aqueous sodium cyanide. The expected 1-methylindoleacetonitrile (V) was obtained in about 50% yield, along with a much smaller amount of a more volatile isomer. The structure of this isomeric product is under investigation.

In the proof of the structure of the nitrile (V) the acid (VI) was prepared by hydrolysis. The product obtained melted slightly lower than that described in the literature,[6,7] and its picrate melted about twelve degrees lower than that previously reported.[6] However, reduction of the nitrile with sodium and ethanol gave 1-methyltryptamine (VIII), several derivatives of which had melting points identical with previously reported values. Also, 1,3-dimethylindole (VII) was produced in small quantity in the sodium–alcohol reduction,[8] and it proved to be identical with an authentic specimen made from skatyl sodium and methyl iodide. Decarboxylation of the acid produced the same 1,3-dimethylindole. The various samples of the dimethylindole were compared as pic-

rates by the aid of melting points, mixed melting points, and infrared absorption analyses[9] (see the figure). These observations prove that the methylindoleacetic acid obtained by hydrolysis of the nitrile had the structure VI.

The formation of the nitrile (V) from IV and sodium cyanide in water solution shows that the salt (IV), like gramine methiodide (I), is more reactive than simple quaternary salts containing benzyl groups. For example, benzylphenyldimethylammonium chloride is not cleaved by aqueous sodium cyanide.[3] It is probable that alkylations with gramine methiodide and the methylgramine methiodide proceed by the same mechanism, and that reactions of gramine methiodide do not proceed through a process of the Michael type (equation 1). The study of this problem is being continued.

Experimental[10,11]

1-Methylindole (II), prepared from N-methylphenylhydrazine and pyruvic acid by the method of Fischer and Hess[12] boiled at 134–135° (31 mm.) and had n^{20}D 1.6062. Material prepared by the methylation of the sodium derivative of indole with methyl iodide[13] was unsatisfactory owing to contamination by –N–H compounds, the presence of which was revealed by infrared absorption analysis.

1-Methyl-3-dimethylaminomethylindole (III).—A mixture of 36 ml. of 25% aqueous dimethylamine and 40 ml. of glacial acetic acid was cooled in an ice-bath; when the temperature had fallen to 5°, 15 ml. of 40% aqueous formaldehyde was added. The resulting mixture was cooled to 5° and added in one lot to 23.7 g. of N-methylindole. The reaction mixture was shaken gently until it became homogeneous; during the shaking the temperature rose to about 50°. The mixture then was allowed to stand at room temperature for twenty-four hours. The reaction mixture was poured into a solution of 40 g. of sodium hydroxide in 400 ml. of water, and the oil which separated was collected by extraction with one 300-ml. portion and one 200-ml. portion of ether. The ether extracts were washed exhaustively with 1 *N* hydrochloric acid (until the extracts no longer became turbid when made alkaline), about 500 ml. of the acid being required. The combined acid extract was made alkaline by the addition of an excess of 10% sodium hydroxide solution. The liberated base was collected by extraction with two 200-ml. portions of ether. The ether extract was washed, dried, and concentrated, and the residue distilled *in vacuo*. The main fraction, collected at 94–97° (0.2 mm.), weighed 26.3–26.9 g. (77.5–79.3% yield). The analytical sample was redistilled; b. p. 94–96° (0.2 mm.); n^{20}D 1.5743.

Anal. Calcd. for $C_{12}H_{16}N_2$: C, 76.52; H, 8.57. Found: C, 76.64; H, 8.62.

The **picrate** crystallized from alcohol as yellow prisms melting at 145–146°.

Anal. Calcd. for $C_{18}H_{19}N_5O_7$: C, 51.81; H, 4.59. Found: C, 52.05; H, 4.55.

1-Methyl-3-dimethylaminomethylindole Methiodide (IV).—To a solution of 8.5 g. of the base (III) in 40 ml. of absolute ethanol was added in one portion 7.8 g. of methyl iodide. An exothermic reaction occurred, so the mixture was cooled to prevent the loss of methyl iodide. The mixture was allowed to stand for one hour at room temperature, during which period most of the product crystallized. Crystallization was completed by cooling, and the solid was collected and washed twice with absolute ethanol and thrice with anhydrous ether. After drying under nitrogen the salt weighed 14.3–14.6 g. (96–98%); the instantaneous decomposition point, determined on a Maquenne block, was 193°. The analytical sample, recrystallized three times from absolute ethanol, decomposed at 195°.

Anal. Calcd. for $C_{13}H_{19}N_2I$: C, 47.28; H, 5.84; N, 8.43. Found: C, 47.37; H, 5.84; N, 8.51.

1-Methylindole-3-acetonitrile (V).—To a solution of 10 g. of sodium cyanide in 100 ml. of water was added 16.5 g. of the crude methiodide (IV) and the mixture was boiled under reflux for two and one-fourth hours, during which period an oil separated from the aqueous solution and a solid appeared in the condenser. The oil and solid were collected from the cooled mixture by extraction with two 50-ml. portions of ether. The ether solution was washed three times with water, dried over sodium sulfate, filtered, and concentrated; the residue was distilled *in*

(9) The authors are indebted to Mrs. Agatha Roberts Johnson for the absorption studies.

(10) All melting points are corrected.

(11) Microanalyses by Miss Theta Spoor and Miss Betty A. Snyder.

vacuo. A small fraction (*ca.* 0.6 g.), which solidified in the receiver, was collected at 96–122° (0.15 mm.); it melted at 70–71° after three recrystallizations from petroleum ether (b. p. 30–60°). The main fraction, b. p. 123–131° (0.15 mm.), weighed 5.2–5.4 g. (60–64%); it solidified after standing in the ice-box and melted at 58–59° after an extraction with petroleum ether followed by two recrystallizations from a mixture of ether and petroleum ether (b. p. 30–60°).

Anal. Calcd. for $C_{11}H_{10}N_2$: C, 77.62; H, 5.92. Found: (higher-melting product) C, 77.54; H, 6.16; (lower-melting product) C, 77.89; H, 5.95.

1-Methylindole-3-acetic Acid (VI).—A mixture of 2 g. of the lower-melting nitrile (V) with a solution of 5 g. of potassium hydroxide, 5 ml. of water, and 20 ml. of 95% ethanol was refluxed for seventeen hours. The solution was diluted with 50 ml. of water and distilled to remove most of the alcohol. The resulting clear solution was extracted three times with ether, heated with Norit, and filtered. The filtrate was very cautiously acidified with 3 *N* hydrochloric acid, and the first (dark-colored) solid which separated was removed by filtration. The acid (VI) was precipitated by acidification of the filtrate to congo red paper. It was collected on a filter, washed with ice-water, and dried in a vacuum desiccator. The material so obtained was a nearly white solid melting at 127–128.5°; wt. 2 g. (90%). Recrystallization from benzene improved the color but had no effect on the melting point; recrystallization from water and high-vacuum sublimation likewise had no effect on the melting point.

Anal. Calcd. for $C_{11}H_{11}NO_2$: C, 69.81; H, 5.86; N, 7.40. Found: C, 70.03; H, 5.99; N, 7.41.

The **picrate** crystallized from benzene as red needles melting at 160.5–161.5°.

Anal. Calcd. for $C_{17}H_{14}N_4O_9$: C, 48.81; H, 3.37. Found: C, 48.91; H, 3.49.

1,3-Dimethylindole: From VI.—In the lower bulb of a two-bulb microdistillation apparatus 0.55 g. of the acid (VI) was heated at 200° until gas evolution ceased. The resulting brown oil was distilled into the upper bulb at 20 mm., with the bath temperature at 140–170°. The light-colored distillate ($n^{20}D$ 1.5920) was converted to the picrate which, after two recrystallizations from absolute ethanol, melted at 142.5–143.5° (lit., 143–144°).

From Skatole.—A modification of the method of Weissgerber[13] was employed. The product was fractionated at atmospheric pressure and the portion boiling at 220–240° was redistilled over sodium. The distillate from this treatment was fractionated *in vacuo* and the fraction boiling at 122–127° (20 mm.) was collected; $n^{20}D$ 1.5901. Infrared absorption analysis of this material showed the presence of appreciable amounts of —NH— compounds. The **picrate** obtained from this fraction melted at 141–142° after five recrystallizations from absolute ethanol, and the melting point was not changed by admixture of the picrate described in the previous paragraph.

1-Methyltryptamine (VIII).—To a hot solution of 3.4 g. of the nitrile (V) in 60 ml. of absolute ethanol was added, over a period of ten minutes, 4 g. of finely cut sodium. The mixture was refluxed until all the metal had dissolved; it was then diluted with 60 ml. of water and concentrated *in vacuo* to remove most of the alcohol. The residual solution was diluted with 40 ml. of water and extracted with two 100-ml. portions of ether. The base (*ca.* 2.4 g.) was recovered from the ether solution by extraction with 2 *N* hydrochloric acid (*ca.* 75 ml.), neutralization of the acid with an excess of aqueous sodium hydroxide, extraction of the alkaline solution with ether, drying of the ether solution, removal of the solvent, and distillation of the residue. It was obtained as a nearly colorless oil boiling at 108–110° at about 0.1 mm. The picrate melted at 178–179° (lit.[14] 180–181°), the hydrochloride at 199–201° (lit.[15] 198°), and the phthalimide at 176.5–177° (lit.[15] 177.5°).

The ether extract of the reaction mixture, after the extraction with 2 *N* hydrochloric acid described above, was concentrated. The resulting oil, wt. about 1.2 g., was distilled from a modified test-tube at about 0.1 mm. Two fractions, approximately equal in weight, were obtained, one boiling at a bath temperature of 90–100° and the other at 140–170°. The first fraction was identified as 1,3-dimethylindole by conversion to the picrate, m. p. 142–143°; the melting point of this picrate was not depressed by admixture with either of the samples described above, and its infrared absorption curve was identical with that shown in the figure. The higher-boiling fraction crystallized when seeded and was identified as 1-methylindole-3-acetonitrile by mixed melting point.

Summary

1-Methylindole reacts with formaldehyde and dimethylamine in the presence of acetic acid to give 1-methyl-3-dimethylaminomethylindole in good yield. The methiodide of this base reacts readily with aqueous sodium cyanide to give 1-methylindole-3-acetonitrile, along with a small amount of an isomeric substance. The structure of 1-methylindole-3-acetonitrile is proved by hydrolysis to 1-methylindole-3-acetic acid and by reduction to 1-methyltryptamine and 1,3-dimethylindole. The methiodide of 1-methyl-3-dimethylaminomethylindole and the methiodide of gramine (3-dimethylaminomethylindole) are more reactive as alkylating agents than simple quaternary ammonium salts containing benzyl groups.

The Preparation of Substituted Tricyclohexylgermanes

BY O. H. JOHNSON AND W. H. NEBERGALL

Generally the use of an excess of Grignard reagent on germanium tetrachloride yields tetrasubstituted germanium compounds. Bauer and Burschkies,[1] using the conventional Grignard reaction, found that the action of an excess of cyclohexylmagnesium bromide on germanium tetrachloride resulted solely in bromotricyclohexylgermane, apparently according to the reaction

$$3C_6H_{11}MgBr + GeCl_4 \longrightarrow (C_6H_{11})_3GeBr + MgBr_2 + 2MgCl_2$$

The results reported by Bauer and Burschkies led us to determine whether other groups could be substituted for bromine in the tricyclohexylgermanium compound. Accordingly we have prepared a number of new compounds by means of the reaction of bromotricyclohexylgermane with various Grignard reagents and with sodium metal.

Bromotricyclohexylgermane was prepared from cyclohexyl bromide and germanium tetrachloride[2] by the method of Bauer and Burschkies. The substituent groups for the bromine atom in the bromotricyclohexylgermane were introduced by forming Grignard reagents in the usual manner with the appropriate alkyl or aryl halide and adding the bromotricyclohexylgermane in dry benzene

$$RMgBr + (C_6H_{11})_3GeBr \longrightarrow (C_6H_{11})_3GeR + MgBr_2$$

The reaction between bromotricyclohexylgermane and methyl-, ethyl-, *n*-propyl-, *n*-butyl-, *n*-amyl-, and benzylmagnesium bromides proceeded smoothly. It was found that the isopropyl, the phenyl and the cyclohexylmagnesium bromides did not react under the conditions that gave good yields of the *n*-alkyl and benzyl compounds. Failure to introduce the isopropyl, phenyl and cyclohexyl groups may be due to possible steric effects.

Formation of hexacyclohexyldigermane by the Wurtz synthesis using sodium metal and bromotricyclohexylgermane was successful.

Experimental

Substituted Germanes.—Grignard reagent was prepared by treating 0.264 mole of alkyl bromide with 0.270 mole of magnesium in 200 ml. of absolute ether. To this mixture was added 0.032 mole of bromotricyclohexylgermane dissolved in 100 ml. of dry benzene. The ether was removed by distillation and the reaction mixture refluxed on the steam-bath for three hours. The excess Grignard was destroyed by dilute acetic acid. The aqueous and the organic layers were separated and the aqueous layer extracted twice with 50 ml. of benzene. The benzene solution was dried over anhydrous calcium chloride and the benzene removed by distillation, leaving an oily liquid. This residual oily liquid was dissolved in boiling absolute ethanol and upon cooling the substituted tricyclohexylgermane precipitated as fine white crystals. The product was purified by recrystallizing four times from absolute ethanol.

Substituted Digermane.—An excess of sodium was added to a solution of 5.5 g. of bromotricyclohexylgermane in 75 ml. of dry toluene and refluxed for two hours. The hot mixture was filtered, allowed to cool and about one-half of the toluene removed by air evaporation by an electric fan. The cooling and the evaporation of the solvent were accompanied by the precipitation of white crystals. These crystals were filtered off, washed with dry toluene, and dried in a pistol for two hours using toluene for a refluxing agent. The analysis indicated that it was hexacyclohexyldigermane, m. p., d. *ca.* 316°; yield, 85%.

Anal. Calcd.: C, 67.31; H, 10.33; Ge, 22.54. Found: C, 67.15; H, 10.59; Ge, 22.49.

Comments on Analytical Procedure.—The standard microcombustion method for determining carbon and hydrogen gave consistently low values for carbon. The cause of these low results is believed to be the formation of germanium carbides which resisted oxidation. To minimize this factor the procedure was modified[3] by increasing the volume of oxygen to 150 ml. for a period of thirty minutes followed by a current of air for another thirty minutes, the heating being continued for twenty minutes after the oxygen was discontinued. The platinum boat was placed as close to the furnace as possible to limit the area to be heated.

Germanium was determined as the dioxide by an adaptation of the method of Bauer and Burschkies.[1] A sample of 0.05 to 0.07 g. weight was heated in a platinum crucible over a steam bath for an hour with a mixture of three parts fuming nitric acid and one part concentrated sulfuric acid. The crucible and mixture were then heated on an electric hot-plate until a brown color appeared. More fuming nitric acid was added from time to time and the process repeated several times until a white residue remained upon evaporation. The residue was ignited and weighed as germanium dioxide.

Results.—Table I gives the results of the analyses and the melting points of the compounds prepared.

(1) Bauer and Burschkies, *Ber.*, **65B**, 956 (1932).

(2) Obtained from Research Department, Eagle-Picher Co., Joplin, Mo.

(3) As suggested by R. W. Amidon who made the analyses for carbon and hydrogen.

Solubility.—The compounds prepared were found to be insoluble in water, slightly soluble in acetone and cold ethanol and soluble in ether, benzene, toluene, chloroform, petroleum ether and hot ethanol.

Summary

1. Seven new compounds of germanium, methyl-, ethyl-, *n*-propyl-, *n*-butyl-, *n*-amyl- and benzyltricyclohexylgermane, and hexacyclohexyldigermane have been prepared and some properties described.

2. Possible steric effects were encountered in attempts to introduce the isopropyl, the phenyl and the cyclohexyl group as the fourth group into tricyclohexylgermane.

3. Hexacyclohexyldigermane was prepared from bromotricyclohexylgermane by the Wurtz synthesis.

Properties of Electrolytic Solutions. XXXII. Conductance of Some Long Chain Salts in Ethylene Chloride and Nitrobenzene at 25°[1]

BY HAROLD E. WEAVER[2] AND CHARLES A. KRAUS

I. Introduction

Conductance measurements with aqueous solutions[3] of salts containing hydrocarbon chains of progressively increasing length indicate that the characteristic effect—ascribed to micelle formation—first becomes noticeable with the *n*-nonyl group. In order to determine whether similar effects occur in solutions of such electrolytes in non-aqueous solvents, measurements were carried out with several salts in ethylene chloride and nitrobenzene. At the time that this investigation was initiated, no data were available on the conductance of long chain salts in solvents other than water; in the meantime, however, results of measurements by several investigators have appeared.[4]

The following salts have been studied: octadecyltrimethylammonium and octadecyltributylammonium nitrates in ethylene chloride and dioctadecyldimethylammonium, octadecyltributylammonium and octadecylpyridonium nitrates in nitrobenzene. The octadecyl salts are well adapted to the purpose of the present investigation since octadecyl alcohol of high purity is readily available and the quaternary salts are readily crystallized from a variety of solvents.

II. Experimental

Apparatus and Procedure.—These have been fully described in earlier papers of this series. Bright platinum electrodes were used.

Materials.—Ethylene chloride was purified according to the method described by Mead.[5] The specific conductance was always less than 5×10^{-11}, making solvent corrections unnecessary.

Nitrobenzene was purified as described by Witschonke.[6] The specific conductance of the material was less than 5×10^{-10} so that corrections were unnecessary.

n-Octadecyl alcohol served as the starting material in the preparation of the salts used in this investigation. One recrystallization of the alcohol from nitromethane gave a product which melted at 57.5–58.5°.

n-Octadecyl iodide was obtained by heating the alcohol with iodine and red phosphorus in a sealed tube at 180° for one hour according to the method of Levene, West and van der Scheer.[7] The resulting mixture was extracted with hexane, in which the iodide is very soluble; the excess phosphorus was separated by filtration. The *n*-octadecyl iodide was recrystallized from hexane by slow cooling to 0° in a refrigerator; m. p., 34–35°.

n-Octadecyltri-*n*-butylammonium iodide was prepared by heating *n*-octadecyl iodide with tri-*n*-butylamine (10% excess) in a stoppered flask at 60° for from four to six days. The salt was recrystallized from hexane containing a trace of alcohol; m. p., 97–98°.

n-Octadecyltrimethylammonium iodide was prepared by heating *n*-octadecyl iodide with trimethylamine (20% excess) in a water–alcohol solution in a sealed tube at 60° for from a week to ten days. The salt was recrystallized from hexane containing 3–5% of alcohol; m. p., 234.5–236°.

n-Octadecylpyridonium iodide was prepared by heating *n*-octadecyl iodide with excess pyridine for from twelve to eighteen hours at 60° in a stoppered flask. The excess pyridine was evaporated and the salt was recrystallized from hexane containing a trace of alcohol; m. p., 101.5–103°.

Di-*n*-octadecyldimethylammonium iodide was prepared by Dr. E. C. Evers by heating *n*-octadecyl iodide with excess dimethylamine in water–alcohol solution. The product was recrystallized from hexane containing a trace of alcohol; m. p., 154°.

The corresponding nitrates were obtained from the iodides by metathesis with silver nitrate in an alcohol–water mixture containing 75% alcohol. As a rule, several hours of digestion at 60° were required to coagulate the colloidal silver iodide. Care was exercised to avoid peptization of the coagulated silver iodide on filtration. The solutions were evaporated to dryness and the salts redissolved and crystallized from suitable solvents.

Di-*n*-octadecyldimethylammonium nitrate is very soluble in pure hexane but crystallizes on cooling to Dry Ice temperatures; m. p., 79–81°.

(6) Witschonke and Kraus, THIS JOURNAL, **69**, 2472 (1947).

(7) Levene, West and van der Scheer, *J. Biol. Chem.*, **20**, 525 (1915).

The other nitrates were recrystallized from hexane containing alcohol in amounts varying from a trace for the *n*-octadecylpyridonium and *n*-octadecyltri-*n*-butylammonium salts to two or three per cent. for *n*-octadecyltrimethylammonium nitrate. The solutions were cooled to 0° in a refrigerator. The melting points were: *n*-octadecyltrimethylammonium nitrate—softens at 170°—melts to a clear liquid at 190°; *n*-octadecyltri-*n*-butylammonium nitrate, 90–91°; *n*-octadecylpyridonium nitrate, 71–73°.

It may be noted that accurate observation of the melting point of long chain salts is often difficult because of gradual changes in the crystalline structure. In addition, pronounced shrinkage occurs between 90 and 100° and in some cases this extends as far as the actual melting point.

III. Results

Values of the equivalent conductance, Λ, and the concentration, *C*, in moles per liter of solution, are presented in Tables I and II. In Table I are given the results in ethylene chloride solution; the densities of the solutions have been taken as that of the pure solvent, 1.2455.[8] In Table II are given the results for nitrobenzene solutions; the densities of the solutions have been taken as 1.1986,[9] the value for pure nitrobenzene. All measurements were at 25 ± 0.01°. Although two series of measurements were made with each salt, with one exception, results from only one of these are reported here; the additional determinations, however, are shown on the plots.

TABLE I

CONDUCTANCE OF LONG CHAIN SALTS IN ETHYLENE CHLORIDE

n-Octadecyltri-*n*-butylammonium nitrate		*n*-Octadecyltrimethylammonium nitrate	
$C \times 10^5$	Λ	$C \times 10^5$	Λ
118.8	20.31	65.73	10.68
35.86	28.86	34.06	13.90
7.989	41.26	11.79	20.93

IV. Discussion

1. Ethylene Chloride.—The conductance data for ethylene chloride solutions have been analyzed by the method of Fuoss. The results are shown graphically in Fig. 1; values of Λ_0 and *K* for each salt are presented in Table III. Solutions of long chain salts begin to show deviations from the theoretical at concentrations of approximately 1.5×10^{-4} *N*.

TABLE III

CONSTANTS OF SOME LONG CHAIN ELECTROLYTES IN ETHYLENE CHLORIDE

Salt	Λ_0	Λ_0^+	$K \times 10^4$
$(n\text{-}C_{18}H_{37})(CH_3)_3NNO_3$	63.7	23.6	0.157
$(n\text{-}C_{18}H_{37})(n\text{-}C_4H_9)_3NNO_3$	58.2	18.1	1.27

The cation conductances shown in Table IV have been obtained using Tucker's value of 40.1 for the limiting conductance of the nitrate ion.[10]

Since the plots of F/Λ against $C\Lambda f^2/F$ are straight lines in the concentration range investigated, it appears that, at these concentrations, the behavior of solutions of long chain salts is normal. There is no evidence of micelle formation at concentrations up to several thousandths normal.

The interrelation between ion conductances and chain length remains qualitative until additional data are available. It may be pointed out here that the conductance of the octadecyltrimethylammonium ion with 21 carbon atoms is slightly higher than that of the tetra-*n*-amylammonium ion[10] with 20 carbon atoms.

The dissociation constants of the long chain salts exhibit no exceptional properties. When only one long hydrocarbon group is present in the

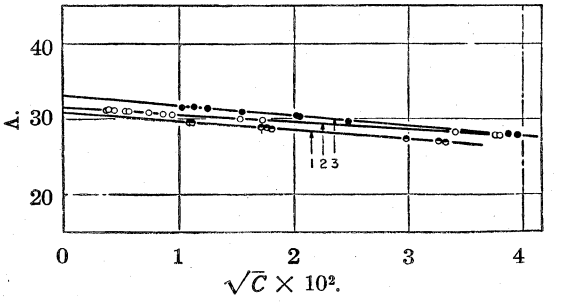

Fig. 2.—Square root plots for long chain salts in nitrobenzene: 1, *n*-octadecyltrimethylammonium nitrate; 2, *n*-octadecyltri-*n*-butylammonium nitrate; 3, *n*-octadecylpyridonium nitrate.

(9) Walden and Birr, *ibid.*, **163A**, 281 (1932).

(10) Tucker and Kraus, THIS JOURNAL, **69**, 457 (1947).

cation, the value of the dissociation constant is approximately that which might have been expected for an ion-pair in which the distance of closest approach is determined by the field around the three smaller alkyl groups.

2. Nitrobenzene.—In Table IV are given the limiting conductances of three quaternary ammonium nitrates containing long hydrocarbon chains in the cation. The cation conductances are given in column 3 and have been calculated on the assumption that the nitrate ion has a conductance of 22.6.[6]

TABLE IV

LIMITING CONDUCTANCES OF ELECTROLYTES IN NITROBENZENE

Salt	Λ_0	Λ_0^+
$(n\text{-}C_{18}H_{37})_2(CH_3)_2NNO_3$	30.7	8.1
$(n\text{-}C_{18}H_{37})(n\text{-}C_4H_9)_3NNO_3$	31.5	8.9
$(n\text{-}C_{18}H_{37})(C_5H_5N)NO_3$	32.9	10.3

The above Λ_0 values for the three salts have been obtained by extrapolation of the plots shown in Fig. 2, in which values of Λ_0 are plotted against values of $C^{1/2}$. These plots are linear over a considerable range of concentrations although the slopes of the lines are somewhat greater than the theoretical; this is doubtless due to ion-pair formation. Ion conductances decrease with increasing number of carbon atoms in the cation but rather less than one might otherwise expect.

V. Summary

1. The conductance of octadecyltrimethylammonium and octadecyltributylammonium nitrates in ethylene chloride and of octadecyltributylammonium, dioctadecyldimethylammonium and octadecylpyridonium nitrates in nitrobenzene have been measured.

2. These long chains salts are normal electrolytes over the concentration range studied in both ethylene chloride and nitrobenzene.

3. Limiting conductances and dissociation constants have been evaluated in ethylene chloride and limiting conductances in nitrobenzene.

4. Ion conductances have been evaluated in both solvents.

Properties of Electrolytic Solutions. XXXIII. The Conductance of Some Salts in Acetone at 25°[1]

BY MYRON B. REYNOLDS[2] AND CHARLES A. KRAUS

I. Introduction

Acetone is a solvent that differs markedly in type from those previously investigated in this Laboratory; it has a dielectric constant of 20.5 and is a fair solvent for a number of uni-univalent inorganic salts. Solutions in this solvent have been investigated earlier by several different investigators[3] but with the exception of Lannung, who was chiefly concerned with solubilities, their results are uncertain because of the high conductance of the solvent which introduced large and often uncertain corrections with solutions of low concentration. In this connection, it may be pointed out that, since the only laws that are known to apply to electrolytic solutions are of limiting type, it is of particular importance that experimental errors be kept at a minimum at low concentrations. *If a solvent cannot be adequately purified, there is little point in carrying out conductance measurements.*

In the present investigation, the solvent has been purified to a point where correction for solvent conductance was negligible. The electrolytes investigated were, for the most part, salts of the tetrabutylammonium ion with various negative ions. The picrates of lithium, sodium and potassium were measured as were also potassium iodide and thiocyanate. It may be noted that numerous salts which have been measured by earlier investigators were found to be too difficultly soluble in the pure solvent to permit of ready measurement.[3b]

Owing to uncertainties in the value of the physical constants of acetone, these (dielectric constant, viscosity and density) were redetermined.

The results of conductance measurements have been treated by the method of Fuoss[4] and values of the limiting conductance, Λ_0, and the dissociation constant, K, have been derived. Ion conductances have been evaluated according to the method of Fowler.[5]

II. Experimental

Apparatus.—Conductance measurements were carried out as described in earlier papers of this series, using a Jones type a. c. bridge and Erlenmeyer conductance cells with bright platinum electrodes. All measurements were carried out at 25 ± 0.01°.

The dielectric constant of acetone was measured at 25°,

(1) This paper comprises a portion of a thesis presented by Myron B. Reynolds in partial fulfillment of the requirements for the Degree of Doctor of Philosophy in the Graduate School of Brown University, June, 1947.

(5) Fowler and Kraus, *ibid.*, **62**, 2237 (1940).

using a parallel substitution type a. c. bridge[6] and a cell especially designed to minimize lead errors. Solvent conductance was also measured with this bridge.

Solvent viscosity was measured at 25°, using a modified Ostwald viscometer calibrated against water and benzene. Solvent density was determined by means of an Ostwald–Sprengel pycnometer.

Materials.—Commercial acetone[7] was dried by agitation over calcium chloride and then distilled twice from activated alumina pellets.[8]

In each distillation, the middle fraction only was saved and the final distillation was preceded by a few hours of refluxing. The conductance of acetone prepared in this way was in the range of 1 to 2 × 10^{-9} reciprocal ohm centimeters; corrections for solvent conductance were thus negligible.

Tetra-*n*-butylammonium triphenylborofluoride was prepared by Dr. G. L. Brown, of this Laboratory, and purified by successive recrystallizations from ether–ethanol mixtures. It was dried at room temperature *in vacuo;* m. p. 165–166°.

Tetra-*n*-butylammonium picrate from laboratory stock was recrystallized from ethanol, and dried *in vacuo* at slightly elevated temperature; m. p. 89°.

Tetra-*n*-butylammonium iodide from laboratory stock was purified by recrystallization from nitromethane and dried *in vacuo* at room temperature; m. p. 146°.

Tetra-*n*-butylammonium bromide was prepared by treating *n*-butyl bromide with tri-*n*-butylamine in ethanol solution at about 70°. The crude salt was recrystallized several times from ethyl acetate and twice from benzene–petroleum ether mixtures; a portion was recrystallized from an ether–ethyl acetate mixture. Both samples were dried to constant weight *in vacuo* at 50 to 60°; m. p. 118°.

Tetra-*n*-butylammonium nitrate was prepared by Dr. H. L. Pickering, of this Laboratory, purified by recrystallizations from benzene, and dried *in vacuo* at room temperature; m. p. 149°.

Tetra-*n*-butylammonium perchlorate was prepared in this Laboratory by Dr. L. E. Strong. Further purification was effected by recrystallization from ether–acetone mixtures, followed by drying *in vacuo* at room temperature; m. p. 213°.

Tetraethylammonium picrate, furnished by Dr. C. J. Carignan, of this Laboratory, was recrystallized from ethanol and dried to constant weight *in vacuo* at 65–80°.

Tetramethylammonium triphenylborofluoride from laboratory stock was recrystallized from acetone and from acetone–ethanol mixtures and dried *in vacuo* at room temperature; m. p. 186°.

Tetramethylammonium fluoride was prepared in this Laboratory by Dr. C. J. Carignan. The salt was purified by precipitation from ethanol solution by addition of ethyl acetate and also by recrystallization from ethanol–acetone mixtures. Samples were dried to constant weight at 50° *in vacuo;* m. p. 268–269°, with decomposition.

Lithium picrate, prepared in this Laboratory, by Dr. C. J. Carignan, was purified both by recrystallizations from ethanol–nitromethane mixtures and from acetone–nitromethane mixtures. The salt was dried *in vacuo* at 80°.

Sodium picrate was prepared by neutralizing an ethanol solution of picric acid with aqueous sodium hydroxide solution. The resulting salt was recrystallized several times from ethanol–water mixtures and dried to constant weight *in vacuo* at 70–80°.

Pure samples of potassium picrate were available from laboratory stock and were dried to constant weight *in vacuo* at 65°.

Reagent grade potassium iodide was recrystallized from water and also from water–ethanol mixtures. The recrystallized samples were dried *in vacuo* at 70°.

Reagent grade potassium thiocyanate was further purified by recrystallization from water and from acetone–water mixtures, and dried *in vacuo* at 50°.

samples the specific conductance of which varied between 0.51 and 1.7 × 10^{-9}. The average value found for the dielectric constant was 20.47, with a mean deviation of 0.05 and a maximum deviation of 0.2.

The viscosity was determined with sixteen different samples of acetone of which only two had a specific conductance above 2 × 10^{-9}; thirteen of these samples were identical with those used in the dielectric constant measurements. The average value of the viscosity in poise was found to be 3.040 × 10^{-3} with a mean deviation of 0.008 × 10^{-3}.

The density of acetone was determined to be 0.7845. All the above values were at 25°.

Conductances.—Equivalent conductances, Λ, and concentrations, C, expressed in moles of salt per liter of solution, are given in Table I. Two or more series of measurements were carried out with salt samples resulting from successive recrystallizations and the salts were assumed to be pure when conductances for successive recrystallizations for a given salt agreed within the limit of experimental error, 0.1%.

IV. Discussion

The data of Table I were analyzed by the method of Fuoss by plotting values of F/Λ against values of $c\Lambda f^2/F$. The plots are shown in Figs. 1, 2 and 3, on which appear values for two series of measurements for each salt. Inspection of the plots will show that Λ_0 may be determined with considerable precision, particularly in the case of the stronger salts. All plots are linear within the limit of experimental error up to about 7 × $10^{-4}N$.[8a] The slopes of the plots serve in the evaluation of the dissociation constant, K, of the ion pairs; the curves are the steeper, the lower the constant. Values of Λ_0 and K as determined

Ion Conductances.—Ion conductances have been evaluated by the method of Fowler according to which the two ions of tetrabutylammonium triphenylborofluoride are assumed to have the same conductance. The value so found for the tetrabutylammonium ion is 67.1 and the ion conductances recorded in columns 4 and 5 of Table II are based on this value.

The conductance of negative ions is markedly higher than that of comparable positive ions. Thus the conductance of the perchlorate ion is 115.3 while that of the tetramethylammonium ion is only 98.0. The conductance of the alkali metal ions decreases markedly with decreasing atomic weight, the change from sodium to lithium being particularly marked. Considering the tetraethylammonium ion with nine atoms other than hydrogen and a conductance of 91.2, the low conductance of the lithium ion (72.8) indicates a high degree of interaction with the solvent dipoles. There may be actual solvation of the lithium ion, but we have no satisfactory means of distinguishing between solvation and simple interaction of the charge on the ion with the dipoles of the solvent molecules. The low conductance of the tetramethylammonium ion in comparison with that of the perchlorate ion cannot well be ascribed to solvation in the strict sense of the term.

The high conductance of the thiocyanate ion, as also that of the nitrate ion, is worthy of note. The bromide ion has a slightly higher conductance than the iodide ion, but the fluoride ion has a very low conductance. But, even here, we find the conductance of an exceptionally small negative ion markedly greater than that of the ion of the much larger potassium atom, 85 as against 80.6.

There is only one case among the salts in the table where ion conductances as derived from different pairs of ions may be compared. The conductance of the potassium ion as derived from its picrate is 80.6 while that derived from the iodide is 80.5. The difference lies within the limit of experimental error.

There is only scanty material in the literature that can be employed for purposes of comparison. Seemingly, the most reliable conductance measurements with solutions of salts in acetone are due to Ross Kane but, unfortunately, the details of his measurements are unavailable, and only rounded ion conductances at 25° have been reported.[9]

In the case of several salts (KI and Et_4NPi), our conductance values are in good agreement with those of Ross Kane. In other instances, the difference usually lies between 0.5 and 1.0%. If Ross Kane's limiting conductance values were obtained by extrapolation of the usual square root plot, discrepancies might well be accounted for by extrapolation errors.

Dissociation Constants.—In accord with the dielectric constant of acetone (D 20.47), solutions of salts in this solvent are fairly highly ionized, but all show marked ion pair association so that the evaluation of Λ_0 by extrapolation of the Λ–$\sqrt{C}$ plot is not permissible.

Since the energy necessary to separate a pair of ions is a function of the distance between centers of charge in the ion pairs, it follows that salts having large ions have relatively large dissociation constants while salts with small ions will have small constants. Since large ions have lower conductances than small ions, we should expect that salts having ions of lower conductance would have larger dissociation constants.

However, such a simple relation does not hold, chiefly, because of certain specific factors:

1. The effective size of an ion may be due either to a large structure, as in the case of the tetrabutylammonium ion, or, on the other hand, it may be the result of interaction of a small ion with the molecules (dipoles) of the solvent. In the latter case, the solvent molecules may, in some instances, be definitely attached to the ion; in others, the structure may be a very loose one; and, in still others, both types of interaction may be involved. The smallest ions, lithium and fluoride, have very low conductances but yield relatively small dissociation constants. Evidently, solvent molecules, which may be attached to the free ions, are largely lost in the ion pairs. The nitrate ion has a much higher conductance than the bromide ion, yet its tetrabutylammonium salt is much stronger than the corresponding bromide.

2. Steric effects have a marked influence on the dissociation constant. Thus, potassium iodide is much stronger than potassium picrate, yet the constant of tetrabutylammonium picrate is three times that of the iodide. Then again, the constant for tetrabutylammonium picrate is but little greater than that of the corresponding tetraethylammonium salt. This indicates that the picrate ion penetrates into the shell of butyl groups about the nitrogen atom to a depth that approximates the dimensions of the tetraethylammonium group.

As was shown in an earlier paper of this series,[10] a quantity "a," which may be interpreted as an approximation to the distance between charges in the ion pairs, may be computed from the dissociation constant. For the salts whose constants are given in Table II, the value of "a" varies from 2.42 Å. for tetramethylammonium fluoride to 9.48 Å. for tetrabutylammonium picrate. That interaction with solvent molecules is a factor in determining ion-pair dimensions in acetone, even in the case of lithium picrate, is shown clearly by the results with the same salt in nitrobenzene (D 34.5).[11] The "a" distance for this salt in the two solvents is, respectively, 2.55 and 0.62 Å. The dissociation constant of 1.03×10^{-3} for lithium picrate in acetone of dielectric constant 20.5 as against one of 6×10^{-8} in a solvent of dielectric

(10) Fuoss and Kraus, THIS JOURNAL, **55**, 1019 (1933).

(11) Witschonke and Kraus, *ibid.*, **69**, 2472 (1947).

constant 34.5 can only be due to interaction between the ions (in the ion pairs) with the acetone molecules, on the one hand, and lack of such interaction with nitrobenzene molecules, on the other. A comparison of sodium and potassium picrates in acetone and nitrobenzene shows that these salts behave in a manner similar to that of lithium picrate. The Walden conductance viscosity product for the sodium and potassium ions in acetone is 0.238 and 0.242, respectively, while in nitrobenzene[11] it is 0.295 and 0.322. Thus, the free ions in this solvent are of very nearly the same size. The corresponding K values $\times 10^4$ are, respectively, 13.5 and 34.3 in acetone and 0.28 and 6.86 in nitrobenzene. The effective size of these ions in the ion pairs is much smaller in nitrobenzene than in acetone and is progressively more so as the (lattice) ion is smaller.

V. Summary

A simplified procedure for the purification of acetone has been developed, making use of activated alumina pellets.

The density, viscosity and dielectric constant of purified acetone at 25° have been determined.

Conductance data have been obtained for fourteen different salts in acetone solution at 25°.

Limiting conductances and dissociation constants have been calculated for these salts, using the extrapolation method of Fuoss.

Limiting ion conductances have been computed by the method of Fowler.

Anion conductances have been found to be, in general, greater than corresponding cation conductances, suggesting specific solvent interaction with cations.

The conductance of the fluoride ion has been found to be markedly lower than that of the other halide ions and abnormally low for an anion.

The Effect of Various Gases on Nitrogen Fixation by *Azotobacter*[1]

BY DOROTHY M. MOLNAR, R. H. BURRIS AND P. W. WILSON

Molecular hydrogen was demonstrated by Wilson and his associates[2,3,4] to inhibit nitrogen fixation, specifically and competitively, in both free-living *Azotobacter* and the symbiotic system of red clover plus *Rhizobium*. It has been suggested[5] that the inhibition might be primarily a physical effect dependent on the relative adsorption of the two gases on the surface of the nitrogen-fixing enzyme. The observation that the enzyme-substrate dissociation constants of hydrogen and nitrogen in *Azotobacter* have essentially the same ratio as their van der Waals constants offers some support for this view.[6] Although this may be only fortuitous, an examination of the effect of gases with different physical properties, appears to be desirable.

Experimental

Methods.—Cultures of *Azotobacter vinelandii* were maintained by daily transfer to 50 ml. of Burk's medium[3] in 500-ml. Erlenmeyer "shake" flasks. Weekly tests for purity were made by microscopic examination (Gram stain) and by inoculation of beef extract–peptone broth.[5] For the microrespirometer studies, ten drops of a culture (seventeen to nineteen hours) was diluted with 40 ml. of sterile Burk's medium, and 2 ml. transferred to the respiration flask. The conventional techniques for supplying different gas mixtures in respiratory experiments were followed.[7] Manometer readings were taken at half-hour intervals over a period of five hours, at 30°. The gas mixtures were: p_{N_2}, 0.2 atm.; p_{O_2}, 0.2 atm.; helium, argon, neon, hydrogen, ethane, or nitrous oxide, 0.6 atm. At a partial pressure of nitrogen of 0.2 atm. the rate of fixation is about 95% of maximum (in the absence of a competitive inhibitor, such as H_2), and small variations in the pressure (± 0.02 atm.) cause little change. The partial pressure of oxygen likewise is near optimum; to insure that is was kept reasonably constant, the oxygen used in respiration was replaced periodically. The mixtures were made from ordinary cylinder gases (about 98–99% pure) with the exception of the nitrous oxide, which was the grade used for anaesthesia. Errors arising from variation in the composition were reduced by preparing separate mixtures for the replicate experiments.

In a few trials, the conclusions from the microrespiration data were checked by estimating the initial and final total nitrogen in representative flasks by a modification of the micromethod of Johnson.[8] One macro experiment was made: Ten ml. of an eighteen-hour culture was diluted with 300 ml. of sterile Burk's medium, and 25-ml. aliquots were pipetted into sterile 250 ml. Erlenmeyer flasks. Each flask contained a tube of potash to absorb respiratory carbon dioxide and was made gas-tight with a rubber stopper fitted with an inlet tube. After the desired gas mixture was supplied through the inlet tube, the flasks were incubated in a conventional shaking apparatus at 30° for fifteen hours, then total nitrogen determined on aliquots by the micromethod.

Results and Discussion

The van der Waals constant a for the gases tested varied from 0.00007 (helium) to 0.01074

(ethane); a wide range in physical properties such as solubility, adsorption on solids, boiling point, are known to be associated with this variation. If the physiological response of *Azotobacter* to hydrogen is to be ascribed to the physical characteristics of the gases in the mixture supplied as expressed in the van der Waals forces, one should expect some correlation of nitrogen fixation with the value of a of the diluent gas. The data in Tables I, II and III and in Fig. 1 demonstrate that there is no such correlation.

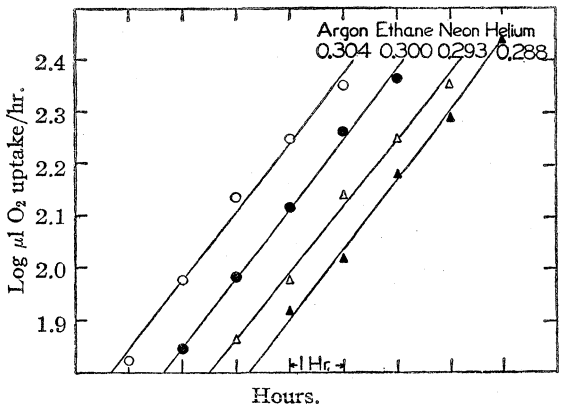

Fig. 1.—Effect of different gases on nitrogen fixation by *Azotobacter vinelandii*. Points are the means of duplicates for ethane, of triplicates for the others. Each division of the abscissa in Figs. 1 and 2 is one hour.

Table I summarizes results from two representative experiments. The initial and final rates of respiration are included to illustrate the effect of the gas tested on final total nitrogen as measured by rate of respiration. But, as has been emphasized in the previous papers,[3,4] a more suitable criterion of the effect is given by the first order velocity constant of growth, k. The values of k were estimated from the slopes of the lines obtained when the rate of respiration was plotted as a function of time. The standard deviation of k, S_k, was calculated by the usual statistical procedure; it measures the departure of the points from a straight line and is in effect an estimate of the precision of the data. The slope of each line, and hence k, was calculated by the method of least squares. The variation in the k values of the replicate samples measures the reproducibility of the results. Considering these variations, together with the observed values of S_k, it is concluded that for single determinations differences of 10–20% are necessary for significance, but if 2–3 replicates are combined, differences of 5–10% are probably significant. The precision obtained when replicate samples are combined is illustrated graphically by the lines in Fig. 1.

Table II summarizes the results of all the microrespiration experiments. For convenience, the van der Waals constant, a, is included, together with the boiling point of the gases, a physical property known to be correlated with a. In each experiment a helium control was included since it has been previously demonstrated that this gas does not affect fixation; this point was checked occasionally by including an air control. It is evident from the table that the physiological function of nitrogen fixation in *Azotobacter* shows no such response to changes in the van der Waals forces of the diluent gas as does a typical physical quantity (b. p.). Explanation of inhibition of nitrogen fixation in *Azotobacter* by a hypothesis based on purely physical competition between hydrogen and nitrogen, therefore, appears unlikely. The

physiological explanation,[9] based on enzyme mechanisms, thus receives indirect support.

An important by-product of these experiments was the demonstration that nitrous oxide is a specific inhibitor of nitrogen fixation by *Azotobacter vinelandii*. Because of the possible implication of this discovery for the mechanism of fixation, ten separate experiments were made to establish this finding. Inhibition was obtained in every trial, ranging from 21 to 63% with an average of 45 ± 3.9%. Confirmation of the data from the microrespiration experiments by determining the actual quantities of nitrogen fixed is furnished by the results given in Table III.

(5.20)			46.0
	A		42.6
			50.6
	N_2O		17.4
			15.4
			23.4
			14.8

[a] Figures in parentheses in this column represent initial nitrogen content in γ/ml. Experiment VI is a macro experiment; the others are samples taken from microrespiration experiments.

That the inhibition by nitrous oxide is specific for nitrogen fixation as distinguished from assimilation of combined nitrogen is shown by the results in Table IV and in Fig. 2. Assimilation of ammonium apparently is slightly stimulated by nitrous oxide in the atmosphere, but as this effect is not consistently obtained in all trials, its establishment would require much more additional evidence.

Previously, only hydrogen and carbon monoxide were known to influence the fixation reaction *specifically* in *Azotobacter*. Not only does the finding that nitrous oxide is likewise a specific inhibitor provide a new tool for investigation but it may also possess special significance for the mechanism. In a recent review Wilson and Burris[6] suggested that a possible intermediate in the fixation reaction might be a compound that is formally analogous to hyponitrous acid though not necessarily identical with it. The fact that nitrous oxide, the anhydride of hyponitrous acid, is not utilized by

		.306	.331	.320

[a] Data are *k* values calculated from lines.

Azotobacter but does interfere with the assimilation of molecular nitrogen could be interpreted as supporting evidence for this view. Final decision as to its significance must await a more detailed study, particularly whether the inhibition is competitive or non-competitive.

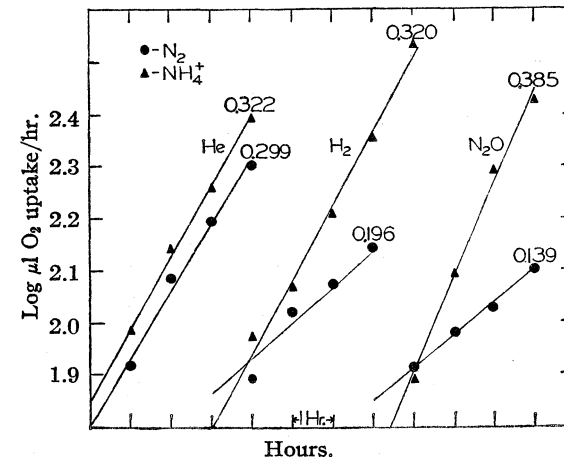

Fig. 2.—Specific inhibition of nitrogen fixation by *Azotobacter vinelandii*. Each point is the mean of duplicates.

Summary

The hypothesis that the inhibition by molecular hydrogen of nitrogen fixation in *Azotobacter* is explicable on the basis of the physical properties of the two gases was tested by comparing the effects of helium, argon, neon, hydrogen, nitrous oxide and ethane on the fixation reaction. The microrespiration technique was used for most of the experiments, but the results were verified by total nitrogen determinations.

The van der Waals constant, *a*, of the gases tested ranged from 0.00007 to 0.01074. Although the physical properties of the gases are correlated with the van der Waals forces, no such correlation

appeared in their effect on the physiological function of nitrogen fixation in *Azotobacter*. It is concluded, therefore, that an explanation based on the relative physical properties of hydrogen and nitrogen is unlikely.

Nitrous oxide was found to be a specific inhibitor for nitrogen fixation by *Azotobacter*. Its inhibition may have important implications for the mechanism of the reaction.

Kinetics of the Reactions between Iodine and Certain Substituted Phenols

BY CHOH HAO LI

In previous studies[1] it was shown that the reaction of tyrosine with iodine follows a bimolecular rate law and that the most reactive iodinating agent is hypoiodous acid. It was also demonstrated[2] that the formation of diiodotyrosine is catalyzed by phosphate and other basic ions. The present investigation extends such studies with other para substituted phenols.

Reactions were carried out at 25° in acetate buffers of *p*H 5.23 and 5.65 containing different iodide ion concentrations. *p*-Chlorophenol and *p*-hydroxyphenylethylamine (tyramine), C. P. crystalline preparations, were employed without further purification; glycyl-tyrosine was kindly supplied by Dr. J. S. Fruton and the late Dr. Max Bergmann. The reaction rates were followed in the manner previously[1] described. The rate law was found to be identical with that for the formation of diiodotyrosine and may be expressed by the equation

$$-\mathrm{d(Phenol)}/\mathrm{d}t = k_2(\mathrm{phenol})(\mathrm{I_3^-}) \qquad (1)$$

where k_2 is the specific rate constant for the reaction Phenol + $2I_2 \rightarrow$ diiodophenol + $2H^+$ + $2I^-$

Table I summarizes the specific rate constants for the formation of diiodophenols[3]; the values for the reaction between iodine and tyrosine were estimated from previous studies.[1] The concentrations are in moles per liter, and time in minutes. It may be noted that the product of $k_2(I^-)^2$ in each buffer appears to be rather constant at the range of iodide concentration studied. In concentrations of iodide beyond the range studied, $k_2(I^-)^2$ was not found to be constant.

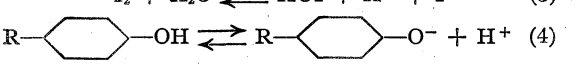
In the study of diiodotyrosine formation,[1] it was found that the reaction involves four paths: namely, iodine and phenol, iodine and phenolate, hypoiodous acid and phenol, and hypoiodous acid and phenolate. It was further noted that the most reactive pair is hypoiodous acid and phenolate, whereas the reaction between iodine and phenol is the least reactive. For first approximations, the reaction between iodine and phenol may be represented by equation (1a).

$$-\mathrm{d(phenol)}/\mathrm{d}t = k'(\mathrm{phenol})(\mathrm{HOI}) + k''(\mathrm{phenolate})(\mathrm{HOI}) \qquad (1a)$$

From the equilibria

$$I^-_3 \rightleftharpoons I_2 + I^- \qquad (2)$$

$$I_2 + H_2O \rightleftharpoons HOI + H^+ + I^- \qquad (3)$$



(4)

TABLE I

SPECIFIC REACTION RATE, k_2, OF IODINATING *p*-CHLOROPHENOL, GLYCYLTYROSINE, TYRAMINE AND TYROSINE[a] IN ACETATE BUFFERS OF *p*H 5.23 AND *p*H 5.65 CONTAINING DIFFERENT IODIDE CONCENTRATION AT 25°

k_2 in gram moles per liter per minute

	*p*H 5.23	*p*H 5.65	*p*H 5.23	*p*H 5.65	*p*H 5.23	*p*H 5.65	*p*H 5.23	*p*H 5.65
3.34	0.135(0.128)[b]	0.40(0.34)	0.70(0.72)	2.03(2.29)	0.91(0.94)	3.15(3.21)	0.52(0.53)	1.82(1.94)
4.08	.081(.085)	.26(.26)	.45(.45)	1.63(1.49)	.63(.63)	2.16(2.14)	.38(.36)	1.20(1.30)
4.84	.060(.061)	.18(.18)	.35(.38)	1.09(1.07)	.45(.49)	1.55(1.55)	.28(.26)	0.90(0.93)
6.34	.033(.035)	.11(.11)	.20(.22)	0.63(0.62)			.16(.15)	0.53(0.54)

[a] Reaction rates for tyrosine are from a previous paper (see ref. 1). [b] The figures in parentheses are computed values from Equations 7, 8, 9 and 10.

Equation (1a) becomes

$$-\frac{\mathrm{d(phenol)}}{\mathrm{d}t} = \frac{K_2}{(I^-)^2(H^+)}\left[k'K_3 + \frac{k''K_3K_4}{(H^+)}\right](\mathrm{phenol})(\mathrm{I_3^-}) \qquad (5)$$

where K_2, K_3 and K_4 are the equilibrium constants of equations 2, 3, and 4, respectively. Thus, by comparing the equations (1) and (5), the observed specific rate constant, k_2, is a function of iodide and

(1) Li, THIS JOURNAL, **64**, 1147 (1942).

(2) Li, *ibid.*, **66**, 228 (1944).

(3) The preparation of N-glycyl-3,5-diiodotyrosine has been reported by Abderhalden and Guggenheim [*Ber.*, **41**, 1241 (1908)]. Diiodotyramine has also been prepared by Abderhalden and his coworkers [*Arch. ges. Physiol.*, **195**, 167 (1922)]. As far as we are aware there is no report concerning the preparation of *p*-chloro-3,5-diiodophenol. In the present experiments we have observed that *p*-chloro-3,5-diiodophenol is very insoluble in acetate buffers and it is gradually crystallized out in fine needles as the reaction proceeds. The colorless crystals have a melting point at 108.5°. *Anal.* Calcd. for $HOC_6H_2I_2Cl$: I, 66.74. Found: I, 66.82.

hydrogen ion concentration as shown by the expression

$$k_2 = \frac{K_2}{(I^-)^2(H^+)}\left[k'K_3 + \frac{k''K_3K_4}{(H^+)}\right] \quad (6)$$

It is obvious from equation (6) that when the hydrogen-ion concentration is maintained unchanged, the product of $k_2(I^-)^2$ becomes a constant. Since the equilibrium constants[4] of equations (2) and (3) and the dissociation constants of *p*-chlorophenol,[5] tyramine,[6] glycyltyrosine[7] and tyrosine[8] are known, the specific rate constants k' and k'' can be computed from the data in Table I. The results are summarized in Table II. Therefore, in a solution of known hydrogen-ion and iodide-ion concentrations, the observed specific rates for iodinating *p*-chlorophenol, tyrosine, tyramine and glycyltyrosine may be computed from the equations

TABLE II

THE COMPUTED VALUES OF k' AND k'' FOR *p*-CHLOROPHENOL, TYRAMINE, TYROSINE AND GLYCYLTYROSINE IN ACETATE BUFFER AT 25°

Phenols	Dissociation constant K (10^{11})	$k' \times (10^{-6})$	$k'' \times (10^{-10})$
p-Chlorophenol	66.0 (5)[a]	1.7	0.2
Tyrosine	8.5 (8)	8.1	1.1
Glycyltyrosine	4.0 (7)	12.0	40.0
Tyramine	1.26 (6)	10.0	58.0

[a] Numbers in parentheses refer to the reference in the text.

p-Chlorophenol:

$$k_2 = \frac{1}{(I^-)^2(H^+)}\left[7.2 \times 10^{-10} + \frac{5.5 \times 10^{-16}}{(H^+)}\right] \quad (7)$$

Tyrosine:

$$k_2 = \frac{1}{(I^-)^2(H^+)}\left[3.4 \times 10^{-9} + \frac{4.0 \times 10^{-16}}{(H^+)}\right] \quad (8)$$

Tyramine:

$$k_2 = \frac{1}{(I^-)^2(H^+)}\left[4.2 \times 10^{-9} + \frac{3.06 \times 10^{-15}}{(H^+)}\right] \quad (9)$$

Glycyltyrosine:

$$k_2 = \frac{1}{(I^-)^2(H^+)}\left[5.0 \times 10^{-9} + \frac{6.7 \times 10^{-15}}{(H^+)}\right] \quad (10)$$

The computed specific rates are listed in Table I; it may be noted that the agreements between the calculated and observed values are satisfactory.

From Table II, it is evident that, in each phenol studied, the value of k' is always much smaller than that of k''. This indicates that the phenolate ion is far more reactive than the undissociated phenol. It is also clear that the smaller is the dissociation constant of a phenol, the faster is the reaction rate. For instance, the dissociation constant of *p*-chlorophenol is fifty times higher than that of tyramine and yet the latter reacts with hypoiodous acid much faster than *p*-chlorophenol.

It is of interest to note that the specific rate for glycyltyrosine is greater than the value for tyrosine. It appears to indicate that the presence of a peptide linkage enhances the rate of iodination. This inference may also be arrived at by an experiment using carbobenzoxyglutamyltyrosine. In acetate buffer of *p*H 5.65 containing an iodide concentration of 3.34×10^{-2} *m* at 25°, the biomolecular specific rate, k_2, of iodinating carbobenzoxyglutamyltyrosine was found to be 4.24 gram-mols per liter per minute which is more than twice the specific rate for tyrosine. Whether the conclusion can be generalized for other peptides requires further investigation.

The absence of the carboxyl group in tyrosine causes an increase in iodination rate. Thus, k'' for tyramine is about 50 times larger than that for tyrosine. On the other hand, a replacement of $-CH_2CH_2NH_2$ group in tyramine by —Cl radical greatly diminishes the specific rates of iodination. No satisfactory explanation can be offered at present to correlate the structure of substituents on the iodination rate of phenols.

Summary

The rate of the reactions between iodine and *p*-chlorophenol, tyramine and glycyltyrosine have been determined at 25° in acetate buffers. In the range of iodide concentrations studied, the rate can be represented by: rate = k' (phenol)(HOI) + k'' (phenolate)(HOI). The specific rate of the reaction between phenolate and hypoiodous acid decreases in the order: tyramine > glycyltyrosine > tyrosine > *p*-chlorophenol.

Preparation and Structure of the Carbides of Uranium[1]

BY LAWRENCE M. LITZ,[2] A. B. GARRETT AND FRANK C. CROXTON

This paper presents data on the preparation and crystal structure of the carbides of uranium, namely, UC and UC_2. On hydrolysis, the dicarbide, UC_2, is reported to yield a mixture of gaseous, liquid, and solid hydrocarbons, a fair percentage being in the high molecular weight range.[3] This unusual fact led to a program on the investigation of the hydrolysis of heavy metal carbides, of which work this research is a part.

Preparation.—In preparing uranium carbide, previous investigators had treated U_3O_8, the "green" oxide of uranium, with graphite in an electric arc furnace. The product obtained by this method was a crystalline carbide of questionable composition containing varying amounts of impurities. In 1896, Henri Moissan,[3] who first prepared this substance, assigned it the formula U_2C_3. Later, uranium carbide was prepared by others by this method, and they assigned the formula UC_2 to the resulting compound.[4]

Because it was desirable that the carbide to be used for the hydrolysis reactions should be of high purity and definite composition, other methods of preparation were investigated. The finely divided carbide needed for the studies is pyrophoric; hence a method of preparing it in the hydrolysis apparatus was devised. The reaction between uranium metal and methane was investigated as a probable method of making the carbide with the required properties. It is known that some metals react with hydrocarbons, such as methane, below the thermal decomposition temperature of the hydrocarbons, according to the equation

$$xM + yCH_4 = M_xC_y + 2yH_2$$

It was found that finely divided uranium metal would undergo such a reaction at temperatures as low as 625°. The product of this reaction was not the dicarbide, UC_2, as had been expected, but rather a monocarbide, UC, which had not been reported previously in the literature. It has been learned since that the monocarbide, UC, was prepared and studied earlier on the Manhattan Project.[5]

The identity of the monocarbide was determined from the following experimental facts: (1) The pressure change on reaction indicated that only one mole of methane reacted per mole of uranium. (2) A molecular weight of 250 was calculated from the weight of carbide produced per unit weight of uranium metal. (3) Chemical analysis indicated the absence of free carbon and confirmed the formula UC. (4) X-Ray diffraction studies showed that, to the limit of detection, metallic uranium and free graphite were absent. (5) A single phase having a face-centered cubic structure was indicated for the monocarbide; the dicarbide, UC_2, is tetragonal.

The apparatus in which the reaction between methane and uranium metal was carried out is illustrated in Fig. 1. It is designed so that the hydrolysis studies may also be carried out following the preparation of the carbide. The basic parts are the "Vycor" furnace tube, surrounded by an electrical resistance furnace; vacuum pumps capable of evacuating the system to a pressure of 10^{-5} mm. of mercury; a McLeod gage and mercury manometers for pressure measurement; a Toepler pump which is used to transfer gases from one part of the system to another; reservoirs for purified hydrogen and methane; and, a constant-volume buret. Advantage is taken of the ease of formation and decomposition of uranium hydride, as determined by F. H. Driggs,[6] to convert the uranium metal into a very finely divided form. A weighed quantity of metal is placed in a platinum boat in the furnace tube and the system is evacuated. Hydrogen is then admitted and allowed to react with the metal at 225°, where the equilibrium pressure of the hydride is about 3 mm. When all of the metal has been converted to hydride, the temperature is raised to 450°, where the equilibrium pressure is greater than 700 mm., and the hydride is caused to decompose by keeping the pressure in the system below this value. This cycle is repeated three times, after which the hydrogen is pumped off, the temperature increased to the desired reaction temperature, and a measured quantity of methane is added. The reaction is allowed to proceed until equilibrium is reached, after which the gaseous products are withdrawn for analysis and a second charge of methane is added. This process is continued until no further reaction is observed. When a fixed quantity of methane is added each time, the resulting equilibrium pressure of methane and hydrogen, at a fixed temperature, is dependent on the substances present in the solid phase. Thus, the equilibrium pressure over a mixture of uranium and uranium monocarbide is higher than that over a mixture of uranium monocarbide and uranium dicarbide. By plotting the equilibrium pressure against the per cent. of carbon in the solid phase, as determined by the amount of methane which has reacted, vertical breaks in the curve will be obtained

(5) Pending publication of the Manhattan District's work in this field, the following statement is made at the suggestion of Dr. F. H. Spedding, Project Director of the Atomic Research Institute, Ames, Iowa: "The monocarbide, UC, was discovered on the Manhattan Project at the Iowa State College at Ames in 1942 through X-ray diffraction. The lattice and structure were determined by R. Rundle, and the chemical identity was established by V. H. Carter and A. D. Tevebaugh. The U-C phase diagram was carefully studied in the UC range by Carter, A. H. Daane, Rundle, and A. I. Snow. These studies will be published when released." This information was, however, unknown to the present authors until after the completion of the studies reported in this paper.

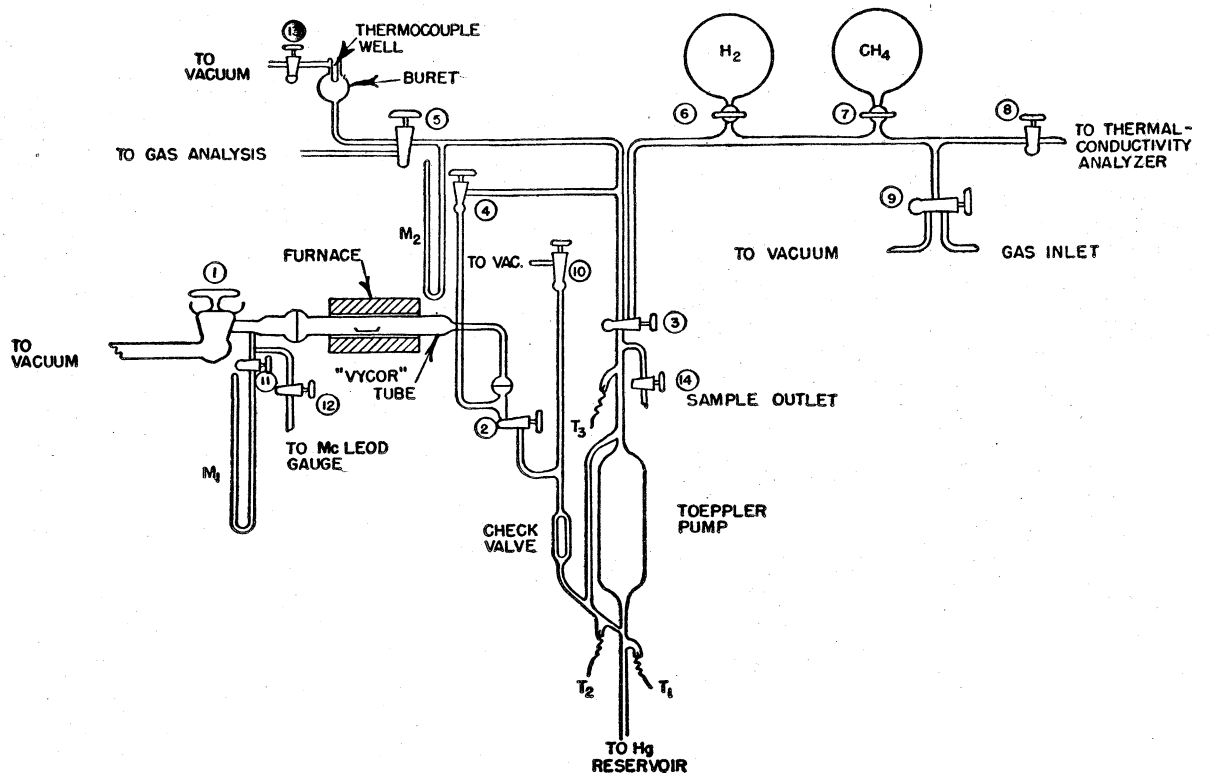

Fig. 1.—Vacuum apparatus for the investigation of the uranium metal–methane reaction.

which will indicate phase changes. In the case of uranium, no lower carbides than the monocarbide were observed, and the rate of reaction between the methane and the monocarbide at temperatures up to 900° was too slow to allow investigation of higher carbide phases.

Other methods of preparing both these carbides were investigated. The following equations indicate the reactions which were successfully used

(1)	$U + C = UC$	(2100°)
(2)	$U + 2C = UC_2$	(2400°)
(3)	$U_3O_8 + 11C = 3UC + 8CO$	(1800°)
(4)	$U_3O_8 + 14C = 3UC_2 + 8CO$	(2400°)

By treating uranium metal with graphite at 2100°, well-defined metallic crystals of the monocarbide were produced. By increasing the reaction temperature to approximately 2400°, the dicarbide was obtained. The preparation of the monocarbide by reaction of the U_3O_8 with graphite is accomplished easily by heating a powdered mixture of the two, of stoichiometric proportions, as indicated by equation (3), to 1800°, a sintered, coke-like mass being produced by this means. Higher temperatures are again required to prepare pure UC_2, for if the mixture, made up according to the indicated equation, is heated to temperatures below 2400°, the proportion of UC_2 in the product decreases as lower temperatures are used. At 2400°, the dicarbide is formed as large crystalline masses by this latter process. Both the monocarbide and the dicarbide form crystals which are hard and brittle and metallic in appearance. In neither case were these large enough for single crystal X-ray studies.

Because the preparation of the dicarbide, UC_2, made necessary the use of very high temperatures, the furnace assembly (Fig. 2) was employed. H is a 30-turn, water-cooled, copper induction coil which was activated by a 60KVA Ajax high-frequency converter. The graphite crucible A was heated inductively and it, in turn, heated the graphite crucible B, which carried the reactants, by radiation. Temperatures were measured through the hole in the lid by means of a Leeds and Northrup optical pyrometer. Heat loss was prevented by the lampblack insulation J, and excessive burning at the top was inhibited by the sillimanite cover D. Because of the arrangement at the top of the crucible A, influx of air into the reacting system was at a minimum, and there was no noticeable oxidation of the crucibles B and C, or of the product.

X-Ray Measurements.—The X-ray diffraction patterns were recorded both photographically and by a motor-driven spectrometer synchronized with a Brown recording potentiometer. The crystal lattice constants were determined with a Debye–Scherrer cylindrical camera of 37.8-mm. radius using Cu-Kα radiation. A suspension of the fine powder in Canada balsam was painted on a hair which was then mounted on the geometric axis of the camera in a fixture which rotated it during the exposure. Quantitative intensity measurements were made on an X-ray spectrometer using a Geiger tube as the detector. This can be connected either to a standard scaling circuit or to an integrating circuit connected to the potentiometer.

For accurate work, the motor drive and potentiometer were cut out of the system and the quantity of radiation per unit-time interval was counted at manually set positions of the detector. To obtain the intensity, the number of counts was plotted as a function of angle and the area under the curve determined, the intensity being proportional to the area. To insure total reflection of the incident beam, the sample employed was made of a thick block of the finely ground carbide, sieved to pass 325-mesh screen. Considerable difficulty was encountered with these compacts because of what appeared to be orientation of the particles. In the case of the monocarbide, this was evidenced by a very large increase in intensity of the (200) line relative to the (111) line, the former being approximately twice as strong as the latter in the most extreme case encountered. As is seen in Table I, the calculated values are in the reverse order. By suspending the sample in paraffin wax or by using a carbide

of very small crystal size, as is prepared by reaction of very finely divided uranium metal with methane, this effect may be eliminated.

Because of the arrangement of the X-ray tube in the spectrometer, only those lines obtained by diffraction through a Bragg angle less than 45° can be measured. Therefore, for those lines appearing in the back-reflection direction, only estimated intensity values, obtained from the Debye–Scherrer films, could be determined. Also, in the case of the dicarbide, many of the lines were too close together for adequate resolution, and only four of the relatively important lines were measured and these are listed in Table II. Relative intensities were determined in all cases.

Crystal Structure of Uranium Monocarbide.—The diffraction pattern obtained by the Debye–Scherrer method indicated that uranium monocarbide is face-centered cubic with $a_0 = 4.955$ Å. The observed spacings and intensities are given in Table I. In deciding on the positions of the carbon atoms, one is faced with two possibilities. If the carbon atoms occupy the octahedral interstices in the lattice formed by the uranium atoms, the sodium chloride structure is obtained, as in Fig. 3a; whereas, if the alternate tetrahedral holes are

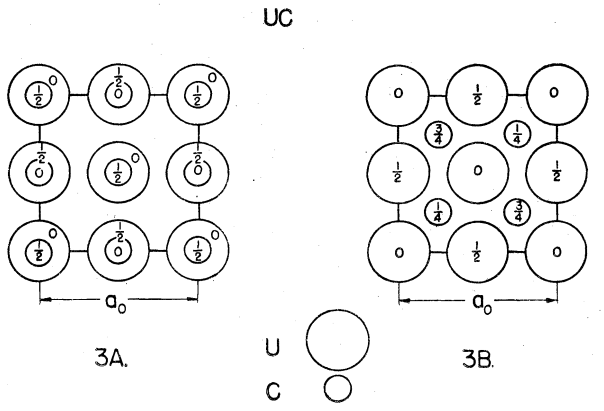

Fig. 3.—A, Sodium chloride structure; B, zinc sulfide structure.

filled, the zinc blende structure, Fig. 3b, is obtained. The space groups and the equivalent points for the two structures are

Sodium chloride structure $O_h^5 - Fm3m$
(0,0,0; 0,1/2,1/2; 1/2,0,1/2; 1/2,1/2,0) +
U 4(*a*) 0,0,0
C 4(*b*) 1/2,1/2,1/2

Zinc blende structure $T_d^2 - F\bar{4}3m$
(0,0,0; 0,1/2,1/2; 1/2,0,1/2; 1/2,1/2,0) +
U 4(*a*) 0,0,0
C 4(*c*) 1/4,1/4,1/4

The calculated values of Table I are the intensities relative to the (111) line for each of the structures. The relation

$$I \propto pF^2 \frac{1 + \cos^2 2\theta}{\sin^2 \theta \cos \theta}$$

was used to obtain the calculated intensities. p is a multiplicity factor, F, the crystal structure factor, and the trigonometric function of the Bragg angle, θ, contains the Lorentz and polarization factor and a geometric factor entering because of the experimental method. The intensity of the diffracted radiation from both the thin sample on the hair and the thick block of powdered material is given by this formula. Because the necessary data were not available, the structure factor was not corrected for temperature effect. Only the constant of proportionality is different for the two methods, and this is not of interest in the calculation of relative intensities. All of the required quantities were obtained from the "Internationale Tabellen."[7]

By comparing the measured intensities, as obtained on the X-ray spectrometer, with those calculated for the two possible structures, it was found that satisfactory agreement is obtained with the sodium chloride structure. The relative magnitude of the first two lines is particularly significant. The Debye–Scherrer films also support the sodium chloride structure in that it is observed that the (420) line is of slightly greater intensity than the (331) line. The calculations indicate the reverse to be true for the zinc blende structure. The proximity of these two lines on the photographic film permits rather accurate estimates of their relative intensity—a fact suggested to the authors by R. Rundle, who determined the structure of this compound for the Manhattan District project.

Crystal Structure of Uranium Dicarbide.—The dicarbide is reported in the literature to have a tetragonal structure with $c/a = 1.7$ for the body-centered tetragonal cell,[8] in agreement with the observations of the authors. However, the lattice constants are not given and in order to obtain them it was necessary to index the lines. This was accomplished with the aid of a Davey chart for body-centered tetragonal lattices. The values obtained were $a_0 = 3.54$ Å., $c_0 = 5.99$ Å. The observed spacings and those calculated from these values of the lattice constants are given in Table II. It has been noticed that when the dicarbide contains some monocarbide, as the result of incomplete conversion, a noticeable decrease in the lattice spacing occurs, particularly in the direction of a_0.

The problem of determining the positions of the carbon atoms in uranium dicarbide is somewhat more complicated than in the monocarbide. The

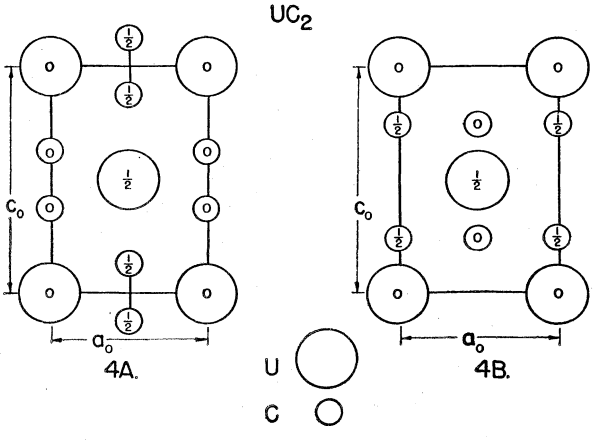

Fig. 4.—A, Calcium carbide structure; B, elongated fluorite structure.

(7) "Internationale Tabellen zur Bestimmung von Kristallstrukturen," 2 Band, 1935.

(8) *Strukturber.*, **2**, 276 (1928–1932); G. Hagg, *Z. physik. Chem.*, **B 12**, 42 (1931).

two structures which might be obtained by adding another carbon atom to the structures considered for the monocarbide are indicated in Fig. 4. By placing two carbon atoms in each of the octahedral interstices in the uranium lattice in a manner so that the carbon–carbon axis are parallel to one edge of the unit cell, one obtains the calcium carbide structure indicated in Fig. 4a. This was the structure assigned to uranium dicarbide by Hagg, presumably because the axial ratio is the same as that of calcium carbide. In the other structure, derived from the zinc blende structure, each carbon atom is at the center of a deformed tetrahedron, as in Fig. 4b. This is similar to the fluorite structure with tetragonal deformation. The space groups and equivalent points for these two structures are given below

Calcium carbide structure
D_{4h}^{17} (0,0,0; $\frac{1}{2},\frac{1}{2},\frac{1}{2}$) +
U 2(*a*) 0,0,0
C 4(*e*) 0,0,*z*; 0,0$\bar{z}$

Elongated fluorite structure
D_{4h}^{17} (0,0,0; $\frac{1}{2},\frac{1}{2},\frac{1}{2}$) +
U 2(*a*) 0,0,0
C 4(*d*) $\frac{1}{2}$,0,$\frac{1}{4}$; 0,$\frac{1}{2}$,$\frac{1}{4}$

Intensity calculations made for several values of the carbon-to-carbon distance of the two adjacent carbon atoms in the calcium carbide structure showed variations too small in magnitude to aid in deciding the correct distance. The values in the fifth column of Table II are for $z = 3/8$, which corresponds to a carbon-to-carbon distance of 1.50 Å., slightly less than the single bond distance.

The observed intensities are seen to be in best agreement with the calcium carbide structure. Points of significance are the relative intensities of the (110) and (112) lines and the (204) and (105) lines, where the calculated intensity gradient is in the opposite sense for the two structures. In both cases, the observed values are in the direction predicted by the calcium carbide structure. Because of the low resolving power of the spectrometer, adjacent lines overlap in several instances and, for this reason, only the (110), (112), (200), and (103) lines were measured spectrometrically. The general trend of values obtained from the spectrometer is in agreement with the estimated order of intensities obtained from the photographic method.

Discussion.—Before the completion of the experimental work on the determination of the positions of the carbon atoms, the problem had been approached using the concept of atomic radii. Calculations applying this method had indicated that the structures arrived at later experimentally were the less likely. In the case of both the monocarbide and the dicarbide, the uranium radii required to provide atom-to-atom contact in Structures 3A and 4A were decidedly greater than those existing in the metal and, since the radii of a metal usually decrease on compound formation, these structures had appeared unlikely. With the zinc blende and elongated fluorite structures, Figs. 3B and 4B, the required uranium radii agreed very well with metallic radii for uranium. The evidence obtained from the X-ray diffraction studies appears rather strong in the other direction, and it would seem that these materials represent an anomaly in the theory of atomic radii. The pronounced orientation effect observed with the monocarbide also supports the conclusion that its structure is that of sodium chloride, as the strengthening of the (200) line indicates cleavage along the cube faces. Since cleavage usually occurs along planes of highest density of atoms, and this is the (100) plane in the sodium chloride and the (111) plane in the zincblende structure, the former is preferred.

Information gathered in the study of the hydrolysis of these carbides may help to clarify this apparent anomaly.

Summary

Uranium dicarbide, UC_2, and the previously unreported monocarbide, UC, have been prepared by several methods. The crystal lattice constants have been determined for the two structures, and X-ray diffraction evidence is presented which indicates that the monocarbide has the sodium chloride type of structure, and the dicarbide has the calcium carbide type of structure.

The lattice constants observed are: UC, a_0 = 4.995 Å.; UC_2, a_0 = 3.54 Å.; c_0 = 5.99 Å.

Liquid and Vapor Curves in the System Ethyl Alcohol–Benzene–Carbon Tetrachloride at Constant Pressure

BY A. N. CAMPBELL AND W. J. DULMAGE

While the constituent binary systems of the system alcohol–benzene–carbon tetrachloride have been investigated repeatedly, only an imperfect study of the ternary system exists. This is that of Schreinemakers,[1] who determined by a dynamic method the boiling temperatures under different pressures of ternary mixtures of these substances. From the pressure–temperature curves thus obtained, he deduced the pressure–concentration relations and, more important to the present work, the temperature–concentration relations. The latter data when plotted on a plane triangle give the projection of the boiling point surface for different constant pressures, and this diagram, given by Schreinemakers, is similar to Fig. 3 of this paper. Despite the rather crude method used by Schreinemakers, his results are in qualitative, and rough quantitative, agreement with ours.[2]

Although Schreinemakers' treatment of the vapor pressure relations is adequate, liquid–vapor composition data are necessarily lacking, since his experimental method was incapable of giving such information. Hence, the vapor surface corresponding to Schreinemakers' liquid surface was unknown. It was the aim of the present study to complete Schreinemakers' work, by an investigation of the liquid–vapor equilibria under isobaric conditions. The pressure chosen was that of the standard atmosphere (760.0 mm. at 0°) and the boiling points of all mixtures were determined, although, for reasons detailed later, we claim no greater absolute accuracy than $\pm 0.05°$ for the temperature measurements.

For the sake of completeness, the binary systems were also investigated, although two of these systems, *viz.*, alcohol–benzene and alcohol–carbon tetrachloride, have been investigated previously in an exhaustive manner: as is well known, these systems show azeotropic minima on their boiling point curves. Considerable doubt has existed hitherto regarding the system benzene–carbon tetrachloride. Because of the closeness of the boiling points of the constituents and the close similarity in composition between liquid and equilibrium vapor, and other criteria, it has been suggested that this system may exhibit an azeotropic mixture of minimum boiling point very close to the carbon tetrachloride end of the curve. Indeed, Young[3] states that "it is certain that benzene and carbon tetrachloride form such a mixture" (of minimum boiling point); and again (ref. 3, p. 92.) "these two liquids can form such a mixture, though the difference between the maximum pressure and the vapor pressure of carbon tetrachloride is probably too small to be determined by direct experiment." Hildebrand,[4] however, states, without authority, that carbon tetrachloride does not form a minimum boiling point mixture with benzene. Lecat,[5] whose work is considered definitive up to the year of its publication, leaves the question open. We show in this paper that, despite an apparent minimum of about 0.05°, which the inaccuracy of our temperature measurements deprives of significance, the vapor phase is never richer in benzene than the liquid phase, over a range from 1 to 99% benzene; that is, there is no reversal of composition, as there would be in passing through an azeotropic point.

Experimental

The apparatus used for the establishment of equilibrium was that of Scatchard.[6] The advantages of Scatchard's equilibrium still are that traditional difficulties such as superheating of liquid, reflux condensation and entrainment of vapor, and lack of equilibrium are eliminated by the use of a Cottrell-type pump, a double boiler, and a hold up trap. This still simplifies the removal of liquid and condensed vapor samples from the inner boiler and the condensate trap, respectively. The barostat, shown in Fig. 1, was modelled on that of Matthews and Faville,[7] but modified by the introduction of two controlled stages, as shown in Fig. 1. In the first stage, which was controlled simply by an ordinary magnetic relay, the pressure was kept by the pump at about 20 mm. above that in the second stage, which was controlled by the device of Leroy,[8] using an electronic relay which operated when the circuit broke. The mercury column in stage 2 was thermostatically controlled and of such a length as to correspond to 760.0 mm. of mercury at 0°. The final adjustment was made by boiling pure water in Scatchard's apparatus under barostatic control, and altering the pressure in stage 2 by small additions and removals of mercury until the water boiled at 100.00°.

To obviate the possibility of a flutter in the mercury surface we introduced the second slow leak L_1, the effective orifice of which was such as to give approximate balance between the two leaks, L_1 and L_2. Under these conditions no tremor of the mercury could be detected in the field of vision of a telescope and the boiling point of pure benzene remained absolutely constant as measured by a Beckmann thermometer.

Temperature Measurement.—As we possessed neither a multiple junction thermocouple nor a resistance thermometer, we were obliged to measure temperature with a

mercury-in-glass thermometer, graduated to 0.1° Such is the uncertainty of the exposed stem correction, that we do not feel justified in claiming a higher absolute accuracy than ±0.05°, although the agreement between consecutive determinations on the same day is no doubt better than this. About two hours of boiling were allowed for the attainment of equilibrium in each determination. After the reading of temperature, samples were removed from "liquid" and "vapor" chambers for analysis. There is a small, and probably inevitable, error introduced when using Scatchard's apparatus at pressures above that of the laboratory. Since sampling must be done immediately boiling is discontinued, on opening the apparatus there is a tendency for boiling to recommence when the pressure falls. This may produce a small amount of distillation, and the resulting disturbance of equilibrium can be detected.

Method of Analysis.—The method of analysis, which is very accurate, has been described elsewhere.[9] The method consists in the determination of refractive indices and densities, and yields an analytical accuracy of 0.3% of the total of each component, using pure materials. Our liquid and vapor curves are therefore correct to this limit. In the binary systems, density determinations only were made, and here the accuracy is still higher. Unfortunately, the flatness of the boiling point curves and the uncertainty of our temperature measurements renders a precise comparison of our data with existing data impossible, but there is no doubt the agreement is very good for the two well established systems, alcohol–benzene and alcohol–carbon tetrachloride.

Purity of Materials.—All materials were purified by the methods used by Campbell and Miller[9] when they calibrated the analytical curves.

(9) A. N. Campbell and S. I. Miller, *Can. J. Research*, **B25**, 228–242 (1947).

Distillation Curves.—After determining the liquid–vapor relations in the ternary system (Fig. 3) and knowing the boiling temperature of each point plotted, it is an easy matter to draw a diagram descriptive, in a qualitative manner, of the course of distillation, that is, the direction in which the residue will change its composition with rising temperature. This has been done in Fig. 4. A few rough experiments were carried out to confirm this. Certain typical mixtures were submitted to distillation through a fractionating column, and successive distillates, and occasionally the residue, analyzed. Barostatic control was not imposed and the results therefore correspond to an average laboratory pressure of 740 mm.

Results

The results for the equilibrium concentrations of liquid and vapor are expressed numerically in Table I and graphically in Figs. 2 and 3, where concentrations are expressed in mole per cent.: the figures for the well-known binary systems:

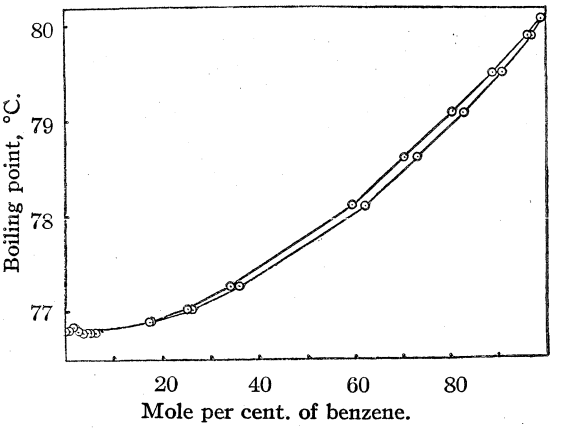

Fig. 2.—Boiling point–composition diagram for the system benzene–carbon tetrachloride.

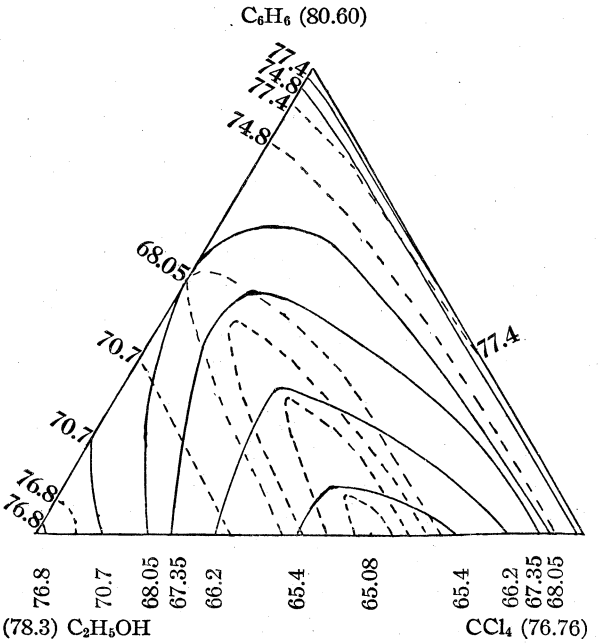

Fig. 3.—Liquid and vapor isothermals in the ternary system (concentrations in mole per cent.).

benzene–alcohol and carbon tetrachloride–alcohol are not given. In the ternary figure (Fig. 3) the full curves represent liquid solutions and the dotted curves equilibrium mixtures of vapor; the pairs are identified by the temperatures which are given at the end of each curve. To avoid confusion, no tie-lines have been drawn, but these can be put in by the reader from the data of Table I.

From the data of Table I, the distillation diagram (Fig. 4) has been deduced. The results of experimental distillations, conducted under laboratory pressure and without barostatic control, were in qualitative agreement with the predictions of Fig. 4.

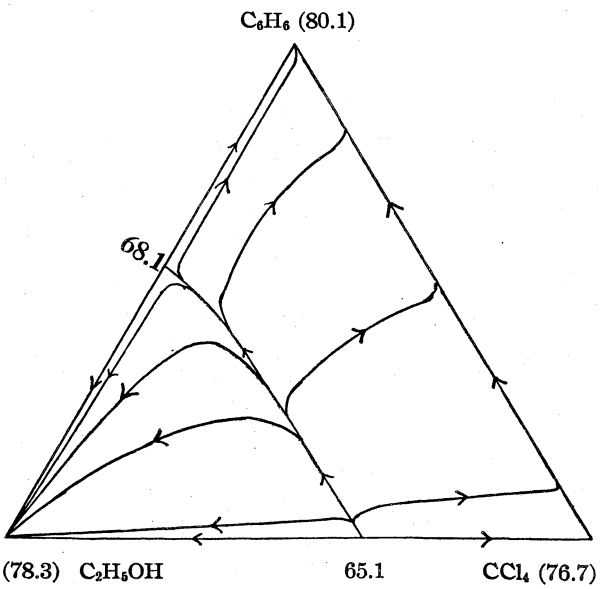

Fig. 4.—Course of the distillation: the arrows represent the direction of rising temperature.

Discussion

Nothing need be said about the binary systems: alcohol–benzene and alcohol–carbon tetrachloride except that our results were in good agreement

with published data and better than most in respect of composition, though not of temperature. The disputed system benzene–carbon tetrachloride does not show an azeotropic minimum on the boiling point curve, despite the fact that our own results appear to show a minimum temperature about 0.05° below the boiling point of carbon tetrachloride: this temperature difference is the error of measurement. The evidence against the minimum rests on our very accurate method of analysis. No matter how low the benzene content the tie-lines never reverse; that is, the vapor is a ways richer in carbon tetrachloride. It is admitted that if there were any azeotropic mixture it could not contain more than ten mole per cent. benzene, and from 10 to 2.47% benzene our results show a higher content of carbon tetrachloride in the vapor, while for 1.54 and 0.65 mole per cent. the vapor appears to have the same composition. This apparent identity is due to our inability to read the analytical curve to any higher degree of accuracy than, say, 0.02%; the density determinations themselves still indicated a higher carbon tetrachloride content in the vapor.

The ternary diagram shows the existence of a trough of minimum boiling point running across the diagram from 65.08° and about 39 mole per cent. alcohol, in the alcohol–carbon tetrachloride system, to 68.05° and about 45 mole per cent. alcohol, in the alcohol–benzene system. This trough has itself no minimum of temperature and therefore the liquid and vapor curves coincide only at its ends. The method of investigation actually used was to proceed across the diagram from the alcohol corner along lines of approximately constant benzene:carbon tetrachloride ratio. Proceeding in this way, the following behavior of the tie-lines is general over the diagram. At first, *i. e.*, for mixtures rich in alcohol, the vapor is much richer in benzene and carbon tetrachloride, the direction of the tie-line being symmetrical with respect to the sides of the triangle. As the content of alcohol decreases, the tie-line shortens and changes direction as it approaches the trough. A liquid mixture lying in the trough (which is almost, though not quite, a straight line) has a tie-line also lying almost in the trough, but the slightest change in liquid composition causes the tie-line to deviate considerably in one or the other direction. The experimentally determined tie-lines lying over the trough, of which there are several, were obtained by proceeding along the trough itself, a difficult procedure involving much trial and error. Proceeding along a line of constant benzene–carbon tetrachloride ratio, after crossing the trough, the tieline turns rapidly to assume a position at almost 180° to its former position; that is, the vapor is now richer in alcohol. In the solid model, the temperature slope from the trough to the benzene–carbon tetrachloride side is much steeper than the corresponding slope from the trough to the alcohol apex and, as Fig. 4 shows, the former slope increases very rapidly at the last. In agreement with this, it is found that the tie-line, which now slopes somewhat toward the carbon tetrachloride corner, retains this slope almost till the last and then, as the last trace of alcohol leaves the mixture, undergoes a sharp change to occupy its position in the binary surface benzene–carbon tetrachloride.

This detailed knowledge of the behavior of the tie-lines enables one to predict the course of distillation of any mixture. Referring to Fig. 4, consider a liquid mixture lying in the triangle to the left of the trough. The residue will move in the direction of the arrow, the temperature rising and the mixture becoming richer in alcohol, until pure alcohol is left in the boiler. The first distillate will be poorer in alcohol than the original mixture. Redistillation of distillates will eventually give a mixture lying in the trough: the trough can never be crossed. It might be supposed that a mixture on the trough, lying as it does in an (almost) pseudo-binary system, might be separated by distillation into a distillate of the low boiling azeotrope of the alcohol–carbon tetrachloride system, and a residue of the higher boiling azeotrope of the alcohol–benzene system. This is not true, however, because the projections of liquid and vapor compositions do not quite coincide in the trough of minimum boiling point. Hence, though the distillate will always approximate to the trough, the residue soon deviates from it, because the tie-lines change their direction rapidly on both sides of the trough. It would seem, then, that the final results of fractional distillation of any mixture in the triangle described above would be a residue of pure alcohol and a distillate of the low boiling azeotrope alcohol–carbon tetrachloride; but this obviously cannot describe the fate of the whole mass of the mixture, since the mixture as a whole contains benzene. The benzene is to be found in the middle fractions which approximate more and more to the trough and move up it in the direction of the higher boiling azeotrope To summarize, a mixture containing benzene, alcohol and carbon tetrachloride in such proportions that the mixture lies to the left of the trough can be separated by distillation into a residue of pure alcohol, a refined distillate of the low boiling azeotrope of the alcohol–carbon tetrachloride system and an intermediate mixture approximating in composition to the higher boiling azeotrope of the alcohol–benzene system. The same result could of course be obtained by using a fractionating column of suitable length and drawing off fractions at suitable heights.

In the quadrilateral area lying between the trough and the benzene and carbon tetrachloride corners, distillation eventually yields a distillate of the low boiling azeotrope, while the residue rapidly approaches in composition the binary system benzene–carbon tetrachloride. But shortly before the last trace of alcohol is removed from the res-

idue, the direction of change of composition of the residue alters abruptly in the direction of the benzene corner, so that when eventually the last trace of alcohol is removed, the binary mixture produced is much richer in benzene than the original mixture. From this binary mixture both benzene and carbon tetrachloride can (theoretically) be obtained by distillation, since the binary mixture benzene–carbon tetrachloride shows neither minimum nor maximum on the boiling point curve. It appears, therefore, that in the quadrilateral area pure benzene, pure carbon tetrachloride and the low boiling azeotrope can be obtained by fractionation. In addition, however, certain of the middle fractions would tend to approximate to the higher boiling azeotrope of benzene–alcohol but, as with the triangular area, it is doubtful whether in practice any of this binary azeotrope, uncontaminated by carbon tetrachloride, would be obtained, because of the strong curvature of the tie-lines around the trough.

The above predictions were borne out in practice by our distillation experiments.

Summary

The boiling temperatures, under constant pressure, of the binary systems alcohol–benzene, alcohol–carbon tetrachloride, and benzene–carbon tetrachloride, as well as those of the ternary system alcohol–benzene–carbon tetrachloride, have been investigated. The equilibrium concentrations of liquid and vapor for the above systems have been determined, with an accuracy of 0.3 weight per cent.

It is shown that the system benzene–carbon tetrachloride does not exhibit an azeotropic minimum on its boiling point curve. An improved barostat is described.

The liquid–vapor composition diagram is discussed and the course of distillation predicted. The course of distillation has been verified qualitatively by experiment.

Modifications of the Brunauer, Emmett and Teller Equation II[1]

BY ROBERT B. ANDERSON[2] AND W. KEITH HALL[2]

The simple Brunauer, Emmett and Teller equation[3] (hereafter abbreviated to B.E.T.) has been useful in the estimation of surface areas from physical adsorption isotherms. This equation will fit satisfactorily experimental data for almost all isotherms except those of Type I of Brunauer, Deming, Deming and Teller[4] in the relative pressure range of 0.05 to 0.40. Several modifications of the simple B.E.T. equation have extended the range of applicability. In most cases the adsorbent structure is pictured as a series of parallel plates which will permit the adsorption of only n-layers from each side. An n-equation derived by B.E.T.[3] and Hill[5] extends the fit to higher relative pressures for most isotherms, but it is somewhat difficult to apply to experimental data.[6] Brunauer, Deming, Deming, and Teller[4] derived a more elaborate n-equation in which the heat of adsorption of the last layer adsorbed in a condenser plate capillary was higher than the heat of liquefaction. Although this equation can be fitted to the entire isotherm, its application is too difficult to be of any practical value as a method of characterizing isotherms.

Pickett[7] presented a simpler type of n-equation than that of B.E.T., one which is more easily applicable to adsorption data and probably fits over a greater range. The simplest derivation of this equation assumes that the volume of gas adsorbed in any layer is independent of the molecules adsorbed in higher layers; whereas, the n-equation of B.E.T.[3] implies that adsorption of molecules in higher layers stabilizes the molecules in underlying layers.

Recently, Anderson[8] suggested that the parallel plate type of pore structure is probably not a good physical picture of most porous adsorbents. A pore structure in which the area available to each subsequent layer is less than the area of the underlying layer is probably a better physical picture. In this paper it was also shown that for isotherms of finely divided, presumably non-porous solids such as carbon black, titania, etc., the modified B.E.T. equation could be fitted to the range of relative pressure of 0.05 to 0.7 by assuming the free energy of adsorption in the several layers after the first to be less than the free energy of liquefaction.

In the present paper, an equation embodying the same assumptions is derived in a manner similar to that of the B.E.T. equation. It can be satisfactorily fitted to isotherms of Type I and those approaching Type I by assuming the free energy of adsorption in the second and subsequent layers

The plus sign indicates where the data begin to deviate from the linear plot.

equal to that of liquefaction. The same equation can be fitted to Type IV isotherms,[4] which flatten below relative pressures of 0.85 by assuming the free energy of adsorption to be greater than that of liquefaction. This equation was used to integrate the equation of Kistler[9] for the latter type of isotherms. The areas computed with Kistler's equation were at least of the same order of magnitude as areas from the modified B.E.T. equation presented here or the simple B.E.T. equation.

In this paper adsorption in a capillary is assumed to occur in the same manner as on a free surface with capillary forces causing the pores to fill at relative pressures less than 1. Isotherms used as examples in this paper were determined by conventional volumetric and gravimetric methods, and either have been or will soon be described in the literature.

Derivation of a Modified B. E. T. Equation and Application to Type IV Isotherms.—The derivation follows that of the original B.E.T. equation[3] in which

$$V/V_m = \sum_0^\infty is_i / \sum_0^\infty s_i \qquad (1)$$

where V is the number of adsorbed gas molecules, V_m the number of molecules required to form a monolayer, and s_i is the number of sites covered with stacks i molecules high. In pore systems in which the area available to each layer is less than that of the layer underneath, it is assumed that at any relative pressure the volume adsorbed in the i-th layer is equal to the amount that would be adsorbed in this layer on a plane surface multiplied by A_n/V_m where A_n is the number of molecules required to fill the n-th layer. Although the relationship of A_n to V_m for any postulated type of pore is a function too complicated to give a simple summation of equation (1), it may be satisfactorily approximated in many cases by assuming $A_n/A_{n-1} = j$, where j is a constant less than 1. Since the surface area is defined as the area occupied by the first layer, the j correction will not be applied to it. This results in the relationship[10] that $s_i = s_0 c j^{i-1} x^i$. Thus

$$\frac{V}{V_m} = \frac{cs_0 \sum_1^\infty ij^{i-1}x^i}{s_0\left(1 + c\sum_1^\infty j^{i-1}x^i\right)} = \frac{cx}{(1 - jx)[1 + (c - j)x]} \qquad (2)$$

where, as in the simple B.E.T. equation, x is identified as p/p_0. At $x = 1$, almost all of the pores should be filled and since c is usually 5 to 100 and $1 > j > 0$

$$V/V_m = c/(1 - j)(1 - j + c) \cong 1/(1 - j) \cong V_s/V_m \qquad (3)$$

where V_s is the number of adsorbate molecules required to fill the pore system.

If the free energy of adsorption in the second and subsequent layers differs from the free energy of liquefaction by an equal amount d, then following the derivation by Anderson[8]

$$\frac{V}{V_m} = \frac{ckx}{(1 - jkx)[1 + (c - j)kx]} \qquad (4)$$

where $k = \exp d/RT$. The energy terms in the exponents of the equations for c and k are free energies of desorption and are opposite in sign to free energies of adsorption. Thus, if d is positive (k greater than 1), the free energy change in adsorption in the second and subsequent layers is more negative than the free energy of liquefaction, and the pores of the adsorbent should fill at relative pressures less than 1. In equation 4, almost all of the pores will be filled at $x = 1/k$. In systems of small pores the free energy of adsorption in second and subsequent layers may be expected to be less than that of liquefaction, since surface

(9) Kistler, Fischer and Freeman, *ibid.*, **65**, 1909 (1943).

(10) This relationship is not obvious but can be shown in the following manner: let V_i be the number of sites covered by i or more layers; then, for adsorption on a plane surface, $V_i = \sum_i^\infty s_i = s_i/(1-x)$, and $V_i/V_{i-1} = s_i/s_{i-1}$. For adsorption in a capillary the value of V_i/V_{i-1} should be multiplied by j, and hence the ratios s_i/s_{i-1} should also be multiplied by j. Thus, $s_i'/s_{i-1}' = js_i/s_{i-1} = jx$ where the primes indicate the values of s_i and s_{i-1} for adsorption in a capillary. In the rest of the derivation the primes will be omitted.

area decreases as the amount adsorbed increases. Equation 4 is similar to the equation derived previously[8] using the same assumptions as Pickett,[7] except that $(c - j)$ appears in the second term in the denominator instead of $(c - 1)$. The difference is negligible except for values of c near 1 and values of j near zero.

Equation (4) can be fitted to adsorption data by plotting $x/V(1 - jkx)$ against x with the constant jk varied to give the best straight line, and $1/V_m$ = slope + kj (intercept). To simplify computation, the volume adsorbed was read from the isotherms in intervals of 0.05 relative pressure unit. Tables of $x/(1 - jkx)$ were prepared, with corresponding values of x and for values of jk in intervals of 0.05 in the range of 0.00 to 1.40. Then, in making the modified B.E.T. plots, it was necessary only to divide the values in these tables by the volume adsorbed. Since fairly close approximations of j and k can be made from the isotherms, usually only one to three plots were necessary to establish the best value of the product jk. For evaluation of constant c, the adsorption equation was solved for c with $V = V_m$ in terms of x_m, the relative pressure at which $V = V_m$.

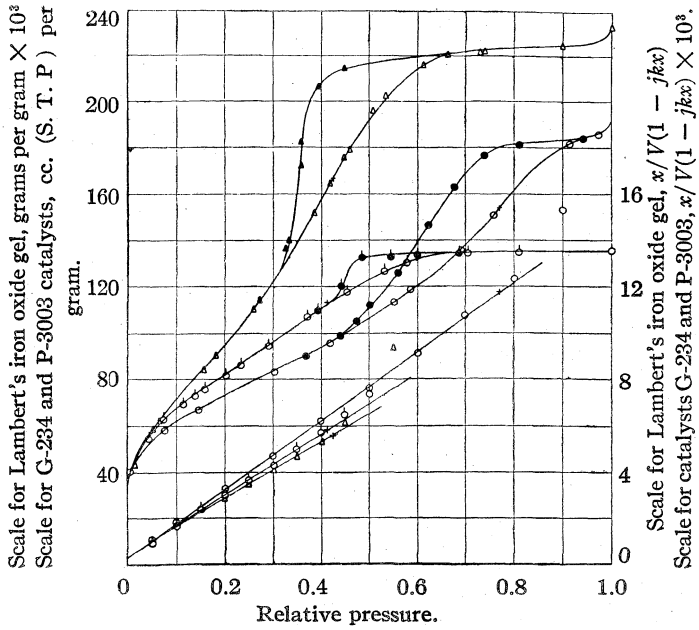

Fig. 2.—Isotherms and linear plots of benzene on Lambert's iron oxide gel at 50° with jk = 1.30; △, nitrogen on Fe_2O_3–CuO–K_2CO_3 Fischer–Tropsch catalyst P 3003 at −195° with jk = 0.90, ○, and nitrogen on Fe_2O_3–CuO–CaO–Kieselguhr Fischer–Tropsch catalysts G 234 with jk = 0.75, ○. Desorption points are solid, and the plus signs indicate where the data begin to deviate from the linear plot.

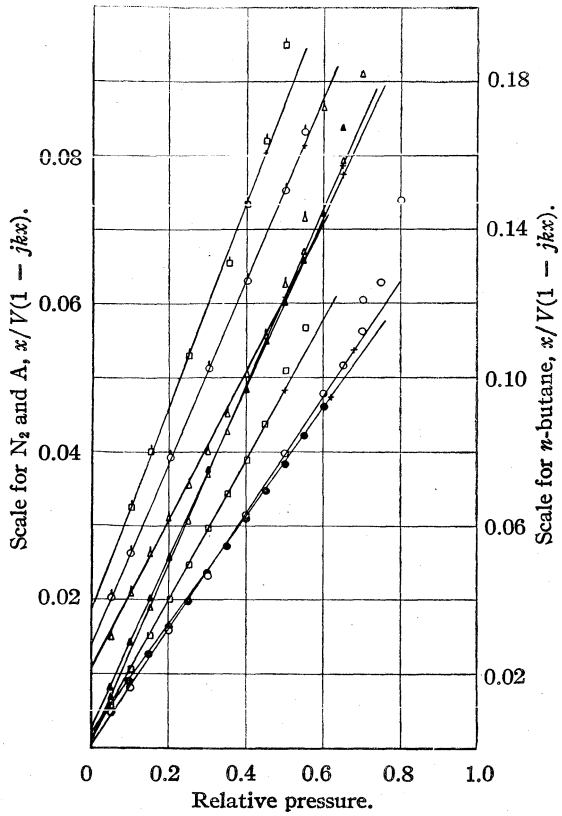

Fig. 3.—Linear plots of adsorption isotherms on porous glass where O, ● and ⏀ represent nitrogen, argon and n-butane on 0.253 g. of porous glass 3, □ and ⊟ represent nitrogen and n-butane on 0.157 g. of porous glass 5, and △, ▲ and ⧋ represent nitrogen, argon and n-butane on porous glass 7. The plus mark indicates the highest point at which the points fall on the straight line. Nitrogen and argon isotherms were determined at −195° and n-butane at 0°.

Application of equation (4) to the nitrogen adsorption and desorption isotherms of iron oxide gel catalyst 47C[11] is shown in Fig. 1. For the adsorption isotherm, the linear plot is satisfactory to the point marked +, which is about the point of inflection of the adsorption branch. The constants of the equation are V_m = 44.1 cc. and jk = 1, in this case the linear plot being identical to that of the simple B.E.T. equation. From equation (3) evaluated with V_s = 151.5, j = 0.7111 and thus k = 1.408. The isotherm calculated for relative pressures higher than the + mark is shown by the broken curve. This curve, which appears to be an extrapolation of the adsorption isotherm below +, intersects V_s at a relative pressure equal to $1/k$. This is useful in approximating the choice of jk, since j can be estimated from equation (3) assuming V_m to occur at x = 0.1.

In Fig. 1, equation (4) has also been applied to the desorption isotherm. The plots for the best choices of jk, 1.1 and 1.2, are not satisfactory, indicating the equation is not applicable to the desorption branch.

Equation (4) has been applied to the adsorption isotherms of nitrogen, argon, butane, and benzene on several ferric oxide gels and porous glasses with equal success. The equation has been fitted satisfactorily to all isotherms of this type which flatten below a relative pressure of 0.85. Isotherms of nitrogen on ferric oxide–copper oxide–potassium carbonate Fischer–Tropsch catalyst P3003, German ferric oxide–copper oxide–calcium oxide–kieselguhr catalyst 234, and benzene on ferric oxide gel of Lambert[12] and the corresponding plots of equation (4) are presented in Fig. 2. In Fig. 3 are linear plots of data for adsorption isotherms of nitrogen, argon, and butane on porous glasses 3, 5, and 7.[13] Data for the application of equation (4) to the isotherms shown in Figs. 1, 2, and 3 and several similar isotherms are summarized in Table I. Included in the table are data for two isotherms of nitrogen on silica gels which flatten above 0.85. These data, as well as data on average pore diameters, will be described in later sections. The value of V_m computed from equation (4) will vary slightly from the V_m computed from the simple B.E.T. equation, being higher for jk lower than 1 and lower for jk higher than 1. Since the difference is less than 10% in all cases, V_m from the simple B.E.T. equation has not been included. With the exception of the two silica gel isotherms, equation (4) could be satisfactorily fitted to the adsorption isotherm from relative pressures of 0.05 to the point of inflection, but the equation could not be fitted to the desorption isotherm.

The physical interpretation of equation (4) is that the capillary forces shift the p_0 value of the adsorbate from p_0 to p_0/k, and at a relative pressure of $1/k$ all, or almost all, of the pores are filled. The lack of fit above the point marked + may be due to the rather crude approximation of the assumptions of equation (4) to the pore structure of the adsorbent. Some isotherms such as those shown in Figs. 1 and 2 flatten and then rise again at high relative pressures. This is very probably due to a small fraction of very large pores. The value of V_s in these cases is taken as the point where the isotherm begins to rise again.

For isotherms which flatten above relative pressures of 0.8 or 0.85, equation (4) does not fit data satisfactorily to the point of inflection as in Fig. 4, although the data can usually be fitted to relative pressures of 0.7. This is interpreted as indicating that in systems of larger pores it is not permissible to assume the capillary forces effective in all layers, but that these forces become effective only in the third or higher layers. Equations embodying the assumption that the free energy of adsorption becomes less than that of

(11) Hofer, Peebles and Dieter, THIS JOURNAL, 68, 1953 (1946).

liquefaction in the third or higher and subsequent layers can be derived, but the difficulty in application to data is too great for them to be of interest as a simple method of characterizing isotherms with a few constants. Examples of isotherms of this type are those of the silica gel catalyst and a silica aerogel, as shown in Fig. 4. The values of k were 1.04 and 0.87, respectively, for these isotherms. This suggests a transition in systems of large pores of the values of k from greater than 1 as characteristic of small pores to values of k less than 1 as observed for non-porous solids. Kistler[9] has postulated the structure of aerogels to be a "felt" of fibers. Hence, when the surface is covered with only two or three layers it may act as a non-porous adsorbent.

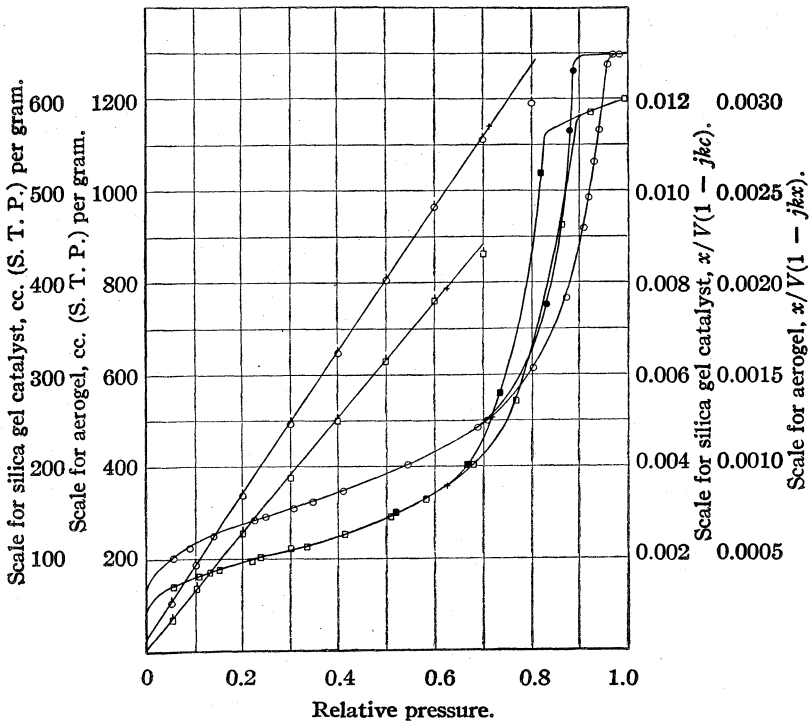

Fig. 4.—Adsorption isotherms and linear plots of nitrogen at −195° on silica catalyst □ and on aerogel O. Desorption points are solid and points of linear plot have tails. The plus sign indicates where data begin to deviate from linear plot.

Kistler[9] presented an equation for determining surface area without the assumption of an area per adsorbed molecule. In this equation, the free energy change in completely filling a system of capillaries covered by a monolayer (as computed from the adsorption isotherm) was equated to the decrease in surface area per gram, ΔA, times the normal surface tension of the liquid, σ. That is

$$\Delta A = -(RT/M\sigma)\int_0^{W(x=1)} \ln x \, dW \qquad (5)$$

where W is the total weight adsorbed minus the weight of adsorbate in the first layer in grams per gram of adsorbent. W was computed by subtracting a Langmuir-type isotherm fitted to points at low relative pressures from the adsorption isotherm, and the integral was evaluated graphically. It should be noted that: (a) equation 5 is only applicable to porous adsorbents in which all of the pores are completely filled at $x = 1$, (b) identification of the surface free energy of the first layer with the normal surface tension of the liquid may be a poor assumption, and (c) this equation does not confirm or deny multilayer adsorption.

Equation 5 may be written as

$$\Delta A = \Delta F_n'/\gamma \qquad (6)$$

where $\Delta F_n'$ is the free energy change in the process of going from a system of pores covered with a monolayer to a completely filled capillary system, and γ is the surface free energy, which is not necessarily equal to the normal surface tension. In equation 7, $\Delta F_n'$ is expressed in terms of ΔV, the volume of gas adsorbed in the second and subsequent layers in cc. (S.T.P.) per gram, that is, $\Delta V = V - V_1$, where V_1 is the volume adsorbed in the first layer. The variables of the integration have also been changed.[14]

$$\Delta F_n' = -\frac{RT}{22{,}400}\int_0^{V(x=1)} \ln x \, d\Delta V = \frac{RT}{22{,}400}\int_0^1 \Delta V \, d \ln x \qquad (7)$$

Thus for Type IV isotherms which flatten below relative pressures of 0.85 (isotherms to which equation (4) is applicable), equation (7) may be evaluated with

$$\frac{V_1}{V_m} = \frac{\sum_1^\infty s_i}{\sum_0^\infty s_i} = \frac{ckx}{1 + (c - j)kx} \qquad (8)$$

Equations (4) and (8) may be substituted into the last term of equation (7), and the integral evaluated to point I of Fig. 1 ($x = 1/k$) with $\Delta V = V - V_i$ and from $x = 1/k$ to $x = 1$ with $\Delta V =$

(14) This transformation is made as follows

$$\int_0^{V(x=1)} \ln x \, d\Delta V = -\int_0^1 \Delta V \, d \ln x + \Delta V \ln x \Big|_{x=0}^{x=1}$$

The upper limit of the second term of the right side of the equation is zero, and since at very low relative pressures $\Delta V = ckx$,[2] equation 4 minus equation 8, the indeterminate lower limit can be shown to be zero.

[a] Adsorbents described in Table I. [b] Computed from equation 9. [c] Normal surface tension of liquid in ergs/sq. cm. [d] Surface free energy of the first layer of adsorbate in ergs/sq. cm., computed by dividing $\Delta F_n'$ by $S(1+j)/2$.

$V_s - V_m$. This gives

$$\Delta F_n' = \frac{2.3\ RT\ V_m}{22{,}400}\left\{\frac{j}{c-j}\log_{10}(1+c-j)+\log_{10}(1-j)-\frac{j}{1-j}\log_{10}k\right\} \quad (9)$$

Data for the application of equation (9) to isotherms of Table I are given in Table II. Surface areas, ΔA, computed from the free energy divided by normal surface tension were usually larger than S, the area computed from V_m. The decrease in area, ΔA, is the area of the interface between the first and second layer. As an approximation this can be taken as half the sum of the areas of the first and second layers, which is $S(1+j)/2$; however, this area gives poorer agreement with ΔA than S. A small part of the discrepancy is due to the fact that equation (4) predicts a larger volume adsorbed than that of the actual isotherm in the vicinity of point I as shown in Fig. 1. In all cases the areas predicted from equations (4) and (9) are of the same order of magnitude.

The surface free energy, γ, was computed by

[a] Data of V_m and V_s expressed as grams adsorbate per gram for isotherms of Lambert[13] and cc. (S. T. P.)/g. for isotherms of Anderson and Emmett.[15] [b] Average pore diameter calculated from equation of Emmett and DeWitt,[16] equations (10) and (11) in text. [c] Ref. 13. [d] Ref. 15. [e] These isotherms are of Type IV, but without hysteresis.

assuming the values of surface area from $S(1 + j)/2$ and the free energies from equation (9) to be correct. These computed surface free energies given in the last column of Table II are usually always larger than the normal surface tension, in some cases being nearly twice as large. The data for the isotherms of *n*-butane are computed for both of the surface areas given in Table I.

Application of Equation (4) to Type I Isotherms.—Equation (4) is useful in characterizing Type I isotherms[4] as shown in Figs. 5 and 6 for silica gels and charcoals. The data for these and similar isotherms are given in Table III. Lambert's isotherms of benzene on silica gel are definitely of Type I, while the ethanol isotherms as shown in Fig. 5 appear similar to those of some iron gels. Although the values of j and k vary considerably, the surface areas calculated from benzene and ethanol isotherms are nearly identical. Recently, Emmett and Anderson[15] presented isotherms showing the effect of high temperature evacuation on charcoals. In charcoal PCI-1042 (Fig. 6) the evacuation caused sintering and enlargement of pores indicated by a decrease in V_m and an increase in the value of j, as shown in Table III. With charcoal NS_5 less sintering and relatively less pore size alteration occurred as indicated by the changes in V_m and j.

Relation of j to Average Pore Diameter.—Emmett and DeWitt[16] presented a useful method of estimating the average pore diameter, based on cylindrical pores

$$\bar{d} = 4V_L/A \qquad (10)$$

where V_L is the volume of adsorbate necessary to fill pores computed as normal liquid and A the surface area. Introducing equation (3) into equation (10)

$$\bar{d} = 6.56 \frac{M}{\rho a} \frac{1}{1 - j} \qquad (11)$$

where d is the average pore diameter in Å., M and ρ the molecular weight and density of adsorbate, respectively, and a the cross-sectional area of the adsorbate molecule in sq. Å.

Equation (11) has been used to compute average pore diameters from the isotherms of Tables I and III. The average pore diameters from the nitrogen and argon isotherms agreed quite satisfactorily, but the diameters from the butane isotherms were considerably larger. It has been pointed out in the literature that the cross-sectional area of molecules as computed by the method of B.E.T.[3] may not be correct, especially with long molecules like *n*-butane. If the cross-sectional area of butane is taken 1.75 (the average of the ratios of the areas from nitrogen and argon to areas from butane, computed by the usual B.E.T. methods) times the value of 32.1 Å.,[2] the average pore diameters computed from isotherms of the three gases are in fairly good agreement as shown in Table I. For pores that are the order of several molecular diameters, equation (11) does not hold, the diameter calculated being larger than the actual diameter. For the limiting case when the only one molecule fits into the capillary, $\bar{d} = 4V_L/\pi A$. For values of j less than 0.16 (the value of j for a pore of 3 molecular diameters), the constant in equation (11) should be less than 6.56 and greater than 2.09. Since in equation (9) $\bar{d} = \Sigma d^2/\Sigma d$, this average pore diameter will be larger than the arithmetic mean if there is a wide distribution of pore diameters; therefore, any diameter computed by equations (10) and (11) may be regarded as an upper limit of the pore diameter.

Discussion

Constant k of equation (4) is an average value of the k's for all of the adsorbed layers in the capillary system. Since d in the expression $k = \exp d/RT$ is equal to the change in surface area times the surface free energy, the values of k for a given pore system should be greater in higher layers than in those near the surface. Similarly for the same adsorbate on different adsorbents k should be nearly equal to 1 for large pores and

(15) Emmett and Anderson, *J. Phys. Colloid Chem.*, **51**, 1308 (1947).

(16) Emmett and DeWitt, THIS JOURNAL, **65**, 1253 (1943).

have higher values for small pores. Should the adsorbent offer considerable convex surface to adsorption in the first several layers, the value of k may be expected to be less than 1. This is shown in the data of Table I. It is difficult to explain the values of $k = 1$ observed for isotherms approaching Type I. There is no objection to $k = 1$ for isotherms that are strictly of Type I in which all of the adsorption occurs in the first layer. However, for the isotherms of the two PCI-1042 charcoals the values of k might be expected to be considerably larger than 1, since the isotherms indicate multilayer adsorption and since the average pore diameters are smaller than those of the Type IV isotherms of Table I. It is possible that these charcoals are composed of small pores plus a fraction of larger pores that cause the adsorption at higher relative pressures. In this case equation (4) may be regarded as somewhat empirical; however, V_m from this equation and the values of j probably have their usual significance.

With most isotherms the simple B.E.T. equation usually predicts larger adsorption above relative pressures of 0.35 than the actual isotherm, and deviation in this direction is usually considered to occur with all isotherms. It is interesting to note that the isotherms in Table I for which jk is greater than 1 deviate from the simple B.E.T. equation in the opposite direction.

In a previous section adsorption was postulated to occur in the same manner as multilayer adsorption with the decreased free energy of adsorption due to capillary forces causing the pores to fill at a lower relative pressure than 1. Equation (4) was found to satisfactorily fit the data for the adsorption branch of the isotherms, but could not be fitted to the desorption branch. This may indicate that desorption occurs in a different manner. In the authors' opinion desorption occurs from menisci of filled pores to leave the pores covered with the number of layers predicted by equation (4) remaining on the surface. This is similar to the picture of adsorption and desorption given by Cohan[17] except that he postulated that the pore will empty completely on capillary evaporation.

Equation (4) provides a systematic method of determining V_m for isotherms to which the simple B.E.T. equation cannot be fitted. This is also true of isotherms which appear to be a composite of several types of simple isotherms such as those of the porous carbon blacks previously described,[8] and some of the isotherms of active magnesia of Zettlemoyer and Walker.[18] In the latter case equation (4) can be applied satisfactorily to relative pressures of 0.4 by taking jk greater than 1.

Acknowledgment.—The authors wish to thank Dr. P. H. Emmett for his constructive criticisms of the manuscript and for permission to use the isotherms of porous glasses and silica aerogel.

Summary

1. A modified B.E.T. equation similar to that of Anderson[8] has been derived and applied to physical adsorption isotherms of Types I and IV.[4]

2. With Type I isotherms satisfactory fit of this equation can be obtained if the free energy of adsorption in the second and subsequent layers is taken to be equal to the heat of liquefaction.

3. For isotherms of Type IV which flatten below relative pressures of 0.85, the equation satisfactorily fits the data, if the free energy of adsorption was taken less than that of liquefaction. For this kind of Type IV isotherm the equation was used to integrate the equation of Kistler,[9] and the resulting expression gave surface areas of the same order of magnitude as the B.E.T. areas.

4. The equation is believed to be a simple method of characterizing isotherms with four constants.

The Sorption of Gases on a Plane Surface of Two Stainless Iron–Chromium–Nickel Alloys at 20, −78 and −183°[1]

BY MARION H. ARMBRUSTER

The resistance to corrosion and other properties of the stainless iron alloy containing approximately 18% chromium and 8% nickel suggest that the surface of the alloy may differ considerably from that of ordinary steels. As it seemed likely that the sorption of gases on such an alloy might yield a clue to the character of the surface and, by comparison with data for steels, might indicate differences in the nature of the surface, the sorption of hydrogen, neon, argon, nitrogen, carbon monoxide and oxygen has been measured at 20, −78 and −183° and at pressures up to 0.1 cm. mercury. The sorption of carbon dioxide has been determined at −78 and −183°.

The apparatus used, its calibration and method of operation have previously been described.[2] The gases were likewise those used in an earlier study of sorption on mild carbon steel.[3]

(3) Armbruster and Austin, *ibid.*, **66**, 159 (1944).

Samples.—Two samples of the alloy were used. The first (no. 25262), hereafter referred to as Alloy A, is the same sample used in an earlier determination of the solubility of hydrogen[4]; its composition was: C, 0.07; Mn, 0.37; P, 0.006; S, 0.005; Si, 0.47; Ni, 9.92; Cr, 18.30. After measurements with carbon monoxide and carbon dioxide at 400° on this alloy, the surface showed a very faint straw color which the usual reduction procedure with pure hydrogen at 450° did not appear to alter. The second sample (no. 25276), hereafter called Alloy B, is the same sample used in earlier measurements of the sorption of water vapor[5]; its composition was: C, 0.12; Mn, 0.37; P, 0.016; S, 0.005; Si, 0.44; Ni, 9.48; Cr, 18.48. Data collated by Maier[6] indicate that an alloy of this type is covered by an invisible yet protective oxide film not reducible by pure hydrogen. Both samples were commercial materials and are considered representative of this class of alloy within the regular tolerances. The sorbing surface in each case was a bundle of thin strips, each strip approximately 11.0 × 1.9 × 0.009 cm., with a geometric area, determined by summing the areas of the individual strips, of 11,130 sq. cm., the same as that of mild steel samples 1 (no. 25261) and 2 (no. 25277).[3]

Treatment of Samples.—The surface was degreased with absolute alcohol and anhydrous ether distilled over sodium, care being taken not to touch the surface with the fingers. Before each run the sample was reduced in place for about eight hours at 450° in a stream of hydrogen freed from traces of oxygen or water vapor; it was then outgassed for sixteen hours at 450° under a pressure of less than 10^{-6} mm., and finally was brought to the temperature at which the measurement was to be made in an atmosphere of hydrogen, which direct measurement has shown is not measurably adsorbed on this surface. The hydrogen was then pumped off and the pressure reduced to 10^{-6} mm. before the start of the run. In one series of measurements with Alloy A, the hydrogen reduction was omitted.

Orientation of Grains.—Microscopic examination showed that the grains are practically equiaxed. The X-ray pole figures of the two samples showed that there may be a slight preferred orientation of the grains with the (112) planes in the rolling plane.[7]

Microscopic Examination of Samples.—Examination of a polished but unetched section of each sample under the microscope showed that the amount of non-metallic inclusions was very small, less than 0.1%, these being of the same rounded type. Photomicrographs of the samples in the etched condition showed a shower precipitation of carbides mostly at the grain boundaries and to a lesser degree within the grains, mostly at crystallographic planes. The type of precipitation and sub-microscopic size of the individual particles make it impossible to specify the amount of carbides, or possibly nitrides, or to state positively that there is more carbide precipitate in Alloy B. The remainder of the surface is metallic, a solid solution of iron, chromium and nickel.

Results

The sorption of each gas was determined by building up the pressure in several increments, allowing sufficient time at each step for equilibrium to be attained. Several independent runs were made with each gas, the result being reproducible within the limit of measurement; moreover, the results for the two samples showed satisfactory agreement. Neon and hydrogen are not sorbed at any temperature, that is, the sorption, if any, is less than 3×10^{-4} cc. or less than 1% surface coverage.

Reduced Surface −183°.—Typical isotherms selected from concordant runs are shown for the several gases in Fig. 1, in which the amount of sorbed gas, expressed as a volume at 20° and 76 cm., is plotted for various pressures. Argon is

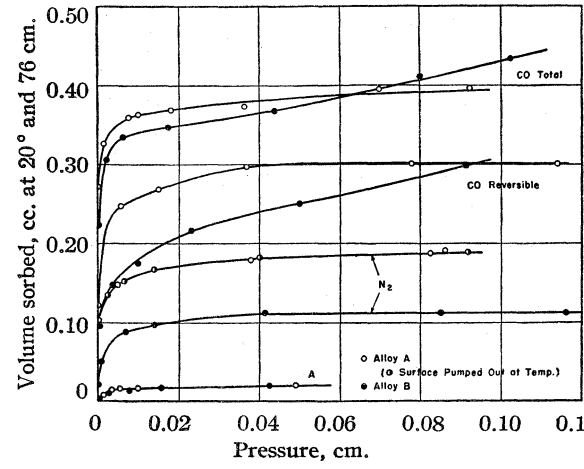

Fig. 1.—Typical adsorption isotherms of the several gases on reduced surface of stainless alloys at −183°.

sorbed very slightly and the gas taken up cannot be removed by pumping at this temperature. The rate of sorption of argon is virtually instantaneous. Nitrogen is sorbed in appreciable quantity and the sorption is completely reversible. The rate of adsorption is practically instantaneous, 99.7% being taken up within the time of measurement, two minutes, and the final increment slowly. Carbon monoxide is sorbed to a much greater extent. Approximately two-thirds of the sorbed carbon monoxide can be removed by evacuating the system at temperature, but the remaining one-third cannot be so removed. The rate of sorption is almost instantaneous, 99% being sorbed in a minute or two, the remainder very slowly, a drift being observed. Typical isotherms at all temperatures for oxygen are shown separately in Fig. 4: about one-tenth of the total oxygen can be removed by evacuating the system, the remainder is strongly held. The initial sorption is very rapid but is followed by a slow process of measurable rate.

Reduced Surface, −78°.—Argon and nitrogen are not measurably sorbed on either surface at this temperature. Typical isotherms for carbon monoxide and carbon dioxide are shown in Fig. 2. Carbon monoxide is slightly sorbed and cannot be removed by pumping at −78°; this chemisorption is appreciably less than that at −183°. The amount of carbon dioxide sorbed is relatively large and not completely reversible so that it is possible to differentiate two kinds: one

(5) Armbruster, *ibid.*, **68**, 1342 (1946).

(6) C. G. Maier, U. S. Bur. Mines, Bulletin 436, 1942, p. 17.

(7) The density of packing is believed less for the (112) plane than the average of that calculated for the other crystallographic planes. On the basis that in these alloys the iron is of the face centered cubic form, and that the distance between the centers of two iron atoms is a_0 = 3.55 Å. the areas per iron atom for the several planes are:

plane	(100)	(111)	(110)	(112)
area (sq. Å./iron atom)	6.3	5.5	8.9	15.4

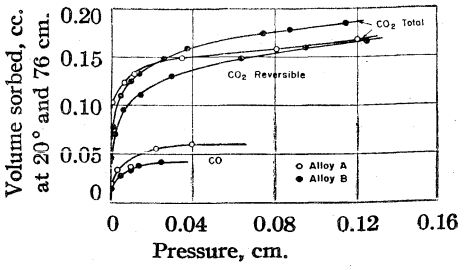

Fig. 2.—Typical isotherms for CO and CO_2 on reduced surface of stainless alloys at −78°.

in which 6% of the surface is covered by strongly held molecules; the other in which one-half of the surface is covered by weakly-held molecules. The sorption of oxygen (Fig. 4) is 30% greater than at −183°, apparently independent of pressure and too strongly held to be removed except by reducing with hydrogen and evacuating at 450°.

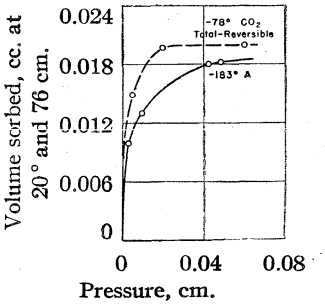

Fig. 3.—Sorption of argon at −183° and irreversible carbon dioxide at −78° on reduced surface of stainless alloy B.

Reduced Surface, 20°.—At room temperature the only gas sorbed to greater extent than the limit of error of measurement is oxygen, as is shown in Fig. 4. The amount of oxygen, which, as at −78°, appears to be independent of pressure, is almost twice as great as that sorbed at −183° and about 50% greater than at −78°.

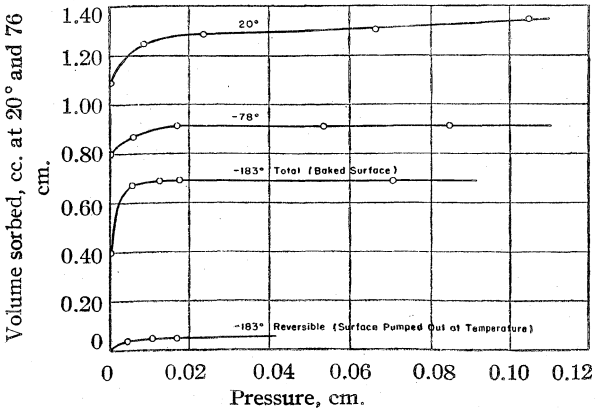

Fig. 4.—Typical isotherms for oxygen on reduced surface of stainless alloy A.

Unreduced Surface, −78°.—Measurements on the unreduced surface were limited to Alloy A at −78°, and typical isotherms are given in Fig. 5. The sorption of carbon monoxide is appreciable and, contrary to usual observation with this gas at −78° on steel, all of the sorbed gas is not strongly held. Only about 25% of the sorbed molecules are strongly held and the remainder can be pumped off at temperature. The total sorption of carbon dioxide is made up of a reversible sorption which corresponds to about 75% and a strongly held sorption which corresponds to about 25%.

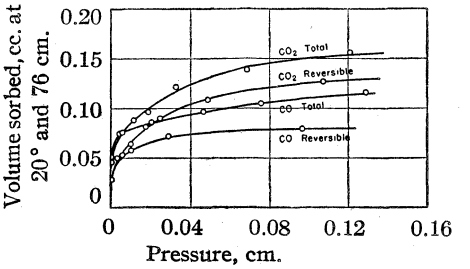

Fig. 5.—Typical isotherms for CO and CO_2 on unreduced surface of stainless alloy A at −78°.

Calculations and Discussion

Form of Isotherms.—The isotherms in Figs. 1, 2, 4 and 5 so greatly resemble in form those obtained for the same gases on mild steel as to suggest application of the Freundlich and Langmuir isotherms.

Freundlich Isotherm.—For initial comparison the data are expressed in the form of the exponential relation of Freundlich, $v = ap^{1/n}$, in which v is the volume sorbed at pressure p; a and n are constants. At lowest pressures this purely empirical expression had more satisfactorily represented the data for mild steels[3] than did the Langmuir equation. Typical Freundlich isotherms for several reversibly sorbed gases on these alloys are given in Fig. 6 in which the sorbed volume is plotted against pressure on double logarithmic coördinates and a straight line is obtained over a pressure range of a hundred fold or more.

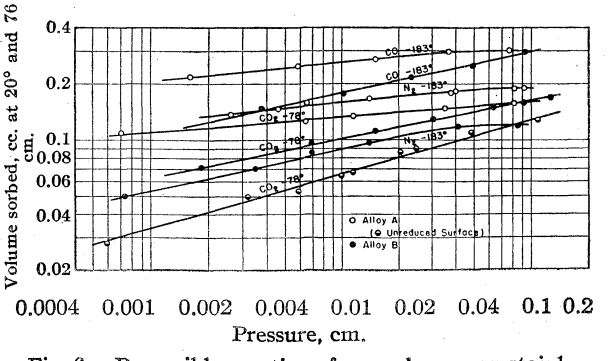

Fig. 6.—Reversible sorption of several gases on stainless alloys plotted on double logarithmic coördinates to illustrate application of parabolic or Freundlich relation.

The slope of the line corresponds to the exponent $1/n$ in the above equation. On the reduced Alloy B these slopes yield values of n which correspond with those for the same gases on mild steel surfaces.[3,5] For example nitrogen is 3, carbon monoxide 4 to 5 at −183°, and water is 3 at 20°. It is of interest to note that for carbon dioxide at −78° on Alloy B (reduced) n is 5. Generally in the case of Alloy A the slopes are less and the values of n are about twice as great as those for Alloy B. This point deserves further consideration in light of the interpretation of n as a measure of the departure of the sorbed film from that of an ideal two dimensional gas.

Langmuir Isotherm.—The Langmuir equation more satisfactorily represents the data over the whole range except at lowest pressures where the deviation is in the direction of greater volume sorbed than that required by the relation. This is shown in Fig. 7 in which typical isotherms are plotted as p/v against p and a linear relation is obtained down to about 0.01 cm. pressure. It is of

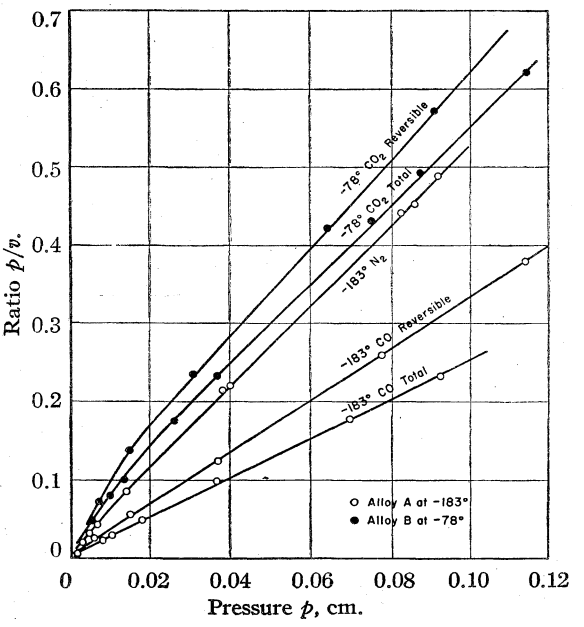

Fig. 7.—Typical isotherms for several gases on stainless alloys plotted as p/v against p.

significant interest to note that for the particular gas carbon monoxide on Alloy A this deviation at lowest pressure is least marked but for the same gas on Alloy B very marked deviation is evident below about 0.015 cm. as shown in a separate p/v against p plot given in Fig. 8. More marked deviation in this pressure range has generally been observed as characteristic of a reduced and not of an unreduced surface in the study of mild steels.[5] Possibly this may be interpreted as indicating more free metal or less oxide on alloy B than on Alloy A. If the Langmuir isotherms for carbon monoxide at −183° shown in Fig. 8 are considered further, the curves for Alloys B and A seem analo-

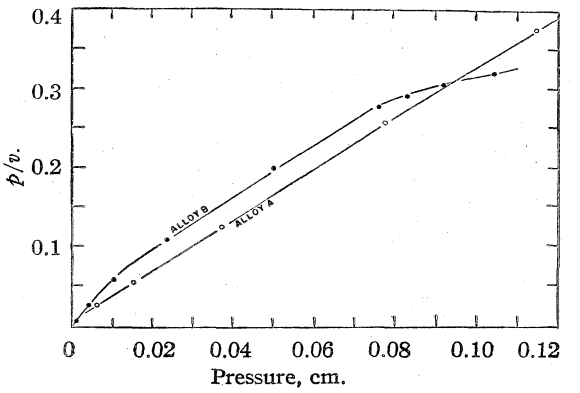

Fig. 8.—Isotherms for reversible sorption of CO at −183° plotted to show deviation from Langmuir relation.

gous in form to those for ethyl iodide on a reduced and unreduced surface of iron, respectively,[8] where there is evidence of a second layer forming on the reduced surface. The curve for Alloy B not only shows more marked deviation at lowest pressures but at higher pressures intersects the curve for Alloy A at about 0.095 cm. indicating that above this pressure the concentration of adsorbed carbon monoxide is greater on Alloy B than on Alloy A. In the intermediate pressure range the two curves are linear and have the same slope which shows that the same amount of gas is required as the limiting volume sorbed to complete a monolayer on the two surfaces. Then the increased adsorption at highest pressure for Alloy B may represent the beginning of a second layer and this behavior, by analogy with the increased adsorption of ethyl iodide on reduced but not on unreduced iron, suggests that the surface of Alloy B may be reduced to a higher degree than that of Alloy A. This deduction supports the earlier conclusion drawn from the adsorption behavior at lowest pressure that there may be less oxide or a lower oxide on Alloy B than on Alloy A.

Combined Form of Equation.—The isotherms may be represented over the entire range by a combined form of the Freundlich and Langmuir equations, namely,

$$v = v_s \sqrt[n]{ap/(1 + ap)}$$

in which a and n are constants, n corresponding to the value determined from the slope of the Freundlich plot for a particular temperature and system.

Comparison of Data

Reduced Surface.—The applicability of the Langmuir equation makes it possible to compare the results in terms of v_s, the so-called limiting volume sorbed, as obtained from such a plot. This comparison is made in Table I which contains: (a) the values of v_s derived from the Langmuir plot; (b) the per cent. surface coverage

	CO_2	Strongly held	.019	.021	7	8	.06	.06

[a] Corresponding ratios with nitrogen at −183° as standard for comparison may be obtained by multiplying the factor for Alloy A and B by 1.54 and 2.58, respectively.

derived from v_s, the known geometric area and cross sectional area of the molecule[9]; and (c) the ratio v_s/v_s (reversible CO −183°), the relative number of molecules sorbed per unit area, a ratio in which it may be assumed that v_s is a measure of the concentration of molecules in a close packed monolayer and that v_s (reversible CO −183°) is a measure of the specific area of the surface. Whereas the per cent. coverage in the middle two columns is merely an apparent coverage, the ratio in the last two columns shows, on the basis of these assumptions, the extent to which the surface is covered by a monolayer and reduces the data to constant specific area.

Several deductions are possible from this comparison, together with our experience with mild steels at low pressure and the investigations of Emmett and Brunauer of iron catalysts, pure and promoted[10,11] at considerably higher pressure: (1) Argon is very slightly sorbed and so strongly held that it cannot be removed by pumping at temperature. Furthermore the amount of argon sorbed at −183° is practically the same as that of the chemisorbed carbon dioxide at −78°, namely, 5–7 and 6% surface coverage, respectively, for the two alloys. This is shown in Fig. 3 in which the chemisorbed carbon dioxide curve is the difference between the total and the reversible sorption data. These gases may, therefore, be sorbed on the same places, such as cracks, grain boundaries and virtual depressions on the surface. Similar strong adsorption has been reported in earlier study: for example, of argon and carbon monoxide on mica[12] in which the sorbed molecules appeared to be held in positions vacated by potassium ions during cleavage. Likewise argon, carbon monoxide and nitrogen strongly held on unreduced iron surfaces may be held on certain positions on the surface, resulting from the structure of the oxide film, on which the sorbed gas comes so close to oxygen atoms that the van der Waals forces are stronger. The existence of such sites on stainless alloy surface could explain the constant fraction (about 6 per cent.) of the surface covered by argon at −183° and chemisorbed carbon dioxide at −78°.

(2) All sorption, except for carbon monoxide, is less than a monolayer, even that of argon and nitrogen. Argon does not give a measure of surface area and one cannot be sure of nitrogen, since the limiting volume of nitrogen sorbed is only one-half that of reversibly sorbed carbon monoxide. If nitrogen were taken as a standard, as can readily be done by multiplying the values in the last two columns of Table I by the factor 1.54 and 2.58, respectively, and the limiting volume be assumed to correspond to a monolayer, it yields a true surface area only one-half that of the known geometric area, which is not reasonable. Also, reversible carbon dioxide at −78° as a measure of surface area is certainly in question. Hence the significant result follows that for a stainless alloy only the reversible sorption of carbon monoxide at −183° is a reliable measure of the surface area in the low pressure range studied. In contrast, Emmett and Brunauer[10] find for pure iron catalysts the same surface area is given by nitrogen −183°, carbon monoxide reversible −183° and carbon dioxide reversible −78°. Their work is at considerably higher pressure and applies an equation derived for multimolecular adsorption which, at low pressure, is formally identical to the Langmuir equation. Our experience with mild steels, reduced and unreduced, shows that nitrogen (−183°), carbon monoxide reversible (−183°) and argon reversible (−183°) may form a complete monolayer but that carbon dioxide reversible (−78°) is certainly in question.

(3) The following points deal with the sorption of carbon monoxide: (a) In all the reduced samples studied the total sorption of carbon monoxide at −78° is strongly held; there is no reversible sorption of this gas at −78° although this occurs at −183°. (b) Comparing carbon monoxide chemisorbed at −183° and at −78°, it is seen that

(9) The values for the cross sectional areas of the molecules are the same as cited previously in reference 3.

(10) Emmett and Brunauer, THIS JOURNAL, **59**, 1553 (1937).

(11) Emmett and Brunauer, *ibid.*, **59**, 310 (1937).

(12) Armbruster and Austin, *ibid.*, **60**, 467 (1938).

for Alloy A, carbon monoxide chemisorbed (−183°) is only slightly greater than at −78°, whereas for Alloy B, the chemisorption at −183° is three times greater than at −78°. In the work with mild steels, reduced, the chemisorbed carbon monoxide at −78° varied in amount from none to the same as that at −183°. Emmett and Brunauer[10] state that the chemisorption of this gas at the two temperatures is the same, though Brunauer[13] later mentions that with strongly sintered iron surfaces this chemisorption of carbon monoxide may be decreased and the binding forces of gas to iron may be weakened. (c) On Alloy B, carbon monoxide is chemisorbed at −183° in greater amount than on Alloy A. If carbon monoxide is considered sorbed on free metal, the fact that this corresponds to 30% and 43% for Alloys A and B, respectively, indicates that there is proportionally more free metal on Alloy B. Evidence afforded by the form of the isotherms supports further this conclusion. (d) It has been suggested that carbon monoxide chemisorbed at −183° may be not only a direct measure of the free metal present but also an indirect measure of the amount of oxide. Emmett and Brunauer[10] concluded that carbon monoxide chemisorbed at −183° is equivalent to van der Waals adsorption (a monolayer) if no oxide exists, but that if oxide is present chemisorbed carbon monoxide at −183° is less than a monolayer by an amount corresponding to the oxide. On this basis, if the chemisorbed carbon monoxide at −183° on Alloys A and B is 30 and 43%, respectively, which is less than a monolayer and indicates oxide exists, the corresponding oxide is 70 and 57%.

(4) Nitrogen may perhaps be sorbed on the non-metallic part of the surface of these alloys. The fact that sorption of nitrogen appears to be unreliable at the low pressures used in the present work as a measure of total surface area on these alloys, suggests that it is sorbed on some definite portion of the surface. For Alloys A and B the coverage is 65 and 40%, respectively, so that possibly the nitrogen-sorbing portion of the surface of Alloy B is less. Direct comparison of the ratio of nitrogen sorbed on Alloy A to that on Alloy B at definite pressure over the range studied can be made from the data presented in Fig. 1. This ratio varies from 1.76 to 1.64 over the pressure range 0.005 to 0.1 cm. which suggests, by its constancy, that the difference in nitrogen sorption on the two alloys is due to a difference in area of the nitrogen-sorbing portion of the surface and, by its value, that this portion of the surface is 60% greater for Alloy A. Lastly, if for Alloys A and B it is assumed that nitrogen is sorbed on metal, one would expect (*cf.* 3c and d) 30 and 43% coverage, respectively; but, if it is assumed that nitrogen is not sorbed on metal, one would expect 70 and 57% coverage, respectively, which is in better agreement with observation.

(13) Brunauer, private communication to Beebe and Stevens, THIS JOURNAL, 62, 2134 (1940), footnote 14.

Sorption of Oxygen, −183°.—Typical data for the sorption of oxygen at the several temperatures are shown graphically in Fig. 4 to facilitate separate consideration. The surface of Alloy A in the reduced condition chemisorbs oxygen equivalent to a film two molecules thick; it also sorbs physically about one-fifth of a monolayer of oxygen. The concentration of oxygen sorbed reversibly is less than that of the other gases sorbed physically at this temperature: 80% less than reversible carbon monoxide which is considered as corresponding to a monolayer; 70% less than nitrogen which corresponds to one-half monolayer. In the case of a reduced mild steel the concentration of oxygen sorbed reversibly is the same as nitrogen and is equivalent to a monolayer. The relatively larger amount of chemisorption as compared to physical sorption is characteristic of a reduced rather than an unreduced steel surface.

Of this sorption a large amount is taken up instantaneously and the remainder over a period of hours. For instance, when the freshly reduced surface of Alloy A was exposed to oxygen at a pressure of 0.0325 cm. a volume of 0.394 cc. was sorbed instantaneously followed by a slower sorption in which 0.397 cc. had been sorbed at the end of an hour and the oxygen pressure had fallen to 3×10^{-5} cm. The instantaneous sorption is equivalent to a concentration of 0.892×10^{-15} molecules/sq.cm. which corresponds to a complete monolayer of sorbed oxygen atoms upon which the slower sorption may take place.

The rate of adsorption is initially very rapid and subsequently falls off gradually. The rate of the slow sorption which follows the instantaneous one obeys the equation for a first order reaction, expressed as

$$\log v_e/(v_e - v) = kt$$

v being the volume sorbed at time t, v_e that sorbed at equilibrium and k the rate constant. Values of k thus calculated are given in Table II and approximate 8.1×10^{-5} sec.$^{-1}$, that is, about 0.008% of the oxygen present is sorbed per second.

TABLE II

REACTION VELOCITY CONSTANT FOR SORPTION OF OXYGEN AT −183° ON REDUCED ALLOY A

(v_e = 0.273 cc.)

t, sec.	v, cc.	$v_e - v$, cc.	$k = \log(v_e/v_e - v)/$
90	0.008	0.265	14.2×10^{-5}
300	.020	.253	11.0
600	.029	.244	8.12
1200	.055	.218	8.13
2100	.089	.184	8.17
3660	.135	.138	8.09
4800	.161	.112	8.13
7200	.201	.072	8.04
9600	.227	.046	8.05
12300	.245	.028	8.03
15300	.256	.017	7.98
23520	.269	.004	7.70

This is not appreciably greater than the rate observed with mild steel where $k = 1.4 \times 10^{-5}$ sec.$^{-1}$ for the reduced and the unreduced surface.

The energy of activation, E, has been estimated from the rate data by means of the relation

$$\frac{\text{no. of molecules sorbed/sq. cm./sec.}}{\text{no. of molecules striking/unit surface/sec.}} = e^{-E/RT}$$

in which $R = 1.987$ cal./deg./mole and T is the absolute temperature; it is also assumed that the adsorbed gas behaves ideally and forms a mobile layer.[14] For example, at about 0.1 mm. pressure the numerator and denominator become 1.23×10^{11} and 6.54×10^{19} molecules/sq. cm./sec., respectively, so that E is 3600 cal.

Sorption of Oxygen, −78° and 20°.—At −78° the oxygen chemisorbed on reduced Alloy A corresponds to about three layers and at 20° to about five layers. In each case, a large sorption, too rapid for measurement of its rate, occurs. The amount of oxygen instantly sorbed varies with the initial oxygen pressure: if this is less than about 0.001 cm., the sorption is instantaneous; if greater, part of the sorption is instantaneous and part slow. As illustration, 0.80 cc. was instantly sorbed at −78° and 1.0 cc. at 20°, which represents a sorbed layer two and three molecules thick if the specific area of the surface is considered unity. At these temperatures the rate of the slow reaction, after making correction for the instantaneous one, does not follow the first order reaction equation but is a logarithmic function of time as shown in Fig. 9 for oxygen at 20°.

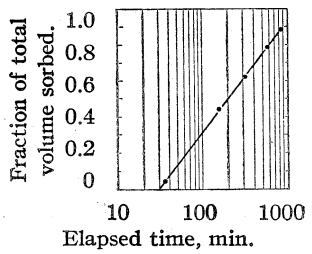

Fig. 9.—Logarithmic rate of formation of oxide film at 20° on reduced surface of alloy A.

All of these observations are quite similar to those reported for mild steel[15] and support the conclusion that the mechanism of the oxidation process of the stainless alloy as well as of iron is determined by the temperature.

The relative number of molecular layers of oxygen sorbed on stainless Alloy A and mild steel #1[3] are arbitrarily compared in Table III. For each sample, the coverage was estimated in the two ways used to obtain the middle two and last two columns of Table I, namely (a) from the limiting volume of nitrogen sorbed, the cross sectional area of the oxygen molecule, and the geometric area of the surface, and (b) from the ratio of the limiting volume of oxygen sorbed at a given temperature to that of carbon monoxide reversibly sorbed at −183°, the latter being assumed to correspond to a close packed monolayer. These two ways of estimating the coverage or thickness of the sorbed oxygen layer show good agreement. The samples are similar in that the total sorption at all temperatures is large, and the chemisorption is relatively much larger than the physical sorption at −183°. The sorption on the stainless alloy, however, is always less than on the mild steel; at −183° the reversible and chemisorption are one-third and two-thirds, respectively, of that on the mild steel and at −78 and 20° about one-half. This difference is one of degree and may well be attributed to the replacement of iron atoms by chromium and nickel, the presence and distribution of which on the surface of a crystal of solid solution may alter the structure, and nature of the oxygen film.

TABLE III

COMPARISON OF NUMBER OF LAYERS OF OXYGEN SORBED ON STAINLESS ALLOY A AND MILD STEEL 1[a]

Temp., °C.	Type of sorption	Stainless alloy A number of layers: Comparison with CO rev.	Stainless alloy A number of layers: From known area	Mild steel 1 number of layers: Comparison with CO rev.	Mild steel 1 number of layers: From known area
−183	Total	2.3	2.1	3.1	3.8
	Reversible	0.18	0.16	0.9	1.1
	Strongly held	2.1	1.9	2.2	2.7
− 78	Total (chemisorbed)	2.8	3.1	5.1	6.0
20	Total (chemisorbed)	4.0	4.5	8.6	10

[a] Complete data for this steel are reported in previous papers.[3,5]

Unreduced Surface −78°.—The data for the sorption of carbon monoxide and carbon dioxide at −78° on reduced Alloy A are compared with the results for the same alloy in the unreduced condition in Table IV. The chemisorption of carbon monoxide at −78° is more than twice as great on the reduced surface as the ratio shows, a fact which supports the assumption that carbon monoxide is chemisorbed on free metal. A noticeable difference in the case of the unreduced surface is that a large part of the sorption of carbon monoxide is reversible. As to carbon dioxide, the

TABLE IV

RATIO OF LIMITING VOLUME v_s (RELATIVE NUMBER OF MOLECULES) OF THE GASES SORBED AT −78° ON REDUCED SURFACE TO THAT ON UNREDUCED SURFACE OF ALLOY A

Gas	Type of sorption	v_s red.	v_s unred.	Ratio, red./unred.
CO_2	Reversible	0.146	0.138	1.04
CO_2	Total	.165	.170	0.97
CO_2	Chemisorbed	.019	.032	.59
CO	Reversible	0	.094	..
CO	Total	.070	.124	.56
CO	Chemisorbed	.070	.030	2.33

(15) Armbruster and Austin, THIS JOURNAL, 68, 1347 (1946).

ratio of 1.04 for the reversibly sorbed gas indicates that the concentration of molecules in this layer is the same for reduced and unreduced alloy. The number of strongly held molecules of carbon dioxide is about twice as great for the unreduced surface. The greater chemisorption for the unreduced surface, which should be rougher, is in agreement with the earlier supposition that this gas may be held on cracks and grain boundaries.

Heat of Adsorption.—The "average heat of adsorption" on the less active part of the surface has been calculated for gases which are reversibly sorbed at −183° and −78° by the method of Brunauer, Emmett and Teller[16] from the linear, higher pressure, region of the isotherms plotted in Fig. 7. Although this method is usually applied to a higher range of relative pressure (p/p_0, p_0 being the saturation pressure of the gas) the results derived by it are given in Table V for comparison. The heat effects at −183° are 3.2 (±0.2) kcal. per mole for the several gases on these surfaces which is in close agreement with those for the same gases on other metals.[3,5] Such correspondence within the error of calculation for the same gases at a given temperature on surfaces as chemically different in nature as a mild carbon steel and a stainless chromium nickel alloy points to a greater dependence of this heat on the physical state of the surface than its chemical composition or on that of the gas. The heat of sorption for oxygen agrees with that calculated by an independent method from rate data. At −78° this heat quantity for carbon dioxide is about 8 kcal. and is twice as great as the heat of liquefaction of the gas at the same temperature obtained from extrapolation of data.

TABLE V

AVERAGE HEAT OF REVERSIBLE ADSORPTION OF GASES ON STAINLESS ALLOYS AS DERIVED BY THE METHOD OF BRUNAUER, EMMETT AND TELLER

Gas	Temp., °C.	Heat of liquefaction at temp., kcal./mole	Heat of adsorption, kcal./mole Alloy A	Alloy B
N_2	−183	1.33	3.3	3.4
CO	−183	1.41	3.6	3.2
O_2	−183	1.63	3.5	...
CO_2[a]	− 78	3.94	8.3	7.6
CO_2[b]	− 78	3.94	7.5	...
CO_2	− 78	3.94	...	7.4

[a] This adsorption is on the unreduced surface of Alloy A whereas all other data are for the reduced surface. [b] The heat effect on a reduced mild steel (no. 3)[3] is included for comparison of the same gas at the same temperature on a chemically different surface.

Force–Area Curves.—Force–area curves for the sorption of the several gases have been derived by the method of Innes and Rowley[17] and in general are smooth over the whole range of measurement and are displaced from the curve for an ideal two-dimensional gas to an extent characterized by the exponent n of the Freundlich or parabolic equation which represents the isotherm. The force–area curve for the reversible sorption of carbon monoxide at −183° on the reduced surface of Alloy B is shown in Fig. 10. The curve lies well above that for an ideal two-dimensional gas and close to the curve represented by $FA = 4kT$, as might be expected since its isotherm follows the Freundlich relation $v = ap^{1/4}$. In this instance the curve is not smooth but shows a suggestion of a plateau. This behavior was previously observed to be characteristic of a film on a surface which already holds strongly, either physically or chemically, some molecules attached to definite sites; for example, reversible carbon monoxide on reduced mild steel at −183 and −195°, also nitrogen on unreduced mild steel at −195°.[3] In the reversible sorption of carbon monoxide on this stainless alloy the surface already has on it chemisorbed molecules of carbon monoxide; in the adsorption of nitrogen on the same surface no molecules are already strongly held and the curve is smooth. The discontinuity may represent a phase change of the first order resulting from the influence of the strongly held molecules on the more mobile molecules of the reversibly adsorbed layer, showing close resemblance of the phase formed by the condensation of the reversibly sorbed monolayer on a metal or solid to the expanded phase of an insoluble liquid film on water.[18]

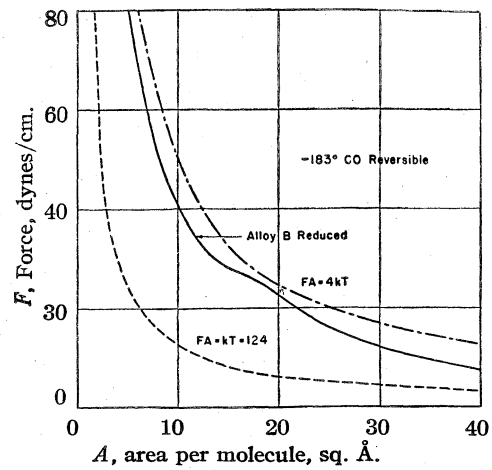

Fig. 10.—Typical force–area curves for film of carbon monoxide sorbed reversibly at −183° on reduced surface of stainless alloy B derived from data plotted as ln (p/v) *versus* v by method of Innes and Rowley.

Summary and Conclusions

The sorption of argon, neon, hydrogen, nitrogen, carbon monoxide, oxygen and carbon dioxide on two stainless iron–chromium–nickel alloys has been measured at −183, −78 and 20° and at pressures up to 0.1 cm. These determinations were made on a surface which had been degreased,

outgassed and reduced by hydrogen, and subsequently outgassed; a few measurements were made on the degreased, outgassed surface. The surface was more readily conditioned to reproducibility of the sorption within the error of measurement than for mild steel.

Neon and hydrogen are not measurably sorbed in the range of temperature and pressure studied. Argon is very slightly sorbed at −183° and cannot be removed by pumping at temperature; the magnitude of the sorption is about the same as that of strongly held carbon dioxide at −78°. Nitrogen is sorbed to a greater extent at −183°, sufficient at apparent saturation to cover about one-half of the measured geometric surface and the sorption is completely reversible.

Carbon monoxide is the only gas which is physically adsorbed to as great an extent as a complete monolayer; furthermore the reversible sorption of this gas confirms the measured geometric area of the surface. Hence, it is concluded that at the low pressures used in this work only the reversible sorption of carbon monoxide at −183° is a reasonably reliable criterion of surface area in the case of stainless alloys whereas on mild steels nitrogen and argon are also satisfactory.

The agreement of the sorption data for the two alloys indicates that the surfaces are of the same specific area and this appears to approximate unity.

There is evidence of a tendency to form a second adsorbed layer in the case of Alloy B. Sorption data for Alloy B also show more marked deviation from the Langmuir equation in the lowest pressure region. These observations suggest that the surface of Alloy B is in a more reduced condition than that of Alloy A. Furthermore the proportionally greater chemisorption of carbon monoxide at −183° on Alloy B leads to the conclusion that there is more free metal on this surface.

The sorption of oxygen at −183° consists of a fraction of a monolayer reversibly held and about two monolayers which are chemisorbed. At −78 and 20° three and four layers, respectively, of oxygen are chemisorbed.

Isomerization of Saturated Hydrocarbons. V.[1] The Effect of Cyclohexene upon the Isomerization of Methylcyclopentane and Cyclohexane

BY HERMAN PINES, B. M. ABRAHAM[2] AND V. N. IPATIEFF

It was shown previously[1,3] that under certain carefully controlled conditions aluminum bromide–hydrogen bromide or aluminum chloride–hydrogen chloride did not cause the isomerization of *n*-butane to isobutane unless traces of olefins were present. This study has now been extended to the investigation of the reversible isomerization of methylcyclopentane to cyclohexane using aluminum bromide–hydrogen bromide as the catalyst. A high vacuum technique was used for the purification of materials, and for charging and discharging of the products.

It was found that methylcyclopentane did not undergo isomerization when shaken in a sealed tube for nineteen hours at 25° in the presence of as much as 9 mole per cent. of aluminum bromide[4] and 1 mole per cent. of hydrogen bromide. When the hydrogen bromide concentration was increased to 3.2 mole per cent., the yield of cyclohexane produced was 2%. However, when 0.05 mole per cent. of olefin such as cyclohexene was added to the reaction mixture, 28 mole per cent. of the methylcyclopentane was converted to cyclohexane. By increasing the molal ratio of the cyclohexene from 0.05 to 0.07 and to 0.1 mole per cent. the amount of cyclohexane formed increased to 30 to 38 mole per cent., respectively. The results are summarized in Table I. The amount of methylcyclopentane listed in the above table and in subsequent experiments was 8.00 to 10.00 g. ± 0.001 g.

TABLE I

THE EFFECT OF OLEFINS ON ISOMERIZATION

Reaction time 19 hrs. The amount of methylcyclopentane used in the various experiments varied from 8–10 g.

	Reagents: moles/100 moles methylcyclopentane			
No.	$AlBr_3$	HBr		Analysis mole % cyclohexane
1	1.0	1.0	0.0	0
2	9.0	1.0	.0	0
3	9.0	3.2	.0	2
4	9.0	1.0	.05	28
5	9.0	1.1	.07	30
6	9.0	1.0	.10	38
7	1.0	1.0	.20	58

A 58% yield of cyclohexane was obtained when the concentration of cyclohexene added was 0.2 mole per cent.; in this particular experiment the

(4) Throughout this paper for the purpose of calculation the aluminum bromide was considered to be monomeric.

concentration of aluminum bromide was 1 mole per cent. instead of the usual 9 mole per cent. In the absence of hydrogen bromide, aluminum bromide does not isomerize methylcyclopentane even in the presence of olefins.

Cyclohexane reacted in the presence of an aluminum bromide–hydrogen bromide catalyst in a manner similar to methylcyclopentane. Isomerization did not occur when a solution consisting of 100 mole per cent. of cyclohexane was treated for nineteen hours at 25 ± 0.1° with 2.00 mole per cent. of aluminum bromide and 0.99 mole per cent. of hydrogen bromide. In the presence, however, of 0.107 mole per cent. of cyclohexene, 9% of cyclohexane isomerized to methylcyclopentane.

In order to determine the effect of the different variables upon the degree of isomerization of methylcyclopentane, the effect of hydrogen bromide and aluminum bromide concentration was investigated.

By maintaining the molal ratio of methylcyclopentane to aluminum bromide and to cyclohexene (cyclohexyl bromide) constant at about 100:9.0:0.08 and by varying the concentration of hydrogen bromide a definite trend in the degree of isomerization was observed. This effect was most pronounced when the concentration of hydrogen bromide was raised from 1.1 to 3 mole per cent.; in this case the degree of isomerization increased from 30 to 78%. Under similar conditions but in the absence of hydrogen bromide and cyclohexyl bromide no isomerization of methylcyclopentane was observed; this definitely establishes that the initiator is the alkyl halide or its equivalent. The results are summarized in Table II.

TABLE II

THE EFFECT OF HBr CONCENTRATION ON ISOMERIZATION

No.	Reaction time, hours	Reagents: moles/100 moles hydrocarbon $AlBr_3$	HBr		Analysis mole % cyclohexane
8	19	9.1		0.08[a]	17
9	19	8.9	0.02	.08[a]	25
10	19	9.1	0.28	.08	20

14	1	1.0	3.1	.1	36
15	1	1.0	1.0	.1[a]	21
16	1	1.0	0	.1	0

[a] Olefin added as cyclohexyl bromide.

An increase in the isomerization of methylcyclopentane with an increase of hydrogen bromide concentration was also noticed when the aluminum bromide was maintained at lower concentrations and the contact time was one hour instead of the usual nineteen hours.

It was found that by decreasing the aluminum bromide concentration from 9 to 1 mole per cent. based on methylcyclopentane present and maintaining the molal concentration of hydrogen bromide at 1 and of cyclohexene at 0.1 mole per cent., the degree of isomerization within the experimental error was unchanged (Table III, Experiments 6 and 21). These results show that even 1 mole per cent. of aluminum bromide under the experimental conditions used seems to be in excess of that required to catalyze the isomerization. At about 9 mole per cent. concentration aluminum bromide is near the saturation point at 25°.

TABLE III

THE EXTENT OF ISOMERIZATION WITH TIME

No.	Reaction time, hours	Reagents: moles/100 moles hydrocarbon $AlBr_3$	HBr		Analysis mole % cyclohexane
17	0.5	1.0	1.0	0.10	12
18	1.0	1.0	1.0	.10	21
13	1.0	1.6	1.0	.10	19

6	19	9.0	1.1	.10	38

The isomerization catalyst comprised of aluminum bromide–hydrogen bromide and promoted by cyclohexene loses its activity with time. This was shown in Experiment 22 (Table IV) in which methylcyclopentane was treated by this catalyst for a period of nineteen hours; a sample was then withdrawn for analysis and the contents of the reaction tube were diluted with an equal volume of methylcyclopentane; the tube was agitated for an additional nineteen hours at 25°. It was found that no additional isomerization occurred. These results suggested that the isomerization reaction must have stopped before the first nineteen-hour period was ended. This was shown more clearly in Experiment 20 (Table IV) in which the reaction was carried out for only two hours; the hydrocarbons were then withdrawn and the reaction tube was recharged with fresh methylcyclopentane and with the recovered hydrogen bromide. The tube was then agitated for two hours at 25°. From the results obtained it is seen that the reaction was almost complete during the first two hours.

On the basis of the above-described experiments it was believed that the loss of the catalyst activity was due primarily to the disappearance of the promoter through secondary reactions. This was demonstrated more clearly in Experiment 23 in which methylcyclopentane was treated with aluminum bromide–hydrogen bromide promoted by 0.11% of cyclohexene. After nineteen hours a small sample was withdrawn for analysis; it contained 38% of cyclohexane. In order to be certain that the catalyst had lost its activity, the reaction tube was resealed and shaken in the constant temperature bath for an additional nineteen

TABLE IV

THE STUDY OF CATALYTIC ACTIVITY AS A FUNCTION OF TIME AND INITIATOR: THE CHANGE IN CATALYST ACTIVITY WITH TIME

	Reagents: initial charge, moles/100 mole of methylcyclopentane

[a] Removed equivalent of 7 moles for analysis; diluted with an equivalent of 93 moles of methylcyclopentane. [b] Replaced first batch of hydrocarbon. The hydrocarbons from the first period of reaction were removed and replaced with 100 mole equivalent of fresh methylcyclopentane. [c] The reaction was continued for an additional nineteen hours between first and second period. No additional isomerization occurred. [d] Cyclohexene was added to the reaction mixture.

hours and then retested; it was found that no further isomerization occurred. The introduction, however, of 0.12% of cyclohexene restored and increased the activity of the catalyst; the reaction mixture after this treatment consisted of 80% cyclohexane.

Discussion of Results

The experimental data given above indicate that under controlled conditions methylcyclopentane does not undergo isomerization in the presence of aluminum bromide–hydrogen bromide catalyst unless traces of cyclohexene or cyclohexyl bromide are present. These results are in accordance with a similar observation made when isomerizing *n*-butane[3] and can be explained by the following chain mechanism similar to that suggested for *n*-butane.[5]

Eq. 1 R^0 (olefins) + HBr $\rightleftharpoons$ RBr

Eq. 2 RBr + $AlBr_3$ $\rightleftharpoons$ $[R^+ AlBr_4^-]$

Eq. 3 
Eq. 4 
Eq. 5 
Although the addition of small amounts of cyclohexene or cyclohexyl bromide causes the isomerization to proceed, in no case was an equilibrium mixture of methylcyclopentane and cyclohexane obtained,[6] this is probably due to a chain-breaking reaction in which the carbonium ion of either of the original additives is involved or the one formed through a hydrogen transfer reaction as exemplified by Equation 3. The chain-breaking can be caused by such reactions as conjunct polymerization,[7] cycloalkylation, or condensation which involves a transfer of hydrogen.[8] The conjunct polymerization involves the transformation of the olefins into saturated hydrocarbons of the same or higher molecular weight and the formation of highly unsaturated hydrocarbons which form a complex with the catalyst which is insoluble in hydrocarbons. This might explain the formation of an oily film during isomerization which can be detected on the walls of the reaction tube. The conjunct polymerization is probably one of the chief reactions causing the destruction of the carbonium ions; this reaction is relatively rapid and pronounced when the concentration of the olefins is relatively high. For that reason, in order to obtain the most benefit from the olefins added, it is preferred that the olefins be not added at once but at intervals and in small quantities. This is brought up in Table IV.

Experimental

A high vacuum apparatus similar to that reported previously[3] was constructed (Fig. 1); all liquid reactants once purified in this apparatus were kept out of contact with air or moisture.

The aluminum bromide was a resublimed commercial grade which was further purified by a vacuum sublimation through a series of constrictions into a receiver. This receiver contained several weighed and numbered capsules. To fill these capsules the following procedure was adopted: A few millimeters pressure of dry air was admitted to the line and the aluminum bromide was heated to the melting point; as soon as the salt became molten an atmosphere of dry gas was admitted thus forcing the molten salt into the capsule. After the material had solidified the capsules were removed from the line, sealed and reweighed. Each capsule contained from 1.7–2.2 g. of aluminum bromide. In Fig. 2 is illustrated the reaction tube with an aluminum bromide capsule in place.

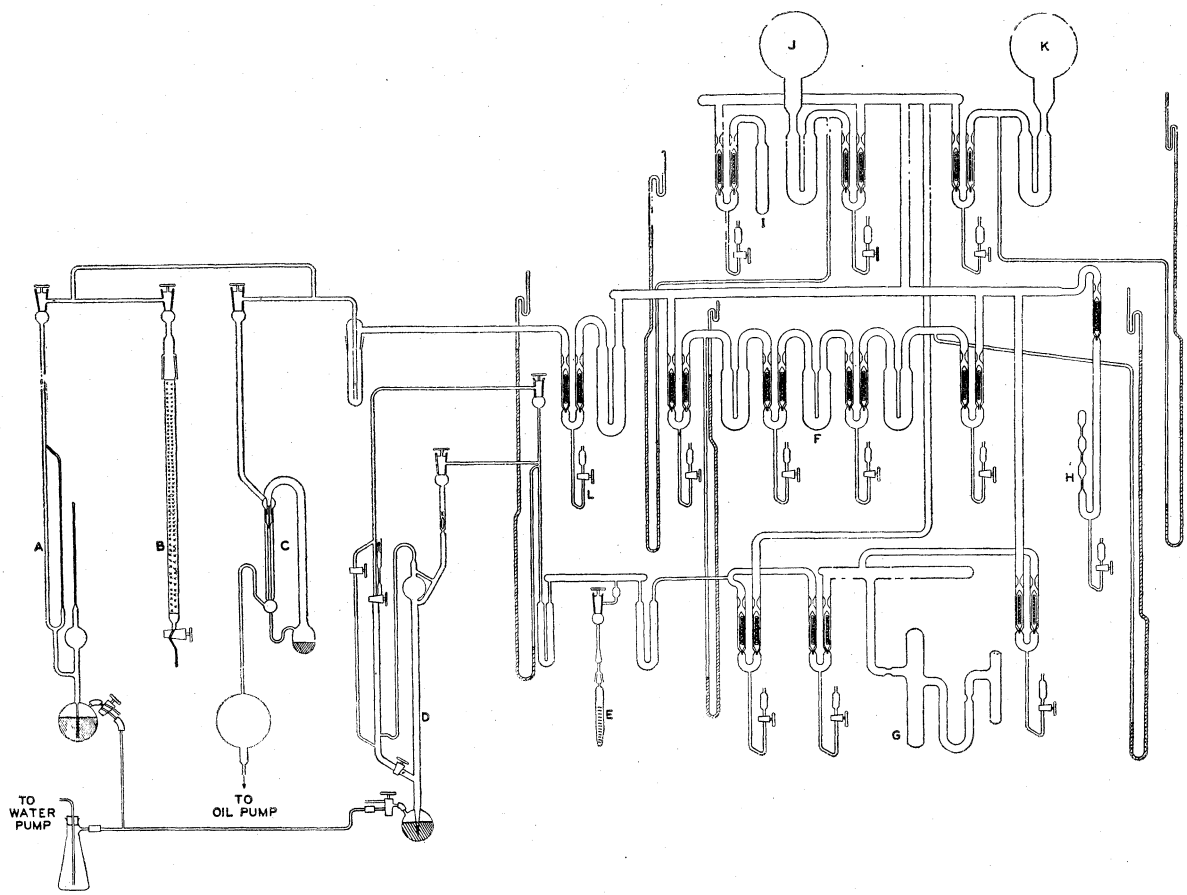

Fig. 1.—Isomerization apparatus: A, McLeod gage; B, phosphorus pentoxide drying tower; C, mercury diffusion pump; D, Toepler pump; E, sample inlet; F, fractionation system; G, reaction tube; H, small volume aliquoting tube; I, cyclohexene storage; J, gaseous olefins storage; K, hydrogen bromide storage; L, stock valve.

The methylcyclopentane used in this work was prepared from cyclohexane by catalytic isomerization; this was accomplished by refluxing the cyclohexane in the presence of aluminum chloride activated by the addition of about 2–3% of water. The methylcyclopentane thus formed, boiling lower than its isomer, was continuously removed on a 50-plate column. The distillate which contained 85–90% methylcyclopentane was washed with alkali, dried, and redistilled on a 100-plate column. The methylcyclopentane fraction used in these experiments did not show any impurities as determined by index of refraction, $n^{20}D$ 1.4100, or by infrared or ultraviolet spectroscopy. The methylcyclopentane thus obtained was weighed out to give the proper molal ratio for a given aluminum bromide capsule. The liquid was then distilled into a numbered tube which contained liquid sodium–potassium alloy and stored until used (Fig. 3).

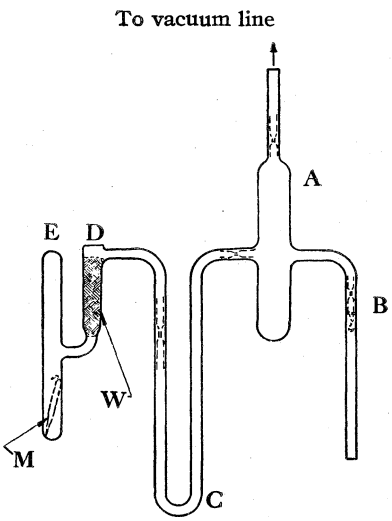

Fig. 2.—Reaction tube: W, glass wool; M, aluminum bromide.

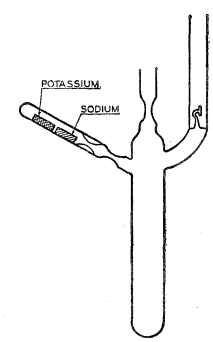

Fig. 3.—Hydrocarbon purification tube.

The cyclohexene was stored *in vacuo* over sodium–potassium alloy and removed as needed. The olefin was measured as a gas in one of the calibrated U tubes on the apparatus (Section F, Fig. 1).

Hydrogen bromide was prepared by dropping bromine on tetralin. The material was fractionated on the line, discarding generous first and last fractions. The middle fraction which had a dry-ice–ether vapor tension of 400

mm. ("International Critical Tables" value 401 mm.) was stored in a 5-liter bulb (Section K, Fig. 1).

The experimental technique used was as follows: A reaction tube (Fig. 2) was sealed on the line (Section G, Fig. 1), evacuated and degassed. Dry air was then admitted through a phosphorus pentoxide drying column and a small hole was blown in the side tube (Section E, Fig. 2). An aluminum bromide capsule was then dropped into the side-arm after the tip had been broken. The hole was sealed and the tube re-evacuated. When the pressure had dropped to *ca.* 10^{-3} mm. of mercury the aluminum bromide was sublimed through the glass wool, into the U-tube (Section C, Fig. 2); Sections E and D were sealed off. The aluminum bromide was then sublimed into the reaction tube proper and Section C was sealed off. In later experiments the glass wool in D was eliminated. The oily film which is put on the glass during fabrication was difficult to remove and seemed to influence the results. The methylcyclopentane was next added, then the olefin, and finally the hydrogen bromide. The reaction tube was sealed off the line at A and warmed to room temperature. The tube was then placed in the constant temperature bath and agitated for the period of the experiment.

If no olefin or alkyl halide had been added the solution was clear; however, if either of these compounds was present in the reaction mixture, droplets of light yellow oil—insoluble in the hydrocarbon—were always noticed to be formed on the glass. When cyclohexyl bromide was used, cyclohexene was mixed with hydrogen bromide in equimolal amounts in a small capsule. The sealed capsule was then placed in the reaction tube. In this case all reagents except cyclohexene were added as previously described. After the aluminum bromide had dissolved in the methylcyclopentane, the tip of the capsule was broken by shaking the reaction tube. Immediately the whole solution became turbid and yellow; in a short while the oil separated on the glass. In the light of the variation in the experimental results mixing is a very serious problem with these rapid reactions.

After the agitation period, the tubes were attached to the line by sealing a ground joint on tube B, Fig. 2, and inserting this joint at E, Fig. 1. The tube was opened by dropping an iron weight enclosed in glass on the break-off in tube B, Fig. 2. The volatile gases were tested for the presence of non-condensables such as hydrogen or methane. In no case was more than 0.04 cc. S. T. P. of gas recovered (*ca.* 0.0001 mole per cent.). The value was determined with the aid of the Toepler pump (Section D, Fig. 1). The hydrogen bromide was difficult to separate quantitatively from methylcyclopentane so no analysis was attempted here. The hydrocarbon was analyzed by index of refraction and infrared spectroscopy. In no case did the infrared analysis reveal the presence of constituents other than cyclohexane and/or methylcyclopentane.

Summary

The reversible isomerization of methylcyclopentane to cyclohexane in the presence of aluminum bromide–hydrogen bromide catalyst has been studied using high vacuum technique. It was found that under certain controlled conditions methylcyclopentane does not undergo isomerization to cyclohexane unless cyclohexene or cyclohexyl bromide in amounts of about 0.05 mole per cent. or higher are present.

The effect of olefins, hydrogen bromide, and aluminum bromide concentrations upon the isomerization of methylcyclopentane has been studied.

A mechanism of isomerization has been proposed.

EVANSTON, ILLINOIS RECEIVED DECEMBER 11, 1947

Synthesis of Syringaldehyde[1]

BY IRWIN A. PEARL

In a study of the separation of guaiacyl from syringyl compounds in fractions obtained from lignin oxidations it was necessary to use large amounts of syringaldehyde. A review of the literature revealed numerous reported syntheses of syringaldehyde,[2-8] but yields were all negligible or low, and syringaldehyde has remained more or less of a laboratory curiosity. However, one obvious synthesis of syringaldehyde has been overlooked by other investigators and that is the series of reactions analogous to the synthesis of vanillin from eugenol.

For years vanillin has been manufactured on a large scale from eugenol (the chief constituent of oil of cloves and cinnamon leaf oil) by two general methods. In the first, eugenol is treated with alkali to isomerize it to isoeugenol which, in turn, is oxidized to vanillin by some mild oxidizing agent, such as nitrobenzene and alkali. In the second method, eugenol is acetylated to protect the hydroxyl group, and the acetyleugenol is oxidized by a strong oxidizing agent, such as dichromate and acid or permanganate. The resulting acetylvanillin is then hydrolyzed to vanillin. The present paper describes a synthesis of syringaldehyde analogous to the first of these vanillin syntheses.

Although the syringyl analog of eugenol is not an easily obtained natural product or article of commerce, its preparation from pyrogallol 1,3-dimethyl ether in good yield has been recorded.[9,10] Pyrogallol 1,3-dimethyl ether is easily prepared by the controlled methylation of pyrogallol according to Krauss and Crede.[11]

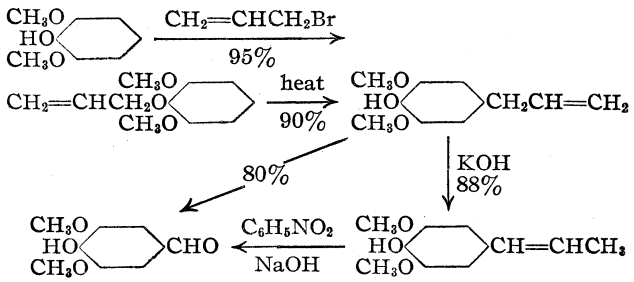
Pyrogallol 1,3-dimethyl ether was treated with allyl bromide in anhydrous acetone in the presence of anhydrous potassium carbonate and yielded 95% of 2-allyloxy-1,3-dimethoxybenzene; this underwent the Claisen rearrangement to 4-hydroxy-3,5-dimethoxyallylbenzene by boiling under reflux at 75 mm. pressure in a yield of 90%. Isomerization of 4-hydroxy-3,5-dimethoxyallylbenzene to 4-hydroxy-3,5-dimethoxypropenylbenzene by the action of alkali proved to be a more difficult problem. The methods ordinarily employed for isomerizing eugenol to isoeugenol were inoperative because the alkali metal salts of 4-hydroxy-3,5-dimethoxyallylbenzene are only slightly soluble in water. The use of aniline as a solvent solved the problem and a high yield of 4-hydroxy-3,5-dimethoxypropenylbenzene and of syringaldehyde was obtained by an adoption of the process described by Bots[12] for preparing vanillin from eugenol. 4-Hydroxy-3,5-dimethoxyallylbenzene was isomerized to 4-hydroxy-3,5-dimethoxypropenylbenzene by boiling with potassium hydroxide in aniline solution. The propenyl derivative could be isolated in 88% yield. Without separation of the propenyl compound, the entire reaction mixture was treated with more alkali and nitrobenzene and heated to yield 80% of syringaldehyde. The reactions involved are shown by the following formulas.



The ultraviolet absorption spectra of these compounds were determined in anhydrous dioxane with a Beckman spectrophotometer at minimum slit width. These spectra are shown in Fig. 1. The curve for syringaldehyde agrees fairly well with that reported by Patterson and Hibbert,[13] who determined their curve in ethanol. However, the present curve shows the fine structure of the principal 3050 Å. band.

The curves for the isomers—2-allyloxy-1,3-dimethoxybenzene, 4-hydroxy-3,5-dimethoxyallylbenzene and 4-hydroxy-3,5-dimethoxypropenylbenzene—illustrate the effect of structure on the ultraviolet absorption spectra and emphasize the difference between a conjugated and unconjugated unsaturated side chain. The double bond only becomes a strong resonator in this portion of the ultraviolet when it is conjugated with the ring. Change from an oxygen–allyl linkage to a carbon–allyl linkage results only in slight bathochromic and hyperchromic shifts. These data concur with those of Patterson and Hibbert for eugenol and isoeugenol.

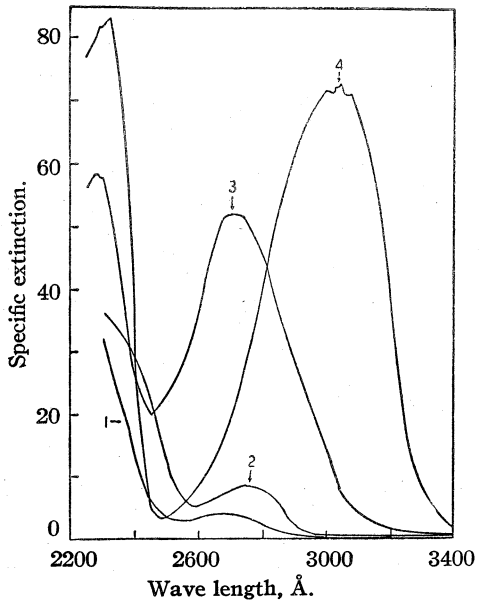

Fig. 1.—1, 2-Allyloxy-1,3-dimethoxybenzene; 2, 4-hydroxy-3,5-dimethoxyallylbenzene; 3, 4-hydroxy-3,5-dimethoxypropenylbenzene; 4, syringaldehyde.

Experimental

All melting points and boiling points are uncorrected.

2-Allyloxy-1,3-dimethoxybenzene.—Pyrogallol 1,3-dimethyl ether (154 g., 1.0 mole) was treated with 121 g. (1.1 mole) of allyl bromide and 180 g. (1.3 moles) of finely powdered anhydrous potassium carbonate in 400 ml. of anhydrous acetone according to the general procedure described by Hahn and Wassmuth.[10] 2-Allyloxy-1,3-dimethoxybenzene was obtained in 184 g. (95%) yield as a colorless fluid oil, b. p. 102° at 2 mm., refractive index $n^{22}D$ 1.5301.

4-Hydroxy-3,5-dimethoxyallylbenzene.—2-Allyloxy-1,3-dimethoxybenzene was boiled under reflux at 75 mm. pressure according to Hahn and Wassmuth[10] to yield 90% of 4-hydroxy-3,5-dimethoxyallylbenzene as a colorless viscous oil, b. p. 123–125° at 2 mm., refractive index $n^{22}D$ 1.5478.

4-Hydroxy-3,5-dimethoxypropenylbenzene.—Into a one-liter flask was placed a mixture of 100 g. of 4-hydroxy-3,5-dimethoxyallylbenzene and 50 g. of potassium hydroxide dissolved in 200 g. of water. The flask was connected to a distillation assembly and heated to boiling. After approximately 75 cc. of water had distilled, the boiling temperature began to rise. When the temperature of the mixture reached 110°, 450 g. of aniline was added and the mixture was distilled again. After about 100 ml. of distillate was collected, the boiling solution became thick with precipitate, but all precipitate dissolved when the last traces of water distilled and the temperature of the mixture began to rise. Approximately 150 ml. of distillate had been collected at this point. The distillation was continued until approximately 100 ml. of aniline was collected. The temperature at this point was 179–180°. The mixture was allowed to cool, and the solid material was treated with an excess of water and extracted with ether. The aqueous layer was acidified with hydrochloric acid and extracted with ether. The ether extract was thoroughly washed with dilute hydrochloric acid, and then with water, and finally dried with sodium sulfate and distilled. The residual oil was distilled under vacuum

to yield 22 g. (88%) of 4-hydroxy-3,5-dimethoxypropenylbenzene as a yellow oil, b. p. 107–108° at 0.05 mm., refractive index $n^{27}D$ 1.5741.

Anal. Calcd. for $C_{11}H_{14}O_3$: CH_3O, 31.9. Found: CH_3O, 31.9.

Syringaldehyde.—The above reaction was carried through the cooling stage before the treatment with water. The solidified mixture was covered with 400 g. of nitrobenzene and 135 g. of 50% sodium hydroxide solution, and with vigorous stirring it was boiled under reflux for three hours. The reaction mixture was distilled with steam until almost no oil distilled with the steam. The mixture was then cooled, diluted with water, and extracted with ether. The aqueous solution was acidified with dilute hydrochloric acid and extracted with ether. The ether extract was extracted with 21% sodium bisulfite solution. The bisulfite extract was acidified with 50% sulfuric acid and aspirated with air while heating on the steam-bath. After all traces of sulfur dioxide were removed, the solution was allowed to cool. The heavy crystals which separated were filtered, washed with water and air dried to yield 53.5 g. (52%) of syringaldehyde melting at 109–110°. Recrystallization from petroleum ether (b. p. 65–110°) yielded very pale yellow needles melting at 109–110°.

Anal. Calcd. for $C_9H_{10}O_4$: CH_3O, 34.07. Found: CH_3O, 34.01.

The aqueous filtrate was extracted with ether, and the ether was dried with sodium sulfate and distilled, leaving an additional 16 g. (23%) of crude syringaldehyde melting at 108–110°. Recrystallization from petroleum ether raised the melting point to 109–110°.

Ultraviolet Absorption Spectra.—The ultraviolet absorption spectra were determined with a Beckman model DU quartz spectrophotometer employing 1.0-cm. quartz cells and minimum slit widths. Measurements were made on freshly and accurately prepared solutions containing approximately 0.02 g. per liter in specially purified dioxane.

Acknowledgment.—The author is indebted to the Analytical Department of The Institute of Paper Chemistry for the analyses and ultraviolet absorption spectra reported in this paper.

Summary

Syringaldehyde has been synthesized from 4-hydroxy-3,5-dimethoxyallylbenzene by nitrobenzene oxidation in aniline solution. The intermediate 4-hydroxy-3,5-dimethoxypropenylbenzene has been isolated and characterized. This method affords a simple procedure for obtaining syringaldehyde from pyrogallol or pyrogallol 1,3-dimethyl ether. All steps in the synthesis give high yields. The ultraviolet absorption spectra of the intermediates have been determined.

Some Derivatives of Dibenzothiophene

BY ROBERT K. BROWN, ROBERT G. CHRISTIANSEN AND REUBEN B. SANDIN

The discovery of the carcinogenic action of the versatile 2-acetaminofluorene (VII) by Wilson, DeEds and Cox[1] has suggested the possibility that 3-acetaminodibenzothiophene might show similar activity. In this communication is described the preparation of this substance and some related compounds.

The orientation and derivatives of dibenzothiophene have been studied extensively by Gilman and co-workers.[2]

Recently Gilman and Nobis[3] have shown that 4-iododibenzothiophene undergoes an interesting rearrangement when treated with sodamide in liquid ammonia to give 3-aminodibenzothiophene.

In the present work it has been found that by using the sulfoxide of dibenzothiophene in which the oxygen is susceptible to reducing agents, a conversion of dibenzothiophene into 3-aminodibenzothiophene in an over-all yield of 45% can be accomplished. The preparation of dibenzothiophene-5-oxide from dibenzothiophene proceeds without difficulty and in high yields. Subsequent mono-nitration and reduction with stannous chloride and concentrated hydrochloric acid also proceed without difficulty and both reactions afford satisfactory yields of the desired products. The step-wise reduction of 3-nitrodibenzothiophene-5-oxide with stannous chloride and dilute hydrochloric acid has also been carried out, and has afforded 3-aminodibenzothiophene-5-oxide in good yield.

(3) Gilman and Nobis, THIS JOURNAL, **67**, 1479 (1945).

Experimental[4]

Dibenzothiophene-5-oxide (II).—Dibenzothiophene (I) was prepared by the excellent method of Gilman and Jacoby.[2] For the preparation of the sulfoxide the procedure of Fries and Vogt[5] was used. A solution of 15 g. of I in carbon tetrachloride (150 ml.) was treated at 0–5° with chlorine until 6 g. had been added. The solution became red and the addition compound which was produced was hydrolyzed by vigorously shaking the reaction mixture with ice and water. The solid was filtered off and washed with water. The yield of dibenzothiophene-5-oxide melting at 174–180° was 15.8 g. (97%). It was crystallized from benzene and the yield of pure compound was 12.5 g. (77%); m. p. 185–187°.

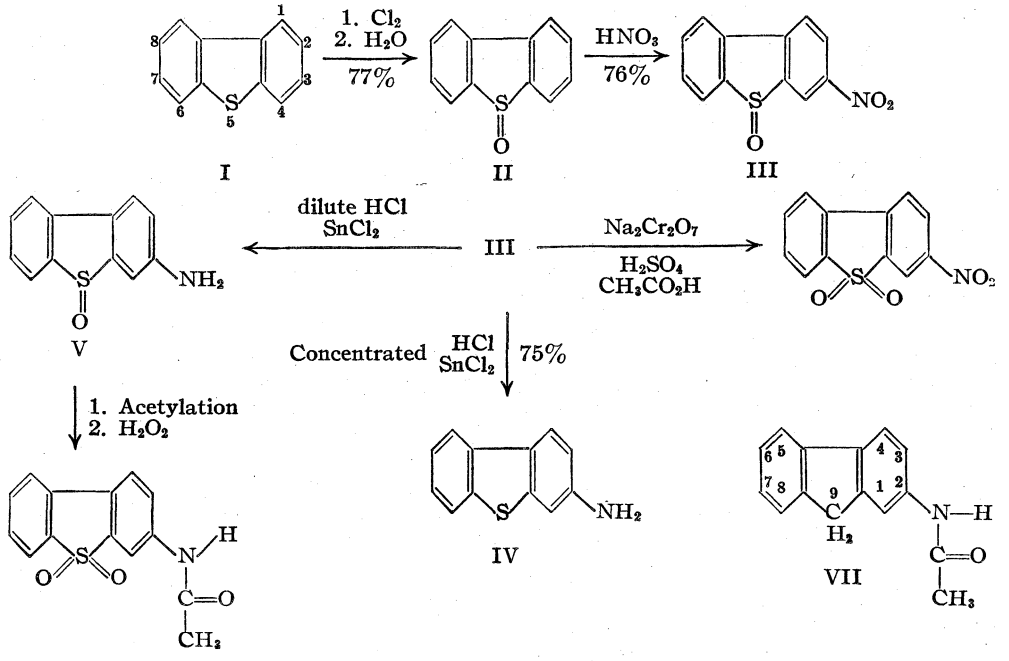
Anal. Calcd. for $C_{12}H_8OS$: S, 16.0. Found: S, 16.15.

The reduction of dibenzothiophene-5-oxide with stannous chloride and concentrated hydrochloric acid afforded an 85% yield of pure dibenzothiophene.

3-Nitrodibenzothiophene-5-oxide (III).—The nitration of II was carried out by the procedure developed by Gilman and Jacoby[2] for the nitration of the corresponding dioxide. To an ice-cold mixture of 15 g. of II, 33 ml. of glacial acetic acid and 33 ml. of concentrated sulfuric acid, was added with stirring 36 ml. of fuming nitric acid (sp. gr. 1.5) during a period of fifteen minutes. After the resulting clear solution had stood at 0–5° for thirty

(4) All melting points are uncorrected.

(5) Fries and Vogt, *Ann.*, **381**, 341 (1911).



minutes, it was poured into 200 g. of cracked ice. The gummy solid which was formed soon hardened and was filtered off and washed with water. The crude material weighed 16.5 g. (87%) and melted at 201–205°. After crystallization from ethyl alcohol the pure 3-nitrodibenzothiophene-5-oxide weighed 14 g. (76%) and melted at 209.5–210.5°.

Anal. Calcd. for $C_{12}H_7O_3NS$: S, 13.06. Found: S, 13.15.

3-Nitrodibenzothiophene-5-oxide was oxidized with a mixture of sodium dichromate, acetic acid and dilute sulfuric acid (1:1). The product after crystallization from acetone was shown to be identical with an authentic sample of 3-nitrodibenzothiophene-5-dioxide.[2]

3-Aminodibenzothiophene (IV).—To a solution of 10 g. of III in 100 ml. of glacial acetic acid was added a solution of 51 g. of hydrated stannous chloride in 65 ml. of concentrated hydrochloric acid. The reaction was exothermic and a solid was formed. After standing at room temperature for twelve hours the solid was filtered off and washed with a mixture of equal parts of glacial acetic and concentrated hydrochloric acid. The amine was liberated with dilute sodium hydroxide solution and the weight of crude material, melting at 113–117°, was 8.1 g. (99%). The pure compound after crystallization from dilute ethyl alcohol weighed 6.1 g. (75%), and melted at 121–122.5°. A mixed melting point with the above amine and the amine prepared by the action of sodamide in liquid ammonia on 4-iododibenzothiophene (kindly furnished by Drs. Gilman and Nobis), was not depressed.

The acetylation of 3-aminodibenzothiophene was readily accomplished by the procedure of Gilman and Nobis.[3] After purification from ethyl alcohol it melted at 196–197°.

3-Aminodibenzothiophene-5-oxide (V).—To a solution of 5 g. of III in 60 ml. of glacial acetic acid was added 26 g. of hydrated stannous chloride in 40 ml. of dilute (6 *N*) hydrochloric acid. The reaction mixture was kept at 40° for thirty minutes and then allowed to stand at room temperature for three hours, after which it was cooled to 0° and the yellow solid was then filtered off. The amine was liberated with sodium hydroxide solution and afforded 4 g. (91%) of compound melting at 206–207.5°. The light yellow compound slowly darkened on exposure to air. For analytical purposes it was crystallized from dilute alcohol, m. p. 208–209°.

Anal. Calcd. for $C_{12}H_9ONS$: S, 14.87. Found: S, 15.05.

The amino sulfoxide is sensitive to heat and for that reason a temperature below 60° during the process of crystallization is desirable.

3-Acetaminodibenzothiophene-5-oxide (VI).—To a solution of 1.8 g. of V in 30 ml. of benzene was added 4 ml. of acetic anhydride. The reaction mixture was allowed to stand for twelve hours. The light yellow solid which was formed melted at 262–264°; yield, 95%. It was crystallized from absolute alcohol; m. p. 265–267°.

Anal. Calcd. for $C_{14}H_{11}O_2NS$: S, 12.44. Found: S, 12.47.

The oxidation of VI in glacial acetic acid with 30% hydrogen peroxide afforded 3-acetaminodibenzothiophene-5-dioxide, m. p. 308–310° (cor. m. p. 322–324°). A mixed melting point carried out with an authentic sample of 3-acetaminodibenzothiophene-5-dioxide[3] was not depressed.

Acknowledgment.—The authors are very grateful to the Alberta Branch of the Canadian Cancer Society for financial aid in support of this work. We are also grateful to Drs. J. A. Miller and E. C. Miller of the McArdle Memorial Laboratory, Madison, Wisconsin, for determining the carcinogenic properties of 3-acetaminodibenzothiophene. Their results will be published elsewhere.

Summary

The reduction of 3-nitrodibenzothiophene-5-oxide with stannous chloride and concentrated hydrochloric acid affords 3-aminodibenzothiophene. With stannous chloride and dilute hydrochloric acid reduction to 3-aminodibenzothiophene-5-oxide can be accomplished. Some new derivatives of dibenzothiophene have been prepared.

Reaction of Diazo Compounds with Sulfamic Acid

BY H. W. GRIMMEL AND JACK F. MORGAN

Sulfamic acid has long been used both in industry and in the laboratory to remove excess nitrous acid following diazotization of amines. Obviously, it has been generally assumed that the diazo compounds were unaffected by sulfamic acid under the conditions employed. It has been demonstrated in this Laboratory that a number of diazo compounds do react with sulfamic acid even in strongly acid solution. In fact, in certain cases this reaction is a rapid and quantitative one yielding the products shown in the net equation

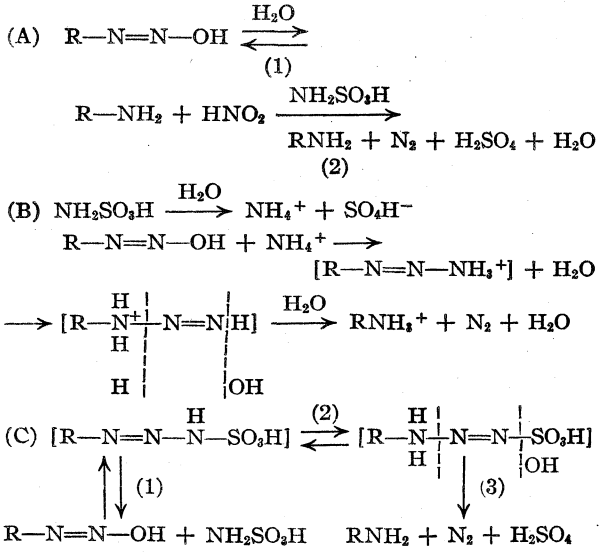
$$R{-}N{=}N{-}OH + NH_2SO_3H \longrightarrow RNH_2 + H_2SO_4 + N_2$$

Scope of the Reaction

Only the most reactive diazo compounds are capable of reacting with sulfamic acid in mineral acid solution. For example, diazo compounds derived from *p*-chloroaniline, aniline or *p*-toluidine do not react with sulfamic acid in strong acid solution. 2,5-Dichloroaniline and *p*-nitroaniline yield diazo compounds which react very slowly with sulfamic acid while the diazo compounds from 2,4-dinitroaniline and 2,6-dichloro-4-nitroaniline react quite rapidly. Most reactive of all are the diazo compounds derived from 5-aminotetrazole and 5-amino-1,2,4-triazole-3-carboxylic acid.

Mechanism

Three explanations of the reaction are listed. Evidence will be presented to show that the first two, A and B, are untenable and that C is probably a true picture of what takes place.



Explanation A is incorrect. If equilibrium (1) existed and the sulfamic acid were merely reacting with nitrous acid, it is obvious that the role of sulfamic acid in (2) could be played by urea. However, it was shown by experiment that urea did not react at all to reverse the diazotization reaction.

Explanation B breaks down on at least two counts. First of all the hydrolysis of sulfamic acid in cold strongly acid solution is at least ten thousand fold too slow to account for the reaction. The reaction of excess sulfamic acid with the diazo compound derived from 5-amino-1,2,4-triazole-3-carboxylic acid at 0–5° is complete within five minutes. However, no barium sulfate precipitate results when an aqueous solution of sulfamic acid, hydrochloric acid, and barium chloride is kept at 5° for a week. Secondly, the 5-diazo-1,2,4-triazole-3-carboxylic acid did not react at all with ammonium chloride in dilute hydrochloric acid.

Explanation C is proposed as the correct mechanism for the reaction. Since the first stage of the reaction does not involve hydrolysis of either of the two reactants (mechanisms A or B) it follows that the first step in the reaction directly involves the diazo compound and the sulfamic acid *per se*. Step (1) of mechanism C appears to be the only logical way for the reaction to start if the final products are to include nitrogen and the original amine.

Experimental

5-Diazo-1,2,4-triazole-3-carboxylic Acid.[1]—5-Amino-1,2,4-triazole-3-carboxylic acid (50 g.) was dissolved by warming in water (400 ml.) and concentrated hydrochloric acid (200 ml.). Diazotization was effected at −5° by addition of a slight excess of sodium nitrite solution. The white solid diazo compound was separated by filtration, washed thoroughly with ice water and pressed on the funnel. One gram of this stable presscake was titrated in cold acid solution with 0.05 *N* 2-naphthylamine hydrochloride solution to determine its strength. The yield of isolated diazo compound usually amounted to 75% of the theoretical.

(a) **Reaction with Sulfamic Acid.**—The filter cake of the diazo compound (0.05 mole) was slurried in 1 *N* hydrochloric acid solution (200 ml.) and treated with a solution (100 ml.) of sulfamic acid (0.15 mole). Nitrogen was evolved rapidly and the diazo compound was entirely destroyed within five minutes as shown by failure to couple with β-naphthylamine. When acidic solutions of ammonium chloride or urea replaced the sulfamic acid solution, no reaction took place even in several days.

In a second experiment a suspension of the diazo compound was "reversed" to the amine with a slight excess of sulfamic acid, rediazotized, and the newly formed precipitate removed by filtration. This precipitate proved to be identical with the original diazo compound by identical X-ray diffraction patterns.

In a third experiment aliquots of a dilute solution of diazotized 5-amino-1,2,4-triazole-3-carboxylic acid were (a) titrated with 0.05 *N* 2-naphthylamine hydrochloride and (b) "reversed" to the amine with sulfamic acid, rediazotized, and titrated with 2-naphthylamine. The results of these titrations gave a minimum of 94% yield for the "reversal" and rediazotization.

(1) W. Manchot and R. Noll, *Ann.*, **343**, 1 (1905).

Comparison of Reaction Rates of Various Diazo Compounds with Sulfamic Acid.—Tenth normal solutions of diazo compounds were prepared by known procedures and 50-ml. aliquots (0.005 mole) employed in each experiment. For each diazo compound the 50-ml. aliquots were treated with solutions (50 ml.) containing 0, 1, 10, or 20 equivalent amounts of sulfamic acid and the nitrogen gas evolved measured continuously by means of a rate nitrometer.[2] In all cases the *p*H was <1 and the temperature 25° except in the case of diazotetrazole which was run at 0–5°.

The original amine was isolated and identified as the primary reaction product except in the case of 2-chloro-4-nitroaniline. In this latter case, the diazoamino compound was isolated in good yield with the expected (50%) amount of N_2 liberated. Typical reaction rate curves are shown in Fig. 1.

2,5-Dichloroaniline and *p*-Nitroaniline.—The diazo compounds of these two amines were not sufficiently reactive for study with the rate nitrometer. Consequently, 0.05 *N* solutions of these diazo compounds were treated with 0, 1 and 10 equivalent amounts of sulfamic acid and stored at 5° for ten days. At the end of this time the solutions were filtered and the amounts of solid diazoamino compounds determined. Yields are given in Table I.

TABLE I

YIELD OF DIAZOAMINO COMPOUNDS

Sulfamic acid	% Yield from diazotized *p*-nitroaniline	% Yield from diazotized 2,5-dichloroaniline
None	..	..
1 equiv.	3.6	6.2
10 equiv.	12.0	19.0

Summary

1. Certain diazo compounds were shown to react with sulfamic acid in acid solution to yield the original amine from which the diazo compound was derived together with nitrogen and sulfuric acid.

2. A mechanism has been proposed to explain the reaction.

3. Relative reaction rates of various diazo compounds with sulfamic acid were compared by means of a rate nitrometer.

α-L-Glucose-1-phosphate

BY A. L. POTTER, JOHN C. SOWDEN, W. Z. HASSID AND M. DOUDOROFF

An enzyme obtained from the bacterium *Pseudomonas saccharophila* has been named sucrose phosphorylase because it catalyzes the reversible reaction between fructose and α-D-glucose-1-phosphate to form sucrose. This enzyme is also capable of catalyzing the reaction between other monosaccharides and the same ester, thus forming a number of disaccharides, namely, D-glucosido-L-sorboside, D-glucosido-D-xyloketoside, D-glucosido-L-araboketoside, and D-glucosido-L-arabinose.[1] The formation of these disaccharides demonstrates the versatility of the enzyme with regard to the non-glucose substrates which act as "glucose acceptors" in the synthetic reactions. However, the enzyme appears to be specific toward the glucose portion of its substrate. It has been found that the sucrose phosphorylase will not form compound sugars when α-maltose-1-phosphate, α-D-galactose-1-phosphate, or α-D-xylose-1-phosphate is substituted for α-D-glucose-1-phosphate. Similarly, potato and muscle phosphorylases will not form polysaccharides when these phosphorylated sugars are substituted for α-D-glucose-1-phosphate.

In this connection, it was of interest to test whether or not α-L-glucose-1-phosphate could be substituted for its optical isomer, α-D-glucose-1-phosphate in the enzymatic reaction with potato phosphorylase for polysaccharide synthesis or with sucrose phosphorylase for disaccharide formation.

In the present work the preparation of α-L-glucose-1-phosphate from L-glucose is described and

(1) M. Doudoroff, W. Z. Hassid and H. A. Barker, *J. Biol. Chem.*, **168**, 733 (1947); W. Z. Hassid, M. Doudoroff, A. L. Potter and H. A. Barker, THIS JOURNAL, **70**, 306 (1948).

its behavior as a substrate in these enzymatic reactions is determined.

Experimental

Preparation of α-L-Glucose-1-(barium phosphate).—L-Glucose was synthesized by the method previously described.[2] β-Pentaacetyl-L-glucose was prepared by heating 15 g. of L-glucose with 75 g. of acetic anhydride and 7.2 g. of powdered anhydrous sodium acetate according to the method of Fischer.[3] The yield of the acetylated derivative was 23.4 g. or 72%.

α-Bromotetraacetyl-L-glucose[4] was prepared as follows: fourteen grams of β-pentaacetyl-L-glucose was treated with 9.1 ml. of 30 to 32% solution of hydrogen bromide in glacial acetic acid and the mixture allowed to stand at room temperature for two hours. The solution was diluted with 60 ml. of chloroform, poured into 200 ml. of ice water and stirred rapidly. The chloroform layer was separated and the aqueous phase extracted once more with 15 ml. of chloroform. The chloroform extracts were washed twice with ice water, dried with calcium chloride and evaporated *in vacuo* at 40° to a thick sirup. The sirup was taken up with 35 ml. of anhydrous ether and petroleum ether was added until a second liquid phase began to appear. Crystallization was then allowed to take place. The yield of the crystalline acetobromo-L-glucose was 13.5 g. (91.6%).

α-L-Glucose-1-(barium phosphate) was prepared by treating 13.5 g. of α-bromotetraacetyl-L-glucose with trisilver phosphate, then partially hydrolyzing the intermediate product, presumably tri-(tetraacetyl-L-glucose-1)-phosphate, for twelve hours in 0.2 *N* hydrochloric acid in methanol at 23°, and neutralization with barium hydroxide.[5] A yield of 1.09 g. of the barium salt was obtained (22.2%). Analysis of the salt shows that it contains three molecules of water of crystallization. It is an amorphous, non-hygroscopic white powder, which is easily soluble in water and insoluble in 50% alcohol.

Anal. Calcd. for $C_6H_{11}O_5 \cdot O \cdot PO_3Ba \cdot 3H_2O$: P, 6.9. Found: P, 7.1; specific rotation, $[\alpha]_D$ −73.2° (*c*, 1.01, anhydrous barium salt, in water). Cori, Colowick and Cori's[5] value for the D-form of the barium salt, $[\alpha]_D$ +75°.

Preparation of α-L-Glucose-1-(dipotassium phosphate).—A portion of the barium salt (0.8 g.) was dissolved in 12 ml. of warm water and treated with an equivalent amount (0.31 g.) of potassium sulfate. The precipitated barium sulfate was removed through a precoated diatomaceous silica filter and absolute ethanol was added to the filtrate until a slight cloudiness appeared. The solution was allowed to remain at room temperature, and 1.7 volumes of absolute alcohol was added gradually. Crystallization was then allowed to take place. The crystals were filtered, washed with 65% ethanol and recrystallized from water by addition of an equal volume of ethanol. A yield of 0.48 g. was obtained (73%).

The L-glucose-1-(dipotassium phosphate) thus prepared is a white non-hygroscopic crystalline product, containing two molecules of water of crystallization and, except for its negative rotation, is similar in its physical and chemical properties to the D-form of the hexosephosphate.

Anal. Calcd. for $C_6H_{11}O_5 \cdot O \cdot PO_3K_2 \cdot 2H_2O$: C, 19.35; H, 4.06; P, 8.33; aldose, 48.4. Found: C, 19.19; H, 4.03; P, 8.40; aldose, 48.7. Specific rotation, $[\alpha]_D$ −78.2° (in water, *c*, 1.01). Hanes'[6] value for the D-form of the dipotassium salt, $[\alpha]_D$ +78.5° (in water, *c*, 1.24).

The L-glucose-1-phosphate is readily hydrolyzed with dilute acid, is stable in alkali, and shows no Fehling reduction on prolonged boiling. The ester is completely hydrolyzed to glucose and inorganic phosphate when heated for seven minutes in 1 *N* hydrochloric acid in a boiling water-bath. Upon hydrolysis of the ester the reducing sugar produced was identified as glucose by the preparation of glucosazone.

Oxidation of α-L-Glucose-1-(dipotassium phosphate) with Sodium Periodate.—In oxidizing the L-glucose-1-phosphate Wolfrom and Pletcher's[7] procedure for oxidation of the D form of this ester was used. The results showed that in the oxidation of one mole of dipotassium dihydrate L-glucose-1-phosphate 2.0 moles of periodate were consumed with the production of 1.1 moles of formic acid. These data closely agree with the theoretical requirements of two moles of periodate and one mole of formic acid, assuming that the L-glucose of this ester exists in the pyranose configuration.

Action of Potato Phosphorylase and Sucrose Phosphorylase from *P. saccharophila* on α-L-Glucose-1-(dipotassium phosphate).—A solution of α-L-glucose-1-phosphate was adjusted with acetic acid to *p*H 6.0 and treated with potato phosphorylase. The mixture was analyzed for inorganic phosphorus at several thirty-minute intervals. No inorganic phosphate was liberated, except for a small amount which was attributed to hydrolytic decomposition of the ester. In a control experiment with D-glucose-1-phosphate, inorganic phosphate was rapidly liberated.

A similar experiment was performed with a mixture of α-L-glucose-1-phosphate, D-fructose and sucrose phosphorylase extracted from *P. saccharophila*. No liberation of inorganic phosphate could be observed. Neither was inorganic phosphate liberated when L-fructose[8] was substituted for D-fructose in the mixture. In a control experiment with D-glucose-1-phosphate, D-fructose and the same enzyme, inorganic phosphate was liberated under these conditions.

Acknowledgments.—The work reported in this paper was supported in part by a grant from the Corn Industries Research Foundation.

Summary

The barium salt of α-L-glucose-1-phosphoric acid has been synthesized and converted into the dipotassium salt. An elementary analysis and data obtained from oxidation with sodium periodate of the potassium salt of this ester agree with the composition $C_6H_{11}O_5 \cdot O \cdot PO_3K_2 \cdot 2H_2O$. Except for the negative rotation, $[\alpha]_D$ −78.2°, of the α-L-glucose-1-phosphate, its physical and chemical properties agree with those of its optical isomer, α-D-glucose-1-phosphate.

α-L-Glucose-1-phosphate is not converted by potato phosphorylase to polysaccharide. Neither can it be used as substrate by sucrose phosphorylase from *P. saccharophila* with either D- or L-fructose to form a disaccharide.

The Synthesis of 5-Halogeno-2-thiouracil and 6-Methyl-5-halogeno-2-thiouracil Derivatives[1]

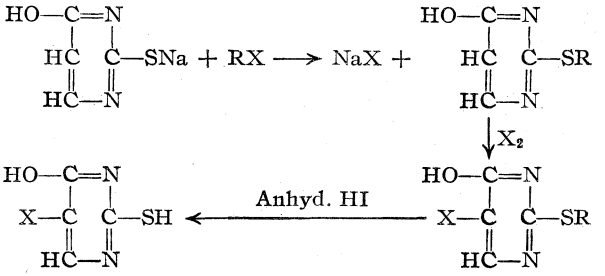
BY HAROLD W. BARRETT,[2] IRVING GOODMAN AND KARL DITTMER

Following Astwood's discovery in 1943 of the relatively high antithyroid activity and low toxicity of 2-thiouracil,[3] numerous derivatives of this compound were prepared and tested for physiological activity.[4-6] In general, it has been found that substitution on either the sulfur[4] or the nitrogen[5] of the molecule decreased or destroyed the antithyroid potency of the parent compound, while substitution of a small alkyl group in either the 5- or the 6-position enhanced such activity, as did substitution of a benzyl, phenethyl or thenyl group in the 6 position.[4,6] A large variety of other substituents in either of these positions, including saturation of the 5,6-double bond, diminished the activity so that the resulting compound was no longer useful as an antithyroid agent.

Clinically, the more highly active derivatives have not corrected the basic defects of 2-thiouracil itself; they frequently provoke toxic reactions which limit or preclude their use, and also induce thyroid hyperemia and friability consequent to blocking hormone synthesis. Attempts to overcome these defects by simultaneous administration of iodine,[7,8] thyroxine,[8] folic acid,[9,10] or various other vitamins[11] have not been uniformly successful; hence there has been a continuing search for new types of derivatives for both research and clinical purposes.

In view of the effect of 5-substitution on the activity of thiouracil, it seemed of interest to prepare the 5-halogeno-2-thiouracils, and to test their physiological action. It seemed especially desirable to obtain the 5-iodo derivative which would permit the simultaneous administration of an organic iodide and a possible antithyroid compound. In this paper, we wish to report the synthesis of 5-chloro, 5-bromo, and 5-iodo-2-thiouracil, and the corresponding halogeno derivatives of 6-methyl-2-thiouracil. The antithyroid potency of three of these halogenated derivatives was compared with that of 2-thiouracil using the rat as the assay animal. Assigning an arbitrary value of 100% to 2-thiouracil, the relative potencies of the 5-chloro-, 5-bromo-, and 5-iodo compounds in producing increased thyroid weights were +125, −2 and +35%, respectively. The relative potencies in producing decreased thyroid iodine levels were 86, 68 and 66%, respectively. The detailed results of these physiological tests will be reported later.

The synthesis of these derivatives is summarized by the following steps



5-Halogeno-2-thiouracil

Although Johnson and Johns[12] prepared the 5-bromo derivative of 6-amino-4-oxy-2-mercaptopyrimidine by direct bromination of the pyrimidine in glacial acetic acid, it appears that 2-thiouracil can be halogenated only when the sulfur is blocked by an alkyl or aryl group. Attempts to obtain the halogenated derivatives by condensation methods or by halogenation of the unsubstituted molecule failed; and, although 2-thiouracil will react with 7.7 equivalents of iodine in neutral or alkaline solution,[13] no iodine can be found in the product following purification. The 2-thiocyanate (m. p. 148–149° with decomposition) was formed by adding an alcoholic solution of cyanogen bromide to an aqueous solution of sodium thiouracil, but this derivative could not be brominated in the ring. Attempts were made to form the S-benzoyl and the S-sulfonyl derivatives by the Schotten–Baumann method, but the products were too unstable to isolate.

In preliminary work with the S-alkyl derivatives, a sample of 5-bromo-2-ethylthiouracil was prepared by the method of Wheeler and Johnson,[14] and treated with dry hydrogen chloride to remove the ethyl group.[15] However, this compound slowly decomposed at the melting point, and when the hydrogen chloride was passed through for a few minutes, only a red tar remained. The same result was obtained with the analogous methyl

derivative. A quantity of 2-benzylthiouracil was prepared[15] and brominated in the same manner as the ethyl derivative to yield 5-bromo-2-benzylthiouracil (m. p. 184–185° with decomposition). This compound could be partially debenzylated, but with considerable decomposition, by passing dry hydrogen chloride through a tube of the crystals at 120° or by dissolving the compound in glacial acetic acid and passing dry hydrogen bromide through the solution which was kept near the boiling point. An attempt was made to split this derivative with cyanogen bromide[16] in glacial acetic acid, but little reaction took place even when the mixture was heated to 90–100° in a sealed tube.

Finally it was determined that 5-bromo-2-benzylthiouracil, as well as the corresponding S-alkyl derivatives, could be split to give fair yields of the desired 5-halogeno-2-thiouracils by dissolving the intermediate in glacial acetic acid and treating the solution with dry hydrogen iodide at the appropriate temperature. Since a controlled flow of hydrogen iodide gas was difficult to obtain, the splitting was originally carried out by adding 50% hydriodic acid to a large excess of acetic acid–acetic anhydride mixture, and adding the resulting solution dropwise to the hot glacial acetic acid solution of the pyrimidine. Upon subsequent cooling, a part of the final product precipitated out, and the remainder was obtained by evaporating the excess solvent under reduced pressure. During the preparation of a larger quantity of 5-iodo-2-thiouracil the splitting reaction with anhydrous hydrogen iodide was greatly improved by carrying out this reaction in the apparatus illustrated in Fig. 1. This apparatus provides a convenient method for the preparation of anhydrous hydrogen iodide from 50% hydriodic acid without the possibility of introducing water into the reaction mixture, and also permits working with much less solvent. This technique was used in the preparation of 5-iodo-2-thiouracil and 6-methyl-5-iodo-2-thiouracil in better yields than was obtained by the method employed for the other halogeno compounds.

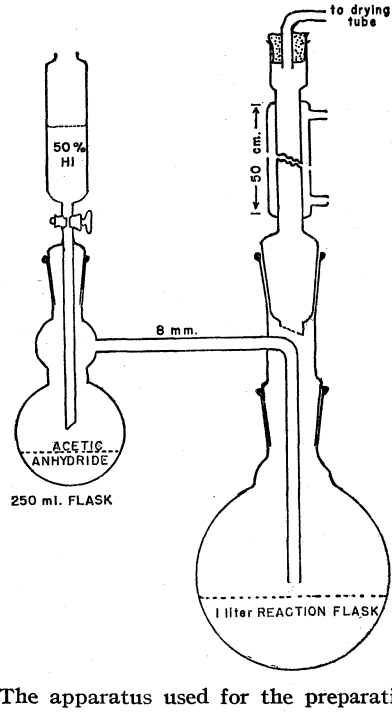

Fig. 1.—The apparatus used for the preparation of anhydrous hydrogen iodide.

(16) Braun and Englebertz, *Ber.*, **56**, 1573 (1923).

Although bromine was very readily introduced in the 5 position of the S-alkyl derivatives of 2-thiouracil, the same was not true of chlorine. When an acetic acid solution of the pyrimidine was treated with chlorine, it appeared that either a hydrochloride salt[14] or a sulfonium chloride was formed,[17] and when the product was taken up in water it decomposed to form uracil and a mercaptan. It was found necessary to use a ferric chloride catalyst with heating to introduce the chlorine into the 5-position. The product was then taken up in a water–pyridine mixture to avoid decomposition.

Experimental[18]

2-Methylthiouracil.—Wheeler and McFarland[19] prepared 2-methylthiouracil by the action of methyl iodide on 2-thiouracil in a solution of absolute alcohol and sodium alcoholate. It was found more convenient to prepare the intermediate in the manner described here.

A mixture of 12.8 g. of 2-thiouracil and 4.3 g. of sodium hydroxide was placed in a 500-ml. Erlenmeyer flask, and dissolved on the steam-bath with a minimum amount of water. Twice the volume of 95% alcohol was then added, the solution cooled to about 30°, and 6.3 ml. of methyl iodide added. The solution was reheated to 50–60° for twenty minutes, then cooled to room temperature. The precipitate was filtered off, and, after acidifying the filtrate with acetic acid, the excess solvent was removed *in vacuo*. The combined precipitates were thoroughly washed with water and recrystallized from alcohol to give a final yield of 9.0 g. (63% of the theoretical yield) of 2-methylthiouracil, capillary m. p. 198°.

5-Chloro-2-methylthiouracil.—Nine grams of 2-methylthiouracil was dissolved in an excess of glacial acetic acid containing 5% acetic anhydride to remove any moisture. A trace of ferric chloride was added as catalyst. The solution was then treated with a 20% excess of chlorine in carbon tetrachloride. The solution became warm and the temperature was maintained at 50–60° until most of the hydrogen chloride fumes were evolved. After cooling, a small amount of precipitate formed; more was obtained when the filtrate was evaporated *in vacuo* to a small volume. The combined precipitates were taken up in excess aqueous pyridine, and the solvent allowed to evaporate at room temperature. The residue was taken up in water, acidified with glacial acetic acid, filtered, and washed several times with water. After several recrystallizations from alcohol the final yield of 5-chloro-2-methylthiouracil was 2.2 g. (20%), m. p. 258–260°.

Anal. Calcd. for $C_5H_5N_2OSCl$: Cl, 20.08. Found: Cl, 20.02.

5-Chloro-2-methylthiouracil was obtained in the same yield when the chlorination was carried out by adding a

(19) Wheeler and McFarland, *Am. Chem. J.*, **42**, 101 (1909).

20% excess of sulfuryl chloride to the acetic acid–acetic anhydride solution of 2-methylthiouracil, with ferric chloride as the catalyst.

5-Chloro-2-thiouracil.—Two and two-tenths grams of 5-chloro-2-methylthiouracil was dissolved in 100 ml. of glacial acetic acid containing 20% acetic anhydride. This solution was placed in a round bottom flask provided with a ground glass joint and reflux condenser with a funnel at the top. While the solution was kept at its boiling temperature, a mixture consisting of 3.5 ml. of 50% hydriodic acid (specific gravity 1.5), 60 ml. of glacial acetic acid, and 20 ml. of acetic anhydride was added dropwise through a reflux condenser. Heating was continued for an hour after all the hydriodic acid was added. Crude 5-chloro-2-thiouracil precipitated on cooling, and more was obtained when the remaining solution was concentrated to a small volume. The combined precipitates were taken up in dilute ammonium hydroxide and heated until solution was complete. The hot solution was acidified with acetic acid, cooled and the 5-chloro-2-thiouracil collected on the filter. It was recrystallized first from alcohol and then from water to yield 1.5 g. (72%) of pure 5-chloro-2-thiouracil, m. p. 264–270° with decomposition.

Anal. Calcd. for $C_4H_3N_2OSCl$: Cl, 21.80; N, 17.23; S, 19.71. Found: Cl, 21.90; N, 17.54; S, 19.52.

6-Methyl-5-chloro-2-ethylthiouracil.—A sample of 6-methyl-2-ethylthiouracil was prepared by the method of Johns,[20] and chlorinated in glacial acetic acid and acetic anhydride as described for the preparation of 5-chloro-2-methylthiouracil. A 10-g. sample of 6-methyl-2-ethylthiouracil was chlorinated and the product recrystallized from alcohol. A 24% yield of 6-methyl-5-chloro-2-ethylthiouracil, m. p. 188–190°, was obtained.

Anal. Calcd. for $C_7H_9N_2OSCl$: Cl, 17.32. Found: Cl, 17.20.

6-Methyl-5-chloro-2-thiouracil.—The 6-methyl-5-chloro-2-ethylthiouracil was split and the product isolated in the same manner as has been described for the preparation of 5-chloro-2-thiouracil, except that after all the hydriodic acid was added the reaction mixture was vigorously boiled for two hours. The yield from 10 g. of 6-methyl-5-chloro-2-thiouracil was 50–60%. The 6-methyl-5-chloro-2-thiouracil had a m. p. of 265–270° with decomposition.

Anal. Calcd. for $C_5H_5N_2OSCl$: Cl, 20.08; N, 15.86. Found: Cl, 20.18; N, 15.52.

6-Methyl-5-chloro-2-isopropylthiouracil.—6-Methyl-2-isopropylthiouracil, m. p. 155°, was prepared in the same manner as the S-ethyl analog, and upon chlorination gave a 36% yield of 6-methyl-5-chloro-2-isopropylthiouracil, m. p. 162–163°.

Anal. Calcd. for $C_8H_{11}N_2OSCl$: Cl, 16.21. Found: Cl, 16.39.

Unfortunately, the isopropyl group was so difficult to remove that this derivative was not used further.

5-Bromo-2-methylthiouracil.—The intermediate 5-bromo-2-methylthiouracil was prepared by the method described by Wheeler and Johnson[14] for the preparation of the S-ethyl analog. It is best to repeat the bromination, since some unreacted material precipitates out during the first bromination. Fourteen grams of 2-methylthiouracil was dissolved in glacial acetic acid containing 5% acetic anhydride. To this solution was added 7.3 ml. of bromine in 15 ml. of glacial acetic acid. The precipitated product was filtered off, washed with glacial acetic acid and suspended in hot glacial acetic acid. To this suspension was added 1 ml. of bromine in 5 ml. of glacial acetic acid. The product was collected on the filter, washed with glacial acetic acid and recrystallized from ethyl alcohol. The yield of 5-bromo-2-methylthiouracil was 17.4 g. (80%), m. p. 255°. When heated in a capillary it turned yellow at 205°, red at 217°, and decomposed completely to a red liquid at 219°.

Anal. Calcd. for $C_5H_5N_2OSBr$: Br, 36.15. Found: Br, 36.07.

5-Bromo-2-thiouracil from the S-Methyl Intermediate.—The methyl group was removed by hydriodic acid, and the 5-bromo-2-thiouracil isolated, in the same way as described for the chlorinated derivative. Yields obtained, when 10 g. of 5-bromo-2-methylthiouracil was split, varied from 30–49%. The 5-bromo-2-thiouracil crystallized out of either water or alcohol as long, colorless prisms, m. p. 270° with decomposition; when heated slowly in a capillary it turned brown around 170° and decomposed to a red liquid near 200°. As with the chloro derivative, it is necessary to identify this compound and verify its purity by analysis.

Anal. Calcd. for $C_4H_3N_2OSBr$: Br, 38.59; N, 13.53; S, 15.48. Found: Br, 38.70; N, 13.44; S, 15.30.

5-Bromo-2-thiouracil from the S-Benzyl Intermediate.—5-Bromo-2-thiouracil was prepared from 5-bromo-2-benzylthiouracil in the same manner as from the S-methyl derivative but at a temperature of 100°. This preparation, however, was not employed because 2-benzylthiouracil decomposed appreciably during bromination. The 5-bromo-2-benzylthiouracil, m. p. 184° with decomposition, was usually obtained in yields of 40 to 50%.

Anal. Calcd. for $C_{11}H_9N_2OSBr$: Br, 26.9. Found: Br, 26.8.

6-Methyl-5-bromo-2-methylthiouracil.—Ten grams of 6-methyl-2-methylthiouracil was brominated and isolated in the same manner as 5-bromo-2-methylthiouracil to yield 13 g. (91%) of 6-methyl-5-bromo-2-methylthiouracil, m. p. 255–256° with decomposition.

Anal. Calcd. for $C_6H_7N_2OSBr$: Br, 34.00. Found: Br, 34.08.

6-Methyl-5-bromo-2-thiouracil.—Eleven grams of 6-methyl-5-bromo-2-methylthiouracil was treated with hydriodic acid in acetic acid–acetic anhydride solution according to the above described directions to yield 1.8 g. of 6-methyl-5-bromo-2-thiouracil, m. p. 268–272° with decomposition; capillary melting point was 230° with decomposition.

Anal. Calcd. for $C_5H_5N_2OSBr$: Br, 36.15. Found: Br, 36.28.

5-Iodo-2-benzylthiouracil.—This compound was made by iodinating 2-benzylthiouracil according to the method of Johnson and Johns[21] for the preparation of 5-iodo-2-ethylthiouracil. When a quantity of 10.5 g. of 2-benzylthiouracil was iodinated, a yield was obtained of 9.3 g. (56%) of 5-iodo-2-benzylthiouracil, m. p. 178–180°.

Anal. Calcd. for $C_{11}H_9N_2OSI$: I, 36.87. Found: I, 36.83.

5-Iodo-2-thiouracil.—A sample of 5-iodo-2-ethylthiouracil was prepared according to the method of Johnson and Johns,[21] but in attempting to de-ethylate the compound with hydriodic acid as previously described, it was found that practically all the iodine was lost from the ring, while little splitting occurred. Essentially the same result was obtained with the S-methyl derivative. For this reason the 5-iodo-2-benzylthiouracil was used, since it could be satisfactorily split by keeping the temperature between 90 and 100° while adding anhydrous hydrogen iodide by the use of the apparatus illustrated in Fig. 1.

Sixty-five and four-tenths grams of 5-iodo-2-benzylthiouracil was dissolved in 400 ml. of glacial acetic acid containing 10 ml. of acetic anhydride and placed in the reaction vessel. In the side flask was placed 95 ml. of acetic anhydride, and in the dropping funnel 75 ml. of 50% hydriodic acid. While maintaining the temperature of the reaction flask at approximately 100° with a boiling water-bath, the hydriodic acid was added dropwise to the acetic anhydride in the side flask. This mixture became hot, and the hydrogen iodide as it was liberated was conducted into the reaction flask. As the hydrogen iodide came in contact with the solution of the S-benzyl deriva-

(20) Johns, *Am. Chem. J.*, **40**, 348 (1908).

(21) Johnson and Johns, *J. Biol. Chem.*, **1**, 305 (1905).

tive, a ring of precipitate of the split product formed under the inlet tube. When all the hydriodic acid was added to the acetic anhydride, the remaining hydrogen iodide was forced over by heating the hydrogen iodide generator with a small flame. The reaction was considered complete when no more precipitate formed in the reaction flask. After the reaction mixture was cool and the precipitation complete, the supernatant liquid was poured off and the 5-iodo-2-thiouracil was washed on the Buchner funnel with peroxide-free ether to remove the residual iodine. It was then twice extracted with hot glacial acetic acid to remove unreacted material, then washed alternately with water and alcohol to remove the acetic acid. The almost pure product was purified by dissolving in dilute sodium hydroxide with gentle warming; the addition of acetic acid precipitated 27 g. of 5-iodo-2-thiouracil (57%).

The supernatant liquid from the reaction mixture was concentrated *in vacuo* and 7.4 g. of unreacted 5-iodo-2-benzylthiouracil was recovered.

When the 5-iodo-2-thiouracil was heated in a capillary the product became discernibly yellow at 190°; slowly darkened to brown at 210°; and decomposed to a black tar at 214–215°. On the Dennis melting point bar it decomposed slowly with melting at 231–236° and melted instantaneously with decomposition at 278–280°.

Anal. Calcd. for $C_4H_3N_2OSI$: I, 49.95; N, 11.03; S, 12.62. Found: I, 50.08; N, 10.9; S, 12.77.

5-Iodo-2-thiouracil and 5-iodo-2-benzylthiouracil are light sensitive and are best dried over phosphorus pentoxide *in vacuo*.

6-Methyl-5-iodo-2-benzylthiouracil.—Twelve grams of 6-methyl-2-benzylthiouracil was iodinated as described above but, since some of the material escaped iodination, the product was washed thoroughly with water, and reiodinated. Eleven grams (58%) of 6-methyl-5-iodo-2-benzylthiouracil was obtained, m. p. 180–181° with decomposition.

Anal. Calcd. for $C_{12}H_{11}N_2OSI$: I, 35.44. Found: I, 35.65.

6-Methyl-5-iodo-2-thiouracil.—Ten grams of 6-methyl-2-benzylthiouracil was split as described for the preparation of 5-iodo-2-thiouracil. The yield was 3 g. (40%). On the Dennis melting point bar it decomposed slowly above 220°; it melted instantly at 285–289° with decomposition. When heated slowly in the capillary 6-methyl-5-iodo-2-thiouracil began to darken at 175°, progressively decomposed with loss of iodine, and decomposed completely at 195° without melting.

Anal. Calcd. for $C_5H_5N_2OSI$: I, 47.34. Found: I, 47.10.

Acknowledgment.—The authors wish to thank Dr. Noel E. Foss of the Calco Chemical Division of the American Cyanamid Company for generous supplies of thiouracil.

Summary

Methods are described for the preparation of 5-iodo-, 5-bromo- and 5-chloro-2-thiouracil, and the 5-iodo-, 5-bromo-, and 5-chloro-6-methyl-2-thiouracil. These compounds were prepared by the direct halogenation of either the S-methyl or S-benzyl derivatives followed by splitting with anhydrous hydrogen iodide.

An apparatus is illustrated for the convenient preparation of anhydrous hydrogen iodide.

The Preparation of D- and L-Homoserine[1]

BY MARVIN D. ARMSTRONG

In the course of the synthesis of some biologically interesting compounds, it became necessary to prepare a considerable amount of pure L-homoserine (α-amino-γ-hydroxybutyric acid). A review of the literature revealed that little work had been accomplished on homoserine since its first preparation by Fischer and Blumenthal[1a] in 1907. Kitagawa's discovery of canavanine[2] and his demonstration that it was α-amino-γ-guanidinoxy-*n*-butyric acid[3–6] was the beginning of an increasing number of references to homoserine in the later literature. The main emphasis in such reports has been in connection with both syntheses and degradations of methionine.[7–12]

The previously reported O-phenylhomoserine[1a] provided a suitable intermediate for the preparation of the optically active homoserines. The N-formyl derivative was easily prepared and was found to give a crystalline strychnine salt; the use of 50% aqueous methanol as a solvent gave a good separation of the two diastereoisomers in one step, the salt of the D-isomer being more insoluble.

That the more soluble strychnine salt was of the L-configuration was shown by an application of the rule of Lutz and Jirgensons[13] to the crude (+)-O-phenylhomoserine obtained by decomposition of the mother liquors from the first crystallization of the strychnine salt. A definite negative maxi-

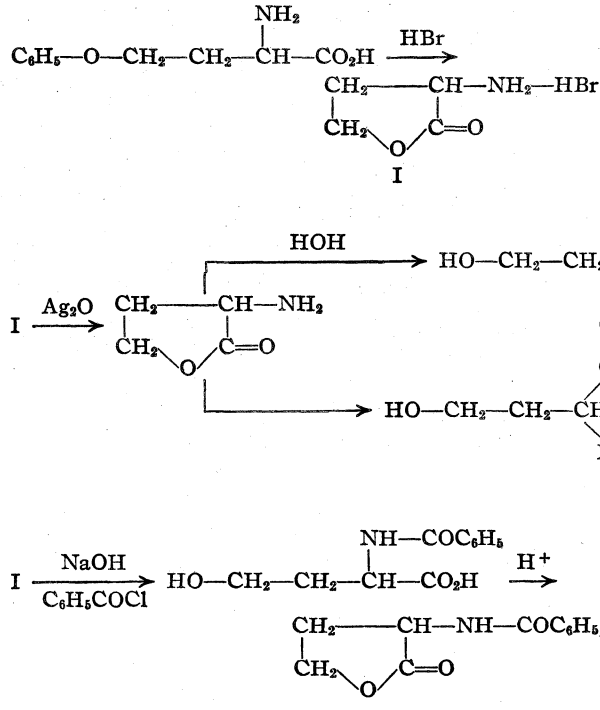
mum of rotation at the isoelectric point was shown when its rotation was measured in solutions containing different concentrations of acid and alkali (Fig. 1). Further confirmation was found when the free homoserine was obtained by hydrolysis of this isomer; its properties checked those reported by Kitagawa[3,4] for the homoserine obtained upon degradation of canavanine. Canavanine, itself, had earlier been shown to possess the L configuration by a study of the effect of acid concentration on its rotation.[14]



As indicated in the equations the active O-phenylhomoserines were readily converted to the active lactone hydrobromides of homoserine; other derivatives were prepared in the manner described by Fischer and Blumenthal in their original description of DL-homoserine.

Relatively poor yields of the active lactone hydrobromides were obtained as compared with the yield of the racemic compound. This was due to a significant amount of racemization (10–20%) under the conditions employed for the hydrolysis of the active O-phenylhomoserines. Fortunately the optically active derivatives could be easily obtained by recrystallization of the crude product from the hydrolysis; usually one recrystallization from aqueous ethanol sufficed to produce an optically pure compound.

Unsatisfactory yields were also obtained in the conversion of the isomers of α-aminobutyrolactone hydrobromide to the corresponding isomers of homoserine. However, by evaporating the mother liquors from the first recrystallization of the free homoserine to dryness, refluxing the residue for a short time with 48% hydrobromic acid and reworking the solution, most of the lost homoserine could be reisolated as the lactone hydrobromide. It is probable that formation of the diketopiperazines under the conditions for the preparation of homoserine caused the low yields.

Experimental

O-Phenyl-DL-homoserine.—This compound was prepared according to the method of Painter.[15] From 340 g. of ethyl acetamidomalonate and 350 g. of β-bromoethylphenyl ether 235 g. (76% yield) of product, m. p. 235–236° dec., was obtained.

This product is sufficiently pure for formylation and subsequent resolution. For analysis a small sample was recrystallized from hot water, m. p. 236–237° dec.

Anal. Calcd. for $C_{10}H_{13}O_3N$: N, 7.17. Found: N, 7.03.

N-Formyl-O-phenyl-DL-homoserine.—A solution of 200 g. of O-phenylhomoserine in 1700 ml. of 88% formic acid was warmed to 50° and 600 ml. of acetic anhydride was added dropwise at such a rate that the temperature remained at 50–60°. After the addition was completed the solution was allowed to stand for six hours at room temperature, at the end of which time 500 ml. of water was added and the reaction mixture was allowed to stand overnight. It was then concentrated to dryness *in vacuo*, keeping the bath temperature below 50°, and the last traces of water, formic acid and acetic acid were removed by repeated additions of 500 ml. portions of benzene followed by reconcentration to dryness. This treatment was repeated until the residue was dry and almost odorless.

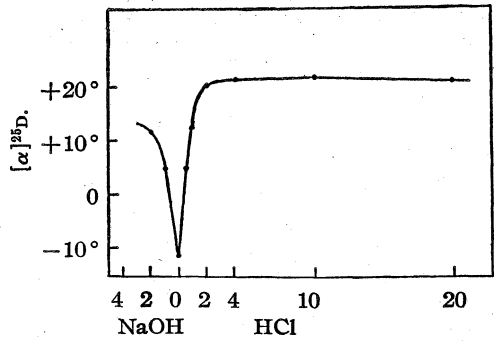


Fig. 1.—The effect of acid and alkali on the rotation of (+)-O-phenylhomoserine. The abscissa gives the ratio of the number of moles of acid and alkali, respectively, to the number of moles of amino acid in solution. A 1% aq. solution of the compound was used.

The dry residue was suspended in 800 ml. of boiling 95% ethanol and the suspension was filtered while hot. The residue was resuspended in 400 ml. of hot ethanol and filtered; the residue of recovered impure O-phenylhomoserine (48 g., m. p. 195–199° dec.) is suitable for reformylation. The combined filtrates were cooled overnight in a refrigerator and filtered; 95 g., m. p. 137–154° dec., of crude formyl derivative was obtained. The filtrate was concentrated to dryness *in vacuo* and the residue was recrystallized from 130 ml. of hot ethanol

(14) J. F. Cadden, *Proc. Soc. Exptl. Biol. Med.*, **45**, 224 (1940).

(15) E. P. Painter, THIS JOURNAL, **69**, 233 (1947).

(5 g. of crude O-phenylhomoserine was separated by filtering the hot solution); an additional 57 g. of crude N-formyl derivative was obtained. The crude N-formyl-O-phenylhomoserine (152 g.) was recrystallized from 200 ml. of hot 95% ethanol; 126 g., m. p. 135–143°, suitable for resolution, was obtained.

By concentrating the combined mother liquors to dryness and refluxing the residue with 1 *N* HCl an almost quantitative recovery of unformylated O-phenylhomoserine may be made.

For analysis a sample of the N-formyl-O-phenylhomoserine was recrystallized two times from aqueous ethanol; m. p. 137–137.5°.

Anal. Calcd. for $C_{11}H_{13}O_4N$: N, 6.27. Found: N, 6.45.

Resolution of N-Formyl-O-phenyl-DL-homoserine.—To a dry mixture of 112 g. (0.5 mole) of N-formyl-O-phenylhomoserine and 170 g. (0.5 mole) of powdered strychnine was added 5 liters of hot 50% methanol and the suspension was swirled and heated in a water-bath until almost all of the solids had dissolved. The solution was filtered while hot and was allowed to stand overnight at room temperature. The crystalline strychnine salt of N-formyl-O-phenyl-D-homoserine was collected on a filter, washed with a small amount of cold water, and dried; yield, 152 g.; $[\alpha]^{27}D$ −28° (1% in HOAc). One recrystallization from 4 liters of hot 50% methanol yielded 128 g.; $[\alpha]^{26}D$ −27° (1% in HOAc). Four more recrystallizations of the salt from aqueous methanol produced a pure strychnine salt, $[\alpha]^{27}D$ −25° (1% in HOAc), but in practice the best method of obtaining the pure isomer proved to be recrystallization of the free O-phenyl-D-homoserine resulting from the decomposition of the once recrystallized strychnine salt.

O-Phenyl-L-homoserine.—The original mother liquors from the crystalline strychnine salt were concentrated to a volume of approximately 2.5 liters, made alkaline by the addition of 20 ml. of concd. ammonia, cooled and filtered; the strychnine may be dried and reused. The filtrate was concentrated to a volume of about 1500 ml., made 1 *N* in hydrochloric acid by the addition of the proper amount of concd. hydrochloric acid and refluxed for two hours. The solution was then concentrated to dryness under reduced pressure and the residue was dissolved in 200 ml. of hot water; the hot solution was made neutral to congo red by the careful addition of concd. sodium hydroxide solution, the suspension was cooled and filtered. The residue was recrystallized from 500 ml. of hot water; yield, 35 g., m. p. 210–211° dec., $[\alpha]^{25}D$ +21.5° (1% in 1 *N* HCl). The combined mother liquors were concentrated to a volume of approximately 500 ml., cooled and filtered, yielding an additional 13 g. of impure product; m. p. 196–204° dec.; $[\alpha]^{26}D$ +5° (1% in 1 *N* HCl).

Two more recrystallizations of the pure derivative from 400-ml. portions of hot water yielded 22.0 g. of pure O-phenyl-L-homoserine; m. p. 241–242° dec., $[\alpha]^{26}D$ +23.5° (1% in 1 *N* HCl).

Anal. Calcd. for $C_{10}H_{13}O_3N$: N, 7.17. Found: N, 7.21.

O-Phenyl-D-homoserine.—A solution of 125 g. of the strychnine salt of N-formyl-O-phenyl-D-homoserine in 4 liters of hot 50% methanol was made alkaline by the addition of 20 ml. of concd. ammonia. The solution was cooled overnight in a refrigerator, the strychnine was removed by filtration, and the crude O-phenyl-D-homoserine was prepared in the same manner as previously described for the L-isomer; yield 38.5 g., m. p. 216–219° dec., $[\alpha]^{24}D$ −19° (1% in 1 *N* HCl). By reworking the mother liquors 6 g. of impure compound was obtained; m. p. 214–216° dec., $[\alpha]^{26}D$ −10° (1% in 1 *N* HCl).

Two recrystallizations of the first crop from 300 ml. portions of hot water yielded 26.5 g., m. p. 218–220° dec., $[\alpha]^{26}D$ −22.0° (1% in 1 *N* HCl). One more recrystallization from 500 ml. of hot water yielded 22 g., m. p. 241° dec., $[\alpha]^{24}D$ −23.5° (1% in 1 *N* HCl).

Anal. Calcd. for $C_{10}H_{13}O_3N$: N, 7.17. Found: N, 7.32.

In spite of its low solubility the D isomer possesses a definitely sweet taste, whereas the L isomer is tasteless or nearly so.

Preparation of DL-α-Aminobutyrolactone Hydrobromide.—A solution of 10 g. of O-phenyl-DL-homoserine in 100 ml. of 48% hydrobromic acid was refluxed for twenty hours[16] and was then concentrated to dryness *in vacuo*. The contents of the flask were dissolved in 50 ml. of distilled water and the solution was heated to boiling, treated with Norit, and filtered. The filtrate was concentrated to dryness *in vacuo* and the residue was suspended in 20 ml. of cold absolute ethanol and filtered; the solid residue was washed once with a 10 ml. portion of cold alcohol. The combined alcoholic filtrates were again concentrated to dryness, and the procedure was repeated. The weight of pure white α-aminobutyrolactone hydrobromide obtained was 7.5 g. (81% yield), m. p. 225–228° dec. It was recrystallized by dissolving it in a mixture of 3 ml. of water and 3 ml. of absolute ethanol, the hot solution was diluted with 54 ml. of warm absolute alcohol and allowed to stand in a refrigerator overnight. Only 65–70% recovery can be made upon recrystallization of the compound but the remainder can be obtained by reworking the mother liquors; m. p. 226–228° dec. (F. and B., 227° dec.).

Anal. Calcd. for $C_4H_8O_2NBr$: N, 7.69. Found: N, 7.89.

L-α-Aminobutyrolactone Hydrobromide.—A solution of 10 g. of O-phenyl-L-homoserine ($[\alpha]^{25}D$ +23.5°) in 100 ml. of 48% hydrobromic acid was refluxed for twenty hours and was worked up as described for the DL-α-aminobutyrolactone hydrobromide. After one recrystallization, 4.1 g. (44% yield) was obtained; m. p. 242–244° dec., $[\alpha]^{27}D$ −21.0° (1% in water).

Anal. Calcd. for $C_4H_8O_2NBr$: N, 7.69. Found: N, 7.63.

D-α-Aminobutyrolactone Hydrobromide.—Ten grams of O-phenyl-D-homoserine ($[\alpha]^{25}D$ −23.5°) was hydrolyzed and worked up in the same manner as described for the L compound; yield, 2.8 g. (41% yield); m. p. 242–244° dec., $[\alpha]^{27}D$ +21.0° (1% in water).

Anal. Calcd. for $C_4H_8O_2NBr$: N, 7.69. Found: N, 7.68.

N-Benzoyl-DL-homoserine.—Prepared from α-aminobutyrolactone hydrobromide according to the directions of Fischer and Blumenthal[16]; m. p. 126–127° (F. and B., 121°).

Anal. Calcd. for $C_{11}H_{13}O_4N$: N, 6.27. Found: N, 6.18.

DL-α-Benzamidobutyrolactone.—The benzoyl derivative was dissolved in a small amount of hot water containing a trace of hydrochloric acid, the solution was heated a few minutes and was then cooled. The α-benzamidobutyrolactone that crystallized was collected and was recrystallized from hot water; m. p. 140–141° (F. and B., 142°).

Anal. Calcd. for $C_{11}H_{17}O_4N$: N, 6.82. Found: N, 6.96.

L-α-Benzamidobutyrolactone.—A solution of 1.0 g. of L-α-aminobutyrolactone hydrobromide in 11 ml. of 1 *N* NaOH was cooled to 0° and benzoylation was carried out in the customary manner using 0.85 g. of benzoyl chloride and 2 ml. of 3 *N* NaOH. The reaction mixture was worked up by making the solution just acid to congo red, extracting the excess benzoic acid with ether, and recrystallizing the precipitate of crude N-benzoyl-L-homoserine by warming the mixture just enough to dissolve the solid and then

(16) Fischer and Blumenthal report complete hydrolysis after seven hours refluxing. This laboratory is located at an elevation of 5000 ft. with a usual barometric perssure of approximately 630 mm. of mercury, hence many of the reaction times in refluxing solutions or amounts of solvents needed for recrystallization may vary considerably at ordinary elevations from those reported herein. In this particular experiment it was found that fifteen hours of refluxing was not sufficient for complete hydrolysis.

quickly cooling the solution. It was collected on a filter, washed with water and dried: N-benzoyl-L-homoserine[17]; m. p. 139–141°.

The N-benzoyl-L-homoserine obtained was dissolved in 20 ml. of hot water containing two drops of concd. hydrochloric acid, the solution was boiled for two minutes and cooled. Beautifully formed needles of L-α-benzamidobutyrolactone crystallized and were collected; m. p. 139°, $[\alpha]^{20}D$ −21.5° (1.25% in 95% EtOH).[18]

3,6-bis-(β-Hydroxyethyl)-2,5-diketopiperazine.—Prepared from 3.34 g. of DL-α-aminobutyrolactone hydrobromide according to the directions of Livak, *et al.*[10]; yield, 1.10 g. (60% yield); m. p. 189–191° dec.

Anal. Calcd. for $C_8H_{14}O_4N_2$: N, 13.86. Found: N, 14.22.

L-3,6-bis-(β-Hydroxyethyl)-2,5-diketopiperazine.—The above reaction was repeated using 3.34 g. of L-α-aminobutyrolactone hydrobromide; yield, 1.25 g. (67% yield); m. p. 190.5–191° dec.; $[\alpha]^{27}D$ −30.0° (1% in water).

Anal. Calcd. for $C_8H_{14}O_4N_2$: N, 13.86. Found: N, 13.79.

Acknowledgment.—The author wishes to thank Marie S. Hanson for performing the nitrogen analyses reported in this paper.

Summary

D- and L-homoserine have been prepared by the acid hydrolysis of the corresponding O-phenylhomoserines. The properties of L-homoserine were shown to agree with those reported for the optically active α-amino-γ-hydroxybutyric acid obtained by the degradation of canavanine.

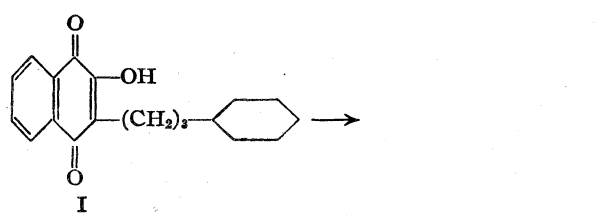
The Synthesis of 2-Hydroxy-3-[3′-*cis*-(4-hydroxycyclohexyl)-propyl]-1,4-naphthoquinone

BY WILLIAM G. DAUBEN AND RAYLENE E. ADAMS

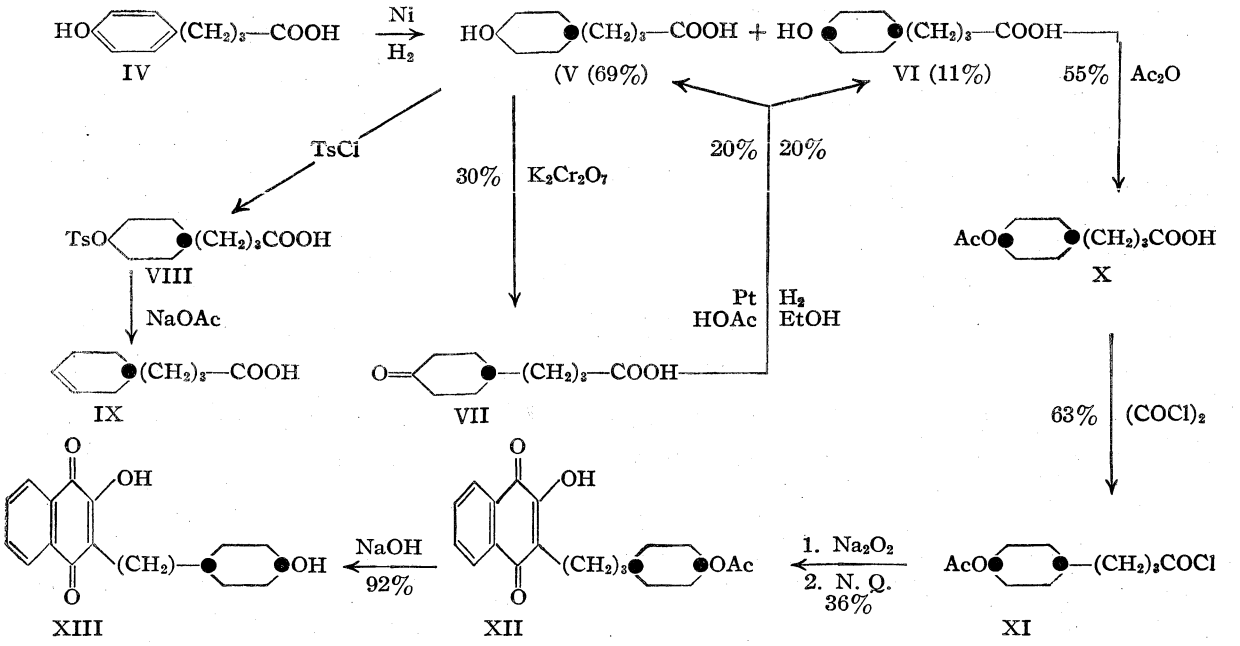
It has recently been reported by Fieser[1] that various [2-hydroxy-3-alkyl-1,4-naphthoquinones when administered to humans undergo degradation. It was found that when the alkyl group was 3-cyclohexylpropyl (I), two hydroxylated quinones (II and III) could be isolated. Compound II, which melts at 155°, was shown to be 2-hydroxy-3-[3′-(4-hydroxycyclohexyl)-propyl]-1,4-naphthoquinone by synthesis from γ-(*p*-hydroxycyclohexyl)-butyric acid (V). This series of compounds can be assumed to be of the *trans* configuration since the starting acid (V) was obtained by the hydrogenation of γ-(*p*-hydroxyphenyl)-butyric acid (IV) in basic solution over Raney nickel catalyst.[2] Compound III was shown to be optically inactive, to contain a secondary hydroxyl group, and to melt at 112°. In view of these facts it was thought that this degradation product might be the *cis*-isomer of compound II and the synthesis of this isomer is reported in this paper.



R = 2-Hydroxy-1,4-naphthoquinone-3-yl

(1) Fieser and co-workers, THIS JOURNAL, in preparation.

(2) (a) Macbeth and Mills, *J. Chem. Soc.*, 709 (1945); (b) Skita, *Ber.*, **53**, 1792 (1920), and later papers.



It was found that fractionation of the hydrogenation product of γ-(*p*-hydroxyphenyl)-butyric acid (IV) gave, in addition to the *trans* acid (V), 11% of the *cis* isomer (VI). However, since a large amount of the *trans* compound was formed in the hydrogenation, a study was made of the possible methods for conversion of it to the *cis* isomer.

It is well-known that alcohols can be inverted by the process of tosylation and subsequent displacement with acetate ion.[3] For example, Kenyon and co-workers have inverted *trans*-4-methoxycyclohexanol in a yield of 30% by this method. However, the major reaction product was 4-methyl-1-cyclohexene. When the *trans* acid (V) was tosylated in pyridine solution and then treated with an alcoholic solution of sodium acetate only the unsaturated acid (IX) was obtained.

Another mode of preparation of *cis–trans*-isomers in the cyclohexanol series is the hydrogenation of the corresponding ketone.[2a] MacBeth and Mills have found that when *trans*-3-methylcyclohexanol was oxidized to 3-methyl-1-cyclohexanone and the ketone hydrogenated at room temperature over Adams catalyst in acetic acid solution the *cis*-3-methylcyclohexanol was obtained in 69% yield.

Various methods were tried in order to prepare γ-(*p*-cyclohexanone)-butyric acid (VII). Numerous Oppenauer oxidations were conducted on the methyl ester of the *trans* acid using either acetone or cyclohexanone as the hydrogen acceptor. No ketone or ketone derivative could be isolated. A dark red oil was always obtained and it is believed that an aldol-type condensation may have occurred under the conditions of the reaction. The catalyst, aluminum *t*-butoxide, was checked for its activity by oxidizing cyclohexanol. High yields of cyclohexanone were always obtained.

Various chemical methods are described in the literature for the oxidation of analogous secondary alcohols to ketones. However, with the *trans*-acid (V) very low yields were obtained by almost all the methods. It was found that the keto-acid (VII) could be prepared in a yield of 30–45% by means of potassium dichromate, acetic acid, sulfuric acid, and water at room temperature.

The hydrogenation of the keto-acid (VII) was attempted with various catalysts and solvents, but the amount of *cis* isomer isolated was invariably low (0–20%). A mixture containing small amounts of the *cis* and *trans*-hydroxycyclohexylbutyric acids, a large amount of the cyclohexylbutyric acid, and often a little unreacted ketone was usually received. The best results were obtained when platinum oxide was used as the catalyst and ethanol containing one drop of acetic acid or hydrochloric acid as the solvent. The various unsuccessful methods were platinum oxide in water or absolute ethanol, platinum black in ethanol and Raney nickel in ethanol or water. No reduction occurred when barium sulfate containing ten per cent. palladium was used as the catalyst and ethanol or acetic acid as the solvent.

The results of these experiments are quite similar to those obtained recently by Hardegger, Heusser and Blank.[4] These workers have reported that the hydrogenation of α-hydroxy-β-(*p*-cyclohexanone)-butanolide in aqueous acetic acid over Adams catalyst gave mainly the hydrogenolysis product. The small amount of the desired hydroxyl compound obtained was a mixture of the

(4) Hardegger, Heusser and Blank, *Helv. Chim. Acta*, **29**, 477 (1946).

cis and *trans* isomers. Gauthier[5] also has reported that 4-propylcyclohexanone is hydrogenated in acetic acid in the presence of hydrochloric acid and platinum catalyst to a mixture of *cis* and *trans* isomers.

The *cis* isomer of the naphthoquinone (XIII) was prepared following the usual methods.[1] The *cis*-γ-(*p*-acetoxycyclohexyl)-butyric acid (X) was obtained in a yield of 55% by treating the *cis*-hydroxy acid (VI) with acetic anhydride in the presence of a catalytic amount of concentrated sulfuric acid. This acid was then converted to the acid chloride with oxalyl chloride in 63% yield. The acid chloride was allowed to react with sodium peroxide following the general procedure of Fieser and Oxford[6] to give the peroxide which in turn was decomposed in an acetic acid solution of 2-hydroxy-1,4-naphthoquinone. The 2-hydroxy-3-[3′-*cis*-(4-acetoxycyclohexyl)-propyl]-1,4-naphthoquinone (XII) was isolated in 36% yield and then deactylated to give *cis*-hydroxy compound (XIII). This latter compound melts at 136–137°. Hence the compound III isolated in the metabolism studies is not the *cis* isomer of compound II. L. F. Fieser has reported in a private communication that the *cis* compound, XIII, is completely inactive when assayed by the antirespiration method previously described by him.[1] The isolated degradation products, II and III, however, show definite activity.

Acknowledgment.—The authors wish to express their appreciation to Professor L. F. Fieser for his interest in this work, and to the Abbott Laboratories for their financial aid.

Experimental[7]

β-(*p*-Anisoyl)-propionic Acid.—The acid was prepared from anisole and succinic anhydride according to the procedure of Rosemund and Shapiro[8] using nitrobenzene as the solvent. The yield was 75–85%. When nitroethane was employed as the solvent the yield was slightly less but this method was more convenient since anhydrous aluminum chloride is soluble in this solvent and could be added in the form of a solution.

γ-(*p*-Methoxyphenyl)-butyric Acid.—The reduced acid was prepared from the above keto-acid either by the Martin modification[9] of the Clemmensen reduction or by the Huang-Minlon[10] modification of the Wolff–Kishner reaction. This latter method was more convenient and the product was obtained in 75% yield.

γ-(*p*-Hydroxyphenyl)-butyric Acid.—The methoxy-acid was demethylated by heating under reflux with 48% hydrobromic acid. The crude acid was recrystallized from benzene and the pure acid melts at 107–108°.

γ-(*p*-Hydroxycyclohexyl)-butyric Acid (V and VI).—This acid was prepared following the procedure described by Fieser and co-workers.[1] From 45 g. (0.25 mole) of γ-(*p*-hydroxyphenyl)-butyric acid, 40 g. (86%) of crude product, which sinters from 80° and melts by 114°, was obtained. This material was added to 300 cc. of ether and the mixture heated under reflux for fifteen minutes. The solid which did not dissolve was filtered and it melts from 118–122°. After recrystallization from aqueous acetic acid, the pure acid melts from 123–124°, yield 32 g. (68.9%). This compound is presumably the *trans* isomer.

The above ethereal extract was concentrated and then petroleum ether was added until turbidity. On cooling, white crystals (6.1 g.) which sinter at 80° and melt from 84–89° were obtained. This solid was fractionally crystallized from a mixture of ether and petroleum ether. The first small fraction was impure *trans* isomer. The second fraction contained 5.0 g. (10.7%) of the pure *cis* acid, m. p. 83–84°. *Anal.* Calcd. for $C_{10}H_{18}O_3$: C, 64.48; H, 9.74. Found: C, 64.77; H, 9.95.

***cis*-γ-(*p*-Acetoxycyclohexyl)-butyric Acid (X).**—*cis*-γ-(*p*-Hydroxycyclohexyl)-butyric acid (1.0 g., 0.006 mole) was mixed with 6 cc. of acetic anhydride and three drops of concentrated sulfuric acid, allowed to stand at room temperature for eighteen hours, and then poured into 250 cc. of water. The aqueous mixture was extracted with three 25-cc. portions of ether. The water layer then was concentrated, saturated with sodium chloride, and extracted again with ether.

The combined ethereal extracts were washed, dried, and the solvent evaporated. The residual liquid was distilled in a sublimation-type still at a block temperature of 125° and a pressure of 2 mm. The yield was 0.55 g. (44.7%).

Anal. Calcd. for $C_{12}H_{20}O_4$: C, 63.13; H, 8.83. Found: C, 63.40; H, 8.57.

***cis*-γ-(*p*-Acetoxycyclohexyl)-butyryl Chloride (XI).**—A mixture of 7.2 g. (0.032 mole) of the *cis*-acetoxy acid and 12.2 g. (8.2 cc., 0.01 mole) of oxalyl chloride was warmed at 70° for a period of four hours. The excess oxalyl chloride was then removed and the product distilled, b. p. 139–141° (1 mm.), yield 4.9 g. (63%).

Di-[*cis*-γ-(*p*-acetoxycyclohexyl)-butyryl] Peroxide.—The peroxide was prepared following the procedure of Fieser and Oxford[6] using 4.9 g. (0.02 mole) of acid chloride. A yield of 88% was indicated by titration of an aliquot.[11]

2-Hydroxy-3-[3′-*cis*-(4-acetoxycyclohexyl)-propyl]-1,4-naphthoquinone (XII).—The alkylation was conducted in the flash-off manner[1] using 1.50 g. (0.086 mole) of 2-hydroxy-1,4-naphthoquinone, the peroxide prepared above and 35 cc. of acetic acid. After the evolution of carbon dioxide had ceased, the mixture was refluxed for one hour and the acetic acid removed under reduced pressure. The residual sirup was dissolved in ether and the ethereal solution extracted with dilute, freshly-prepared, aqueous sodium bicarbonate until only a faint pink color was discernible in the aqueous layer. After removal of the ether, the residue was crystallized from aqueous methanol. After several recrystallizations, the yellow solid sinters slightly from 79–99° and melts from 99–100°. When a sample was immersed in a bath at 94°, it melted completely. The yield of the dimorphic compound was 1.1 g. (35.7%) and no single form of dimorph could be isolated.

Anal. Calcd. for $C_{21}H_{24}O_5$: C, 70.77; H, 6.79. Found: C, 70.46; H, 6.58.

2-Hydroxy-3-[3′-*cis*-(4-hydroxycyclohexyl)-propyl]-1,4-naphthoquinone (XIII).—A solution of 0.43 g. (0.0012 mole) of the acetyl compound, 0.1 g. (0.018 mole) of potassium hydroxide and 30 cc. of water was refluxed for one hour. The solution was acidified and a small volume of ethanol was added to effect solution. The product crystallized slowly from this mixture. The yellow solid was best recrystallized by long standing in a large volume of ethanol highly diluted with water containing a trace of acetic acid. The yield was 0.35 g. (92.2%), m. p. 136–137°.

Anal. Calcd. for $C_{19}H_{22}O_4$: C, 72.59; H, 7.06. Found: C, 72.71; H, 7.10.

γ-(*p*-Cyclohexanone)-butyric Acid (VII).—A mixture of 3.5 g. of γ-(*p*-hydroxycyclohexyl)-butyric acid (0.019 mole), 10 cc. of acetic acid and 40 cc. of water was placed in a flask equipped with a mechanical stirrer, a dropping funnel and a thermometer which was immersed in the liquid and warmed to 60°. After the acid had dissolved, the solution was cooled to 35° and kept at that temperature for the rest of the reaction.

An oxidizing mixture of 1.9 g. (0.0065 mole) of potassium dichromate, 6 cc. of concentrated sulfuric acid and 14 cc. of water was added over a period of fifteen minutes to the stirred solution. The reaction mixture was stirred for an additional thirty minutes and then it was allowed to stand until all of the oxidizing agent had been consumed. This usually required eight to ten hours. The mixture was then diluted with 200 cc. of water, saturated with sodium chloride and was extracted with ether. Upon evaporation of the ether, a yellow sirup remained which on cooling and scratching crystallized. The product was recrystallized from a mixture of ether and ligroin, yield 1.05 g. (30%), m. p. 81–82°.

Anal. Calcd. for $C_{10}H_{16}O_3$: C, 65.19; H, 8.76. Found: C, 64.91; H, 8.74.

The semicarbazone melts at 183–184°.

Summary

1. 2-Hydroxy-3-[3′-*cis*-(4-hydroxycyclohexyl)-propyl]-1,4-naphthoquinone has been prepared and has been shown to be different from the low melting metabolite of 2-hydroxy-3-(3′-cyclohexyl-propyl)-1,4-naphthoquinone isolated by Fieser and associates.

2. The hydrogenation of γ-(*p*-cyclohexanone)-butyric acid has been studied.

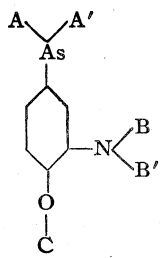
3-Amino-4-hydroxybenzenearsonous Acid. II. Derivatives

BY C. K. BANKS, JOHN CONTROULIS, D. F. WALKER, E. W. TILLITSON,[1] L. A. SWEET AND O. M. GRUHZIT

The amine salts and arsenite hemiesters of 3-amino-4-hydroxybenzenearsonous acid (I, oxophenarsine) were described in the first paper of this series.[2] All of these compounds, as well as the dihalo derivatives, equilibrate readily in solution to a common ion, postulated to be 3-ammonium-4-hydroxybenzenearsonite. Since this nucleus has been unique in therapeutic agents for the treatment of spirochetal diseases, further variations of the general structure II have been made.



II

Previously reported compounds of this type include the aforementioned salts, hemiesters and acid adducts,[2] mercaptan derivatives in which A and A′ were mercaptoacetic acid, mercaptoacetamide and cysteine,[3] the acetyl derivative (B = $COCH_3$)[4] and compounds in which C was replaced by hydroxyalkyl[5–7] and alkyl groups.[8] Since variations in C appeared to be explored adequately, the principal variants studied were those of A and B. Since 3-amino-4-β-hydroxyethoxybenzenearsonous acid (III)[5] has been found to have practically the same *in vivo* spirochetal activity as I, the β-hydroxyethyl group was selected as the C variant for the study of multiple substitution.

The mercaptol derivatives of I were extended to include mercaptoacetone, octyl mercaptoacetate, thiomalic acid and unsubstituted sulfides. Hydrogen sulfide reacted with I to yield compounds having —$As(SH)_2$, —As(SH)(OH) and —AsS structures, depending on the conditions employed. The mercaptoacetic acid, octyl mercaptoacetate and mercaptoacetamide derivatives of III were also formed. The octyl mercaptoacetates were of interest in that they are soluble in oils.

The amine group was modified by substituting B and B′ with the acid succinamide, benzal, formaldehyde bisulfite and glucose bisulfite groups. Attempts to prepare the analogous formaldehyde sulfoxylate resulted in neoarsphenamine types. Similar amine derivatives were prepared in which A and A′ were replaced by thiols and where C was the hydroxyethyl group. The formaldehyde sul-

foxylates of the thiol substituted arsenicals were prepared without difficulty.

I was also diazotized and 3-diazonium-4-hydroxybenzenetrichloroarsonite (IV) isolated on strong acidification. This proved to be identical with the reduction product of 3-diazonium-4-hydroxybenzenearsonate described by Schmidt and Hoffmann.[9] However, decomposition of this compound in methanol followed by precipitation

(9) Schmidt and Hoffmann, *Ber.*, **59**, 560 (1926).

with ether did not result in 3-diazido-3,4-quinone-1-dichloroarsine as they report but in 3-diazonium-4-hydroxybenzenedichloroarsonite. This was confirmed by elemental analysis for C, H, N, As and Cl, and by the reactions of the substance. The compounds prepared, their toxicity and trypanocidal activity are listed in Table I. The treponemacidal effect of selected compounds is given in Table II.

TABLE II

RELATIVE TREPONEMACIDAL ACTIVITY

No. in Table I	CD_{50}, mg./kg. × 3, I. V. rabbits	No. in Table I	CD_{50}, mg./kg. × 3, I. V. rabbits

2	1.0	33	4.0
3	1.0	35	5.25
5	1.5	36	1.5
9	1.5	46	1.75

Experimental

3-Amino-4-hydroxybenzenearsonous acid and 3-amino-4-β-hydroxybenzenearsonous acid were prepared according to previously published methods.[2,5]

Sulfides.—A solution of 3-amino-4-hydroxybenzenearsonous acid (0.1 mole), prepared by dissolving the acid in 100 ml. of water with an excess of hydrochloric acid and then neutralizing the solution to *p*H 6, was saturated with hydrogen sulfide. On standing in the refrigerator, the —As(SH)(OH) compound separated. When the addition of hydrogen sulfide was made in the presence of two equivalents of hydrochloric acid, the corresponding *hydrochloride* separated. On drying at 0.5 mm. and 37° over phosphorus pentoxide, the analogous —AsS compounds were formed. Addition of ammonium sulfide to the original solution precipitated the $As(SH)_2$ compound.

Mercapto Products.—Mercaptoacetic acid (0.2 mole) was added to a solution of the arsonous acid (0.1 mole) and the *p*H adjusted to 7 with sodium hydroxide. Seven volumes of alcohol were added to crystallize the *sodium salts*. The free *mercaptoacetic acid derivatives* were formed by acidification of aqueous solutions of their sodium salts with hydrochloric acid. Other mercapto derivatives were prepared by the reaction of an alcohol solution of the mercaptan with an alcohol solution of the arsonous acid. The *hydrochlorides* were crystallized by the addition of dry hydrogen chloride gas, with cooling, and the *free bases* liberated from aqueous solutions of the hydrochlorides by neutralization with sodium hydroxide.

Formaldehyde and Glucose Bisulfites.—Water (40 ml.) was heated to boiling for a few minutes, then allowed to cool. At 90° the sodium aldehyde bisulfite (0.1 mole) was added and when cooled to 70°, the arsonous acid, or other arylamino arsenical, was added (0.1 mole) and stirred until solution occurred. The solution was clarified with charcoal, filtered and cooled to 30° and 600 ml. of ethanol added. On standing in an ice-bath, the products crystallized.

Formaldehyde Sulfoxylates.—Water (40 ml.), previously boiled and cooled under nitrogen, was used to dissolve sodium formaldehyde-sulfoxylate (0.1 mole) and the arylaminoarsenical (0.1 mole). When the reaction was complete, the solution was clarified with charcoal and the product crystallized by the addition of six volumes of ethanol.

Acyl Derivatives.—The corresponding arsonic acids were reduced by previously described techniques.[2]

3-Diazonium-4-hydroxybenzenetrichloroarsonite.—3-Amino-4-hydroxybenzenearsonous acid (217 g.) was suspended in 60.0 ml. of 3 *N* hydrochloric acid. The solution was cooled externally and a mole of sodium nitrite, dissolved in water, added slowly. As soon as the diazotization was complete, the resulting solution was filtered and a liter of cold concentrated hydrochloric acid added slowly with cooling. The crystalline product was filtered off and washed with glacial acetic acid and ether.

The compound is a pale yellow powder, soluble in water, alcohols, acetone, and dioxane but insoluble in benzene, ether and petrolic ether. The compound exploded on heating. Solutions of the substance in water coupled with β-naphthol and α-dimethylaminonaphthalene to yield deeply colored dyes.

3-Diazonium-4-hydroxybenzenedichloroarsonite.—Ten grams of the trichloroarsonite was dissolved in a minimum of absolute methanol, allowed to stand a few minutes until gas evolution ceased and an excess of anhydrous ether added. A bright yellow product separated. It was filtered off, and dried in a vacuum desiccator. It has the same solubilities and reactions as the trichloro compounds.

Pharmacological Evaluations

Toxicity.—The intravenous toxicity of each compound was determined in albino male rats as previously described.[10] The dose which was lethal for 50% of the animals (LD_{50}) was calculated by the method of Dragstedt and Lang.[11] The LD_{50} and LD_5 are given in Table I in terms of mg. compound per kg. body weight of animal. The LD_{50} values in terms of compound administered also were converted to LD_{50} figures in terms of mg. As per kg. for purposes of comparison.

It can be seen that all of the simple salts and haloarsine derivatives of compound 1 have approximately the same toxicity in terms of arsenic administered (compound 10 may be considered an exception). This is compatible with the hypothesis that all derivatives of this type (1–10 incl.) are converted in aqueous solution to the same form.

The substitution of mercapto groups on arsenic (14, 15, 17, 19, 21, 32, 33, 34, 35) either did not affect or increased the relative toxicity. No general postulations can be made as to the result of substituting hydrogens of the amino group.

Trypanocidal Activity.—The compounds were administered to albino male rats previously infected with a standardized strain of *Trypanosoma equiperdum*. The techniques have been described previously.[10] The minimum therapeutic dose (M.Th.D.) is designated as the minimal dose of drug which entirely eliminated trypanosomes from the peripheral blood forty-eight hours after treatment and the minimum curative dose (M.C.D.) as that dose which prevented relapse of the infection for four weeks. The therapeutic index (Th.I.) is taken as the ratio LD_{50}/M.Th.D. and the curative index (C.I.) as the ratio LD_{50}/M.C.D. The results are given in Table I. Those compounds which can generate No. 1 on solution and neutralization all have comparable activities (2–10 incl.). Sulfhydryl derivatives were of the same or lower order of activity. In general, the trypanocidal effect was lessened when the amino group was substituted. While the substitution of the hydroxyl by a β-hydroxyalkoxyl group did not appreciably affect activity, further substitution on arsenic or nitrogen had approximately the same effect as was noted in the analogous hydroxyl compounds.

Treponemacidal Activity.[12]—Healthy normal rabbits of different breeds were infected with a virulent Nichols strain of *Treponema pallidum* and held until lesions became well developed. The rabbits were treated intravenously with selected compounds three times on alternate days. They were observed for regression of the lesions and by microscopic darkfield examination for the disappearance of spirochetes. The popliteal lymph glands of those rabbits showing no lesions three months after treatment were excised and implanted intratesticularly in normal

(12) A more complete discussion of procedures may be found in Gruhzit, O.M., *Arch. Derm. Syph.*, **32**, 848 (1935).

animals. Absence of syphilitic lesions in the transfer animals over a period of three months was taken as the criterion of cure. The results are given in Table II. In general, compounds which revert to 1 in solution had approximately equal activity, mercapto derivatives being about equally active. Substitution of hydroxyalkoxyl groups for hydroxyl may have decreased the activity slightly but substitution of amino hydrogen resulted in marked reduction of activity.

Summary

1. A number of new derivatives of 3-amino-4-hydroxybenzenearsonous acid have been prepared for trypanocidal and treponemacidal studies. These consisted of variations in which easily and difficultly hydrolyzable groups were attached to the arsenic, nitrogen and phenolic oxygen atoms.

2. Animal studies indicated that none of the compounds was more active than the parent compound and that only those compounds having readily hydrolyzed groups retained any appreciable activity.

Antimalarial Constituents of Chinese Drug, Ch'ang Shan, *Dichroa febrifuga* Lour

BY T. Q. CHOU, F. Y. FU AND Y. S. KAO

A brief account on the isolation of an antimalarial alkaloid named dichroine from the Chinese drug, Ch'ang Shan, identified as *Dichroa febrifuga* Lour., has been reported.[1] Mention should be made that the name dichroine has been used previously by Hartwich[2] to indicate a carbohydrate of an indefinite nature isolated from the same plant. The alkaloid dichroine has the composition $C_{16}H_{21}O_3N_3$ and easily undergoes isomeric change under the action of heat, acids, and alkalies, and even with different solvents used. Three isomerides, which are provisionally named, α-, β- and γ-dichroines, have been obtained, melting, respectively, at 136, 145 and 160°, and being convertible into each other under suitable conditions. Oxidized with potassium permanganate, dichroine yields 4-quinazolone and some other products not yet identified. Hydrolysis with sodium hydroxide gives easily the decomposition products, anthranilic acid, formic acid, and ammonia, together with a compound which behaves like a pyrrole derivative. Benzoylation with benzoyl chloride furnishes most probably a tribenzoyl derivative of dichroine according to its nitrogen content. No presence of carboxyl-, methoxyl- and methylenedioxy- groups could be detected in the molecule of dichroine. Dichroine forms both normal and acid salts and a nitroso compound. Besides dichroine, 4-quinazolone, a base with the composition $C_{18}H_{23}N_3O_3$, and umbelliferon have also been isolated from the roots of Ch'ang Shan; the first one may be originally present in the plant or resulted during chemical manipulation. Synthetic quinazoline derivatives used as antimalarials have recently been investigated extensively by Magidson and Yolovchinskaya[3] and others. The isolation of 4-quinazolone from a natural plant affords a remarkable coincidence with the chemical research along this line, although the quinazolone nucleus has already been found in certain alkaloids.[4] Regarding the antimalarial activity of dichroines, the γ-isomeride shows the greatest, and α-isomeride the least; the curative dose for chicken malaria being found to be 4 mg. of γ-isomer per kg.[5]

Experimental

The finely powdered root of Ch'ang Shan is percolated with 90% alcohol at room temperature for two days and the extract evaporated in a vacuum. The residue is taken up with dilute hydrochloric acid, filtered, and extracted repeatedly with ether, which constitutes fraction A. The acid solution is rendered slightly alkaline with sodium bicarbonate and shaken well with ether containing about 20% of chloroform (fraction B). The aqueous solution is then made strongly alkaline with potassium carbonate and extracted several times with chloroform (fraction C).

Umbelliferon, $C_9H_6O_3$.—The residue obtained from fraction A, by distilling off ether, crystallizes from alcohol in colorless needles, m. p. 224–227°, sparingly soluble in water, but easily soluble in chloroform, alcohol, and alkaline solutions, the last possessing an intense blue fluorescence. Its properties and analysis correspond well to umbelliferon (7-hydroxycoumarine). *Anal.* Calcd. for $C_9H_6O_3$: C, 66.6; H, 3.7. Found: C, 66.6; H, 3.9.

4-Quinazolone.—Fraction B, on evaporation of ether–chloroform mixture, gives a product which crystallizes from alcohol in silky long needles, m. p. 212–213°. It is identical in all respects with a sample of 4-quinazolone prepared by heating 2 g. of anthranilic acid and 1 g. of formamide for two hours at 120–130° and crystallizing the resulting products from alcohol. Its analysis as well as those of its hydrochloride and platinum salt confirms its composition $C_8H_6ON_2$. *Anal.* Calcd. for $C_8H_6ON_2$: C, 65.8; H, 4.1; N, 19.1. Found: C, 65.6; H, 4.4; N, 19.1.

Hydrochloride.—It is obtained by treating an alcoholic solution of 4-quinazolone with hydrochloric acid gas dissolved in alcohol and adding a sufficient quantity of ether; needles, m. p. 247°. Its aqueous solution is acid to litmus paper. *Anal.* Calcd. for $C_8H_6ON_2 \cdot HCl$: N, 15.3; Cl, 19.4. Found: N, 15.0; Cl, 19.2.

Platinum Salt.—It is obtained by treating an alcoholic solution of 4-quinazolone with an aqueous solution of platinum chloride in the presence of hydrochloric acid and

recrystallizing the resulting precipitate from aqueous alcohol; yellowish prisms, m. p. above 250°. *Anal.* Calcd. for $(C_8H_6ON_2 \cdot HCl)_2 \cdot PtCl_4$: Pt, 27.8. Found: Pt, 28.0.

Alkaloid, $C_{18}H_{23}O_3N_3$.—It is isolated from the mother liquor of 4-quinazolone by fractional crystallization with alcohol. When crystallized pure from acetone, it forms small prisms, m. p. 212–213°. *Anal.* Calcd. for $C_{18}H_{23}O_3N_3$: C, 65.6; H, 7.0; N, 12.7. Found: C, 65.6; H, 6.7; N, 12.6.

Dichroines.—Three isomerides, which are named α-, β- and γ-dichroines, are isolated as follows: the chloroform extract (fraction C) is evaporated and the residue taken up with about five times its volume of absolute alcohol. On neutralizing with hydrochloric acid gas in alcohol, a mixture of hydrochlorides, chiefly of β- and γ-dichroines, crystallizes rapidly. The alcoholic mother liquor is evaporated in a vacuum, and the residue taken up with water and filtered. On alkalinization with sodium carbonate, the liberated base is extracted with chloroform, distilled, and neutralized with sulfuric acid in alcohol, at which time α-dichroine sulfate crystallizes out in almost a pure state, being soluble in alcohol or cold water with difficulty.

α-Dichroine can be prepared easily by dissolving its sulfate as described above in warm water, making alkaline with sodium carbonate, and extracting the liberated base with chloroform. It crystallizes from alcohol in colorless hard prisms, m. p. 136°, being soluble in chloroform, alcohol, or acetone and much less so in cold water. When heated to its melting point and maintained at that temperature for a few minutes, or its aqueous solution is warmed on the water-bath for an hour or so, it is converted into β-dichroine, m. p. 145°. It forms a hydrochloride, prismatic needles from alcohol, m. p. 210°; a sulfate, silky needles from alcohol, m. p. 220°; and a nitroso compound, needles from alcohol or acetone, m. p. 182°. Its dihydrochloride and acid sulfate can also be prepared when excess of respective acids is used (all analyses are given in Table I).

β-Dichroine.—When the crude dichroine bases are crystallized from an organic solvent such as chloroform, it is always the β-dichroine which crystallizes out slowly on standing; needles, m. p. 145°. It is much more soluble in cold water than α-dichroine. It forms a hydrochloride, prisms, m. p. 220°, easily soluble in methyl alcohol or water; a dihydrochloride, needles, m. p. 236°; a neutral sulfate, needles, m. p. 224°; and a nitroso derivative, rhombic prisms, m. p. 170°; alcohol being used for crystallization of either the salts or nitroso compound (see Table I for analyses).

γ-Dichroine is prepared by heating α- or β-dichroine to a temperature of about 145° for ten to twenty minutes and crystallizing the resulting product rapidly from a small amount of acetone. It forms silky needles, m. p. 160°. When crystallized slowly from alcohol or chloroform, it converts back to β-dichroine, m. p. 145°. Its hydrochloride, dihydrochloride, sulfate, and nitroso compound are found to be the same as those of β-dichroine, possessing the same physical and chemical properties (Table I).

Benzoylation.—A solution of 0.5 g. of β-dichroine in 3 cc. of 10% sodium hydroxide is treated with 1.5 cc. of benzoyl chloride with vigorous shaking. The resulting semi-solid mass is taken up with ether and the ethereal solution washed with dilute sodium carbonate solution, dried with anhydrous sodium sulfate, and distilled. The residue refuses to crystallize from any of the usual organic solvents tried. Its nitrogen content corresponds to that of the tribenzoyl derivative when analyzed (Table I). Similar results are obtained with either α- or γ-dichroine.

Oxidation with Potassium Permanganate.—To a solution of 0.2 g. of α-dichroine in 20 cc. of water is added 10 cc. of a 5% potassium permanganate solution. After being allowed to stand at room temperature for two hours, the aqueous solution is filtered, decolorized with a few drops of sodium thiosulfate solution, mixed with some sodium bicarbonate, and extracted with ether. The ethereal solution is dried and distilled, and the residue taken up with a little alcohol, whereupon 4-quinazolone crystallizes in needles, m. p. 212–213°. When mixed with a pure specimen of 4-quinazolone isolated from the plant or prepared synthetically, as above described, its melting point remains unchanged.

Hydrolysis with Sodium Hydroxide.—A solution of 2 g. of α-dichroine in 40 cc. of water with addition of 20 cc. of 15% sodium hydroxide solution is refluxed on the water-bath for an hour and then steam distilled. The distillate smells of ammonia. When neutralized with hydrochloric acid and evaporated to dryness, the residue crystallizes from dilute alcohol in needles, subliming when heated, and being identical to ammonium chloride. The alkaline solution, after steam distillation, is acidified with acetic acid and extracted with ether. The ethereal solution is distilled and the residue crystallized from hot water, small prisms, m. p. 145°; when mixed with pure anthranilic acid, its melting point remains unchanged. *Anal.* Calcd. for anthranilic acid, $C_7H_7O_2N$: C, 61.3;

H, 5.2; N, 10.2. Found: C, 61.3; H, 5.4; N, 10.5. After removal of anthranilic acid, as above, the acid solution is made alkaline with sodium bicarbonate and extracted with ether. The ethereal solution, when evaporated, leaves behind an oily basic residue which behaves like a pyrrole derivative, imparting a red color to a pine shaving moistened with hydrochloric acid. The alkaline solution is again acidified with sulfuric acid and steam distilled. The steam distillate is acid to congo paper, and after neutralization with sodium hydroxide and evaporation, leaves behind a salt identical to sodium formate. *Anal.* Calcd. for HCOONa: Na, 33.3. Found: Na, 31.8.

Summary

From the Chinese drug, Ch'ang Shan, identified as *Dichroa febrifuga* Lour., there have been isolated umbelliferon, 4-quinazolone, a base with the composition $C_{18}H_{23}O_3N_3$, and a water soluble alkaloid named dichroine. The last compound has the composition $C_{16}H_{21}O_3N_3$ and undergoes easily isomeric change with the formation of three isomerides, which are provisionally named α-, β- and γ-dichroines, being convertible into each other under suitable conditions. Regarding their antimalarial activity, the γ-isomeride shows the greatest, and the α-isomeride the least. Based on the results of oxidation and alkaline hydrolysis, dichroine appears to be composed of 4-quinazolone and a pyrrole derivative which requires further investigation. Dichroine forms both normal and acid salts and a nitroso compound. The isolation of 4-quinazolone from a natural plant, Ch'ang Shan, affords a remarkable coincidence with the chemical research for antimalarials along this line.

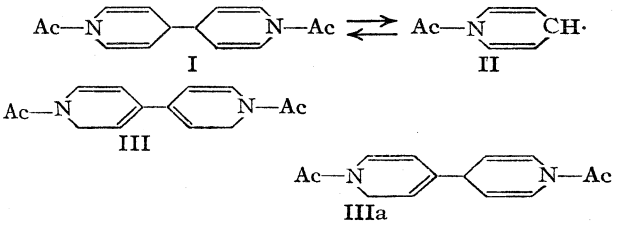
Pyridines. II. The Dissociation of N,N'-Diacetyltetrahydro-4,4'-dipyridyl[1]

BY ROBERT L. FRANK, FLOYD PELLETIER AND FRED W. STARKS

The reductive acetylation of pyridine by means of zinc and acetic anhydride was first reported by Dimroth and Heene[2] to yield the bimolecular product N,N'-diacetyltetrahydro-4,4'-dipyridyl (I). They observed that the compound exists in two interconvertible modifications, one white, the other yellow. Dimroth and Frister[3] later suggested that the yellow color might be due to an impurity, N,N'-diacetyldihydro-4,4'-dipyridyl.

It has occurred to us that either of two phenomena might be responsible for the existence of the two forms of this compound. The easy cleavage of the 4,4' valence bond between the rings in compounds of this type[2-6] suggests that the yellow color is connected with dissociation of the colorless form (I) into radicals (II).[7] On the other hand the work of Mumm and co-workers[5] on N-alkylated tetrahydrodipyridyls and the fact that α-dihydropyridines are yellow while the γ-isomers are colorless[8] presents the alternative proposition that the white and yellow forms may be represented by Structures I and III (or IIIa), respectively, owing to isomerism of double bonds.

The evidence presented herein favors the dissociation theory and renders unlikely the rearrangement of double bonds.



The interconversion of the two modifications depends on the solvent and on the temperature. If the white form is dissolved in methanol, ethanol, acetone or dioxane, it stays white until heated, then turns yellow. On cooling it again becomes colorless. In acetic acid or chloroform the white form turns yellow on standing at room temperature, or more quickly on heating.

Both forms have been reported to have the same m. p.[2] The reason for this is that the white crystals can be observed to turn yellow before melting. This change is first evident at about 105° and the material is bright yellow just before melting at 130–131°. This thermal conversion from white to yellow conforms with the idea that the yellow form contains radicals, since dissociation should be more likely at elevated temperatures.

Further, the yellow color in solutions is dispelled by small amounts of air. This is to be expected of radicals,[9] and may signify the formation of a peroxide from the dissociated form. No peroxide has been found, however, and complete air oxidation either of solutions or of the crystalline forms, yields 4,4'-dipyridyl.[2]

Measurements of the magnetic susceptibility of the two crystalline forms further indicate the presence of radicals in the yellow modification. The

yellow form was found to be paramagnetic ($K = +0.437 \times 10^{-6}$), while the white is diamagnetic ($K = -0.199 \times 10^{-6}$).

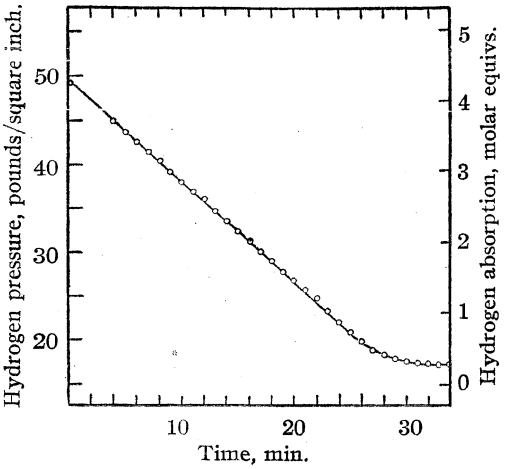

Fig. 1.—Rate of hydrogenation of N,N′-diacetyltetrahydro-4,4′-dipyridyl.

Considering now the data which rule out Structure III (or IIIa) for the yellow form, the rate of complete hydrogenation of yellow N,N′-diacetyltetrahydro-4,4′-dipyridyl over platinum oxide in acetic acid showed that all four double bonds absorb hydrogen at the same rate (Fig. 1). This indicates four unconjugated double bonds, as in Structure I. Structure III would be expected to absorb the last mole of hydrogen more slowly than the first three.

tetrahydro-4,4′-dipyridyl gave succinic acid as the only isolable product. Succinic acid would be expected from Structure I, but is not possible from Structures III or IIIa.

Although the above evidence is best interpreted by dissociation of Structure I into free radicals, the amount of dissociation at room temperature is probably slight, since the catalytic hydrogenation of the yellow form gave only N,N′-diacetyl-4,4′-dipiperidyl. No N-acetylpiperidine, the expected reduction product of the radical (II), was found.

One further experiment was considered, the effect of the white and yellow forms on the polymerization of styrene. When a trace of either form was added to styrene and the styrene heated in a sealed viscosimeter at 58°, the solution containing the white form turned yellow, and in either case polymerization of the styrene was completely inhibited.

Experimental

N,N′-Diacetyltetrahydro-4,4′-dipyridyl (I).—A yield of 23.6 g. (20%) of the yellow form was obtained using the directions of Wibaut and Arens[9] from 50.0 g. (0.632 mole) of freshly-distilled pyridine. From this was obtained in 75% yield the colorless modification by means of 0.5% methanolic potassium hydroxide.[6,11] The b. p. of 10.00 ml. of chloroform was raised 0.128° by 0.10995 g. of the compound (yellow in boiling chloroform); mol. wt. 224 (calcd. for undissociated molecule 244).

Behavior in Solutions and in Air.—Small amounts (0.1–1.0%) of colorless N,N′-diacetyltetrahydro-4,4′-dipyridyl dissolved in methanol, ethanol, acetone or dioxane become yellow on warming in a stoppered flask. On cooling, the solution becomes colorless. If the heated flask is opened to the air and shaken, the solution becomes colorless, but gradually turns yellow again if restoppered. The

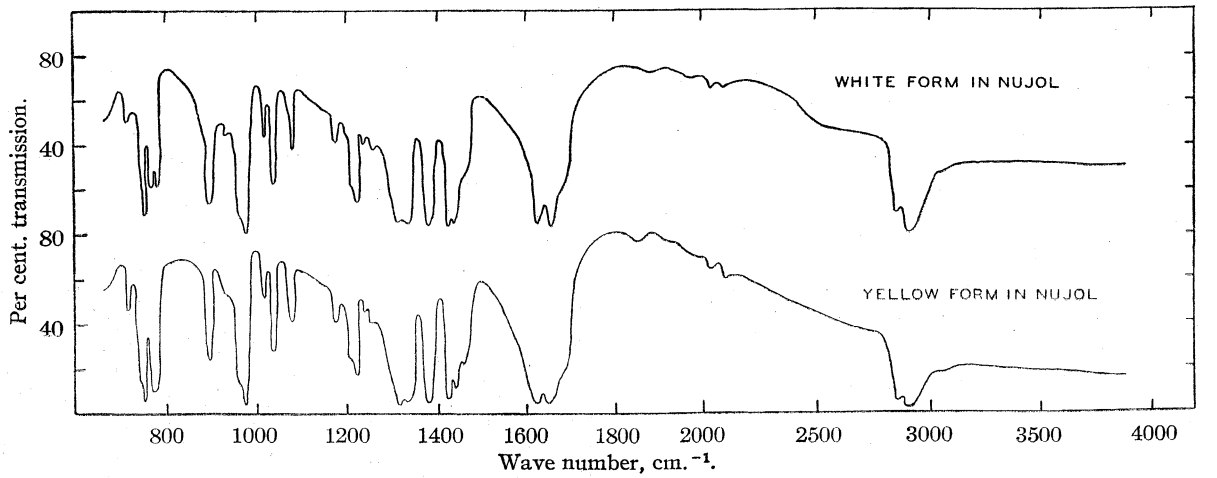

Fig. 2.—Infrared spectra of solid, N,N′-diacetyltetrahydro-4,4′-dipyridyl.

Infrared (Fig. 2) and ultraviolet (maximum at 239 mμ (log ε = 3.73)) absorption spectra of both white and yellow forms are essentially identical, which would not be expected if the forms differed in the manner of Structure I and III (or IIIa).[10]

Ozonolysis of the yellow form of N,N′-diacetyl

yellow crystalline modification, dissolved (0.1%) in any of these solvents open to the atmosphere at room temperature, becomes colorless in five to ten minutes.

The same properties are exhibited in glacial acetic acid or chloroform, except that in these solvents the yellow

(10) Barnes, Gore, Liddel and Williams, "Infrared Spectroscopy," Reinhold Publishing Corp., New York, N. Y., 1944, pp. 1–25.

(11) This "conversion" of the yellow to the white form is probably not a conversion at all, but rather the oxidative destruction of the small amount of yellow dissociated material present, with subsequent recovery of the remaining undissociated compound.

color predominates at room temperature as well as at higher temperatures.

Prolonged heating of the yellow acetic acid (or ethanol) solution gives rise to the deep blue color observed and studied by Dimroth and co-workers.[2,3]

In the crystalline form both modifications decompose on standing in air (the yellow form apparently more readily) to give a brown oil having the odor of pyridine. From one such sample was isolated a small quantity of 4,4′-dipyridyl as its crystalline hydrate, m. p. 105–106°; m. p. of picrate 252–254° (Dimroth and Heene[2] have reported the isolation of 4,4′-dipyridyl from air-oxidized ethanolic solutions).

Magnetic Susceptibility.—The measurements were kindly carried out by Mr. Clayton Callis using the apparatus described by Driggs and Hopkins.[12] All measurements were taken at 25° on the two solid forms of N,N′-diacetyltetrahydro-4,4′-dipyridyl and the magnetic susceptibility (K) calculated in units per gram.

Quantitative Catalytic Hydrogenation.—Eight and six-tenths grams (0.035 mole) of yellow N,N′-diacetyltetrahydro-4,4′-dipyridyl dissolved in 130 ml. of glacial acetic acid was hydrogenated over 0.2 g. of platinum oxide at room temperature and 50 pounds per square inch initial pressure. Hydrogen was absorbed as shown in Fig. 1. Removal of the solvent under reduced pressure gave a white residue which yielded on recrystallization from dioxane 6.3 g. (74%) of shiny colorless plates of N,N′-diacetyl-4,4′-dipiperidyl, m. p. 173.5–174.5° (reported,[13] 174°). Attempts to hydrogenate N,N′-diacetyltetrahydro-4,4′-dipyridyl using Raney nickel in dioxane or methanol under pressures of 50–1400 pounds per square inch and temperatures of 25–70° generally failed to reduce the compound. Zinc and methanolic sodium hydroxide also failed to effect reduction.

Absorption Spectra.—Infrared determinations were kindly carried out by Mrs. J. L. Johnson using the crystalline white and yellow forms in Nujol. The instrument was a Perkin-Elmer Model 12B infrared spectrometer with rock salt optics.

Ultraviolet determinations were kindly made by Mr. John C. Brantley using a Model D Beckman spectrophotometer with 95% ethanolic solutions of the white (5.22 mg. per liter of solution) and yellow (12.1 mg. per liter of solution) forms.

Ozonolysis.—Five and five-tenths grams (0.025 mole) of yellow N,N′-diacetyltetrahydro-4,4′-dipyridyl dissolved in 40 ml. of glacial acetic acid was ozonized for forty-eight hours at 20° with 3% ozone flowing at a rate of 2.2 ml. per minute. The acetic acid solution was then added dropwise at 0° to 300 ml. of water and 30 ml. of 30% hydrogen peroxide. The mixture was allowed to stand overnight, then heated to 90° for ten minutes. The solvent was removed by distillation, leaving a residue of 3.5 g. of crude yellowish succinic acid, m. p. 160–178°. From this was prepared a *p*-bromophenacyl ester by the method of Shriner and Fuson,[14] m. p. 210–212°. Succinamide was also prepared in 43% yield through the methyl ester from 0.692 g. of the crude acid, using the method of Morrell.[15] The colorless needles, recrystallized from water, melted at 260–261°. A mixed m. p. with an authentic sample was not depressed.

Effect on Polymerization of Styrene.—The flow times of solutions of 0.10 g. of the white and yellow forms of N,N′-diacetyltetrahydro-4,4′-dipyridyl in 13.3 ml. of freshly-distilled styrene were periodically compared with those of pure styrene in Foord-type viscosimeters[16] maintained at 58°. The viscosity of the pure styrene increased steadily, until after two days the liquid was too thick to flow. The flow times of the solutions were unchanged after two days at 58°, and still unchanged after five months at room temperature.

Summary

Evidence is presented to suggest that N,N′-diacetyltetrahydro-4,4′-dipyridyl dissociates into free radicals which give rise to the yellow modification of the compound.

The Reaction of Azlactones with Secondary Amines

BY DAVID K. BARNES,[1] E. CAMPAIGNE AND R. L. SHRINER[2]

No systematic study has been made of the reaction of secondary amines with azlactones.[3] Only a few scattered examples of the reaction have been reported in the literature.[4–8] In view of this fact, it was considered desirable to investigate the reactions of 2-phenyl-4-benzal-5-oxazolone (an unsaturated azlactone) and 2-phenyl-4-benzyl-5-oxazolone (a saturated azlactone) with the following series of secondary amines: piperidine, morpholine, dimethylamine, diethylamine, methylaniline, ethylaniline, diphenylamine, indole and carbazole. These amines were chosen because they represented different degrees of basicity.

Erlenmeyer[4] reported that 2-phenyl-4-benzal-5-oxazolone (I) reacted with piperidine to produce α-benzoylaminocinnamapiperidide with a melting point of 178°. In the present work, it has been found that two isomeric products may be isolated from the reaction of 2-phenyl-4-benzal-5-oxazolone[9] with piperidine. When equivalent amounts of the reactants were employed, Piperidide A,

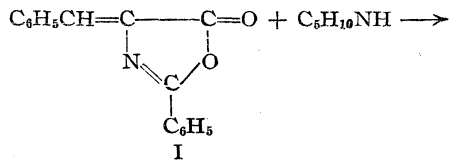
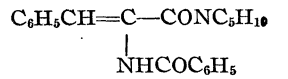
(8) Doherty, Tietzman and Bergmann, *J. Biol. Chem.*, **147**, 617 (1943).

(9) Two isomeric forms, (*cis* and *trans*) of this azlactone have been described by Carter and Risser, *J. Biol. Chem.*, **139**, 255 (1941). Only the readily available higher melting isomer was used by Erlenmeyer and also in the present work.

melting at 161–162.5° was obtained. The use of a large excess of piperidine in the reaction resulted in the formation and isolation of Piperidide B, melting at 187–188°.



I

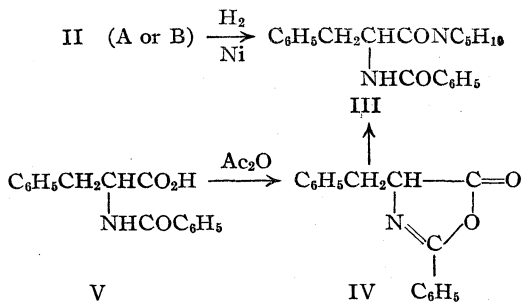


Piperidine-A, m. p. 161–162°
Piperidide-B, m. p. 187–188°

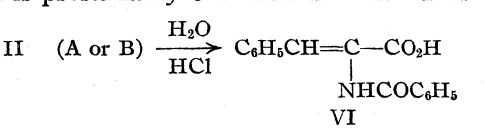
II

Analyses showed that both of these compounds were formed from one mole of the azlactone and one mole of piperidine. No compound corresponding to the addition of a second mole of amine to the unsaturated amide was found in spite of changes in mole ratio of reactants and time, temperature and solvents.

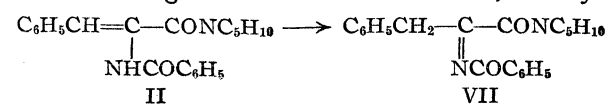
A study of the reactions of these isomers showed that they possessed the same chemical properties. For example, catalytic reduction of both piperidides (II, A and B) produced α-benzoylaminocinnamapiperidide (III) which was identical with a sample of this compound obtained by treatment of 2-phenyl-4-benzyl-5-oxazolone (IV) with piperidine. The saturated azlactone (IV) was made by the action of acetic anhydride on *dl*-benzoylphenylalanine (V).



Hydrolysis of both piperidides with dilute hydrochloric acid gave piperidine and the same α-benzoylaminocinnamic acid (VI) m. p. 229–230°, which is presumably the *trans*-isomer. This was somewhat surprising since, if the two piperidides are *cis–trans* isomers, it might be expected that the *cis*- and *trans*-forms of VI would be formed. It is of course possible that interconversion occurred during the hydrolysis.



Both piperidides were converted to the original oxazolone (I) and piperidine when heated in tetralin or glacial acetic acid. Although the isomerism of the two compounds might be due to the shift of the double bond and proton (Formulas II, VII), the above regeneration of the oxazolone, and hydrolysis to VI favor the possibility that they are *cis* and *trans* isomers. It was also found that the lower melting isomer (IIA) was converted to the higher melting form (IIB) by heating with piperidine or pyridine; reagents which have previously been shown to cause conversion of *cis* to *trans* isomers.[9,10]



II VII

Similarly, two isomeric products were obtained from the reaction of morpholine with 2-phenyl-4-benzal-5-oxazolone. Catalytic reduction of each isomer resulted in the formation of α-benzoylaminohydrocinnamamorpholide, and acid hydrolysis yielded α-benzoylaminocinnamic acid (VI) and morpholine.

Isomeric products were not obtained with the other amines, although there may have been small amounts of the lower melting forms present. Table I in the Experimental Part summarizes the products obtained from secondary amines and 2-phenyl-4-benzyl-5-oxazolone, and Table II, the substituted amides obtained from 2-phenyl-4-benzal-5-oxazolone. The weakly basic amines, diphenylamine, indole and carbazole failed to open the azlactone ring.

Experimental

2-Phenyl-4-benzal-5-oxazolone.—The 2-phenyl-4-benzal-5-oxazolone used in this work was prepared according to the method of Gillespie and Snyder.[11] The product was obtained in 53–73% yield, melting at 165–166° without recrystallization.

N-Benzoyl-*dl*-phenylalanine.—Reduction of 2-phenyl-4-benzal-5-oxazolone with phosphorus and hydriodic acid, according to the method of Gillespie and Snyder[11] afforded *dl*-phenylalanine in 50–60% yields. Treatment of this product with benzoyl chloride and sodium hydroxide[12] resulted in the preparation of N-benzoyl-*dl*-phenylalanine melting at 184–186° in 70–75% yields.

2-Phenyl-4-benzyl-5-oxazolone.—N-Benzoyl-*dl*-phenylalanine was converted to 2-phenyl-4-benzyl-5-oxazolone by dehydration in acetic anhydride, according to the method of Mohr and Stroschein.[13] The yields ranged from 58–63% of the azlactone which melted at 70–71°. Due to the ease of hydrolysis of the saturated azlactone, the pure material was stored in a vacuum desiccator over phosphorus pentoxide prior to use.

The Reaction of Piperidine with 2-Phenyl-4-benzyl-5-oxazolone.—In a 25-ml. Erlenmeyer flask, 10 ml. (0.1 mole) of piperidine was added to 1.0 g. (0.004 mole) of 2-phenyl-4-benzyl-5-oxazolone. Heat was evolved as the solid azlactone dissolved. The reaction mixture was heated in a boiling water-bath for ten minutes. After cooling, the white, crystalline precipitate was filtered with suction and washed on the filter with petroleum ether. The α-benzoylaminohydrocinnamapiperidide was

(13) Mohr and Stroschein, *Ber.*, **42**, 2521 (1909).

recrystallized from dilute ethanol; the weight, after drying, was 1.3 g. (98%) of white crystals which melted at 162–162.5°.

The same procedure was used for the reaction of morpholine, methylaniline and ethylaniline with 2-phenyl-4-benzyl-5-oxazolone. Dimethylamine, diethylamine and di-*n*-butylamine gave satisfactory yields when the reaction was carried out in dry solvents such as ligroin or chloroform. The melting points and analyses of the products are given in Table I.

TABLE I

N,N-SUBSTITUTED α-BENZOYLAMINOHYDROCINNAMAMIDES

Amide group	M. p. of product, °C.	Formula	Nitrogen, % Calcd.	Found
Piperidide	162–162.5	$C_{21}H_{24}O_2N_2$	8.33	8.21
Morpholide	171–172	$C_{20}H_{22}O_3N_2$	8.28	8.34
Dimethylamide	148.5–149	$C_{18}H_{20}O_2N_2$	9.46	9.27
Diethylamide	121.5–122.5	$C_{20}H_{24}O_2N_2$	8.64	8.57
Methylanilide	163–164	$C_{23}H_{22}O_2N_2$	7.82	7.59
Ethylanilide	184.5–185	$C_{24}H_{24}O_2N_2$	7.52	7.33

Diphenylamine, indole and carbazole did not form substituted cinnamides. A by-product melting at 269° was formed in the reaction of the aliphatic amines with the saturated azlactone. This may be a condensation product of the azlactone with itself (see ref. 3).

The Reaction of Piperidine with 2-Phenyl-4-benzal-5-oxazolone. Method A.—In a 125-ml. Erlenmeyer flask fitted with a reflux condenser, 12.5 g. (0.05 mole) of 2-phenyl-4-benzal-5-oxazolone was suspended in 50 ml. of dry benzene, and 4.25 g. (0.05 mole) of freshly distilled piperidine was added. The reaction mixture warmed spontaneously, and was further heated for thirty minutes in a boiling water-bath. During this time the reaction mixture became homogeneous. Approximately two-thirds of the solvent was removed under reduced pressure, the product precipitating when the concentrated solution was allowed to cool. The white, powdery solid was filtered with suction and washed on the filter with petroleum ether. The weight of crude Piperidide A was 14.6 g. (86.5%) m. p. 151–153°. After recrystallization from 300 ml. of 95% ethanol, the product weighed 13.9 g. (83%) m. p. 161–162.5°. This melting point is the same as that of α-benzoylaminohydrocinnamapiperidide but the melting point of a mixture of the two was markedly lowered.

This method was utilized for the preparation of the corresponding Morpholide A from the reaction of 2-phenyl-4-benzal-5-oxazolone with an equivalent amount of morpholine.

Method B.—To 5.0 g. (0.02 mole) of 2-phenyl-4-benzal-5-oxazolone was added 25 ml. (0.25 mole) of piperidine. The azlactone dissolved rapidly with the evolution of heat. The homogeneous, yellow solution was heated in a boiling water-bath for ten minutes, during which time a white solid began to precipitate. The reaction mixture was allowed to cool, and the product was filtered with suction and washed with cold acetone. The weight of crude Piperidide B was 5.0 g., m. p. 181–183°. After recrystallization from benzene, the weight was 4.2 g. (63%), m. p. 187–188°.

This method was utilized for the preparation of Morpholide B from the reaction of 2-phenyl-4-benzal-5-oxazolone with morpholine. These two general methods were used in the reaction of dimethylamine, diethylamine, methylaniline, and ethylaniline, with 2-phenyl-4-benzal-5-oxazolone. Isomers were not obtained from these amines but may have been present. Examination of the mother liquors from the crystallization of the reaction products gave small amounts of unchanged azlactone but no definite pure isomers could be separated. The melting points and analyses of the products are given in Table II.

Diphenylamine, indole and carbazole failed to react with the unsaturated azlactone. The reactants were recovered unchanged except when Method A was employed with carbazole. In this case, the recovered azlactone melted at 148–149°. When it was treated with pyridine it changed to the higher melting isomer, m. p. 165–166°. This corresponds to the isomerization reported by Carter and Risser.[9]

TABLE II

N,N-SUBSTITUTED α-BENZOYLAMINOCINNAMAMIDES

Amide group	M. p. of product, °C.	Formula	Analyses, % Calcd.	Found

Reduction of N,N-Substituted α-Benzoylaminocinnamamides.—In a 500-ml. hydrogenation bottle were placed 0.005 mole of the N,N-substituted α-benzoylaminocinnamamide, 100 ml. of absolute ethanol and 2–3 g. of Raney nickel.[14] The bottle was placed on a Parr hydrogenation apparatus and the solution shaken with hydrogen at a pressure of 45 lb. The calculated pressure drop occurred in about five minutes, but the mixture was allowed to shake for fifteen minutes to ensure complete reduction. After removing the Raney nickel by filtration, the filtrate was concentrated to approximately one-fourth the original volume under reduced pressure. Upon cooling the solution to room temperature, a white, crystalline product precipitated which was filtered with suction and dried. The reduced products were identified by comparison with the corresponding hydrocinnamamides prepared from the reaction of 2-phenyl-4-benzyl-5-oxazolone with secondary amines (see Table I).

Acid Hydrolysis of N,N-Substituted α-Benzoylaminocinnamamides.—The following method was used for the hydrolysis of each of the isomeric piperidides and morpholides. In a 200-ml. round-bottomed flask fitted with a reflux condenser, 0.003 mole of the N-substituted-α-benzoylaminocinnamamide was boiled in 100 ml. of dilute (3:1) hydrochloric acid for three hours. The white, crystalline, acid-insoluble material was filtered with suction and washed on the filter with water. When dry, this product melted at 228–230° and was readily soluble in 10% sodium hydroxide. A mixed melting point with α-benzoylaminocinnamic acid showed no depression.

The acidic filtrate was cooled in an ice–water-bath, and made alkaline to litmus by the addition of 30% sodium hydroxide. A strong amine-like odor was usually noticeable. Five milliliters of benzenesulfonyl chloride and 5 ml. of 30% sodium hydroxide were added to the reaction mixture; the flask was corked tightly and shaken vigorously for thirty minutes. The white, flocculent sulfonamide was filtered with suction and washed thoroughly with water. The benzene sulfonamides were recrystallized from dilute ethanol and compared with authentic samples.

Conversion of Piperidide A to Piperidide B.—In a 50-ml. round-bottomed flask fitted with a reflux condenser were placed 2.5 g. (0.006 mole) of α-benzoylaminocinnamapiperidide (Piperidide A), 10 ml. (0.1 mole) of piperidine and 10 ml. of benzene. The flask was immersed in a boiling water-bath and the mixture refluxed for thirty minutes. The solution became homogeneous, but after cooling, a white, crystalline precipitate was obtained. The solid was filtered with suction and washed on the filter with several small portions of petroleum ether.

(14) R. Mozingo, "Org. Syntheses," **21**, 15 (1941).

The dry material weighed 1.2 g. and melted at 166–167°. An additional 1.0 g. was obtained by evaporating the filtrate to dryness under reduced pressure. The two fractions were combined and recrystallized from benzene. The yield of pure Piperidide B was 2.0 g., melting at 187–188°. Boiling pyridine also converted the low melting isomer to the higher melting compound. In a similar way the low melting Morpholide A was converted to the higher melting Morpholide B.

Summary

1. A series of α-benzoylamino-N,N-disubstituted hydrocinnamamides has been prepared by the reaction of 2-phenyl-4-benzyl-5-oxazolone with dimethylamine, diethylamine, methylaniline, ethylaniline, piperidine and morpholine.

2. A series of α-benzoylamino-N,N-disubstituted cinnamamides has been prepared by the reaction of 2-phenyl-4-benzal-5-oxazolone with the same secondary amines. Each of these compounds was catalytically hydrogenated to the corresponding hydrocinnamamide.

3. Piperidine and morpholine were found to react with 2-phenyl-4-benzal-5-oxazolone to yield two isomeric products in each case. The isomeric piperidides were both hydrolyzed to the same α-benzoylaminocinnamic acid, and reduced to α-benzoylaminohydrocinnamapiperidide and morpholide, respectively.

4. Diphenylamine, indole and carbazole failed to react with 2-phenyl-4-benzyl-5-oxazolone or 2-phenyl-4-benzal-5-oxazolone under the conditions employed in this work.

Monomers and Polymers. III. A New Synthesis for α-Methylstyrenes[1,2]

BY G. BRYANT BACHMAN AND HENRY M. HELLMAN

Most α-methylstyrenes so far described have been prepared by two general types of syntheses. The first involves the conversion of carbonyl or carbalkoxyl groups to isopropenyl groups, *e. g.*

(1) $R—COCH_3 \xrightarrow[(2)\ \text{acid}]{(1)\ CH_3MgX} R—C(CH_3)_2OH \xrightarrow{-H_2O} R—C(CH_3)=CH_2$

(2) $R—CO_2CH_3$

The method is limited to intermediates which contain no other groups affected by Grignard reagents and is impractical for large scale production. The second type involves the conversion of isopropyl groups to isopropenyl groups, *e. g.*

(3) $R—CH(CH_3)_2 \xrightarrow{Al_2O_3} R—C(CH_3)=CH_2 + H_2$

(4) $R—CH(CH_3)_2 \xrightarrow{Cl_2} R—C(CH_3)_2Cl \xrightarrow[\text{base}]{} RC(CH_3)=CH_2$

It is better suited for commercial production but is also limited as to other groups which may be present. Thus alkyl substituents are especially troublesome because of their indiscriminant attack by the dehydrogenation catalyst or by the halogen. Furthermore, the tertiary halides produced (Equation 4) tend to dehydrohalogenate during distillation giving difficulty separable mixtures.

We have sought for and found a synthesis which can be applied more or less generally to substitute α-methylstyrenes, especially of the types difficultly obtainable by previously known methods, and which might be adapted to large scale production. The synthesis is illustrated by the following equations in which R represents one or more nuclear substituents.

(5) 
(6) 
Aromatic compounds have been alkylated before with alcohols and with alkyl halides[3] but never apparently with halohydrins. We have found that secondary alcohols react so much more readily than primary halides in this synthesis that condensation with two aryl nuclei to form diarylpropanes may be made of minor importance. Positional isomers are formed but the para derivative (with monosubstituted benzenes) is the chief product.

In Table I are shown the haloalkylation products of a number of substituted benzenes. The method appears to work especially well with alkylated benzenes, probably because the alkyl group activates the nucleus to further substitution.

[a] Known compound, *cf.* Beilstein or indicated reference. [b] Reported recently by Mowry, Huber and Ringwald, THIS JOURNAL, **69**, 851 (1947), b. p. 88–89° (15); $n^{25}D$ 1.5543. [c] From chloroisopropylated α-chloronaphthalene. [d] An α-ethylstyrene, *cf.* Griskevich–Trokhimovskii, *C. A.*, **5**, 3799 (1911). [e] E represents element analyzed for.

Boron trifluoride alone as catalyst is satisfactory, but the yields of condensation products are often improved (5–10%) by the addition of dehydrating agents such as sulfuric acid or phosphorus pentoxide. The low yields with anisole may be attributed to combination between the ether oxygen and the boron trifluoride molecule creating a group-complex ($-\overset{+}{O}R \rightarrow \bar{B}F_3$) whose dipolar character is such as to deactivate the nucleus. Haloalkylation of thiophene was unsuccessful, probably for similar reasons, and because of cleavage of the thiophene ring.

In attempting to extend the utility of the reaction to homologs of propylene halohydrins it was found that the halohydrin of 1-butene (1-bromo-2-butanol) reacted very satisfactorily with toluene. There appears to be no reason why α-alkylstyrenes generally should not be readily available by this synthesis.

The α-methylstyrenes prepared by dehydrohalogenation (Table II) showed evidence of being mixtures of positional isomers not completely separated by distillation through a 42-cm. glass helices packed column. The products boiled over a range and showed varying refractive indices, but the several cuts gave correct bromine numbers and correct analyses. The styrenes were therefore redistilled through a 3-foot, 1/4 inch tantalum spiral column with an efficiency of about 10 theoretical plates. The separated isomers were then oxidized with 6 molar nitric acid to the corresponding substituted benzoic acids. Comparison of the m. p.'s of these acids with values reported in the literature led to a determination of the structures of the original styrenes.

An advantage of this synthesis is that the haloisopropylated benzene obtained as an intermediate may easily be further substituted nuclearly before

dehydrohalogenation. Thus *p*-(chloroisopropyl)-toluene was brominated and then dehydrohalogenated to give 3-bromo-4-methyl-α-methylstyrene. In this way products with substituents in the meta and para positions rather than in the ortho positions are obtained, and even deactivating (electron-withdrawing) groups may be introduced without interfering with the subsequent styrene formation.

All of the styrenes prepared except those with ortho substituents copolymerized satisfactorily with butadiene in emulsion systems to give rubber-like materials similar to GR-S in appearance. They also copolymerized with styrene, methyl methacrylate and maleic anhydride, but they did not polymerize alone with peroxide catalysts.

Acknowledgment.—The authors are indebted to the General Tire and Rubber Company and the Purdue Research Foundation for financial assistance in the form of a fellowship.

Experimental[4,5]

1-Halo-2-arylpropanes.—The chloroalkylation of *o*-chlorotoluene is typical for all of the compounds in this series. A cooled, stirred solution of 1920 g. (15 moles) of *o*-chlorotoluene and 520 g. (5.5 moles) of freshly distilled propylene chlorohydrin was saturated with boron trifluoride at temperatures below 10°, and then 196 g. (1.4 moles) of phosphorus pentoxide was added. The resulting two phase mixture was heated at 75° for four hours. During the heating period boron trifluoride was evolved and vented into a water trap. The layers were separated after cooling, the top layer was washed several times with water, dried, and rectified through a 43-cm. Fenske column; yield 358 g. (32%), b. p. (2 mm.) 95–97°, d^{25}_{25} 1.164, $n^{25}D$ 1.5392. It is interesting to note that the narrow b. p. range and constant n_D values give no evidence of the presence of isomers, although the styrenes later obtained by dehydrohalogenation separated into fractions on distillation and were definitely shown to contain positional isomers by oxidation to known isomeric benzoic acids. In Table I are listed the haloalkylated aromatic compounds together with their physical constants and analyses.

1,2-Diarylalkanes.—The chloroalkylation of benzene, isopropylbenzene, *o*-xylene, and toluene led to 1,2-diarylalkanes as by-products. The yields and properties of these compounds are shown in Table III.

Bromination of Chloroisopropylated Toluene.—Chloroisopropylated toluene (250 g., 1.5 moles) was mixed with 0.6 g. of iodine, and 76 ml. (1.5 moles) of bromine was added dropwise to the cooled, stirred mixture which was shielded from light. After twenty-four hours, the color of bromine was still apparent; hence, about 0.1 g. of iron filings was added and the mixture was allowed to stand at room temperature for an additional twenty-four hours, after which it was washed with water, dilute sodium hydroxide, twice again with water, distilled, washed with sodium thiosulfate solution, and rectified. There was obtained 257 g. of product b. p. (2 mm.) 108–113°; $n^{25}D$ 1.5590; d^{25}_{25} 1.3896. It is interesting to compare these properties with those of chloroisopropylated *o*-bromotoluene which were: $n^{25}D$ 1.5592; d^{25}_{25} 1.3893; b. p. (1–2 mm.) 109–112°. The yield on the bromination was 70%.

Substituted α-Methylstyrenes.—The preparation of 3-chloro-2-methyl- and 3-chloro-4-methyl-α-methylstyrenes is typical. Chloroisopropylated *o*-chlorotoluene (2 moles) was refluxed with a filtered solution of 466 g. (7 moles) of 85% potassium hydroxide in 1850 ml. of methanol. Most of the methanol was removed by distillation and the residual liquid was washed with water, dried with calcium chloride, and rectified through an efficient column giving 90 g. (26%) of 3-chloro-2-methyl-α-methylstyrene (I) (b. p. (4 mm.) 64–65°; $n^{25}D$ 1.5340; d^{25}_{25} 1.043) and 152 g. (48%) of 3-chloro-4-methyl-α-methylstyrene (II) (b. p. (4 mm.) 73–74°; $n^{25}D$ 1.5520; d^{25}_{25} 1.056).

Anal. Calcd. for $C_{10}H_{11}Cl$: Cl, 21.3; bromine number, 96. Found: (I) Cl, 21.4; bromine number, 96. Found: (II) Cl, 21.3; bromine number, 99.

Oxidation of (I) and (II) with dilute nitric acid gave respectively 3-chloro-2-methylbenzoic acid (m. p. 152–153°; neutral equivalent 172)[6] and 3-chloro-4-methylbenzoic acid (m. p. 205–206°; neutral equivalent 171).[7]

In Table II are listed the substituted α-methylstyrenes together with their physical constants and analyses.

Preparation of Copolymers.—Copolymers of the substituted α-methylstyrenes with methyl methacrylate, maleic anhydride and styrene were made at 65–70° in small stoppered test-tubes, using 0.5% benzoyl peroxide as catalyst. Copolymers with butadiene[8] were made at 40° in small sealed tubes, using the following formula: butadiene 7.5 parts, substituted α-methylstyrene 2.5 parts, water 18 parts, soap 0.5 part, a peroxide 0.03 part and lauryl mercaptan 0.06 part. Copolymers were obtained from all of the alpha-methylstyrenes except those with ortho substituents (*e. g.* 3-chloro-2-methyl-alpha-methylstyrene). None of the alpha-methylstyrenes copolymerized with vinyl acetate.

Summary

A new synthesis of α-methylstyrenes has been developed which involves the catalytic condensation of aromatic compounds with propylene chlorohydrin and the dehydrohalogenation of the resulting halopropylated derivatives. Several new α-methylstyrenes have been prepared and copolymerized with butadiene, methyl methacrylate, styrene and maleic anhydride.

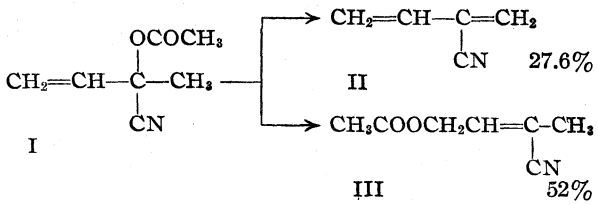
An Allylic Rearrangement in the Pyrolysis of 3-Acetoxy-3-cyano-1-butene[1]

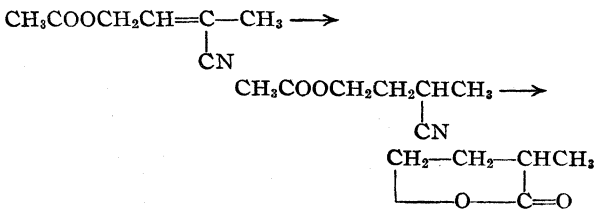
BY C. S. MARVEL AND NEAL O. BRACE

2-Cyano-1,3-butadiene (II) has been prepared by Carter and Johnson[2] by the pyrolysis of 3-acetoxy-3-cyano-1-butene (I) but details on the yields or side reactions involved have not been reported. In repeating this preparation we have found that the main reaction is the allylic rearrangement of the acetoxy group to give 1-acetoxy-3-cyano-2-butene (III); only a small part of the original material is converted to 2-cyano-1,3-butadiene. When the rearrangement product (III) was recycled through the pyrolysis chamber it was recovered unchanged. This rearrangement



is related to that reported by Heilbron, James, McCombie and Weedon[3] for 3-acetoxy-1,4-hexadiene.

The structure of the 1-acetoxy-3-cyano-2-butene was established by reduction of the olefin group and subsequent hydrolysis of the nitrile to yield α-methylbutyrolactone, which was identified by its physical properties and those of its hydrazide.[4]



The benzoate of the cyanohydrin of methyl vinyl ketone was also prepared and pyrolyzed. In this case only 10% yield of 2-cyano-1,3-butadiene was obtained and the major product was a rearranged ester isomeric with the starting material. This undoubtedly is also the result of an allylic shift of the benzoxyl group.

Experimental

Methyl Vinyl Ketone Cyanohydrin.—This was prepared by the procedure of Leupold and Vollmann[5] with potassium cyanide as the alkaline catalyst. It was necessary to control the temperature of the reaction mixture very carefully since little addition occurred below 5° and above 10° the product of addition was levulinonitrile.[6] It was also important to remove the phosphoric acid layer promptly at the end of the reaction. When these precautions were followed the yields of cyanohydrin were consistently between 60 and 70% when 200–400 g. of ketone was used. The product boiled at 60° under 5 mm. pressure, $n^{20}D$ 1.4264 (lit.[5] $n^{17.5}D$ 1.4264).

Acetate of Methyl Vinyl Ketone Cyanohydrin.—In a 1-liter, round-bottom flask were placed 428 g. (4.2 moles) of acetic anhydride and 5 g. of acetyl chloride. The flask was equipped with a Y-adapter fitted with a reflux condenser and dropping funnel. To the boiling mixture 388 g. (4.0 moles) of methyl vinyl ketone cyanohydrin was added slowly, and sufficient heat was applied to maintain gentle reflux. About two hours were required for the addition. Heating was continued for one-half hour. Distillation through a 10-in., helix-packed, electrically-heated column yielded 536 g. (96%) of 3-acetoxy-3-cyano-1-butene, b. p. 89–90° at 19 mm., $n^{20}D$ 1.4270, d^{20}_4 1.0070. The literature reports[3] b. p. 89–90° at 17 mm.

Anal.[7] Calcd. for $C_7H_9O_2N$: C, 60.27; H, 6.50; N, 10.04; *MR*, 35.47. Found: C, 60.53; H, 6.31; N, 10.24; *MR*, 35.48.

Benzoate of Methyl Vinyl Ketone Cyanohydrin.—To a mixture of 31.7 g. (0.3 mole) of methyl vinyl ketone cyanohydrin and 42 g. (0.3 mole) of benzoyl chloride in a 600-ml. beaker cooled in an ice–salt-bath was added slowly with stirring 40 g. (0.5 mole) of pyridine, so that the temperature was maintained between 8–15°. Care was taken to keep the mass that forms broken up, in order to aid in control of the temperature. After the pyridine had been added, the lumps were broken up and 500 ml. of water added with stirring. The suspended solid was collected on a Buchner funnel and washed with three 500-ml. portions of water. Recrystallization from a water–ethanol mixture yielded 47.5 g. (79%) of the benzoate of methyl vinyl ketone cyanohydrin, m. p. 49–50°. A small sample was recrystallized from a dioxane–water mixture, m. p. 53.5° and submitted for analysis.

Anal. Calcd. for $C_{12}H_{11}O_2N$: C, 71.62; H, 5.51; N, 6.96. Found: C, 71.44; H, 5.24; N, 6.75.

Pyrolysis of the Acetate of Methyl Vinyl Ketone Cyanohydrin.—Pyrolysis of the acetate of methyl vinyl ketone cyanohydrin was accomplished by passing the ester dropwise through a Pyrex tube (outside diameter 19 mm.) packed for a distance of 12 inches with 4-mm. glass beads and heated to 475° by means of an electrically-heated combustion furnace. The acetate was added at a rate of one drop every three seconds and a diluting stream of purified nitrogen gas was passed through the hot tube during pyrolysis. The pyrolysate was collected in a 500-ml. suction flask cooled by a Dry Ice-bath and connected with a vapor trap cooled with Dry Ice. The liquid pyrolysate was washed with four 100-ml. portions of an aqueous sodium chloride solution, and the organic material separated and dried over anhydrous sodium sulfate. About 0.1 g. of picric acid was added to prevent polymerization and the material was distilled through a 4-in., helix-packed column. From 219 g. (1.56 moles) of the acetate there was obtained 34 g. (27.6%) of 2-cyano-1,3-butadiene, b. p. 30–40° (4 mm.), $n^{20}D$ 1.4450 and 114.0 g. of an ester, b. p. 95° (10 mm.), $n^{20}D$ 1.4500, d^{20}_4 1.0280 that was not the acetate of methyl vinyl ketone cyanohydrin. This represents 52% of the original ester.

(1) The work described in this communication was carried out under the sponsorship of the Office of Rubber Reserve, Reconstruction Finance Corporation, in connection with the Government Synthetic Rubber Program.

Anal. Calcd. for $C_7H_9O_2N$: C, 60.27; H, 6.50; N, 10.04; *MR*, 35.47. Found: C, 60.53; H, 6.66; N, 10.29; *MR*, 36.36 (exaltation of 0.9).

Identification of the Ester Produced in the Pyrolysis.—Hydrogenation of 13.9 g. of the recovered ester dissolved in 100 ml. of absolute ethanol was accomplished in an Adams hydrogenation apparatus at room temperature using as catalyst 1 g. of 10% palladium on charcoal. The compound absorbed 82% of the theoretical amount of hydrogen. The catalyst was removed by filtration and the ethanol removed by distillation. Distillation of the residue through a 10-in., helix-packed column yielded 8 g. of a saturated derivative, b. p. 110° (18 mm.), $n^{20}D$ 1.4280.

Anal. Calcd. for $C_7H_{11}O_2N$: C, 59.56; H, 7.86; N, 9.92. Found: C, 58.89; H, 7.21; N, 9.65.

Six grams of the compound was added to a solution of 5 g. of sodium hydroxide in 20 ml. of distilled water in a 100-ml. round-bottom flask fitted with a reflux condenser. The mixture was refluxed for two hours, after which it was cooled in an ice-bath and 9 ml. of 50% sulfuric acid slowly added. The acidified solution was again refluxed for two hours. The organic layer was separated, and the aqueous layer extracted with two 15-ml. portions of benzene. The combined extracts and the original layer were dried over anhydrous magnesium sulfate, the drying agent removed by filtration, and the residue distilled through a 6-in. Vigreux column, giving 2.5 g. of a clear liquid, b. p. 197°, $n^{20}D$ 1.4320, d^{20}_4 1.0570.

Anal. Calcd. for $C_5H_8O_2$: C, 59.98; H, 8.05. Found: C, 59.70; H, 7.73.

Adams and Rogers[4a] report the following constants for α-methylbutyrolactone: b. p. 200–201°, $n^{24}D$ 1.4282, d^{26}_4 1.047. A hydrazide of this material was prepared by treating 1.0 g. with 0.5 g. of 85% hydrazine hydrate in 10 ml. of absolute ethanol. The mixture was refluxed for eight hours and the hydrazide isolated by distillation,[8] b. p. 72–75° (12 mm.). Recrystallization of this material from ethyl acetate yielded white crystals, m. p. 90–91°. This corresponds to the melting point reported by Cavallito and Haskell,[4b] for the hydrazide of α-methylbutyrolactone.

Anal. Calcd. for $C_5H_{12}O_2N_2$: C, 45.43; H, 9.15; N, 21.20. Found: C, 45.70; H, 9.00; N, 20.78.

Pyrolysis of Benzoate of Methyl Vinyl Ketone Cyanohydrin.—Into the hot tube heated to 550° was dropped 169.5 g. of melted benzoate at a rate of one drop every two seconds using some nitrogen gas as a diluent. There was obtained by distillation of the pyrolysis mixture 7 g. (10%) of impure 2-cyanobutadiene, b. p. 24–31° (30 mm.). The remaining residue was washed several times with 5% sodium bicarbonate solution, and then twice with 100 cc. of 5% sodium hydroxide solution. The acid-free material was dried over anhydrous sodium sulfate and distilled from an oil-bath at high vacuum. A small amount of oil with an ester-like odor, b. p. 73–81° (5 mm.), came over first and then 12 g. of liquid, b. p. 150° (1 mm.), $n^{20}D$ 1.5315. This compound is nearly odorless and remained a liquid. It is isomeric with the original benzoate.

Anal. Calcd. for $C_{12}H_{11}O_2N$: C, 71.62; H, 5.51; N, 6.96. Found: C, 70.69; H, 5.28; N, 7.37.

Summary

Pyrolysis of the acetate of methyl vinyl ketone cyanohydrin gives a 27% yield of 2-cyano-1,3-butadiene but the major portion of the ester undergoes an allylic rearrangement to yield 1-acetoxy-3-cyano-2-butene. A similar rearrangement has been observed with the corresponding benzoate.

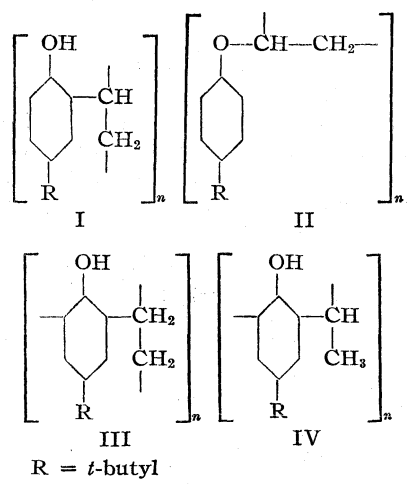
The Pyrolysis of Koresin[1]

BY J. W. LEMAISTRE AND R. B. SEYMOUR

Koresin, a synthetic resin used as a tackefier for synthetic rubber, is made[2,3] by condensation of acetylene with 4-*t*-butylphenol. Probable formulations for this resin include structures I–IV.[4]

The possibility of the polymeric material having structure I led us to study the pyrolysis of Koresin as a source of hydroxybutylstyrene. It has been shown[5,6] that vinyl polymers are thermally decomposed into the corresponding monomers or low polymers.

The pyrolysis of Koresin at 300–400° did not produce a substituted styrene but gave 55% (by weight) of 4-*t*-butylphenol, 20% of alkali-insoluble distillate and 25% of tarry non-volatile residue. The yield of 4-*t*-butylphenol was thus 65% of the theoretical.[4]



R = *t*-butyl

(2) G. M. Kline, *Modern Plastics*, **23** [11], 151 (1946).

(3) A. O. Zoss, W. E. Hanford and C. E. Schildknecht, paper presented at the Sept. 1947 A. C. S. meeting, New York.

(4) Actually an excess of acetylene over the 1:1 molar ratio indicated by these structures is used in manufacture. The 1:1 ratio was, however, assumed for calculations of yields and analyses.

(5) R. B. Seymour, *Ind. Eng. Chem.* **40**, 524 (1948).

(6) G. B. Bachman, *et al.*, *J. Org. Chem.*, **12**, 108 (1947).

Since this result did not conform to structure I, some other reactions of Koresin were studied. In carbon tetrachloride solution, Koresin reacted with 0.94 mole of bromine per structural unit of the resin with evolution of hydrogen bromide. The product was a brittle, mahogany-colored resin which lost 60% of its bromine on refluxing for one and one-half hours with 1 *N* alcoholic potassium hydroxide. The brominated resin also lost hydrogen bromide on heating above 180° and, on further heating, gave an alkali-soluble distillate from which 4-*t*-butylphenol was isolated.

The presence of free hydroxyl groups in Koresin was confirmed by acetylation. The saponification equivalent of the ester indicated an acetyl content of 87% of that calculated.[4] This ester was fairly stable to pyrolysis but broke down at 340–400° to give a distillate which was partly soluble in alkali. While the alkali-soluble portion could not be crystallized, 4-*t*-butylphenol was isolated from the distillate by saponification of the alkali-insoluble portion.

The data obtained for acetylation and the degree of bromination are not in accord with structure II nor does the lability of the bromine introduced agree with either I or III The ease of bromination is thought to accord better with structure IV which contains a tertiary carbon atom than with III which was proposed by Kline.[2] Structure II would probably produce the alkylphenol on pyrolysis if its decomposition was similar to simple alkyl aryl ethers[7] but pyrolysis of the brominated product should yield a bromophenol. From an analogy with bibenzyl, structure III would be expected to yield a *t*-butylphenol having methyl groups *ortho* to the hydroxyl group.[8] While structure IV which has also been proposed by Zoss, *et al.*,[3] appears most probable for Koresin, the resin may not be homogeneous and it is not excluded that the other structures may occur to some extent. Structure IV also resembles the formulation of aldehyde-alkyl phenol resins[9] which are likewise said to be effective tackefiers for synthetic rubber. This structure is also in accord with that proposed by Nieuwland and Vogt[10] for the product obtained by the condensation of benzene and acetylene.

Experimental

Pyrolysis of Koresin.—Koresin[11] (20.0 g.) was heated rapidly over a free flame in a distilling flask. Significant formation of volatile material began at a pot temperature of 300°. In the course of one hour the temperature was raised from 300 to 400°. During this time there was steady distillation of an amber oil. Little uncondensable gas was formed. The residue was viscous and froze on cooling to a brittle, black solid, 4.9 g. The distillate was extracted with 5% sodium hydroxide solution, leaving an insoluble amber oil, 4.0 g. On acidification of the alkaline wash a pale yellow oil separated and soon crystallized, 11.0 g. The latter product was recrystallized from *n*-heptane and identified as 4-*t*-butylphenol (yield, 64%) by melting point, 97–98°, as well as by conversion to the benzoate, m. p. 81°, mixed with an authentic sample, 81°.

Bromination of Koresin.—To 1.76 g. of Koresin dissolved in 15 g. of carbon tetrachloride was added a solution of 2.40 g. of bromine (0.0150 mole) in 50 g. of carbon tetrachloride. The mixture soon gave off colorless fumes. After two hours at room temperature, the solution was washed with excess potassium iodide solution. Titration of the latter with standard thiosulfate showed 0.0056 mole of unreacted bromine to have been present, corresponding to a consumption of 0.0094 mole. The carbon tetrachloride solution was evaporated on a water-bath to a mahogany-colored brittle resin which was taken up in dioxane and evaporated again to remove carbon tetrachloride. The residue dried at 100° weighed 2.5 g. (98%). A weighed sample was hydrolyzed by refluxing for 1.5 hours with 1 *N* potassium hydroxide in ethanol and the solution was titrated with standard acid. Alkali consumption was 0.0023 mole per gram of brominated Koresin, calcd. 0.00376 if all the bromine were removed by alkali.

Pyrolysis of Brominated Koresin.—To a solution of 17.6 g. of Koresin in 150 g. of carbon tetrachloride was added dropwise 16.0 g. of bromine. The solution was let stand overnight and then washed successively with water, sodium sulfite solution and water. The solvent was distilled and the residue destructively distilled. When the still temperature reached 180–190°, evolution of hydrogen bromide began and continued as the temperature was raised. Between 270 and 400° an amber liquid distilled, 6.5 g. The residue was a spongy black tar, 9.9 g. The gas absorbed in a water trap was shown by titration with silver nitrate to contain 0.048 mole hydrogen bromide. The liquid distillate was nearly all soluble in 5% sodium hydroxide and the oil separated by acidification of the alkaline solution partly crystallized on standing. The crystals were identified as 4-*t*-butylphenol after recrystallization from *n*-heptane by melting point, 97–98°, and mixed melting point, 97–99°.

Acetylation of Koresin.—Koresin (17.6 g.) was dissolved in 50 g. of acetic anhydride containing 0.5 g. of anhydrous sodium acetate. The mixture was refluxed for two hours and then poured into cold water. The precipitated resin was taken up in 100 ml. of ethyl ether and washed well with sodium hydroxide solution and then with water. The ether layer was dried over anhydrous calcium sulfate and evaporated to yield a brittle, yellow resin, 21 g. (96%); saponification equivalent (by refluxing with 1 *N* potassium hydroxide in ethanol for one hour), 251, calcd., 218.

Pyrolysis of Acetylated Koresin.—Acetylated Koresin (15 g.) was heated in a distilling flask. Decomposition began at a still temperature of 340° and continued slowly as the temperature was raised to 400°. The residue was a black tar, 6 g. The oily distillate, 6.5 g., smelled of acetic acid. The distillate was washed with sodium hydroxide solution and the insoluble portion, 4.5 g., was refluxed for one-half hour with 25 ml. of 10% potassium hydroxide in ethanol. Water was added, the ethanol distilled off and the residual solution acidified. The separated oil slowly crystallized and, after recrystallization from *n*-heptane, was identified as 4-*t*-butylphenol by melting point, 96–97°, and mixed melting point, 97°.

Summary

1. The principal product of pyrolysis of Koresin is 4-*t*-butylphenol.

The Mechanism of the Methane Fermentation

BY A. M. BUSWELL AND F. W. SOLLO, JR.[1]

Three possible mechanisms for the methane fermentation of acetic acid are suggested by the findings and reasoning of previous workers in this field. From the work of Omelianskii[2,3] and Söhngen[4,5] we would expect a preliminary decomposition of the acetic acid to hydrogen and carbon dioxide, with subsequent reduction of carbon dioxide to methane by the hydrogen. Barker's work[6] indicates that carbon dioxide would be directly reduced to methane and the acetic acid thereby oxidized to carbon dioxide. The reasoning of Buswell and Neave[7] leads to simple decarboxylation as the mechanism.

The first mechanism was based on the similarity of the hydrogen and methane fermentations, but the low concentration of hydrogen found in the gas from the methane fermentation of acetic acid is evidence against this mechanism. If we examine the data of Symons and Buswell[8] we find that only 3.5 liters of methane was formed over a period of one hundred days with regular circulation of hydrogen and carbon dioxide through a culture of 2.0 liters total volume. In the same time, such a culture fermenting acetic acid could be expected to form 75[8,9] liters of methane.

The second mechanism avoids this weakness by implying a direct reduction of the carbon dioxide, without the intermediate stage of free hydrogen. This mechanism seems rather indirect and involved, but parallels that found by Barker in the oxidation of alcohols.

The last mechanism appears to be the simplest and most direct. A similar reaction *in vitro* is the chemical decarboxylation of sodium acetate with sodium hydroxide. The internal oxidation reduction could be effected by the transfer of the hydrogen atom from the carboxyl to the methyl group. Evidence against this mechanism is found in Thayer's work.[10] He reasoned that this reaction was a decarboxylation, and that the fermentation of propionic and butyric acids should yield ethane and propane. However, his results were entirely negative, for no hydrocarbon other than methane was found. This has been confirmed in all work where the gas was analyzed. Therefore, if we are to accept this mechanism of simple decarboxylation for acetic acid, it must be as a special case, not applicable to the higher fatty acids.

Barker, Ruben and Kamen[11] found evidence for the reduction of carbon dioxide in the fermentation of acetic acid through the use of $C^{11}O_2$, but they stated that the radioactive methane found might have been due to the presence of methanol carried over with the inoculum. It should also be mentioned that these workers were using a pure culture of *Methanosarcina methanica*, and that even if methane should be formed by reduction of carbon dioxide in that case, that might not be the predominant mechanism in the general methane fermentation where a mixed culture is used.

This question of the mechanism of fermentation of acetic acid is of more than academic interest. Culture failure is almost invariably accompanied by, or preceded by, the accumulation of high concentrations of volatile organic acids, largely acetic. Thus any information concerning this mechanism might lead to methods of treatment or operation which would alleviate or prevent this accumulation of acids and possibly the failure of many cultures.

It may be seen at once that if the carbon of the carbon dioxide were marked isotopically, this question of mechanism could be settled. If either of the mechanisms involving reduction of carbon dioxide were involved, the methane produced should be similarly marked. If the reaction were a simple decarboxylation, the methane should not be so marked.

Radioactive C^{14} was chosen as the most easily handled of the carbon isotopes which could be used for this purpose.

Experimental

The radioactive carbon was obtained through the Manhattan district in the form of barium carbonate. This material was converted to sodium carbonate by acidification with perchloric acid and absorption of the carbon dioxide in a solution of sodium hydroxide. The solution resulting was found to yield 3.24×10^5 counts per minute per ml. One ml. of this solution was added to each culture before feeding and incubating.

The fermentations were carried out in 30-ml. round-bottomed flasks, connected to brine displacement gas collectors. Fifteen ml. of inoculum was taken from a digester which had been fermenting acetic acid for several months. To this was added 1.00 ml. of the radioactive sodium carbonate solution, and 1.0 ml. of 1.0% acetic acid. To the first three cultures, similar portions of acetic acid were added after two days of incubation, and again after the third day. The fourth culture was fed only once and analyzed after two days.

The first culture was analyzed after four days of incubation. The other two were kept in the incubator until they were analyzed, total incubation time being six days for the second and twelve days for the third.

The culture to be analyzed was acidified and boiled to free the dissolved carbon dioxide and to drive the gas over into the gas collector. Oxygen was added and after mixing, the sample was drawn through a train in which the carbon dioxide was first absorbed on carbon dioxide free Mikobite. A catalyst[12] of copper and cobalt oxides impregnated on porcelain, kept at 550°, effected the oxidation of the methane to carbon dioxide and water. This carbon dioxide was similarly absorbed. The carbonate was washed off the respective portions of Mikobite with hot water and precipitated with barium nitrate.

These operations were carried out in a carbon dioxide free atmosphere.

The precipitated barium carbonate was suspended in ethanol and deposited on an aluminum sample pan, by transferring to a brass tube, at the bottom of which was fastened the sample pan. The alcohol was evaporated under an electric heat lamp.

The samples thus prepared were counted with a conventional type Geiger–Mueller counter. The tube used was a pressure seal type mica window counter (Radiation Counter Laboratories, Mark 1, Model 2A, window thickness 2.19 mg. per sq. cm.). Background counts averaged from 40 to 45 counts per minute.

Correction for geometry was unnecessary, since only one geometry was used, and no correction for absorption by the window was made since the same tube was used throughout. The data of Yankwich, Rollefson and Norris[13] were used to calculate the correction of self absorption.

The specific activity of the methane was calculated by dividing the total counts by the weight of barium carbonate derived therefrom. The average specific activity of the carbon dioxide was calculated by dividing the average of the initial and final counts by the average of the initial and final equivalent weights of barium carbonate. From these, the activity ratio between the methane and the carbon dioxide, on the basis of the activity of the barium carbonate resulting, was calculated.

The activity ratio was found to vary with the time of incubation. It was for this reason that the additional sample with short incubation time was analyzed. The results are listed in Table I below.

TABLE I

Culture number	1	2	3	4
Days incubated	4	6	12	2
Acetic acid fed (g.)	0.0315	0.0315	0.0315	0.0105
CO_2 at start (mg. $BaCO_3$)	102.5	103.2	110.4	95.2
CO_2 at end (mg. $BaCO_3$)	197.4	215.5	226.4	136.8
Total counts per minute added	3.24×10^5	3.24×10^5	3.24×10^5	3.24×10^5
Activity of CO_2 at end (total counts per min.)	.....	2.58×10^5	2.48×10^5	2.50×10^5
Average activity of CO_2 (counts/min./mg. $BaCO_3$)	1913	1805	1705	2474
Methane produced (mg. $BaCO_3$)	94.9	112.3	116.0	41.6
Total activity of CH_4 (counts/min.)	3415	6324	9903	549
Activity of CH_4 (counts/min./mg. $BaCO_3$)	36	56.3	85.4	13.2
Activity of CH_4/activity of CO_2	0.0188	0.0312	0.0501	0.0053

Discussion

If the mechanism of the fermentation of acetic acid involved the reduction of carbon dioxide to methane, the barium carbonate derived from the methane should have the same specific activity as the carbon dioxide had during the fermentation. The data show that the activity of the methane is only a few hundredths of that of the carbon dioxide, which makes it immediately apparent that the methane is derived from the acetic acid itself.

Calculation of the average activity of the carbon dioxide is an approximation, since we do not have an accurate measure of the activity at the various stages of methane production. The average figure used for this activity was thought to be the nearest estimate possible with the data obtained. It must be noted though, that even if we assumed the lowest possible activity, that found at the end of the incubation period, the ratio of the activities would be only slightly raised. For example, in culture no. 2, where the ratio found was 0.0312, use of the lower total activity would raise this figure to only 0.0358.

In Fig. 1, the ratio of activities is plotted against time of incubation. This curve indicates that there is a lag period, with a subsequent gradual rise in the activity ratio. It seems likely that from this we can assume that very little carbon dioxide is directly reduced to methane in this fermentation, and that the source of the radioactive methane is an indirect fixation of carbon dioxide, with subsequent decomposition of the material formed therefrom. Whether we assume fixation into cell

material with later autolysis, or the formation of endogenous compounds, makes little difference. In any case we must conclude that the predominant reaction in the methane fermentation of acetic acid does not involve reduction of carbon dioxide.

This work indicates that the methane is produced by some mechanism other than the reduction of carbon dioxide, and must therefore be derived from the acetic acid. A simple decarboxylation seems to be the most likely mechanism, but is not definitely established. It is still possible that some preliminary condensation might take place, with subsequent decomposition of the condensation product, but this point cannot be proved by this method of attack.

Summary

It was suggested by previous workers that the methane fermentation of acetic acid might proceed by reduction of carbon dioxide to methane, as was shown to be the case for several alcohols.

In order to determine whether or not this was the case, radioactive C^{14} was used to mark the carbon atom of the carbon dioxide. The gases resulting from the fermentation were separated and converted to barium carbonate for measurement of the radioactivity.

By comparing the activity of the methane and the carbon dioxide, it was shown that only a very small portion of the methane was derived from the carbon dioxide. By studying the relation of the amount of methane formed by reduction of carbon dioxide to the time of incubation, a correlation was found which was interpreted as indicating a slow reduction unassociated with the general fermentation, such as the formation of cell substance and subsequent autolysis. From this it was concluded that the acetic acid was fermented entirely, or very nearly so, without reduction of carbon dioxide, and that the methane is predominantly derived from the acetic acid and not from carbon dioxide.

Acylation Reactions with Organosilicon Compounds[1]

BY ROBERT A. BENKESER AND ROBERT B. CURRIE[2]

Apparently, the only attempt to carry out a Friedel–Crafts reaction involving an organosilicon compound is the work of Kipping.[3] He reported that if a compound like tetraphenylsilane is heated with aluminum chloride the only product isolated is silicon tetrachloride (80% yield). Viewed from the generalized Lewis concept of acids[4] this is not surprising since it has long been known that the aromatic carbon–silicon bond is readily cleaved by acidic reagents.[5–7] The electropositive silicon atom tends to combine with a more electronegative element than carbon when given the opportunity.

It has now been found that using the mild catalyst iodine, an acylation reaction can be carried out with certain organosilicon compounds. In the experiments herein reported, 2-thienyltrimethylsilane and 2-furyltrimethylsilane were acetylated with acetic anhydride at 50°. The yields were of the order of 20–25%. The equations indicate the general sequence of reactions with furan

The proof of structure of 2-acetyl-5-trimethylsilylfuran (IV) was accomplished by the hypoiodite degradation to the corresponding acid. This acid was identical with that obtained by the metalation of 2-furyltrimethylsilane (I) with *n*-butyllithium. Finally this acid (II) was converted to the known 5-bromo-2-furoic acid by treatment with bromine.

The thiophene sequence was essentially the same as that indicated above for furan except that metalation of thiophene with *n*-butyllithium is known to occur in the 2-position.[8] This established the structure of 2-thienyltrimethylsilane. The acid obtained from the metalation of this compound with *n*-butyllithium and from the hypoiodite degradation of 2-acetyl-5-trimethylsilylthiophene was shown to be 5-trimethylsilyl-2-thiophenecarboxylic acid by cleaving it with hydrogen chloride to the known 2-thiophenecarboxylic acid.

Experimental

2-Thienyltrimethylsilane.—To 84 g. (1.0 mole) of thiophene[9] was added 325 ml. of an ethereal solution of *n*-butyllithium[10] containing 0.98 mole of the organometallic.[11] The addition was made as rapidly as the evolved butane would allow. The mixture was refluxed three hours and then permitted to stand overnight at room temperature. Eighty grams (0.74 mole) of trimethylchlorosilane was added slowly and when the addition was complete the mixture was refluxed an additional three hours. After hydrolyzing with 10% sulfuric acid, the ether layer was separated and shaken with 10% sodium hydroxide. After drying over Drierite the ether was removed, and the residue was fractionated through a short, glass-spiral column. Eighty-six grams (75%) of a colorless oil was collected boiling at 159–160° (748 mm.), $n^{20}D$ 1.4966, d^{20}_4 0.945.

Anal. Calcd. for $C_7H_{12}SSi$: C, 53.8; H, 7.70. Found: C, 53.3; H, 7.78.

If the thienyllithium prepared above is carbonated the acid can be shown to be 2-thiophenecarboxylic acid[8] thus establishing the position of the trimethylsilyl group.

2-Acetyl-5-trimethylsilylthiophene.—A mixture of 30 g. (0.19 mole) of 2-thienyltrimethylsilane, 30 g. (0.29 mole) of acetic anhydride, and 0.25 g. of iodine[12] was heated for one hour at 50°. The dark solution was shaken with 10% potassium hydroxide until the washings were basic. Ether was added; the residue was washed several times with water and then with a concentrated solution of sodium thiosulfate. After drying over anhydrous sodium sulfate, the ether was removed and the residue was fractionated through a small glass-spiral column. Five grams (13%) of a yellow oil boiling at 104–105° (4 mm.) was collected, $n^{20}D$ 1.5289, d^{20}_4 1.028.

Anal. Calcd. for $C_9H_{14}OSSi$: Si, 14.1; C, 54.5; H, 7.07. Found: Si, 13.7; C, 54.3; H, 7.08.

The semicarbazone of this ketone was prepared in the conventional manner and it melted with decomposition at 217–220°.

Anal, Calcd. for $C_{10}H_{17}ON_3SSi$: N, 16.46. Found: N, 16.30 and 16.47.

5-Trimethylsilyl-2-thiophenecarboxylic Acid.—To 8 g. (0.05 mole) of 2-thienyltrimethylsilane was added 54 ml. of an ethereal solution of *n*-butyllithium[10] containing 0.05 mole of the organometallic.[11] The mixture was refluxed four hours and then carbonated by pouring jet-wise onto powdered Dry Ice. After allowing the mixture to warm to room temperature, water was added with vigorous stirring. The clear ether layer was discarded and, upon acidifying the basic water layer with concentrated hydrochloric acid, 6.3 g. (62%) of 5-trimethylsilyl-2-thiophenecarboxylic acid separated and after crystallization from dilute ethanol it melted at 134–135°.

Anal. Calcd. for $C_8H_{12}O_2SSi$: Si, 14.0. Found: Si, 13.7.

This same acid was isolated (mixed m. p.) when 2-acetyl-5-trimethylsilylthiophene was treated with sodium hydroxide and iodine in a typical iodoform reaction.

2-Thiophenecarboxylic Acid.—Approximately 0.5 g. of 5-trimethylsilyl-2-thiophenecarboxylic acid was dissolved in 15 ml. of benzene, and while refluxing the solution, hydrogen chloride was bubbled through for one hour. Extraction with 10% sodium hydroxide, followed by acidification of the water layer gave a crystalline solid melting at 126–127° which showed no depression with an authentic sample of 2-thiophenecarboxylic acid. This establishes the position of both the carboxyl and acetyl group.

2-Furyltrimethylsilane.—To 68 g. (1.0 mole) of furan[13] was added 325 ml. of an ethereal solution of *n*-butyllithium[10] containing 0.98 mole of the organometallic.[11] The remainder of the directions are identical with those described above for 2-thienyltrimethylsilane. Rectification of the residue gave 53 g. (52%) of a colorless oil boiling at 124–125° (750 mm.), $n^{20}D$ 1.4470, d^{20}_4 0.880.

Anal. Calcd. for $C_7H_{12}OSi$: C, 60.0; H, 8.58. Found: C, 59.5; H, 8.71.

2-Acetyl-5-trimethylsilylfuran.—A mixture of 35 g. (0.25 mole) of 2-furyltrimethylsilane, 28.4 g. (0.27 mole) of acetic anhydride and 0.3 g. of iodine[12] was heated with stirring to an internal temperature of about 50°. At this point the reaction became exothermic and some cooling and later heating was necessary to keep the temperature between 45–55° for one hour. At the end of this time 15 ml. of water was added, and after stirring for a few minutes the dark solution was shaken with small quantities of 10% potassium hydroxide until the washings were basic. It was washed once with water and again with a concentrated solution of sodium thiosulfate. Upon removal of the solvent and rectification of the residue there was obtained 11.3 g. (25%) of a yellow oil (darkens rapidly on standing) boiling at 78.5–79° (3–4 mm.), $n^{20}D$ 1.4925, d^{20}_4 0.978.

Anal. Calcd. for $C_9H_{14}O_2Si$: Si, 15.4. Found: Si, 15.0.

The semicarbazone of this ketone, prepared in the usual way, melted at 200–201°.

Anal. Calcd. for $C_{10}H_{17}O_2N_3Si$: N, 17.56. Found: N, 17.72 and 17.59.

5-Trimethylsilyl-2-furoic Acid.—To 10 g. (0.07 mole) of 2-furyltrimethylsilane was added 67 ml. of an ethereal solution of *n*-butyllithium[10] containing 0.07 mole of the organometallic.[11] The mixture was refluxed four hours, and then allowed to stand overnight at room temperature. The mixture was carbonated and worked up in a manner similar to that described for 5-trimethylsilyl-2-thiophenecarboxylic acid. After reprecipitating the acid from 10% potassium hydroxide and crystallizing it twice from dilute ethanol, 8 g. (62%) of a light tan solid was obtained melting at 110–111°.

Anal. Calcd. for $C_8H_{12}O_3Si$: Si, 15.2. Found: Si, 14.9.

This same acid was isolated (mixed m. p.) when 2-acetyl-5-trimethylsilylfuran was treated with sodium hydroxide and iodine.

5-Bromo-2-furoic Acid.—A mixture of 1 g. (0.005 mole) of 5-trimethylsilyl-2-furoic acid and 1.5 g. (0.009 g. atom) of bromine in 15 ml. of dry carbon tetrachloride was refluxed one hour. The solid which had separated was

filtered off and crystallized from hot water. It melted at 185.5–187° and was shown to be identical (mixed m. p.) with an authentic specimen of 5-bromo-2-furoic acid prepared according to the method of Whittaker.[14]

Summary

2-Furyltrimethylsilane and 2-thienyltrimethylsilane were synthesized from 2-furyllithium and 2-thienyllithium. The reaction of acetic anhydride with the above organosilicon compouunds, using iodine as the catalyst, gave 2-acetyl-5-trimethylsilylfuran and 2-acetyl-5-trimethylsilylthiophene, respectively.

The Mechanism of the Nitration of Anisole

BY R. M. SCHRAMM AND F. H. WESTHEIMER

In the course of an investigation of the oxynitration of benzene,[1] the nitration of several phenols and of anisole was studied. The nitration of anisole leads to the formation of a mixture of nitroanisoles[2] and of nitrophenols[3] in proportions which depend upon experimental conditions. It is here shown that the nitration of anisole in dilute nitric acid solution is nitrite-catalyzed and that the nitrosoanisoles are probably intermediates in the reaction. These facts are of current interest because Bunton, Hughes, Ingold and Reed[4] have recently found that, under certain conditions, nitrosophenols are likewise intermediates in the nitration of phenols to nitrophenols.

More precisely, anisole has been found to react rapidly with 40 or 50% nitric acid containing a little nitrous acid, but fails during many hours to react with nitric acid containing urea.[5] When anisole is nitrated with 40% nitric acid (containing nitrous acid), the principal products are nitrophenols; when more concentrated (*e. g.* 60%) nitric acid is used, the principal products are nitroanisoles. The quantitative results of several experiments are reported in Table I.

TABLE I

(5) This nitration is thus similar to that of phenol; see Martinsen, *Z. physik. Chem.*, **50**, 385 (1905).

p-Nitroanisole cannot be an intermediate in the nitrite-catalyzed nitration of anisole to nitrophenols because, if this substance is added to a nitrating mixture which reacts rapidly with anisole, it may be quantitatively recovered. On the other hand, experiments with *p*-nitrosoanisole show that it reacts readily with the same nitrating mixture.[6] The products obtained by the nitration of *p*-nitrosoanisole under a wide variety of conditions parallel those obtained from anisole under corresponding conditions (see Table II). Thus it appears that nitrosoanisole is an intermediate in the nitrite-catalyzed nitration of anisole.

TABLE II

THE REACTION OF *p*-NITROSOANISOLE WITH NITRIC ACID AND NITRITE

Conc. HNO_3, %	Conc. HNO_2, m./l.	Time of addition of anisole in minutes	Yield of nitroanisoles, % of theoretical	Yield of 2,4-dinitrophenol, % of theoretical

50	.18	1	62	29
50	.18	10	54	36
50	.18	70	60	30
60	.18	60	91	5

Although the proportions of the two products (nitroanisoles and nitrophenols) obtained from *p*-nitrosoanisole are about the same as those obtained from anisole, there is no exact correspondence between the two nitrations. Several reasons for this discrepancy may be suggested. In the first place, anisole, when nitrated with nitric acid and nitrite, must yield a certain amount of *o*-nitrosoanisole[2] as an intermediate, and this isomer would not necessarily give further reaction products in the same proportions as does *p*-nitrosoanisole. In the second place, the actual nitrite concentrations are not exactly those given in the two tables, because, during the reaction, anisole and nitrosoanisole produced different amounts of oxides of nitrogen. Thirdly, the addition of gross quantities of *p*-nitrosoanisole to the reaction mixture rather than the formation of this compound

(6) *Cf.* Bayer and Knorr, *Ber.*, **35**, 3034 (1902).

in situ (as in the reaction of anisole with nitric acid and nitrite) may have some effect on the course of the reaction. However, this effect is probably unimportant, since the period of addition of *p*-nitrosoanisole may be varied from one to seventy minutes without materially affecting the proportions of the reaction products.

Experimental

The Effect of Nitrite on the Reaction of Anisole with Nitric Acid.—(1) Anisole (20 g.) was added dropwise to 400 cc. of 40% nitric acid containing approximately 0.04 m./l. of nitrous acid. The addition required about half an hour; the reaction mixture was held at 30° and stirred for forty-eight hours. This long reaction time was necessary to convert all the mononitrophenols first formed into the more readily isolated dinitrophenol.[1] The mixture was then chilled in ice and filtered. The crude product obtained weighed 26.5 g. and melted at 100–108°. By recrystallization of this material from alcohol, 20 g. (59%) of pure dinitrophenol (m. p. 112–114°) was obtained. The identity of this compound was established by its melting point, the melting point of its mixture with an authentic sample of 2,4-dinitrophenol, and by the preparation of 6-bromo-2,4-dinitrophenol, m. p. 117–118°. In this experiment, the reaction mixture was not worked up for nitroanisoles; the product or products which arise from the methyl group of anisole have not been determined.

(2) In a second experiment, anisole (20 g.) was added dropwise over a period of one-half hour to 400 cc. of 40% nitric acid to which (one hour previously) 4 g. of urea had been added. After the mixture had been stirred for eighteen hours at about 30°, the reaction mixture was transferred to a separatory funnel and extracted with three successive 50 cc. portions of benzene. The benzene extract was washed with 60 cc. of water and dried over anhydrous sodium sulfate. Distillation from a small Claisen flask yielded 16.3 g. of anisole (81% of that used) boiling in the range 153–155°. There was no high-boiling residue.

(3) Seventy-five cc. of 50% nitric acid was allowed to stand with 1 g. of urea for three hours. Then anisole (about three g.) was added. The reaction mixture, after standing at room temperature for twelve hours was decidedly colored. The cause of the color was not determined; however, the extent of reaction was slight, since a three-drop sample of the mixture, when dissolved in a large excess sodium hydroxide solution, gave only a negligible yellow color. This test for nitrophenols is quite sensitive; and will easily reveal the presence of five parts per million of these compounds.

(4) One-hundred cc. of 50% nitric acid containing 0.1 m./l. of nitrous acid was mixed with three grams of anisole. The reaction mixture, after standing for two minutes at room temperature, was very dark. A three-drop sample of this reaction mixture, when dissolved in excess sodium hydroxide, gave a strong yellow color. The color was identified as that of nitrophenols, since (a) it was much more intense than that of a similarly diluted but neutral sample of the reaction mixture and (b) the coloring material had the indicator properties of nitrophenols.

(5) One-hundred cc. of 60% nitric acid containing 0.1 m./l. of nitrous acid was mixed with 0° with 1 g. of anisole. Reaction occurred instantly and proceeded autocatalytically. These conditions are probably not very different from those which were used for the preparation nitration of anisole to a mixture of ortho and para nitroanisoles.[2]

(6) Five-hundred cc. of 60% nitric acid was allowed to stand for an hour with 8 g. of urea; the solution was cooled to 0°, where urea nitrate crystallized. Three grams of anisole was then added. After two hours at 0°, 200 cc. of water was added and the mixture extracted with three 50-cc. portions of benzene. The benzene extract was washed and then fractionated through a short (10″) distilling column (tantalum-wire spiral type). After all the benzene was removed, the residue was distilled from a small Claisen flask. Anisole (1.9 g. distilling at 152–155°) was recovered. A small high boiling residue presumably contained nitro anisoles. At room temperature, 60% nitric acid containing urea gives no evidence of reaction for several minutes; then vigorous and autocatalytic nitration (with evolution of oxides of nitrogen) occurs.

The Reaction of *p*-Nitroanisole with Nitric Acid in the Presence of Nitrite.—Nine grams of *p*-nitroanisole was stirred at 50° for four and a half hours with 200 cc. of 50% nitric acid which contained 0.017 m./l. of sodium nitrite. When the mixture was filtered, 8.5 g. of *p*-nitroanisole, m. p. 50–52°, was recovered.

In a second experiment, *p*-nitroanisole (8.0 g.) was stirred at 50° for four and one-half hours with 200 cc. of 70% nitric acid containing 0.034 m./l. of nitrous acid. The reaction mixture in this case was homogeneous, whereas a slurry was obtained in the first experiment. When the mixture was cooled, diluted with water and filtered, 7.5 g. of *p*-nitroanisole, (identified by melting point and by the melting point of a mixture with an authentic sample) was recovered.

The Products of the Reaction of Anisole and of *p*-Nitrosoanisole with Nitric Acid and Nitrite.—Anisole (or *p*-nitrosoanisole) was added dropwise to about 200 cc. of a reaction mixture composed of nitric and nitrous acids (see Table I and II). During the addition, the reaction mixture was stirred vigorously and maintained at 50°. The amount of anisole or *p*-nitrosoanisole added was in each case between 3 and 4 g. After the addition was complete, the reaction mixture was heated long enough[1] to convert any mononitrophenols which had been formed into the more readily isolated 2,4-dinitrophenol. The mixture was then cooled and extracted with four successive 100-cc. portions of benzene. The benzene extract was concentrated to a volume of about 100 cc., and was then extracted with about 100 cc. of aqueous triethanolamine solution. Acidification of the aqueous extract threw down a precipitate of 2,4-dinitrophenol, which was filtered off, dried in a vacuum desiccator and weighed. The nitroanisole fraction was obtained from the residual benzene solution by removing the benzene under reduced pressure at room temperature.

In several instances, the above procedure was slightly varied. When the yield of nitroanisoles was relatively high, practically pure *p*-nitroanisole crystallized from the reaction mixture when it was cooled, and was recovered by filtration. This product was identified by its melting point and by the melting point of a mixture with an authentic sample of *p*-nitroanisole. In the reaction with *p*-nitrosoanisole, the nitroanisole isolated from the benzene extract was also practically pure *p*-nitroanisole. In the reactions with anisole, however, the product similarly isolated was an oil, probably a mixture of *o*- and *p*-nitroanisoles. These mixtures were usually worked up for *p*-nitroanisole, but were tested for the presence of nitrophenols only by their color reaction with alkali. In no case was an appreciable amount of nitrophenol found. The presumption that these oils were actually mixtures of *o*- and *p*-nitroanisoles was based first on the comparison with similar preparations previously reported.[2] In addition (in one instance), 1.40 g. of pure *p*-nitroanisole was isolated from 3.13 g. of the oil by recrystallization from aqueous alcohol. In another experiment, where the reaction with anisole gave a high yield of nitroanisoles, the initial yield of crystals from the reaction mixture was collected and found to be practically pure *p*-nitroanisole. In this case, 2.00 g. of *p*-nitroanisole was obtained from a total yield of 2.96 g. of crude oil.

Summary

The nitration of anisole in 40, 50 and 60% nitric acid is nitrite-catalyzed. The reaction product is a mixture of nitroanisoles and nitrophenols, in which the former compounds predominate when

60% acid is used and the latter when 40% acid is used. Under the same experimental conditions the same products can be obtained in roughly the same proportions from both nitrosoanisole and from anisole. This fact strongly indicates that the nitrosoanisoles are intermediates in the nitrite-catalyzed nitration of anisole.

The Vapor Pressures and Some Related Quantities of Pentene-1 from 0 to 200°

BY H. O. DAY AND D. E. NICHOLSON WITH W. A. FELSING

Introduction

The determination of the thermodynamic properties of hydrocarbons has been a part of the research program of this laboratory for a number of years. Thus, heat capacities, heats of vaporization, and compressibilities for a number of hydrocarbons have been determined and reported.[1] The increasing importance of olefinic hydrocarbons has indicated a study of the pentenes and this report covers a portion of the work on pentene-1. In determining *p–v–t* data on both gaseous and liquid pentene-1, it was found that adequate data on vapor pressures over the range of temperatures from room temperature to the vicinity of its critical temperatures were lacking. This paper, hence, reports the experimentally determined vapor pressures for the range 0 to 200°.

Previous Investigations

The existing vapor pressure data have been examined critically by Stull[2] and he has reported the most probable values for the temperature range of −80.4 to 30.1°.

The normal boiling points, as recorded in the literature, differ considerably, due probably to differences in the purity of the samples of pentene-1 used. The most probable value, as selected by Stull[2] and as reported by Sherrill and Walter[3] is 30.1°, though the value of 29.97° was chosen by the A.P.I. Project No. 44.[4]

Methods and Apparatus

The dead-weight piston gage apparatus used in this Laboratory in *p–v–t* investigations was limited to a low pressure value of about 5 atmospheres, as determined by the weight of the piston and scale pan. Hence, vapor pressures up to 7.5 atmospheres were determined by means of a glass-contained compound mercury manometer, as described by Wilson,[5] attached to a static vapor pressure determining apparatus used by Felsing and Thomas.[6] The loading device employed by Felsing and Durban[7] was used to introduce pure, air-free pentene-1 into the piezometer at about −65°. A reasonable fraction, usually one-third, of the liquid was then evaporated out of the piezometer into the vacuum system to insure complete freedom from dissolved gases. An internal stirrer, actuated by a solenoid and metronome, served to prevent temperature gradients in the liquid. The entire apparatus was constructed of Pyrex glass. Mercury levels in the manometer were determined by means of a Gaertner cathetometer which could easily be read to 0.05 mm. Temperatures within the Dewar-flask bath were measured by short range mercurial thermometers calibrated by the National Bureau of Standards. The overall precision of these measurements was ±0.3%.

For vapor pressures from about 6 to 40 atmospheres, a dead-weight piston gage previously described,[8] was employed. Thermostat temperatures were controlled to ±0.005° by means of a platinum resistance thermometer in conjunction with a Mueller bridge and a photoelectric cell relay. The actual thermostat temperature was simultaneously determined by the resistance thermometer (calibrated by the National Bureau of Standards). In determining the vapor pressures, the volume of the vapor phase was varied from 0.2 to 15 cc.; this change in vapor volume had no effect on the observed pressures, indicating a high purity of the pentene-1. Three separate runs on three separate fillings gave closely agreeing values; the precision of the measurements was within ±0.1%.

The region above 200° is *not* considered in this paper, since the critical pressure is in the neighborhood of 201°; this critical region and liquid and vapor compressibilities will be reported in a later paper.

Material Used

The pentene-1 for this investigation was obtained from the Phillips Petroleum Company. The National Bureau of Standards, from freezing point data on representative samples of this lot, reported a purity of 99.34 ± 0.40 mole per cent. The most probable impurity was isopentane. The densities of the liquid under its own vapor pressure as a function of the temperature over the range 0–50° are represented by the equation

$$d(\text{g./cc.}) = 0.6630 - 0.001034t$$

where t is in degrees centigrade. The normal boiling point, as calculated from the vapor pressure equation, was found to be 30.07 ± 0.02°.

Treatment of Data

The experimental data were plotted to large scale as log p (mm.) against the reciprocal of the absolute temperature. Three linear equations were fitted by the method of least squares to separate portions of the line

(1) 0– 35°: $\log_{10} p$ (mm.) $= 7.40607 - 1372.194/T$
(2) 40– 95°: $= 7.31561 - 1342.407/T$
(3) 100–170°: $= 7.26782 - 1324.730/T$

The ice-point was taken as 273.16°K.

(6) Felsing and Thomas, *J. Ind. Eng. Chem.*, **21**, 1269 (1929).

(7) Felsing and Durban, THIS JOURNAL, **48**, 2885 (1926).

(8) Kelso with Felsing, *ibid.*, **62**, 3132 (1940).

From 170 to 200°, as the critical region was approached, the logarithm of the vapor pressure no longer could be represented by a linear function of the reciprocal of the absolute temperature. The equation, derived by aid of a central difference table, was found to be

(4) 170–200°: $\log_{10} p$ (mm.) = $-2089.553682 + 233{,}084.9289/T + 7034.8267 \times 10^{-3} T - 1049.16605 \times 10^{-5} T^2 + 5868.8889 \times 10^{-3} T^3$

Equations (1) and (2) reproduce the data to within ±0.3%, while equations (3) and (4) are reliable to a mean deviation of ±0.1 per cent.

The vapor pressures calculated by means of these equations at a few selected rounded temperatures are given in Table I.

The latent heats of vaporization were calculated for 0 and 30.07° by means of the exact Clapeyron equation; the vapor volume was calculated by means of the van der Waals equation, the constants of which for pentene-1 were derived from critical data. These values are 6225 and 6117 calories per gram mole for 0 and 30.07°.

TABLE I

SOME VAPOR PRESSURES OF PENTENE-1 FROM 0 TO 200°

Temp., °C.	Vapor pressure, mm.	Temp., °C.	Vapor pressure, mm.
0	241.3	100	5,221

80	3269	200	30,203

[a] Normal boiling point.

Summary

1. The densities of liquid pentene-1 under its vapor pressure were determined from 0 to 50°.

2. The vapor pressures of pentene-1 were determined from 0 to 200°;

3. Calculated heats of vaporization are reported at 0 and 30.07°.

Densities and Liquid–Vapor Equilibria of the System Ethanol–Isoöctane (2,2,4-Trimethylpentane) between 0 and 50°

BY CARL B. KRETSCHMER, JANINA NOWAKOWSKA AND RICHARD WIEBE

The present investigation is part of a systematic program in progress at this Laboratory to determine certain physical properties of ethanol–hydrocarbon systems. A considerable amount of experimental and theoretical material on solutions of aliphatic alcohols in non-polar solvents has been published and will be referred to in its proper place.

Density Measurements

Commercial absolute ethanol was fractionated in a 5-foot column packed with glass helices and then treated with magnesium ethylate.[2] The final product of d^{25}_4 0.78506 was kept under its own vapor pressure in a sealed container over magnesium ethylate and samples were withdrawn by vacuum distillation. Certified isoöctane (2,2,4-trimethylpentane) was fractionated in the same column. The middle fraction taken was filtered through a column of silica gel to remove the small content of olefins.[3] The final density was found to be d^{25}_4 0.68777.

The 13-ml. pycnometer shown in Fig. 1A was used for measuring the densities of the air-saturated liquids and solutions at 25°. No noticeable loss of liquid through evaporation was experienced during weighing because of the smallness of the capillaries (0.3 mm.). By applying gentle suction at the top, filling was accomplished by means of a device shown in Fig. 1B, and the turned-down tip[4] greatly facilitated the adjustment of volume. The accuracy of measurement was estimated to be 2×10^{-5} g./ml. or better.

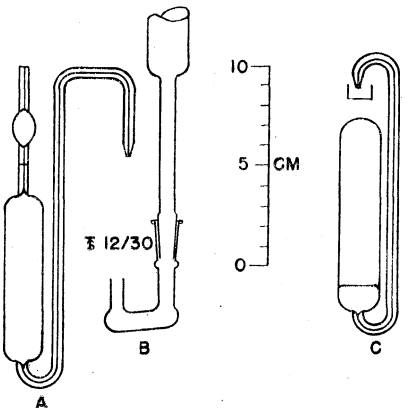

Fig. 1.—A, pycnometer; B, filling device; C, weight dilatometer.

The densities of the two pure liquids at 0 and 50° relative to their values at 25° were measured in a 14-ml. Pyrex weight dilatometer (Fig. 1C). Both apparatus and method were similar to those

(1) One of the laboratories of the Bureau of Agricultural and Industrial Chemistry, Agricultural Research Administration, United States Department of Agriculture.

(2) H. Lund and J. Bjerrum, *Ber.*, **64**, 210 (1931).

(3) B. J. Mair and A. F. Forziati, *J. Research Nat. Bur. Standards*, **32**, 151, 165 (1944).

(4) G. F. Hennion, *Ind. Eng. Chem., Anal. Ed.*, **9**, 479 (1937).

described by Burlew.[5] Temperatures were measured by means of a standard platinum resistance thermometer and were not in error by more than 0.003°. The correction for the exposed portion of the capillary amounted to 5×10^{-6} g./ml.

The values obtained for ethanol are given in the last column of Table I. For isoöctane the values obtained were 0.708120, 0.687773 and 0.666855 g./ml. at 0, 25, and 50°, respectively. These values are the means of two or three determinations which differed by amounts indicating a precision of 4×10^{-6} g./ml. in the change of density over each 25° interval. In addition, the densities at all three temperatures are affected equally by the uncertainty of 2×10^{-5} g./ml. in the pycnometer measurements at 25° which were used to calculate the weight of liquid in the dilatometer. The densities given refer to liquids containing enough dissolved air to saturate them at 25°.

In Table I values recorded in the literature for the density of ethanol between 0° and 50° are compared with those obtained in this work. Osborne's[6] values from 10° to 40° are generally believed to be very reliable. At room temperature, our value and that of Riiber[7] are in good agreement with them. Tyrer's[8] densities are higher than the others, probably because of water in his sample. His value of thermal expansion from 0° to 25° is lower than ours, while the reverse is true for the interval 25–50°, the difference in each case being of the order of 10^{-4} ml./g. Our value of the density at 0° is slightly higher than those of Young,[9] Klason and Norlin,[10] and of Merriman,[11] while our value at 50° is appreciably lower than that of Young.

TABLE I

RECORDED VALUES FOR DENSITY OF ETHANOL, 0 TO 50°, G./ML.

(8) D. Tyrer, *J. Chem. Soc.*, 2534 (1914).

(9) S. Young, *ibid.*, 707 (1902); *Sci. Proc. Roy. Dublin Soc.*, **12**, 374 (1910).

(10) P. Klason and E. Norlin, *Arkiv Kemi Mineral. Geol.*, **2**, No. 24, 1 (1906).

(11) R. W. Merriman, *J. Chem. Soc.*, 628 (1913).

(12) D. B. Brooks, F. L. Howard and H. C. Crafton, *J. Research Nat. Bur. Standards*, **24**, 33 (1940).

The following equations fit the data for ethanol and isoöctane, respectively, for the range 0 to 50°

Ethanol

$$d^t_4 = 0.806306 - 8.4456 \times 10^{-4}t - 3.52 \times 10^{-6}t^2 - 6.82 \times 10^{-9}t^3$$

Isoöctane

$$d^t_4 = 0.708120 - 8.0481 \times 10^{-4}t - 3.168 \times 10^{-7}t^2 - 1.87 \times 10^{-9}t^3$$

The cubic terms were chosen to make the equation for ethanol agree with Osborne's figures, and to make the equation for isoöctane agree with Brooks, Howard and Crafton's value at 20°, all to within 1×10^{-5} g./ml.

Solutions were prepared by distilling the individual components into an evacuated bulb, and the amounts determined by weighing. In this way any loss, as well as any correction for the displacement of air, was avoided. Transfer to the pycnometer (Fig. 1A) was effected through displacement by mercury. The results shown in Table II were used in subsequent work for converting densities to compositions.

shown in Fig. 1A, with an estimated accuracy of 7×10^{-5} g./ml. Results are given in Table III.

Discussion

Data of relative expansion of mixing, $(V/V_0) - 1$, where V is the volume of the solution and V_0 the sum of the volumes of the components, given in Tables II and III, are plotted in Fig. 2. Harms,[13] using the mass law, calculated this volume increase on mixing for several aliphatic alcohols in cyclohexane on the basis of dissociation of complexes containing from two to an infinite number of alcohol molecules. On this basis he obtained excellent agreement between experimental and calculated values for ethanol–cyclohexane solutions, whose volumetric behavior closely resembles that of the system ethanol–isoöctane. We feel, however, that the discussion is based on an oversimplified physical picture, and that the agreement is partly due to the fact that Harms' treatment contains two adjustable constants.

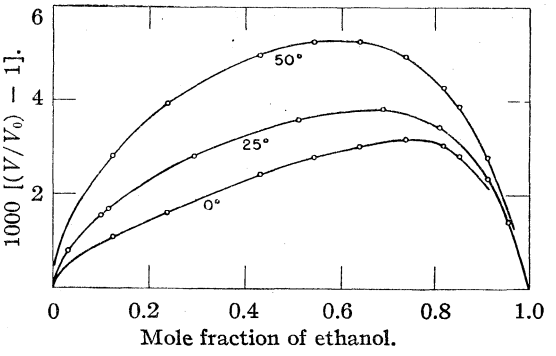

Fig. 2.—Relative expansion of mixing.

Liquid–Vapor Equilibrium Measurements

After a thorough consideration of existing methods, including actual trials, which emphasized the desirability of generating vapor in a separate boiler rather than depending on the boiling process itself to give equilibrium, the equilibrium still of Scatchard and co-workers[14] was selected as a basis.

Purification and density of the ethanol and isooctane used have been described previously. Figure 3 shows the equilibrium still. A water-bath was substituted for the vapor jacket used by Scatchard, which simplified construction and tended to maintain A at a more uniform temperature. Vapor was generated in boiler D and passed into the vapor-lift tube B where liquid was entrained and lifted to the top of chamber A. The mixture of liquid and vapor descended through the annular space packed with 3-mm. glass helices surrounding the thermometer well, and the vapor which separated passed through tube E to a condenser and finally to trap F. A heater located at the bend prevented any condensation during the passage. Bulb J was used to remove any possible traces of water as the ternary azeotrope. When a steady state was reached, the composition of the vapor in A was the same as that of the liquid in F, and the liquid and vapor samples were taken by means of evacuated sampling containers G. The tubes connecting the sampling containers G to the apparatus were full of air for all practical purposes and the error due to liquid holdup from this cause was negligible. No trouble was experienced using Apiezon grease L on stopcocks and joints when suitable precautions were taken.

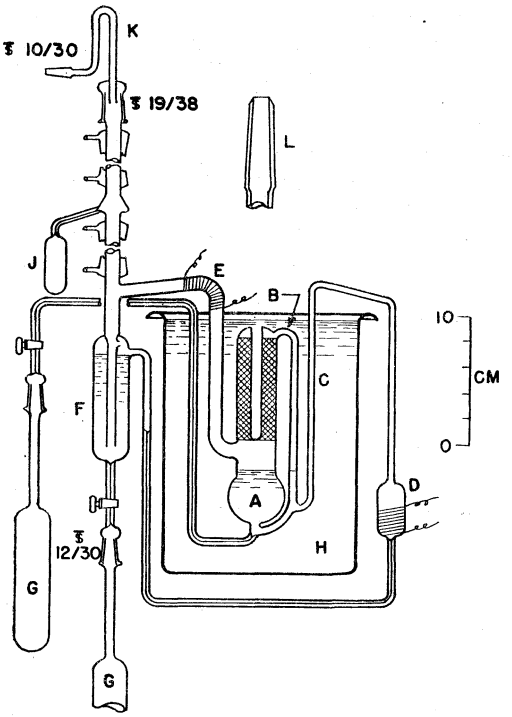

Fig. 3.—Equilibrium still: L, detail of sample bulb.

A platinum resistance thermometer and Mueller bridge, both recently calibrated, were used for temperature measurement. The condenser above trap F was connected to a 20-liter ballast and a manometer through trap K, an inverted U-tube surrounded by solid carbon dioxide. The manometer of 12 mm. i. d. tubing had provision for evacuating the vacuum arm when necessary. It was read with a Gaertner cathetometer (model M901) at a distance of 250 mm. Readings could easily be estimated to 0.02 mm., and no errors of this magnitude were found when the cathetometer was checked at the same working distance against a Gaertner standard meter calibrated by the Bureau of Standards. The vapor pressures are given in International mm. of mercury and have an estimated accuracy of 0.05 mm.

After complete evacuation, dry air was admitted and approximately 52 ml. of solution was introduced into the apparatus. Distillation rates were about 35 ml./hr. at 25° and 100 ml./hr. at

(13) H. Harms, *Z. physik. Chem.*, **53B**, 280 (1943).

(14) G. Scatchard, *et al.*, THIS JOURNAL, **60**, 1275, 1278 (1938); **61**, 3206 (1939); **62**, 712 (1940); and **68**, 1957, 1960 (1946).

50°. The pressure was regulated manually to keep the resistance thermometer reading exactly at 25.00° or 50.00°. The bath temperature was regulated to keep a constant amount of liquid (about 3 ml.) in boiler D, which required that the bath be several hundredths of a degree above the temperature in A. During initial operation a small amount was distilled into J to eliminate any possible traces of water, as explained previously. The steady state was maintained for considerable time after which temperature and pressure were measured in quick succession, heaters turned off, the apparatus was brought to atmospheric pressure, and samples were taken.

In addition, static measurements were made of the total vapor pressure of the solutions at 0 and 25°, by use of a vapor-pressure cell equipped with a magnetic stirrer and connected directly to the manometer. The solutions were freed of dissolved gases and traces of water by slowly distilling off part of the sample while the stirrer was in operation. This process was continued until McLeod gage readings on the portion of distillate uncondensed at −78° showed no more gases were being evolved. Vapor pressure and density of the remaining solution were then measured.

Results

Static vapor pressures at 0 and 25° and liquid–vapor equilibrium measurements at 25 and 50° are presented in Tables IV and V, respectively. The good agreement between static and dynamic vapor pressure measurements at 25° is indicated in Fig. 4; the actual agreement is within 0.2 mm.

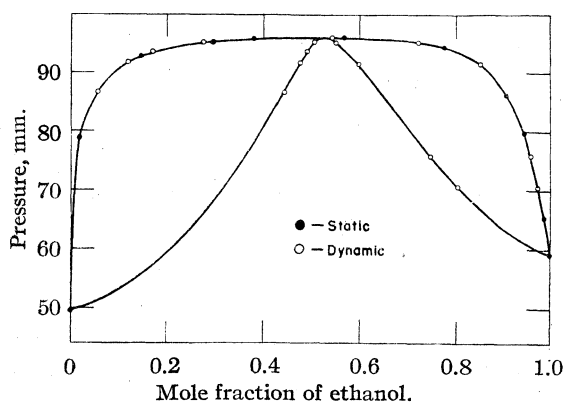

Fig. 4.—Vapor pressure at 25°.

The vapor curve below 0.4 mole fraction ethanol is conjectural. The data for 50° give curves of similar shape The azeotropic mole fraction of ethanol at 25° is 0.5270 and at 50° is 0.5941; the corresponding vapor pressures are 96.1 and 318.8 mm.

Vapor pressures for isoöctane reported here are in good agreement with the ones calculated from the equation published by Willingham and coworkers,[15] as shown in the following comparison at 0, 25 and 50° with their values in parentheses: 13.04 (12.99), 49.31 (49.34) and 146.47 (146.51). Since the value quoted by Willingham, *et al.*, for 0° represents an extrapolation from their lowest experimental point of nearly 25°, the agreement demonstrates the suitability of the Antoine equation used by them.

A comparison of the vapor pressures of ethanol at 0, 25 and 50° reported here with those of Merriman[11] in parentheses: 11.95 (12.0), 59.02 (59.0) and 220.94 (222.2) shows a good agreement except at 50°. Recorded values for the vapor pressure at 50° range from 219.8 mm.[16] to Merriman's

Discussion

The partial molal free energy equation for binary solutions

$$x_1 \frac{d\bar{F}_1}{dx_1} + x_2 \frac{d\bar{F}_2}{dx_1} = 0$$

has been used extensively in the form of the Duhem–Margules equation

$$x_1 \frac{d \ln P_1}{dx_1} + x_2 \frac{d \ln P_2}{dx_1} = 0$$

or substituting total pressure times the corresponding mole fraction in the vapor phase Py and $P(1-y)$ for the partial pressures, the equation becomes[18]

$$d \ln P = \frac{y - x}{1 - y} d \ln y,$$

where deviations from ideal behavior of the vapor phase are neglected. This equation was integrated numerically, using our experimental values of mole fraction of ethanol in the liquid, x, and in the vapor, y. The differences $\Delta \log P$ between observed values of $\log P$ and those resulting from the integration are given in Table V. These deviations are made up of the experimental error plus the correction for vapor imperfections. The latter correction is proportional to the vapor pressure; at the low pressures involved in this work it is comparable in magnitude to the contribution of experimental errors to the integral. Hence, no significant evaluation of the parameters in the equation of state of the vapor can be obtained from the listed values of $\Delta \log P$. The agreement between calculated and observed pressures is reasonably satisfactory, however, since only two values of $\Delta \log P$ exceed 0.005.

Liquid–vapor compositions at 0° given in Table VI were calculated from the data in Table V on the assumption of additive specific heats. Using the same assumption, the differences $F - F_i = F^E$ and $S - S_i = S^E$ as well as H^M were computed, where F^E and S^E are the amounts of free energy and entropy above that of the ideal solution as indicated and H^M is the heat of mixing. They are shown in Table VII and Fig. 5. Detailed exposition of the method is given by Scatchard.[14] No correction was made for the imperfection of the vapor since it was found insignificant. The system carbon tetrachloride–methanol[14] shows a practically identical shape of curve for S^E *vs.* x as well as negative values for TS^E over the entire range. As pointed out, this must be due, in part at least, to the strong interaction of the two components. The entropy of mixing was discussed recently by Wood[19] at some length and it was stated that the orientational distribution is the principal factor. The negative values of S^E obtained in this investigation, as well as those obtained by Scatchard and co-workers for solutions of methanol in carbon tetrachloride and benzene,[14] would then be explained by increased orientation of the non-polar solvent molecules caused by the presence of alcohol molecules. Such an interaction is fairly plausible for carbon tetrachloride which contains chlorine atoms that can interact with the hydroxyl hydrogen, but it is somewhat surprising for the hydrocarbons, benzene and isooctane.

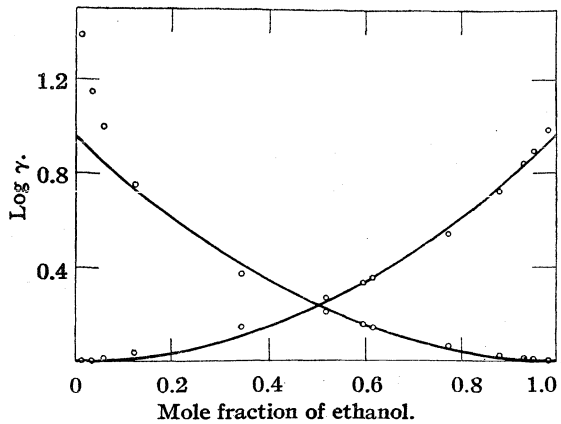

Fig. 6.—Logarithms of activity coefficients at 50°: circles, experimental values; curves, calculated from Van Laar equations.

Figure 6 shows the experimental activity coefficients at 50° compared with curves calculated from the Van Laar equations[20] fitted to the azeotropic composition and pressure. The two-constant Margules equations would give nearly identical curves since the terminal activity coefficients are nearly equal.[20] The agreement is seen to be fairly close except below 0.1 mole fraction where the equations fail to reproduce the rapidly increasing activity coefficient of ethanol. A better fit can be obtained only by using equations with more than two adjustable constants. However, the Van Laar equations would be useful in extending data on other hydrocarbon–alcohol systems, provided the peculiar behavior at low alcohol concentrations were kept in mind.

Summary

Densities of ethanol, isoöctane and of isoöctane–ethanol solutions were measured at 0, 25 and 50°. Equations giving the density of ethanol and isoöctane as a function of temperature are presented. The volume expansion on mixing increases rapidly with temperature.

Static vapor pressures at 0 and 25° and liquid–vapor equilibria at 25 and 50° were determined. Good agreement was obtained between the two sets of measurements at 25°. Satisfactory agreement was also obtained when calculating vapor pressures by means of the Duhem–Margules equation without corrections for imperfection of the vapor.

The excess thermodynamic functions F^E, TS^E and H^M were computed. Activity coefficients were calculated using the Van Laar equation and approximate reproduction of the experimental data were obtained.

Melting Point Curves of Optical Isomers

BY CHARLES L. BICKEL AND ALFRED T. PEASLEE, JR.[1]

The problem of the melting points of mixtures of optical isomers was placed on a sound theoretical basis by Roozeboom[2] who showed that three types of melting point curves might be expected. Several of the substances studied[3,4] give the mixed-crystal curve predicted by Roozeboom, a continuous curve joining the melting points of the two optical isomers and a straight line in its simplest form. Most of the compounds investigated[3,4,5] give a curve with two minima and a maximum, indicating the formation of a racemic compound. Ross and Somerville[4] reported that pinene gave the third type of curve, characteristic of a simple mixture and consisting of two parts with a minimum at the point of intersection. However, Timmermans[6] stated that the "dextro" pinene used by Ross and Somerville was a mixture of the two isomers of α-pinene, so that these investigators were working with a ternary mixture and not with optical opposites.

The present study of the dextro and levo forms of β-benzoylhydratropic acid indicates that these optical opposites give a simple mixture. The identity of the isomers appears to be definitely established[7,8,9] so that the question involved in the case of pinene should not be raised in this case.[10] The experimental data for the acids are presented graphically in Fig. 1.

This study has been extended to include the methyl esters of the above acids. Figure 2 indicates that a racemic compound is formed. The behavior of the methyl esters therefore resembles that of most of the acids and esters previously investigated.

(10) Since the submission of this manuscript the observations of Singh and Tewari [*Proc. Indian Acad. Sci.*, **25A**, 389 (1947)] regarding 3-nitro-*p*-toluidinomethylenecamphor have come to our attention. The *d* and *l* isomers of this substance appear to form a simple mixture, the melting point of the eutectic being only 1.8° below the melting point of each pure isomer.

This investigation was assisted by a grant from the Cyrus M. Warren Fund of the American Academy of Arts and Sciences.

Experimental

A previous paper from this Laboratory[7] adequately described the preparation of the dextro and levo forms of β-benzoylhydratropic acid as well as their methyl esters. Each of these compounds was repeatedly crystallized to ensure purity, the acids from acetone and the esters from a mixture of ether and petroleum ether. The racemic methyl ester, prepared directly from the hydrogen cyanide addition product of benzylideneacetophenone by the action of methanol and concentrated sulfuric acid, was purified by repeated crystallization from methanol.

Each sample, weighing one-half gram and weighed to the nearest half milligram, was placed in an 8 by 75 mm. Pyrex test-tube which was centered in a sulfuric acid-bath equipped with an efficient motor stirrer and heated by a small burner with chimney. A calibrated tenth-degree thermometer was used, all temperature readings being corrected for emergent stem. The temperature rise of the bath did not exceed one-tenth degree per minute in the region of the melting point of each sample.

Each sample was melted, allowed to solidify, remelted, solidified, and melted at least once more. The original melting points were disregarded in the case of the mixtures. The values for the melting points of each acid mixture agreed to the nearest tenth degree; the tabulated values for the melting points of the ester mixtures are average values, the maximum deviation being one half degree for the mixture containing 90 per cent. of the dextro ester. There was no evidence of racemization or decomposition for either the acids or the esters.

The experimental data are collected below in tabular form.

Acids		Esters	
% Dextro[a]	M. p. in °C.	% Dextro[b]	M. p. in °C.
100	182.1	100	50.3
90	177.8	97	49.2
80	173.3	95	48.8
70	167.1	90	75.7
60	160.2	85	85.9
56	157.3	80	92.5
53	155.5	70	99.7
50	153.9	60	104.3
		55	105.4
		50	106.0

[a] These mixtures were prepared from the dextro and levo acids. The 50% mixture was also realized by using the inactive acid directly. [b] These mixtures were prepared from the dextro and racemic esters. The 50% mixture was also prepared from the dextro and levo esters.

The hope of obtaining reliable freezing point curves[11] for these mixtures could not be realized because of marked supercooling of the melts. For example, a five-gram sample of the fifty per cent. acid mixture, melting at 153.9°, showed an initial halt in the freezing point curve at 134° and then at 139° when the experiment was repeated with the same sample. Moreover, the ester mixtures containing a high proportion of either dextro or levo ester remained liquid for several hours in some cases and for several days in others.

(11) Bickel, THIS JOURNAL, 68, 866 (1946).

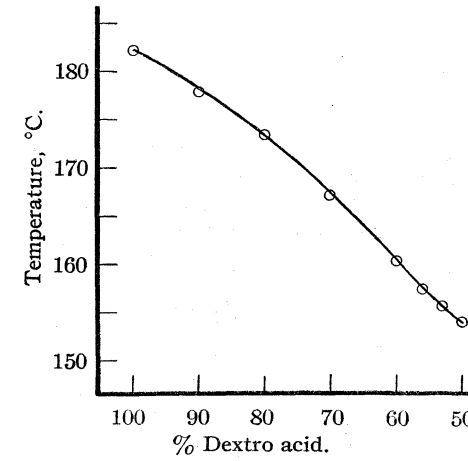

Fig. 1.

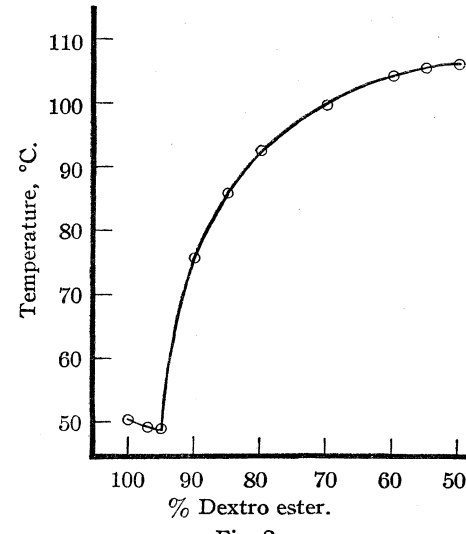

Fig. 2.

Summary

The melting point curve of the dextro and levo forms of β-benzoylhydratropic acid indicates that these isomers give a simple mixture.

The methyl esters of these acids, however, form a racemic compound.

The Surface Tension of Chloroform

BY R. FANELLI

The surface tension of chloroform has been determined previously by numerous investigators using various methods. With few exceptions, the determined values fall on two straight lines which differ by less than one dyne per cm.[1] as shown in Fig. 1.

With the exception of Akhamatov's[2] value, all of the earlier data on the lower curve are due to Ramsay and Aston[5] while the upper curve encompasses almost all other values save that of Tyler[8] which obviously is too high. Because of the novel and less well established methods employed by Akhamatov and Tyler, their values may be justifiably disregarded.

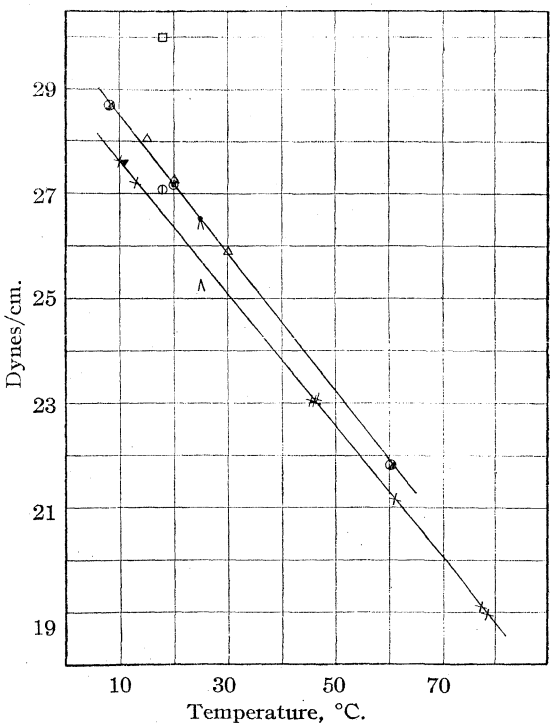

Fig. 1.—Surface tension of chloroform determined by various investigators: O, Richards and Carver[3] (capillary rise); △, Hennaut-Roland and Lek[4] (capillary rise); ×, Ramsay and Aston[5] (capillary rise); ◑, Schiff[6] (differential capillary rise); ▼, Akhamatov[2] (differential pressure corresponding to differential capillary rise); O, Harkins, Clark and Roberts[7] (drop weight); □, Tyler[8] (ripple); O, Addison[9] (vibrating jet); ⊕, Whatmough[10] (maximum bubble pressure, single capillary); ∧, Cupples[11] (maximum bubble pressure, single capillary); ●, Fanelli (maximum bubble pressure, Sugden's double capillary).

Explanation of Ramsay and Aston's low values probably lies in their failure to correct for the capillary rise in the wide tube (bore not given) and in other errors inherent in the method followed in 1894. Ramsay and Shields[12] using the same method and procedure (bore of wide tube, 1 cm.) and correcting for capillary rise in the wide tube in the case of water, obtained four values in the range 10 to 40°. They are 2.3 to 2.1 (av. 2.2) dynes per cm. too low, indicating that the method and procedure in that period tended to give low results. A correction factor for Ramsay and Aston's values may be approximated by multiplying the ratio of their chloroform value at 25° (25.7 dynes per cm.) to Ramsay and Shield's result for water at 25° (69.9 dynes per cm.) by the above average, 2.2. This factor, 0.8 dyne per cm., is equivalent to the discrepancy shown by the curves in Fig. 1. Richards and Coombs[13] using the capillary rise method attribute the low values of the early investigators to failure to correct all factors which tend to give low results.

At the time Cupple's paper appeared, Sugden's[14,15] form of maximum bubble pressure apparatus employing two capillaries was being standardized against chloroform. Therefore, the effect of saturating the inlet gas with chloroform vapor before entering the capillaries was determined.

Experimental

The apparatus and method of calculation employed have been described by Sugden.[15] The bore of the fine capillary was close to 0.2 mm.; the wider capillary was 3.66 mm. A Meriam Micromanometer reading directly to 0.001 in. (±0.001 in.) with water as the gage liquid measured pressure. Dried nitrogen gas forced through the capillaries was used for bubble formation. The bubble rate was varied between 60 per min. and 60 per 140 sec. In the main each result represents a different bubble rate. The constant temperature bath was kept well within 0.1° of the operating temperature.

The instrument was calibrated against benzene at 20 and 25°. Eastman Kodak Co. thiophene-free benzene,

(1) Dr. Cupples discussed these data in a recent article (11) but he was misled by plotting Richards and Carver's data for 20° incorrectly at 25°. This was confirmed by a private communication from Dr. Cupples.

Ramsay's and Aston's value of 19.98 dynes per cm. at 77.6° is misprinted in the original paper. Recalculation of their data gives the corrected value of 19.08 dynes per cm.

m. p. 5°, was fractionally distilled and the middle fraction boiling close to 80° was used. Six determinations were made at varying bubble rates with an average deviation from the mean of less than one part in a thousand. Saturating the nitrogen gas with benzene vapor before entering the capillaries had no effect whatever on the values. Values given by the original unpurified benzene differed but slightly from those given by the purified product.

The chloroform used was prepared from the C. P. analyzed grade by washing with water, drying over calcium chloride, and finally fractionally distilling. The portion boiling close to 61° was used.

The surface tension values obtained at 25.0° using dried nitrogen were: 26.47, 26.49, 26.52, 26.57, 26.56, 26.54; average 26.53 dynes per cm., average deviation from the mean <1/1000.

At 25.0°, using dried nitrogen saturated with chloroform vapor, the following values were obtained: 26.37, 26.47, 26.47, 26.52; average 26.46 dynes per cm., average deviation, <3/2000.

The above values show that saturating the inlet gas with chloroform vapor has little effect upon the surface tension values obtained by using the dried gas alone in Sugden's apparatus.

The values obtained at 20.0° using dried nitrogen were: 27.20, 27.15, 27.16, 27.14, 27.17, 27.14; average, 27.16 dynes per cm., average deviation, <1/1000. These values are very close to Richards and Carver's[3] and with those obtained at 25° fall squarely on the upper curve.

Like benzene, the unpurified chloroform gave essentially the same values as the purified liquid. This confirms Sugden's observation that the normal impurities in water and benzene have but slight effect on their respective surface tension values when the maximum bubble pressure method is used.

Summary

The surface tension of chloroform has been determined at 20 and 25° using Sugden's form of maximum bubble pressure apparatus. The values obtained check Richards and Carver's[3] results very closely.

Using Sugden's apparatus, saturation of the inlet gas with chloroform vapor before entering the capillaries has very little effect on the surface tension values. This confirms Whatmough's[10] observation, contrary to Cupples' findings. The probable explanation for the low values of Ramsay and Aston is reiterated.

The Systems Chromic Ammonium Sulfate–Ferric Ammonium Sulfate–Water and Chromic Ammonium Sulfate–Aluminum Ammonium Sulfate–Water at 25°

BY NORMAN O. SMITH AND CHARLES S. LENNOX

In a summary of the results of a series of isothermal investigations of ternary systems consisting of pairs of isomorphous salts and water Hill, Durham and Ricci[1] showed that the distribution of the salts between liquid and solid solutions obeys the semi-empirical relation

$$\log R_1 = \log K + m \log R_s \qquad (1)$$

where R_1 is the mole ratio of the salts in the liquid, R_s that in the coexisting solid solution, and m and K are constants for a particular system. The distribution constant K was shown to equal $(S_1\gamma_1^0/S_2\gamma_2^0)^{\nu/b}$, where S_1 and S_2 are the aqueous molal solubilities of the component salts, γ_1^0 and γ_2^0 the respective mean ion activity coefficients at these concentrations, ν the total number of ions per molecule of salt and b the number of ions per molecule of the ion which is being interchanged. Originally applied to alums and picromerites equation (1) has since been found to hold also for other isomorphous salt pairs.[2] In the case of alums m, in general, is unity, implying that solid solutions of alums are ideal. Of the five alum pairs reported, however, the ferric ammonium–aluminum ammonium pair did not obey the above relation satisfactorily. It was concluded[1] that this was the result of experimental error, but at the same time it was pointed out that this pair differed fundamentally from the other four in involving an interchange of the trivalent instead of the univalent cation. In order to examine further the effect of interchanging the trivalent cation the distribution studies of the present paper were undertaken.

(1) Hill, Durham and Ricci, THIS JOURNAL, **62**, 2723 (1940).

(2) See, for example, Ricci and Smiley, *ibid.*, **66**, 1011 (1944), and Simons and Ricci, *ibid.*, **68**, 2194 (1946).

Experimental

The technique employed was that of the previous alum studies: Complexes of known composition were made up in duplicate from the two alums and water in glass-stoppered test-tubes, glass marbles were added and the tubes rotated in a thermostat at 25 ± 0.03° for many weeks, at the end of which time both the liquid and solid phases were analyzed, the latter after being filtered from the liquid, centrifuged and air-dried for a few minutes. In the chromium–iron system two marbles were used but in the chromium–aluminum system one marble. In most cases the tubes contained about 35 g. of material but in regions of low chromium this was increased to 60 g. The members of each duplicate pair differed only in the order of addition of the components, one alum being dissolved in the water (by slight warming where necessary) before the other was added. In this way each point in the system was approached from two directions thereby establishing the attainment of equilibrium. The fact that a chrome alum was a component of both systems suggested that no less than three months of rotation would be required as it had been shown[3] that well over two months of time is required merely to attain the simple solubility equilibrium of a chrome alum in water. It was found, however, that for the chromium–iron system only nine weeks gave agreement of the duplicates. In

[a] By algebraic extrapolation.

the chromium-aluminum system about three months of rotation was allowed.

Materials.—The aluminum ammonium and chromic ammonium alums were recrystallized Baker Analyzed chemicals and the ferric ammonium alum was recrystallized British Drug Houses Analar product. These three alums will henceforth be referred to as the aluminum, chrome and iron alums, respectively. The first-mentioned retained its theoretical composition indefinitely; the other two effloresced slightly so that their analytical composition at the time of using was employed in calculating the compositions of the complexes.

Analysis.—In both systems the liquids and solids were analyzed for total ammonium and chromium. Ammonium was determined by alkaline distillation in steam of the ammonia into excess boric acid and titration of the excess of the latter with standard hydrochloric acid.[4] Chromium was determined by oxidation with persulfate in the presence of silver nitrate, precipitation of silver with hydrochloric acid, addition of a measured excess of standard ferrous sulfate and titration of the excess of the latter with standard dichromate in the presence of phosphoric acid using barium diphenylamine sulfonate as internal indicator. By preliminary trials these analytical methods were found to give an accuracy of better than 0.2% even for low proportions of chromium.

Results and Discussion

Tables I and II give the analytical compositions of the liquid and solid phases for the chrome–iron and chrome–aluminum systems, respectively. In Table I the A data are for those tubes in which the chrome alum, and the B data the iron alum, was present as the initial solid phase. In Table II chrome alum was the initial solid for the A data and aluminum alum for the B data. The single solubilities of the alums are those of a previous paper.[3]

The agreement of the duplicates indicates satisfactory approach to equilibrium. To test the consistency of the analyses the per cent. of chromic ammonium sulfate in each solid was calculated by algebraic extrapolation from the compositions of

the liquid and complex to the analytical water content of the solid and compared with the observed per cent. In the first system the average absolute deviation for all the tubes was only 0.48% and in the second 0.71%.

The plots of the data are shown in Figs. 1 and 2. It is seen that in both systems there is a complete series of solid solutions as found (with one exception[5]) in all previous alum studies. The points for the liquid lie on a smoother curve for the first than for the second system suggesting a less complete attainment of equilibrium in the latter in spite of the longer period of rotation—the result, doubtless, of a less effective grinding of the solids during rotation (only one marble used).

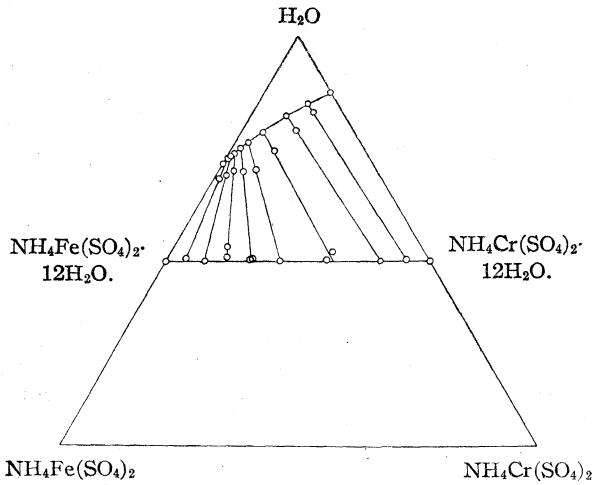

Fig. 1.—The system $NH_4Cr(SO_4)_2$–$NH_4Fe(SO_4)_2$–H_2O at 25°.

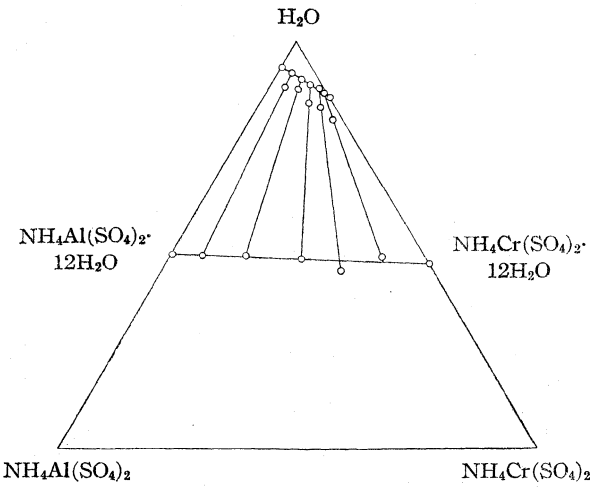

Fig. 2.—The system $NH_4Cr(SO_4)_2$–$NH_4Al(SO_4)_2$–H_2O at 25°.

In order to test the applicability of the distribution relation (1) log R_1 is plotted against log R_s in Fig. 3 from the values listed in Tables I and II. These are the logarithms of the ratios, in liquid

(5) Hill and Kaplan, THIS JOURNAL, **60**, 550 (1938).

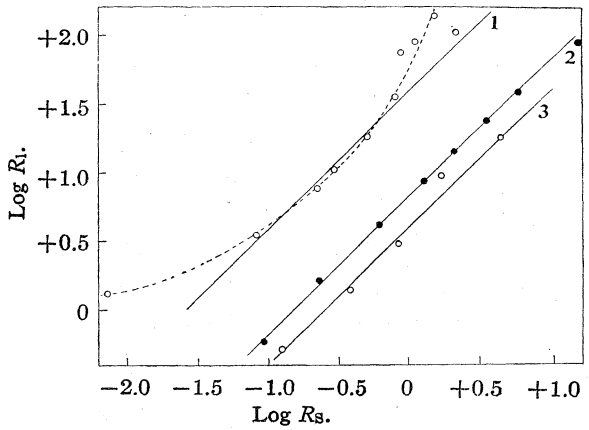

Fig. 3.—Distribution in alum systems: (1) $NH_4Fe(SO_4)_2$–$NH_4Al(SO_4)_2$–H_2O, (2) $NH_4Fe(SO_4)_2$–$NH_4Cr(SO_4)_2$–H_2O, (3) $NH_4Cr(SO_4)_2$–$NH_4Al(SO_4)_2$–H_2O.

and coexisting solid, respectively, of the molal concentration of the alum with the greater molal solubility to that of the alum with the lower. It is evident that the present systems, particularly the chrome–iron pair where more complete equilibrium was attained, give, within the limits of experimental error, a linear relation between log R_1 and log R_s and furthermore that the slope is unity. The data, therefore, obey equation (1) where m is unity, and the intercepts on the vertical axis, namely, 0.82 for the chrome–iron and 0.59 for the chrome–aluminum pair, should give the value of log K defined earlier. Because of lack of data on activity coefficients of alums these intercepts can, as yet, only be tested by the approximation[1]

$$K = (S_1/S_2)^{\nu/2b} \qquad (2)$$

based on the observation that for bi-bivalent sulfates $\gamma \cong A + B/\sqrt{\mu}$ over a limited concentration range, where μ is ionic strength, A is a very small constant and B a constant for most of the sulfates for which data were then available. It may be noted here that recent measurements in this Laboratory[6] show that this is also nearly true for chromic potassium and chromic ammonium sulfates from $\sqrt{\mu} = 0.9$ to $\sqrt{\mu} = 2.3$. Similarly, available data on chromic,[7] aluminum[7] and indium[8] sulfates suggest that these too satisfy the relation approximately, except that B is half as large. Thus the assumed applicability[1] of the relation to higher valence types is to some extent confirmed. Calculation of log K from (2) for the chrome–iron system gives 0.90 and for the chrome–aluminum system 0.68 in satisfactory agreement with the observed intercepts.

Another consequence of the linear relationships of Fig. 3 is that both systems can be assigned to Type I of the Roozeboom classification,[9] for the slope of each line is unity.

(6) Smith, *ibid.*, **69**, 91 (1947).
(7) Robinson, *ibid.*, **59**, 84 (1937).
(8) Hattox and DeVries, *ibid.*, **58**, 2126 (1936).
(9) Roozeboom, *Z. physik. Chem.*, **8**, 521 (1891).

Included in Fig. 3 for purposes of comparison are the data of Hill and Kaplan[5] for the ferric ammonium–aluminum ammonium system. The suggestion of Hill, Durham and Ricci that the distribution in this system is also a linear one in spite of the fact that the points tend to lie on a curve is therefore further supported by the two analogous systems here reported.

The relation

$$\log R_1 = \text{constant} + \log R_s \qquad (3)$$

thus found valid in all alum systems so far studied has been shown[1] to have a theoretical basis as a special case of

$$\log R_1 = \log K + \log (f_B/f_{B'}) - \log (\gamma_B/\gamma_{B'}) + \log R_s \qquad (4)$$

where f_B and $f_{B'}$ are the rational activity coefficients of the interchanging ions in the solid solution and γ_B and $\gamma_{B'}$ their practical activity coefficients in the coexisting liquid solution. To reduce this to (3) requires that $f_B/f_{B'}$ and $\gamma_B/\gamma_{B'}$ shall be constant at all points across the diagram and Hill, Durham and Ricci propose that in systems where m is unity both ratios are not only constant but unity. This assumption is, of course, necessary if the intercepts of Fig. 3 are to be identified with $\log K$.

It is possible to raise an objection to the identification of the intercepts with $\log K$ in the light of data of ref. 6 as applied to the chromic potassium–chromic ammonium alum pair.[3] The values of the molal solubilities of these alums are 0.817 and 0.603, respectively, in which solutions the respective mean ion activity coefficients are 0.0358 and 0.0465. This gives $\log K = \log (0.817 \times 0.0358/0.603 \times 0.0465)^4 = 0.07$. The intercept on the $\log R_1$ *vs.* $\log R_s$ plot is given[1] as 0.20 which equals the sum of the first three terms on the right side of (4). This means that $\log (f_K/f_{NH_4}) - \log (\gamma_K/\gamma_{NH_4}) = 0.13$, a finite constant for all proportions of the two alums. It is very unlikely that as one passes across the diagram the f and γ ratios both alter in such a way that the difference of their logarithms is constant; it is more reasonable to suppose that they are both constant, but then both could not be unity. It is interesting to note that if f_K/f_{NH_4} is regarded as unity then $\log (\gamma_K/\gamma_{NH_4})$, becomes -0.13 which may be compared with that estimated as follows: The ratio of the mean ion activity coefficient of chromic potassium sulfate to that of chromic ammonium sulfate is reasonably constant (about 0.88) over the range of ionic strengths of the isotherm. If the activity coefficients of chromic and sulfate ions are assumed to be the same in solutions of single alums as they are in mixed alums of the same ionic strength then $\log (\gamma_K/\gamma_{NH_4})$ should be given roughly by $\log (0.88)^4 = -0.22$. On the other hand, the uncertainties involved in the evaluation of the activity coefficients of the alums may have combined to produce a large error in $\log K$ thus invalidating the above argument.

Summary

1. The systems chromic ammonium sulfate–ferric ammonium sulfate–water and chromic ammonium sulfate–aluminum ammonium sulfate–water have been investigated at 25°.

2. Both systems exhibit a complete series of solid solutions at this temperature, and, as the distribution of the components follows the relation $\log R_1 = \text{constant} + \log R_s$, they are assigned to Type I of the Roozeboom classification. The values of the constant for each system compare favorably with the values estimated from the individual solubilities of the component alums.

3. A possible objection is raised to the assumption of a value of unity for the ratio of the activity coefficients of the interchanging ions in the liquid.

The System Ammonium Nitrate–Ammonium Sulfamate[1]

BY JACK H. THELIN[2] AND P. A. VAN DER MEULEN

The present research represents the initial investigation of the phase equilibria in the reciprocal salt pair system sodium nitrate–ammonium sulfamate. This included the phase diagram of the binary system ammonium nitrate–ammonium sulfamate.

Ammonium nitrate is known to exist in five crystalline modifications. Early and Lowry[3] have re-examined the transition temperatures of the various modifications and have summarized the results. Two of the transition points are of importance in the present investigation. They are the transition temperatures of 125.2° at which the cubic changes to the tetragonal and 84.2° at which the tetragonal changes to the monoclinic modification. There are no published records concerning possible polymorphism of ammonium sulfamate.

Experimental Method

Purification of Materials.—Merck ammonium nitrate was crystallized twice from distilled water and dried under

(1) Based on a thesis submitted by Jack H. Thelin to the graduate faculty of Rutgers University in partial fullfillment of the requirements for the degree of Doctor of Philosophy.

(3) R. G. Early and T. M. Lowry, *J. Chem. Soc.*, **115**, 1387 (1919).

vacuum with phosphorus pentoxide at 40° with frequent grinding. Heating was found to be necessary to obtain the accepted freezing point of 169.6° as given by Early and Lowry.[3] Samples dried for two months at room temperature under vacuum with phosphorus pentoxide gave a freezing point of only 169.2°. In all experiments the ammonium nitrate used in this research had a freezing point of 169.5–169.6° (cor.).

The ammonium sulfamate was obtained from E. I. du Pont de Nemours and Company, Inc., Wilmington, Delaware, and was their technical grade. It was recrystallized twice from distilled water with care taken not to heat above 60°. An odor of ammonia was plainly noticeable at 80°. The freezing point obtained by us after two crystallizations from water and drying under vacuum with phosphorus pentoxide with intermittent heating to 100° on a water-bath was 132.9° (cor.). Gordon and Cupery[4] report a melting point of 131°. The purity was established by reaction of the ammonium sulfamate with potassium nitrite to form the sulfate and subsequent determination as barium sulfate. Two determinations gave 28.17 and 28.15% sulfur (calcd. 28.07). Dilatometric measurements using a high boiling kerosene fraction as medium showed no transition within the temperature range of 47° and the melting point.

Apparatus Used.—The freezing point apparatus is shown in Fig. 1. The oil-bath consisted of a one-liter Griffin-type beaker filled with Nujol in which the jacketed freezing point tube was placed. The inner tube which held the melted salts was made from a small Pyrex test-tube (13 × 100 mm.). The platinum wire used to agitate the melt was driven by a suitable mechanism at 120 strokes per minute. A loop of glass tubing through which water could be circulated was suspended in the oil-bath to aid cooling at temperatures below 100°. When the flame under the oil-bath was adjusted so that no variation of the oil-bath temperature was noted, the flowing of a few milliliters of water through the coil lowered the temperature of the melt as little as 0.05° a minute. Such slow cooling was advantageous in treating melts which had a strong tendency to supercool.

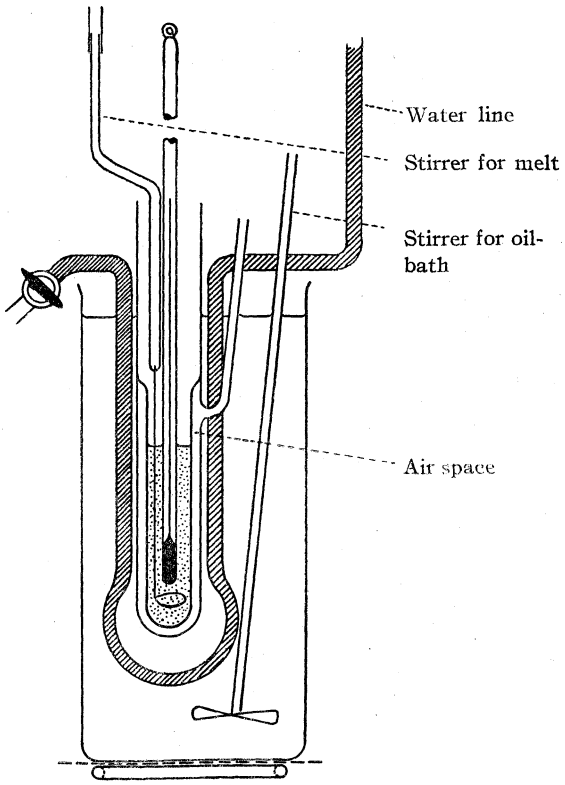

Fig. 1.

The thermometers were graduated in fifths of a degree and were standardized against thermometers recently checked by the Bureau of Standards. Corrections for emergent stem were made.

Technique.—The salt charge of approximately 4 g. was weighed by difference, placed in the aluminum boat of the apparatus shown in Fig. 2, and dried under vacuum at 56° (boiling acetone) for one to two hours with phosphorus pentoxide. In this way any moisture absorbed while weighing was removed. After drying, the mixtures were quickly transferred to the freezing point tube and placed in the previously heated oil-bath.

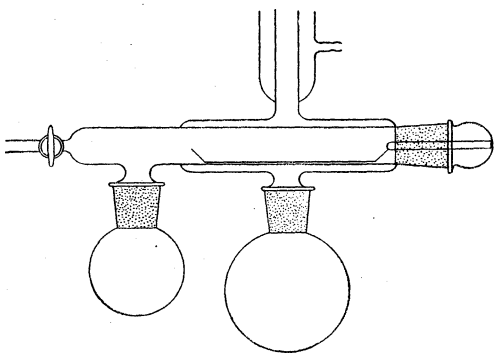

Fig. 2.—Modified Abderhalden drying pistol.

The drying apparatus of Fig. 2 is a modification of the Abderhalden drying pistol. In the conventional type the vacuum pump connection, the phosphorus pentoxide bulb and the sample itself are all attached at the front of the apparatus. In the present modification the drying chamber is extended through to the rear and the vacuum connection and the phosphorus pentoxide bulb are attached at the back out of the way. The boat is fastened to the glass stopper by a short piece of glass rod.

The usual cooling rate was 0.2–0.4° per minute. Seeding was accomplished by dipping a platinum wire into the melt at one-minute intervals and allowing the melt clinging to the tip to solidify. Enough of the melt adhered to the wire to "seed" the melt on the next trial. All recorded temperatures represent visual observation of initial crystal formation.

Experimental.—The data given in Table I were obtained as described under Experimental Method. Each recorded temperature represents a freshly prepared melt.

Figure 3 is a plot of the data with temperature as ordinates and composition as abscissas. The composition indicated by the intersection of the liquidus curves is 54.8% $NH_4SO_3NH_2$. Supercooling effects were observed, however, so that the eutectic temperature of 75.3° finally obtained with all mixtures is higher than the temperatures indicated by the intersection of the two liquidus curves. This leaves the precise composition of the eutectic mixture in doubt to the extent of about 1% of ammonium sulfamate. An enlarged plot of the curve gave 125.7° for the transition temperature of $NH_4NO_3(I) \rightleftarrows NH_4NO_3(II)$. Early and Lowry give 125.2° as the transition point for pure ammonium nitrate. Fig. 3.—Freezing point of mixtures of $NH_4SO_3NH_2$ and NH_4NO_3

report 126.2° from a reinvestigation of the system ammonium nitrate–sodium nitrate. Perman and Harrison[6] report the transition temperature as 122° from a study of the system lithium and ammonium nitrates. The absence of the inversion point at 84.2° has been reported previously[7] in a study of the solubility of ammonium nitrate in water.

Howells,[8] on the basis of a study of the system urea–ammonium nitrate also states that no inversion point was obtained at 83°.

Summary

1. The freezing point of ammonium sulfamate is 132.9°.

2. Dilatometric measurements indicate that ammonium sulfamate exists in only one crystalline modification in the temperature range from 47° up to the melting point.

3. The binary system NH_4NO_3–$NH_4SO_3NH_2$ has a eutectic point at 75.3° and *ca.* 54.8% ammonium sulfamate with NH_4NO_3 and $NH_4SO_3NH_2$ as the solid phases.

4. The transition from NH_4NO_3(I) to NH_4NO_3(II) takes place at 125.7°.

The Systems Ammonium Sulfamate–Sodium Sulfamate and Sodium Sulfamate–Sodium Nitrate

BY STEPHEN H. LANING[1] AND P. A. VAN DER MEULEN

The present paper describes the binary systems ammonium sulfamate–sodium sulfamate and sodium sulfamate–sodium nitrate.

Preparation and Purification of Materials.—The method used in the purification of ammonium sulfamate was described in the previous paper.

Merck sodium nitrate C. P. was crystallized twice from distilled water and dried under vacuum with phosphorus pentoxide.

Sodium sulfamate was prepared by the method described by Laning and van der Meulen.[2]

The Binary System Ammonium Sulfamate–Sodium Sulfamate.—Mixtures of weighed quantities of the components were prepared and placed in the melting point apparatus described in the previous paper. They were melted and allowed to crystallize slowly. The initial freezing point was taken, and then the melt was slowly warmed and the temperature at which the last crystals disappeared was also taken. In most cases the two temperatures were not more than a half degree apart. The mean of the temperatures at which crystals were just formed and at which the last crystal disappeared was taken as the freezing point. This procedure was necessary because the high viscosity of most of the melts led to extensive supercooling and exceedingly slow crystallization even when the melt was seeded.

The results of these determinations are given in Table I, and represented graphically in Fig. 1.

TABLE I

100.0	250.5		

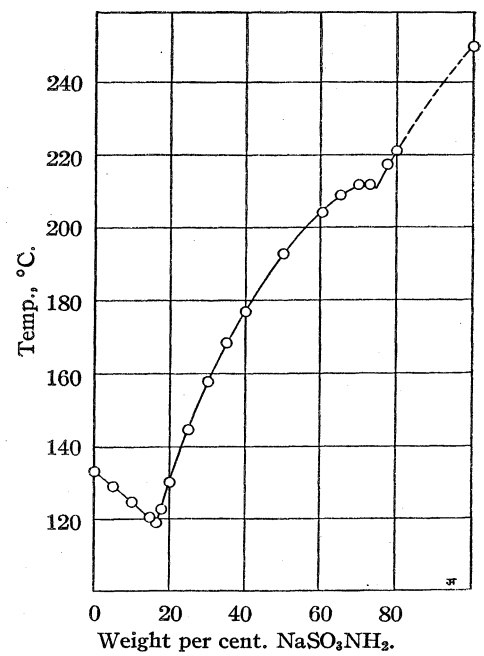

Fig. 1.—Freezing points of mixtures of $NH_4SO_3NH_2$ and $NaSO_3NH_2$.

The curve shows two eutectics. The lower occurs at a composition of 16.95% sodium sulfamate, and a temperature of 118.8°. The solid phases at this point are ammonium sulfamate and a compound $2NH_4SO_3NH_2 \cdot 5NaSO_3NH_2$. The latter compound melts congruently at 213 ± 1°. Since at temperatures above 170° decomposition of ammonium sulfamate occurs, it was necessary to work rapidly, especially at temperatures above 200°. An accurate determination of the upper eutectic point was not possible, but it lies near a temperature of 212° and a composition of 73.0% sodium sulfamate. From melts containing more sodium sulfamate, the solid which separates is pure sodium sulfamate.

The Binary System Sodium Sulfamate–Sodium Nitrate.—A preliminary investigation indicated that only a limited range of compositions could be studied. Mixtures containing

(1) Based on a thesis submitted by Stephen H. Laning to the graduate faculty of Rutgers University in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

(2) Laning and van der Meulen, THIS JOURNAL, **69**, 1828 (1947).

less that 15% or more than 60% of sodium nitrate have melting points at which decomposition is sufficiently rapid to prevent accurate determinations of melting points.

The melting points of mixtures in the range in which decomposition does not occur are given in Table II and are shown graphically in Fig. 2.

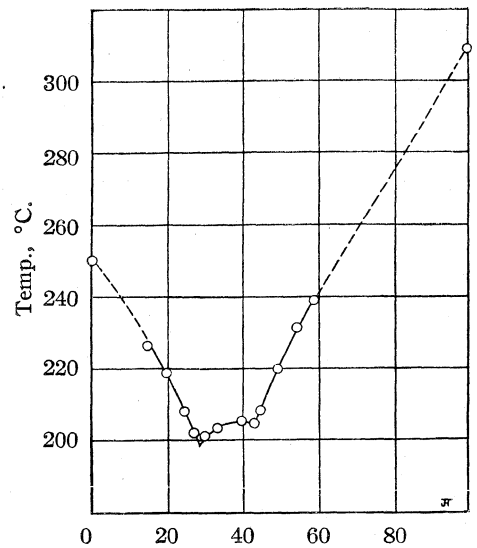

Fig. 2.—Freezing point of mixtures of $NaSO_3NH_2$ and $NaNO_3$.

From melts containing less than 28.5% sodium nitrate, the first crystals which separate are sodium sulfamate. The lower eutectic mixture contains 28.5% sodium nitrate, and melts at 199°. The other eutectic mixture contains 43.4% sodium nitrate and melts at a temperature of 205.0°. There is a compound $NaSO_3NH_2 \cdot NaNO_3$ with a melting point of 205.7°. It contains 41.68% sodium nitrate. From melts containing more than 43.4% sodium nitrate, the first crystals which separate on cooling are sodium nitrate.

TABLE II

FREEZING POINTS OF MIXTURES OF SODIUM SULFAMATE (C) AND SODIUM NITRATE (D)

Dimethylgermanium Sulfide and Dimethylgermanium Oxide

BY EUGENE G. ROCHOW*

Organogermanium oxides of varying degree of complexity have been prepared,[1,2,3] some of them closely analogous to the organosilicon condensation products prepared by Kipping.[4] The ready availability of dimethylgermanium dichloride[5] suggests the preparation of dimethylgermanium oxide to determine whether it has polymeric forms and whether such forms resemble the corresponding methylpolysiloxanes or silicones.

It also is of interest to note that aqueous solutions of germanium dioxide and related inorganic compounds of germanium have been shown to stimulate the production of red blood cells in mammals.[6] New organogermanium oxides or related compounds may provide more suitable reagents for such studies.

Experimental

Preliminary.—Methyl silicones may be prepared by hydrolyzing the corresponding chlorosilanes, separating the water-insoluble methyl siloxane, and processing it to produce the desired polymer. It soon was found that the behavior of the germanium analogs was entirely different. Dimethylgermanium dichloride did not produce a water-repellent film on solids as does dimethyldichlorosilane[7]; instead it dissolved completely in 100 volumes of water. When this solution was evaporated to dryness, no residue was left. When the dimethylgermanium dichloride was hydrolyzed in dilute ammonium hydroxide and the resulting clear solution was evaporated, only ammonium chloride remained. This behavior suggests either volatile hydrolysis products or a readily reversible reaction

$$(CH_3)_2GeCl_2 + 2H_2O \rightleftarrows (CH_3)_2Ge(OH)_2 + 2HCl$$

4.44 g. of dimethylgermanium dichloride was refluxed with two equivalents (0.92 g.) of water for fifteen minutes and allowed to stand overnight. Samples of the aqueous layer then were withdrawn and titrated, and were found to be 3.19 *N* to hydrochloric acid, showing that the reaction equilibrium was far to the left.

Other techniques of direct hydrolysis, including repeated extraction of the dichloride with small portions of cold water, produced some resinous products in poor yield but were ineffective in producing a pure dimethylgermanium oxide. A pure preparation was achieved only by conversion of the sulfide.

Dimethylgermanium Sulfide.—When dimethylgermanium dichloride was dissolved in 6 *N* sulfuric acid and treated with hydrogen sulfide as in the determination of germanium,[8] there was precipitated a waxy white solid which was soluble in acetone (which GeS_2 is not) and insoluble in dilute ammonium hydroxide (which dissolves GeS_2). This precipitate was found to be dimethylgermanium sulfide, $(CH_3)_2GeS$.

100 g. of dimethylgermanium dichloride was stirred with 1000 g. of water[9] and treated with hydrogen sulfide over a period of several days. The precipitate was washed, dissolved in 100 ml. of warm alcohol, and reprecipitated by the addition of four volumes of cold water.[10] The mixture was chilled and saturated with hydrogen sulfide to prevent hydrolysis, and then filtered with suction. The crystals were washed on the filter with water containing hydrogen sulfide, and dried in a desiccator; yield, 73.4 g., or 94.5% of theoretical.

Anal. Calcd.: C, 17.83; H, 4.49; Ge, 53.9; S, 23.80. Found: C, 17.92, 17.77; H, 4.52, 4.46; Ge, 51.6, 52.0[11]; S, 23.42, 24.07, 23.80.[12]

The dimethylgermanium sulfide so prepared crystallizes in flat plates which melt at 55.5° and boil at 302°. These have a peculiar pepper-and-onions odor, and hydrolyze very slowly in moist air to liberate hydrogen sulfide. Hydrolysis also is slow in boiling water, but more rapid in dilute acids or dilute solutions of hydrogen peroxide.

Dimethylgermanium Oxide.—The hydrolysis of dimethylgermanium sulfide in a 10% aqueous solution of hydrogen peroxide yields a clear water solution of methylgermanium oxides or hydroxides, from which resinous and crystalline substances may be obtained upon evaporation. If the original dimethylgermanium dichloride contained some methylgermanium trichloride, or if the treatment with hydrogen peroxide is sufficiently vigorous to oxidize a minor fraction of the methyl groups, there is obtained a sirupy mass which becomes resinous when chilled. The resin is soluble in hot water, in benzene, and in alcohol. Upon long standing, white crystals (presumably of hydroxide) slowly grow in the mass but dissolve upon reheating. A resinous sample which had an average of but 1.2 methyl groups per germanium atom by analysis did not crystallize on standing and was found to be infusible though slightly soluble in water.

The effect of hydrogen peroxide in accelerating the hydrolysis of dimethylgermanium sulfide might be interpreted as the oxidation of a small amount of sulfide ion to sulfate, following by acid hydrolysis of the remainder of the organogermanium sulfide. If so, dilute sulfuric acid would be preferable to hydrogen peroxide as a hydrolytic

(9) Six normal sulfuric acid was used in the preliminary experiments because the initial observation came out of attempts to analyze dimethylgermanium dichloride. Later experiments showed that the same crystalline sulfide is precipitated from a water solution or suspension of the dichloride. The products from water and 6 *N* H_2SO_4 had the same melting point and the same mixed melting point. Lacking an investigation of the crystal structure, it is not known whether the structural units are monomeric $(CH_3)_2GeS$ or some association of several monomeric units.

(10) Well-formed crystals may be obtained merely by cooling the alcohol, but better separation from residual chlorine is obtained by precipitating tiny crystals by the water dilution method.

(11) Germanium was determined by wet oxidation with fuming nitric acid and ammonium persulfate (THIS JOURNAL, **69**, 1730, (1947)), but volatilization of GeO was encountered repeatedly at the beginning of ignition of the residues. Oxidation in a Parr bomb followed by precipitation of the germanium as GeS_2 is being studied.

(12) Sulfur was determined by Dr. L. P. Pepkowitz, using a new method which he has developed for the analysis of microgram samples.

medium for making a pure dimethylgermanium oxide because it has been shown that it does not affect the methyl groups. Accordingly, 7.63 g. of pure distilled $(CH_3)_2GeS$ was refluxed with 20 ml. of water and 0.5 ml. of concentrated sulfuric acid for seven hours, or until there no longer was a rapid evolution of hydrogen sulfide. A solution of barium hydroxide then was added dropwise until the solution was just alkaline to phenolphthalein, and the barium sulfate was filtered off.[13] The clear filtrated was evaporated under reduced pressure to a sirup. The remaining water was distilled off, along with some volatile dimethylgermanium oxide or hydroxide, in the range 100 to 105°, and then the boiling point rose rapidly to over 200° and a polymer of dimethylgermanium oxide distilled. The empirical composition was shown to correspond to $(CH_3)_2GeO$.

Anal. Calcd.: C, 20.24; H, 5.10; Ge, 61.2. Found: C, 20.34, 20.52; H, 5.25, 5.16; Ge, 60.96, 60.28.

The dimethylgermanium oxide so prepared melts at 133.4°[14] and boils at 211°. It does not dissolve readily in water, benzene or cyclohexane. It dissolves in alcohol, and upon addition of water is not precipitated but reverts to the water-soluble form encountered during the preparation. Cryoscopic determinations of the molecular weight of the solid in cyclohexane were inconclusive, probably because of the very limited solubility of the substance. Camphor was found to be a good solvent, however, and determinations of molecular weight (found, 491; calcd. for $(CH_3)_2GeO$, 118.7) indicate that the substance is a tetramer.[15] However, upon repeated melting of the camphor solutions in sealed tubes the depression of the freezing point was found to increase in a way that suggests an (as yet unknown) alteration of the polymeric state of the oxide.

(13) The weight of dried barium sulfate was slightly under the weight expected from the amount of sulfuric acid originally used, showing that there was no oxidation of sulfide to sulfate during the hydrolysis.

(14) Melted samples solidify to a glassy phase which then melts at about 125°.

Summary

1. The hydrolysis of dimethylgermanium dichloride is shown to be reversible to an extent which makes impractical the preparation of dimethylgermanium oxide by the techniques used for preparing silicones.

2. Dimethylgermanium sulfide (m. p. 55.5°, b. p. 302°) has been prepared.

3. Dimethylgermanium oxide has been obtained in a crystalline polymeric form (m. p. 133.4°, b. p. 211°) by hydrolysis of the sulfide.

(15) Probably cyclic, see related tetramer of $(C_6H_5)_2GeO$ in Morgan and Drew, ref. 4.

Alcoholysis of Ethyl Phosphate. The Preparation of Mixed Ethyl Butyl Phosphates

BY WALTER H. C. RUEGGEBERG AND JACOB CHERNACK

Examples of the alcoholysis of esters derived from inorganic acids are not nearly so plentiful in the chemical literature as are those of the organic acid esters. Recently, the alcoholysis of alkyl silicates was studied by Peppard, Brown and Johnson,[1] who found that in some cases the alcoholysis of silicates proceeded without the addition of catalysts to yield mixed silicic acid esters, while, in other instances, hydrogen chloride or silicon tetrachloride was needed to catalyze the reaction. A similar transalkylation reaction between butyl silicate and ethyl silicate under the catalytic influence of aluminum chloride or the alkoxides of aluminum, antimony or magnesium was also found by these same authors[2] to produce mixed alkyl silicates.

Morel and Friedel[3] have shown that under the influence of sodium ethylate, a mixture of ethanol and phenyl phosphate will yield mixed ethyl phenyl phosphates as well as phenetole. The latter property of alkylation is an interesting feature in this reaction and has been extended by Noller and Dutton.[4] Toy[5] has found that methyl alkyl ethers can be prepared by refluxing a mixture of trimethyl phosphate and alcohols whose boiling points are greater than 160°. The residue products in this reaction are described by Toy to be alkali soluble mixtures of alkyl acid phosphates.

The reaction between *n*-butanol and ethyl phosphate was studied in this Laboratory with the view of obtaining diethyl *n*-butyl and ethyl di-*n*-butyl phosphates. It was observed that an equimolar mixture of ethyl phosphate and *n*-butanol would not undergo appreciable reaction even at temperatures of about 160°. In the presence of small amounts of sodium butylate, however, alcoholysis proceeded rapidly at temperatures between 90 and 120°. In Table I, it can be seen that the relative amounts of diethyl *n*-butyl phosphate and ethyl di-*n*-butyl phosphate depend upon the relative amounts of sodium butylate present in the reaction mixture and also upon the mole ratio of ethyl phosphate to *n*-butanol. Some physical properties of the mixed esters are presented in Table II.

In addition to the products of alcoholysis, there were obtained other products which proved to be ethers of which ethyl *n*-butyl ether predominated.

The mole ratio of ether to mixed butyl esters formed (calculated as difference between moles butanol in products and residue and moles butanol originally used) is about 1 to 7. This indicates that sodium butylate acts catalytically in the alcoholysis but is destroyed through ether formation.

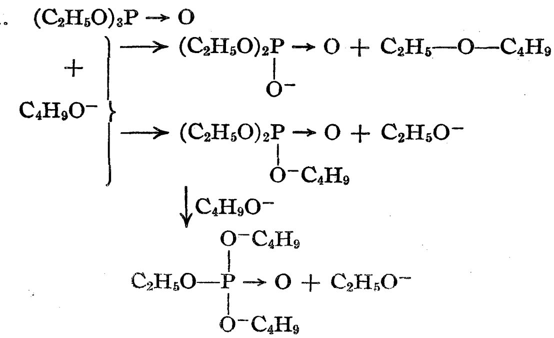
The alkylation of butylate ion by ethyl phosphate is in many respects similar to the alkylation of aromatic amines studied by Billman, Radike and Mundy.[6] In order to establish the similarity between the alkylation of amines and of butylate ion, the reaction of an equimolar mixture of morpholine and ethyl phosphate was investigated. It was found that upon heating an oily, non-volatile substance, presumably an ammonium salt, was formed which upon hydrolysis with aqueous caustic yielded pure N-ethylmorpholine. Although amidation of the phosphoric acid ester, similar to alcoholysis, was not detected, this reaction may be of value in the de-alkylation of phosphoric acid esters.[7]

(6) Billman, Radike and Mundy, THIS JOURNAL, **64**, 2977 (1942).

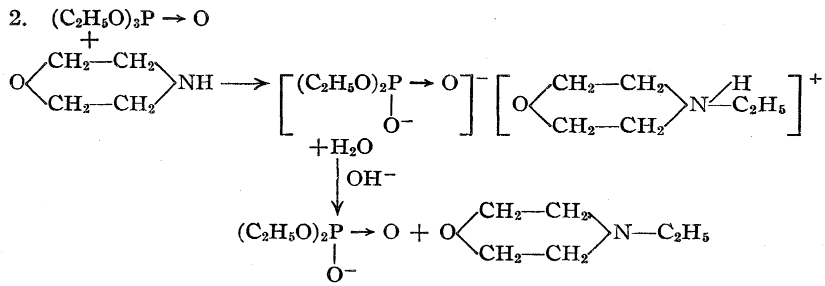
(7) Similar work is being considered at Cambridge University, England, and was learned by one of us (WHCR) through a personal communication with Prof. A. R. Todd of Cambridge.

These reactions may be summarized by the equations

1.



2.



It is obvious from reaction 1, above, that small amounts of diethyl as well as dibutyl ether are to be expected through further reaction of the ethylate and butylate ions on the phosphates, and indeed these substances are found.

Experimental

Alcoholysis of Ethyl Phosphate.—*n*-Butanol, clean metallic sodium and ethyl phosphate were placed in the kettle of an all-glass, fifteen-plate column still in the order indicated. The amounts of reagents used in each particular run are given in Table I. Ethyl phosphate was not added to the other components until all of the sodium had dissolved in the butanol. The complete reaction mixture was heated by means of a Glas-Col heating mantle. Boiling of the reagents occurred when the kettle temperature reached about 115°. The still head was set to constant reflux until boiling and the reflux rate became steady. Then, a low boiling fraction (about 0.5 g., n^{20}_D 1.3655, probably diethyl ether) was removed. The fraction boiling from 36 to 93° was collected and found to be a mixture of ethanol and chiefly ethyl *n*-butyl ether, containing from 75–80% ethanol as found by acetylation with acetic anhydride. The refractive index of these cuts varied between n^{20}_D 1.365 to 1.368 and the densities, d^{20}_4, from 0.780 to 0.788 g./ml. During the removal of this fraction, the kettle temperature rose slowly to 140°

and on occasions the temperature was allowed to climb to 160° in order to remove all of this fraction at atmospheric pressure.

The pressure was subsequently reduced to 50 to 60 mm. and *n*-butanol ($n^{20}D$ 1.390 to 1.398) was removed. After removing unreacted ethyl phosphate at pressures varying between 3 and 10 mm. of mercury (b. p. 66–69° at 3 to 4 mm.; $n^{20}D$ 1.404–1.4055), diethyl *n*-butyl phosphate (b. p. 82–87° at 3 to 4 mm.) and ethyl di-*n*-butyl phosphate (b. p. 95–96° at 3 to 4 mm.) were fractionated out of the reaction mixture.

Anal. Calcd. for $C_8H_{19}PO_4$: P, 14.7; M_R 51.1.[8] Found: P, 14.9; M_R 51.5. Calcd. for $C_{10}H_{23}PO_4$; P, 13.0; M_R 60.5. Found: P, 13.2; M_R 59.8.[8]

The material balances in all runs including residues amounted to 97 to 99%.

Isolation of Ethyl *n*-Butyl Ether.—Fifty grams of the ethanol–ether fraction (b. p. 36–93°) was added to 180 ml. of water. The upper layer, amounting to 8.9 g., was separated, dried over activated silica gel and distilled. The main fraction boiled at 90–93° and was found to have the following constants: d^{20}_4, 0.752; $n^{20}D$ 1.3818; M_R calcd., 31.6; found, 31.6.

Anal. Calcd. for $C_6H_{14}O$: C, 70.5; H, 13.8. Found: C, 70.6; H, 13.9.

Treatment of the ether with hydriodic acid yielded ethyl and *n*-butyl iodides.

Alkylation of Morpholine.—An equimolar mixture of morpholine and ethyl phosphate was charged to a round-bottomed flask equipped with a water-cooled reflux condenser. The mixture was heated by means of a Glas-Col mantle and brought to 150° in fifteen to twenty minutes. At this temperature, vigorous refluxing took place due to heat of reaction, and the mixture changed from a water white to a reddish brown color. If too well insulated, the reaction temperature may rise to 190°. It was found, however, that by maintaining the reaction temperature between 157 and 159° good results can be obtained. The product was poured into 500 ml. of water and heated with 10% excess (44 g.) of sodium hydroxide. The basic aqueous solution was charged to a still and the amine distilled with water as an azeotrope over the range 95–99.8°. The azeotropic distillate was saturated with potassium carbonate whereupon the amine was salted out. After separating from the aqueous layer, the amine was dried over sodium sulfate, filtered and distilled; b. p. 137–138°, d^{20}_4 0.919, $n^{20}D$ 1.4418; yield 70%.

Anal. Calcd. for $C_6H_{13}NO$: C, 62.2; H, 11.4; N, 12.2. Found: C, 62.3; H, 11.5; N, 11.9.

All physical constants given for known compounds agree satisfactorily with those previously published.

Acknowledgment.—The authors are indebted to Messrs. N. Beitsch, S. Sass and B. Zeffert of this Laboratory for having performed the necessary analytical and physical determinations.

Summary

Sodium butylate behaves catalytically on a mixture of *n*-butanol and ethyl phosphate yielding diethyl *n*-butyl phosphate and ethyl di-*n*-butyl phosphate. This alcoholysis is accompanied by a side reaction which causes the alkylation of the butylate ion to ethyl *n*-butyl ether.

This behavior indicates that ethyl phosphate under the conditions employed behaves both as a true ester undergoing alcoholysis and as an alkylating agent. The degree to which each of the products of reaction is produced depends upon the concentration of sodium butylate as well as upon the mole ratio of *n*-butanol to ethyl phosphate.

The alkylation of morpholine to N-ethylmorpholine by means of ethyl phosphate is also described.

ARMY CHEMICAL CENTER, MD.

Study of the Reaction of Buna Rubbers with Aliphatic Mercaptans[1]

BY G. E. SERNIUK, F. W. BANES AND M. W. SWANEY

Introduction

The relative proportion of 1,4- *versus* 1,2-addition of diene units and the elucidation of the partial structure of polymers and copolymers of butadiene have been investigated by various chemical and physical methods such as ozonolysis,[2–5] perbenzoic acid oxidation,[6,7] potassium permanganate oxidation,[6] and infrared absorption.[8] The work presented in this paper was undertaken in an attempt to obtain further information regarding the structure of butadiene polymers and copolymers by studying the reaction of these polymers with aliphatic mercaptans.

The reaction of mercaptans with unsaturated compounds including natural and synthetic rubbers is not new. Posner,[9] Gunnar, Axberg and Holmberg,[10] Hoag and Eichwald,[11] Kharasch, Read and Mayo,[12] Jones and Reid,[13] Cunneen,[14] and others have treated mercaptans with various types of unsaturated compounds. Holmberg[15] treated natural pale crepe rubber with thiogly-

colic acid, and more recently, Kolthoff and co-workers,[16] and Marvel and co-workers[17] studied the reaction of aliphatic mercaptans with butadiene polymers and copolymers in latex form.

From a preliminary study of the reaction of mercaptans with model compounds it was found that ethylenic bonds in conjugated, vinyl, terminal butenyl, and in closed ring structures added mercaptans readily, while internal, non-conjugated ethylenic bonds reacted at a relatively slower rate. Thioglycolic acid added to simple olefins more vigorously than *n*-aliphatic mercaptans. Since this paper was originally submitted, Cunneen[14] reported the reactions of unsaturated hydrocarbons and various thiols. An apparent order of reactivity was found to be cyclohexene > dihydromyrcene > squalene > rubber; and for the thiols, thioglycolic acid > thiophenol ~ isopentanethiol. It is evident that the ease with which an ethylenic bond can add thiols is dependent, in part, upon the structural unit retaining the double bond.

It is quite probable that diene polymers contain several types of ethylenic bonds, but from ozonolysis data[2-5] it must be concluded that a major portion of these bonds results from either 1,2- or 1,4-addition of butadiene units to the polymer chains. These two types of ethylenic bonds should exhibit different rates of mercaptan addition and the determination of the proportion of mercaptan-reactive units in the polymer chains should represent a measure of the per cent. of ethylenic bonds present as side vinyl groups. Ethylenic bonds in structures formed by intramolecular cyclization reactions should likewise be mercaptan reactive. Obviously mercaptan addition reactions will not show complete selectivity for side vinyl groups but it is quite probable that mercaptan-reactive structures other than the side vinyl groups will represent only a very minor portion of the total unsaturation of the butadiene polymers.

This paper records the reaction of thioglycolic acid and *n*-aliphatic mercaptans of C_2 to C_{16} chain length with diene polymers, and the reaction of thioglycolic acid and a *n*-C_{12} mercaptan with model compounds. Polymer-mercaptan reactions were effected in solution, mass and in latex form at various temperatures, in the presence of air, or in the presence of additives which were evaluated as catalysts. The experimental data indicate a pronounced difference in the rate and extent of mercaptan addition by the various diene polymers, and the difference in rate and extent of addition has been utilized in estimating the relative proportion of external and internal ethylenic bonds in the polymer chains.

Experimental

Materials

Polymers.—The polymers used in studying the polymer–mercaptan reactions were natural rubber, polyisoprene, polybutadiene, and copolymers of butadiene and acrylonitrile, butadiene and styrene, and butadiene and alpha methyl para-methylstyrene. Both emulsion and sodium catalyzed polymers of butadiene were used, but in all other cases, emulsion polymers and copolymers were employed. The emulsion polymers were prepared by the standard technique. The polymerization reactions were discontinued when 75% of the monomers were converted to polymer. The latices were freed of unconverted monomers by steam stripping under a pressure of 50–60 mm. Polymers required for solution and mass reactions were obtained by coagulating the stripped latices with 99% isopropyl alcohol, followed by water washing and drying at 175° F. No attempt was made to fractionate the resulting polymers, or to free them of any developed peroxide materials.

Mercaptans.—Mercaptans of C_2 to C_4 chain length were obtained from Eastman Kodak and were used after distillation. Thioglycolic acid was first dried by removing the water as a benzene azeotrope before distilling under vacuum. Normal mercaptans of C_8 to C_{16} chain length were of research grade from the Connecticut Hard Rubber Company. These mercaptans were used directly without further purification. Sharples 3B mercaptan was used after distillation.

Procedure.—A modification of the procedure used by Holmberg[15] was used in effecting the reaction of various polymers with thioglycolic acid. A 5% solution of polymer in benzene was placed in a flask and agitated while a calculated amount of dry thioglycolic acid was added slowly to the solution at room temperature. The reactants were allowed free access to air throughout the course of the reaction. With butadiene polymers and copolymers the reaction was exothermic, and after a short time the solution became cloudy and an insoluble layer separated. The separated product was solubilized by the addition of *n*-hexanol and the reaction continued. Samples were withdrawn periodically for analysis. The polymer–thioglycolic acid reaction products were purified by water washing the benzene–*n*-hexanol solutions until no further test for free thioglycolic acid could be obtained by titration with 0.1 *N* iodine solution. The solvents were then removed by heating the solutions on a steam-bath under high vacuum. The reaction products were further dried in a vacuum oven at 70°. Sulfur analyses of the products were obtained by combustion in a Parr bomb.

Polymers in latex form were treated with mercaptans in 2 oz. and one quart glass reactors which were charged to varying levels and then agitated in a thermostated bath at 50° for varying periods of time. The amount of mercaptan employed corresponded to a 100% excess over the amount theoretically required for complete double bond saturation. Several conditions were employed wherein the free space of the reactors was flushed either with nitrogen, air, or pure oxygen; and the amount of persulfate in the systems was varied. The polymer–mercaptan reaction products were isolated from the emulsions by coagulating in an excess of 99% isopropyl alcohol. The products were thoroughly washed in fresh portions of alcohol and then dried in a vacuum oven at 70°.

Mass reactions of dry polymers and mercaptans were carried out under essentially the same conditions employed by Jones and Reid[13] in their study of the reaction of mercaptans with unsaturated compounds. The dry polymer was dissolved in the desired mercaptan, two mols of mercaptan being used per mol of diene in the polymer. The solutions were agitated in a glass reactor, sealed from the atmosphere without displacing the air in the reactor, at 180–200° for varying periods of time. Samples of the reaction mixture were removed at intervals for purification and analysis. The polymer–mercaptan reaction products were isolated by coagulating the reaction mixture with a large volume of 99% isopropyl alcohol followed by repeated dissolution of the mass in petroleum ether and coagulation until the mixed solvents showed no trace of free mercaptan as determined by titration with 0.1 *N* iodine solution. The purified reaction mass was stripped of solvents and moisture under vacuum at 80°.

(16) Kolthoff and co-workers, private communication.
(17) Marvel and co-workers, private communication.

Calculations.—The calculation of the per cent. of double bonds saturated by a particular mercaptan is based on the sulfur content of the reaction product, molecular weight of the mercaptan, and the unsaturation value of the polymer expressed as Wijs number. It is assumed that the total sulfur of the reaction product minus the sulfur value of the original polymer represents the total sulfur introduced into the polymer by the additive fixation of the mercaptan. The percentage of double bonds saturated was calculated from the expression

$$\% \text{ D.B. saturated} = \frac{2.54 \times 10^6 (\% \text{ Sa} - \% \text{ Sp})}{[3200 - (\% \text{ Sa} - \% \text{ Sp})(\text{Mol. wt. RSH})]I_{2p}}$$

where

Sa = % Sulfur of the reaction product
Sp = % Sulfur of the original polymer
I_{2p} = Wijs number of original polymer

Results and Discussion

Reactions of Mercaptans and Unsaturated Compounds.—In determining the relative reactivities of various types of ethylenic bonds with aliphatic mercaptans, model compounds were employed which possessed either terminal or internal unsaturation. The results of these experiments are given below and indicate that compounds possessing terminal methylene groups or double bonds in closed ring structures add mercaptans vigorously while internally located double bonds react very slowly with mercaptans.

Oleic acid (0.1 mole), free of linoleic and linolenic acids, and thioglycolic acid (0.1 mole) when combined in benzene (50 cc.) at room temperature did not produce an exothermic reaction. The product isolated from the reaction mixture after standing at room temperature for ten days with access to air, contained 6.60% S (calcd. for $C_{20}H_{38}O_4S$: S, 8.53%). By treating linoleic acid (0.1 mole) and thioglycolic (0.2 mole) in the manner described above, a yield of 40.3 g. of adduct and unreacted linoleic acid was obtained after 29 days' reaction time at room temperature (calcd. amount of adduct 46.44 g.). On the other hand, when one-tenth molar proportions of 10-undecylenic acid and thioglycolic acid were combined as above, a highly exothermic reaction resulted. The solid, crude product, isolated from the water-washed benzene solution, contained 12.36% S (calcd. for $C_{13}H_{24}O_4S$: S, 11.58%).

Cyclohexene (0.1 mole), and thioglycolic acid (0.1 mole) also reacted exothermally in benzene in the presence of air. The product, after being water washed and dried under vacuum and undistilled, showed a sulfur content of 20% (calcd. for $C_8H_{14}O_2S$: S, 18.4%). This reaction was described by Cunneen.[14]

Molar proportions of 10-undecylenic acid and *n*-dodecyl mercaptan reacted exothermally in benzene solution in the presence of air. This reaction was less vigorous than when thioglycolic acid was used. The solid reaction product after a single crystallization from benzene showed a sulfur content of 8.20% (calcd. for $C_{23}H_{46}O_2S$: S, 8.30%).

Reaction of Polymers.—An emulsion copolymer of butadiene and styrene, prepared from an initial feed ratio of 78 parts of butadiene and 22 parts of styrene by weight, reacted exothermally with thioglycolic acid after a few minutes of contact. Reaction products isolated after 3, 25, 45, 70 and 144 hours, showed 47, 42, 38, 43 and 42% double bond saturation values, respectively. These data indicate that the reaction is exceedingly rapid and apparently reaches a saturation value corresponding to about 38–47% double bond saturation. Under the same conditions a copolymer prepared from an initial feed of 74 parts of butadiene and 26 parts of acrylonitrile, and a polybutadiene prepared by sodium catalysis, reacted exothermally with thioglycolic acid and after twenty-five hours the products were isolated and showed 42 and 39% double bond saturation values, respectively. Natural smoked sheet, purified by acetone extraction, solution, and precipitation showed no exothermic reaction with thioglycolic acid in benzene solution under the same conditions. After one month the isolated product showed a sulfur content of 7.04% which corresponds to 18.8% double bond saturation. Cunneen[14] found but a slight reaction between natural rubber and thioglycolic acid under peroxidic conditions and high vacuum. The above experiments emphasize a pronounced difference in the reaction rate between mercaptans and butadiene polymers and natural rubber. The difference in reaction rates is undoubtedly due to the presence of different double bond structures in the respective polymers.

The double bond saturation values obtained for butadiene polymers and natural rubber, treated in latex form with mercaptans, also indicate a pronounced difference in the reaction rate and the extent of reaction. Emulsion polymer latices, containing equivalent amounts of residual potassium persulfate catalyst, when sealed in reactor vessels with an excess of ethyl mercaptan in such a manner that the vessel was flushed with nitrogen and mercaptan vapor, reacted with a definite and reproducible amount of mercaptan. This addition proceeded rapidly during the first three to six hours of reaction time at 50°, and reached a limiting value which was unique for the type of polymer being treated. These observations are illustrated by the data of Table I. It will be noted that polymers and copolymers of butadiene showed a relatively greater proportion of double bonds reacted than emulsion polyisoprene or natural rubber in air-free systems containing equivalent amounts of persulfate catalyst.

The effect of oxygen and peroxides on the rate and extent of ethyl mercaptan addition to Buna N polymers was followed by effecting the reactions in vessels charged to varying levels. The charged reactors were flushed with air prior to sealing. It will be noted from the results presented in Table II that when the reactors were completely filled, the amount of ethyl mercaptan which added to the polymer double bonds was the same as when oxy-

gen had been flushed from the systems. However, when the amount of free air space of the reactors was increased, the amount of mercaptan reacting with the polymer also increased, apparently approaching a limiting value of 35–45% double bond saturation. This saturation value did not change appreciably as a result of a prolonged reaction time, increased or decreased potassium persulfate concentrations used in the original polymerization charge, or by substituting *n*-propyl or *n*-butyl for ethyl mercaptan. Further, it was observed that flushing the reactors with oxygen instead of air, or the addition to the reaction charge of 0.05 part of benzoyl peroxide, based on the polymer, did not affect the extent of mercaptan addition to the polymer. These data indicate that the reaction of mercaptans with Buna rubbers in latex form is catalyzed by oxygen, and the extent of double bond saturation is of the same order of magnitude as was found when this polymer reacted with thioglycolic acid.

The data presented in Table III relate to the C_8 to C_{16} chain length mercaptan saturation values for polybutadiene, butadiene–styrene, and butadiene–α - methyl–p - methylstyrene copolymers. The reactions were effected in mass at high temperatures. The data do not include the reaction rates, but only summarize the values obtained during reaction times in which reaction apparently ceased. Although it was observed that the rate of mercaptan addition varied, the final polymer double bond saturation values were of about the same order of magnitude. Sharples 3B mercaptan gave rise to gel polymers of low sulfur content under the same reaction conditions.

The selectivity of the mass reaction at elevated temperatures appears to be overcome when a continuous stream of air is passed through the reaction mixture. Under such conditions 75% of the double bonds in a butadiene–styrene copolymer were saturated by a normal mercaptan of C_{14} chain length. The presence of volatile reaction products possessing an odor suggestive of aldehydes would indicate that under such drastic conditions the polymer was degraded.

In further experiments polybutadiene reacted in mass with Lorol mercaptan in the presence of possible activating agents at various temperatures in order to determine whether the time of the reaction could be decreased, and whether activating agents have any effect upon the selectivity of the reaction. Piperidine, zinc dibutyldithiocarbamate, anthraquinone, benzoyl disulfide, sulfur, and benzoyl peroxide were evaluated in concentrations of 2 to 10%, based on the polymer, at temperatures of 75 to 180° for varying periods of time. Piperidine and anthraquinone exhibited an activating effect, but the extent of polymer double bond saturation was unaltered.

Based on the partially known structure of buta-

diene polymers and copolymers and upon the vast difference in the rate at which vinyl and internal ethylenic bonds add mercaptans, it would appear that the 38 to 47% of ethylenic bonds which added mercaptans readily are probably those derived from 1,2-addition of butadiene units to the polymer chains, or those arising from 1,2-addition and intramolecular cyclization reactions.

The saturation values obtained by the reactions between various types of mercaptans and butadiene polymers are in fair agreement in spite of a wide range of reaction conditions.

If it is assumed that the polymer double bonds which added mercaptans readily are those present in side vinyl groups, then the mercaptan saturation values found are in fair agreement with the value of 48% for a butadiene–styrene copolymer as determined by potassium permanganate oxidation,[6] and 34.5 and 42.8% as determined by ozonolysis[3] for a butadiene–styrene and a sodium catalyzed polybutadiene, respectively. The mercaptan saturation values are not, however, in full agreement with those found by perbenzoic acid oxidation whereby emulsion butadiene–styrene copolymers showed 1,2-values of 27[6] and 20–22[7] per cent. while sodium catalyzed polybutadiene showed 58[7] per cent. side vinyl groups.

Summary

Thioglycolic acid added exothermally to butadiene polymers and copolymers in benzene solution under mild conditions to give apparent double bond saturation values of 38 to 47%. When the same polymers reacted with aliphatic mercaptans of C_2 to C_{16} chain length, in mass or latex reactions, saturation values were obtained which were in accord with those found by thioglycolic acid addition.

It is suggested that the double bonds in butadiene polymers and copolymers which were readily saturated by the above mercaptans are predominately those present in the polymer chains as vinyl side groups.

Porphyrin Studies. V.[1] The Metal Complex Salts of α,β,γ,δ-Tetraphenylporphine

BY PAUL ROTHEMUND AND AMEL R. MENOTTI[2,3]

In the preceding paper of this series[1] we reported the synthesis of α,β,γ,δ-tetraphenylporphine (hereafter to be abbreviated T.P.P.) on a preparative scale. Thus sufficient quantities of this porphyrin became available for the preparation and study of a large number of its metal complex salts, fifteen of which have been obtained in the present investigation in crystalline form and five in solution only.

This is probably the largest number of metal complex salts ever prepared from any one porphyrin, and the work was undertaken with the aim of furnishing reliable material for physico-chemical studies on the structure of porphyrin metal complexes, especially in connection with the study of chlorophyll. Spectrophotometric measurements on the above-mentioned series of compounds are in progress at the Charles F. Kettering Foundation in order to determine possible correlations between absorption and fluorescence spectra; some of the findings have already been published.[4]

The metal complex salts described are the derivatives of T.P.P. which shows the "etio type"[5] spectrum and has its first absorption band in ether solution at 648 mμ. Derivatives of isomers and of other polynuclear pyrrole pigments, by-products in the synthesis of T.P.P., will be described in a separate publication.

In the preparation of these metal complexes three general methods were employed which are described in detail in the experimental part.

General Properties of the Metal Complex Salts.—All of the salts isolated were well-crystallized compounds of high surface luster. They showed selective absorption in the visible region of the spectrum and had melting points ranging from 400 to 520°. On heating from 400 to 450° all but the manganese chloride and the gold salts sublimed. During this sublimation partial decomposition of the complex occurred.

The complexes varied markedly in stability. Thus, the potassium and one thallium complex decomposed when dissolved in neutral solvents such as benzene and ether; the magnesium, mercury, and lead complexes split when shaken with 50% acetic acid. The zinc and silver complexes were stable to 50% acetic acid but decomposed slowly in hydrochloric acid solutions. In every case of these decomposition conditions the presence of free porphyrin in the solution was ascertained. The iron chloride, manganese chloride, cobalt, nickel, copper, stannous chloride, and gold complexes were heated in the steam-bath with

concentrated hydrochloric acid for hours without any sign of decomposition.

The complexes of lithium, sodium, potassium, rubidium and cesium decomposed rapidly when their solutions were exposed to strong light; the magnesium and thallium (stabile compound) complexes showed spectrum shifts under these conditions. Solutions of the magnesium salt first showed a decrease in the intensity of the absorption band in the red and then decomposed to a solution without porphyrin spectrum on further exposure. The solubility data of the complex salts are given in Table I.

Upon heating of magnesium phthalocyanin with commercial tetralin Helberger[6] observed a new case of chemiluminescence, and demonstrated that a number of metal complex salts of different types of porphyrin pigments exhibit this luminescence reaction. Later Helberger and Hevér[7] studied the mechanism of the reaction in detail and ascertained that the presence of tetralin peroxide in commercial tetralin was responsible for the positive result; with other solvents these authors arrived at similar findings and rendered it highly probable that in every case impurities of peroxide types are present in the solvent. It is to be hoped that they will succeed in elucidating the conditions for this reaction, which may be of great interest in the field of photosynthesis research. From this point of view it seems desirable to test all new porphyrin metal complex salts under the conditions of Helberger's chemiluminescence reaction and give the results as additional characteristics of the compounds discussed. Of the complex salts described above, the magnesium, zinc, and cadmium salts were tested thus far. Each of them exhibited bright red chemiluminescence when heated above 125° in tetralin, xylene, *p*-cymene, or bromocyclohexane. When freshly distilled tetralin was employed, only a faint glow of short duration was obtained. On adding to the hot solution a few drops of tetralin which had been standing for some time, however, the bright red glow reappeared.

Experimental

General Remarks.—Three methods of preparation of the metal complex salts were used; they will be referred to in the following text by number, and only quantities of reagents and variants from the general procedure will be indicated specially.

Method 1 (Acid Medium).—The porphyrin solution in acetic (or formic) acid was heated under reflux with the acetate of the metal. In the preparation of the silver complex the di-silver salt was formed under these conditions; the mono-silver complex was obtained by adding a chloroform solution of the porphyrin to the solution of silver acetate in glacial acetic acid and heating under reflux. This variant was also useful in those cases where the slight solubility of the porphyrin in glacial acetic acid alone would have required large quantities of solvent. The reaction mixture was examined spectroscopically from time to time; after completion of the reaction the solution was concentrated to a small volume and the crystalline product removed by filtration after cooling.

Method 2 (Weakly Alkaline Medium).—The metal salt was added to the hot solution of the porphyrin in pyridine; the reaction mixture was heated until conversion was complete and concentrated under reduced pressure on a steam-bath to obtain the crystalline product. Thallium yielded two complexes, one relatively labile one directly, and a stabile one when hydrogen peroxide had been added to the reaction mixture.

Method 3 (Strongly Alkaline Medium).—To a porphyrin solution in pyridine the required metal salt and 40% methanolic potassium hydroxide were added.

The acetates of the metals gave the best results in forming the complex salts. Gold chloride ($AuCl_3$) and tin chloride ($SnCl_2$) were used for the preparation of the gold and tin complex salts, respectively. It was best to obtain complete conversion of the free porphyrin into the complex metal salt before attempting to isolate the product. The separation of any free porphyrin remaining as an impurity was usually difficult. This point of complete conversion could be ascertained by diluting a few drops of the reaction mixture with ether (acetic acid present was removed with water) and examining the ether solution spectroscopically for the bands of free T.P.P. In case of their presence the solution had to be refluxed longer, occasionally with the addition of more inorganic salt. In Method 1 above it was sometimes necessary to distil off the chloroform and to reflux the remaining acetic acid solution to obtain complete conversion. In the preparation of the cadmium, lead and thallium complexes a small amount of free T.P.P. always remained in the pyridine mother liquid; however, since these complexes were insoluble in pyridine and crystallized out while the free porphyrin was quite soluble, a good separation was obtained.

Copper Complex Salt. Preparation, (a) Method 1.—T.P.P.,[8] 50 ml. of chloroform, 200 mg. of copper acetate in 50 ml. of glacial acetic acid; yield, quantitative. Recrystallized by extraction from Soxhlet thimble with benzene.

Elimination of Copper from the Complex.—The crystals were moistened with water, and phosphorus pentachloride

[a] Pyridine.

was added until further addition caused no reaction. The solution was then poured into ether and neutralized with sodium carbonate solution. The ether layer contained the free porphyrin.

(b) **From Formic Acid Solution.**—Constant boiling formic acid, approximately 90% HCOOH, is a good solvent for the free porphyrin. From this solution a complex copper salt of the porphyrin could be obtained which differed from that prepared above, Method 1, in that it possessed an additional intense absorption band at 651.8. T.P.P.[8] was dissolved in 200 ml. of 90% formic acid, 400 mg. of copper acetate was added and the whole refluxed on a steam-bath for one hour. At the end of this time conversion was complete and the yield was quantitative. The analysis of this material, recrystallized from benzene, was identical with that of the copper complex salt prepared under (a).

Mono Silver Complex Salt. Preparation, Method 1.—T.P.P.,[8] 50 ml. of chloroform, 500 mg. of silver acetate, 50 ml. of glacial acetic acid. For analysis the material was recrystallized twice from benzene.

Di Silver Complex Salt.—A silver complex salt containing two atoms of silver in the molecule was obtained from glacial acetic acid solutions with silver acetate. Five hundred ml. of glacial acetic acid containing 150 mg. of the porphyrin was refluxed with 150 mg. of silver acetate for one-half hour; yield, 90 mg. blue violet crystals on cooling.

Gold Complex Salt. Preparation, Method 1.—Two hundred mg. of porphyrin, 50 ml. of chloroform, 200 mg. of gold chloride, 1 g. of sodium acetate, 50 ml. of glacial acetic acid. The chloroform was distilled off and the solution refluxed fifteen minutes, cooled and filtered. Three hundred mg. of blue crystals was obtained. They were recrystallized by extracting from a Soxhlet thimble with a mixture of 20 ml. of chloroform and 50 ml. of benzene; yield, 200 mg. blue-red crystals.

Magnesium Complex Salt, "Phyllin." Preparation, Method 3.—A sealing tube similar to that employed in the synthesis of the porphyrin[1] was filled with the following: 300 mg. of T.P.P. in 25 ml. of hot pyridine, 500 mg. of magnesium acetate, 60 ml. of 40% methanolic potassium hydroxide. The air in the tube was displaced by nitrogen to render sealing safer, and the sealed tube was supported in a large Carius furnace. For this experiment the furnace was tilted at an angle of 30° or more to prevent the porphyrin from creeping into the upper part of the tube not bathed in liquid. The furnace was left at 170° for sixteen hours, then the contents of the cooled tube were poured into approximately 100 g. of ice made from distilled water. When the ice had melted, the crystalline precipitate was filtered off, washed with water, and the crystals dried by suction. This dried material was then recrystallized by extracting from a thimble with 20–30 ml. of ether. The "phyllin" was very photolabile; the reaction mixture or solutions of the "phyllin" should not be exposed to light. The reaction tube was wrapped in towelling on removing from the furnace and the extraction apparatus for recrystallizing was wrapped in black paper, or better still, the extraction was carried on in a dark room. Solutions of the "phyllin" could be exposed for brief periods to diffuse light but a half hour exposure to daylight, not direct sunlight, caused a visible decrease in the intensity of the absorption band at 624.4 mμ. On exposing dilute ether solutions of the "phyllin" to daylight, northern exposure, the first visible change was a decrease in the intensity of the absorption band at 624.4 mμ. After two hours this band had usually disappeared completely. During this time the other absorption bands remained visibly unchanged. On further exposure the "phyllin" slowly decomposed to yield a pale yellow ether solution. Analysis of different batches of the "phyllin," prepared as described above, consistently yielded low values for carbon. Assuming hydrolytic cleavage of one bond from magnesium to nitrogen during the precipitation with ice of the "phyllin" from the reaction mixture and calculating for one hydroxyl group in the molecule, the analysis compares with the new theory as shown in Table II.

Zinc Complex Salt. Preparation, Method 1.—T.P.P.,[8] 50 ml. of chloroform, 250 mg. of zinc acetate, and 250 ml. of glacial acetic acid were refluxed for one hour on the steam-bath, and quantitative yield was obtained; the substance was recrystallized by extracting from a Soxhlet thimble with a mixture of 40 ml. of ether and 20 ml. of methanol.

Cadmium Complex Salt. Preparation, Method 2.—One gram of T.P.P. in 100 ml. of hot pyridine, 800 mg. of cadmium acetate, and 40 ml. of 40% methanolic potassium hydroxide were refluxed for two hours on the steam-bath. To this hot solution 240 ml. of hot water was added, and the contents allowed to cool; yield, 1.5 g. of very fine crystals which were washed several times with 2-ml. portions of cold water, dried and extracted from a Soxhlet thimble with 100 ml. of pure ether. For analysis the material was recrystallized once from ether and dried overnight in a phosphorus pentoxide desiccator; it contained 1 mole of pyridine of crystallization. When dried at 175° for eighteen hours to constant weight in a Pregl block, the substance lost 9.6%, corresponding to the pyridine value (see Table II).

TABLE III

ABSORPTION SPECTRA OF METAL COMPLEX SALTS OF α,β,γ,δ-TETRAPHENYLPORPHINE

The spectra were visually measured in the conventional manner by determining points of equal intensity at the edges of each absorption band which are given in mμ. The center of the band (absorption maximum) was for symmetrical bands calculated by averaging the two values measured. Unsymmetrical bands are indicated by dashes, *e. g.*, ---546.0 shows that the maximum of intensity is located at 546.0 with the more gradual increase of the intensity toward the red region of the spectrum. In recording the order of intensity (Int.:) marked differences in intensity have been separated by a semicolon.

All solutions of the metal complex salts showed red fluorescence; solutions of the cadmium, stabile thallium, iron chloride, manganese and cobalt complex exhibited it intensely. The red fluorescence was most conspicuous in the solutions of the alkali complexes and of the magnesium and zinc salt.

Name	Solvent	Color of solution	Absorption spectrum
Copper	Ether	Pink	I, 610.6; II, 574.7; III, 538.0; IV, 497.3; E. A. 446.6. Int.: III; I, IV, II

[a] In pyridine solution the absorption bands are slightly shifted toward the red region. [b] This change did not occur in the dark. [c] In the pyridine mother liquid above remained a small amount of a substance of bluish lavender color in pyridine–ether solution. Spectroscopically it showed an additional absorption band at 651.4 and a more intense 627.4 band.

Mercury Complex Salt. Preparation, Method 2.—T.P.P.,[8] 50 ml. of pyridine and 500 mg. of mercuric acetate were refluxed for two and one-half hours on a steam-bath. The conversion was complete and yielded approximately

0.5 g. of blue needles from the solution after cooling. The substance was recrystallized twice from benzene by extracting from a Soxhlet thimble and air dried.

The spectra in benzene and in pyridine are recorded in Table III. In piperidine and quinoline the absorption spectrum was similar to that in pyridine, the only difference lying in a shift of the absorption bands toward the red, this shift being greatest for piperidine. The color and spectrum shifted to that observable in the organic base if a drop of the base was added to the benzene solution.

Labile Thallium Complex Salt. Preparation, Method 2.—Two hundred mg. of T.P.P., 20 ml. of pyridine and 200 mg. of thallous acetate were refluxed overnight on a steam-bath. One hundred mg. of dark green crystals was obtained from the cold solution. Addition of more thallous acetate to the mother liquid and repeating the refluxing yielded a second crop of complex salt. This thallium complex was very unstable in solution, the mother liquid always containing unchanged porphyrin. When the above green crystals were dissolved in pyridine, the free T.P.P. spectrum appeared immediately in the spectrum of the salt. A pure complex salt spectrum was obtained only in hot pyridine solution in the presence of thallous acetate. On standing the free porphyrin spectrum appeared in this solution also. The complex was easily split by water to form the free porphyrin.

Stable Thallium Complex Salt. Preparation, Method 2.—The thallous acetate used must be oxidized in order to prevent the formation of the unstable thallium complex described above. The thallous salt was oxidized in acetic acid with 30% hydrogen peroxide solution, and the crystals obtained on evaporating the solution were used, or 30% hydrogen peroxide was added directly to a pyridine solution of the porphyrin containing thallous acetate. Both methods were used, the latter being described below. A solution of T.P.P.,[8] 50 ml. of pyridine, 500 mg. of thallous acetate and 2 ml. of 30% hydrogen peroxide boiled down to a total volume of 30 ml. After addition of 20 ml. of pyridine and 1 ml. of 30% hydrogen peroxide solution and concentrating to 20 ml. by boiling, the conversion was complete. Forty ml. of hot methanol was poured into the hot solution. Five hundred mg. of lustrous blue crystals formed on cooling. The material was extracted from a Soxhlet thimble with benzene, filtered, the benzene solution concentrated to 20 ml., and 50 ml. of hot methanol added; yield, 450 mg.

Tin Chloride Complex Salt. Preparation, Method 2.—T.P.P.[8] in 50 ml. of pyridine and 400 mg. of stannous chloride: Refluxing for two hours yielded 500 mg. of fine lavender crystals on cooling, which were recrystallized by extracting from a thimble with a mixture of 15 ml. of chloroform and 40 ml. of benzene.

Lead Complex Salt. Formation, Method 2.—T.P.P.,[8] 50 ml. of pyridine, and 500 mg. of lead acetate were heated for one hour. On cooling approximately 500 mg. of dark blue-green crystals was obtained and recrystallized twice by extracting from a thimble with 40 ml. of benzene. The analytical results check for 1 mole of pyridine in the molecule. There was no loss in weight upon heating at 175° for eighteen hours.

Manganese Chloride Complex Salt. Formation, Method 1.—T.P.P.,[8] 50 ml. of chloroform, 70 ml. of glacial acetic acid, 500 mg. of manganous acetate and 100 mg. of sodium chloride were refluxed for six hours. The solvents were distilled off under vacuum and 50 ml. of glacial acetic acid was added to the dry residue and the resulting solution concentrated to approximately 15 ml. The crystals in the cooled solution were filtered off, washed with glacial acetic acid, air dried, and recrystallized by extracting from a Soxhlet thimble with ether; yield, approximately 300 mg. of dark green crystals of high luster. The manganese chloride complex was extremely soluble in methanol. Crystals could be obtained if the methanol solution was added to ligroin and the methanol evaporated. The spectrum of the resulting crystals in methanol differed little from that in ether, which is given in Table III.

Iron Chloride Complex Salt, "Hemin." Preparation, Method 1.—T.P.P.[8] was dissolved in 50 ml. of chloroform and 200 mg. of sodium chloride was added. Into this solution was filtered, hot, 150 ml. of glacial acetic acid saturated with ferrous acetate. This was prepared by dissolving pure iron filings in boiling glacial acetic acid and filtering the hot solution into the chloroform. After refluxing for two hours, concentrating to approximately 50 ml., cooling and filtering, approximately 500 mg. of impure crystals was obtained. The crystals were extracted from a thimble with chloroform, the solution concentrated to 10 ml. and approximately 80 ml. of hot methanol was added. Dark blue crystals formed on cooling. Prolonged heating had to be avoided since this caused the formation of a substance with spectrum differing from that given above for the "hemin." For analysis the material was recrystallized twice from chloroform–methanol.

Cobalt Complex Salt. Preparation, Method 1.—T.P.P.,[8] 50 ml. of chloroform, 250 mg. of cobaltous acetate, and 50 ml. of glacial acetic acid were refluxed for one-half hour. On cooling fine maroon crystals formed quantitatively and were recrystallized by extracting from a thimble with ether.

Nickel Complex Salt.—Nickel acetate was substituted for cobalt acetate in the above procedure and the solution was heated for one hour. Five hundred ten mg. of blue crystals, filtered from the cooled solution, were recrystallized by extracting from a thimble with benzene.

Lithium Complex Salt. Formation.—A methanolic solution of lithium hydroxide was added to a solution of the porphyrin in pyridine.

Sodium Complex Salt. Formation.—Same as above, substituting sodium hydroxide for the lithium salt.

Potassium Complex Salt. Preparation.—50 mg. of T.P.P. in 20 ml. pyridine was added to 20 ml. of 40% methanolic potassium hydroxide. After a few hours of standing the solution was filtered through a fritted glass filter. It was not possible to prepare the pure complex salt since it was unstable in solutions not containing dissolved potassium hydroxide.

Rubidium Complex Salt. Formation.—A methanolic solution of rubidium hydroxide was added to a solution of the porphyrin in pyridine. The hydroxide was obtained by shaking rubidium chloride with silver oxide in methanol.

Cesium Complex Salt. Formation.—Same as above, substituting cesium hydroxide for rubidium hydroxide.

Summary

1. The preparation of the complex salts of α,β,γ,δ-tetraphenylporphine with the following metals is reported: lithium, sodium, potassium, rubidium, cesium, copper, mono silver, di silver, gold chloride, magnesium ("phyllin"), zinc, cadmium, mercury, tin chloride, lead, thallium (stabile complex salt), thallium (labile complex salt), manganese chloride, ferric chloride ("hemin"), cobalt and nickel.

2. The data for the absorption spectra of these compounds in the visual region of the spectrum are presented.

3. The elementary analyses by microanalytical procedures show that most of these salts are normal complexes; the gold salt crystallizes from benzene with 1 mole of gold chloride, the "phyllin" as magnesium hydroxide, cadmium and lead salt with 1 mole of pyridine. The structure of the tin chloride complex remains to be investigated further. The isolation and analysis of the complexes of the alkali metals—for which the spectra only are given—have not been performed as yet.

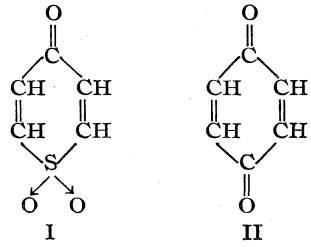
Studies in the Thiapyran Series. The Preparation, Properties and Reactions of 1,4-Thiapyrone-1-dioxide

BY EDWARD A. FEHNEL[1] AND MARVIN CARMACK

A comparison of the structural formulas of 1,4-thiapyrone-1-dioxide (I) and *p*-benzoquinone (II) suggests that these two compounds might possess



I II

many chemical and pharmacological properties in common. Several investigators[2] have demonstrated the similarity in the behavior of α,β-unsaturated sulfones and α,β-unsaturated ketones in addition reactions involving both symmetrical and unsymmetrical reagents, and Kohler and Larsen[3] have shown that the addition reactions of α-phenylsulfonyl-β-benzoylethylene with unsymmetrical reagents are similar to those of β-benzoylacrylic esters, the mode of addition being controlled by the conjugated system —C=C—C=O. Although these and other investigations[4] have provided evidence for the temporary expansion of the valence shell of sulfur to accommodate ten electrons, the characteristic enolization of the initial 1,4-addition products of quinones to yield stable hydroquinones as the final products would not be expected to have a counterpart in the thiapyrone dioxide series.

The preparation of 1,4-thiapyrone-1-dioxide has been described by Arndt and Bekir,[5] who obtained a very small amount of the compound as the final product of a five-step synthesis starting with ethyl β-thiodipropionate.[6] In order to prepare the relatively large amounts of I required in the present work, we have re-investigated each step in the original procedure and by applying various modifications have succeeded in obtaining a greatly improved over-all yield of the desired product.

1,4-Thiapyrone-1-dioxide, like its carbonyl analog, *p*-benzoquinone, is a sternutator, stains the skin yellow, and is decomposed by aqueous alkali with the formation of a deep red color. The ultraviolet absorption spectra of *p*-benzoquinone, 1,4-thiapyrone-1-dioxide, and 2,3-dihydro-1,4-thiapyrone-1-dioxide are compared in Fig. 1.

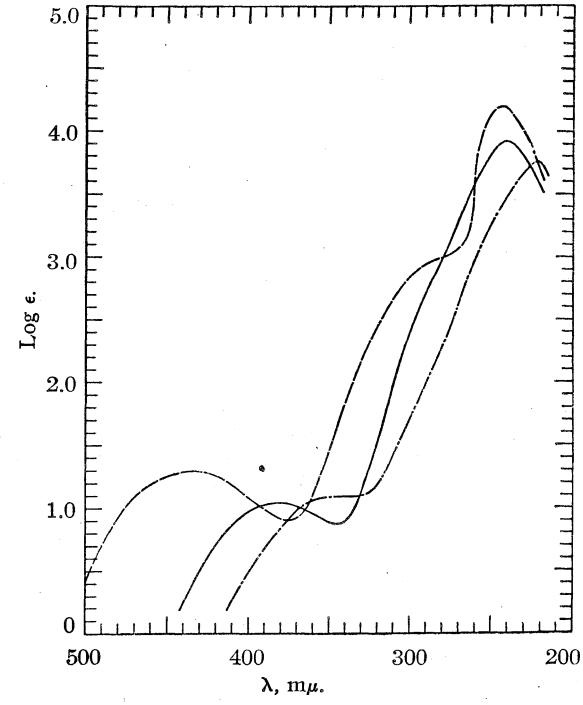

Fig. 1.—Absorption spectra of 1,4-thiapyrone-1-dioxide, ——; 2,3-dihydro-1,4-thiapyrone-1-dioxide, —·—·—; *p*-benzoquinone, — — —.

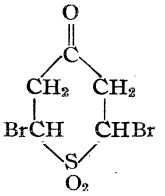
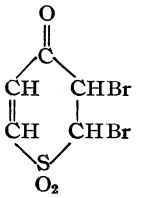
On treatment with zinc and acetic acid, 1,4-thiapyrone-1-dioxide is smoothly reduced to the corresponding saturated heterocycle, tetrahydro-1,4-thiapyrone-1-dioxide. Two molecules of hydrogen bromide may be added to I in the presence of a large excess of the reagent in acetic acid solution, but the reaction appears to be reversible and the dibromo compound readily loses hydrogen bromide on warming in aqueous or acetic acid solution. This rather unstable addition product (m. p. 130–133° dec.) has quite different properties from the stable isomer, 3,5-dibromotetrahydro-1,4-thiapyrone-1-dioxide (m. p. 220–222° dec.) obtained by bromination of tetrahydrothiapyrone dioxide,[5] and has been assigned structure III on the basis of Kohler and Larsen's observations[3] regarding the mode of addition of unsymmetrical addenda to unsaturated ketosulfones.

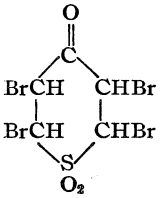


III

The addition of either one or two molecules of bromine to I proceeds readily at room temperature, giving as the initial products the dibromide IV and the tetrabromide V. The isolation of

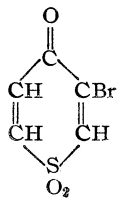


IV

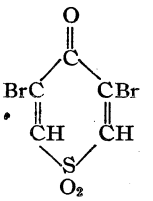


V

these compounds proved to be rather difficult, since, like the corresponding quinone bromides,[7] they readily lose hydrogen bromide on warming and are gradually converted into the mono- and dibromothiapyrone dioxides, VI and VII. The structures assigned to the latter compounds, which



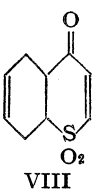
VI



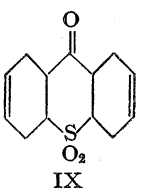
VII

are the only isolable products of bromination when no special precautions are taken to prevent the dehydrobromination of the initial adducts, follow from a consideration of the relative ease of dehydrobromination of the 3,5- and 2,6-dibromotetrahydrothiapyrone dioxides.

The stepwise addition of butadiene to I occurs slowly at room temperature and more rapidly at elevated temperatures, yielding mono- and di-adducts (VIII and IX) analogous to the products obtained in a similar manner from *p*-benzoquinone.[8]

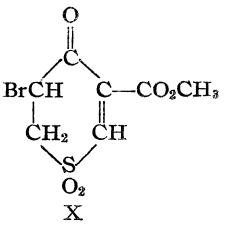


VIII

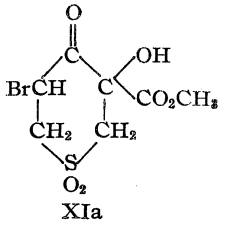


IX

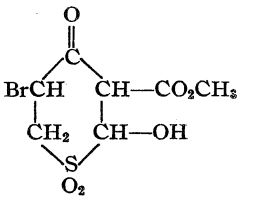
3,5-Dibromo-3-carbomethoxytetrahydro-1,4-thiapyrone-1-dioxide, prepared in the course of this investigation by the bromination of 3-carbomethoxytetrahydro - 1,4 - thiapyrone - 1 - dioxide, was found to lose one molecule of hydrogen bromide so readily that a good yield of a monobromocarbomethoxydihydrothiapyrone dioxide



X



XIa



XIb

was obtained merely by refluxing the dibromo compound with aqueous acetic acid. The product is undoubtedly the 2,3-dihydro compound X. In one similar experiment, however, the product isolated appeared, on the basis of the analytical data, to be a bromohydroxycarbomethoxytetrahydrothiapyrone dioxide. Either structure XIa or XIb might be assigned to this compound, depending on whether the bromine atom was replaced directly by a hydroxyl group or, as is more probable, hydrogen bromide was first split out to give X, which then added a molecule of water, the hydroxyl becoming attached to the carbon *beta* to the carbonyl function. All attempts to repeat the preparation of this compound, starting with either the dibromo derivative or with X, were unsuccessful, and its structure was not further investigated.

Experimental[9]

Improved Preparation of 1,4-Thiapyrone-1-dioxide (I).—A mixture of 289 g. (1.4 moles) of methyl β-thiodipropionate,[10] 2.8 moles of alcohol-free sodium methoxide (freshly prepared from 64.3 g. of sodium), and 1 liter of anhydrous ether was stirred and refluxed for three hours. The mixture was cooled quickly to room temperature and poured into an ice-cold solution of 178 ml. of acetic acid in 1 liter of water. After vigorous agitation, the layers were separated and the aqueous layer was extracted repeatedly with small portions of ether until the extracts no longer gave a violet color with ferric chloride solution. The extracts were added to the original ether layer, and the combined solution was washed with aqueous sodium bicarbonate and dried over anhydrous magnesium sulfate. After removal of the ether, the residual oil was distilled under diminished pressure to yield 158.8 g. (65%) of **3-carbomethoxytetrahydro-1,4-thiapyrone** as a colorless oil, b. p. 120–125° at 5 mm. The analytical sample was obtained by redistillation of a small portion of this material; b. p. 120° at 5 mm., $n^{20}D$ 1.5234.

Anal. Calcd. for $C_7H_{10}O_5S$: C, 48.26; H, 5.79. Found: C, 48.31; H, 5.79.

Hydrolysis and decarboxylation of the cyclic ketoester was accomplished in a single step by treatment with 10%

sulfuric acid according to the method of Bennett and Scorah.[6a] A reflux period of two hours sufficed to complete the reaction in the case of the methyl ester. Evaporation of the dried ether extract afforded colorless crystals of crude tetrahydro-1,4-thiapyrone melting at 58–62° (reported[6a] m. p., 65–66°); yield, 84%.

To a solution of 56.0 g. (0.48 mole) of tetrahydrothiapyrone in 500 ml. of glacial acetic acid, 114 ml. (1.00 mole) of 30% hydrogen peroxide was added in small portions while the mixture was cooled under the tap to moderate the reaction. After the strongly exothermic reaction had subsided, 400 ml. of the solvent was distilled from the mixture and the residue was cooled to crystallize out the major portion of the product as almost colorless needles melting at 164–167° (reported[6b] m. p., 170°). A further small quantity of crude product was obtained by evaporation of the filtrate to dryness on the steam-bath and recrystallization of the residue from acetic acid; total yield of tetrahydro-1,4-thiapyrone-1-dioxide, 54.7 g. (77%).

A warm solution of 38.3 g. (0.26 mole) of the crude dioxide in 450 ml. of glacial acetic acid was shaken with 83.2 g. (0.52 mole) of bromine for several minutes and was then cooled to room temperature and filtered. 3,5-Dibromotetrahydro-1,4-thiapyrone-1-dioxide was thus obtained as colorless needles, m. p. 220–222° dec. (reported[5] m. p., 220° dec.); yield, 71.9 g. (91%).

Attempts to dehydrobrominate this material by treatment with pyridine according to the original method of Arndt and Bekir[5] led to the formation of considerable tarry material and only small amounts of the desired product. Almost quantitative yields of pure product were obtained, however, when the dibromo compound was treated briefly with sodium acetate in refluxing acetone. In a typical experiment, a suspension of 12.2 g. (0.04 mole) of the dibromo compound in 150 ml. of hot acetone was added gradually over a fifteen-minute period to a mechanically stirred, refluxing suspension of 27.2 g. (0.20 mole) of powdered sodium acetate trihydrate in 150 ml. of acetone. Stirring and refluxing were continued for another ten minutes, and the dark red mixture was cooled and filtered. Concentrated hydrochloric acid was added dropwise to the filtrate until the color of the solution changed from red to yellow, and the mixture was refiltered to remove the precipitate of sodium chloride. The clear yellow filtrate was evaporated to dryness on the steam-bath, leaving a yellow-brown crystalline residue which was recrystallized from glacial acetic acid (Norit) to yield 3.9 g. of yellow crystals, m. p. 173–174° (reported[5] m. p., 174°). The mother liquor was worked up to provide a second crop of crystals, which was recrystallized and added to the original product to give a combined yield of 1,4-thiapyrone-1-dioxide (I) of 5.5 g. (96%). This compound is readily soluble in water, ethanol, and acetone; slightly soluble in cold acetic acid; and insoluble in hydrocarbon solvents. It sublimes as long yellow needles at temperatures somewhat below its melting point. Purified samples appear to be entirely stable when stored in contact with air.

The **oxime** was obtained as colorless needles which, after recrystallization from water, decomposed violently without melting at 196°.

Anal. Calcd. for $C_5H_5NO_3S$: C, 37.72; H, 3.17. Found: C, 37.77; H, 2.93.

The **semicarbazone** was obtained as a pale yellow microcrystalline powder, m. p. 237–239° dec., after recrystallization from water (Norit).

Anal. Calcd. for $C_6H_7N_3O_3S$: C, 35.81; H, 3.51. Found: C, 35.67, 35.86; H, 3.76, 3.35.

Reduction of 1,4-Thiapyrone-1-dioxide.—A mixture of 1.00 g. of I, 2.0 g. of zinc dust, and 15 ml. of glacial acetic acid was refluxed for one hour, after which the yellow color of the solution had disappeared. The unreacted zinc was filtered off, and the filtrate was saturated with hydrogen sulfide and refiltered. Evaporation of the clear filtrate to dryness on the steam-bath afforded 0.89 g. (87%) of almost colorless crystals which melted at 167–169° after recrystallization from acetic acid and exhibited no melting-point depression when mixed with authentic tetrahydro-1,4-thiapyrone-1-dioxide.

2,6-Dibromotetrahydro-1,4-thiapyrone-1-dioxide (III).—One gram of I was dissolved in 6 ml. of glacial acetic acid saturated with dry hydrogen bromide, and more hydrogen bromide was passed into the solution until precipitation was complete. The crystalline precipitate was collected and dried at room temperature to yield 0.9 g. of 2,6-dibromotetrahydro-1,4-thiapyrone-1-dioxide as brownish needles, m. p. 126–131° dec. Although this material appeared to be only slightly soluble in cold acetic acid, all attempts to recrystallize it from this solvent resulted in the formation of yellow solutions from which only negligible amounts of the dibromo compound could be recovered on cooling; m. p. 130–133° dec.

Anal. Calcd. for $C_5H_6Br_2O_3S$: C, 19.62; H, 1.99. Found: C, 20.06; H, 1.99.

When a sample of this compound was boiled with water for a few seconds, and was then cooled, acidified with dilute nitric acid, and treated with aqueous silver nitrate, a copious precipitate of silver bromide formed at once.

3-Bromo-1,4-thiapyrone-1-dioxide (VI).—To a solution of 1.00 g. (0.007 mole) of I in 25 ml. of glacial acetic acid there was added 1.11 g. (0.007 mole) of bromine, and the mixture was allowed to stand for four hours at 5°. After removal of the solvent by evaporation *in vacuo* at room temperature, the dark-colored, semicrystalline residue was recrystallized from methanol (Norit) to yield 0.50 g. (32%) of pale yellow crystals, m. p. 173–174° dec. with previous sintering. Another recrystallization from methanol gave the pure compound melting at 189–190° dec., when immersed in a bath at 185° and heated rapidly; considerable decomposition occurred above 150° when the compound was heated slowly from room temperature.

Anal. Calcd. for $C_5H_3BrO_3S$: C, 26.92; H, 1.36. Found: C, 26.96; H, 1.29.

3,5-Dibromo-1,4-thiapyrone-1-dioxide (VII).—A mixture of 1.44 g. (0.01 mole) of I, 3.20 g. (0.02 mole) of bromine, and 30 ml. of glacial acetic acid was allowed to stand at 5° until all the solid had dissolved and the color of the solution had faded to pale yellow. The mixture was poured into 60 ml. of ice-water and the resultant yellow precipitate was collected, washed with water, and dried; m. p. 157–161°; yield, 1.87 g. (62%). Recrystallization from methanol (Norit) gave pale yellow needles, m. p. 160–162°.

Anal. Calcd. for $C_5H_2Br_2O_3S$: C, 19.88; H, 0.67. Found: C, 19.79; H, 0.67.

2,3-Dibromo-2,3-dihydro-1,4-thiapyrone-1-dioxide (IV).—A solution of 1.44 g. (0.01 mole) of I in 50 ml. of hot chloroform was cooled to precipitate the thiapyrone dioxide as a microcrystalline suspension. A solution of 1.60 g. (0.01 mole) of bromine in 10 ml. of chloroform was added to this suspension in small portions over a thirty-minute period with vigorous agitation after each addition. The solvent was removed by evaporation under reduced pressure at room temperature, leaving a dark-colored sirup which slowly solidified on standing for several days. This product was digested with a little hot benzene, care being taken not to prolong the period of heating any longer than absolutely necessary, and the benzene extract was cooled to precipitate 0.6 g. of colorless powder, m. p. 133–135° dec. Cautious recrystallization of this material from benzene gave the dibromide as colorless crystals, m. p. 138–139° dec.

Anal. Calcd. for $C_5H_4Br_2O_3S$: C, 19.75; H, 1.33. Found: C, 20.74; H, 1.25.

This compound lost hydrogen bromide so readily that further purification could not be effected by repeated recrystallization. Analytical and melting-point data obtained for the same sample on different dates also indicate that the compound gradually undergoes dehydrobromination on standing at room temperature.

2,3,5,6-Tetrabromotetrahydro-1,4-thiapyrone-1-dioxide (V).—A mixture of 1.44 g. (0.01 mole) of I, 3.20 g. (0.02

mole) of bromine, and 65 ml. of chloroform was allowed to stand for one hour at room temperature with occasional agitation, and the solvent was then removed by evaporation under reduced pressure. The dark-colored residue was heated for a few minutes with a little acetic acid and the suspension was cooled and filtered. The insoluble portion was washed with a little cold acetic acid and dried *in vacuo* to yield 0.4 g. of colorless powder, m. p. 195–198° dec. with previous sintering and blackening. This compound dissolved slowly in hot acetic acid, water, and methanol with the production of a yellow color.

Anal. Calcd. for $C_5H_4Br_4O_3S$: C, 12.95; H, 0.87. Found: C, 13.20; H, 0.85.

The acetic acid filtrate from the isolation of the tetrabromide was evaporated and the residue was worked up with methanol to yield 1.6 g. of pale yellow needles. After repeated recrystallization from methanol, this material melted at 158–160° and failed to depress the melting point of the 3,5-dibromo-1,4-thiapyrone-1-dioxide described above.

3-Bromotetrahydro-1,4-thiapyrone-1-dioxide.—To a microcrystalline suspension obtained by cooling a hot solution of 7.40 g. (0.05 mole) of tetrahydro-1,4-thiapyrone-1-dioxide in 100 ml. of glacial acetic acid, 8.00 g. (0.05 mole) of bromine was added dropwise over a twenty-minute period. The mixture was agitated vigorously after each addition, and after all the bromine had been added the precipitate was filtered off and dried *in vacuo* over potassium hydroxide to yield 8.39 g. (74%) of colorless silky needles, m. p. 176–179°. Recrystallization from acetic acid raised the melting point to 182–183°.

Anal. Calcd. for $C_5H_7BrO_3S$: Br, 35.19. Found: Br, 35.66.

2,3-Dihydro-1,4-thiapyrone-1-dioxide.—3-Bromotetrahydro-1,4-thiapyrone-1-dioxide (6.81 g., 0.03 mole) was dehydrobrominated by treatment with sodium acetate trihydrate (9.5 g., 0.07 mole) in boiling acetone (100 ml.) exactly as in the case of the 3,5-dibromo compound. The first crystallization of the crude product from acetic acid (Norit) afforded 3.41 g. (78%) of very pale yellow needles, m. p. 144–146°. Several further recrystallizations from this solvent raised the melting point to 147–148°. This compound gave a deep red color on treatment with aqueous alkali.

Anal. Calcd. for $C_5H_6O_3S$: C, 41.07; H, 4.14. Found: C, 41.11; H, 4.11.

The **oxime** was obtained as colorless needles which melted at 178–179°, dec., after recrystallization from water.

Anal. Calcd. for $C_5H_7NO_3S$: C, 37.24; H, 4.38. Found: C, 37.01; H, 4.53.

$\Delta^{2,7}$-Octahydrothiaxanthone-5-dioxide (IX).—Twenty-five milliliters of purified dioxane[11] was saturated with butadiene (*ca.* 3.8 g., 0.070 mole) at room temperature, 2.0 g. (0.014 mole) of I was added, and the mixture was heated in an autoclave at 140–150° for four hours. On cooling, most of the product crystallized out of the solution in a nearly pure condition; yield, 2.5 g. (72%) of almost colorless plates, m. p. 228–234°, dec., when immersed in a bath previously heated to above 200°. Recrystallization from acetic acid afforded colorless needles, m. p. 235–236°, dec. This compound gave no color on treatment with aqueous sodium hydroxide.

Anal. Calcd. for $C_{13}H_{16}O_3S$: C, 61.88; H, 6.39. Found: C, 61.78; H, 6.21.

Δ^{6}-Tetrahydro-1,4-benzothiapyrone-1-dioxide (VIII).—A mixture of 2.00 g. (0.014 mole) of I, 3.8 g. (0.070 mole) of butadiene, and 25 ml. of purified dioxane was heated in an autoclave at 100° for four hours, after which the solvent was distilled off and the semicrystalline residue was extracted repeatedly with boiling water. On cooling, the combined aqueous extracts deposited 1.10 g. (40%) of colorless needles, m. p. 146–156°. After several recrystallizations from ethanol, this compound melted at 157–159° and gave a deep yellow color with aqueous sodium hydroxide.

Anal. Calcd. for $C_9H_{10}O_3S$: C, 54.54; H, 5.09. Found: C, 54.57; H, 4.85.

A small amount (*ca.* 0.3 g.) of the di-addition product was isolated from the water-insoluble residue by extraction with hot acetic acid. On dilution with several volumes of water, the acetic acid extract slowly deposited a white solid which melted at 229–231° dec. after recrystallization from acetic acid and which failed to depress the melting point of the di-adduct described above.

In an experiment in which a suspension of I in an ethanol solution of butadiene was allowed to stand at room temperature for seven days, a small amount of crystalline material melting at 153–156° was isolated and identified as the mono-adduct by the method of mixed melting points.

3-Carbomethoxytetrahydro-1,4-thiapyrone-1-dioxide.—Oxidation of 1.74 g. (0.01 mole) of 3-carbomethoxytetrahydro-1,4-thiapyrone with 2.5 ml. (0.022 mole) of 30% hydrogen peroxide in 12 ml. of glacial acetic acid afforded 1.35 g. (65%) of colorless crystals melting at 115–116° after recrystallization from water. This compound gave a blood-red color with ferric chloride solution.

Anal. Calcd. for $C_7H_{10}O_5S$: C, 40.75; H, 4.89. Found: C, 40.84; H, 5.01.

3,5-Dibromo-3-carbomethoxytetrahydro-1,4-thiapyrone-1-dioxide.—Bromine (2.72 g., 0.017 mole) was added to a suspension of 1.75 g. (0.0085 mole) of the above ketoester in 10 ml. of glacial acetic acid, and the mixture was agitated until all the solid had dissolved. The clear red solution was placed in a vacuum desiccator over potassium hydroxide and allowed to stand for two weeks. At the end of this time all of the solvent had evaporated and 2.90 g. (94%) of a pale yellow crystalline solid, m. p. 155–165° dec., remained. After repeated recrystallization from ethyl acetate, the pure product was obtained as colorless needles melting at 182–183° dec.

Anal. Calcd. for $C_7H_8Br_2O_5S$: C, 23.10; H, 2.22. Found: C, 23.26, 23.27; H, 2.38, 2.24.

3-Bromo-5-carbomethoxy-2,3-dihydro-1,4-thiapyrone-1-dioxide (X).—A solution of 2.00 g. of the above dibromo compound in 50 ml. of 50% aqueous acetic acid was refluxed for ten minutes, and the crystalline precipitate obtained on cooling was recrystallized from ethyl acetate to yield 1.10 g. (71%) of colorless plates, m. p. 156–157° with previous sintering. This compound gave a positive Beilstein test for halogen.

Anal. Calcd. for $C_7H_7BrO_5S$: C, 29.70; H, 2.49. Found: C, 29.50; H, 2.29.

5-Bromo-3(or 2?)-hydroxy-3-carbomethoxytetrahydro-1,4-thiapyrone-1-dioxide (XI).—In one experiment in which 3,5-dibromo-3-carbomethoxytetrahydro-1,4-thiapyrone-1-dioxide was heated briefly with aqueous acetic acid as above, a colorless crystalline compound melting at 175–177°, dec., after recrystallization from ethyl acetate was obtained. Subsequent attempts to repeat

the preparation of this compound afforded only the dihydro compound X or unchanged starting material.

Anal. Calcd. for $C_7H_9BrO_6S$: C, 27.92; H, 3.01. Found: C, 27.86, 28.10, 27.88; H, 3.21, 3.12, 3.25.

Ultraviolet Absorption Spectra.—The spectra were determined in purified dioxane with a Beckman Quartz Spectrophotometer, Model DU, using an approximately constant spectral band width of *ca.* 1 mμ. *p*-Benzoquinone (Eastman practical grade) was purified by recrystallization from water and subsequent sublimation at 100°; m. p. 114–115°. 1,4-Thiapyrone-1-dioxide and 2,3-dihydro-1,4-thiapyrone-1-dioxide were both recrystallized from acetic acid and then sublimed *in vacuo* at temperatures slightly below their melting points; the sublimed samples melted at 174–175° and 147–148°, respectively. The wave lengths and extinction coefficients at the absorption maxima are summarized in Table I.

Summary

An improved procedure for the synthesis of 1,4-thiapyrone-1-dioxide, a sulfonyl analog of *p*-benzoquinone, has been described, and the addition reactions of this compound with hydrogen, hydrogen bromide, bromine and butadiene have been investigated. A number of new thiapyrone derivatives have been prepared and characterized. The ultraviolet absorption spectra of 1,4-thiapyrone-1-dioxide and 2,3-dihydro-1,4-thiapyrone-1-dioxide have been determined and compared with the spectrum of *p*-benzoquinone.

[A CONTRIBUTION OF THE CHEMICAL LABORATORY OF CLARK UNIVERSITY]

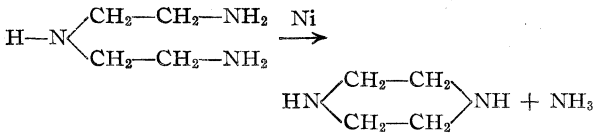
Preparation of Piperazine[1]

BY WILLIAM B. MARTIN AND ARTHUR E. MARTELL

The formation of secondary amines from primary amines by catalytic deamination has been mentioned by Adkins in the case of the formation of dibenzylamine from benzylamine. Also, C. W. Hoerr, *et al.*,[2] have recently prepared secondary aliphatic amines by the same method.

Kyrides[3] has described the preparation of piperazine from ethylenediamine and diethylenetriamine by the same method. The reaction was carried out without solvent at high temperatures (about 235°) in an autoclave. No yields were reported. This reaction has been subjected to considerable investigation in this Laboratory, and it seemed desirable at this time to report on the investigation to supplement the disclosures of the Kyrides patent.

Diethylenetriamine was heated with Raney nickel under various experimental conditions. The results of these experiments are tabulated below. In all cases ammonia was evolved and piperazine was formed according to the reaction



A temperature of about 150° or somewhat higher was found to be most suitable for the reaction. When a low-boiling solvent such as xylene or toluene was used at atmospheric pressure, the reaction proceeded very slowly and little piperazine was obtained. The reaction seemed to be endothermic, and an increase of the rate of heating at atmospheric pressure merely resulted in a more rapid evolution of ammonia. After the reaction had proceeded for a while the temperature would gradually rise to the reflux point of the solvent.

Allowing the ammonia to escape from the reaction mixture does not tend to improve the yield of piperazine. The yields are in general somewhat higher when the reaction is carried out in an autoclave. This may have been due in part to the loss of piperazine through volatilization in the escaping ammonia, since the vapor pressure of piperazine, even at room temperature, is fairly high. At any rate, the reaction does not approach a state of equilibrium. In all cases in which the ammonia was not allowed to escape, very little unreacted diethylenetriamine was isolated. As a further test, piperazine was treated with several molar proportions of alcoholic ammonia in an autoclave at 150° for ten hours in the presence of Raney nickel catalyst. No diethylenetriamine or ethylenediamine was obtained, and substantially all the piperazine was recovered by fractional distillation.

In all the reactions attempted some high-boiling fractions and viscous high molecular weight residues were obtained. These were evidently mixtures of higher "polyalkylene polyamines" which probably resulted from linear deamination of diethylenetriamine to form tetraethylenepentamine and higher homologs. The use of solvent is important in cutting down intermolecular condensation and in improving the yield of piperazine. This was also found to be the case by Pollard, *et al.*,[4] in the preparation of piperazine by the catalytic dehydration of hydroxyethylethylenediamine. In general, the use of a solvent decreased the formation of high boiling tarry residues. Of the solvents employed, moderately high boiling hydrocarbons gave the best results.

Similar results were obtained when the experi-

TABLE I

YIELDS OF PIPERAZINE UNDER VARIOUS REACTION CONDITIONS

Reagent	G.	Solvent	Temperature, °C.	Time, hr.	Yield of piperazine, g.	Yield %
Diethylenetriamine	103	None	Reflux	10	46	53
Diethylenetriamine		Tetrahydronaphthalene	Reflux	12	53	62
Diethylenetriamine		None	150, autoclave	8	33	38
Diethylenetriamine		Dipentene	160, autoclave	8	63	73
Diethylenetriamine		Xylene	Reflux	7	15	17
Diethylenetriamine		Dioxane	160, autoclave	7	28	32
Ethylenediamine	60	Tetrahydronaphthalene	150, autoclave	6	17	39

ments were repeated using ethylenediamine instead of diethylenetriamine. The formation of piperazine from ethylenediamine probably resulted through preliminary formation of diethylenetriamine which then condensed to form piperazine as described above.

$$2H_2NCH_2CH_2NH_2 \longrightarrow H{-}N\begin{matrix}CH_2{-}CH_2{-}NH_2\\ CH_2{-}CH_2{-}NH_2\end{matrix} + NH_3$$

The piperazine was isolated as white crystals upon distillation and was identified in each case as the dibenzoyl derivative.

Experimental

The experimental conditions are summarized in Table I. Ethylenediamine and diethylenetriamine were purified by drying the commercial material over potassium hydroxide pellets and subsequent fractional distillation. Ethylenediamine was collected between 117 and 119°, while the diethylenetriamine used distilled from 83 to 86° at 3 mm. pressure. All solvents were dried and purified by distillation with the exception of dioxane which was first refluxed with sodium and aniline and then distilled. In each of the reactions listed in Table I, 10 g. of Raney nickel was used.

The reaction mixture was fractionally distilled in each case to remove solvent and separate the products. The piperazine was isolated as colorless prisms, all samples melting within a few degrees of 100°. In each case the dibenzoyl derivative was prepared. The melting points of the dibenzoyl derivatives of each reaction product ranged from 193 to 195°. In all cases, a mixed melting point with an authentic sample of dibenzoylpiperazine showed no depression.

Acknowledgment.—The authors express their appreciation to the F. C. Bersworth Laboratories of Framingham, Massachusetts, for supplying the materials used in this investigation.

Summary

Experimental conditions for the preparation of piperazine by catalytic deamination of diethylenetriamine and of ethylenediamine are described.

Pyrimidine. II. Amino Alcohols Derived from Pyrimidine[1]

BY RAY A. CLARKE AND BERT E. CHRISTENSEN

This laboratory has previously synthesized[2] a number of amino alcohols with this substituent in the 5 position of pyrimidine nucleus, by the application of the Mannich reaction to various 5-acetylpyrimidines.

The usual methods for the preparation of such compounds involve the Mannich reaction on the acetyl derivative or the coupling of the bromomethyl ketone with the desired amine. The bromomethyl ketones are prepared either by direct bromination of the acetyl derivative or by means of the Arndt–Eistert reaction. Whenever possible, this latter method is preferable since it utilizes the acid rather than the less common acetyl derivative of the desired nucleus. Furthermore, there is less possibility of brominating other positions in the molecule and hence fewer separations and characterization problems.

Several 4-pyrimidinecarboxylic acid derivatives have been reported.[3,4,5] In this laboratory, 5-methyl-6-oxo-2-phenyl-4-pyrimidinecarboxylic acid was prepared in 50 to 60% yield from sodio diethyloxalpropionate and benzamidine. The acid in this instance was obtained directly in contrast to the diethyl oxalacetate condensation described by both Pinner[3] and Rappeport.[4]

5 - Methyl - 6 - oxo - 2 - phenyl - 4 - pyrimidinecarboxylic acid I was readily converted through the series of intermediates, 6-chloro-5-methyl-2-phenylpyrimidine-4-carbonyl chloride II → 4-bromoacetyl - 6 - chloro - 5 - methyl - 2 - phenylpyrimidine III → 4-(2-diethylamino-1-oxoethyl)-6-chloro-5-methyl-2-phenylpyrimidine hydrochloride IV to the amino alcohol, 4-(2-diethylamino-

1 - hydroxyethyl) - 6 - chloro - 5 - methyl - 2-phenylpyrimidine hydrochloride V. These reactions were all straight-forward, giving good yields of crystalline intermediates. The free base of the amino ketone as is frequently the case was rather unstable.

Experimental

5-Methyl-6-oxo-2-phenyl-4-pyrimidinecarboxylic Acid (I).—An aqueous solution of sodio diethyloxalpropionate was prepared according to the directions of Johnson and Mackenzie[5] except that benzene was substituted for ether as the solvent. To the aqueous solution was added 34.8 g. (0.22 mole) of benzamidine hydrochloride and a solution containing 21 g. (0.445 mole, assuming 85% purity) of sodium hydroxide. The mixture was allowed to stand for one hour. A small amount of solid material was filtered off. The filtrate was acidified with concentrated hydrochloric acid causing a precipitate to form. After cooling in the refrigerator the white- to tan-colored solid was filtered by suction, washed with water, and dried. The yield of acid was 27 g. (53%). This acid was purified for analysis by dissolving in dilute alkali, decolorizing with charcoal, and reprecipitating with hydrochloric acid. The acid melted at 274° with decomposition.

Anal. Calcd. for $C_{12}H_{10}N_2O_3$: C, 62.61; H, 4.35; N, 12.18; neutral equivalent, 230. Found: C, 62.35; H, 4.24; N, 12.29; neutral equivalent, 228.

6-Chloro-5-methyl-2-phenylpyrimidine-4-carbonyl Chloride (II).—Sixteen grams of I (0.07 mole) and 85.5 g. (0.42 mole) of phosphorus pentachloride were mixed and heated in an oil-bath at 130° for one hour. The mixture on cooling solidified to a solid mass. The acid chloride was extracted from the excess phosphorus pentachloride with warm dry ether. By partial evaporation and cooling of the ether, the acid chloride crystallized and was removed by filtration. The yield of very nearly pure acid chloride was 16 g. (86%). Thirteen and one-half grams of pure product was obtained by recrystallization from 50 ml. of heptane, m. p. 99–101°.

Anal. Calcd. for $C_{12}H_8Cl_2N_2O$: C, 54.0; H, 3.00; N, 10.49; Cl, 26.6. Found: C, 53.5; H, 3.36; N, 10.53; Cl, 26.4.

4-Bromoacetyl-6-chloro-5-methyl-2-phenylpyrimidine (III).—A solution of 12 g. of II (0.045 mole) in 60 ml. of dry benzene was added dropwise with stirring to 200 ml. of a cold benzene solution of diazomethane (0.135 mole). The reaction appeared to take place rapidly as evidenced by the vigorous evolution of nitrogen. The solution was allowed to warm up to room temperature and after standing for about one hour, the benzene was evaporated under reduced pressure. The solid residue was suspended in ether and 25 ml. of 48% hydrobromic acid was added slowly with stirring. The bromomethyl ketone precipitated and nitrogen was evolved. The crude product (13.0 g.) was removed by filtration. Some additional material was obtained by evaporation of the ether. This residue and crude product when combined and recrystallized from heptane, gave 12.6 g. (86% yield) of slightly yellow needles. For analysis a portion of this product was recrystallized twice from heptane after decolorizing with charcoal (m. p. 139–141°).

Anal. Calcd. for $C_{13}H_{10}BrClN_2O$: C, 47.93; H, 3.08; total halogen, 35.4. Found: C, 48.38; H, 3.39; total halogen, 35.4.

6-Chloro-4-chloroacetyl-5-methyl-2-phenylpyrimidine.—The chloromethyl ketone was prepared in a manner similar to the bromomethyl ketone. From 4.00 g. of the acid chloride was obtained 3.48 g. of the crystalline chloromethyl ketone, m. p. 155–156°. This was purified for analysis by recrystallization from heptane.

Anal. Calcd. for $C_{13}H_{10}Cl_2N_2O$: N, 9.96; Cl, 25.2. Found: N, 10.02; Cl, 24.8.

6-Chloro-4-(2-diethylamino-1-oxoethyl)-5-methyl-2-phenylpyrimidine Hydrochloride (IV).—Two grams (0.00615 mole) of III was dissolved in 20 ml. of dry benzene and 1.26 ml. (0.0123 mole) of diethylamine were added dropwise. The formation of crystalline diethylamine hydrobromide was very rapid. After standing for fifteen minutes, the mixture was diluted with dry ether and the crystalline solid (0.82 g.) was filtered with suction and washed with dry ether.

Dry hydrogen chloride was passed into the filtrate to precipitate the condensate as the hydrochloride. The solid was filtered with suction and washed with dry ether. The weight of crude product was 2.15 g. This material after purification by three recrystallizations from isopropyl alcohol gave 0.61 g. of crystalline product, m. p. 170–178° (red melt).

Anal. Calcd. for $C_{17}H_{21}Cl_2N_3O$: N, 11.86; total Cl, 20.0; ionizable Cl, 10.0. Found: N, 12.10; total Cl, 20.0; ionizable Cl, 9.84.

6-Chloro-4-(2-diethylamino-1-hydroxyethyl)-5-methyl-2-phenylpyrimidine Hydrochloride (V).—The amino ketone (0.50 g.) was dissolved in 20 ml. of methanol and reduced in a low pressure hydrogenation apparatus at 34 pounds pressure using 30 mg. of platinum oxide catalyst. After about two hours the catalyst was removed by filtration and the solvent evaporated. The residue was taken up in 10 ml. of warm isopropyl alcohol and upon cooling deposited 0.29 g. of white solid. This product partially melted at 160°, resolidified and finally melted at 170–172°.

Anal. Calcd. for $C_{17}H_{23}Cl_2N_3O$: N, 11.80; total Cl, 19.9; ionizable Cl, 9.82. Found: N, 12.15; total Cl, 19.5; ionizable Cl, 9.95.

6-Chloro-4-(2-di-*n*-propylamino-1-oxoethyl)-5-methyl-2-phenylpyrimidine Hydrochloride.—The condensation of the bromomethyl ketone with di-*n*-propylamine was carried out in the same manner as that with diethylamine. From 2.00 g. (0.00615 mole) of the bromomethyl ketone, 1.85 g. of crude amino ketone hydrochloride was obtained. This was recrystallized twice from a minimum amount of isopropyl alcohol yielding 0.85 g. of product, m. p. 170–178° (red melt).

Anal. Calcd. for $C_{19}H_{25}Cl_2N_3O$: N, 11.00; total Cl, 18.6; ionizable Cl, 9.28. Found: N, 11.06; total Cl, 18.3; ionizable Cl, 9.45.

6-Chloro-4-(2-di-*n*-propylamino-1-hydroxyethyl)-5-methyl-2-phenylpyrimidine Hydrochloride.—The reduction to the di-*n*-propylamino alcohol was carried out in the same way as that given for the preparation of the diethylamino alcohol. This amino alcohol crystallized very slowly with low recovery from a minimum of isopropyl alcohol; from 0.50 g. of the amino ketone was obtained 0.20 g. of solid product, m. p. 180–181°.

Anal. Calcd. for $C_{19}H_{27}Cl_2N_3O$: N, 10.94; total Cl, 18.5; ionizable Cl, 9.23. Found: N, 11.33; total Cl, 18.3; ionizable Cl, 9.18.

Summary

4-Bromo(and chloro)-acetyl-6-chloro-5-methyl-2-phenylpyrimidine were prepared by application of the diazomethane synthesis to the acid chloride prepared from 5-methyl-6-oxo-2-phenyl-4-pyrimidinecarboxylic acid.

The amino alcohols, 6-chloro-4-(2-di-*n*-propylamino-1-hydroxyethyl)-5-methyl-2-phenylpyrimidine hydrochloride, 6-chloro-4-(2-diethylamino-1-hydroxyethyl)-5-methyl-2-phenylpyrimidine hydrochloride, were prepared by coupling the bromoacetylpyrimidine with the appropriate secondary amine and subsequent reducing of the amino ketones.

CORVALLIS, OREGON RECEIVED AUGUST 7, 1947

[Contribution from the Laboratory of Organic Chemistry of the University of Wisconsin]

Piperidine Derivatives. XVIII. The Condensation of Aromatic Aldehydes with 1-Methyl-4-piperidone

By S. M. McElvain and Kurt Rorig[1]

The preparation of 3-substituted-4-piperidones via the condensation of aromatic aldehydes with 1-methyl-4-piperidone (I) was the purpose of the work here reported. Only two examples of such a condensation appear in the literature: benzaldehyde with 4-piperidone[2] and 1-methyl-4-piperidone.[3] Both of these condensations, however, yielded only the corresponding 3,5-dibenzal-4-piperidones.[4]

When 1-methyl-4-piperidone was treated with benzaldehyde in a 4% solution of potassium hydroxide in 40% ethanol–water (which was just sufficient alcohol to keep the reaction mixture homogeneous) a rapid reaction occurred, but none of the monobenzal derivative (IV) was found among the several reaction products. The main reaction product was 1-methyl-3,5-dibenzal-4-piperidone (VIII) which precipitated from the reaction mixture; in addition to this compound phenyl - bis - 3 - (1 - methyl - 4 - ketopiperidyl)-methane (X) and two apparently similar products with wide melting ranges, which were separated by their solubility differences in dilute ethanol, were obtained by dilution of the reaction mixture with water. In contrast to the dibenzalpiperidone (VIII), the ethylenic bonds of which are rapidly and completely hydrogenated over Adams platinum oxide catalyst, these latter two products absorb hydrogen slowly and incompletely for one ethylenic bond per molecule. Elemental analyses indicate that one of these products, A, is a mixture of the monobenzalpiperidone (IV) and the carbinol (III) and that the other product, B, is a mixture of the monobenzalpiperidone (IV) and the dicarbinol (VI) *or* a mixture of the carbinol (III) and the benzalcarbinol (VII).

In one of the first experiments with this procedure two products, having elemental analyses corresponding to the carbinol (III), were isolated at the point where mixtures A and B appeared in subsequent experiments. These were, undoubtedly, the two racemic forms of III, but neither could be isolated completely free of the other.

When benzaldehyde was allowed to react with 1-methyl-4-piperidone in a 4% solution of potassium hydroxide in 55–60% ethanol–water solvent, 1-methyl-3-benzal-4-piperidone (IV) *slowly* precipitated from the solution.[5] It was the sole product of the reaction and was obtained in 61% yield.

Since the dibenzalpiperidone (VIII) was rapidly precipitated from a 40% ethanol–water solvent in which it is insoluble and not formed in the 60% ethanol–water solvent in which it is quite soluble, it appears that the reaction of the piperidone (I) with benzaldehyde in the presence of alkali is best represented by a series of equilibria from which either the mono- or dibenzal derivative may be obtained, depending on the solubility of the product in the reaction solvent. This conclusion is further indicated by the fact that either of the carbinol mixtures A and B, the two racemic forms of III, as well as the dibenzal derivative (VIII), which were formed in 40% ethanol–water solvent, were converted to the monobenzal derivative (IV) when allowed to stand in a 4% potassium hydroxide solution in 60% ethanol–water. The conversion of VIII to IV amounts to 78%.

It is a curious fact that the monobenzal derivative IV does not precipitate from the 40% ethanol–water solvent in which it is as insoluble as is the dibenzal derivative VIII. The most obvious explanation of this fact is that the series of equilibria involved in the transformation of II (or IIa) → VIII are attained more rapidly than that of II → IV. This is indicated by the rapid (see Table I) precipitation of VIII from the 40% ethanol–water solvent and the consequent shift of the reaction in this direction; when VIII is kept in solution by the 60% ethanol–water solvent, there is opportunity for the slower change of II (or IIa) into IV and the latter compound precipitates over a period of several days (see Table I). The mixtures of IV with the carbinols, which are present in the 40% ethanol–water solvent and are precipitated by dilution with water, may be molecular complexes that prevent the precipitation of IV.

It seems likely that the benzal derivatives IV and VIII are formed from the ions IIa and VIIa rather than from the direct dehydration of the carbinols III and VI. The carbinol mixtures were completely resistant to dehydration with hydrogen chloride in absolute ethanol, and when refluxed with acetic anhydride in pyridine, or with acetic anhydride containing *p*-toluenesulfonic acid, were converted to a product, the analyses and molecular weight of which approximates the structure IX, and which corresponds to the dodecahydrotriphenylene formed from cyclohexanone[6]

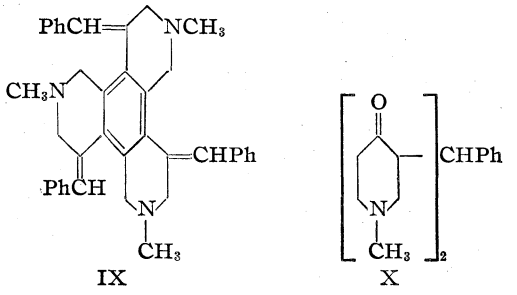
and to the *sym*-tris-2,3-thiocoumaronobenzene formed from thioindoxyl by the action of acetic anhydride with zinc chloride.[7]



The fourth product X isolated from the base-catalyzed condensation of benzaldehyde with the piperidone I is the result of the condensation of two moles of the piperidone with one of the aldehyde. The yields of X vary with the ratio of reactants as may be seen from Table I, which summarizes the results of typical runs in a 4% potassium hydroxide solution in various solvents.

TABLE I

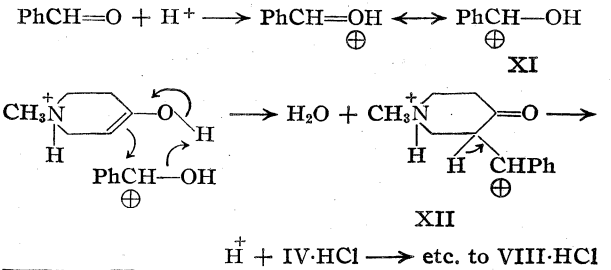
BASE-CATALYZED REACTION OF BENZALDEHYDE WITH 1-METHYL-4-PIPERIDONE (I)

PhCHO/I, moles	Solvent	Yield of VIII, %	Yield of mixtures A + B, %	Yield of IV, %	Yield of X, %
1.0	40% EtOH	44[a]	36	...	8
2.0	40% EtOH	66	28	...	0.3
1.0	60% EtOH	...	..	61[b]	..
0.12	12% EtOH	45	16	...	11
1.0	Water[c]	25	30	...	19

[a] Precipitated in fifteen minutes; the weaker base, sodium bicarbonate, gave similar yields but required several days to produce them. [b] About five days required for this amount of IV to precipitate. [c] Benzaldehyde added dropwise over a period of 2.5 hours to an aqueous solution of potassium hydroxide and the piperidone.

(7) Dalgliesh and Mann, *J. Chem. Soc.*, 910 (1945).

The condensation of benzaldehyde with the piperidone (I) may also be effected by acid catalysis. This reaction was carried out in absolute ethanol saturated with hydrogen chloride and the sole product was the hydrochloride of VIII, which precipitated in 86% yield over a period of three days. In this case it seems certain that the carbinols III or VI *are not* intermediates in the formation of VIII, because the mixtures (A and B from the base-catalyzed reaction) containing these carbinols remain unchanged in the medium used for the acid-catalyzed reaction. The reaction mechanism, therefore, cannot permit the formation of a carbinol. The simultaneous coupling and loss of water between the enolic form[8] of the piperidone and the carbonium ion (XI) to produce the car-



(8) Although the amount of the enolic form of the ketone as well as the rate of its formation may be increased by the acidic medium [*cf.* Hauser and Breslow, THIS JOURNAL, **62**, 2391 (1940)]; Schwarzenbach and Wittwer, *Helv. Chim. Acta*, **30**, 659 (1947); Hammett, "Physical Organic Chemistry," McGraw-Hill Book Co., Inc., New York, 1940, p. 237], the concentration of the enolic form may well be the limiting factor that determines the over-all rate of reaction.

bonium ion XII, which then passes into a benzal derivative, would seem to rationalize the acid-catalyzed condensation of benzaldehyde with I.

The solubilities of the hydrochlorides of IV and VIII in absolute ethanol are the reverse of those of IV and VIII in the 60% ethanol–water medium used in the base-catalyzed reaction. The hydrochloride of IV is soluble in absolute ethanol while the hydrochloride of VIII is quite insoluble. If a solvent in which the hydrochloride of I is soluble and the hydrochloride of IV is insoluble could be found, it might be possible to prepare IV by an acid-catalyzed reaction; as yet such a solvent has not been found.

Condensation of Other Aldehydes with I.—The study of the condensation of benzaldehyde with I was intended to serve as a model for the determination of the proper conditions for the condensation of other aldehydes, particularly the quinoline aldehydes, with this piperidone. Actually the benzaldehyde condensation proved to be the most complex from the standpoint of the number of reaction products. With the other aldehydes only those products corresponding to the mono- and dibenzal derivatives IV and VIII were obtained; none of the carbinols or the bispiperidylarylmethanes, corresponding to X, were found.

The course of the condensation of quinoline-2 and 4-aldehydes with I showed a curious dependence on the amount of alkali used to catalyze the reaction. In a 4% solution of potassium hydroxide in ethanol–water, in which the molar ratio of alkali to I was 3.5:1, the 2-aldehyde gave a dark oil from which only a 9% yield of the diquinolinal derivative could be isolated. However, when a 0.25% solution of the alkali, containing an alkali to piperidone ratio of 0.54 was used, a 39% yield of the diquinolinol derivative and a trace of the monoquinolinol derivative were obtained. The quinoline-4-aldehyde yielded either the mono- or diquinolinol derivative depending on the amount of alkali used. Both of these quinoline aldehydes gave useless brown tars when hydrogen chloride in absolute ethanol was used as the reaction medium.

Table II

Condensation of Certain Aldehydes, ArCHO, with 1-Methyl-4-piperidone (I)

Ar is	ArCHO/I, moles	KOH/I, moles	Yield of mono—al, %	Yield of di—al, %[b]
2-Quinolyl	2	3.55	0	9
2-Quinolyl	2	0.54	Some[a]	39
4-Quinolyl	1	1.37	95	..
4-Quinolyl	2	0.73	Some[a]	79
α-Naphthyl	1	1.78	Some[a]	80
α-Naphthyl	1	0.27	Some[a]	88
o-Chlorophenyl	1	1.42	Some[a]	74
o-Chlorophenyl	2	1.78	0	90
o-Chlorophenyl	1	0.27	Some[a]	82

[a] Percentage yield not given since this product was not obtained pure; analyses indicated it to be mainly the mono—al derivative. [b] Yield based on amount of aldehyde used.

Neither benzaldehyde, o-chlorobenzaldehyde or α-naphthaldehyde showed any variations in reaction products with variations in the amount of alkali used to effect the condensations.

The condensations of these aldehydes with I in the presence of varying amounts of potassium hydroxide are summarized in Table II. In each case water containing sufficient ethanol to make the initial reaction mixture homogenous was used as the solvent.

Experimental

Methyl-di-(β-carbethoxyethyl)-amine.—A cooled one-liter reaction bomb was filled with 432 ml. (400 g.) of ethyl acrylate (containing 0.25% hydroquinone inhibitor) and 86 ml. (62 g.) of liquefied methylamine. Crystallization occurred upon stirring these chilled reactants. The cover was quickly secured since the temperature rose to around 80° within five minutes. The reaction vessel was heated in a water-bath at 60–70° for one hour. The bomb was cooled, opened, and the reaction mixture distilled. The fraction boiling at 110–119° (mainly at 118–119°) at 0.5 mm. was methyl-di(β-carbethoxyethyl)-amine; it weighed 367 g.

1-Methyl-3-carbethoxy-4-piperidone Hydrochloride.—Although this compound could be prepared in good yields (80%) by the cyclization of methyl-di-(β-carbethoxyethyl)-amine with sodium ethoxide,[9] the following procedure using sodium hydride was found more satisfactory.

Into a three-liter, three-necked flask equipped with a Hershberg stirrer, dropping funnel, and a reflux condenser, were placed 800 ml. of dry thiophene-free benzene and 54 g. of sodium hydride. After flushing the apparatus with nitrogen, 30 g. of methyl-di-(β-carbethoxyethyl)-amine was added to the vigorously stirred suspension of sodium hydride in benzene.

Five minutes after adding two milliliters of absolute ethanol the reaction started as evidenced by the evolution of hydrogen. When, after five minutes more, the reaction mixture was noticeably warm, 201 g. of methyl-di-(β-carbethoxyethyl)-amine was added at such a rate as to keep the mixture refluxing briskly. During this addition of the di-ester the appearance of the reaction mixture gradually changed from a dark-gray fluid to an almost white paste. To facilitate stirring an additional 250 ml. of benzene was added after addition of the di-ester was completed. The mixture then was stirred and refluxed with external heating until no more hydrogen was evolved.

A crock of crushed ice was placed under the reaction flask to cool the mixture while 135 g. of glacial acetic acid was added. To this very slightly acid solution, cooled to 5°, 123 ml. of water was added to precipitate sodium acetate trihydrate. This salt was filtered off and washed with 350 ml. of benzene.

The combined filtrates were distilled to remove ethanol and water. After 600 ml. of distillate had been collected, a refractive index showed that pure benzene was distilling over. The residual solution of 1-methyl-3-carbethoxy-4-piperidone in benzene was diluted with 500 ml. of absolute ether. This solution then was cooled in an ice-salt-bath and treated with dry hydrogen chloride until the 1-methyl-3-carbethoxy-4-piperidone hydrochloride had precipitated. The yield of product softening at 115°, melting at 125–128°, was 201 g. (91%).

1-Methyl-4-piperidone (I).—To a one-liter flask containing 350 ml. of 20% hydrochloric acid was added 86.0 g. of 1-methyl-3-carbethoxy-4-piperidone hydrochloride. After refluxing for one hour, the ferric chloride reagent gave no coloration. The solution was evaporated to dryness on a steam-bath at 10 mm. pressure. The solid product, heated at 100° for four hours at 0.1 mm. and further dried over solid potassium hydroxide for twenty-four hours, weighed 57.7 g., m. p. 80–120°. Although this

(9) Prill and McElvain, This Journal, 55, 1233 (1933).

melting range goes above that of the pure compound, 0.45 g. of crude material dissolved in 90 ml. of hot acetone gave 0.40 g. of pure compound melting at 93–95°. Other samples of the crude piperidone hydrochloride showed even higher upper limits of the melting points than that mentioned above, yet this apparently impure material always gave good yields of sharp melting product when recrystallized. Thus the crude material can be used successfully for further work without recrystallization.

To 37.0 g. of crude 1-methyl-4-piperidone hydrochloride dissolved in 50 ml. water was added 14 g. of solid potassium hydroxide. Then 20 g. of potassium carbonate was added to salt out the free amine. This basic solution was extracted with seven 100-ml. portions of ether. The ethereal solution was dried overnight with anhydrous sodium sulfate and the ether distilled. The higher boiling residue was distilled at 19 mm. pressure. A forerun weighing 1.7 g. was collected to 67°. The 1-methyl-4-piperidone fraction boiled from 67–69° and weighed 18.7 g.

The phenylhydrazone of this piperidone melted at 100–104°.[10]

The semicarbazone, prepared in the usual manner, did not precipitate from the reaction medium until salted out with potassium carbonate. After filtering and washing with a small amount of ice water it melted at 182–184°; recrystallization from ethyl acetate did not raise this m. p.

Anal. Calcd. for $C_7H_{14}N_4O$: C, 49.39; H, 8.29. Found: C, 48.85; H, 8.04.

The 2,4-dinitrophenylhydrazone hydrochloride was also made, m. p. 249° d. The free base was obtained by dissolving 1.0 g. of the hydrochloride in 75 ml. water, neutralizing with sodium bicarbonate, filtering, and recrystallizing from ethyl acetate. The orange prisms melted 172.0–173.5°.

Anal. Calcd. for $C_{12}H_{15}N_5O_4$: N, 23.88. Found: N, 24.0.

The Condensation of Benzaldehyde with the Piperidone (I) in 40% Ethanol.—To a solution of 7.5 g. of 1-methyl-4-piperidone and 7.0 g. of freshly distilled benzaldehyde in 69 ml. of 40% ethanol was added 3.0 g. of potassium hydroxide. The flask was then stoppered and shaken for fifteen minutes. The yellow solid that precipitated then was filtered off and the filtrate diluted with 75 ml. water. The white precipitate from the diluted reaction medium was labeled mixture A. It weighed 1.31 g. and melted at 115–150° dec.

Anal. Found: C, 76.42; H, 7.15; N, 6.59.

These analytical data indicate mixture A to be composed of the carbinol (III) and the monobenzal derivative (IV) (see below for the elemental content of these compounds).

The yellow solid which had been filtered from the 40% ethanol solution was dissolved in 250 ml. of hot 5% hydrochloric acid. Upon cooling 4.93 g. of fine yellow needles of **1-methyl-3,5-dibenzal-4-piperidone hydrochloride,** m. p. 243.5–244.5°, was obtained. This compound has been reported to melt at 240–241°.[3]

Anal. Calcd. for $C_{20}H_{20}ClNO$: Cl, 10.9. Found: Cl, 10.8.

The 1-methyl-3,5-dibenzal-4-piperidone was obtained in quantitative yield from its hydrochloride by dissolving the salt in hot 50% ethanol, adding sufficient sodium bicarbonate solution to neutralize the hydrogen chloride, cooling and filtering. After two recrystallizations from dilute alcohol, the canary-yellow **1-methyl-3,5-dibenzal-4-piperidone** melted at 116.5–117.5°.

Anal. Calcd. for $C_{20}H_{19}NO$: C, 83.01; H, 6.62; N, 4.84. Found: C, 83.04; H, 6.39; N, 4.76.

This compound has been previously reported by Howton[3,11] to melt 117.2–118.2°.

The acidic filtrate from which the dibenzal piperidone hydrochloride had been obtained was neutralized with sodium bicarbonate to precipitate 2.92 g. of the white mixture B, m. p. 115–160° dec.

Anal. Found: C, 75.16; H, 6.93; N, 5.85.

These analytical data indicate mixture B to be composed of IV (see below) and the dicarbinol (VI) (calcd. C, 73.9%; H, 7.1%; N, 4.3%) *or* of the carbinol (III) (see below) and the benzalcarbinol (VII) (calcd. C, 78.3%; H, 6.88%; N, 4.53%).

The dilute alkaline reaction mixture from which mixture A had been obtained deposited massive white rosettes on standing three days.[12] The amount increased until after two weeks 0.82 g. of **phenyl-bis-3-(1-methyl-4-keto-piperidyl)-methane,** m. p. 221–225°, was filtered off. After two recrystallizations from dilute ethanol an analytical sample melted 233–234°.

Anal. Calcd. for $C_{19}H_{26}N_2O_2$: C, 72.58; H, 8.34. Found: C, 72.23; H, 7.95.

Phenyl-3-(1-methyl-4-keto-piperidyl)-carbinol (III).—One of the first reactions carried out as described above yielded a product the analysis of which corresponded to phenyl-3-(1-methyl-4-keto-piperidyl)-carbinol. Instead of mixture A, 1.90 g. of white solid, m. p. 115–126°, was obtained. On attempted recrystallization from dilute ethanol, it repeatedly precipitated as an oil.

Anal. Calcd. for $C_{13}H_{17}NO_2$: C, 71.20; H, 7.82. Found: C, 71.03; H, 7.42.

The hydrochloride of this compound was made by dissolving it in a small quantity of absolute ethanol, diluting with absolute ether, and treating the solution with hydrogen chloride. After decanting the supernatant liquid from the precipitated salt, it was redissolved in ethanol and reprecipitated with ether. This was repeated twice to obtain an analytical sample melting at 230–235° dec.

Anal. Calcd. for $C_{13}H_{18}ClNO_2$: Cl, 13.9. Found: Cl, 14.1.

At the place where mixture B was obtained in the previously described reaction, 3.09 g. of a product melting at 90–120° d. precipitated. The hydrochloride, made as described above, melted at 243–245° dec.

Anal. Calcd. for $C_{13}H_{18}ClNO_2$: C, 61.05; H, 7.09; Cl, 13.9. Found: C, 60.80; H, 7.14; Cl, 14.0.

The melting point of a mixture of the carbinol hydrochloride melting at 243–245° with that melting at 230–235° was 110–160° dec. It was concluded that these carbinols are the two racemic forms, each contaminated with a small amount of the other.

None of the later experiments yielded either of these carbinols; only the mixtures A and B, with analyses approximating those given above, were obtained.

Neither of these carbinols were affected when allowed to stand in solution in absolute ethanol saturated with hydrogen chloride. Both yielded the same product, m. p. 187–189° d., with acetic anhydride as that obtained in the following experiment with mixture B.

A solution of 4.83 g. of mixture B in 32 ml. of pyridine and 35 ml. of acetic anhydride was refluxed five hours. The brown solution then was poured into 400 ml. of ice-water to hydrolyze the acetic anhydride. Upon neutralization with sodium bicarbonate a dark, tacky oil precipitated. After standing four days, the oil solidified so that it could be filtered off. The crystalline material weighed 1.07 g. It was recrystallized four times from dilute ethanol to give 0.81 g. of a white solid, m. p. 187–189° dec. This compound rapidly darkened on exposure to light and air.

The elemental content and molecular weight of this product approximated that of the cyclic dehydration trimer (IX) of the benzalpiperidone.

(10) *Cf.* Cook and Reed, *J. Chem. Soc.*, 401 (1945).

(11) Although Howton reported correct nitrogen and hydrogen analyses for his 1-methyl-3,5-dibenzal-4-piperidone, the carbon values were consistently 2% lower than the theoretical value.

(12) On the two occasions that a very small amount of 1-methyl-3-benzal-4-piperidone was obtained from such a reaction, it crystallized from the dilute alkaline reaction medium one day after filtering off mixture A. The monobenzal derivative was thus removed before the dipiperidyl methane started to precipitate.

Anal. Calcd. for $C_{39}H_{39}N_3$: C, 85.21; H, 7.15; mol. wt., 550. Found: C, 84.87; H, 6.72; mol. wt., 504 (Rast).

Mixture A, when refluxed with acetic anhydride and pyridine as described above, gave a 15% yield of this product, m. p. 187–189° dec.

The Condensation of Benzaldehyde with the Piperidone (I) in 60% Ethanol. 1-Methyl 3-benzal-4-piperidone (IV).—To a solution of 1.06 g. (0.01 mole) of benzaldehyde and 1.13 g. (0.01 mole) of 1-methyl-4-piperidone in 45 ml. of 60% ethanol was added 0.3 g. of potassium hydroxide. The solution became yellow almost at once. After standing one day a very small quantity of oil appeared. The solution was heated slightly to dissolve this oil which did not reappear on cooling. No further visible reaction occurred until a seed of 1-methyl-3-benzal-4-piperidone was added. Two days after adding this seed 0.78 g. of 1-methyl-3-benzal-4-piperidone, m. p. 213–215°, was filtered off. On successive days three additional crops totaling 0.27 g., and melting at 214–217° were obtained. The mother liquor then was diluted with 18 ml. of water and decanted from 0.16 g. of oil. This oil, when it solidified, melted at 85–105° and could not be recrystallized from dilute ethanol. One day after the oil had been removed from the diluted reaction mixture another 0.17 g. of product, m. p. 216–219° was obtained. The total yield of crystalline product was 1.32 g. (61%). An analytical sample, twice recrystallized from water–ethanol solvent, m. p. 224–225°, had a faint yellow color.

Anal. Calcd. for $C_{13}H_{15}NO$: C, 77.58; H, 7.51. Found: C, 77.30; H, 7.38.

The benzalpiperidone (IV) was also obtained from mixtures A and B, and from the dibenzalpiperidone (VIII) in the following manner.

To 0.36 g. of mixture A in 17.5 ml. of 54% ethanol was added 0.2 g. of potassium hydroxide. Within one day crystals began to deposit. After standing for two weeks at room temperature 0.18 g. (53%) of IV, m. p. 215–218°, was obtained.

A solution of 0.50 g. of mixture B and 0.2 g. of potassium hydroxide in 17.5 ml. 60% ethanol stood for one week at room temperature without precipitating the monobenzal piperidone. The solution was then heated at reflux for ten minutes and allowed to stand at room temperature again. A week after heating the mixture, crystals of IV began to separate. After one month 0.13 g. (28%) of monobenzalpiperidone, m. p. 214–216°, was obtained.

A solution of 0.48 g. of pure 1-methyl-3,5-dibenzal-4-piperidone (VIII), 0.19 g. of 1-methyl-4-piperidone and 1.0 g. of potassium hydroxide in 26 ml. of 60% ethanol was prepared. After standing for three days the solution was refluxed for five minutes while 4.0 ml. of hot water was added. After seventeen days of standing at room temperature 0.23 g. of IV, m. p. 211–215°, was filtered off. A second crop weighing 0.07 g. was obtained eighteen days after the first crop was filtered off. The total yield was 45% of that theoretically possible from the dibenzalpiperidone and the added 1-methyl-4-piperidone. However, the yield is 78% of theoretical, if based on the decomposition of dibenzalpiperidone only.

The Condensation of Benzaldehyde with the Piperidone I with Ethanolic Hydrogen Chloride.—Benzaldehyde (1.06 g.) and 1-methyl-4-piperidone (1.13 g.) were dissolved in 15 ml. of absolute alcohol. Anhydrous hydrogen chloride was passed in until the solution was saturated. The flask was allowed to stand at room temperature for two days during which time a crystalline deposit slowly formed. The hydrochloride of the dibenzal derivative so obtained melted 234–240° and weighed 1.40 g. (86%) (see above for analytical data of this salt).

1-Methyl-3,5-dibenzyl-4-piperidone.—In an apparatus for hydrogenation at atmospheric pressure[13] 5.14 g. of 1-methyl-3,5-dibenzal-4-piperidone hydrochloride in 60 ml. of ethanol was hydrogenated over 0.48 g. of Adams platinum oxide catalyst. Although the dibenzalpiperidone was not completely soluble in the ethanol, the hydrogenated product was and, consequently, the insoluble material disappeared, as the hydrogenation proceeded. After the theoretical amount of hydrogen was taken up (fifteen minutes), the catalyst was filtered off, the solvent evaporated, and the product neutralized with sodium bicarbonate. The brown, oily product did not crystallize and was dissolved in petroleum ether (b. p. 60–68°)–benzene solution (three volumes of benzene to two volumes of petroleum ether) and filtered through a twenty-five centimeter column of activated aluminum oxide. Upon evaporation of the filtrate 2.45 g. of oily, white crystals was obtained. Since these crystals were soluble at room temperature in all common organic solvents, they were triturated with 10 ml. of ice-cold petroleum ether (b. p. 40–60°) to give 1.31 g. of product m. p. 76–79°. An analytical sample was obtained by dissolving the crystals in a minimum amount of petroleum ether (b. p. 40–60°), then cooling the solution to −10°. After three such recrystallizations the melting point of 1-methyl-3,5-dibenzyl-4-piperidone was 84.0–85.5°.

Anal. Calcd. for $C_{20}H_{23}NO$: C, 81.87; H, 7.90. Found: C, 82.12; H, 7.62.

The Condensation of Other Aldehydes with I. Quinoline-2-aldehyde.—To 1.58 g. (0.01 mole) of quinoline-2-aldehyde[14] and 0.56 g. (0.005 mole) of 1-methyl-4-piperidone dissolved in 51 ml. of 30% aqueous ethanol, 0.15 g. (0.002 mole) of potassium hydroxide was added. The solution became yellow immediately and a precipitate appeared within one minute. After shaking the solution for twenty-five minutes, a single lump of semi-solid product was removed. When dried this yellow material weighed 1.87 g. and melted at 143–147°. The residual reaction liquid was diluted with 60 ml. of water to obtain a second crop (0.04 g.) of yellow solid, m. p. 140–146°. This reaction product was recrystallized from 80 ml. of 95% ethanol to give 0.72 g.[15] of long slender yellow needles of **1-methyl-3,5-di-(2-quinolinal)-4-piperidone,** m. p. 153–154°. A thrice recrystallized sample, m. p. 158–159°, was used for analyses.

Anal. Calcd. for $C_{26}H_{21}N_3O$: C, 79.77; H, 5.41. Found: C, 79.72; H, 5.24.

The filtrate from this recrystallization was evaporated to dryness and the residue redissolved in 30 ml. of benzene. Hot petroleum ether (b. p. 60–68°) was added to the boiling benzene and the solution was cooled. In this manner 0.54 g. of tan powder, m. p. 150–160°, was obtained. The purity of this product was not improved by recrystallization, since the contaminant seemed to be as soluble in various solvents as the main portion. Furthermore, recrystallization was discouraged by the heat-sensitivity of the product. An elemental analysis suggested that it was mainly a mono-quinolinal piperidone.

Anal. Calcd. for $C_{16}H_{16}N_2O$: C, 76.16; H, 6.39. Found: C, 76.32; H, 5.28.

Quinoline-4-aldehyde.—To 5.73 g. (0.03 mole) of quinoline-4-aldehyde hydrate[16] and 3.70 (0.03 mole) of 1-methyl-4-piperidone, dissolved in 75 ml. of 67% aqueous ethanol, 2.5 g. (0.05 mole) of solid potassium hydroxide was added. This solution was shaken for fifteen minutes, diluted with 200 ml. of water, then shaken for twenty minutes and diluted with another 200 ml. of water. After a final ten minutes of shaking the light-tan solid was filtered and dried. It weighed 7.36 g. (95%) and melted at 190–203°. A 6.05-g. sample of this crude product was triturated with a few ml. of cold benzene,

(13) Fieser and Hershberg, This Journal, **60**, 944 (1938).

(14) Kaplan, *ibid.*, **63**, 2654 (1941).

(15) This large loss on recrystallization is due partly to decomposition. For example, when 0.58 g. of pure 1-methyl-4,5-di-(2-quinolinal)-4-piperidone was recrystallized from 45 ml. of 95% ethanol only 0.46 g. was recovered. The filtrate, when evaporated to dryness, gave 0.09 g. of a brown powder which was much more ethanol-soluble and higher-melting than the di-quinolinalpiperidone.

(16) Kwartler and Lindwall, This Journal, **59**, 524 (1937).

filtered, and dried. The **1-methyl-3-(4-quinolinal)-4-piperidone** thus obtained weighed 5.96 g. and melted 222–225° dec. For an analytical sample this triturated product was recrystallized from 95% ethanol. It melted at 250–252° dec. when heated from room temperature; when introduced at a bath temperature of 240°, however, it melted at 252–253°.

Anal. Calcd. for $C_{16}H_{16}N_2O$: C, 76.16; H, 6.39. Found: C, 76.06; H, 6.04.

A mixture of 0.42 g. (0.0037 mole) of 1-methyl-4-piperidone, 1.30 g. (0.0074 mole) of quinoline-4-aldehyde, and 0.15 g. (0.002 mole) of potassium hydroxide in 50 ml. of 30% aqueous ethanol was shaken for twenty minutes. The yellow solid which formed was filtered off and recrystallized from hot methanol. The first crop of long yellow needles of **1-methyl-3,5-di-(4-quinolinal)-4-piperidone** weighed 0.94 g., m. p. 198–200°. A second crop (0.20 g.) of this same product, m. p. 193–196°, was obtained by diluting the ethanol filtrate with a few ml. of water. On further dilution a third crop of crystals weighing 0.09 g. was obtained. The latter product softened at 190° but the major portion did not melt until 245°. This behavior indicates this product to be mainly the mono-4-quinolinal derivative described above.

An analytical sample of **1-methyl-3,5-di-(4-quinolinal)-4-piperidone**, m. p. 199–200°, was obtained by recrystallization from methanol.

Anal. Calcd. for $C_{26}H_{21}N_3O$: C, 79.77; H, 5.41. Found: C, 79.85; H, 5.41.

***o*-Chlorobenzaldehyde.**—To 1.75 g. (0.01 mole) of freshly distilled *o*-chlorobenzaldehyde and 1.40 g. (0.012 mole) of 1-methyl-4-piperidone in 26 ml. of 62% aqueous ethanol was added 1.0 g. of solid potassium hydroxide. After shaking for fifteen minutes the crude, yellow **1-methyl-3,5-di-(*o*-chlorobenzal)-4-piperidone** was filtered off. Recrystallization from ethanol gave 1.63 g. (73%) of yellow needles, m. p. 152–155°. A thrice recrystallized sample, m. p. 152–154°, was used for analytical purposes.

Anal. Calcd. for $C_{20}H_{17}Cl_2NO$: C, 67.04; H, 4.78. Found: C, 67.25; H, 4.73.

The **hydrochloride** of 1-methyl-3,5-di-(*o*-chlorobenzal)-4-piperidone, after recrystallization from an ethanol–ether mixture, melted at 227–229° d.

Anal. Calcd. for $C_{20}H_{17}Cl_2NO \cdot HCl$: ionic Cl, 9.0. Found: ionic Cl, 9.0.

The reaction mixture from which the dibenzal derivative had been filtered was diluted with 60 ml. of water to precipitate 0.764 g. of an almost white powder, m. p. 120–135°. After five recrystallizations from ethanol–water, this product melted at 150–155°. An elemental analysis indicated that this somewhat impure sample was mainly **1-methyl-3-(*o*-chlorobenzal)-4-piperidone.**

Anal. Calcd. for $C_{18}H_{14}ClNO$: C, 66.24; H, 5.99. Found: C, 65.93; H, 5.34.

α-Naphthaldehyde.—The condensation of this aldehyde with the piperidone I was carried out in a manner similar to that of *o*-chlorobenzaldehyde. The crude, yellow dinaphthal derivative, m. p. 160–170°, was obtained in 80% yield. Recrystallization from ethanol gave an analytical sample of **1-methyl-3,5-di-(α-naphthal)-4-piperidone**, m. p. 173–175°.

Anal. Calcd. for $C_{28}H_{23}NO$: C, 86.34; H, 6.09. Found: C, 86.74; H, 6.22.

A small amount of an ivory-colored powder, m. p. 177–181°, the analyses of which indicated it to be an impure mononaphthal derivative, also was obtained. Variations in the relative amounts of potassium hydroxide used in the condensations of *o*-chlorobenzaldehyde and α-naphthaldehyde did not materially affect the nature of the reaction products (see Table II).

Summary

The base-catalyzed condensation of benzaldehyde with 1-methyl-4-piperidone has been found to yield either the mono or the dibenzal derivative depending on the nature of the solvent used for the reaction. In addition to these products, other materials corresponding to the phenylpiperidyl carbinols and mixtures of these types with the benzal derivative, as well as bis-dipiperidylphenylmethane, have been isolated.

The base-catalyzed condensation is shown to be reversible by the conversion of the carbinol-containing mixtures, as well as the dibenzal derivative, into the monobenzal derivative.

The acid-catalyzed condensation of benzaldehyde and the piperidone yields only the dibenzal derivative. The carbinol is shown not to be an intermediate in this condensation.

Quinoline-4-aldehyde yields either the mono- or diquinolinal derivative of the piperidone depending on the amount of alkali used to effect the condensation. *o*-Chlorobenzaldehyde and α-naphthaldehyde yields only the dibenzal derivative regardless of the amount of alkali used. Similarly quinoline-2-aldehyde yields mainly a rather unstable diquinolinal derivative.

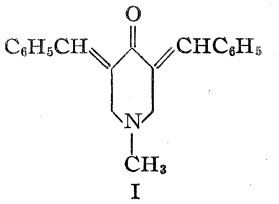
Piperidine Derivatives. XIX. Esters of Substituted 4-Piperidinols

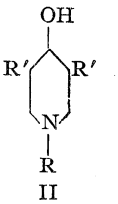
By S. M. McElvain and Kurt Rorig[1]

In the seventh paper of this series the benzoates and *p*-aminobenzoates of a series of 1-alkyl-4-piperidinols (II, R′ = H) were described.[2] The piperidinols were not isolated but were directly acylated in the form of their hydrochlorides, which were obtained by the hydrogenation of the corresponding 1-alkyl-4-piperidone hydrochlorides over Adams platinum oxide catalyst. In the present paper the preparation of 1-methyl-, 1-isopropyl- and 1-*n*-butyl-4-piperidinol and the three inactive stereoisomeric 1-methyl-3,5-dibenzyl-4-piperidinols and certain of their esters are described.

The 1-alkyl-4-piperidinols were obtained in excellent yields by the hydrogenation of the corresponding piperidones over Raney nickel. These piperidinols were converted to the diphenylacetates and 1-methyl-4-piperidinol to the N-phenylcarbamate for pharmacological testing. The benzilic esters could not be prepared either by the direct interaction of benzilic acid with the piperidinol or with the corresponding 4-chloropiperidine according to the procedure of Horenstein and Pählicke.[3]



I



II

There are four theoretically possible stereoisomeric 1-methyl-3,5-dibenzyl-4-piperidinols (II, R = CH_3; R′ = $C_6H_5CH_2$): *d*, *l*, and two *meso* forms. The hydrogenation of 1-methyl-3,5-dibenzal-4-piperidone[4] (I) under various conditions with platinum, nickel and copper chromite catalysts has yielded three different dibenzylpiperidinols, corresponding to the racemic and the two meso forms, as well as a product in which both benzene nuclei are hydrogenated. The separation of these hydrogenation products was difficult and recrystallization losses were high. The proportion of products from any one hydrogenation varied with the temperature, but in no case was the yield of any one more than 68% of the theoretical. The melting points and analyses of these piperidinols together with the catalysts and conditions under which they were produced are summarized in Table I.

Table I

Hydrogenation Products of 1-Methyl-3,5-dibenzal-4-piperidone (I)

Compound	M. p., °C.	Formula	Calcd. C	Calcd. H	Found C	Found H	Catalyst
1-Methyl-3,5-dibenzyl	155–157	$C_{20}H_{25}NO$	81.31	8.33	81.30	8.60	Ni,[a] $CuCrO_3$[b]
4-piperidinol	183–184	$C_{20}H_{25}NO$	81.31	8.33	81.21	8.12	Pt,[c] Ni[d]
	177–178	$C_{20}H_{25}NO$	81.31	8.33	80.97	8.35	$CuCrO_3$[e]
1-Methyl-3,5-di-(hexahydrobenzyl)-4-piperidinol	176–178	$C_{20}H_{37}NO$	78.11	12.13	78.36	12.03	Ni[f]

[a] At 80° under 160 atmospheres of hydrogen for 5 hours. [b] At 200° under 160 atmospheres for 2.5 hours. [c] At 20–25° under 1 atmosphere for 1.5 hours. [d] At 60° under 105 atmospheres for 1 hour. [e] At 215° under 145 atmospheres for 5 hours. [f] At 80° under 160 atmospheres for 5 hours, followed by 180° for 3.5 hours.

With the platinum catalyst the carbon to carbon double bonds were hydrogenated in ten to fifteen minutes; the carbonyl group required an additional one to two hours. Hydrogenation over platinum was never very satisfactory, however, because a colored, oily product resulted and from this oily material pure crystalline compounds were obtained only with considerable difficulty. The nickel and copper chromite catalysts, on the other hand, gave white products that readily crystallized.

The diphenylacetate was prepared from the most abundant 1-methyl-3,5-dibenzyl-4-piperidinol (m. p. 177–178°). The salts of this ester are remarkably insoluble in water; in fact, none were found with sufficient solubility to permit pharmacological testing.

The properties and analyses of the hydrochlorides of the substituted piperidinol esters prepared in this work are summarized in Table II.

The 1-methyl-, 1-isopropyl- and 1-*n*-butyl-4-piperidyl diphenylacetate hydrochlorides were tested for antispasmodic activity by Dr. K. K. Chen and associates of the Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Indiana. On the isolated guinea pig ileum, the 1-methyl-4-piperidyl ester showed about 50% of the activity of atropine sulfate; the higher homologs showed only about 1% of this activity.

Experimental

Alkyl-di-(β-carbethoxyethyl)-amines.—These tertiary amines were prepared by the addition of the appropriate primary amine to ethyl acrylate. Methylamine adds to the acrylate in six hours at 65° to give an 80% yield of the

[a] M. p. 24–27°; this compound has been prepared from chelidonic acid and reported to melt at 28° [Mills, Parkin and Ward, *J. Chem. Soc.*, 2622 (1927)]; its preparation from chelidonic acid also has been reported by Emmert, German Patent 292,871 [*Chem. Zentr.*, **87**, II, 116 (1916)]; Riegel and Reinhard, THIS JOURNAL, **48**, 1344 (1926); Burtner and Cusic, *ibid.*, **65**, 266 (1943).

tertiary amine[4]; isopropylamine requires ten hours at 175° to produce a 56% yield[5]; and n-butylamine requires ten hours at 125° to give a 73% yield of the tertiary amine. The properties of these tertiary amines corresponds to those previously reported.[6]

1-Alkyl-4-piperidones.—These piperidones were obtained by decarboxylation of the 1-alkyl-3-carbethoxy-4-piperidones, resulting from the Dieckmann cyclization of the above tertiary amino-esters, in the same manner as described for 1-methyl-4-piperidone.[4] The properties of these piperidones are listed in Table III.

1-Alkyl-4-piperidinols.—These compounds were obtained in 80–95% yields by the hydrogenation of the 1-alkyl-4-piperidones over Raney nickel at 140 atmospheres and 125° for two hours. The properties and analyses of these piperidinols are summarized in Table IV.

Hydrogenation of I to the 1-Methyl-3,5-dibenzyl-4-piperidinols. (a) Adams Platinum Oxide Catalyst.—A 2.00-g. sample of 1-methyl-3,5-dibenzal-4-piperidone hydrochloride in 33 ml. of 95% ethanol was hydrogenated over 0.20 g. of Adams platinum oxide catalyst. The amount of hydrogen necessary for saturation of the olefinic bonds was taken up in ten minutes. However, hydrogenation of the carbonyl group was so much slower that ninety-two minutes were required for completion. The free basic product was obtained by neutralization and crystallized from an aqueous ethanolic medium. The first crop of crystals, weighing 0.29 g., melted at 176.5–178.0°. Three lower-melting crops, totaling 0.20 g., were obtained by diluting the ethanolic mother liquors.

The first crop was recrystallized once from aqueous ethanol and twice from benzene–petroleum ether (b. p. 60–68°) solvent to give an analytical sample melting at 183.5–184.0°.

(b) Raney Nickel Catalyst.—The 183.5–184° isomer was also obtained by high pressure hydrogenation over Raney nickel. To 2.57 g. of 1-methyl-3,5-dibenzal-4-piperidone and 40 ml. of ethanol in a 270-ml. steel hydrogenation bomb was added 0.4 g. of Raney nickel catalyst prepared according to the directions of Pavlic and Adkins.[7] The bomb was filled with hydrogen to an initial pressure of 105 atmospheres and hydrogenated at 60° for fifty minutes. After filtering off the catalyst and removing the ethanol, the residue was taken up in hot petroleum ether (b. p. 60–68°). On cooling this solution 0.30 g. of material melting at 160–167° was obtained. Three recrystallizations from benzene–petroleum ether mixture raised the melting point to 182–183°. There was no depression of melting point when this sample was mixed with the one previously obtained by hydrogenation over Adams platinum oxide catalyst.

The above hydrogenation was repeated with 7 g. of I in 25 ml. of ethanol over 3 g. of the nickel catalyst at 80° and 160 atmospheres for five hours. After removal of the catalyst and solvent, the product was crystallized from a mixture of two volumes petroleum ether (b. p. 60–68°) and one volume benzene to give 2.4 g. of crude product melting 153–159°. This was recrystallized three times from the benzene–petroleum ether solvent to remove a higher melting impurity. The analytical sample thus obtained melted 155.0–156.0°.

(c) Copper–Chromite Catalyst.—The lower melting 1-methyl-3,5-dibenzyl-4-piperidinol was also obtained by the hydrogenation of a 2.0-g. sample of the dibenzal-piperidone over 1.0 g. of copper–chromite catalyst which

(5) Ziering, Berger, Heineman and Lee, *J. Org. Chem.*, **12**, 901 (1947), recently reported the preparation of this tertiary amine by allowing the reactants to stand in alcohol solution for one week at room temperature.

(6) McElvain, THIS JOURNAL, **46**, 1721 (1924); **48**, 2179 (1926).

(7) Adkins and Pavlic, *ibid*, **68**, 1471 (1946).

was prepared according to Adkins' directions.[8] The bomb was filled initially to a hydrogen pressure of 160 atmospheres, and the hydrogenation run at 200° for two and one-half hours. The recrystallized product (1.36 g.) melted 155–157°. A mixture of this product with that obtained from the Raney nickel hydrogenation melted at 154.5–157°.

When 5.0 g. of 1-methyl-3,5-dibenzal-4-piperidone in ethanol and 2.0 g. of copper chromite catalyst in a bomb containing 145 atmospheres of hydrogen were heated for five hours at 215°, 1.76 g. of white crystals melting at 175–177° was obtained by allowing the hydrogenation product to crystallize from a benzene–petroleum ether (b. p. 60–68°) mixture. This product then was recrystallized from the same solvent mixture to give an analytical sample of 1-methyl-3,5-dibenzyl-4-piperidinol melting at 177.0–178.5°. A mixture of a sample of this material with the 1-methyl-3,5-dibenzyl-4-piperidinol, m. p. 183.5–184.0°, was 153–170°.

1-Methyl-3,5-di-(hexahydrobenzyl)-4-piperidinol.—When the 1-methyl-3,5-dibenzyl-4-piperidinol, melting at 155–157°, was prepared by hydrogenation over Raney nickel the yields were low. A substantial portion of the crude product was much more soluble in petroleum ether (b. p. 60–68°) than the 155–157° melting product. The solubility suggested that the benzene rings had been hydrogenated in the reaction. However, no such product could be isolated from the crude mixture. Accordingly this petroleum ether soluble residue (4.20 g.) was rehydrogenated over fresh Raney nickel (4 g.) for three and one-half hours at 180° and 165 atmospheres hydrogen pressure. After removal of catalyst and solvent, the oily residue was caused to crystallize by rubbing with a few drops of petroleum ether. The resultant semi-crystalline mass then was dissolved in 25 ml. of petroleum ether (b. p. 60–68°) and cooled to −10° to precipitate a crop (1.08 g.) of white, fluffy needles melting 160–167°. These were recrystallized from 50 ml. of petroleum ether to give 0.80 g. of analytically pure product melting at 176.5–178.0°.

The analytical data for these 3,5-substituted N-methylpiperidinols are listed in Table I.

1-Methyl-4-chloropiperidine.—A solution of 7.0 g. of thionyl chloride in 25 ml. of dry benzene was added slowly to 4.15 g. of 1-methyl-4-piperidinol in 25 ml. of dry benzene. An oily precipitate formed almost immediately. This mixture was refluxed for one hour and cooled overnight. The solid, when filtered and dried, weighed 5.5 g., melted at 145–155°, and contained 42.7% chlorine (calcd. for $C_6H_{13}Cl_2N$: Cl, 41.7). When this salt was twice recrystallized from isopropanol and ether, the melting point was raised to 163–165°.

A solution of 4.65 g. of 1-methyl-4-chloropiperidine hydrochloride in 15 ml. of water was neutralized with an excess of potassium carbonate to salt out the free base. This was taken up in ether, dried, and distilled to give 2.81 g. of a liquid with a pungent, ammoniacal odor, b. p. 160–162° (733 mm.). Elementary analyses gave consistent but slightly high results for carbon and hydrogen. This may well be due to the presence of a small amount of the tetrahydropyridine, formed by dehydrohalogenation of the chloropiperidine during distillation. Accordingly the 1-methyl-4-chloropiperidine was redistilled at reduced pressure and three fractions collected. The middle cut, on analysis was found to contain less carbon and hydrogen than before but more than required by theory. There was insufficient material to redistil further.

Anal. Calcd. for $C_6H_{12}ClN$: C, 53.93; H, 9.06. Found: C, 54.87; H, 9.18.

After several days of standing, a brown gum began to deposit from this redistilled 1-methyl-4-chloropiperidine.

Hydrochlorides of Certain 1-Alkyl-4-piperidinol Esters.—The hydrochlorides of the various piperidyl diphenylacetates were obtained from the reaction of diphenylacetyl chloride with the piperidinol in refluxing benzene solution. On cooling the salt separated and was further purified by recrystallization from benzene. 1-Methyl-4-piperidyl N-phenylcarbamate was prepared from the piperidinol and phenyl isocyanate. The free base melted at 125–126°[9]; the hydrochloride was prepared by treatment of an ether solution of the free base with hydrogen chloride. The melting points and analyses of these hydrochlorides are listed in Table II.

In an attempt to prepare 1-methyl-4-piperidylbenzilate by the method of Horenstein and Pählicke,[3] 1.13 g. of freshly distilled 1-methyl-4-chloropiperidine was added to 1.94 g. of benzilic acid in 20 ml. of anhydrous isopropanol. After refluxing for thirteen hours, the solvent was removed by distillation *in vacuo*, and the residue was extracted with ether. From this ethereal extract 1.10 g. of benzilic acid was recovered. The ether-insoluble residue, which should have contained the 1-methyl-4-piperidyl-benzilate hydrochloride, was a water insoluble, brown gum from which no pure product could be isolated.

Summary

All of the possible inactive stereoisomeric 1-methyl-3,5-dibenzyl-4-piperidinols and one of the 1-methyl-3,5-dihexahydrobenzyl-4-piperidinols have been isolated from the hydrogenation of 1-methyl-3,5-dibenzal-4-piperidone.

1-Methyl-, 1-isopropyl- and 1-*n*-butyl-4-piperidinol have been prepared by the hydrogenation of the corresponding 4-piperidones.

Certain esters of these piperidinols have been prepared for pharmacological testing.

Synthesis of Products Related to Vitamin A. VIII. The Synthesis of 1-(Cyclohexen-1′-yl)-3-methyl-3-epoxybutyne-1 and Related Products[1]

BY NICHOLAS A. MILAS, NORMAN S. MACDONALD[2] AND DONALD M. BLACK[3]

The availability of a reliable method for the synthesis of biologically active vitamin A products[4] made it desirable to investigate the effect of various substituents in the cyclohexene ring on the biological activity of the final products. For example, one could synthesize a vitamin A analog without any substituents in the cyclohexene ring, or even substitute a benzene ring for the latter. In order to effect these changes, several new key intermediates have been synthesized and are herein reported.

In the synthesis of the epoxides (VI) and (VII) four different series were studied. In the first series cyclohexanone was acetylenated in liquid ammonia with sodium acetylide and the 1-ethynylcyclohexanol-1 (II, $R_1 = R_2 = R_3 = H$) formed dehydrated at 290–300° using aluminum phosphate as the dehydrating catalyst. This dehydration has been previously studied using alumina[5] and aluminum sulfate[6] catalysts but no analytical data beyond a series of widely different physical constants have been reported. The same holds true with the results of other investigators who prepared this enyne by other procedures.[7,8] The lack of chemical evidence for the existence of the pure enyne is perhaps significant, since even in our case all low boiling fractions were found to possess values for active hydrogen ranging from less than 0.1 to 0.9, in spite of the fact that hydrogenation values and other properties were almost identical to those of the pure enyne.

In the second series, 2-methyl-1-ethynylcyclohexanol-1 was prepared in liquid ammonia from 2-methylcyclohexanone and sodium acetylide. When this ethynylcyclohexanol was allowed to stand at 0° for sixteen hours, it separated into two forms: a solid and a liquid form of approximately equal weight. Since the addition of acetylene to the carbonyl group of the 2-methylcyclohexanone introduces a second asymmetric carbon atom, one would expect two pairs of enantiomorphs, a fact which has been overlooked by earlier investigators[9,10] although Wang and Hu[11] reported both the solid and the liquid forms. Dehydration of both the liquid and the solid forms over aluminum phosphate at 290–295° produced the same ethynylcyclohexene in yields of 52 and 27%, respectively. Ozonization of the enyne, produced from either the solid or the liquid form, yielded the same keto acid, namely, 6-ketoheptoic acid. The 2,4-dinitrophenylhydrazone of this acid from either ozonization product had the same m. p., and mixed m. p. showed no depression. Furthermore, the semicarbazone of the keto-acid from either ozonization product had essentially the same m. p. which was identical with the m. p. of the semicarbazone of 6-ketoheptoic acid reported by Wallach.[12] Therefore, we are forced to conclude that both enynes must have essentially the same structure.

That the solid carbinol presumably corresponds to the *cis* form and the liquid to the *trans* form may be deduced from the tendency of each to dehydrate. It is well known[13] that *trans* elimination of water or halogen acids proceeds more smoothly than the corresponding *cis* elimination, and the low yields of the enyne obtained from the solid carbinol are in accord with these facts.

In the third series 2,6,6-trimethyl-1-ethynylcyclohexanol-1 was prepared in liquid ammonia from 2,6,6-trimethylcyclohexanone and sodium acetylide. Although two pairs of enantiomorphs were also expected in this case, only one product was obtained and attempts to separate it into two forms were not successful. The dehydration of this acetylene carbinol to produce the corresponding enyne in good yields was difficult to accomplish.[14] Methods which were known to yield good results with other acetylene carbinols were either too drastic or too ineffective in producing the proper dehydration. Small yields of the desired enyne were obtained when the acetylene carbinol was dehydrated at 270–290° using aluminum phosphate on pumice as catalyst or when heated with either succinic anhydride in dibutyl phthalate or with a mixture of succinic anhydride and small amounts of glacial metaphosphoric acid. Perhaps

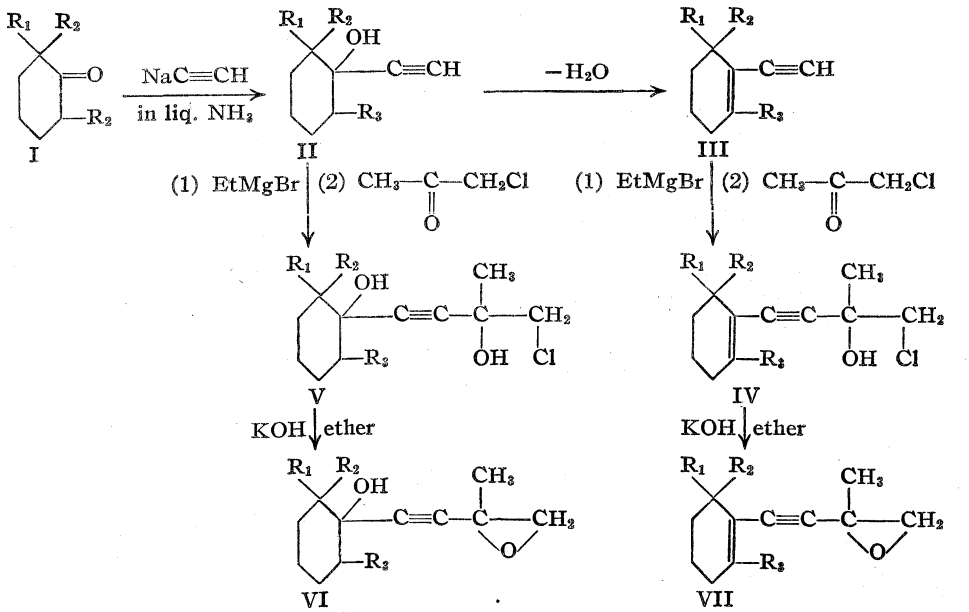
(14) Since this enyne is an important intermediate in the synthesis of vitamin A itself, work is being continued to study the mechanism of its formation.



I, $R_1 = R_2 = R_3 = H$
II, $R_1 = R_2 = H$; $R_3 = CH_3$

IV, $R_1 = R_2 = R_3 = H$;  =

the reason for our difficulty in obtaining good yields of the enyne in this case is due to the possibility of the hydroxyl group being hindered by the methyl groups. A similar case has been reported recently[15] with 1-(2,4-dimethylphenyl)-2,6-dimethylcyclohexanol which could not be dehydrated with potassium acid sulfate at 190–200°, or with boiling acetic anhydride. However, when it was refluxed with anhydrous oxalic acid at 200–220°, a yield of 81% of the corresponding cyclohexene derivative was obtained.[16] When this method was applied to our acetylene carbinol only small amounts (3%) of the pure enyne were obtained.

In the subsequent step of the synthesis of the epoxides either the enynes (III) or the carbinols (II) were allowed to react via their Grignard reagents with chloroacetone to form the corresponding chlorohydrins (V or VI).[17] In this step phenylacetylene was added to the list to afford comparison of the benzene ring with the cyclohexene ring.

Dehydrochlorination of the chlorohydrins was effected with powdered potassium hydroxide in quantities two to three times that of the theoretical. Sodamide was found equally effective, but an organic base such as triethylamine was completely ineffective. All the epoxides prepared in this investigation responded slowly to the fuchsin-aldehyde test, and in acid solution they yielded crystalline 2,4-dinitrophenylhydrazones.

In the vitamin A synthesis cited in the early part of this paper, 1-[2′,6′,6′-trimethylcyclohexen-1′-yl]-3-methylbuten-1-al-4 was the key intermediate. This was either acetylenated in liquid ammonia or allowed to react with a Grignard of an ethynyl compound of the proper structure. Both of these reactions were tested with some of our epoxides. For example, when 1-(cyclohexen-1′-yl)-3-methyl-3-epoxybutyne-1 was allowed to react in liquid ammonia with lithium acetylide, 1-(cyclohexen-1′-yl)-3-methyl-3-hydroxy hexadiyne-1,5 (VIII) was formed. Similarly, when 1-phenyl-3-methyl-3-epoxybutyne-1 was treated with ethylmagnesium bromide the carbinol (IX) was presumably formed, since it is well known[18]

that a Grignard reagent reacts with an unsymmetrically substituted epoxide to form secondary rather than tertiary alcohols. The structure of (VIII) and (IX) are only provisionally proposed and further work is being done to establish the structure of this type of compounds.

It is therefore seen that the success of the synthesis of vitamin A itself or its analogs, in which the methyl groups of the cyclohexene ring may be changed or left out entirely, can be achieved by by-passing β-ionone.

Experimental

1-Ethynylcyclohexanol-1.—Five hundred grams of pure cyclohexanone was added dropwise with stirring to a mixture of sodium acetylide (from 117 g. of sodium) and liquid ammonia (3 l.) at −50° in the course of three hours. Stirring was continued overnight while a slow stream of dry acetylene was allowed to pass through the solution. The ammonia was then allowed to evaporate and the residue acidified with 200 g. of tartaric acid in 500 cc. of water and extracted with ether. After the ether solution was dried and the ether removed, the residue was fractionated through a four-foot packed column and the fraction (518 g., 82%) boiling at 74–77° (15 mm.) or 79–81° (21 mm.) collected and analyzed. The supercooled liquid had an $n^{20}D$ 1.4823. On standing the liquid solidified completely; m. p. 31–32°. Marvel, *et al.*,[19] gave a m. p. of 31–32°.

Anal. Calcd. for $C_8H_{12}O$: active hydrogen, 2.00. Found: A. H. (Zerewitinoff), 1.97, 2.02.

2-Methyl-1-ethynylcyclohexanol-1.—This acetylene carbinol was prepared in exactly the same way as the previous one in liquid ammonia from 560 g. of 2-methylcyclohexanone (b. p. 160.5–161°, $n^{25}D$ 1.4465) and sodium acetylide (from 130 g. of sodium). The product was fractionated through a four-foot packed column and the fraction (464 g., 67%) boiling at 98–105° (45 mm.) collected and allowed to stand at 0° for sixteen hours, whereby it separated into two fractions: a solid fraction (227 g.) and a liquid portion (225 g.). The solid was recrystallized from petroleum ether, m. p. 61.0–61.5° (cor.). The liquid portion was redistilled; b. p. 84° (17 mm.). Further attempts to obtain crystals from the liquid portion were unsuccessful. Wang and Hu[20] gave 60 and 85° (18 mm.), respectively.

Anal. Calcd. for $C_9H_{14}O$: A. H., 2.00. Found (crystalline): A. H. (Zerewitinoff), 2.0, 1.97. Found (liquid): A. H. (Zerewitinoff), 2.0, 2.0.

2,6,6-Trimethyl-1-ethynylcyclohexanol-1.—In a similar manner this acetylene carbinol was prepared in liquid ammonia from 560 g. of 2,6,6-trimethylcyclohexanone [b. p. 177–178.5° (758 mm.), or 69–71.5° (20 mm.); $n^{25}D$ 1.4465][21] and sodium acetylide (from 92 g. of sodium). The final product was fractionated through a four-foot packed column and the fraction (524 g., 79%) boiling at 212–212.4° (760 mm.) or 88–90° (20 mm.) collected and analyzed; $n^{25}D$ 1.4740; d^{25}_4 0.9300; MR_D (calcd.), 50.32; MR_D (obsd.), 50.25.

Anal. Calcd. for $C_{11}H_{18}O$: C, 79.46; H, 10.91; unsaturation, 2.0 ⌐¬; A. H. (Zerewitinoff), 2.0. Found: C, 79.51, 79.45, 79.31; H, 10.86, 11.23, 11.21; unsaturation, 2.11 (Pt), 2.02 (Pd) ⌐¬; A. H. (Zerewitinoff), 2.0, 2.04.

1-Ethynylcyclohexene-1.—1-Ethynylcyclohexanol-1 was dehydrated by passing it upwards at the rate of 75 g. per hour under a slightly reduced pressure (175–180 mm.) through a glass tube 2.5 × 24 cm. packed with a 5:1 mixture of pumice and aluminum phosphate and maintained at a temperature of 290–300°. The vapors were condensed and fractionated through a four-foot packed column and the fraction (52% per pass) boiling at 47° (13 mm.) was collected and analyzed. Although this product showed the correct hydrogenation value, its Zerewitinoff value was between 0.6 and 0.8. It was therefore purified further via its silver derivative which was decomposed either with hydrogen sulfide or ammonium thiocyanate and the pure enyne recovered. For example, from 9 g. of crude 1-ethynylcyclohexene-1 6 g. of pure enyne was obtained boiling at 52–53° (30 mm.) or 63–64° (52 mm.) or 137–138° (760 mm.); $n^{25}D$ 1.4934; d^{25}_4 0.8843; MR_D (calcd.), 34.48; MR_D (obsd.), 34.90. It also showed a maximum in the ultraviolet at 224 mμ, log $\epsilon_{mol.}$ 4.13.

Anal. Calcd. for C_8H_{10}: C, 90.50; H, 9.50; unsaturation, 3.0 ⌐¬; A. H., 1.0. Found: C, 90.44; H, 9.52; unsaturation, 3.19 ⌐¬; A. H. (Zerewitinoff), 1.01, 1.0, 1.03.

2-Methyl-1-ethynylcyclohexene-1.—(a) From liquid 2-methyl-1-ethynylcyclohexanol-1. When 250 g. of this ethynylcarbinol was dehydrated under the same conditions as in the previous case and the crude product fractionated, a fraction (103 g., 47% per pass) was obtained which boiled at 55° (20 mm.) and had a Zerewitinoff value of 0.9. This was further purified through its silver derivative and the recovered enyne had a b. p. of 63–65° (30 mm.) and gave correct analytical values; $n^{25}D$ 1.4895; d^{25}_4 0.8827; MR_D (calcd.), 39.09; MR_D (obsd.), 39.41. It also showed a maximum in the ultraviolet at 229 mμ, log $\epsilon_{mol.}$ 4.0.

Anal. Calcd. for C_9H_{12}: C, 89.93; H, 10.07; A. H., 1.0. Found: C, 89.71; H, 10.16; A. H. (Zerewitinoff), 1.0, 0.97.

(b) From solid 2-methyl-1-ethynylcyclohexanol-1: From 180 g. of solid 2-methyl-1-ethynylcyclohexanol-1, 84 g. of an enyne was obtained which had a b. p. of 57° (30 mm.) and a Zerewitinoff value of 0.5. This corresponds to a 27% yield per pass. This crude enyne was purified through its silver derivative and the pure product had a b. p. of 63.5–64° (30 mm.) and gave correct analytical values; $n^{25}D$ 1.4883; d^{25}_4 0.8820; MR_D (calcd.), 39.09; MR_D (obsd.), 39.26. It also showed a maximum in the ultraviolet at 229 mμ, log $\epsilon_{mol.}$ 4.06.

Anal. Calcd. for C_9H_{12}: C, 89.93; H, 10.07; A. H., 1.0. Found: C, 89.75; H, 10.20; A. H. (Zerewitinoff), 1.0.

Ozonization of the Two 2-Methyl-1-ethynylcyclohexenes.—Using the method developed by Strain,[22] 2 g. of each anyne was ozonized and the 2,4-dinitrophenylhydrazones precipitated and recrystallized from aqueous acetic acid solution.

From the enyne obtained by the dehydration of the solid 2-methyl-1-ethynylcyclohexanol-1, a pure 2,4-dinitrophenylhydrazone was obtained, m. p. 132.6–133.1° (cor.).

Anal. Calcd. for $C_{13}H_{16}O_6N_4$: C, 48.14; H, 4.97; N, 17.28; neut. equiv., 324. Found: C, 47.97; H, 4.89; N, 16.96; neut. equiv., 327.

From the enyne obtained from the liquid 2-methyl-1-ethynylcyclohexanol-1, the pure 2,4-dinitrophenylhydrazone melted at 132.6–133° (cor.) and mixed m. p. with the previous sample showed no depression. A neutralization equivalent was taken and gave a value of 326.

Since the 2,4-dinitrophenylhydrazone of 2-ketoheptoic acid was not known, the acid was prepared by the method of Wallach[23] and this derivative prepared from it and purified; m. p. 132.5° (cor.). Mixed m. p. with the two derivatives mentioned above showed no depression.

The semicarbazone was also prepared from each ozonized product and found to have a m. p. of 145–146° (cor.) from the enyne obtained from the solid acetylene carbinol and 144–145° (cor.) from the enyne obtained from the

liquid acetylene carbinol. Mixed m. p. of the two showed no depression. Wallach[23] gives a m. p. of 144–145° for this derivative.

2,6,6-Trimethyl-1-ethynylcyclohexene-1.—This enyne was made by the dehydration of 2,6,6-trimethyl-1-ethynylcyclohexanol-1. The following dehydrating agents were tried usually at temperatures above the b. p. of the carbinol and in an atmosphere of nitrogen: fused potassium hydrogen sulfate, aluminum oxide on pumice, calcined ammonium alum on pumice, a 50–50 mixture of aluminum oxide–aluminum sulfate on pumice, thorium oxide on pumice, barium oxide, *p*-toluenesulfonic acid, molten succinic anhydride, succinic anhydride and sulfuric acid, succinic anhydride and glacial metaphosphoric acid, succinic anhydride in dibutyl phthalate, anhydrous oxalic acid, aluminum phosphate on pumice and anhydrous magnesium sulfate. Acidic dehydrating agents gave small amounts of the enyne while basic dehydrating agents gave mostly decomposition products. Of all the combinations tried, aluminum phosphate (20 g.) on pumice (30 g.) at 270–290° gave yields of 18–20% of the enyne per pass with only 50–60% of the carbinol recovered unchanged. When 22.6 g. of the acetylenecarbinol was added dropwise to a molten mixture of succinic anhydride (25 g.) and glacial metaphosphoric acid (0.4 g.) at 240–260° and under a slightly reduced nitrogen pressure (400 mm.), a product was obtained which when fractionated gave a fraction (6.7 g.) b. p. 60–80° (18 mm.). On the basis of its Zerewitinoff value, a yield of 26% of the enyne was obtained. However, on account of a large amount of tar formation, very little or no unchanged carbinol was recovered. When a similar dehydration was done in dibutyl phthalate (150 cc.) containing succinic anhydride (16 g.) under similar pressure and temperature conditions, yields of 12–15% of the enyne were obtained with slightly over 80% of the carbinol recovered unchanged. Similarly when 80 g. of the carbinol was heated with 61 g. of anhydrous oxalic acid[16] at 170° under a slightly reduced pressure a product was obtained which when fractionated gave a fraction (26 g.) b. p. 75° (30 mm.). The Zerewininoff value was only 0.3 corresponding to a yield of 10% of the enyne.

Since the silver derivative of this enyne precipitates instantly from an alcoholic ammoniacal silver nitrate solution, and the acetylene carbinol fails to give a precipitate even after one to two hours, the enyne was purified by this method as in the previous cases. The recovered pure enyne was found to boil at 56–57° (18 mm.) or 72–74° (30 mm.) and to give good analytical values; $n^{25}D$ 1.4745; $d^{25}D$ 0.8574; MR_D (calcd.) 48.33; MR_D (obsd.), 48.55.

Anal. Calcd. for $C_{11}H_{16}$: C, 89.11; H, 10.89; unsaturation, 3.0 ⌐¬; A. H., 1.0. Found: C, 89.20, 89.10; H, 10.82, 10.75; unsaturation, 3.28 (Pt); A. H. (Zerewitinoff), 0.90, 1.01.

Phenylacetylene.—This acetylene was prepared by the dehydrobromination of styrene dibromide (m. p. 74–75°) with sodamide in liquid ammonia.[24] A product was obtained which had a b. p. of 139.5–140.5° and an $n^{25}D$ 1.5459.

1-[Cyclohexan-1′-ol-yl]-3-methyl-3-hydroxy-4-chlorobutyne-1.—Using the usual Grignard technique, 372 g. of 1-ethynylcyclohexanol-1 was converted to the corresponding magnesio salt acetylene Grignard by allowing it to react in 3 l. of anhydrous ether with ethylmagnesium bromide prepared from 146 g. of magnesium and 719 g. of ethyl bromide. The acetylene Grignard was then allowed to react with 277.5 g. of freshly distilled chloroacetone. The mixture was then hydrolyzed with an ice–ammonium chloride solution and the product obtained fractionated under a reduced pressure; b. p., 155–157° (4–5 mm.) or 115–116° (10^{-3} mm.); yield 400 g. (62%). When this was allowed to stand at 0° overnight, it solidified and was recrystallized from petroleum ether into colorless prisms; m. p., 58–60°.

Anal. Calcd. for $C_{11}H_{17}O_2Cl$: C, 60.95; H, 7.90; Cl, 16.32; unsaturation, 2.0 ⌐¬; A. H., 2.0. Found: C, 59.90, 60.13; H, 7.76, 7.38; Cl, 16.99, 17.16; unsaturation, 3.55 (Pt), 3.5 (Pd) ⌐¬; A. H. (Zerewitinoff), 1.88, 2.03.

1-[2′,6′,6′-Trimethylcyclohexan-1′-ol-yl]-3-methyl-4-chloro-1-but-1-yn-ol-3.—A Grignard was prepared from 30 g. of magnesium and 138 g. of ethyl bromide in 1500 cc. of anhydrous ether. To this was added in the course of two hours 100 g. of 2,6,6-trimethyl-1-ethynylcyclohexanol-1. After the Grignard of the acetylene carbinol was formed, 55.7 g. of chloroacetone was added slowly at 0° then the mixture stirred overnight at room temperature. The mixture was then hydrolyzed with an ice–ammonium chloride solution and the product obtained fractionated; b. p. 65–67° (10^{-4} mm.). The highly viscous distillate (69 g.) was allowed to stand at 0° for three weeks whereby it solidified. This was recrystallized from petroleum ether into colorless needles; m. p., 41–42°.

Anal. Calcd. for $C_{14}H_{23}O_2Cl$: Cl, 13.72; unsaturation, 2.0 ⌐¬; A. H., 2.0. Found: Cl, 14.04, 14.13; unsaturation, 3.47 (Pt), 2.1 (Pd) ⌐¬; A. H. (Zerewitinoff), 2.24.

1-[Cyclohexen-1′-yl]-3-methyl-4-chloro-1-but-1-yn-ol-3.—Ethylmagnesium bromide (0.5 mol) was made in 500 cc. of anhydrous ether and cooled in nitrogen with an ice–salt mixture. To this was added dropwise with stirring in the course of two hours 60 g. of 1-ethynylcyclohexene-1 (A. H., 0.9) in 200 cc. of ether. The mixture was stirred in nitrogen at room temperature for twenty-four hours, then cooled with an ice–salt mixture and to it added 47.2 g. of chloroacetone in 200 cc. of ether. The solution was stirred at room temperature for six hours then hydrolyzed with 200 cc. of cold saturated ammonium chloride solution. A product was obtained which when fractionated yielded 40 g. (40% yield) of a light orange colored liquid; b. p. 110–116° (4 mm.) or 60–63° (10^{-3} mm.); $n^{25}D$ 1.5259; d^{25}_4 1.1090; MR_D (calcd.), 54.72; MR_D (obsd.), 54.96.

Anal. Calcd. for $C_{11}H_{15}OCl$: C, 66.4; H, 7.56; Cl, 17.9; unsaturation, 3.0 ⌐¬; A. H., 1.0. Found: C, 66.15; H, 7.61; Cl, 18.2; unsaturation, 3.3 (Pt) ⌐¬; A. H. (Zerewitinoff), 1.0.

1-[2′-Methylcyclohexen-1′-yl]-3-methyl-4-chloro-1-but-1-yn-ol-3.—Using a similar technique as in the previous case, a chlorohydrin was obtained in 54% yield from 2-methyl-1-ethynylcyclohexene-1 and chloroacetone. The product obtained had a b. p. of 115–130° (4 mm.) and gave good analytical results; $n^{25}D$ 1.5360; d^{25}_4 1.111; MR_D (calcd.), 59.34; MR_D (obsd.), 59.63. It also had an absorption band in the ultraviolet at 2270 Å., log $\epsilon_{mol.}$ 4.072.

Anal. Calcd. for $C_{12}H_{17}OCl$: C, 67.75; H, 8.06; Cl, 16.77; unsaturation, 3.0 ⌐¬; A. H., 1.0. Found: C, 67.98; H, 8.04; Cl, 16.81; unsaturation, 3.3 (Pt) ⌐¬; A. H. (Zerewitinoff), 1.0.

3-Methyl-1-phenyl-4-chloro-1-but-1-yn-ol-3.—In a similar manner a chlorohydrin was obtained in a yield of 52.5% from phenylacetylene and chloroacetone. This chlorohydrin was found to boil at 94–96° (1 mm.); $n^{25}D$ 1.5624.

Anal. Calcd. for $C_{11}H_{11}OCl$: C, 67.86; H, 5.70; Cl, 18.22. Found: C, 66.91; H, 5.92; Cl, 19.86.

The purification of this chlorohydrin was found to be more difficult than that of the others in view of the presence of small quantities of diphenyldiacetylene which was isolated and identified.[25]

1-[Cyclohexan-1′-ol-yl-]-3-methyl-3-epoxybutyne-1.—A solution of 181 g. of 1-[cyclohexan-1′-ol-yl]-3-methyl-4-chloro-1-but-1-yn-ol-3 in 500 cc. of dry ether was added dropwise in the course of two hours to a well-stirred suspension in nitrogen of 100 g. of freshly powdered potassium hydroxide in 750 cc. of ether. The mixture turned brick-red. Stirring was continued for two hours longer than the mixture treated with 500 cc. of cold water. A product

(24) Nieuwland, Vaughn and Vogt, THIS JOURNAL, **56**, 2121 (1934).

(25) Black, Ph.D. Thesis, M. I. T., July, 1947.

was isolated from the ethereal layer which was fractionated and the fraction (120 g.) boiling at 90–94° (10^{-3} mm.) collected. When allowed to stand at 0° overnight, this product solidified and was recrystallized from petroleum ether; m. p. 47–48°.

Anal. Calcd. for $C_{11}H_{16}O_2$: C, 73.33; H, 8.89; unsaturation, 2.0 ⌐¬; A. H., 1.0. Found: C, 73.03, 73.07; H, 8.89, 8.67; unsaturation, 4.4 (Pt), 3.9 (Pd) ⌐¬; A. H. (Zerewitinoff), 0.93.

This epoxide gave a positive test with the fuchsin aldehyde reagent and formed a 2,4-dinitrophenylhydrazone in dilute hydrochloric acid solution; m. p., 160–164°. It exhibited no band in the ultraviolet; only end absorption.

1-[2',6',6'-Trimethylcyclohexan-1'-ol-yl]-3-methyl-3-epoxybutyne-1.—This epoxide was made from the corresponding chlorohydrin by the usual dehydrochlorina ion technique using powdered potassium hydroxide. A product was obtained which was fractionated under a high vacuum; b. p. 55–58° (10^{-4} mm.). This product was induced to crystallize, then was recrystallized from petroleum ether; m. p., 81–82°.

Anal. Calcd. for $C_{14}H_{22}O_2$: C, 75.63; H, 9.97; unsaturation, 2.0 ⌐¬; A. H., 1.0. Found: C, 75.36, 75.62; H, 10.14, 10.17; unsaturation, 3.3 (Pt), 2.4 (Pd) ⌐¬; A. H. (Zerewitinoff), 1.04.

Although this epoxide gave a negative fuchsin–aldehyde test, it formed a 2,4-dinitrophenyldhydrazone with Lund's reagent; m. p., 185–187°. This phenylhydrazone had an ultraviolet absorption spectrum (alcohol) with a well-defined maximum at 400 mμ, log $\epsilon_{mol.}$ 4.70. This epoxide also showed an end absorption.

1-[Cyclohexen-1'-yl]-3-methyl-3-epoxybutyne-1.—Employing the usual technique this epoxide was prepared by the dehydrochlorination of the corresponding chlorohydrin with powdered potassium hydroxide or sodamide. Purification of this epoxide was rendered more difficult by its instability toward air oxidation, and frequently several fractionations were essential before a pure product was obtained. Physical constants and other analytical data had to be obtained immediately upon final fractionation. A yield of 33.5% of the pure epoxide was obtained; b. p. 64–64.5° (1 mm.); $n^{25}D$ 1.5145; d^{25}_4 0.9960; MR_D (calcd.), 47.77; MR_D (obsd.), 49.01. It showed a maximum in the ultraviolet at 232 mμ, log $\epsilon_{mol.}$ 4.32.

Anal. Calcd. for $C_{11}H_{14}O$: C, 81.44; H, 8.70; unsaturation, 3.0 ⌐¬. Found: C, 80.81; H, 8.63; unsaturation, 3.3 (Pt) ⌐¬.

This epoxide gave a positive test (slow) with the fuchsin–aldehyde reagent and formed an orange 2,4-dinitrophenylhydrazone with Lund's reagent (hot); m. p., 157–158° (cor.).

Anal. Calcd. for $C_{17}H_{18}O_4N_4$: C, 59.61; H, 5.30; N, 16.37. Found: C, 59.49; H, 5.99; N, 16.28.

Its absorption spectrum (alcohol) showed two well-defined maxima at 369 mμ (log $\epsilon_{mol.}$ 4.53) and 258 mμ (log $\epsilon_{mol.}$ 4.44), respectively.

1-[2'-Methylcyclohexen-1'-yl]-3-methyl-3-epoxybutyne-1.—Similarly this epoxide was prepared in 31% yield by the technique given above, and was found to have similar properties as the previous epoxide; b. p., 64–66° (1 mm.); $n^{25}D$ 1.5058; d^{25}_4 0.9942; MR_D (calcd.), 52.39; MR_D (obsd.), 52.70. It also showed a maximum in the ultraviolet at 232 mμ, log $\epsilon_{mol.}$ 4.19.

Anal. Calcd. for $C_{12}H_{16}O$: C, 81.76; H, 9.15; unsaturation, 3.0 ⌐¬. Found: C, 81.33; H, 9.24; unsaturation, 3.2 (Pt) ⌐¬.

This epoxide gave a positive test (slow) with the fuchsin–aldehyde reagent and formed an orange 2,4-dinitrophenylhydrazone; m. p., 158–159° (cor.).

Anal. Calcd. for $C_{19}H_{20}O_4N_4$: C, 60.66; H, 6.65. Found: C, 60.52; H, 6.34.

The absorption spectrum (alcohol) of this phenylhydrazone showed also two well-defined maxima at 377 mμ (log $\epsilon_{mol.}$ 4.35) and 260 mμ (log $\epsilon_{mol.}$ 4.38), respectively.

3-Methyl-1-phenyl-3-epoxybutyne-1.—This epoxide was also prepared by the usual technique in 43.5% yield (using powdered potassium hydroxide) or 40% yield (using sodamide). It boiled at 65–67° (1 mm.); $n^{25}D$ 1.5570; d^{25}_4 0.9968; MR_D (calcd.), 46.84; MR_D (obsd.), 51.02. It also showed a maximum in the ultraviolet at 243 mμ, log $\epsilon_{mol.}$ 4.29.

Anal. Calcd. for $C_{11}H_{10}O$: C, 83.50; H, 6.37; unsaturation, 5.0 ⌐¬. Found: C, 82.84; H, 6.42; unsaturation, 5.2 (Pt) ⌐¬.

A reddish-orange 2,4-dinitrophenylhydrazone was also prepared, m. p., 96–97° (cor.).

Anal. Calcd. for $C_{17}H_{15}O_4N_4$: C, 60.17; H, 4.46; N, 16.52. Found: C, 60.10; H, 4.34; N, 15.65.

1-[Cyclohexen-1'-yl-]-3-methyl-1,5-hexadiyn-3-ol (VIII).—Using lithium acetylide (from 0.8 g. lithium) in liquid ammonia (1.5 liters), 16.4 g. of 1-[cyclohexen-1'-yl]-3-methyl-3-epoxybutyne-1 was converted into the crude carbinol (VIII). The product was fractionated from a pot molecular still and the fraction (7 g.) boiling at bath temperature 100° (10^{-4} mm.) collected and crystallized from petroleum ether; m. p. 63–67°. This product is rather unstable and after a few days it turns dark yellow. With alcoholic ammoniacal silver nitrate it gives a yellowish-white precipitate showing the presence of an acetylene group.

Anal. Calcd. for $C_{13}H_{16}O$: unsaturation, 5 ⌐¬; A. H., 2.0. Found: unsaturation, 4.76 ⌐¬; A. H. (Zerewitinoff), 1.93.

3-Methyl-1-phenyl-1-hexyn-4-ol (IX).—A Grignard reagent was prepared from 3.2 g. of magnesium and 14.6 g. of ethyl bromide in 100 cc. of anhydrous ether. The solution was cooled to 0° and to it was added dropwise 17.5 g. of 3-methyl-1-phenyl-3-epoxybutyne-1 in 40 cc. of ether. The mixture was then stirred in nitrogen at room temperature for three hours then hydrolyzed at 0° with 8 g. of ammonium chloride in 50 cc. of water. A product was obtained which was fractionated and the fraction (12 g., 57.7% yield) boiling at 90–94° (1 mm.) collected and analyzed; $n^{25}D$ 1.5458; d^{25}_4 0.9865; MR_D (calcd.), 58.16; MR_D (obsd.), 60.34.

Anal. Calcd. for $C_{13}H_{16}O$: C, 82.93; H, 8.57; unsaturation, 5.0 ⌐¬. Found: C, 82.95; H, 8.55; unsaturation 5.0 (Pt) ⌐¬; A. H. (Zerewitinoff), 1.0.

3-Methyl-1-phenylhexanol-4.—Seven and a half grams of the foregoing unsaturated carbinol was partially hydrogenated in a mixture of 100 cc. of absolute ethanol and 2 cc. of glacial acetic acid using platinum oxide as catalyst. A product was obtained which was fractionated under a reduced pressure and the fraction (4.3 g., 54.7% yield) boiling at 90–92° (1 mm.) collected and analyzed; $n^{25}D$ 1.5020; d^{25}_4 0.9522; MR_D (calcd.), 60.16; MR_D (obsd.), 61.66.

Anal. Calcd. for $C_{13}H_{20}O$: C, 81.24; H, 10.49; unsaturation, 3.0 ⌐¬; A. H., 1.0. Found: C, 81.20; H, 10.82; unsaturation, 3.0 (Pt) ⌐¬; A. H. (Zerewitinoff), 1.0.

Acknowledgment.—The authors are indebted to Mrs. Silvia P. Solar and Mr. S. M. Nagy for the analyses given in this paper, to Miss Therese M. Harrington for the spectroscopic determinations, to Drs. Emile Sakal and John T. Plati and to Mr. Frank X. Grossi for some of the early experiments in this field. This article is a part of a research program on the synthesis of vitamins A and D, support of which was derived in part through contributions from Abbott Laboratories, Eli Lilly and Company, Merck and Company, Inc., Parke, Davis and Company, The Upjohn Company, and the United Drug Company, such contributions being made through the Research Corporation of New York.

Summary

1. Several intermediates for the synthesis of vitamin A and vitamin A analogs have been synthesized and characterized.

2. 1-[Cyclohexen-1'-yl]-3-methyl-3-epoxybutyne-1 and related epoxides have been synthesized and their physical and chemical properties studied.

Sterols. V. The *i*-Cholesterylamines

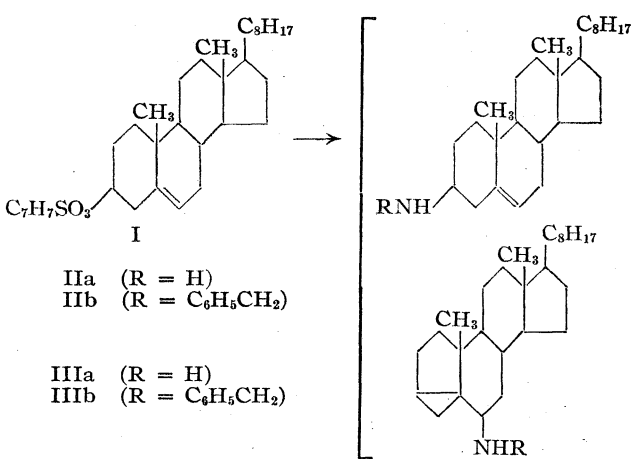
BY PERCY L. JULIAN, ARTHUR MAGNANI, EDWIN W. MEYER AND WAYNE COLE

In connection with transformations involving replacement reactions at the C_3 position of $\Delta^{5,6}$ unsaturated steroids, it was decided to explore carefully the possible role of *i*-steroids as intermediates in such conversions. The formation of an *i*-steroid has been shown to take place readily when the 3-*p*-toluenesulfonate of a $\Delta^{5,6}$-steroid is treated with an appropriate reagent in the presence of a proton acceptor[1]; however, in the absence of the latter a simple replacement seems to occur.

Our attempts to replace the 3-*p*-toluenesulfonate group by amino groups resulted in varying yields of 3-amino steroids, the relative basicity of the reagent employed strongly influencing the course of the reaction. It seemed logical to assume that we might be encountering the hitherto unknown *i*-steroid amines.

The unexpected ether solubility of the hydrochlorides of the *i*-steroid amines obscured at first their presence among the reaction products. Advantage was taken, however, of this property for their separation and characterization. This communication reports a study of certain *i*-cholesterylamines.

When cholesteryl *p*-toluenesulfonate (I) was



IIa (R = H)
IIb (R = $C_6H_5CH_2$)

IIIa (R = H)
IIIb (R = $C_6H_5CH_2$)

heated with ammonia at about 98°, there was obtained not only cholesterylamine (IIa)[2] but an isomeric amine, *i*-cholesterylamine (IIIa), which was the predominant product. The separation of the isomeric cholesterylamines was greatly facilitated by the ether solubility of *i*-cholesterylamine hydrochloride. This hydrochloride, which melted at 212–214°, gave the crystalline *i*-cholesterylamine (IIIa), m. p. 77–79°. Both the *i*-amine and its hydrochloride were dextrorotatory, possessing specific rotations of +34° and +20°, respectively, in contrast to the negative rotation of cholesterylamine and its hydrochloride.

The reaction of cholesteryl *p*-toluenesulfonate (I) and benzylamine was found to proceed in an analogous fashion. Here again two isomeric amines were formed. The reaction mixture was separated into two fractions on the basis of the ether solubilities of the amine hydrochlorides. From the ether-insoluble hydrochloride, there was isolated benzylcholesterylamine (IIb), a levorotatory crystalline solid which melted at 115–117°. The purified ether-soluble hydrochloride which melted at 217–218° and possessed a specific rotation of −27° gave benzyl-*i*-cholesterylamine (IIIb), a viscous liquid which could not be crystallized. Unlike the hydrochloride, the free base was dextrorotatory, $[\alpha]D$ + 12°.

In order to prove the constitution of benzylcholesterylamine, benzyl-*i*-cholesterylamine and *i*-cholesterylamine, these amines were degraded by alkaline decomposition of the respective chloroamines followed by acid hydrolysis.[3] Upon treatment with an ethereal solution of hypochlorous acid, benzylcholesterylamine formed an N-chloro derivative which when decomposed with sodium ethoxide followed by acid hydrolysis gave cholesterylamine, identified as the acetyl derivative.[2] In a similar fashion benzyl-*i*-cholesterylamine was degraded. The product of this degradation, *i*-cholesterylamine, was identified as the crystalline hydrochloride. Further degradation of this hydrochloride via the N-chloro derivative gave a neutral product which, in spite of the inability to crystallize it, was *i*-cholestenone (IV), for upon treatment with hydrochloric acid in acetic acid in the known way,[4] it readily yielded 3(β)-chlorocholestane-6-one. Thus the position

V

of the substituent amino group is adequately demonstrated in each instance.

During the investigation of the formation of benzylcholesterylamine and benzyl-*i*-cholesterylamine it was noted that as the reaction time increased the yield of benzyl-*i*-cholesterylamine decreased while that of benzylcholesterylamine increased. This suggested that the *i*-steroid amine was either the precursor of the C_3 substituted amine or the source of a common intermediate. The validity of this hypothesis was proved by the conversion of benzyl-*i*-cholesterylamine into benzylcholesterylamine with benzylamine in the presence of benzylammonium *p*-toluenesulfonate. Furthermore, reaction of benzyl-*i*-cholesterylamine hydrochloride with aniline gave cholesterylaniline (VII). Both of these transformations failed to proceed in the absence of an ammonium salt. This type of acid catalysis is in harmony with the conditions necessary for the "rearrangement" of *i*-steroid ethers.[5] The analogy of the *i*-steroid amines to the *i*-steroid ethers is strengthened by the nature of the reaction of *i*-cholesteryl methyl ether (VI) with benzylamine or aniline. In the presence of an ammonium salt, these reagents gave benzylcholesterylamine (IIb) and cholesterylaniline (VII), respectively. The attempted conversions failed in the absence of the ammonium salt. It is important to note that benzyl-*i*-cholesterylamine and *i*-cholesteryl methyl ether, in the presence of the proton donor, react more sluggishly with benzylamine than with aniline, an amine with a smaller basic dissociation constant. This may be explained through consideration of the following equilibria

$$RNH_3^+ + i\text{-CholNHCH}_2C_6H_5 \rightleftharpoons RNH_2 + i\text{-Chol}\overset{\cdot\cdot}{\underset{\cdot\cdot}{N}}\overset{H^+}{H}\text{CH}_2C_6H_5$$

$$RNH_3^+ + i\text{-CholOCH}_3 \rightleftharpoons RNH_2 + i\text{-Chol}\overset{\cdot\cdot}{\underset{\cdot\cdot}{O}}\overset{H^+}{H}\text{CH}_3$$

As the basic strength of RNH_2 decreases, the concentration of the steroid ammonium and steroid oxonium ions should increase. Thus if these ions underwent conversion to the C_3 substituted amines, which appears plausible, the "rearrangement" should be more readily effected with amines of low basic strength. In any given instance, the equilibrium may be shifted to the right by an increase in concentration of RNH_3. This fact has been of value in effecting the reactions of benzyl-*i*-cholesterylamine and *i*-cholesteryl methyl ether with benzylamine.

Experimental[6]

Cholesterylamine (IIa) and *i*-Cholesterylamine (IIIa).—A mixture of 15.0 g. of cholesteryl *p*-toluenesulfonate and 18.0 g. of liquid ammonia was placed in a glass-lined steel bomb and heated with steam at about 98° for fifteen hours. After cooling the bomb to room temperature, the excess ammonia was allowed to evaporate and the residue was shaken with ether and 10% sodium hydroxide solution. Upon shaking the ethereal layer with excess 5% hydrochloric acid there separated a white, gelatinous hydrochloride which was centrifuged, washed with ether and dried. (The ether layer and washings which contained the *i*-amine hydrochloride was saved.) The crude, insoluble hydrochloride (4.0 g.) was shaken with 10% sodium hydroxide and ether. The water-washed ether layer gave, upon removal of solvent, 2.6 g. (23%) of white, waxy crystals of cholesterylamine which melted at 89–94°; $[\alpha]^{29}D$ −26° (115 mg. made up to 10 ml. with chloroform, α −0.30°, *l*, 1 dm.). For identification, a sample was converted to N-cholesterylacetamide,[3] m. p. 238–242°.

The ether solution which was separated from the insoluble cholesterylamine hydrochloride was washed with 5% hydrochloric acid and with water, and then concentrated to about 25 ml. After dilution with 50 ml. of acetone, the *i*-cholesterylamine hydrochloride slowly crystallized. The acetone-washed and dried hydrochloride weighed 7.6 g. (64%), m. p. 176–182°. Two crystallizations from ether–acetone raised the melting point to 212–214°; $[\alpha]^{29}D$ +20° (151.9 mg. made up to 5.1 ml. with chloroform, α +0.60°, *l*, 1 dm.).

Anal. Calcd. for $C_{27}H_{47}N\cdot HCl$: N, 3.32; Cl, 8.40. Found: N, 3.20; Cl, 8.13.

This hydrochloride was soluble in ether, benzene or methanol, but relatively insoluble in water or acetone.

The free amine was prepared from the salt by shaking a mixture of 1.0 g. of *i*-cholesterylamine hydrochloride, 100 ml. of ether and 10 ml. of 10% sodium carbonate solution. The clear ether layer was washed twice with sodium carbonate solution, four times with distilled water and then dried and concentrated to a white wax which could be crystallized directly from pentane or sublimed *in vacuo*. At about 1×10^{-2} mm., the amine vaporized

(6) Analyses by Mr. R. Schroeder of this Laboratory, Dr. T. S. Ma of the University of Chicago and Mr. C. W. Beazley of Micro-Tech Laboratories, Skokie, Illinois.

from a bath held at 115° and crystallized in the receiver as white rosettes, m. p. 77–79°. Recrystallization from pentane did not change the melting point; $[\alpha]^{30}D$ +34° (371 mg. made up to 3.64 ml. with chloroform, α +3.42°, l, 1 dm.).

Anal. Calcd. for $C_{27}H_{47}N$: C, 84.08; H, 12.28; N, 3.63. Found: C, 84.10; H, 12.00; N, 3.44.

A sample of the *i*-cholesterylamine was reconverted to the hydrochloride, m. p. 212–214°. The amine failed to give a crystalline derivative with benzaldehyde, but with acetic anhydride in pyridine it gave N-*i*-cholesterylacetamide which crystallized from ether as white prisms, m. p. 142–143°.

Anal. Calcd. for $C_{29}H_{49}ON$: C, 81.43; H, 11.55; N, 3.27. Found: C, 81.35; H, 10.87; N, 3.16.

Benzycholesterylamine (IIb) and Benzyl-*i*-cholesterylamine (IIIb).—A solution of 100 g. of cholesteryl-*p*-toluenesulfonate in 200 ml. of benzylamine was refluxed for two hours, chilled and poured into ether. The benzylammonium *p*-toluenesulfonate (48.7 g.) was filtered and washed with ether. The combined ethereal filtrate was concentrated, steam distilled and the residue was dissolved in ether. The white, gelatinous precipitate which formed upon shaking the water-washed ether solution with 10% hydrochloric acid was separated by centrifugation. The hydrochloride, after dissolving in a small volume of ethanol, was decomposed with 10% sodium hydroxide solution. The free base was then extracted with ether, washed free of alkali and dried. The solid remaining after removal of ether crystallized from acetone yielding 19.6 g. of crude benzylcholesterylamine melting at 110–115°. Several recrystallizations from acetone gave colorless prisms melting at 115.5–117°; $[\alpha]^{33}D$ −25° (164.2 mg. made up to 5 ml. with chloroform, α −0.83°, l, 1 dm.).

Anal. Calcd. for $C_{34}H_{53}N$: C, 85.83; H, 11.22. Found: C, 86.02; H, 10.88.

The amine formed an acetyl derivative melting at 153–154°, a picrate melting at 195–198° (dec.) and a benzenesulfonamide melting at 151–153°.

The ether solution and washings separated from the gelatinous hydrochloride were washed with water, dried and concentrated to a solid residue (40.9 g.). The residue when crystallized from chloroform–acetone gave 34.5 g. (40%) of benzyl-*i*-cholesterylamine hydrochloride melting at 217–218° (dec.), $[\alpha]D$ −27° (126 mg. made up to 5 ml. with chloroform, αD −0.68°, l, 1 dm.).

Anal. Calcd. for $C_{34}H_{53}N$: C, 85.83; H, 11.23. Found: C, 85.42, 85.51; H, 11.34, 10.98.

Upon refluxing the solution of cholesteryl *p*-toluenesulfonate in benzylamine for twenty-two hours, the yield of benzylcholesterylamine was increased to 52%; however, the yield of benzyl-*i*-cholesterylamine was decreased to 10%. A further increase in reflux time (forty-six hours) complicated matters with the formation of considerable tribenzylamine,[7] an amine which also forms an ether and water insoluble hydrochloride.

Degradation of Benzylcholesterylamine.—A 4.75-g. sample of benzylcholesterylamine was dissolved in 100 ml. of dry ether, cooled to −5° and treated with 50 ml. of an ethereal solution of hypochlorous acid[8] (0.0152 g./ml.). The amine which had separated from solution on chilling, dissolved and soon a solid separated. After five minutes at room temperature (solid dissolved on warming) the ether solution was washed with 20 ml. of cold 8% aqueous sulfuric acid, 20 ml. of cold 5% sodium hydroxide solution and finally water until free of alkali. (A small quantity of the N-chloramine was separated as a white solid, m. p. 119–124°.) The dried ether solution was treated with a solution of 1.0 g. of sodium in 100 ml. of ethanol. Sodium chloride separated. The ether was removed by distillation and the remaining solution was refluxed for thirty minutes. The mixture was then steam distilled after the addition of 60 ml. of 1:5 hydrochloric acid. Benzaldehyde was evident in the distillate (gave 1.62 g. of the 2,4-dinitrophenylhydrazone, m. p. 237–238°). The residue was made basic with 50 ml. of 10% sodium hydroxide and extracted with ether. The water-washed ether layer was shaken with an aqueous solution of *p*-toluenesulfonic acid and the resulting precipitate was filtered, washed with ether and dried. The dry cholesterylammonium *p*-toluenesulfonate weighed 4.4 g. and melted at 276–278°.

One gram of this salt was decomposed in ethanol with dilute sodium hydroxide. The amine was taken up in ether, washed with water, dried and concentrated. It was then treated with 1 ml. of acetic anhydride in 20 ml. of ether to yield 0.7 g. of once-recrystallized (ethanol) N-cholesterylacetamide, m. p. 238–240° which gave no depression with that previously described.

Degradation of Benzyl-*i*-cholesterylamine.—A solution of 5.12 g. of benzyl-*i*-cholesterylamine hydrochloride in 100 ml. of ether was shaken with 10% sodium hydroxide, washed with water and dried. This solution was then treated with 50 ml. of hypochlorous acid solution as described above. After treatment with sodium ethoxide, the ethanol solution was refluxed for seventy-five minutes (it no longer liberated iodine from an acidified potassium iodide solution). After the addition of 60 ml. of 1:5 hydrochloric acid, the mixture was refluxed for forty-five minutes and steam distilled (benzaldehyde). The residue, a brown gum, was taken up in ether and washed with 10% sodium hydroxide solution, 10% hydrochloric acid and water. The gum remaining after removal of solvent from the dried ether solution was crystallized from acetone; 2.7 g. of white solid. A 2.2-g. sample recrystallized from chloroform–acetone gave 2.0 g. of material melting at 201–205°. Several recrystallizations from the same solvent mixture and one from ether–acetone raised the melting point to 212–215°. This substance gave no depression in melting point when mixed with a sample of *i*-cholesterylamine hydrochloride.

Degradation of *i*-Cholesterylamine.—A solution of 1.05 g. of *i*-cholesterylamine hydrochloride (material prepared from the *i*-benzyl compound as described above) in ether was shaken with 10% sodium hydroxide solution, washed with water and dried. It was then treated at −10° with 6.2 ml. of an ether solution of hypochlorous acid (0.021 g./ml.). After five minutes, the solution was washed with 5% sodium hydroxide solution, water and dried. Titration of the iodine liberated by 1.0 ml. of the ether solution from acidified potassium iodide indicated that the conversion to the N-chloramine had taken place in 84% yield. The ether solution was then poured into a solution of 0.5 g. of sodium in 25 ml. of ethanol, the ether removed by distillation, and the remainder refluxed for thirty minutes. The mixture was then diluted with 100 ml. of cold water and acidified with dilute hydrochloric acid. After standing overnight, the mixture was extracted with ether. The residue remaining after removal of ether from the washed and dried solution could not be crystallized from methanol or acetone even after seeding with *i*-cholestenone. Thus it was taken up in 10 ml. of warm glacial acetic acid, chilled and treated with 2 ml. of concentrated hydrochloric acid. The solid which crystallized upon scratching was filtered, washed with methanol and dried; 0.5 g., m. p. 126–131°. Recrystallization from methanol raised the melting point to 130–133°. A mixture of this material with an authentic specimen of 3(β)-chlorocholestane-6-one[9] showed no depression in melting point.

Rearrangement of Benzyl-*i*-cholesterylamine to Benzylcholesterylamine.—A solution of 7.5 g. of benzyl-*i*-cholesterylamine and 5.0 g. of benzylammonium *p*-toluenesulfonate in 20 ml. of benzylamine was refluxed for twenty-three hours. The golden-yellow solution was poured into ether and the benzylammonium *p*-toluenesulfonate (5.0 g.) was separated and washed with ether. The ether filtrate was concentrated and steam distilled.

(7) *Cf.* Nozaki, THIS JOURNAL, **64**, 2920 (1942).

(8) Goldschmidt, *Ber.*, **46**, 2728 (1913).

(9) Windaus and Dalmer, *ibid.*, **52**, 162 (1919).

Upon shaking an ethereal solution of the residue with 10% hydrochloric acid, a gelatinous precipitate formed. The hydrochloride was separated by centrifugation, washed three times with ether and decomposed in ethanol solution with 10% sodium hydroxide solution. The amine was extracted with ether and washed with water. The residue remaining after removal of solvent from the dried solution was crystallized from acetone yielding 3.4 g. (56.5%) of fine, white crystals melting at 115–117°. These gave no depression in melting point when mixed with a sample of benzylcholesterylamine.

The ether washings of the gelatinous hydrochloride gave 1.5 g. of unchanged benzyl-*i*-cholesterylamine hydrochloride melting at 216–218° (dec.).

Reaction of Benzyl-*i*-cholesterylamine Hydrochloride with Aniline.—A solution of 3.0 g. of benzyl-*i*-cholesterylamine hydrochloride in 15 ml. of aniline was refluxed for four hours. Upon cooling, the mixture set to a semi-solid mass. It was then digested with ethanol and chilled. The solid was separated, washed with ethanol and dried. The dry material, 2.3 g. (85%) of white plates, melted at 189–191°. A sample of the compound gave no depression in melting point when mixed with cholesterylaniline.[10]

In a similar experiment in which the free amine, benzyl-*i*-cholesterylamine, was employed, the amine was recovered unchanged.

Reaction of *i*-Cholesteryl Methyl Ether with Benzylamine.—A solution of 3.0 g. of *i*-cholesteryl methyl ether[1a] and 3.0 g. of benzylammonium *p*-toluenesulfonate in 20 ml. of benzylamine was refluxed for twenty-two hours. The solution was poured into water and extracted with ether. Upon shaking the ethereal layer with dilute hydrochloric acid an insoluble hydrochloride separated. The hydrochloride was centrifuged, washed three times with ether and then decomposed in ethanol with 10% sodium hydroxide. An ether extract of the free amine was washed with water, dried and concentrated. Upon crystallization from acetone, the yellow residue yielded 1.5 g. of white prisms melting at 115–118°. This material showed no depression in melting point when mixed with a sample of benzylcholesterylamine.

Upon heating a 1.0-g. sample of the *i*-ether with 5 ml. of benzylamine in a closed tube at 240° for eighteen hours, the *i*-ether was recovered unchanged.

Reaction of *i*-Cholesteryl Methyl Ether with Aniline.—A mixture of 0.6 g. of carefully purified *i*-cholesteryl methyl ether and 5 ml. of freshly distilled aniline containing a few mg. of *p*-toluenesulfonic acid was refluxed from an oil-bath at 190° for two hours and then allowed to cool. The semi-solid mass was slurried with 10 ml. of methanol, filtered, washed with methanol and dried. The resulting cholesterylaniline, 0.65 g. of white flakes, melted at 190°. This gave no depression in melting point when mixed with a sample of cholesterylaniline prepared in the known manner.[10]

In a similar experiment, in which the *p*-toluenesulfonic acid was omitted, the *i*-ether was recovered unchanged.

(10) Lieb, Winkelmann and Koeppl, *Ann.*, **509**, 214 (1934).

Summary

1. Cholesteryl *p*-toluenesulfonate reacts with ammonia and with primary aliphatic amines to give 6-amino-*i*-cholestenes accompanied by some 3-amino-5-cholestenes.

2. *i*-Cholesterylamine and benzyl-*i*-cholesterylamine are described and their structures proved by stepwise degradation to the known 3(β)-chlorocholestan-6-one.

3. Benzyl-*i*-cholesterylamine can be transformed into benzylcholesterylamine by treatment with benzylamine and benzylammonium toluenesulfonate. The necessity of the presence of the salt in this reaction points to an ionic mechanism for the conversion of the *i*-steroid into the normal steroid and further corroborates the known acid-catalyzed reactivity of the *i*-steroids.

Preparation of 17-Ketosteroids from Enol Acetates of 20-Ketosteroids[1a]

BY CHARLES W. MARSHALL, THEODORE H. KRITCHEVSKY, SEYMOUR LIEBERMAN[1b] AND T. F. GALLAGHER[1b]

The 20-ketosteroids are obtainable in good yield from accessible natural products. It appeared to us that oxidation of the enol acetates might offer a promising procedure for the preparation of 17-ketosteroids from these substances and we have accordingly investigated this problem using four different 20-ketosteroids. The general reactions are summarized in the partial formulations of Fig. 1. The enol acetates were prepared by the method of Bedoukian[2] and from the three pregnane derivatives studied, only one enol acetate was obtained. The structure of the product was proved by ozonolysis to the corresponding 17-ketosteroid. From 3(β)-hydroxy-20-ketoallopregnane, two stereoisomeric enol acetates were obtained which must be regarded as *cis* and *trans* isomers about the double bond from C-17 to C-20, since both compounds upon ozonolysis followed by saponification yielded isoandrosterone. The compound with higher melting point has been arbitrarily designated as the *trans*-form. For preparative purposes, isolation of the enol acetate is

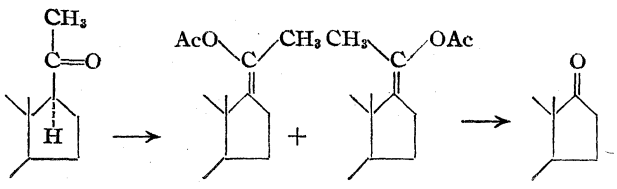

Fig. 1.

unnecessary and the sirupy enol acetate can be directly ozonized without further purification.

Ozonolysis of the enol acetate proceeded smoothly and in satisfactory yield except with 3(α),12(α)-20-triacetoxy-Δ^{17}-pregnene. When this compound was ozonized in the same manner used for the other four substances, two products were obtained in approximately equal amounts. One was the anticipated 17-keto derivative and the other was a crystalline substance of melting point 217–218.5° and $[\alpha]^{25}D$ +40° ($CHCl_3$) which will be reported in detail at a later time. None of the other compounds investigated yielded a comparable by-product.

The enol acetate of 3(α),12(α)-dihydroxy-20-keto-21-benzalpregnane was prepared and the ultraviolet absorption spectrum of this compound is shown in Fig. 2. When this enol acetate was oxidized with O_3 or with CrO_3, no recognizable product was obtained. This experience is similar to that of Koechlin and Reichstein,[3] who oxidized the enol chloride of 3(α),12(α)-diacetoxy-20-keto-21-benzalpregnane without obtaining any detectable amount of the 17-keto derivative, although 3(β)-acetoxy-20-keto-21-benzalallopregnane was converted to isoandrosterone in 45% yield by the same reactions. Since the preparation of 17-ketosteroids over the benzal derivatives appeared to be less advantageous than the method already described, further work on these compounds was abandoned.

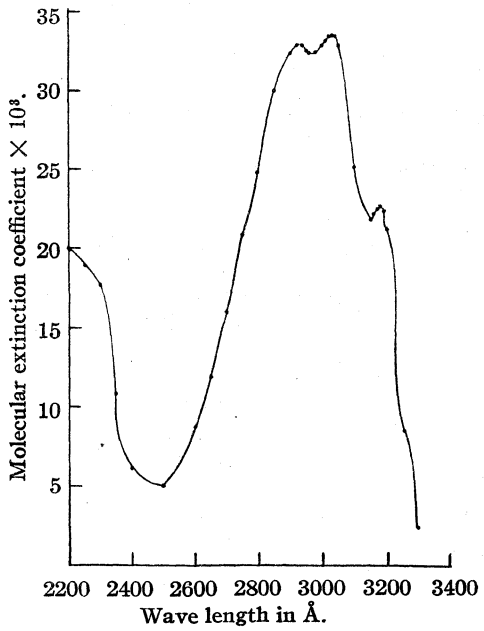

Fig. 2.—Absorption spectrum of the enol acetate of 3(α),12(α)-diacetoxy-20-keto-21-benzalpregnane in 95% ethanol.

(3) Koechlin and Reichstein, *Helv. Chim. Acta*, **27**, 549 (1944).

Experimental

Preparation of Enol Acetates of 20-Ketopregnane Derivatives.—A solution of 2 millimoles of the ketone and 2 millimoles of *p*-toluenesulfonic acid in 75 cc. of acetic anhydride was distilled slowly through a short unpacked column until most of the acetic anhydride had been removed (four to five hours). The residual solution was chilled, water was added, and after a short interval the product was extracted with ether, which was in turn washed with sodium hydroxide solution and with water, dried over sodium sulfate and the ether removed. The dark residue was dissolved in petroleum ether and purified by passage through a column of aluminum oxide. The colorless enol acetates were recovered in the petroluem ether eluates and were recrystallized from this solvent. The characteristics of the products are recorded in Table I. The yield of crystalline enol acetate was between 60 and 70%. The isomers 5 and 6 required extensive chromatography to effect separation, and for this reason the yield was much lower.

Ozonolysis of the Enol Acetates.—The preparation of 3(α),11(α)-diacetoxy-17-ketoetiocholane is typical. A solution of 490 mg. of the enol acetate in 400 cc. of a 1:1 mixture of anhydrous methanol and ethyl acetate was chilled to −40° and five mole equivalents of ozone in a 6% stream were passed through the solution. A 5% palladium–calcium carbonate catalyst (2.5 g.) was added and the mixture was shaken in an atmosphere of hydrogen until there was no further uptake (less than fifteen minutes). After removal of the catalyst and solvent, the product was purified by chromatographic fractionation on aluminum oxide. The yield of analytically pure material based on the enol acetate was 51%. The characteristics of the products are recorded in Table II.

Hydrolysis of Acetylated 17-Ketosteroids.—Partial hydrolysis of compounds number 8 and 11 was accomplished at room temperature with 0.15 *N* sodium hydroxide in 85% ethanol. The monoacetate from 11 was amorphous.[4] The monoacetates obtained from the ozonolysis of compounds number 1, 5 and 6 were also hydrolyzed in this manner. Complete hydrolysis of the diacetate no. 8 was accomplished by heating under a reflux in an atmosphere of nitrogen with 0.5 *N* sodium hydroxide in 75% ethanol for one-half hour; the diacetate no. 11 required heating with 1.0 *N* sodium hydroxide in 75% ethanol for one hour. The constants are recorded in Table II.

[f] Softens at 140°. [g] In $CHCl_3$. [h] +177° in acetone. [i] Identified by melting point of a mixture and comparison of the infrared spectrum with an authentic specimen. The infrared spectra were determined and compared by Dr. Konrad Dobriner, Sloan–Kettering Institute, New York 21, N. Y., to whom we extend our thanks.

Enol Acetate of 3(α),12(α)-Diacetoxy-20-keto-21-benzalpregnane.—This substance is obtained as one of the reaction products from the acetylation of the dihydroxy benzal derivative by heating twenty-four hours with acetic anhydride and pyridine. It is also obtained in small amounts from the acetylation catalyzed with perchloric acid according to the method of Whitman and Schwenk,[10] especially if the reaction mixture is permitted to stand at room temperature for forty-five minutes. It is most readily separated by chromatography upon aluminum oxide or by fractional crystallization of the acetylation product from acetone. It was recrystallized from glacial acetic acid, and its characteristics are recorded in Table I.

3(α)-Acetoxy-12(α)-hydroxy-20-keto-21-benzalpregnane.—When 3(α),12(α)-dihydroxy-20-keto-21-benzalpregnane is acetylated using milder conditions (pyridine–acetic anhydride at room temperature; acetic anhydride in the presence of low concentrations of perchloric acid at 5° for ten minutes), the 3-monoacetoxy derivative is obtained in good yield. The product was recrystallized from acetone as plates, m. p. 210–211°; $[\alpha]^{21}D$ +177° (ethanol).

Anal. Calcd. for $C_{30}H_{40}O_4$: C, 77.25; H, 8.69. Found: C, 77.57; H, 8.68.

Upon more vigorous acetylation with either pyridine and acetic anhydride or with acetic anhydride and sodium acetate, the monoacetate is converted to the known diacetate,[3] m. p. 123–126°.

Summary

1. The conversion of 20-ketosteroids to 17-ketosteroids was accomplished by preparation of the enol acetates followed by ozonolysis.

2. 3(α)-Hydroxy-17-ketoetiocholane, 3(β)-hydroxy-17-ketoetioallocholane, 3(α),12(α)-dihydroxy-17-ketoetiocholane, and 3(α),11(α)-dihydroxy-17-ketoetiocholane were prepared in this way.

3. The enol acetate of 3(β)-hydroxy-20-keto-allopregnane was obtained in two forms which were shown to be geometric isomers by ozonolysis to isoandrosterone.

4. The enol acetate of 3(α),12(α)-diacetoxy-20-keto-21-benzalpregnane was prepared and its ultraviolet absorption spectrum is described.

4,4′-Dichlorodibutyl Ether and its Derivatives from Tetrahydrofuran

BY KLIEM ALEXANDER AND L. E. SCHNIEPP

Cleavage of the tetrahydrofuran ring by acyl halides to give halogen-substituted butyl esters has been reported by Goldfarb and Smorgonskii,[2] Cloke and Pilgrim[3] and Manchen and Schmidt.[4] The reaction of tetrahydrofuran with acetyl chloride, catalyzed with a small amount of anhydrous zinc chloride, gives a good yield of δ-chlorobutyl acetate plus small amounts of compounds of the formulas: $CH_3COO(CH_2)_4O(CH_2)_4Cl$ and $CH_3COO(CH_2)_4O(CH_2)_4O(CH_2)_4Cl$.[3]

Because of the apparent ease with which acyl halides cleave the hydrogenated furan ring, an investigation was undertaken to determine whether or not inorganic acid chlorides react similarly. Preliminary experiments showed that phosphorus oxychloride, thionyl chloride and silicon tetrachloride, when catalyzed with zinc or zinc chloride, reacted vigorously with tetrahydrofuran. In no case was it found possible to isolate the phosphate, sulfite, or silicate esters; however, decomposition

(4) F. Manchen and W. Schmidt, U. S. Patent 2,314,454 (1943).

of the reaction mixtures with water, followed by vacuum distillation of the water-insoluble products, gave a fair yield of 4,4′-dichlorodibutyl ether, a high boiling liquid which has been previously prepared from 4-chlorobutanol by Trieschmann.[5]

During these investigations a number of reports on German technical developments became available through the Office of Technical Services. Several of these reports dealt directly with the reactions under investigation. Delfs[6] in his discussion of the polymerization of alkylene oxides shows that tetrahydrofuran is readily converted to polyalkylene ethers, with chlorine end-groups, by the action of thionyl chloride catalyzed with ferric chloride. Technical development of this reaction led to the production of synthetic lubricants.[7]

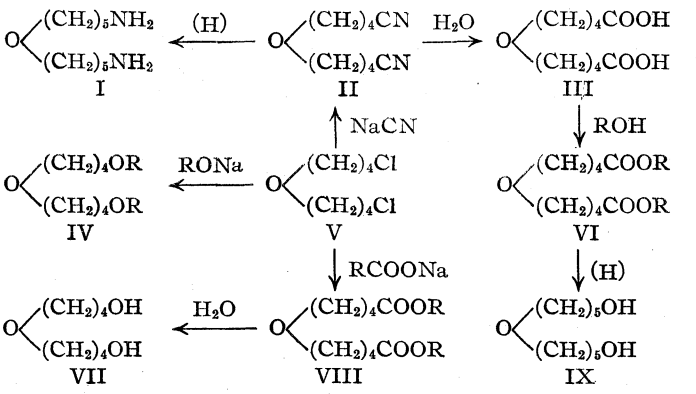
A report by Krzikalla and Maier[8] discusses the cleavage of cyclic ethers with thionyl chloride. The type of catalyst used was found to be of considerable importance. Zinc chloride favored the formation of 1,4-dichlorobutane from tetrahydrofuran, whereas with sulfuric acid as the catalyst high yields of 4,4′-dichlorodibutyl ether were obtained. The type of product was also found to be a direct function of the molar ratio of thionyl chloride to tetrahydrofuran. By varying that ratio, greater or lesser amounts of 1,4-dichlorobutane, 4,4′-dichlorodibutyl ether, and a trimeric ether of the formula $Cl(CH_2)_4O(CH_2)_4O(CH_2)_4Cl$ were obtained.

The superiority of sulfuric acid as a catalyst for the cleavage of tetrahydrofuran by phosphorus oxychloride was established in our subsequent investigations, and yields of 4,4′-dichlorodibutyl ether were improved up to 65–70% of the theoretical.

The conversion of tetrahydrofuran to 4,4′-dichlorodibutyl ether takes place by one of several possible mechanisms. Our failure to isolate chlorobutyl phosphate esters which might convert to the ether on heating, and the observed polymer formation when tetrahydrofuran was treated with thionyl chloride and ferric chloride at room temperature, indicate that the reaction is one of polymerization and depolymerization as discussed by Delfs.[6] This route of formation is also favored by the facts (1) that the high boiling residues from dichloroether distillations can be further converted to dichlorodibutyl ether by retreatment with phosphorus oxychloride, and (2) by the formation of the trimeric ether $Cl(CH_2)_4O(CH_2)_4O(CH_2)_4Cl$ when less than one-third mole of phosphorus oxychloride per mole of tetrahydrofuran is used in the reaction.

4,4′-Dichlorodibutyl ether is an interesting intermediate for the preparation of a variety of difunctional compounds. The halogens are readily replaced by cyano, alkoxy, acyloxy and similar groups. Oxydivaleric acid and its esters, 5,5′-diaminodiamyl ether, 4,4′-dihydroxydibutyl ether and 5,5′-dihydroxydiamyl ether have been prepared from such derivatives.

Derivation of these products may be illustrated as follows



Attempts to apply the same ring cleavage reaction to tetrahydropyran and tetrahydromethylfuran gave much lower yields of the expected dichlorodiamyl ethers. Tetrahydropyran apparently underwent side reactions involving dehydrohalogenation of the cleavage products and yielded a complex reaction product from which only a small yield of 5,5′-dichlorodiamyl ether could be isolated.

Experimental

4,4′-Dichlorodibutyl Ether (V).—A mixture of 72 g. (1.0 mole) of tetrahydrofuran and 51.2 g. (0.33 mole) of phosphorus oxychloride was placed in a 1-liter, three-necked flask equipped with stirrer, reflux condenser, and thermometer. The mixture was cooled in a water bath, and 10 cc. of concentrated sulfuric acid added gradually with stirring. The temperature was then slowly raised by heating in a bath. At about 80° a vigorous exothermic reaction occurred and cooling was necessary to keep the reaction under control. The temperature was controlled at 80–100° until the exothermic reaction subsided. This period usually lasted about forty minutes and was accompanied by refluxing, some evolution of hydrogen chloride, and the precipitation of a gelatinous, phosphorus-containing material. The reaction mixture was then held at 90–100° for an additional ten minutes after which 100 cc. of water was added and heating to reflux continued for thirty minutes longer.

The unchanged tetrahydrofuran and the by-product 1,4-dichlorobutane were removed by distilling their water azeotropes. The water and oil layers were separated after the residue from this distillation had cooled. The aqueous layer was extracted twice with ether, the ether and oil layers combined and water-washed. The ether was evaporated and the residue distilled under reduced pressure. The main fraction of distillate boiling at 83–87° (0.4–0.6 mm.) weighed 64.5 g. and was essentially pure 4,4′-dichlorodibutyl ether. The yield, based on tetrahydrofuran of which 5.5 g. was recovered, was 70% of the theoretical. Three grams of 1,4-dichlorobutane was isolated from the azeotropic distillates.

Refractionation of a composite of 250 g. of 4,4′-dichlorodibutyl ether gave 245 g. of a colorless, water-insoluble product having the following properties: b. p. 84–86° (0.5 mm.), d^{25}_4 1.069, $n^{25}D$ 1.4567. *Anal.* Calcd. for

$C_8H_{16}OCl_2$: C, 48.2; H, 8.09; Cl, 35.6. Found: C, 48.6; H, 7.88; Cl, 35.5. Calcd. for $Cl(CH_2)_4O(CH_2)_4Cl$: M_D 50.52; M_D found 50.70.

The same product was obtained in lower yields by treating tetrahydrofuran with phosphorus trichloride, thionyl chloride, phosgene, and silicon tetrachloride, all catalyzed by sulfuric acid; and with phosphorus oxychloride catalyzed by zinc, zinc chloride, aluminum chloride, ferric chloride, chlorosulfonic acid and metaphosphoric acid.

The reaction was also run in solvents such as benzene, toluene and carbon tetrachloride, but in all cases the yield was lower than by the method described.

Polymerization of Tetrahydrofuran.—Tetrahydrofuran was polymerized by the method of Delfs[6] to determine whether such a polymeric material could be converted to 4,4′-dichlorodibutyl ether.

Tetrahydrofuran was mixed with thionyl chloride and anhydrous ferric chloride in a molar ratio of 85.5:12:2.5 and allowed to stand for eleven days at room temperature, in a flask protected against entry of atmospheric moisture. Water was then added and the unchanged tetrahydrofuran recovered by distillation. The water-insoluble oil layer was separated, washed with water, and heated to 140° under vacuum (0.35 mm.). No distillate other than water was collected. From 92.5 g. of original reaction mixture 46.5 g. of a brown, oily liquid was obtained. This material solidified to a waxy solid when cooled below 0°.

Anal. Found: C, 61.4; H, 10.26; Cl, 9.60.

The chlorine value indicates a molecular weight of 739 and x equal 8.5 for a polymer of the assumed structure $Cl[(CH_2)_4O]_x$-$(CH_2)_4Cl$.

Anhydrous aluminum chloride used in place of ferric chloride gave a comparable product in lower yield.

A 27.4 g. sample of this polymer was heated for two and one-half hours with 14.3 g. of phosphorus oxychloride and 0.25 g. of concentrated sulfuric acid. The reaction was only mildly exothermic at about 100° and the temperature of the reaction mixture was not allowed to exceed 125°. Addition of water, separation of the water-insoluble products, and distillation gave 14 g. (40%) of 4,4′-dichlorodibutyl ether, showing that partial depolymerization occurred on heating with inorganic acid halides.

Based on this observation, 157 g. of high-boiling and polymeric residues from earlier dichlorodibutyl ether preparations was heated with 71 g. of phosphorus oxychloride and 3 cc. of concentrated sulfuric acid. Workup and distillation of this reaction mixture gave 28 g. of 1,4-dichlorobutane, 35.4 g. of 4,4′-dichlorodibutyl ether, and 6.5 g. of a higher boiling [91–155° (0.5 mm.)] material.

4,4′-Dichlorodibutyl ether is partially destroyed under such reaction conditions, 50–75% being recovered, depending upon the severity of the conditions used.

1,4-Di-(δ-chlorobutoxy)-butane.—Tetrahydrofuran, 162 g. (2.25 moles), reacted with 77 g. (0.5 mole) of phosphorus oxychloride and 3 cc. of concentrated sulfuric acid. Distillation of the water-insoluble products of the reaction gave 85 g. (42.7%) of 4,4′-dichlorodibutyl ether, 39.4 g. of a distillate collected over the range of 120–160° at 1 mm., and 18.5 g. of a viscous liquid residue. Redistillation of the higher-boiling product gave a liquid having the following properties: b. p. 133° (0.6 mm.), $n^{23}D$ 1.4535, d^{23}_4 1.0444.

Anal. Calcd. for $C_{12}H_{24}O_2Cl_2$: Cl, 26.15. Found: Cl, 25.9.

This product is probably $Cl(CH_2)_4O(CH_2)_4O(CH_2)_4Cl$.[8]

5,5′-Dichlorodiamyl Ether.—Tetrahydropyran, 86 g. (1 mole), was mixed with 51.2 g. (0.33 mole) of phosphorus oxychloride and 2.5 cc. of concentrated sulfuric acid and the mixture stirred and heated to reflux for twelve hours. There was no evidence of an exothermic reaction such as was observed with tetrahydrofuran. Only a very gradual increase in boiling temperature, from 80 to 112°, occurred during the heating period. Hydrogen chloride was evolved throughout the refluxing period, the amount increasing with the increase in temperature. At the end of the heating period 100 cc. of water was added to the mixture and refluxing continued for one hour. Distillation of the water-insoluble reaction products gave 18 g. of 1,5-dichloropentane, 25 g. of a yellow liquid, b. p. 96–125° (0.5–0.8 mm.), and 26 g. of residue. Refractionation of the yellow liquid fraction gave 8.8 g. of a colorless liquid, b. p. 65–70° (3–4 μ); $n^{27}D$ 1.4580; d^{27}_4 1.0349; M_D calcd. for $Cl(CH_2)_5O(CH_2)_5Cl$, 59.76; M_D found 60.05.

Anal. Calcd. for $C_{10}H_{20}OCl_2$: Cl, 31.25. Found: Cl, 31.2.

No conditions were found whereby this compound could be prepared in better than 10–15% yields.

4,4′-Dichlorodiamyl Ether.—2-Methyltetrahydrofuran, 172 g. (2.0 moles) was mixed with 102.3 g. (0.67 mole) of phosphorus oxychloride and 1.3 g. of anhydrous zinc chloride. The mixture was heated to reflux for five hours during which the temperature gradually increased from 84 to 108°. The reaction mixture was diluted with water and heated to reflux for thirty minutes. The aqueous and oil layers were separated, the oil layer washed with water, and distilled. In addition to unchanged tetrahydromethylfuran, 1,4-dichloropentane and undistillable residue, 54 g. (23.8% yield) of 4,4′-dichlorodiamyl ether boiling at 69–75° (0.3 mm.) was obtained. Redistillation of this product yielded 38 g. of material having the following properties: b. p. 94–95° (0.88 mm.); $n^{25}D$ 1.4533; d^{25}_4 1.0191. M_D calcd., 59.76; found, 60.28.

Anal. Calcd. for $C_{10}H_{20}OCl_2$: C, 52.80; H, 8.87; Cl, 31.25. Found: C, 53.1; H, 8.85; Cl, 30.3.

No attempt was made to determine whether this product was a single compound or a mixture of the three possible isomeric 4,4′-dichlorodiamyl ethers.

Derivatives of 4,4′-Dichlorodibutyl Ether

4,4′-Dicyanodibutyl Ether (Oxydivaleronitrile) (II).—A mixture of 99.5 g. (0.5 mole) of 4,4′-dichlorodibutyl ether, 58 g. (1.18 moles) of pulverized sodium cyanide and 190 cc. of anhydrous methanol was charged into a steel hydrogenation bomb, shaken and heated to 150° for six hours. After the bomb had cooled, the reaction mixture was removed, filtered free of precipitated salt, and the methanol removed by evaporation on a steam-bath. The dark-colored residue was dissolved in ether, the solution filtered, and the filtrate washed with water. The ether was removed by evaporation and the residue heated to 200° at 0.7 mm. pressure. The small amount of distillate, 8 g., gave analytical and refractivity values for 4-methoxy-4′-cyanodibutyl ether.

Anal. Calcd. for $C_{10}H_{19}O_2N$: OCH_3, 16.74; N, 7.57; M_D 51.4. Found: OCH_3, 15.75; N, 7.78; M_D 51.6.

The undistilled material weighed 73 g., an 81% yield of oxydivaleronitrile. A sample of this dark-colored product was purified by distillation under high vacuum and had the following properties: b. p. 75–80° (10^{-4} mm.); $n^{26}D$ 1.4453; d^{26}_4 0.9627; M_D calcd. 49.54; found, 49.70.

Anal. Calcd. for $C_{10}H_{16}ON_2$: C, 66.6; H, 8.95; N, 15.55. Found: C, 66.55; H, 8.82; N, 15.29.

4,4′-Dicarboxydibutyl Ether (Oxydivaleric Acid) (III).—Oxydivaleronitrile, 45 g. (0.25 mole), was hydrolyzed by refluxing for five hours with a mixture consisting of 150 cc. of alcohol, 150 cc. of water, and 40 g. of sodium hydroxide. The alcohol was removed by distillation and the aqueous alkaline solution acidified with 9 N sulfuric acid. The product separated as a brown, crystalline solid. The yield was 49 g. or 90% of the theoretical. This crude product was dissolved in hot water, the solution treated with activated carbon, and filtered. The product crystallized as white leaflets, m. p. 88.5–89.5°.

Anal. Calcd. for $C_{10}H_{18}O_5$: C, 55.03; H, 8.31; neut. equiv., 109.1. Found: C, 55.15; H, 8.13; neut. equiv., 110.4.

Both the crude and the distilled oxydivaleronitrile gave high yields of the desired acid.

A sample of this acid when heated with hydriodic acid

was converted in high yield to δ-iodovaleric acid, m. p. 56–57°.

Esterification with ethyl, *n*-butyl, and tetrahydrofurfuryl alcohols gave good yields of the normal oxydivalerates (VI). The properties of these are listed in Table I.

5,5′-Dihydroxydiamyl Ether (IX).—Diethyl oxydivalerate, 41.2 g. (0.15 mole), was reduced with sodium and alcohol by the procedure described by Manske[9] for the reduction of diethyl sebacate. The product, 20.3 g. (71% yield), had the following properties: m. p. 16–18°, b. p. 141–142° (0.5 mm.); $n^{25}D$ 1.4570; d^{25}_4 0.9727; M_D calcd., 53.08; found, 53.26; soluble in water and ether, insoluble in benzene.

Anal. Calcd. for $C_{10}H_{22}O_3$: C, 63.18; H, 11.66. Found: C, 62.3; H, 11.8.

5,5′-Diaminodiamyl Ether (I).—Oxydivaleronitrile, 30 g. (0.166 mole), was dissolved in 350 cc. of absolute ethanol and the solution heated to boiling. Sodium, 31 g., was added in small pieces to the boiling solution over a period of forty-five minutes. Boiling was continued until all of the sodium had reacted. Most of the alcohol was then removed by distillation and the residue acidified with hydrochloric acid. The acidified mixture was evaporated to dryness and the amine hydrochloride extracted from the sodium chloride with anhydrous ethanol. Addition of ether to the alcoholic extract precipitated the diamine dihydrochloride as a white crystalline solid; yield 30.5 g., 70% of theoretical.

Anal. Calcd. for $C_{10}H_{24}ON_2 \cdot 2HCl$: Cl, 27.1. Found: Cl, 27.6.

A portion of this dihydrochloride was mixed with an excess of 50% potassium hydroxide and the insoluble oil separated by extraction with ether. Evaporation of the ether left a colorless, strongly basic liquid which absorbed carbon dioxide from the air to form a stable carbonate. The free diamine had the following properties: $n^{22}D$ 1.4602; $d^{22}D$ 0.907.

Anal. Calcd. for $C_{10}H_{24}ON_2$: N, 14.87. Found: N, 14.57.

(9) "Organic Syntheses," Coll. Vol. II, John Wiley and Sons, Inc., New York, N. Y., 1943, p. 154.

4,4′-Diacetoxydibutyl Ether (VIII).—4,4′-Dichlorodibutyl ether, 60 g. (0.3 mole), was mixed with 98 g. (1 mole) of fused potassium acetate and 60 cc. of glacial acetic acid. The mixture was refluxed for fifteen hours with occasional stirring to break up incrustations of insoluble salts. The reaction mixture was then cooled, diluted with 600 cc. of water, and the product separated by extraction with ether. Distillation of the residue from ether evaporation gave 60 g. (81% yield) of a colorless liquid, b. p. 115–118° (0.6 mm.); $n^{28}D$ 1.4330; d^{28}_4 1.018.

Anal. Calcd. for $C_{12}H_{22}O_5$: C, 58.5; H, 9.00; acetyl, 34.94; sapn. equiv., 123.1. Found: C, 58.6; H, 8.93; acetyl, 34.92; sapn. equiv., 122.7.

4,4′-Dihydroxydibutyl Ether (VII).—Methyl alcoholysis of 4,4′-diacetoxydibutyl ether gave a quantitative yield of 4,4′-dihydroxydibutyl ether, b. p. 115–116° (0.3 mm.); $n^{26}D$ 1.4544; d^{26}_4 0.9999; M_D calcd., 43.82; found, 43.93. Di-α-naphthylurethan, m. p. 124–125° (*Anal.* Calcd.: N, 5.60. Found: N, 5.56).

4,4′-Dialkoxydibutyl Ethers (IV).—4,4′-Dichlorodibutyl ether was converted to dialkoxydibutyl ethers by refluxing for eight hours with the sodium alkoxides in solutions of the respective alcohols. These dialkoxy products were obtained in yields of 70–80% as colorless mobile liquids (see Table II).

Acknowledgment.—The tetrahydrofuran used in this investigation was generously supplied by the Electrochemicals Department, E. I. du Pont de Nemours and Company. C. H. Van Etten of this Laboratory performed the analyses.

Summary

A method is described for the conversion of tetrahydrofuran to 4,4′-dichlorodibutyl ether in 65–70% yields. Application of the method to tetrahydropyran and tetrahydromethylfuran gave poor yields of the expected dichlorodiamyl ethers.

A number of derivatives of 4,4′-dichlorodibutyl ether, not previously reported, are described.

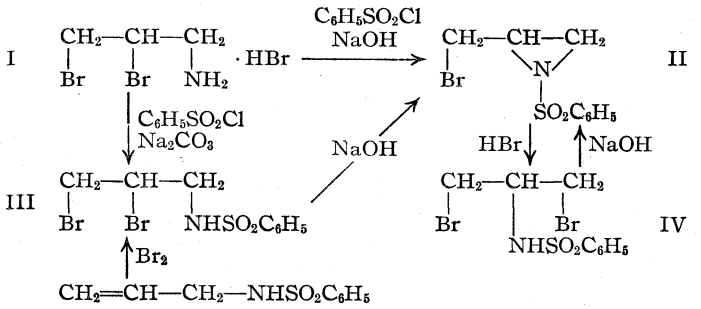
The Benzenesulfonyl Derivatives of 1-Amino-2,3-dibromopropane and 2-Amino-1,3-dibromopropane

BY WALTER J. GENSLER

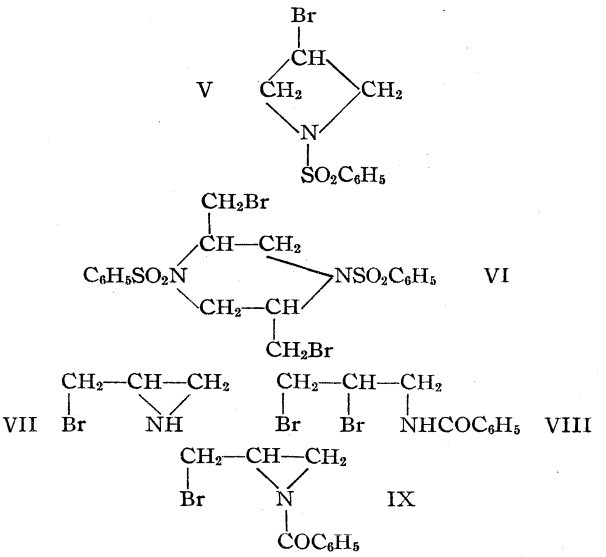
It was reported recently[1] that the action of benzenesulfonyl chloride with 1-amino-2,3-dibromopropane hydrobromide (I) in sodium hydroxide solution resulted in the formation of an alkali insoluble material which furnished analytical figures agreeing not with those calculated for 1-benzenesulfonamido-2,3-dibromopropane (III) but for



III minus a molecule of hydrogen bromide. The structure of 1-benzenesulfonyl-2-bromomethylethyleneimine (II) was proposed for this compound. The present report is concerned with the reactions involved in the formation of II, and the demonstration of its structure.

It was found that III, the normal benzenesulfonyl derivative, could be obtained from the reaction of I and benzenesulfonyl chloride by the use of sodium bicarbonate, or better sodium carbonate, in place of sodium hydroxide. The same compound was formed on the addition of bromine to N-(benzenesulfonyl)-allylamine. Compound III was insoluble in carbonate or bicarbonate solution and could be recovered unchanged after exposure to these reagents. However, when III was treated with dilute sodium hydroxide, a clear solution resulted, which after a few seconds suddenly became milky and deposited a crystalline solid. This solid was identical with the product (II) obtained directly from 1-amino-2,3-dibromopropane.[2]

The facts that 1-benzenesulfonamido-2,3-dibromopropane could be obtained from 1-amino-2,3-dibromopropane under conditions milder than those used in the direct conversion of 1-amino-2,3-dibromopropane to II, and that 1-benzenesulfonamido-2,3-dibromopropane could be converted to II under the same conditions as those in the direct conversion, constituted permissive evidence in favor of the probable course of the reaction, I → [III] → II. It was necessary, however, to consider an alternate course in which 1-amino-2,3-dibromopropane could first cyclize to form 2-bromomethylethyleneimine (VII), which would then react with benzenesulfonyl chloride to yield the product II. To test this possibility 1-amino-2,3-dibromopropane hydrobromide was added to an excess of sodium hydroxide solution. The mixture was allowed to stand for a period equal to the reaction time allowed in the direct formation of II, and under the same conditions. Benzoyl chloride was then added to effect a benzoylation of either the cyclized molecule, VII, or the unchanged starting material. It was found that the product was the derivative of the starting material, 1-benzamido-2,3-dibromopropane, VIII (96% yield, m. p. 125–127°; 66% yield after purification, m. p. 129–129.5°) and not the cyclized form IX. Since no cyclization occurred in the benzoylation experiment, no cyclization to VII was possible in the benzenesulfonation reaction; and therefore in the direct formation of II from 1-amino-2,3-dibromopropane, the reaction path, I → [VII] → II, could be eliminated.



Assignment of the structure of 1-benzenesulfonyl-2-bromomethylethyleneimine (II) for the alkali insoluble compound required proof since at least two other structures, V and VI, could be regarded as reasonably possible. The bimolecular piperazine derivative, VI, was eliminated on the basis of a molecular weight determination, while

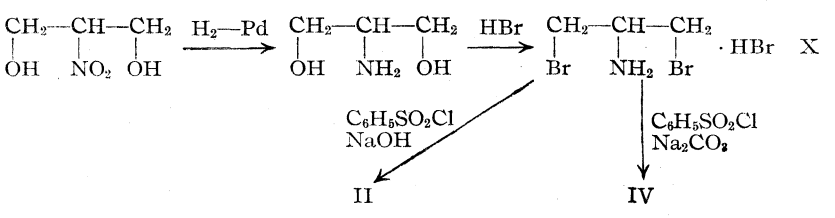
(1) Gensler, THIS JOURNAL, **69**, 1966 (1947).

(2) Similar reactions have been reported before. Adams and Cairns, THIS JOURNAL, **61**, 2464 (1939), converted 1-*p*-bromobenzenesulfonamido-2-methyl-2-chloropropane to 1-*p*-bromobenzenesulfonyl-2,2-dimethylethyleneimine; and Kharasch and Priestley, *ibid.*, p. 3425, obtained N-(*p*-toluenesulfonyl)-styreneimine from 1-*p*-toluenesulfonamido-1-phenyl-2-bromoethane.

the choice of II over V rested on the following two lines of evidence.

Rupture of the ring in the symmetrical trimethyleneimine V with the addition of hydrogen bromide can lead to only one product, 1-benzenesulfonamido-2,3-dibromopropane (III). The unsymmetrical ethyleneimine structure II on the other hand can yield either III or the isomeric compound, 2-benzenesulfonamido-1,3-dibromopropane (IV). On carrying out the experiment using 48% hydrobromic acid there was obtained only one addition product (68% yield) which proved to be not III but IV. The unsymmetrical structure for II was therefore indicated. The structure assigned to IV was supported by its smooth reconversion to II on treatment with alkali.

Conclusive proof was furnished by an unequivocal synthesis of II as well as IV. Hydrogenation of 2-nitro-1,3-dihydroxypropane according to Schmidt and Wilkendorff[3] yielded 2-amino-1,3-dihydroxypropane. Treatment with strong hydrobromic acid at 165–175° converted the aminoglycol to 2-amino-1,3-dibromopropane hydrobromide (X) which was isomeric with compound I. From the reaction of X and benzenesulfonyl chloride in the presence of sodium hydroxide it was possible to obtain a product II identical with the alkali insoluble compound derived from I. The



use of sodium carbonate in place of sodium hydroxide resulted in the formation of 2-benzenesulfonamido-1,3-dibromopropane (IV) identical with the addition product of II and hydrogen bromide. These identities constitute a demonstration of structure, since it is possible to write only the structures of 1-benzenesulfonyl-2-bromomethylethyleneimine (II) and 2-benzenesulfonamido-1,3-dibromopropane (IV) for the compounds derived from 2-amino-1,3-dibromopropane X.

Discussion

The reaction of 1-benzenesulfonamido-2,3-dibromopropane, or 2-benzenesulfonamido-1,3-dibromopropane with alkali to form 1-benzenesulfonyl-2-bromomethylethyleneimine is interpreted on the basis of a nucleophilic attack of the sulfonamide anion on a *beta* carbon atom with the elimination of bromide ion. The dibromo compounds are stable in acidic or weakly alkaline medium since the unshared electron pair on the nitrogen of the undissociated sulfonamide grouping is unavailable for the displacement. At higher *p*H's a proton is removed from the sulfonamide group, and the strongly nucleophilic nitrogen reacts rapidly.

The formation of II rather than V from 1-benzenesulfonamido-2,3-dibromopropane shows that the attack of the sulfonamide anion on the number two carbon is much more rapid than on the number three. Freundlich and Kroepelin[4] have found that the first order rate constants for the cyclization of β-bromoethylamine and γ-bromopropylamine are 0.036 and 0.0005, respectively. If these figures give some measure of the relative tendency of a free unshared electron pair on nitrogen to displace bromide ion from the two- and from the three-positions, then only 1–2% of the four-membered ring compound, V, would be expected in the product from 1-benzenesulfonamido-2,3-dibromopropane. This small amount would be lost in the purification procedure.

In the addition of hydrogen bromide to 1-benzenesulfonyl-2-bromomethylethyleneimine to form 2-benzenesulfonamido-1,3-dibromopropane a solvolysis mechanism is unlikely since it would involve the formation of a primary carbonium ion. On the other hand, by analogy with the behavior of related three-membered ring systems,[5] it is reasonable to regard the reaction as a bimolecular displacement of the sulfonamido group by bromide ion. The electron attracting properties of the sulfonamido group polarize the bond between the nitrogen and carbon of the ring placing the positive end of a dipole at the carbon atom. The resulting low electron density at the carbon together with the normal strain in the three-membered ring would allow a ready attack by bromide ion.

In analogy with related cases the displacement occurs at the methylene rather than at the methine carbon.[6] In this connection it should be pointed out that this mode of ring cleavage is by no means the rule, and that a number of examples

(3) Schmidt and Wilkendorff, *Ber.*, **52**, 389 (1919).

(4) Freundlich and Kroepelin, *Z. physik. Chem.*, **122**, 39 (1926).

(5) In the formation of 1-chloro-2-hydroxy-3-halopropane from aqueous hydrogen halide and epichlorohydrin, an oxygen analog, Brönsted, Kilpatrick and Kilpatrick [THIS JOURNAL, **51**, 428 (1929)] have shown that the rate of reaction is dependent on the halide ion–epichlorohydrin concentration product and also on the halide ion–epichlorohydrin–hydronium ion concentration product. Freundlich and Neumann [*Z. physik. Chem.*, **87**, 69 (1914)] have found that in the reaction of ethyleneimine with excess hydrobromic acid to form β-bromoethylamine, the rate depends on the product of the bromide ion and ethyleneimine (ethyleneimmonium ?) concentrations. In these cases a nucleophilic displacement mechanism of halide ion on a carbon atom is in agreement with the observed kinetics. Further, a displacement process by various donor groups on the ring-carbons of an intermediate quaternary ethyleneimmonium salt has been used satisfactorily to interpret the reaction kinetics of the nitrogen mustards (Ph.D. theses, Harvard University, 1944, by C. Gardiner Swain and by Sidney D. Ross).

(6) For example, in the addition of hydrogen bromide [Gabriel and Ohle, *Ber.*, **50**, 815 (1917)] and of hydrogen chloride [Smith and Platon, *ibid.*, **55**, 3143 (1922)] to propyleneimine; and in the addition of the halogen acids to the oxygen analogs, epichlorohydrin and epibromohydrin ["Beilstein," 4th ed., Vol. XVII, pp. 7–8.]

are known in which the process occurs at the more highly, rather than the less highly, substituted carbon atom of the ethyleneimine ring.[7]

Experimental

1-Benzenesulfonamido-2,3-dibromopropane (III) from 1-Amino-2,3-dibromopropane (I).—To a vigorously stirred solution of 1.20 g. of 1-amino-2,3-dibromopropane hydrobromide[8] (0.0040 mole) in 10 ml. of water was added 0.6 ml. of benzenesulfonyl chloride (0.0047 mole) followed immediately by a solution of 1.2 g. of sodium carbonate (0.011 mole) in 10 ml. of water. After the mixture had been stirred for forty-five minutes at room temperature it was filtered, and the solids washed and pressed on the funnel. This material, dried in the air, weighed 1.33 g. (92%) and had m. p. 91–97° (sintering at 85°). It was crystallized from 8 ml. of carbon tetrachloride to yield 1.05 g. (73%) of 1-benzenesulfonamido-2,3-dibromopropane in the form of fine needle-like crystals, m. p. 97–99°.

Two further crystallizations from alcohol brought the melting point to 98–100°.

Anal. Calcd. for $C_9H_{11}NSO_2Br_2$: C, 30.3; H, 3.1. Found: C, 30.6; H, 3.2.

1-Benzenesulfonamido-2,3-dibromopropane (III) from N-(Benzenesulfonyl)-allylamine.—The product of the reaction of benzenesulfonyl chloride and allylamine in aqueous alkali was readily purified by distillation. The fraction which boiled at 156–158° (2 mm.) and solidified to a white solid, m. p. 39.5–41.5°, was taken as N-(benzenesulfonyl)-allylamine.[9]

Twenty-five milliliters of chloroform containing 4.05 g. of bromine (0.025 mole) was added over a period of one and three-quarters hours to a cold (10°) vigorously stirred solution of 5.00 g. of N-(benzenesulfonyl)-allylamine (0.025 mole) in 50 ml. of chloroform. After the addition was complete the reaction mixture, from which crystals of the product had separated, was allowed to stand at 10–15° for one hour. The solvent was then removed, with only slight warming, by distillation under reduced pressure. To the residue was added 15 ml. of alcohol and again all volatile material was removed with suction. Crystallization of the crude product from alcohol yielded 7.48 g. (83%) of white crystals, m. p. 97.5–101.5°, which showed no depression in mixed melting point with the 1-benzenesulfonamido-2,3-dibromopropane from 1-amino-2,3-dibromopropane. Further crystallizations did not improve the melting point.

1-Benzenesulfonyl-2-bromomethylethyleneimine (II) from 1-Amino-2,3-dibromopropane (I).—A solution of 1.20 g. of 1-amino-2,3-dibromopropane hydrobromide (0.0040 mole) in 5 ml. of water was mixed with 0.70 ml. of benzenesulfonyl chloride (0.0054 mole). Five milliliters of sodium hydroxide solution, containing 0.97 g. or 0.024 mole of sodium hydroxide, was added without delay and with vigorous stirring. Immediately after the addition of the alkali the mixture became almost entirely clear, but after a few seconds a heavy turbidity suddenly developed which soon gave way to a precipitate. After the mixture had been stirred at room temperature for thirty-five minutes, the solids were collected, washed with water, and finally air-dried. The crude product, which weighed 0.95 g. (86%) and melted at 86–88.5°, was purified by crystallization from ethyl alcohol, and furnished 0.82 g. (74%) of 1-benzenesulfonyl-2-bromomethylethyleneimine, m. p. 89–90° (faint sintering at 86°). This material gave no depression in mixed melting point with the analytical sample of the material previously prepared,[1] while the mixed melting point with 1-benzenesulfonamido-2,3-dibromopropane was 76–91°.

A Rast molecular weight determination gave values lying between 272 and 281. The calculated molecular weight for II is 276.

1-Benzenesulfonyl-2-bromomethylethyleneimine (II) from 2-Amino-1,3-dibromopropane (X).—The procedure employed was the same as that described above for the reaction with 1-amino-2,3-dibromopropane. The same product was obtained (melting point and mixed melting point, 89–90°) in 76% yield.

1-Benzenesulfonyl-2-bromomethylethyleneimine (II) from 1-Benzenesulfonamido-2,3-dibromopropane (III).—A solution of 1.4064 g. of 1-benzenesulfonamido-2,3-dibromopropane (0.00394 mole) in 10 ml. of alcohol was added in one portion to 50.00 ml. of 0.099 *N* sodium hydroxide (0.00495 equivalent). The addition was made as complete as possible by rinsing the flask with two 5-ml. portions of alcohol. The stirred solution remained perfectly clear for about fifteen seconds and then suddenly became milky. After the addition of 25 ml. of water the mixture was cooled in an ice-bath and filtered. The time which elapsed between the addition and the filtration was no longer than fifteen minutes. The solids, washed thoroughly on the funnel with approximately 50 ml. of water, pressed, and air-dried, weighed 1.02 g. (94%) and showed m. p. 88.5–90° (sintering at 85°). One crystallization from alcohol afforded 0.76 g. (70%) of pure 1-benzenesulfonyl-2-bromomethylethyleneimine, with melting point and mixed melting point, 89–90°.

The aqueous alkaline filtrate, together with the wash water, was titrated with 9.50 ml. of 0.100 *N* hydrochloric acid to the disappearance of the red color of phenolphthalein. This revealed that the amount of sodium hydroxide consumed in the cyclization process was 0.0040 equivalents, in good agreement with the theoretical value of 0.00394.

1-Benzenesulfonyl-2-bromomethylethyleneimine (II) from 2-Benzenesulfonamido-1,3-dibromopropane (IV).—The cyclization of IV followed essentially the directions given for the cyclization of III. However, it was noted in this case that the addition of the alcoholic solution of the 1,3-dibromide to the aqueous alkali did not result in a clear solution, but in an immediate turbidity. The crude air-dried product (m. p. 87–89°; 99% yield) was crystallized from alcohol, and furnished pure 1-benzenesulfonyl-2-bromomethylethyleneimine, m. p. 89–89.5°, in 81% yield. Mixed melting point determinations with II, III, and IV established the identity of the product.

1-Benzamido-2,3-dibromopropane (VIII).—The benzoylation of 1-amino-2,3-dibromopropane was carried out by following essentially the directions for the preparation of 1-benzenesulfonyl-2-bromomethylethyleneimine from 1-amino-2,3-dibromopropane. From the reaction of 1.20 g. of the amino-dibromide hydrobromide (0.0040 mole), 0.62 ml. of benzoyl chloride (0.0054 mole), and a solution of 0.98 g. of sodium hydroxide, there was obtained 1.18 g. (91%) of washed and air-dried product, m. p. 128–129°. One crystallization of this material from alcohol yielded 0.79 g. (61%) of 1-benzamido-2,3-dibromopropane, m. p. 129–129.5°. Two further crystallizations were carried out to obtain the analytical sample, m. p. 129.5–130°.[10]

Anal. Calcd. for $C_{10}H_{11}NOBr_2$: C, 37.4; H, 3.5. Found: C, 37.5; H, 3.4.

Repetition of this experiment with the one difference of stirring the mixture of amino-dibromide hydrobromide in the sodium hydroxide solution for thirty-five minutes at room temperature before the addition of the benzoyl

(7) This is the case in the formation of 1-*p*-toluenesulfonamido-2-phenyl-2-bromoethane from N-(*p*-toluenesulfonyl)-styreneimine and hydrobromic acid [Kharasch and Priestley, THIS JOURNAL, **61**, 3425 (1939)]; in the formation of 1-amino-2-methylpropanol-2 from isobutyleneimine and dilute sulfuric acid [Cairns, *ibid.*, **63**, 871 (1941)]; and in the action of hydrogen chloride with isobutyleneimine and with 2,2-diphenylethyleneimine to form the tertiary chlorides [Campbell and Campbell, reported at the New York Meeting of the American Chemical Society, September, 1947].

(8) Paal and Hermann, *Ber.*, **22**, 3076 (1889).

(9) Ginzberg, *Ber.*, **36**, 2703 (1903), reported m. p. 40.5–41° for N-(benzenesulfonyl)-allylamine.

(10) Bergmann, Dreyer and Radt, *Ber.*, **54**, 2139 (1921), reported m. p. 135° for this compound. Abderhalden and Paquin, *ibid.*, **53**, 1125 (1920), who prepared the compound without recognizing its structure, found m. p. 130°.

chloride gave practically the same results. There was obtained 1.24 g. (96%) of dry unpurified product, m. p. 125–127°, and after crystallization, 0.85 g. (66%) of white crystals, m. p. 129–129.5°. There was no depression in the mixed melting point with 1-benzamido-2,3-dibromopropane.

2-Benzenesulfonamido-1,3-dibromopropane (IV) from 1-Benzenesulfonyl-2-bromomethylethyleneimine (II).—A stirred mixture of 63 ml. of 48% hydrobromic acid and 3.40 g. of 1-benzenesulfonyl-2-bromomethylethyleneimine (0.012 mole) was heated on the steam-bath under a condenser for three and one-half hours. After the addition of 100 ml. of water, the reaction mixture was cooled in an ice-bath and the solids collected, washed with cold water, and finally air-dried. This material (3.38 g. melting at 91–94.5°) was crystallized from carbon tetrachloride (decolorizing carbon used) to yield 3.0 g. (68%) of well-formed pure white crystals of 2-benzenesulfonyl-1,3-dibromopropane, m. p. 93–93.5°. The melting point was not raised by further recrystallization.

Anal. Calcd. for $C_9H_{11}NO_2SBr_2$: C, 30.3; H, 3.1. Found: C, 30.2; H, 3.0.

The mixed melting point with 1-benzenesulfonamido-2,3-dibromopropane was 70–80°; the mixed melting point with the starting material was 66–78°.

2-Benzenesulfonamido-1,3-dibromopropane (IV) from 2-Amino-1,3-dibromopropane (X).—The directions for the preparation of 1-benzenesulfonamido-2,3-dibromopropane from the corresponding amino-dibromide were followed. However, in this case the water-insoluble material formed in the reaction mixture was only semi-solid after forty-five minutes of stirring. The material was taken up in ether, the ethereal solution washed with water and dried over magnesium sulfate. Removal of all solvent left a colorless mobile oil possessing a strong odor of benzenesulfonyl chloride. The oil crystallized partially on standing; it was found that the addition of low-boiling petroleum ether containing a small amount of ether dissolved only the oily portion and allowed the solids to be collected. There was obtained white crystals, m. p. 87–94.5° (sintering at 65°) in 14% yield. Two crystallizations of this material from carbon tetrachloride yielded pure 2-benzenesulfonamido-1,3-dibromopropane (10%), which melted alone or mixed with the material prepared from 1-benzenesulfonyl-2-bromomethylethyleneimine at 93–93.5°. The mixed melting points with 1-benzenesulfonamido-2,3-dibromopropane and with 1-benzenesulfonyl-2-bromomethylethyleneimine were depressed 17° and 23°, respectively.

Attempts at improving the yield by allowing a longer period for reaction resulted in an oily mixture from which only a small amount of 1-benzenesulfonyl-2-bromomethylethyleneimine could be isolated. A longer reaction period, using bicarbonate instead of carbonate to preclude ring closure, yielded an oil from which no solid product could be obtained.

2-Amino-1,3-dibromopropane Hydrobromide (X).—A warm solution of 5.0 g. of barium hydroxide octahydrate (0.016 mole) in 40 ml. of water was added with stirring to a warm solution of 4.0 g. of 2-amino-1,3-dihydroxypropane oxalate[3] (containing 0.0294 mole of the amino-glycol) in 30 ml. of water. The mixture was filtered and the barium oxalate rinsed thoroughly with water. To remove the excess barium the combined filtrate and washings were saturated with carbon dioxide, then boiled for ten minutes to decompose bicarbonate, and filtered. After acidification of the filtrate with 5 ml. of 48% hydrobromic acid, all the solvent was removed by distillation under reduced pressure. More hydrobromic acid was added and again removed. The residual material dissolved in 23 ml. of hydrobromic acid was saturated at 0° with gaseous hydrogen bromide, and heated in a Carius tube for three hours at 165–175°.

The resulting dark-colored mixture, in which some carbonized material was present, was diluted with 200 ml. of water and treated with decolorizing carbon (Nuchar) to obtain a water-white solution. This was taken to dryness under reduced pressures on the steam-bath, absolute alcohol was added to the crystalline residue, and the volatile matter again removed. The crude product was dissolved in absolute alcohol, and after a small amount of insoluble ammonium bromide was removed, the solution was concentrated to the first appearance of solid and diluted with an excess of ethyl acetate. The white crystalline product was removed from the cooled mixture, washed with ethyl acetate and dried on the steam-bath. 2-Amino-1,3-dibromopropane hydrobromide, m. p. 152–157°, was obtained in a yield of 6.55 g. (75%). One crystallization from absolute alcohol–ethyl acetate (1 to 5) furnished 4.57 g. (52%) of crystals melting at 154–158° (preliminary sintering); a second crystallization gave 3.4 g. (39%) with m. p. 158–162° (preliminary sintering). The material in the mother liquors could be recovered and reworked.

A number of further recrystallizations, involving much loss of material, was necessary before constant melting point of 162–162.5° was reached.

Anal. Calcd. for $C_3H_8NBr_3$: C, 12.1; H, 2.7. Found C, 12.4; H, 2.9.

2-Amino-1,3-dibromopropane hydrobromide differed from the isomeric 1-amino-2,3-dibromopropane hydrobromide (m. p. 167–169.5°) in the crystal form and in solubility behavior (the former was very soluble in absolute alcohol, while the latter could be recrystallized from this solvent); the mixed melting point was depressed 30°.

The attempts at forming 2-amino-1,3-dibromopropane by boiling the amino-glycol with 48% hydrobromic acid and concentrated sulfuric acid, or with hydrobromic acid according to the directions for the conversion of ethanolamine to β-bromoethylamine hydrobromide,[11] failed.

Summary

1-Amino-2,3-dibromopropane and 2-amino-1,3-dibromopropane react with benzenesulfonyl chloride in the presence of aqueous sodium carbonate to form the normal derivatives, 1-benzenesulfonamido-2,3-dibromopropane and 2-benzenesulfonamido-1,3-dibromopropane, respectively. With free alkali the product from either amino-dibromide and benzenesulfonyl chloride, or from either normal benzenesulfonyl derivative is 1-benzenesulfonyl-2-bromomethylethyleneimine.

Synthesis of a Biologically Active Nicotinic Acid Precursor: 2-Amino-3-hydroxybenzoic Acid

BY JOSEPH F. NYC AND HERSCHEL K. MITCHELL

Recent investigations[1,2] in this Laboratory have provided evidence that the mold *Neurospora* synthesizes nicotinic acid from tryptophan through the intermediates kynurenine and hydroxyanthranilic acid (2-amino-3-hydroxybenzoic acid). Although it has also been established that higher animals have the capacity for converting tryptophan to nicotinic acid[3,4] it is not yet known whether or not the mechanism is similar to that in *Neurospora*. In order to provide material for further investigations along these lines, it has been necessary to develop methods for synthesis of 2-amino-3-hydroxybenzoic acid. Since this compound has evidently not been previously synthesized, two independent methods of preparation have been devised in order to establish the structure of the products.

A purported preparation of 2-amino-3-hydroxybenzoic acid by degradation of the alkaloid damascenine was reported by Keller in 1908.[5] It is quite evident, however, that the product described by Keller is actually 2-amino-3-methoxybenzoic acid. The data in Table I are in accord with this conclusion.

TABLE I

MELTING TEMPERATURES OF 2-AMINO-3-HYDROXYBENZOIC ACID, 2-AMINO-3-METHOXYBENZOIC ACID, THE COMPOUND OF KELLER AND THE CORRESPONDING HYDROCHLORIDES

	Compound	M. p., °C.
1	2-Amino-3-hydroxybenzoic acid[a]	254–255 (cor.)
2	2-Amino-3-methoxybenzoic acid[a]	171 (cor.)
3	Compound of Keller	164
4	Hydrochloride of 1[a]	227 (cor.)
5	Hydrochloride of 2[a]	205–206 (cor.)
6	Hydrochloride of 3	199–200

[a] Synthesized in this Laboratory.

In addition to the data in Table I, Keller stated that he did not report a carbon analysis because it was too high. He did report a halogen analysis on the hydrochloride but miscalculated the theoretical value and his analysis actually checks very well with the theoretical figure for the hydrochloride of 2-amino-3-methoxybenzoic acid.

The first method for synthesis of 2-amino-3-hydroxybenzoic acid that has been utilized in this Laboratory involves reduction of 2-nitro-3-methoxybenzoic acid followed by demethylation. The nitro compound was previously prepared from 3-methoxybenzoic acid by Ewins[6] and its reduction by chemical means has been reported by several workers.[6,7,8]

In the present work, the reduction was carried out by catalytic hydrogenation and the final demethylation step by treatment of 2-amino-3-methoxybenzoic acid with hydriodic acid.

The second method of synthesis that is described in this paper involves oxidation of 8-methoxyquinoline to give 2-(N-methyl-N-formyl)-amino-3-methoxybenzoic acid.[9] By appropriate treatment of this product with hydriodic acid 2-amino-3-hydroxybenzoic acid was obtained. The products from the two methods of synthesis possessed identical physical properties and the same biological activity for *Neurospora*.[2]

Experimental

2-Nitro-3-methoxybenzoic Acid.—This compound was prepared by a modification of the method of Ewins.[6] A mixture of 10 g. of 3-methoxybenzoic acid and 40 ml. of nitric acid (sp. gr. 1.4) was heated gently in a 250 ml. flask. After the beginning of the exothermic reaction the mixture was maintained at 55° by occasional immersions in cold water. A voluminous precipitate of nitration products appeared as the reaction progressed. After standing three hours at room temperature the precipitate was filtered off, washed with water and treated with three times its weight of boiling ethyl alcohol. The esulting suspension was filtered hot and the undissolved material was crystallized from a minimum amount of boiling ethanol; yield, 0.85 g., 2-nitro-3-methoxybenzoic acid, m. p. 260–263° (cor.). An additional 0.15 g. of the desired product was obtained by two recrystallizations of the material precipitated after cooling of the filtrate of the first hot alcohol extraction.

2-Amino-3-methoxybenzoic Acid.—One-half gram of 2-nitro-3-methoxybenzoic acid was dissolved in 50 ml. of absolute ethanol and hydrogenated at 1 atmosphere pressure and at room temperature, in the presence of 100 mg. of 5% palladium-on-charcoal. Following filtration the solution was evaporated to dryness and the product was crystallized from boiling benzene, yield, 0.4 g., m. p. 170–171° (cor.).

Anal. Calcd. for $C_8H_9NO_3$: C, 57.48; H, 5.43; N, 8.38. Found: C, 57.73; H, 5.49; N, 8.54. Absorption spectrum Fig. 1, curve B. The hydrochloride of this compound crystallized from concentrated aqueous hydrochloric acid, m. p. 205–206° (cor.).

2-Amino-3-hydroxybenzoic Acid. Method I.—A mixture of 200 mg. of 2-amino-3-methoxybenzoic acid, 50 mg. of red phosphorus and 4 ml. of hydriodic acid (sp. gr. 1.7) was heated in a sealed tube at 100° for eight hours. The hydriodic acid salt of 2-amino-3-hydroxybenzoic acid crystallized on cooling. After filtration this product, containing phosphorus, was dissolved in 15 ml. of water and again filtered. Solid sodium carbonate was carefully added to the filtrate until the acid reaction to congo red just disappeared. The crude product was obtained as a crystalline powder, m. p. 238–242°. Recrystallization from ethanol yielded 124 mg. of compound, m. p. 254–255° (cor.); absorption spectrum, Fig. 1, curve A.

Anal. Calcd. for $C_7H_7NO_3$: C, 54.90; H, 4.61; N, 9.15. Found: C, 55.00; H, 4.83; N, 9.13.

2-Amino-3-hydroxybenzoic Acid Hydrochloride.—This compound crystallized from a hot solution of 2-amino-3-hydroxybenzoic acid in concentrated aqueous hydrochloric acid, m. p. 227° (cor.). *Anal.* Calcd. for $C_7H_8NO_3Cl$: N, 7.39; Cl, 18.70. Found: N, 7.68; Cl, 18.59.

2-Amino-3-hydroxybenzoic Acid. Method II.—2-(N-Methyl-N-formyl)-amino-3-methoxybenzoic acid was prepared according to the procedure of Kaufmann and Rothlen.[9] A mixture of 200 mg. of this compound, 50 mg. of red phosphorus and 4 ml. of hydriodic acid (sp. gr. 1.7) was heated in a sealed tube at 135° for twelve hours. The product was isolated and purified by the procedure described under Method I, yield 57 mg., m. p. 254–255° (cor.), hydrochloride m. p. 227° (cor.).

The products from both methods I and II possessed identical absorption spectra and biological activity on a nicotinic acid requiring mutant of *Neurospora*.[2]

Discussion

Hydroxyanthranilic acid (2-amino-3-hydroxybenzoic acid) has been synthesized by two independent methods each providing in itself nearly conclusive evidence for the structure of the product. It is evident from a consideration of the properties of these products and from the facts given by Keller that the latter investigator did not prepare hydroxyanthranilic acid as reported. No evidence has been found for a synthesis of the compound prior to the present work.

It is to be noted from Fig. 1 that the absorption spectra of some methyl and formyl substituted 2-amino-3-hydroxybenzoic acids are quite similar to that of the parent compound. This is true also for damascenine and damasceninic acid. In the case of the unsubstituted acid considerable variations in spectrum have been observed at wave lengths below 260 mμ. This is evidently due to traces of impurities derived from oxidation of the compound in mildly acid or alkaline solutions. A pure white product can be obtained only from acidic solutions since oxidation is rapid even at neutrality.

Summary

1. Two independent methods have been described for the synthesis of 2-amino-3-hydroxybenzoic acid.

2. Data have been presented to show that the product previously obtained by Keller and reported to be 2-amino-3-hydroxybenzoic acid was actually 2-amino-3-methoxybenzoic acid.

[CONTRIBUTION NO. 638 FROM THE DEPARTMENTS OF CHEMISTRY AND PHYSICS, UNIVERSITY OF PITTSBURGH]

X-Ray Investigation of Glycerides. VII. Diffraction Analyses of Synthetic 1,3-Dielaidin[1]

BY B. F. DAUBERT AND S. S. SIDHU

In a recent publication by Carter and Malkin,[2] X-ray diffraction data were reported for a series of unsaturated symmetrical 1,3-diglycerides, including 1,3-diolein, 1,3-dierucin, and their *trans* isomers, 1,3-dielaidin and 1,3-dibrassidin.

In our study of the physical properties of synthetic glycerides, an X-ray diffraction study of 1,3-dielaidin had been completed but not reported prior to the publication by Carter and Malkin,[2] although X-ray diffraction data for 1,3-diolein, 1,3-dilinolein, and 1,3-dilinolenin were recently reported by Daubert and Lutton.[3]

The purpose, therefore, of the present communication is to report the X-ray data on 1,3-dielaidin prepared both by direct synthesis and elaidinization of 1,3-diolein.

Experimental

Preparation of 1,3-Dielaidin.—1-Monotrityl glycerol (10 g.) (m. p. 109.5–110.0°) was dissolved, with slight warming, in a mixture of quinoline (15 ml.) and dry chloroform (40 ml.). To this mixture elaidyl chloride (18.0 g.) was added slowly. The mixture, after standing

(1) The generous financial assistance of the Buhl Foundation in support of this investigation is gratefully acknowledged.

(2) Carter and Malkin, *J. Chem. Soc.*, 554 (1947).

(3) Daubert and Lutton, THIS JOURNAL, **69**, 1449 (1947).

at room temperature for one hour, was refluxed on a steam-bath for a similar period of time. The mixture, after cooling, was dissolved in ether and the ether solution washed successively with cold 0.5 *N* sulfuric acid, 5% potassium carbonate solution, distilled water, and finally dried over anhydrous sodium sulfate. The ether was removed *in vacuo* and the sirupy liquid remaining was dissolved in a 1:1 mixture of ether and ethyl alcohol. The solution was cooled to −20° for twenty-four hours. The crystalline mass was suction-filtered, recrystallized several times from ethyl ether, and dried over phosphorus pentoxide. The 1-trityl-2,3-dielaidin melted at 36.5–37.0°; mol. wt. 857 (calcd. 863); iodine value 58.5 (calcd. 58.8); yield, 20.2 g., 75.6%.

Anal. Calcd. for $C_{58}H_{86}O_5$: C, 80.69; H, 10.04. Found: C, 80.37, 80.46; H, 10.02, 10.08.

The 1-trityl-2,3-dielaidin (10 g.) was hydrolyzed to 1,3-dielaidin after the method of Verkade, *et al.*[4] The 1,3-dielaidin on slow crystallization from petroleum ether had the following constants: m. p. 54.0–54.5°; mol. wt. 619 (calcd. 621); iodine value 81.6 (calcd. 81.8), yield, 5.3 g., 73.6%. Slow crystallization was accomplished by slowly cooling to room temperature (approximately 25°) a petroleum ether solution of the 1,3-dielaidin saturated at 30–35°. Rapid crystallization, on the other hand, was accomplished by quickly chilling a subsaturated solution of the compound to −20°. Carter and Malkin[2] reported a melting point of 55° for the β form of this diglyceride when prepared by the direct reaction of elaidyl chloride with 1-monoelaidin.

The 1,3-dielaidin was also prepared by the elaidinization of 1,3-diolein[3] (m. p. 21.5°) as follows: 1,3-diolein (2 g.) was floated on 100 ml. of 30% nitric acid at room temperature. Small additions (*ca.* 250 mg.) of sodium nitrite were made, with stirring, until solidification occurred. A total of 1.0 g. of sodium nitrite was required over a period of thirty minutes. The 1,3-dielaidin was suction-filtered and washed with water until free of mineral acid. Slow crystallization from petroleum ether yielded 0.5 g. of a product melting at 55°. Mixed melting point with 1,3-dielaidin obtained by hydrolysis of the trityl derivative showed no depression.

The dielaidins prepared by the two different methods were hydrogenated to 1,3-distearin (m. p. 79.0°) by the method of Daubert, *et al.*[5]

X-Ray Diffraction Analysis.—The X-ray diffraction patterns of the different polymorphic forms were obtained by the same procedure as described by Sidhu and Daubert[6] for symmetrical diacid diglycerides.

In view of the comments of Malkin[2] in a recent publication criticising the X-ray procedure used in the first paper of this series, it is perhaps appropriate to emphasize again that *filtered* radiation has been used exclusively in the diffraction analyses of all of the glycerides thus far reported from this laboratory.

With reference to the mounting of specimens in nylon tubes, the standard procedure in X-ray diffraction work was followed. The diffraction pattern of the tube was taken with and without the specimens, exposing the tube to the same X-ray beam for the same length of time. This procedure has been followed in obtaining all of the data we have published so far on glycerides. The diffraction patterns of the nylon capillary tubes were taken and the lines thus obtained were carefully noted for structure, intensity, and position of the pattern. The effect on the intensities of the diffraction lines originating from the specimen due to superimposition of the nylon tube lines was ascertained by obtaining diffraction patterns of a few of the specimens without the use of nylon capillary tubes. Knowing the number of diffraction lines originating from the nylon tube, their position on the pattern, their intensities, and their effect on the intensities of the lines originating from the specimen, *d* values of the specimen were determined and intensities of the lines estimated. The diffraction data on all glycerides reported by us contain lines obtained from the specimens only.

Discussion

In confirmation of the observations of Carter and Malkin,[2] it was noted that slow crystallization of 1,3-dielaidin from solvent invariably yielded the *beta* form.

The *beta prime* form in the present investigation was obtained by rapid crystallization from solvent. Previous observations in our laboratory on the crystallization of diacid diglycerides[6] demonstrated that under similar crystallization conditions *beta* (*beta-a*) was obtained for some compounds, *beta prime* (*beta-b*) for others. Malkin obtained the *beta prime* form for 1,3-dielaidin from melted layers and rods. It will be seen from the data in Table I that the side spacings for the form obtained by rapid crystallization of dielaidin from solvent are in good agreement with those reported by Malkin for the *beta prime* form. No X-ray evidence could be found for an *alpha* form.

TABLE I

COMPARISON OF X-RAY DIFFRACTION DATA FOR 1,3-DIELAIDIN

	Malkin[2]			This study	
M. p. °C.	β	β′	α	β	β′
Long spacing, Å.	55 52.6	53 49.8	49	54.5–55.0 52.4	52.5 50.0
Side spacing, Å.	4.6 (S) 3.9 (S) 3.7 (S)	4.61 (S) 3.95 (W) 3.75 (S) 3.6 (W)		4.63 (S) 3.88 (S) 3.73 (S)	4.62 (S) 3.91 (W) 3.74 (S) 3.66 (W)

S = strong. W = weak.

In contrast to the data obtained for 1,3-dielaidin, Daubert and Lutton[3] found no X-ray or melting evidence for other than one form of 1,3-diolein. The complexity of the side-spacing data for that diglyceride was not conducive to characterization of the form as *beta prime* or *beta*. Although Carter and Malkin[2] reported a melting point (18°) based on cooling curve data for a supposed *alpha* form of diolein, they were not able to confirm the existence of the form by X-ray evidence.

In agreement with Malkin, it seems that the side-spacing data for the *beta* and *beta prime* forms correspond to those of the saturated diglycerides originally called *beta-a* and *beta-b*, respectively, by Malkin, *et al.*[7]

Summary

The preparation of 1,3-dielaidin by (1) direct synthesis from 1-trityl-2,3-dielaidin, a new compound, and (2) elaidinization of 1,3-diolein is reported.

The X-ray and melting point data confirm the observations of Malkin relative to the existence of two crystalline forms called by him *beta* and *beta prime*.

Regeneration of Insulin from Insulin Fibrils by the Action of Alkali

BY DAVID F. WAUGH

Insulin may be converted into highly asymmetric fibrils having lengths up to tens of thousands of ångström units and widths averaging about 150 Å.[1] Aggregation of these fibrils into spherites and the further clumping of spherites accounts for the visible heat precipitate of insulin.[2] Several investigations in which fibrils are produced by the unfolding of globular proteins and the aligning of polypeptide chains thus produced have been reported.[3] Evidence from monolayers, which showed that films of native insulin and fibrous insulin had the same properties[4] and the fact that mild treatment with alkali would greatly decrease the high viscosity of a suspension of fibrils indicated the possibility that the insulin particle (molecule) was *not* unfolded to any extent during fibril formation. This implies the linkage of corpuscular or globular units, a circumstance to be demonstrated in this publication. The reversible linkage of corpuscular units, along with the relative stability of the fibril, place insulin in a rather unique position of considerable importance.

Additional indications of reversion came from early studies of the "heat precipitate" of insulin.[5,6,7,8] In these it was claimed that the heat precipitate, inactive in itself, could be treated with alkali to give a product having at least 80% of the original activity. Greenstein, however, indicates that insulin may be opened up to expose disulfide groupings without loss of biological activity[9] and Rothen, *et al.*, report that surface films of insulin are active.[10] Thus reversion to the native state cannot be assumed on the basis of biological activity alone.

The present communication considers the reversion of insulin fibrils by alkali and compares the reversion product with native insulin. During the process of reversion of fibrils (or regeneration of insulin) the system contains fibrils and a reversion product which will be referred to as r-insulin. Native insulin will be referred to as n-insulin, insulin treated with alkali as a-insulin, and fibrous insulin as f-insulin.

Preparation of Fibrous Insulin

Quantitative knowledge concerning r-insulin and the process of reversion of f-insulin necessitated finding methods by which insulin could be converted completely into freely suspended insulin fibrils.

The following method is satisfactory. Crystalline zinc insulin 2% by weight in 0.035 to 0.05 *N* hydrochloric acid (*p*H about 1.8) is sealed in acid washed glass ampules, 2 cc. per ampule. The ampules are immersed for about five to twelve minutes in a water-bath at 100°. During this period weak flow double refraction and, in some cases, incipient flocculation appear.[11] At this time the ampule is cooled in tap water, dried, and frozen by immersion in solid carbon dioxide and acetone. After two minutes the tube is withdrawn, thawed, and reimmersed in water at 100° for five to eight minutes.

The initial heating period produces small numbers of relatively long fibrils. The effect of the freezing–thawing is to break such elongated fibrils into short segments. Each of these acts as a new center for elongation. Since fibril elongation is quite rapid at 100°[12] lateral alignment and spherite formation[2] do not take place. The tube gels within a few seconds and may remain clear except for light scattering associated with highly asymmetric particles. After orienting the fibrils (initially oriented at random) the tube shows intense interference colors when viewed between crossed polaroids. Gels prepared in this way will be referred to as standard fibrous gels.

Extent of Fibril Formation in Standard Gel.—The amount of n-insulin and material incapable of forming fibrils present in a standard fibrous gel may be estimated from the following.

1. Filtration through no. 50 Whatman paper removed over 95% of the nitrogen (fibrils) from the original gel. An ultra-fine Buchner funnel removes 99% of the nitrogen even after repeated washings. The great lengths of insulin fibrils may be appreciated from their inability to pass through such a filter paper.

2. It has been shown that insulin fibrils, once formed, will elongate rapidly at room temperature.[12] After mixing 2 ml. of 2% n-insulin and 0.8 ml. 2% fibrous insulin at 25° 86% of the n-insulin was converted into fibrils in forty-six hours. The reaction, which is pseudo monomolecular, has a Q_{10} (temperature coefficient) of about 4.0. If this material had been heated at 100° for six minutes, assuming a temperature coefficient of 4 over the range between 25 and 100°, less than 0.02% would have remained in the n-insulin form.

Under the conditions given for preparing a standard gel it is therefore estimated that conversion to fibrils is better than 99% and that unconverted n-insulin may be neglected. The possibility that n-insulin is adsorbed to fibrils is treated in the discussion.

Crystallization Procedure

A modification of the final crystallization of Romans, Scott and Fisher[13] was used. The preparation to be

(11) Flow double refraction is observed by tilting the vial between crossed polaroids. The flow thus produced aligns only the longer fibrils.

(12) D. F. Waugh, *Proceedings of Federation of Societies for Experimental Biology*, **5**, No. 1, 111 (1946).

(13) R. G. Romans, D. A. Scott and A. M. Fisher, *Ind. Eng. Chem.*, **32**, 908 (1940).

crystallized is brought to *p*H 5.3–5.5 with 0.3 *N* acetic acid and centrifuged for fifteen to twenty minutes with a clinical centrifuge (*ca.* 400 g.). The precipitate is dissolved in sufficient 0.327 *N* acetic acid to give a theoretical insulin concentration of 0.2 to 0.4%. A volume of 0.31 *N* ammonium hydroxide equal to the volume of acetic acid is added and the *p*H adjusted to 8.0. For each 10 ml. solution is then added 0.15 ml. of zinc acetate in 0.3 *N* ammonium acetate buffer at *p*H 6.0–6.3 containing 0.25 mg. of zinc per ml. The *p*H is then adjusted to 5.9–6.1 with 0.31 *N* ammonium hydroxide and crystallization is allowed to proceed for six days, after which the crystals are assayed.

Slight variations, mainly concerned with protein concentration, will be indicated in the text.

Assay of Crystals.—Amounts of crystals were obtained directly by washing in distilled water, drying and weighing. In most instances, however, samples of 10 mg. or less were used. Rapid and effective assays of such crystalline materials were obtained by transferring from the crystallizing vial to an assay tube consisting of a 10 ml. test-tube with a heavy-walled capillary 4 cm. long and 1.3 mm. in internal diameter sealed on the end. The assay tube was centrifuged on a clinical centrifuge for two to three minutes after which the length of capillary tube occupied by the crystals was measured. Insulin crystals, having a density considerably higher than any other materials present, pack first and the upper boundary of the crystalline material may be seen quite easily. The lengths of capillary occupied by the crystals may be converted to mg. of n-insulin in the crystallizing vial or to final mg. crystals with some degree of accuracy as shown in Table I and Table II. In Table I the first column gives the mg. of initial n-insulin crystallized in a final volume of about 10 ml.

TABLE I

THE CAPILLARY ASSAY OF CRYSTALLIZED INSULIN

n-Insulin, mg.	Crystal size	Capillary assay, mm.	Calculated capillary assay, mm./10 mg.
1	Small	1.5	15
2	Medium	3.0	15
3	Large	4.0	13.5
4	Large	5.5	13.7
5	Large	6.5	13.0
10	Large	13.5	13.5
10	Large	13.5	13.5
10	Small	13.5	13.5
10	Medium	13.5	13.5
10	Large	12.8	12.8
10	Large	13.5	13.5
			Av. 13.4 ± 0.1

Crystals from last six determinations weighed 38 mg. after careful washing which reduced the 80.3 mm. recorded above to 79.8 mm.

TABLE II

RELATIONSHIPS BETWEEN WEIGHT AND CAPILLARY ASSAY

Insulin type	Crystal size	Capillary assay mm. crystals	Crystal weight, mg.	M. crystals mm. assay
n-Insulin	Mixed	79.8	38.0	0.48
a-Insulin	Mixed	109.5	53.5	.49
a-Insulin	Small	49.5	25.0	.50
r-Insulin	Large	82.5	47.0	.57
r-Insulin	Mixed	126.5	64.5	.51
a-Insulin	Small	55.5	27.0	.49
			Av.	.51 ± 0.2

Medium crystals are between 30 and 80 μ. Large and small are on either side of this range.

The second column indicates crystal size, the third mm. crystals as measured in the assay capillary and the last column calculated mm. assay column for 10 mg. n-insulin. The first two values in the last column are probably too high due to the fact that small amounts were being assayed in a capillary which had a somewhat rounded end. The remaining figures average 13.4 mm. for each 10 mg. of n-insulin dissolved and crystallized.

Table II shows the relationship between total length in the capillary and the weights of these same crystals. In these, crystals from similar experiments were pooled. The first row of Table II represents the pooling of the last six samples of Table I. In column 1, Table II, a-insulin is insulin which has been first treated with alkali and r-insulin is material obtained after the reversion of fibrils. The second column gives crystal size, the third and fourth mm. in assay tubes and mg. dry weight of the same crystals and the last column the ratio, f, of mg. weight and mm. in assay tubes. The last column averages f = 0.5.

Effects of Alkali on Insulin

Sufficiently strong alkali irreversibly inactivates insulin. At the same time crystallizing potency is lost. These effects, for a given reagent, may be minimized by working at low temperature. Thus, at 36°, 0.033 *N* sodium hydroxide not only inactivates in three hours but, after twenty-five hours, 0.5% hydrogen sulfide appears.[14] At 0–4° the molecule is not appreciably affected after ten hours. According to Jensen and Geiling[15] insulin may be treated with 0.01 *N* alkali at 0° for forty-eight hours without noticeable loss in physiological activity.

The effects of alkali on the crystallizing ability of n-insulin have been examined. Figure 1 and Table III summarize the results. In all cases 10 mg. of n-insulin dissolved in 0.5 ml. of 0.035 *N* hydrochloric acid were added to 5.0 ml. of alkali of appropriate concentration at 0°. After the times indicated, the alkali was neutralized to *p*H 5.35 with 0.3 *N* acetic acid and the precipitate centrifuged and crystallized. The crystals within certain groups shown in Table III were pooled,

TABLE III

THE EFFECT OF 0.03 *N* SODIUM HYDROXIDE ON NATIVE INSULIN AT 0°

Time, min.	Crystal size	Crystal assay, mm.	Group
0	Large	11.25	
60	Small	14.35	
105	Small	14.2	I
180	Small	12.0	
300	Medium	6.0	
1380	Mixed	10.2	
14	Small	14.5	
19	Small	14.4	II
30	Small	14.5	
45	Small	15.5	

Group I, total mm. 49.5; total weight, 25.0 mg.; *f* = 0.50. Group II, total mm. 55.5; total weight, 27.0 mg.; *f* = 0.49.

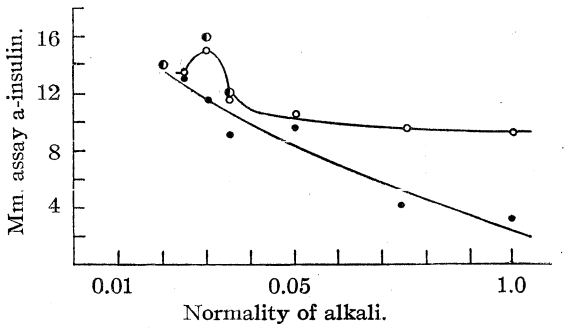

Fig. 1.—The effect of sodium hydroxide treatment on the crystallizing ability of *n*-insulin: ○, 345 min.; ◐, 405 min.; ●, 1380 min.

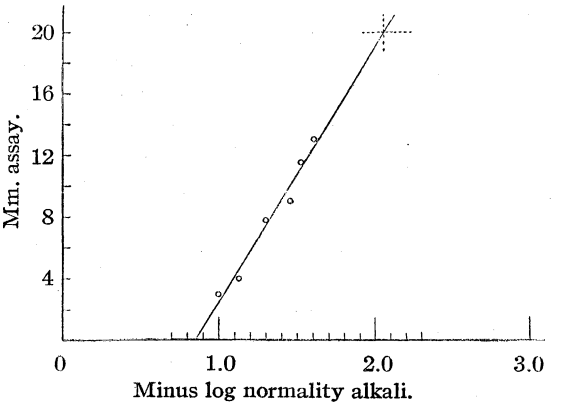

Fig. 2.—Recovery of insulin after 1380 minutes of treatment with sodium hydroxide of different concentrations. The intercept at 0 mm. indicates that 0.141 *N* alkali will abolish crystallization in this time. The abscissa corresponding to 20 mm. recovery indicates that 0.0085 *N* alkali is the maximum concentration which will have no effect in 1380 minutes (twenty-three hours).

washed with distilled water, dried *in vacuo* and weighed. The total mm. crystals and mg. dry weight are given at the base of the table for each group.

The data for 345, 405 and 1380 minutes are represented in Fig. 1. Recovery of crystals in mm. is plotted as ordinate against the normality of the alkali used. It seems that the shorter treatment times with alkali concentrations near 0.03 *N* "condition" the insulin so that a larger yield of crystals is obtained. Thus, although a yield of 13.5 mm. crystals is obtained with no alkaline treatment (see Table I), treatment with 0.03 *N* sodium hydroxide may increase this value to as much as 16 mm. as shown by the double circle of Fig. 1, the maximum for 405 minutes. However, the "conditioning" effect of alkali is not reproducible as seen by comparing the data for 0.03 *N* alkali at 300 and 180 min. in Table III with the values for 0.03 *N* alkali in Fig. 1.[16]

The longest time used, 1380 minutes, indicates a gradual destruction of insulin over the entire alkali range used. Thus one may assume that "conditioning" effects have been maximal at some previous time and that the expected slow destruction of insulin is taking place. Figure 2 represents a plot of the data for 1380 minutes using mm. recovery *versus* minus log normality. A small but undetermined displacement of the curve to higher abscissas and subtraction from 14 would bring these latter values in close correspondence with the *p*H's of the solutions. The alkaline destruction of insulin appears as a linear function of *p*H, thus indicating proton dissociation as being an important step. Extrapolation indicates first, that 0.141 *N* sodium hydroxide would reduce crystallization to 0 mm. in 1380 minutes, and second, that 0.0085 *N* sodium hydroxide is the highest concentration of alkali which will exert no effect on crystallization (recovery of 20 mm.) in the same length of time. Isolated values in the literature are in agreement with those predicted in this way.

The data of Fig. 1 and Table III indicate that 0.03 *N* sodium hydroxide is best for regeneration purposes. Table III, which shows slow destruction with times greater than one to two hours, suggests that regeneration be accomplished within sixty minutes. All recoveries are dependent upon crystallizing procedure.[16] It is felt that improvements in this technique will not appreciably alter these conclusions.

Alkaline Regeneration of Insulin from Fibrils

General Effects of Alkali on Spherites and Fibrils.—As indicated previously: alkali will disperse spherites into their constituent fibrils at *p*H's between 11.0 and 11.5. Above a *p*H of 11.5 the fibrils disappear, more rapidly as the *p*H increases. Thus at *p*H 12 to 14, fibrils disappear within a few hours to a few minutes. To minimize the inactivating effects of alkali experiments were performed at 0°. *p*H values as such were not measured but, as in the case of alkali-treated n-insulin, a standard procedure for treating insulin fibrils was used. Thus 0.5 ml. (containing 10 mg. protein) of the fibril preparation was mixed with 5.0 ml. of carbonate free alkali previously cooled to 0°. After standing the solution was brought to *p*H 5.35 with 0.3 *N* acetic acid, centrifuged, and the precipitate crystallized as described.

Initial Treatments of Standard Fibrous Gel.—As a preliminary, portions of standard gel were treated with 0.02, 0.25 and 0.03 *N* sodium hydroxide for eighteen and sixty-six hours. Even after sixty-six hours flow double refraction was present which decreased in the order 0.02, 0.025, 0.03 *N* alkali. Table IV shows typical results of crystallization. The first column shows

(16) The yield of crystals is a function of the crystallizing procedure as well as the alkaline pretreatment. Thus the "conditioning effect" of alkali might be expected to disappear under those conditions where a quantitative yield of crystallizable protein is obtained. One would expect 20 mm. crystals per 10 mg. insulin. This indicates that the crystallizing technique used recovers about 70 to 80% of the potentially crystallizable protein. It is probable that short alkaline treatments cause a more rapid crystallization, thus increasing relative yields. This is under investigation.

alkali concentration, the second time in hours and the third mm. crystals per 10 mg. of fibrils. With the exception of 0.02 *N* sodium hydroxide the longer treatment times destroy part of the r-insulin for the recovery falls. The low yields of r-insulin with 0.02 *N* sodium hydroxide indicated that longer treatment times would not be particularly effective. Methods were sought by which the rate of liberation of r-insulin could be increased.

TABLE IV

REGENERATION OF r-INSULIN FROM STANDARD FIBROUS GEL WITH ALKALI AT 0°

Alkali normality	Time in alkali hours	Mm. crystals per 10 mg. fibrils mm.
0.02	18	2.2
.02	66	8.2
.025	18	9.9
.025	66	3.7
.03	18	7.7
.03	66	5.5

Further Treatments of Standard Gel.—Among others, it was considered that the reversion of fibrils by alkali might depend upon the number of available fibril ends rather than on the total fibril surface area. Thus, that fibrils disaggregate in a sequence about the reverse of that in which they form. This was tested by freezing standard gel in solid carbon dioxide–acetone and thawing just before subjecting the fibrils to alkaline treatment.

As indicated previously[1] the effect of freezing and thawing is to break the longer fibrils into short segments. Such segments are quite active and will unite again in a matter of minutes at room temperature. Therefore the frozen-thawed material is treated immediately. Standard gels have been subject to multiple freezing-thawing cycles and have been treated with a number of alkali concentrations in the range 0.025 to 0.05 *N*. The results with 0.03 *N* sodium hydroxide are typical. With two freezing-thawing cycles and alkali exposure times of 30, 60, 300 and 1380 minutes assays showed 12.0, 11.0, 10.0 and 8.2 mm. crystals indicating, as found previously, that exposure times of sixty minutes or less are most effective.

Table V shows a typical experiment using forty-five min. exposure times with 0.03 *N* sodium hydroxide at 0°. The samples were frozen-thawed as

TABLE V

FREEZING–THAWING CYCLES AND REGENERATION YIELDS

These data were obtained with a modified crystalline technique

Freezing–thawing cycles	0	1	2	3	4
Calculated recovery, g.	0	5.2	7.2	7.2	7.6

shown in the first row, the row below giving recoveries, in mg., calculated from mm. assay. The sudden rise in regeneration yield with the first cycle and the smaller but significant rise with the second cycle are typical. Little is gained after two freezing–thawing treatments. This agrees with visual observation for, after two cycles, the insulin fibrils are clumped and are not further broken up.

Essentially the same results as those described have been obtained with mechanical methods for breaking fibrils (homogenization) thus eliminating any specific effects of freezing–thawing as increasing regeneration yield and indicating that the numerical increase in fibril ends is the responsible factor.

Table VI shows typical recoveries for 2, 3 and 4 freezing–thawing treatments using 0.3 *N* sodium hydroxide and times, at 0°, of ten, twenty, thirty and forty-five minutes. The averages shown in the last row for thirty and forty-five minutes indicate that about 12.0 mm. crystals may be realized from the reversion of 10 mg. fibrils. This figure may be compared with a figure of 14.5 mm. obtained after a similar alkaline treatment of native insulin (Table III and Fig. 1, 0.03 *N* alkali). If the crystallization properties of a-insulin and r-insulin are the same, 75 to 83% of the insulin in the fibrils may be recovered in crystalline form.

TABLE VI

REGENERATION YIELDS OF r-INSULIN AS AFFECTED BY TIME AND FREEZING–THAWING CYCLES AT 0° USING 0.03 *N* SODIUM HYDROXIDE

Freezing–thawing cycles	Mm. crystals per 10 mg. fibrils after treatment (time, min.) 10	20	30	45	Row
2	6	10.5	12.0	12.0	1
2	9.8	12.2	11.0	12.7	2
3	10.2	12.0	12.0	12.5	3
3	10.2	12.0	12.5	12.7	4
4	8.5	10.5	12.2	10.8	5
4	10.8	12.2	12.1	12.2	6
Average	9.2	11.6	12.0	12.1	7

Total crystals recovered from rows 2 and 3 weighed 47 mg.; from rows 4, 5, and 6, 64.5 mg.

The treatments described do not transform all of the fibrous material. The unreverted fibrils, after the crystallization following the first alkali treatment, may be recovered, washed, and subjected to another reversion treatment. In this way an additional 1–1.5 mm. of crystalline material may be obtained bringing the total recovery to 13 to 13.5 mm. or about 85 to 90% of the original protein. This is in good agreement with determinations of biological activity after alkaline treatment of the heat precipitate[5,6,7,8] in which reactivations of 80 to 100% have been claimed for biological activity and with our more recent regenerations by a variety of reagents.

From the foregoing information it appears that crystalline recoveries of 85 to 90% may be obtained by treating twice frozen–thawed fibrils with 0.03 *N* sodium hydroxide at 0° for forty-five minutes with a ratio of 0.5 ml. of 2% fibrils to 5.0 ml. alkali.

The Effect of Sodium Chloride on Alkaline Reversion of Fibrils.—Reversion has been carried out with the procedure described at the end of the preceding section with the addition of sodium chloride to the alkali. The results are summarized in Fig. 3 which shows mg. of recovery of crystalline r-insulin (calculated from mm. of assay and using 10 mg. of starting fibrils) plotted against the normality of sodium chloride present in the alkali. The resulting curve, an average of several values, shows that inhibition of reversion starts with salt concentrations somewhat in excess of 0.01 *N* and is marked at 1.0 *N*. With 2.0 *N* sodium chloride complete inhibition is obtained. These results will be considered in the discussion.

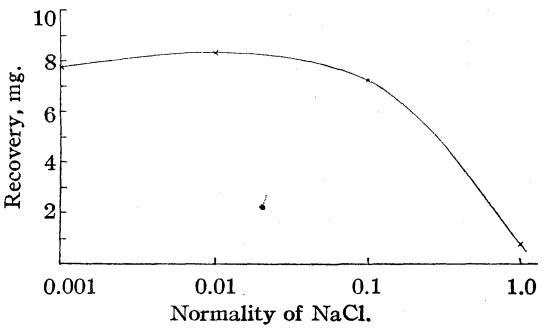

Fig. 3.—Regeneration of insulin from fibrils when various amounts of sodium chloride (abscissa) have been added to the regenerating alkali. Recoveries are calculated from mm. assay using $f = 0.5$.

Properties of r-Insulin Regenerated from Fibrils by Alkali

Crystallizatiom.—In agreement with the properties of n-insulin, crystallization of r-insulin will not proceed in the absence of zinc. Other metal ions which may be substituted for zinc have not been tested. In these experiments relatively zinc free preparations were made by dialyzing an acid solution of r-insulin and by precipitating an acid solution with organic solvents according to Scott.[17] Recrystallization of the same preparations in the presence of zinc produced typical crystals.

r-Insulin and n-insulin have the same crystal form although r-insulin generally gives somewhat larger crystals than n-insulin. A comparison of recrystallized n-insulin and r-insulin with a petrographic microscope reveals the two types of crystals described by Abel, Geiling, Rouiller, Bell and Wintersteiner.[18] The type showing well-defined negative double refraction seemed more numerous in n-insulin samples, r-insulin containing proportionately more crystals having well defined edges with little double refraction.

The recoveries of r-insulin and n-insulin were not significantly different on recrystallization.

Biological Activity.—Crystals of r-insulin and n-insulin were washed with distilled water and dried *in vacuo*. Biological assays arranged by Dr. R. E. Thompson[19] gave

r-insulin, 20.2 units per mg. ± 5.9%
n-insulin, 22.1 units per mg. ± 7.8%

The small difference between regenerated and native insulins is not considered significant and is probably due to inert protein, the drying procedure, or some other uncontrolled factor.

Ultracentrifuge Determinations.—Recrystallized n-insulin was converted to standard fibrous gel and r-insulin was regenerated. The resulting r-insulin crystals were carefully washed and a clear lot isolated. This amounted to 42.4% by weight of the initial insulin. Dr. J. L. Oncley[20] has compared the behavior of n-insulin and r-insulin in the ultracentrifuge.

Dr. Oncley writes, "Solutions of insulin crystals obtained from r-insulin containing 1 and 2% of protein were studied in an air-driven ultracentrifuge[21,22] equipped with a modified Philpot schlieren optical system.[23] The measurements were made in a cell 1.5 cm. high, 1.0 cm. thick, whose center was 6.5 cm. from the axis of rotation. A speed of 54,000 r.p.m., equivalent to centrifugal forces of from 200,000 to 240,000 times gravity, was used and the average temperature was about 24°. Values of sedimentation constant have been reduced to the value in a solvent of the density and viscosity of water at 20°. A phosphate buffer of 0.1 ionic strength, *p*H 7.2, was used as a diluent. The protein solutions were made by dissolving dried insulin crystals in a small volume of dilute hydrochloric acid and neutralizing with a phosphate buffer calculated to yield a final ionic strength of 0.1 and *p*H 7.2. A solution made from ordinary crystalline insulin (from beef)[24] was used for comparison. Sedimentation diagrams of unmodified crystalline insulin and the crystals obtained from r-insulin were compared and found to be practically identical. The sedimentation constant usually assigned to crystalline insulin at this *p*H was obtained, that is, about 3.3 to 3.6.[25,26,27] The diagrams from the r-insulin showed no more evidence of faster moving components than is usually obtained from commercial insulin crystals, and the 'apparent diffusion constant' obtained by analysis of the sedimentation diagrams was only slightly larger than the observed diffusion con-

stant, again indicating the homogeneity of the materials."

In addition the ultracentrifuge data suggest that r-insulin is able to go through the same cycle of reversible fragmentation as n-insulin.

Sensitivity to Alkali.—Crystallization of the isoelectric precipitate obtained after treating 0.5 ml. of 2% crystalline r-insulin (10 mg.) with 5.0 ml. of 0.03 *N* sodium hydroxide at 0° for times of 0 to 400 minutes gave consistent yields of about 95% ± 5% up to times of 200 minutes after which the recovery fell to 86% and at 400 minutes 84%. Up to 200 minutes, therefore, r-insulin seems less sensitive to alkali treatment than n-insulin since treatment of n-insulin with 0.03 *N* alkali usually gives yields of about 80% with times up to 200 minutes (Table III). This difference, at present, cannot be interpreted as showing significant differences between the effects of alkali on r- and n-insulins but could be due to the crystallization procedure which may handle r-insulin somewhat better than n-insulin.[16]

Labile Ammonia.—It has been considered generally that liberation of ammonia accompanied the heat precipitation of insulin although du Vigneaud, Sifferd and Sealock[8] found no relationship between amounts of ammonia liberated and heat precipitate formed. Insulin fibrils seeded into solutions of n-insulin will elongate at room temperature and transform the n-insulin into fibrils.[12] One can therefore test for liberation of ammonia at 25°. n-Insulin and n-insulin seeded with short fibrils (80 mg. n-insulin, 20 mg. short fibrils) were dialyzed against 10 ml. 0.01 *N* hydrochloric acid. All dialysis fluids, by Nesslerization, had the same nitrogen contents within the experimental error. The liberation of 0.03% nitrogen could have been detected.

Disulfide and Sulfhydryl.—The nitroprusside reaction[8] was used to test for free sulfhydryl groups. This has been shown to be negative in n-insulin and fibrous insulin.[28] Free disulfides, as shown by the cyanide–nitroprusside reaction, do not increase on fibril formation. This test is not particularly indicative since n-insulin gives a strong cyanide–nitroprusside reaction equivalent to about 25–30% of the total sulfur present.

In agreement with others[8] reduction with cyanide abolishes the heat precipitate and fibril formation. The status of the disulfide linkage will be treated in the discussion.

Fibril Formation with r-Insulin.—When dissolved in 2% concentrated at *p*H 1.6–1.7 (0.05 *N* hydrochloric acid) n-insulin remains quite stable at 20° or below and shows evidence of fibril formation only after many weeks, and, in instances, months.

Unpurified products of alkaline reversion precipitated at *p*H 5.35 and taken up in acid show rapid fibril formation at room temperature or in the ice chest. Treatment with alkali, however, usually does not revert quantitatively since the presence of unreverted fibrils may be demonstrated by double refraction of flow or other methods. These act as active centers,[12] elongate at low temperatures, and under proper conditions give rise to products ranging from the heat precipitate to a clear fibrous gel. In order to compare r-insulin and n-insulin these unreverted fibrils must be removed. Recrystallization has been used with success. The r-insulin after the first recrystallization differs from n-insulin in forming a fibrous gel having brilliant double refraction in two to three minutes at 100° and in showing slow but appreciable fibril formation at room temperature over a period of several days. The insulin was dissolved in 2% conc. in 0.05 *N* hydrochloric acid (*p*H 1.6–1.7). Under the same conditions twice recrystallized r-insulin, washed many times with distilled water, shows rapid fibril formation at 100° but at room temperature very faint flow double refraction only was detected after several weeks. After a third recrystallization the product, representing 46% by weight of the initial fibrous insulin, showed no double refraction or alterations in other properties, such as viscosity and clarity, over a period of fourteen weeks. At 100° the thrice-recrystallized r-insulin seems to show fibril formation slightly faster than commercial, untreated n-insulin. However, fibril formation is sensitive to a number of variables including salt concentration, *p*H, anions, etc. Thus n-insulin will show varying rates of fibril formation, particularly at higher temperatures, after manipulations such as recrystallization. The rates of fibril formation obtained with thrice recrystallized r-insulin at 100° are well within the normal range.

Repeated crystallization, therefore, leads to an r-insulin which approaches n-insulin in the characteristics of fibril formation at low and high temperatures.

Discussion

The physical, chemical and biological tests applied cannot thus far differentiate between r-insulin and n-insulin. These tests include crystallization, ultracentrifuge analysis, biological activity, changes in labile groups such as amino and disulfide, and fibril formation. Before an analysis is undertaken consideration should be given to the extent to which n-insulin enters into the basic fibril forming reaction. Thus, high yields of r-insulin of 80–90% do not rule out the possibility that 10% of the n-insulin irreversibly unfolds and gives rise to a fiber "skeleton" while the remaining 90% is physically adsorbed to this skeleton as n-insulin. Several lines of evidence exclude this possibility. First, the adsorption of n-insulin onto fibrils has been examined in connection with reaction kinetics. Adsorption becomes important only at *p*H's well above 3.0. Second, fibrils form and elongate at *p*H's which render insulin highly soluble and in which strong repulsive forces would be

(28) M. L. Sackler, Chemical Modifications of Insulin and Their Relation to Fibril Formation, Master's Thesis, 1945, Massachusetts Institute of Technology, Cambridge, Mass.

expected to occur between the molecules.[2] Third, washing a fibrous gel with acid does not produce elution. Fourth, the fibril once initiated can elongate at room temperature or below.[12] Insulin shows its maximal stability at *p*H's close to 2.0 at low temperatures and would not be expected to show spontaneous unfolding under these conditions. Fifth, the fibril, in alkali, liberates r-insulin selectively from its ends and not uniformly over the entire surface as one might expect from a skeleton containing 4 to 9 times its weight of adsorbed material. It seems reasonable to conclude that all of the n-insulin enters the basic fibril structure.

Native insulin may be defined on the basis of certain intrinsic properties such as crystallizability, biological activity and fibril forming capacity. Although there is evidence that these characteristics may be dissociated to some extent (*i. e.*, an insulin which will form fibrils but will not crystallize), certain series are recognized (*i.e.*, if an insulin crystallizes it also has biological activity and shows fibril formation). In this way, crystallization emerges as a delicate test for insulin, other properties requiring less precise structure.

A number of modifications of insulin have been reported. Such modifications may be divided into those involving mainly surface groups and those in which internal structure has been obviously altered. Examples of the first type are the acetylation of insulin with ketene[29] reported by Stern and White and the linking of insulin with diazonium salts reported by Reiner and Lang.[30] In instances these "surface" modifications retain their biological activity and form crystals. A number of reagents, used primarily for surface group modification, are suspected of causing internal structural changes. In these cases both biological activity and crystal formation are irreversibly lost. Directed changes in internal structure have been quantitatively studied thus far by reduction of some of the disulfide groups (of which seven or eight are usually available out of a total of 23). Reduction of an average of 1 or 2 groups per molecule leads to a 50% loss in biological activity.[31] On *reoxidation* the activity decreases to about 1% of original. More drastic reduction[8,28,32] causes a complete loss of crystallizability, biological activity and fibril formation. It should be mentioned here that an extensive unfolding of the protein would be expected to involve the breaking of several disulfide linkages. On the basis of evidence mentioned a refolding with the formation of new disulfide linkages should lead to a product having none of the intrinsic characteristics of insulin. Mild alkaline treatment[28] may lead to a simultaneous loss of biological activity and crystallizability while treatment with concentrated solutions of guanidine and urea may produce a complete loss of crystallizing ability with only a slight diminution in fibril forming capacity.

Thus it would appear that demonstrable changes in internal structure lead to irreversible loss of one or more of the characteristic properties. r-Insulin retains these labile characteristics completely. From this and the fact that fibril elongation may proceed below 20° it is concluded that fibril formation involves the endwise linkage of globular (corpuscular) units which are not appreciably unfolded in the process.

A Note on "Denaturation."—According to most definitions the stable fibrous form of insulin would represent a denatured protein, for the fibrils retain few of the properties of n-insulin. Regeneration, however, shows that the insulin molecules have not lost these properties irreversibly. It seems obvious that four general factors determine the over-all reversibility of this system. These are the strength of the intermolecular bond, the ability of a regenerating agent to overcome this bond, and the ability of the fibrils and reversion product to withstand the damaging action of the reverting (regenerating) agent. The rates of the several reactions enter as important variables. A somewhat stronger inter-insulin bond would require more drastic alkaline treatments. These would effect reversion but the r-insulin liberated would be inactivated and irreversibly altered during the process. If the sequence of events were not clearly recognized, one might conclude that the n-insulin had suffered irreversible changes during the process of fibril formation itself. Many coagulations have been considered irreversible. Evidence should be presented which shows that the structure of the protein has been irreversibly altered during the process of coagulation and not subsequently.

Mechanism of Reversion.—Calculations from amino acid analyses and titration data[33,34] show that a molecule of insulin of molecular weight 40,000 contains about 80 free carboxyl groups, 40 free amino groups, and 50 hydroxyl groups, some of which are available.[9]

Fibril formation and fibril aggregation or heat precipitation[2] have been shown to be dependent to a marked degree on mechanisms which change the repulsive forces between the molecules. It seems clear that acid *p*H's are necessary to produce a variety of insulin which can enter the fibril forming reactions. However, once this condition has been fulfilled the addition of neutral salt, such as sodium chloride, greatly increases the rate of fibril formation, presumably by causing a decrease in electrostatic repulsion. In acid solution, *p*H's below 3.0, one would expect the carboxyl groups to be largely un-ionized and thus a quantity of insulin corresponding to mol. wt. 40,000 would have

about 40 positive charges. The effect of salt would be to decrease the repulsive forces due to these charges and allow a greater proportion of the molecular collisions to be effective in bonding.

At the regenerating *p*H of about 12.3 one would expect the amino groups to lose their charge while the carboxyl groups and some hydroxyl groups would now ionize and become charged. Thus the net charge would change from an average of roughly +40 to over −80. It seems clear that the great increase in net charge in going from acid to alkali would set up stronger repulsive forces which would aid in disrupting the inter-insulin bond. Evidence in support of this mechanism as being part of the process comes from the action of salt, which decreases reversion as shown in Fig. 3, and those experiments which indicate that reversion proceeds at the ends of the fibrils where the inter-insulin bonds would be weakest since fewer insulin units would be engaged in their stabilization. Reversion and the inter-insulin bond are receiving further attention.

Acknowledgment.—The author wishes to acknowledge the generous support which Armour and Company has given to this and other research.

Summary

Insulin fibrils may be reverted by treatment with alkali to give a crystalline product similar to native insulin: the alkali has therefore regenerated an insulin termed r-insulin. Limiting conditions for regeneration procedure were determined by studying the effect of alkali on native insulin. Using 0.5 ml. of 2% insulin (10 mg.) and 5.0 ml. of sodium hydroxide experiments indicated 0.03 *N* alkali, 0°, and forty-five minute treatment time would be optimal. This was found to be the case. In addition reversion of fibrils is greatly accelerated by increasing the number of available fibril ends suggesting that disaggregation occurs mainly at these positions. Sodium chloride in the alkali inhibits reversion by 90% in 1.0 *N* concentration. Thus, the repulsive forces between similarly charged groups may play a part in the mechanism of disaggregation.

The crystalline product from reverted fibrils is not significantly different from native insulin in certain intrinsic properties such as: crystallization, in which r-insulin will not crystallize in the absence of zinc, and recrystallization recovery; biological activity (20 I.U. per mg.); ultracentrifuge pattern (sedimentation constant 3.3–3.6); and fibril formation (at 20 and 100°). Tests for changes in labile groups, such as amino and disulfide, have been negative.

The absence of changes in labile groups, the retention by r-insulin of the characteristic properties of insulin, the known sensitivity of these characteristic properties to structural changes, and the fact that fibril elongation may take place at low temperatures in the *p*H region of maximum stability, are interpreted as showing that only small structural changes take place during fibril formation and that the process is therefore one in which globular or corpuscular units are linked endwise.

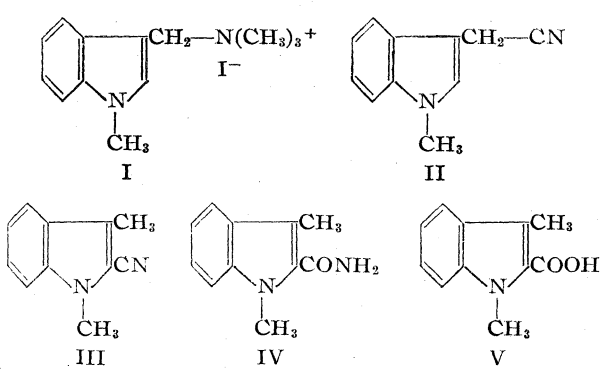
An Allylic Rearrangement in an Alkylation by a Quaternary Ammonium Salt

BY H. R. SNYDER AND ERNEST L. ELIEL

In a previous communication[1] it was stated that the reaction of 1-methylgramine methiodide (I) with aqueous sodium cyanide produced not only 1-methyl-3-indoleacetonitrile (II) but also an isomer of this nitrile. This isomer has now been identified as 1,3-dimethyl-2-cyanoindole (III). The pure isomer (III) was isolated from the reaction mixture in 4.3% yield, but in view of the difficulties encountered in the purification it is believed to have been formed in an appreciably larger amount, perhaps to the extent of 10–15%.

Comparison of the infrared absorption spectra of (II) and its isomer revealed a shift of the CN-absorption band of 36 cm.$^{-1}$ toward smaller wave numbers in the case of the isomer (III) (see the figures), indicating conjugation of the cyano group with one of the double bonds of the rings. Alkaline hydrolysis of the isomeric nitrile (III) yielded mainly the corresponding amide and only very



small amounts of the acid, probably because of steric hindrance of the nitrile function. The acid was finally obtained in poor yield by increasing the concentration of alkali and extending the reaction time in the hydrolysis.

The acid (V) was synthesized by a known

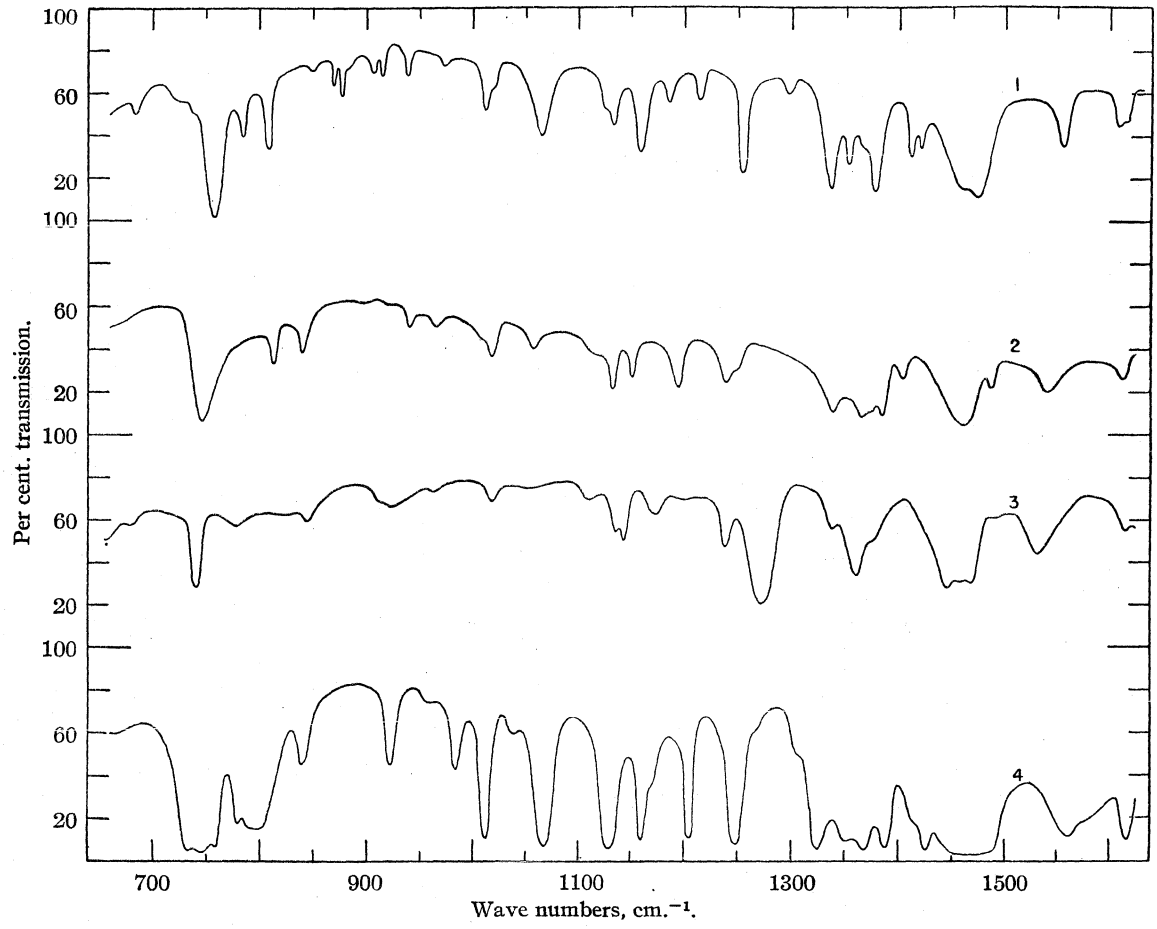
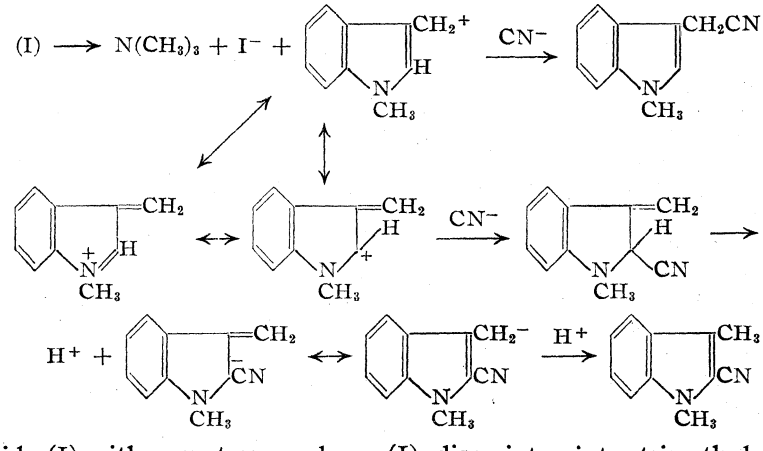


Figs. 1a, b.—Infrared absorption spectra: 1, 1-methyl-3-indoleacetonitrile; 2, 1,3-dimethyl-2-cyanoindole; 3, 1,3-dimethyl-2-indolecarboxylic acid (two identical spectra); 4, 1,3-dimethylindole (two identical spectra). Curves 1, 2 and 3 were obtained from Nujol suspensions. The absorption bands due to Nujol C–H frequencies occur

method[2] from *as*-methylphenylhydrazine and α-ketobutyric acid obtained by hydrolysis of α-benzoylaminocrotonic azlactone.[3,4] 1,3 - Dimethyl - 2 - indolecarboxylic acid (V) thus obtained proved to be identical with the hydrolysis product of the nitrile (III). The acid (V) prepared by nuclear synthesis was converted into its amide by treatment with phosphorus pentachloride in acetyl chloride solution followed by reaction with concentrated aqueous ammonia. This amide was identical with the one from the partial hydrolysis of the nitrile (III). Formulas III and IV must therefore be assigned to this nitrile and the corresponding amide.



It has thus been proved that in the reaction of 1-methylgramine methiodide (I) with sodium cyanide rearrangement occurs along with the normal reaction. The migration may be explained by the provisional assumption that the quaternary base (I) dissociates into trimethylamine and a carbonium ion which may rearrange, as shown in the accompanying diagram. An analogy exists in the reaction of furfuryl chloride with sodium cyanide to give 5-methyl-2-furo-

at 2920, 2855, 1460 and 1375 cm.$^{-1}$. Sample no. 4 was seen in a liquid cell of 0.05 mm. thickness. The low transmission of the two nitriles in the high frequency regions is due to the light scattering of the crystals in the Nujol suspension.

nitrile.[5,6] Simple α,β-unsaturated halides, on the other hand, do not seem to undergo rearrangement in reactions with sodium cyanide,[5] but do so in reactions with sodium carbonate in water and with various metallic acetates in acetic acid solution.[7-10]

Experimental[11,12]

2-Cyano-1,3-dimethylindole (III).—The product of the reaction of 18.1 g. of 1-methylgramine methiodide with sodium cyanide[1] was fractionated *in vacuo* through a short Vigreux column. The fraction collected at 96–109° (0.15 mm.) and twice recrystallized from petroleum ether (b. p. 30–60°) formed large white prisms of m. p. 69.5–70.5°, weight 0.32 g. The next fraction, b. p. 109–120° (0.15 mm.), was twice extracted with hot petroleum ether (b. p. 30–60°). After the waxy residue of this extraction had been freed of insoluble oils by pressing on a porous plate, it dissolved in the hot petroleum ether extract. The crystals which separated from the cooled solution were recrystallized five times from petroleum ether to yield 0.08 g. of material of m. p. 69–70.5° [total yield, 0.40 g. (4.3%)].

1,3-Dimethyl-2-indolecarboxamide (IV). From III.—A solution of 0.39 g. of the above nitrile and 1 g. of potassium hydroxide in 1 ml. of water and 9 ml. of ethanol was refluxed for twenty-two hours. After dilution of the mixture with 4 ml. of water most of the ethanol was distilled. Crystals of the amide (IV) which separated from the cooled solution were collected, washed and dried; yield, 0.30 g. (69.5%). The amide crystallized from benzene in fine white needles, m. p. 213–214°.

Anal. Calcd. for $C_{11}H_{12}N_2O$: C, 70.18; H, 6.43; N, 14.89. Found: C, 70.18; H, 6.48; N, 14.70.

From the alkaline mother liquors of the hydrolysis of the nitrile, only 0.01 g. of acid could be isolated.

1,3-Dimethyl-2-indolecarboxylic Acid. From the Amide.—A solution of 0.19 g. of the above amide and 1 g. of potassium hydroxide in 0.5 ml. of water and 4.5 ml. of ethanol was refluxed for fifty-six hours. After dilution of the mixture with 4.5 ml. of water the alcohol was distilled. The cooled solution was filtered to remove unchanged amide. The filtrate was extracted with ether, boiled with charcoal, filtered, and acidified. The acid was collected, washed with water, and dried; yield, 0.04 g. (21%). After recrystallization from benzene–petroleum ether (b. p. 30–60°), from benzene, and again from benzene–petroleum ether, the acid melted at 215–216° (dec.).

Anal. Calcd. for $C_{11}H_{11}NO_2$: C, 69.81; H, 5.86. Found: C, 69.97; H, 5.79.

From α-Benzoylaminocrotonic Azlactone.—Five grams of a mixture of the *cis* and *trans* forms of α-benzoylaminocrotonic azlactone[13] of m. p. 118–122° was hydrolyzed by refluxing for three hours with 200 ml. of 1 *N* hydrochloric acid.[3] After the solution had cooled, 3 g. of what was presumably a mixture of α-benzoylaminocrotonic and benzoic acids was removed by filtration. The filtrate was neutralized with 2 *N* sodium hydroxide, and a solution of 3.4 g. of *as*-methylphenylhydrazine in 10 ml. of water and 5 ml. of glacial acetic acid was added to it. After standing overnight the solution was chilled and the solid methylphenylhydrazone that had separated was collected and washed. It was suspended in a solution of 15 ml. of concentrated hydrochloric acid in 30 ml. of water, and the mixture was heated on the steam-bath with swirling for thirty minutes. The suspension was cooled and filtered, and the solid was dissolved in aqueous sodium hydroxide. After removal of oily impurities by ether extraction, the aqueous solution was boiled with charcoal, filtered and acidified. The acid that separated was collected, washed with water and dried at 60°; yield, 1.3 g. (29.4% from the azlactone). After three recrystallizations from benzene, the melting point of the acid (and of mixtures with the acid described in the preceding paragraph) was 215–216° (dec., lit.,[2] 213°). The infrared absorption spectra[14] of the samples obtained by the two different methods were identical (see the figures). Both samples separated from benzene solution as needles which in contact with the mother liquor soon changed into crystals of granular texture.

Decarboxylation of the above acid at 225° followed by distillation at 15 mm. (bath temperature 130–160°) yielded 1,3-dimethylindole, identified by its refractive index ($n^{20}D$ 1.5929), infrared absorption spectrum (see the figure), and the melting point and mixed melting point (142.5–143°) of the picrate. The sample used for comparison had been obtained by hydrolysis and decarboxylation of 1-methyl-3-indoleacetonitrile (II).[1]

1,3-Dimethyl-2-indolecarboxamide. From the Acid.—A suspension of 0.32 g. of the above acid (V) in 3.2 ml. of redistilled acetyl chloride was cooled in an ice-bath and 0.42 g. of phosphorus pentachloride was added. The mixture was swirled until homogeneous and then allowed to stand at room temperature for two and three-fourths hours. The solvent was removed *in vacuo* with the bath temperature not exceeding 45°. The solid residue was chilled and 10 ml. of ice-cold concentrated aqueous ammonia solution was added to it. The temperature was slowly raised to 72° over a period of thirty minutes with constant stirring. The suspension of the amide was then cooled and the solid was collected, washed with concentrated aqueous ammonia followed by water, and dried at 60°; yield, 0.28 g. (87.5%). After two recrystallizations from benzene–absolute alcohol the product melted at 213.5–214°. The mixed melting point with the amide obtained by hydrolysis of 1,3-dimethyl-2-cyanoindole (III) was 213–214°.

(13) The azlactone was kindly put at the authors' disposal by Dr. H. E. Carter.

(14) The authors are indebted to Mrs. Agatha Roberts Johnson for the absorption studies.

Summary

The reaction of the methiodide of 1-methyl-3-dimethylaminomethylindole with aqueous sodium cyanide affords, in addition to the normal alkylation product, a small amount of 1,3-dimethyl-2-cyanoindole. The structure of this product has been proved by conversion to the corresponding amide and acid which were identical with compounds obtained by independent syntheses.

Studies on Double Refraction of Flow. IV. Human Serum γ-Globulin and Crystallized Bovine Serum Albumin[1]

BY JOHN T. EDSALL AND JOSEPH F. FOSTER[2]

In previous papers of this series, the molecular dimensions of zein[3] and of fibrinogen[4] have been studied by the method of double refraction of flow, the results being interpreted in the light of viscosity, sedimentation and other measurements. In the present study, we report results of similar investigations on human serum γ-globulin[5] and crystallized bovine albumin.[6] The orientation of these molecules, by means of a velocity gradient, to an extent sufficient for accurate double refraction measurements, required the use of solvents of high viscosity, in order to diminish the rotary Brownian movement. Whereas fibrinogen, with a molecular length near 700 Å., could be readily studied in 40% glycerol, γ-globulin required 60–76% glycerol, and serum albumin approximately 90% glycerol.

(1) This paper is Number 68 in the series "Studies on the Plasma Proteins" from Harvard Medical School, Boston, Massachusetts, on products developed by the Department of Physical Chemistry, and Number XVII in the series "Preparation and Properties of Serum and Plasma Proteins" from the same laboratory.

The preparations of serum globulin employed were prepared from blood collected by the American Red Cross, under a contract recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Harvard University.

Experimental Methods

The apparatus used[7] and the methods of measurement[3,4] have already been described in detail.

The great majority of the measurements on γ-globulin were made on a single preparation (IIG1-L371) prepared from Fraction II + III of human plasma[8] by method 3c as described by Oncley, *et al.*[5] Electrophoretically, this preparation contained 97% γ-globulin, 2% albumin, and 1% β-globulin. Such preparations, however, have been

(8) E. J. Cohn, L. E. Strong, W. L. Hughes, Jr., D. J. Mulford, J. N. Ashworth, M. Melin and H. L. Taylor, THIS JOURNAL, **68**, 459 (1946).

shown by Oncley, Scatchard and Brown[9] to be heterogeneous in the ultracentrifuge. The implications of this heterogeneity are further discussed later in this paper. One run not reported in detail here was made on preparation IIG1-120, with results essentially indistinguishable from others in the series.

The crystallized bovine albumin was from lot 27–315, prepared at the Armour Laboratories according to methods developed by Cohn and Hughes.[6]

The glycerol–water mixtures used as solvents were prepared by the method previously described for the studies on fibrinogen. The γ-globulin preparations contained a small amount of sodium chloride in addition to the glycerol–water used as solvent. No salt was added to the albumin preparations. At the very high glycerol concentrations employed in the studies of albumin (88.5–94.5% by weight) the viscosity varies rapidly with slight changes in the composition of the solvent. Therefore, great care was taken in the control of glycerol concentration. Both γ-globulin and albumin gave clear and stable solutions in the glycerol-water mixtures employed.

Experimental Results

γ-Globulin.—A series of measurements on γ-globulin preparation IIG1-L371 was made at protein concentrations varying from 1.25 to 5 g. per 100 cc., and at glycerol concentrations varying from 60 to 76%. In almost all of these experiments, studies were made at two different temperatures; one set near 6° and the other at 18 to 19°. The results of one experiment are given in detail in Table I, together with the calculated values of the rotary diffusion constants (Θ) derived from the measurements. The values of Θ are not reported as such, but are multiplied by the ratio of the viscosity of the solvent (η) to the absolute temperature (T), since these $\eta\Theta/T$ values should be independent of the particular solvent and temperature employed, as long as the molecules retain their shape. The values of the extinction angle, χ, in two experiments were so close to 45° that the probable error in the calculations is very large, and the resulting values of $\eta\Theta/T$ are given no weight. These values are enclosed in parentheses in the final column of Table I. The other values are all reasonably consistent, and lead to an over-all estimated $\eta\Theta/T$ of 22 poise per sec. per degree (see Table II). The double refraction measurements are reported in the second half of Table I. The measured phase differences are a linear function of the product ($G\eta$) of the velocity gradient and viscosity, at $G\eta$ values up to 4000 or above. The increase of phase difference at higher velocity gradients is slightly less than linear, as would be expected from theoretical considerations.

From the measured value of $\eta\Theta/T$ the length of the molecule may be calculated if it is assumed for simplicity to be an ellipsoid of revolution. An approximate estimate of the axial ratio, derived for instance from viscosity measurements, must be employed in making this calculation, but the value of the derived length is very insensitive to the exact value. The length, l, assuming the molecule to be an elongated ellipsoid of revolution, is given by the equation

$$l^3 = 1.5\frac{kQ}{\pi}\left(\frac{\eta\Theta}{T}\right)^{-1} \qquad (1)$$

where k is Boltzmann's constant and $Q = -1 + 2\ln 2a/b$. For a/b we have taken the value 5.35 given by Oncley, Scatchard and Brown[9] and derived from viscosity and sedimentation data. This gives for γ-globulin a Q value of 3.74, so that the length ($2a$) in Å. becomes $l = 627(\eta\Theta/T)^{-1/3}$. Thus, the calculated length from the experiments in Table I is 224 Å., slightly below the value of 235 reported by Oncley, Scatchard and Brown.[9]

In Table II the results of these and other experiments on γ-globulin are summarized, and some of the data are reported also in Figs. 1, 2 and 3. It is immediately apparent that there is a marked downward trend in $\eta\Theta/T$ as the concen-

[a] Solution in acetate buffer, pH 3.93 before addition of glycerol. All other solutions studied at pH near 7.

(9) J. L. Oncley, G. Scatchard and A. Brown, *J. Phys. Colloid Chem.*, **51**, 184 (1947).

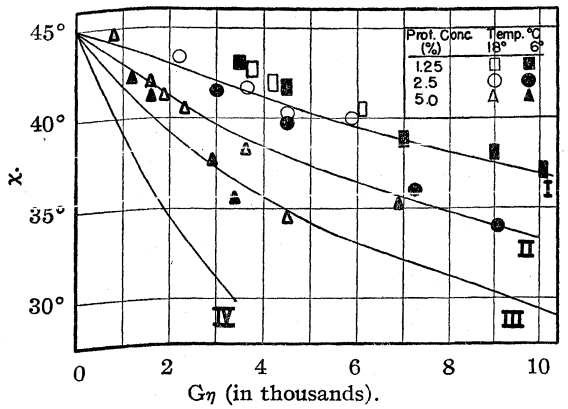

Fig. 1.—Value of χ as a function of $G\eta$ for solutions of human γ-globulin. Curves I, II, III, and IV are calculated as discussed in the text. Curve I is for the pure monomer, 235 × 44 Å. Curve IV is for the pure dimer, 470 × 44 Å. Curve II is for a mixture of 95% monomer and 5% dimer. Curve III is for a mixture of 85% monomer and 15% dimer. Points are experimental values derived under the conditions indicated in the figure.

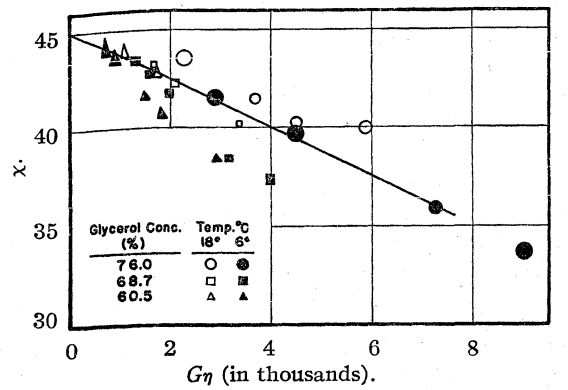

Fig. 2.—χ Values for human γ-globulin solutions as a function of $G\eta$ at various temperatures and glycerol concentrations. Protein concentration in all experiments indicated between 2.5 and 3.3 g./100 cc. Points are experimental values; the curve is calculated for a single molecule, for which $\eta\Theta/T = 13$.

tration of protein increases. This trend is similar to that already observed in the case of zein (concentration range 1 to 3%) and fibrinogen (concentration range 0.12 to 0.5%). Clearly it must be attributed to interactions between the protein molecules. As is to be expected, the influence of increasing concentration becomes apparent at relatively high dilutions in the case of fibrinogen solutions, where the molecules are very long. In the case of zein and γ-globulin, the concentration effects are marked only at concentrations considerably above 1%.

The effect of variation in glycerol concentration (Fig. 2) is rather less striking than that of variation in protein concentration. The observed χ values, at a given value of $G\eta$, deviate somewhat more from 45° in the solvents of low glycerol content and therefore of low viscosity. The effects, however, are relatively small and it is probably premature to attempt to interpret them at this time.

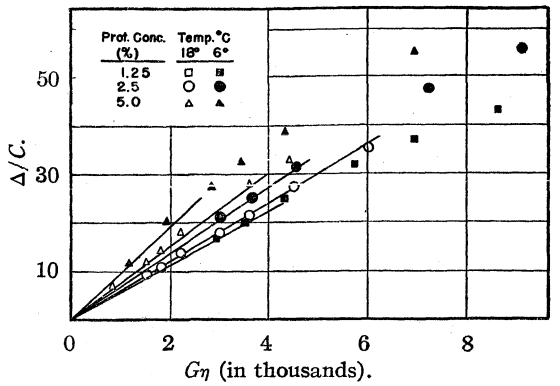

Fig. 3.—Double refraction of γ-globulin as a function of $G\eta$ for three different concentrations and two different temperatures. Ordinates are expressed as measured phase differences divided by concentration; these may be converted to double refraction values ($n_e - n_0$) by the conversion factor given in the footnote to Table IV.

The effects of temperature are indicated in Figs. 1, 2, and 3 by plotting the results at low temperature using shaded symbols, and those at the higher temperature using open symbols. The χ values, plotted as functions of $G\eta$, appear very little affected by temperature. What small effects are discernible are in the direction that would be expected on the basis of decreased Brownian movement and increased protein–protein interaction at the lower temperature.

The specific double refraction values (Δ/c), when plotted as a function of $G\eta$ (see Fig. 3 and Table II) show a definite upward trend with increasing protein concentration and a slight downward trend with increasing temperature at constant concentration. Both these effects are in the direction that would be expected from the effects of concentration and temperature on protein–protein interaction.

In two experiments, indicated by asterisks in the first column of Table II, the *p*H of the γ-globulin solution was adjusted to 3.93 before glycerol was added. The results obtained in these runs were indistinguishable from others in the series, indicating that the size and shape of the γ-globulin molecules were unaltered in the more acid solution.

Calculations for a Two-Component System.—γ-Globulin preparations, of the type studied here, although electrophoretically homogeneous, show at least two major components in the ultracentrifuge. The sedimentation constant, s_{20}, is near 7.2 *S* for the major component (75–85% of the total) and approximately 10 *S* for the chief secondary component. Oncley, Scatchard and Brown,[9] who reported these data, tentatively interpreted them on the assumption that the $s = 10$ component

was a dimer, made up of two molecules of the $s = 7$ component associated end to end. The viscosity data were entirely compatible with this view. We have, therefore, examined the applicability of the same hypothesis to the double refraction of flow measurements.

For simplicity, we have assumed both monomer and dimer to be ellipsoids, the former being 235 Å. long, as assumed by Oncley, Scatchard and Brown,[9] and the latter 470 Å. long. The principal axis of the cross-section of both ellipsoids was taken as 44 Å. Such a model is certainly oversimplified, but the available evidence at this time scarcely warrants a more refined treatment. On calculating rotary diffusion constants for the ellipsoidal molecules, we find for the large molecule (component 1) that $\eta\Theta_1/T = 3.26$ and for the small molecule (component 2) that $\eta\Theta_2/T = 18.2$.

The fundamental equations for double refraction of flow in a polydisperse system have been given by Sadron[10] (see also Peterlin and Stuart[11]). The equations and figures in the papers of Peterlin and Stuart[11,12] give values of χ and of the relative double refraction, f, as a function of $\alpha = G/\Theta$, in a form which may be applied to each individual component with a given Θ value. In evaluating the double refraction given by the system composed of monomer and dimer, we have assumed that both components would give the same amount of double refraction at the same weight fraction in solution, if all the molecules in both solutions could be oriented with their major axes parallel.[13]

Values of χ were calculated for the two component system for two cases, assuming the weight fraction of dimer to be 0.15 in the first case and 0.05 in the second. The resulting curves for χ as a function of $G\eta$, for both these systems, are shown in Fig. 1, together with the corresponding curves for the monomer and dimer alone. Experimental data at several concentrations are indicated by the points in the figure. It is apparent that, at the two lowest concentrations studied, the experimental data approximate very closely to the calculated curve for the small component and show no evidence of the presence of the dimer. At the highest concentration of protein (5%), the data, for the most part, lie in the region between the two calculated curves for the polydispersed system. It is, therefore, possible to interpret the increased molecular interaction which is manifest at the higher protein concentrations, either as being due to an orienting influence exerted by each protein molecule on its neighbors in its field of flow, or to an actual association of some of the molecules into longer units.

(13) Details of the method of calculation for polydisperse systems will be given in a separate note by H. A. Scheraga and the present authors.

These results are obviously different from those of Oncley, Scatchard and Brown[9] who observed a considerable amount of the $s = 10$ component even at the lowest concentrations studied, and did not observe any great change in the ultracentrifuge diagram with change in protein concentration. However, their studies were carried out in aqueous solution, whereas ours were made in 60–76% glycerol. It is possible that the addition of glycerol causes a dissociation of the dimer molecules into the smaller units, and that under these conditions it is necessary to go to considerably higher protein concentrations before association occurs. The most striking conclusion from our own observations, however, is the remarkably good agreement at low protein concentrations between the experiments and the calculated values for a molecule approximately 235 Å. long, postulated as the main component by Oncley, Scatchard and Brown.[9]

We have based our calculation of a length of 220–230 Å. on the values obtained at the lowest protein concentration studied, and have not attempted to extrapolate the data to infinite dilution. If such an extrapolation were made on the basis of the data in Table II, using a linear plot of $\eta\Theta/T$ against concentration, we should obtain a still lower value for the length than that reported above, and the agreement with the other data would be less good. However, the basis for such an extrapolation is still uncertain and we have preferred, for the present, to use the experimental values at the lowest concentration studied.

Bovine Serum Albumin.—Only three experiments on serum albumin were carried out, and two of these gave rather fragmentary results, on account of the great technical difficulty of making observations in media of such extremely high viscosity. The results of the most extensive and satisfactory experiment are listed in Table III. In such experiments, the large amount of energy dissipation in the liquid during the maintenance of a velocity gradient leads to heating of the liquid to an extent which is difficult to compensate for by the circulation of water at constant temperature through the jacket of the outer cylinder. The dissipation of energy in the liquid per second is equal to $G^2\eta$ per unit volume.[14] Even more serious than the rise of temperature produced is the fact that thermal gradients are produced in the liquid, which can distort the path of the light beam and falsify the optical measurements. These difficulties have been discussed in detail by Björnståhl,[15] but we have not attempted to apply his quantitative calculations to our data, since the boundary conditions which Björnståhl assumed at the inner and outer cylinders do not correspond to the conditions existing in our apparatus. All these difficulties indicate that the results of the meas-

Our values for $\eta\Theta/T$ are of the order of magnitude of 30 for serum albumin. For horse serum albumin (carbohydrate free) Oncley[16] has found from dielectric dispersion measurements two critical frequencies (0.44 and 2.1 megacycles, referred to solutions in water at 25°) corresponding to $\eta\Theta/T$ values of 41 and 195, respectively. The higher value would not be detectable in our apparatus, but the lower one is remarkably close to our own measurements, particularly in view of the great difference—200 to 500 fold—in the viscosities of the solvents employed in the two series of measurements. Recent dielectric dispersion studies on human and bovine serum albumin give rotary diffusion constants very close to those of horse serum albumin.[17] On the other hand, the molecular model assumed by Oncley, Scatchard and Brown[9]—namely, an elongated ellipsoid of revolution with a major axis of 150 Å. and a minor axis of 38 Å.—gives a calculated value of $\eta\Theta/T$ of 61. The length calculated from our own data is only about 30% greater than that of the model of Oncley, Scatchard and Brown. On the whole, in view of the difficult conditions under which our measurements were made, it may be concluded that the agreement is remarkably good, and our results may be taken as an approximate confirmation of those deduced[9] from ultracentrifuge, diffusion, viscosity and dielectric dispersion measurements.

Interpretation of Double Refraction Measurements (Phase Differences) for Protein Solutions.—Measurements of the magnitude of the double refraction in solutions of zein, fibrinogen, γ-globulin and serum albumin have been tabulated in this and preceding papers of this series. The data, when expressed as double refraction, $n_e - n_0$, divided by $G\eta c$, show a difference of more than 600-fold between fibrinogen and serum albumin. The values for γ-globulin and zein are roughly twenty times as large as those for albumin, and of the order of one-thirtieth of those for fibrinogen.

These differences, however, are largely a reflection of the very different degrees of orientation obtained, at the same $G\eta$ value, for protein molecules of various lengths. To compare the birefringence of the different proteins in solution, the ideal arrangement would be to obtain completely parallel orientation of the axes of all the protein molecules in each solution, and measure the birefringence under these conditions, which is obviously the maximum attainable for the given system. Such a direct measurement is of course impossible in practice, owing to the Brownian movement of the protein molecules, but the results that would be so obtained can be derived by calculation from the actual experimental data, employing the theoretical treatment of Peterlin and Stuart.[11,12] They have expressed the observed double refraction, $n_e - n_0$, at any given velocity gradient, as the product of an optical factor, $g_1 - g_2$, and an orientation factor $f(\alpha, a/b)$.

$$n_e - n_0 = \frac{2\pi\Phi}{n}(g_1 - g_2)\, f(\alpha, a/b) \qquad (2)$$

Here Φ is the volume fraction of protein in the system, n is the refractive index of the solvent, and a/b is the axial ratio of the ellipsoidal molecule.

The function f is the same orientation function previously mentioned in connection with the calculation for the two component system. At low velocity gradients (low α values) f reduces to the form

$$\lim_{\alpha \to 0} f = \frac{\alpha}{15}\frac{a^2 - b^2}{a^2 + b^2} \qquad (3)$$

When all the molecules of any given species are oriented with their axes parallel, f becomes equal to unity.[18] Hence, from the observed values of the two quantities, $(n_e - n_0)/G\eta c$ and $\eta\Theta/T = G\eta/\alpha T$, it is possible to evaluate the amount of double refraction for any of the proteins studied at the degree of orientation attained when $\alpha = 1$. One may then calculate the maximum double refraction, $n_e - n_0$, for a 1% solution at complete orientation. These values are given in the next to the last column of Table IV. The final column contains the optical anisotropy factor, $g_1 - g_2$, for each protein as calculated from equation 3.

It should be clearly recognized that even the

Gl, followed by a percentage figure, denotes a glycerol–water mixture containing the indicated percentage glycerol; P. G. is propylene glycol. The zein preparation was laboratory zein (Foster and Edsall). Values for refractive index ($n^{20}D$), for glycerol–water mixtures, from L. F. Hoyt, *Ind. and Eng. Chem.*, **26**, 329 (1934); for proyplene glycol, from A. G. Pukirev, *Trans. Inst. Pure Chem. Reagents* (Moscow), **15**, 45 (1937), as reported in *Chem. Abstracts*, **32**, 5378 (1938). Other symbols are explained in text, or previous tables. It should be noted that the double refraction values are given for $\lambda = 546$ mμ, although the available data for the refractive indices of the solvents are given for the sodium D line. The differences in refractive index for the two wave lengths, however, represent only second order effects in the phenomena considered here. For our apparatus (length of cylinder 7 cm.) and for light of wave length 546 mμ, $n_e - n_0$ is related to the observed phase difference Δ, by the equation: $n_e - n_0 = 4.24 \times 10^{-8}\ \Delta$.

values of $g_1 - g_2$ so calculated are not inherent characteristics of the protein molecules themselves. Actually $g_1 - g_2$ is a function of two terms, the intrinsic birefringence of the protein itself and the form birefringence which depends upon the differences in refractive index between the protein molecule and the solvent. The refractive index of most protein molecules for light of the wave lengths here considered is in the range 1.57 to 1.61.[19] For serum albumin, Armstrong, Budka, Morrison and Hasson[20] have calculated a value (nD) of 1.598, and for γ-globulin a value of 1.618. These values are for the anhydrous protein, however, and take no account of solvation. We have attempted to calculate the intrinsic birefringence of the proteins studied here, employing the value 1.60 as the mean refractive index of the protein, and using the values for the refractive index for the solvent given in Table IV.[21] Our calculations yielded negative values for the intrinsic birefringence of all the proteins studied; in other words, if these calculations are to be trusted, the axis of maximum polarizability in these proteins is perpendicular to the long axis of the molecules. We are not yet confident, however, that this conclusion is correct, since the effects of solvation may be important, and may vary from one solvent to another. To draw definite conclusions, it would be necessary to study these proteins in a variety of solvents with a much wider range of refractive index than we have yet employed.[22] It would appear, however, that fibrinogen is not only the most geometrically asymmetrical of all the molecules, but optically the most anisotropic, while serum albumin is the least. γ-Globulin, while less geometrically asymmetrical than zein, shows a higher degree of optic anisotropy. Both γ-globulin and zein were studied in solvents of very nearly the same refractive index; hence this conclusion should apply directly to the intrinsic birefringence of these molecules.

Discussion

The only previous study of double refraction of flow in serum albumin and globulin, of which we are aware, is by Sadron, Bonot and Mosimann.[23] The plasma fractions which they studied were obtained by ammonium sulfate fractionation, and the globulin fractions are not directly comparable to ours.[24] Their serum globulin preparations contained considerable lipid which, in glycerol–water mixtures, became detached from the protein and gave rise to birefringence of opposite sign from that produced by the protein. The γ-globulin preparations studied by us, on the other hand, were practically lipid-free, so that this complication did not arise. From the curves for extinction angle given by Sadron, Bonot and Mosimann[23] for their serum globulin, it is apparent that $\eta\Theta/T$ was of the order of unity but somewhat less; and hence only about one-twentieth of the value found for our γ-globulin. Their figure would correspond closely to that to be expected for a very elongated molecule of the order of 900 Å. in length, of the sort observed in sera of high antibody titer in several species of animals.[25]

(19) M. P. Putzeys and Mlle. J. Brosteaux, *Bull. soc. chim. biol.*, **18**, 1681 (1936). Values close to 1.57 are also obtained from measurements of the double refraction of protein fibers determined in media of varying refractive index; see for instance H. H. Weber, *Arch. ges. Physiol.*, **235**, 205 (1934–1935).

(20) S. H. Armstrong, Jr., M. J. E. Budka, K. C. Morrison and M. Hasson, THIS JOURNAL, **69**, 1747 (1947).

(21) The equation for resolving observed birefringence into form and intrinsic birefringences are given by Peterlin and Stuart, ref. 12, pages 13 and 135. There is a misprint in the formulas as given on page 13; the term L_1L_2 should read $L_1 - L_2$.

(22) The streaming birefringence of tobacco mosaic virus in glycerol–aniline–water mixtures was studied by M. A. Lauffer, *J. Phys. Chem.*, **42**, 935 (1938). The observed birefringence fell practically to zero in a solvent of refractive index near 1.57; hence this virus protein appears to possess little or no intrinsic birefringence.

(23) Ch. Sadron, A. Bonot and H. Mosimann, *J. Chim. Phys.*, **36**, 78 (1939).

(24) The species of animal from which their plasma was taken is not explicitly stated, but it would appear from the context that it was horse plasma.

(25) See for instance E. A. Kabat, *J. Immunol.*, **47**, 513 (1943). It is not necessary to assume that the lipoprotein in the globulin preparations of Sadron, *et al.*, was identical with the elongated component giving rise to double refraction of flow. It seems probable that the preparation contained several components and that the lipoprotein was a less elongated protein molecule than some of the others.

Sadron, *et al.*, could obtain no evidence of double refraction of flow in their crystallized serum albumin preparations. This is in qualitative accord with our own results, since the albumin preparation studied by us gave no detectible double refraction in 70% glycerol, and it was only when the concentration of glycerol approached 90% that a measurable degree of orientation was obtained. Some of the other albumin fractions studied in Sadron's work did show appreciable double refraction, with values of $(n_e - n_0) \times 10^{10}/G\eta c$ ranging from 0.2 to 1.1, as compared with 0.12 for our preparation. Corresponding values for Sadron's globulin fractions G_1 and G_2 were 3.1 and 5, respectively, very close to those for human γ-globulin as reported in Table IV. Thus, the double refraction values of Sadron's preparations are quite similar to ours, although the rotary diffusion constants differ considerably.

Oncley[16] has studied the dielectric dispersion of γ-pseudoglobulin from horse plasma. The two frequencies obtained by him correspond to $\eta\Theta/T$ values of 6 and 53, respectively. The former value is not far from that obtained by us for human γ-globulin in the highest concentrations studied; but, as already indicated, our values under these conditions are greatly influenced by association or molecular interactions, or both. It is probable that the horse γ-pseudoglobulin is a more elongated molecule than the main component of the human γ-globulin. The latter preparation contains a considerable amount of euglobulin, which precipitates at *p*H near 7 at very low ionic strength. Dielectric dispersion measurements on this preparation can be made, therefore, only on the pseudoglobulin component, and are not yet available for comparison.

In the previous study of fibrinogen,[4] we have given a detailed analysis of several possible molecular models, in light of all the available experimental evidence. In the case of albumin and γ-globulin, we have little to add to the discussion already given by Oncley, Scatchard and Brown.[9] The γ-globulin preparations certainly contain more than one component, and therefore a detailed analysis based on a model containing only a single component would hardly be profitable to carry out.[26] The results on serum albumin presented in Table III represent measurements made under extremely difficult conditions, on account of the high viscosity of the liquid and the small amount of double refraction observed. Under the circumstances, we consider it remarkable that the agreement between our data and those obtained from the ultracentrifuge, viscosity and diffusion measurements is as good as it is. Oncley, Scatchard and Brown[9] calculated a length for serum albumin of 150 Å., whereas our estimates would lead to a value of 190–200 Å. We believe that our value deserves far less weight than theirs, and present it simply as confirmatory evidence for the general consistency of our results and those obtained by other methods.

Summary

1. Double refraction of flow measurements have been made on purified human serum γ-globulin and crystalline bovine serum albumin, employing as solvents glycerol–water mixtures of high viscosity.

2. The measurements of γ-globulin lead to an estimated molecular length near 230 Å., in excellent agreement with the value deduced from ultracentrifuge, viscosity and diffusion measurements by Oncley, Scatchard and Brown.[9] The γ-globulin preparations, at least in dilute solution, behaved as if the protein molecules were uniform with respect to molecular length.

3. The measurements of serum albumin lead to an estimated length of 190–200 Å., but this value is considered less reliable than the figure of 150 Å. previously reported by Oncley, Scatchard and Brown.[9]

4. Critical comparison has been given of the amount of double refraction given by four different proteins under comparable conditions.

BOSTON, MASS. RECEIVED JANUARY 2, 1948

(26) It should be remembered in this connection, that Oncley, Scatchard and Brown give dimensions for the *hydrated* protein molecule. Since their measurements were carried out in aqueous solution and ours in glycerol–water mixtures, the degree of solvation of the protein cannot be expected to be identical in these different media. Obviously some change in the frictional coefficient must occur when the protein is transferred from one solvent medium to the other. We have no basis at present for calculating what this change is likely to be, although it seems probable that it is small.

Methane Formation in the Photolysis of Acetone at 130°[1]

BY WALLACE DAVIS, JR.[2]

The quantum yield of carbon monoxide formation during the photochemical decomposition of acetone has been found to be unity at temperatures slightly above 100°,[3] thus permitting this reaction to be used as an actinometer. Ethane has been reported as the main hydrocarbon produced under the experimental conditions used by most authors, although small amounts of methane have usually been found. The work of Spence and Wild[4] indicates that under certain experimental conditions the amount of methane formed may be quite large. Hence in using the photochemical decomposition of acetone as an actinometer the fraction of the products uncondensed by liquid nitrogen must be analyzed for both carbon monoxide and methane (as well as for traces of ethane) to ensure accurate results.

This paper presents results of a study of methane formation during the photochemical decomposition of acetone at temperatures ranging from 126 to 138°. While certain statements concerning the reaction mechanism are permissible at the present time, details will be left for later presentation after further information is available.

Experimental

The methods of purifying the acetone and of analyzing the reaction products have already been described.[5] The light source and filter solutions used for isolation of the 3130 Å. line of mercury have also been described.[6] The basic equations used for calculation of light absorbed[7] have been expanded[5] and need not be repeated here.

Some of the experiments (6A–18A in Table I) were made using the AH-6 General Electric Company high pressure arc, the beam diameter being 10 mm. The remaining experiments (19A–21A in Table I) were performed with a UA30A2 Hanovia medium pressure arc with a beam diameter of 15 mm.

The values of I_a (the "absorbed intensity") given in Table I have been obtained by dividing the number of quanta absorbed per second by the acetone by the volume of the light beam. Since the cell was 200 mm. in length the latter has the values 15.7 and 35.4 cm.^{3}, respectively, for the two light beams referred to in the preceding paragraph. The light absorbed per unit path length is not constant and moreover the intensity is undoubtedly not uniform over a given cross section of the beam. Nevertheless the quantity given is the average number of quanta absorbed per cc. per second in the light beam and it is believed that this figure represents most nearly the one which should be used in rate equations for those cases in which any activated molecules and free atoms or radicals do not diffuse appreciably out of the light beam.

TABLE I

Results and Discussion

Table I presents the data on quantum yield of methane formation from the photochemical decomposition of acetone at temperatures ranging from 120 to 138°. Since it has been shown previously that the quantum yield of carbon monoxide formation is very close to unity at these temperatures,[3] the values are based on that assumption and should be taken, in reality, as relative values.

Since the carbon monoxide yield is certainly very close to unity, any acetyl radicals produced in the primary process must decompose almost immediately either thermally or due to energy retained from the primary process. Hence for this case of high temperatures one may write

$$CH_3COCH_3 + h\nu = 2CH_3 + CO \qquad (1)$$

Methane is almost certainly produced by the reaction

$$CH_3 + CH_3COCH_3 = CH_4 + CH_2COCH_3 \qquad (2)$$

Methyl radicals can disappear by reaction (2) as well as by reactions (3) and (4)

$$CH_3 + CH_3 = C_2H_6 \qquad (3)$$

$$CH_3 + CH_2COCH_3 = CH_3CH_2COCH_3[8] \qquad (4)$$

The acetonyl radicals can also form biacetonyl

$$2CH_2COCH_3 = (CH_2COCH_3)_2 \qquad (5)$$

If reactions (1) to (5), inclusive, are all that can occur and it is assumed that they are all homogeneous gas phase reactions, some kinetic expressions could be derived providing analyses could be

made for all of the products. If C_2H_6, CH_4, and CO were all known certain conclusions would be possible.

The pressures are high enough in the present experiments to ensure that the majority of the bimolecular reactions will occur homogeneously. Consequently the derived expression for the quantum yield becomes so complex that it cannot be applied to the data without making assumptions. It seems best to defer a detailed theoretical treatment until a later date. It may be stated, however, that if the energy of activation for (3) is low,[9] the energy of activation of (2) must also be low.

Summary

1. The quantum yield of methane formation during the photochemical decomposition of acetone in the temperature range 120 to 138° has been determined.

2. In a general way the yield of methane increases with increase in acetone pressure and with decrease in intensity, but a detailed discussion of theory is postponed until a later date.

3. The energy of activation of the reaction $CH_3 + CH_3COCH_3 = CH_4 + CH_3COCH_2$ must be low.

The Photochemical Decomposition of Diethyl Ketone at 3130 Å.[1]

BY WALLACE DAVIS, JR.[2]

Previous work[3] has indicated some ethylene and ethane to be produced along with carbon monoxide and butane during the photochemical decomposition of diethyl ketone at wave lengths below 2000 Å. These same products in different proportions have been reported at longer wave lengths.[3,4] Bamford and Norrish[4] suggested that the Type III decomposition directly into ethylene and propionaldehyde proposed by Norrish and Appleyard[5] would account for the ethylene formed, although these authors did not identify propionaldehyde positively. Disproportionation of ethyl radicals to ethylene and ethane has also been suggested.[3]

This paper presents determinations of the quantum yield of various products during the photochemical decomposition of diethyl ketone.

Experimental

The diethyl ketone used in this work was purified by Dr. A. B. F. Duncan for spectroscopic experiments. C. P. diethyl ketone, b. p. range 5°, was washed with potassium carbonate and sodium bisulfite to remove acids and peroxides. After drying over anhydrous calcium chloride the ketone was fractionally distilled in a column, a portion with a boiling range of 0.1° being kept. This product was further fractionated several times at low pressure.

The determination of carbon monoxide was accomplished by removing that portion of the products not condensed by liquid nitrogen. For short runs combustion of this fraction over CuO at 200–240° indicated pure carbon monoxide within experimental error. For longer runs leading to a larger amount of product, duplicate oxygen combustion analyses indicated that as much as 5% of this fraction was a C_2 hydrocarbon.

The C_2 hydrocarbons (C_2H_4 and C_2H_6) were separated from other products, after removal of carbon monoxide by being removed at −165° using a Ward apparatus[6] with a Toepler pump. In some experiments only the quantity of C_2 hydrocarbons was determined; in others this fraction was burned with oxygen on a platinum filament at about 600°. The combustions were all carried out with a trap immersed in dry ice between the filament and any source of mercury vapor to minimize oxidation of the latter.

After removal of the C_2 hydrocarbons, another fraction was removed at about −120°. This fraction was shown to be butane either by vapor pressure measurements or by combustion.

Other experimental details have already been published.[7-9]

Results and Discussion

The quantum yields of carbon monoxide and of C_2 hydrocarbons from diethyl ketone at several temperatures and intensities are presented in Table I. It will be noted that the variation in pressure is small. Experiments 1D–12D were made with a A-H6 General Electric Company high pressure mercury arc, while runs 13D–16D were made with the Hanovia UA30 A2 Uviarc.

It is seen that $\Phi_{CO} = 1.0$ within a 13% experimental error in runs 1D–7D and 11D. For the uviarc runs $\Phi_{CO} = 1.03 \pm 0.05$, assuming a calibration error of not to exceed 1.6%. Therefore the quantum yield of the primary process

$$C_2H_5COC_2H_5 + h\nu = 2C_2H_5 + CO \qquad (1)$$

must be close to unity unless some secondary reaction gives rise to carbon monoxide formation. The absence of any real increase of carbon mon-

[a] Φ_{CO} for Run 15D taken as the average of Φ_{CO} from Runs 13D and 14D.

In view of the fact that ethane exceeds ethylene considerably under the conditions of these experiments, these two gases cannot be formed mainly by a disproportionation reaction and the ethane can arise from a reaction of the type

$$C_2H_5 + C_2H_5COC_2H_5 = C_2H_6 + C_2H_4COC_2H_5 \quad (2)$$

This reaction would be analogous to that of methane formation in acetone.[10] One of the main competing reactions for ethyl radicals will certainly be that of butane formation

$$C_2H_5 + C_2H_5 = C_4H_{10}$$

Some ethyl radicals may disappear in forming the compound $C_2H_5COC_4H_9$, but a complete analysis of all products would be necessary before a detailed mechanism could be developed.

From equations (2) and (3) the quantum yields of ethane and of butane formation are found to be given by the following expressions

$$\Phi_{C_2H_6} = k_2(C_2H_5)(C_2H_5COC_2H_5)/I_a \quad (4)$$

$$\Phi_{C_4H_{10}} = k_3(C_2H_5)^2/I_a \quad (5)$$

where the subscripts of the k's correspond to the equation numbers. Hence one may write

$$\Phi^2_{C_2H_6}/\Phi_{C_4H_{10}} = k_2^2(C_2H_5COC_2H_5)^2/k_3I_a \quad (6)$$

If it is assumed that butane is formed by all ethyl radicals which do not form ethane, one can apply equation (6) to the data in Table I. Unfortunately the data are not extensive enough to warrant many conclusions, particularly since the fates of all ethyl radicals are undoubtedly not given by equations (2) and (3) alone. However, equation (6) is at least approximately obeyed.

If one writes $k_2 = a_2\ exp\ (-E_2/RT)$ and $k_3 = a_3\ exp\ (-E_3/RT)$ the data at about 136° and at about 26° may be used to calculate $2E_2 - E_3 = 5000$ cal. with an uncertainty of about 1500 cal. While an exact value of E_3 is not known, the figure is considered to be small.[11] Thus E_2 may be as little as 2500 cal. and probably is less than 5000 cal.

It is evident that the amount of ethane depends markedly on light intensity, as well as on temperature, and that at high intensities butane should be formed relatively more than at low intensities. If ethylene is formed solely by a disproportionation reaction its yield also would be expected to increase at high intensities. More work is necessary before details of the mechanism can be stated, but complete analysis for all possible products will be difficult.

Summary

1. The quantum yields of CO and of C_2 hydrocarbons during the photochemical decomposition of diethyl ketone have been determined at several temperatures ranging from 26 to 138°.

2. The C_2 hydrocarbons produced during the reaction consist almost solely of C_2H_6.

3. The energy of activation of the reaction $C_2H_5 + C_2H_5COC_2H_5 = C_2H_6 + C_2H_4COC_2H_5$ may be as low as 2500 cal. and is almost certainly below 5000 cal.

Ionic Hydration and Activity in Electrolyte Solutions

BY R. H. STOKES[1a] AND R. A. ROBINSON[1b]

General Introduction

There are two useful lines of approach to the problem of explaining activity data in electrolyte solutions. The first is to extend the treatment of Debye and Hückel (which was developed for dilute solutions) to moderately high concentrations by applying relevant "corrections." This method has received a great deal of attention in the past twenty years or so. The other is to examine data for very concentrated solutions, where the Debye–Hückel treatment is certainly not applicable, seeking relationships which may throw light on the general problem. In this paper it is shown that the concept of ion–solvent interaction, or ionic hydration, is capable of explaining quantitatively a large body of experimental observations in both cases. Part I discusses a modified form of the Debye–Hückel equation, introducing the effect of ion–solvent interaction in terms of "hydration," which is applicable up to ionic strengths of about 4. In Part II the effect of the solvent at concentrations above about 12 M is approached in another way, similar to that of the Brunauer–Emmett–Teller adsorption isotherm.

I. A One-parameter Equation for Activity Coefficients.—The evaluation by Debye and Hückel[1c] of the free energy change due to the coulomb forces between ions led to a tremendous expansion of our understanding of the behavior of electrolyte solutions. There is now no doubt that the familiar Debye–Hückel expression

$$\log f = -\frac{A\sqrt{c}}{1 + B\mathring{a}\sqrt{c}} \qquad (1)$$

gives an adequate representation of the activity coefficients of normally dissociated salts of 1:1 and 2:1 valence types in sufficiently dilute solutions, in terms of the single arbitrary parameter å (the mean distance of "closest approach" of the ions), and the volume concentration c. Equation (1) however predicts an activity coefficient which is always a decreasing function of the concentration, whereas experimentally a minimum usually occurs, followed by a more or less rapid rise of the activity coefficient at high concentrations. Hückel[2] explained this effect in terms of the change in dielectric constant of the solvent near the ions, which led to a second arbitrary constant D in the equation

$$\log f = -\frac{A\sqrt{c}}{1 + B\mathring{a}\sqrt{c}} + Dc \qquad (2)$$

Equation (2) has been of great practical value, and has been extensively employed for the extrapolation of standard potentials and for the representation of activity coefficient data.[3] Its theoretical foundations have, however, been frequently criticized. Furthermore, it usually fails to give a reasonably accurate representation of observed activity coefficients at ionic strengths much greater than unity. To overcome this, further arbitrary terms in c^2 and even higher powers are sometimes introduced, but such equations are of no theoretical value.

In recent years our knowledge of activity coefficients in concentrated solutions has been greatly extended, mainly through the application of the isopiestic vapor pressure technique. It has become increasingly clear, especially in the case of 2:1 electrolytes, that any treatment of the properties of concentrated solutions must take specific account of the hydration of the ions. There seems to be no adequate alternative explanation of the fantastically high activity coefficients often encountered at high concentrations. For instance, a 5 M solution of magnesium iodide at 25° has a stoichiometric activity coefficient of over 100, while that of 5 M sodium chloride is only 0.874. The first formally correct treatment of the effect of hydration on the activity coefficient appears to have been given by Bjerrum,[4] a few years before the appearance of the Debye–Hückel theory. Apart from recognition by Scatchard[5] in connection with hydrochloric acid, and an important discussion of a "hydration–association" model for electrolytes by Frank,[6] the subject does not appear to have been accorded the attention which its importance warrants in this connection. It will now be shown that by allowing for the ion-solvent interaction in terms of a simple hydration model it is possible to obtain as a first step a two-parameter equation, and by a slight elaboration of the model a one-parameter equation, which will represent the experimental activity coefficients up to remarkably high concentrations. These equations are derived and tested for a large number of salts in aqueous solution at 25°.

The "Hydration Correction" to the Activity Coefficient.[7]—The concentrations, activities, etc., of the hydrated solute will be distinguished by primed symbols, the corresponding "apparent" quantities (computed with neglect of hy-

(7) This treatment leads to a result equivalent to that of Bjerrum, though by a somewhat different route.

dration) being denoted by the usual unprimed symbols. Let 1 molecule of solute give rise in solution to ν ions. We shall now assume that the total interaction between these ν ions and the surrounding solvent, *in all cases where this interaction is significantly large compared to kT*, can be allowed for as a "binding" of n molecules of water in their "hydration shells." We need not at this stage discuss the manner in which this "bound" water is shared between anions and cations.

Then in a solution of molality, m, there are nm molecules of "bound" water to $(55.51 - nm)$ molecules of "free" water. The "true" molality m' (moles of hydrated solute per 1000 g. of "free" water) is therefore

$$m' = \frac{55.51\ m}{55.51 - nm} = \frac{m}{1 - 0.018\ nm} \qquad (3)$$

Then if a' be the activity of the hydrated solute, and a that of the water, the Gibbs–Duhem relation becomes

$$\mathrm{d} \ln a' = -(55.51/m')\ \mathrm{d} \ln a_w$$

This is equally as valid as the ordinary form using the stoichiometric molality and activity, computed with disregard of hydration

$$\mathrm{d} \ln a = -(55.51/m)\ \mathrm{d} \ln a_w$$

Hence, introducing the mean molal activity coefficients γ' and γ, we have

$$\mathrm{d} \ln \gamma' = -(55.51/\nu m')\ \mathrm{d} \ln a_w - \mathrm{d} \ln m' \qquad (4)$$

and

$$\mathrm{d} \ln \gamma = -(55.51/\nu m)\ \mathrm{d} \ln a_w - \mathrm{d} \ln m \qquad (5)$$

from which by substituting for m' from (3) we obtain

$$\begin{aligned} \mathrm{d} \ln \gamma' &= -(55.51/\nu m)\ (1 - 0.108nm)\ \mathrm{d} \ln a_w \\ &\quad - \mathrm{d} \ln m + \mathrm{d} \ln (1 - 0.018nm) \\ &= \mathrm{d} \ln \gamma + (n/\nu)\ \mathrm{d} \ln a_w + \mathrm{d} \ln (1 - 0.018nm). \end{aligned}$$

Upon integrating between molalities zero and m we obtain, remembering that both γ and γ' must approach unity at zero concentration

$$\ln \gamma' = \ln \gamma + (n/\nu) \ln a_w + \ln (1 - 0.018nm) \qquad (6)$$

We shall, however, be concerned rather with the mean *rational* activity coefficient of the hydrated solute, f'. This is clearly related to γ' by the equation

$$\ln f' = \ln \gamma' + \ln (1 + 0.018\nu m') \qquad (7)$$

which is the analog of the familiar (unprimed) equation established by Scatchard[5] for the unhydrated case. Combining (7) with (6), and simplifying with the aid of (3) we obtain

$$\ln \gamma = \ln f' - (n/\nu) \ln a_w - \ln [1 - 0.018(n - \nu)m] \qquad (8)$$

This gives a relation between the observed stoichiometric activity coefficient and the rational activity coefficient of the hydrated solute, in terms of the "hydration parameter" n.[8]

(8) If we allow for a possible variation of n with concentration, we must replace $(n/\nu) \ln a_w$ by $\int_0^m \frac{n}{\nu} \mathrm{d} \ln a_w$.

Application of Equation (8) to the Debye–Hückel Theory.—In order to fit equations (1) or (2) to observed activity coefficients, it is in general necessary to use values of the "mean distance of closest approach of the ions," $\mathring{a}$, which are substantially larger than the known crystallographic radius sums of the ions. This is very reasonably attributed to hydration of the ions. Consequently we should surely regard the Debye–Hückel treatment as predicting the activity coefficient of the *hydrated* ions, *i. e.*, the f' of equation (8). If the hydration effect is alone responsible for the observed increase in the activity coefficient, activity coefficients in water at 25° should be capable of representation by the equation

$$\log \gamma = -\frac{0.5092 z_1 z_2 \sqrt{\mu}}{1 + 0.3286 \mathring{a} \sqrt{\mu}} - \frac{n}{\nu} \log a_w - \log [1 - 0.018(n - \nu)m] \qquad (9)$$

where we have replaced the term $\log f'$ by the Debye–Hückel expression (1), using the modern values[9] of the physical constants involved. Here z_1 and z_2 are the valencies, μ is the ionic strength in volume units, and $\mathring{a}$ is to be expressed in ångström units. The three terms on the right of (9) may conveniently be called the "*D–H* term," the "solvent term," and the "scale term," respectively. The *D–H* term is always negative, and the solvent term is always positive since $a_w < 1$. The scale term is positive, zero, or negative according as $n > \nu$, $n = \nu$, or $n < \nu$. The importance of the solvent term has often been overlooked in discussion of hydration effects. In point of fact the scale term and the solvent term are usually of the same order of magnitude.

Equation (9) still contains two adjustable parameters, a and n. In this form it proves to be capable of representing observed activity coefficients with an accuracy about as good as that of equation (2), but over a much wider range of concentration, extending in many cases to an ionic strength of 5. Its superiority to equation (2) is especially evident in the case of 2:1 halides, where equation (2) generally fails at an ionic strength of about 1 (*i. e.*, about 0.3 *M*). In Table I are listed the n and $\mathring{a}$ values giving the best fits to the experimental γ values, with the range of validity and the average and maximum deviations. The concentrations at which the comparisons are made are those listed in Tables II and III in connection with the one-parameter equation. The experimental activity coefficients with which the comparisons are made are mainly values which we have recently recomputed from our isopiestic measurements, using the most recent standard data for the reference solutions.[10,11] These activity coefficients are also listed in Tables II and III. Those of hydrochloric and hydrobromic acids are from the compilation by Harned and

Owen.[12] These activity coefficients are listed in Tables II and III in connection with the one-parameter equation now to be developed. The solvent term $-n/\nu \log a_w$ can *in principle* be computed from the values of f' for a given n and $\mathring{a}$, but such a procedure would be extremely arduous from the computational point of view. This term has therefore been evaluated from the experimental osmotic coefficients ϕ, since for aqueous solutions, by definition

$$-1/\nu \log a_w = 0.007824 m\phi$$

The One-parameter Equation.—Examination of the n and $\mathring{a}$ values of Table I shows that the $\mathring{a}$ values are much the same as those normally needed in equation (2). The n values, however, are substantially greater than the values we might expect to find on current ideas of hydration, which are largely based on the treatment by Bernal and Fowler[13] of the apparent molal volumes in dilute solutions. Furthermore they do not depend only on the cation as we should at first sight expect if we accept those authors' view that the large anions Cl^-, Br^- and I^- are unhydrated.

We are inclined to accept the idea that it is the cations rather than the anions which are hydrated, especially as it has been shown[13a] by comparing the activity coefficients of the pairs: calcium chloride–sodium sulfate, lanthanum chloride–potassium ferricyanide and thorium nitrate–potassium ferrocyanide, that polyvalent cations lead to high activity coefficients and polyvalent anions to low coefficients. We wish to emphasize, however, that our n is not the same thing as the conventional number of water molecules in the first layer round the ion. It is rather a number introduced to allow for the average effect of all ion–solvent interactions where these are large compared to kT, and may therefore very well contain contributions from solvent molecules outside the first layer. The feature of Table I which does seem difficult to explain is the *increase* of n with increasing anion size, for a given cation. Even this is, however, not necessarily impossible, when we consider that in the concentration range considered the water molecules are not bound simply by the fields of isolated ions, but rather by the resultant field of an ion and its neighbors, which of course depends on their dimensions.

It is clear from Table I that there is some sort of connection between the n and $\mathring{a}$ values, which in general increase together. $\mathring{a}$ is to be interpreted as the closest distance to which the center of the (unhydrated) anion can approach that of the (hydrated) cation. We may estimate the size of the cation from the n value as follows: From the density of pure water, we know that a "normal" water molecule occupies at 25° an effective volume of 30.0 cubic ångström units. Round the smaller cations, however, there is, as Bernal and Fowler[13] have shown, a closer-packing effect which in many cases actually makes the apparent ionic volume of the cation negative. We can allow for this close-packing effect, as well as for the volume occupied by the cation itself, by putting the volume of the n-hydrated cation equal to $(30n + V_+)$, where V_+ is the apparent ionic volume of the cation (in cubic Å. per ion). In most cases V_+ is only a small fraction of $30n$, so that it need not be determined with great accuracy, and any variation of V_+ with concentration can be ignored. To estimate V_+ from the observed apparent molal volumes, we have fol-

TABLE I

CONSTANTS OF THE TWO-PARAMETER EQUATION (9), GIVING BEST FITS TO THE EXPERIMENTAL ACTIVITY COEFFICIENTS

Salt	n	$\mathring{a}$ (ångströms)	Range fitted (molality)	Average difference in γ	Maximum difference in γ

lowed the procedure of Bernal and Fowler with slight modifications. The apparent molal volumes at 1*M* were computed from the density data of "International Critical Tables." It turns out that the values for cesium and rubidium chloride, bromide and iodide can be represented within a few per cent. by $V_{app} = 6.47(r_+^3 + r_-^3)$ cu. Å. per molecule, where r_+ and r_- are Pauling's[14] crystallographic radii (in Å.). The molal volumes in the solid state are also fairly close to this. Since these salts have anions and cations of not greatly differing sizes, it is reasonable to attribute to the anions in other salts a contribution of 6.47 r_-^3 cu. Å./ion toward the apparent molal volume. The contribution of the cation, including the closer-packing effect on the water, is then calculated as $V_+ = (V_{app} - 6.47 z_1 r_-^3)$ where z_1 is the cation valence.

We can now calculate a kind of "idealized" radius r_1 for the *n*-hydrated cation, given by $4/3\pi r_1^3 = 30n + V_+$. Upon adding r_1 to the crystallographic radius of the anion, we obtain an "idealized" distance of closest approach. When this calculation is carried out, we find a clear connection between these "idealized" distances and the $\mathring{a}$ values actually needed (Table I) for the best fit. The sum $(r_1 + r_-)$ exceeds $\mathring{a}$ by a matter of 0.7 Å. for the alkali halides and 1.3 Å. for the alkaline-earth halides. The variation in this difference from salt to salt is scarcely more than can be accounted for by the usual elasticity of a two-parameter equation. We can interpret this difference in two ways: as a penetration of the hydration shell of the cation by the anion (following a suggestion of Frank[6]) or as a distortion of the ions by the field. Either explanation will also cover the fact that the difference is nearly twice as great for doubly charged as for singly charged cations. It is to be noted that the three halide anions considered have radii varying only from 1.81 to 2.16 Å. so that we should expect them all to penetrate to much the same extent.

This admittedly empirical relation between *n* and $\mathring{a}$ turns out to be of sufficient accuracy to make possible the evaluation of $\mathring{a}$ from *n*, the densities of the solutions, and the known crystallographic radii of the ions. We therefore have the activity coefficient in terms of the single parameter *n*, as follows

$$\log \gamma = \frac{0.5092 z_1 z_2 \sqrt{\mu}}{1 + 0.3296\sqrt{\mu}\left\{\left[\frac{3}{4\pi}(30n + V_+)\right]^{1/3} + r_- - \Delta\right\}} - (n/\nu)\log a_w - \log[1 - 0.018(n - \nu)m] \ldots \quad (10)$$

where $\Delta = 0.7$ Å. for the univalent halides and 1.3 Å. for the bivalent metal halides.

By choosing the appropriate value of *n* by a trial-and-error process, equation (10) will give a satisfactory representation of the observed activity coefficients (over a usefully wide range of concentrations) as shown in Tables II and III and Fig. 1.

It is noteworthy that in the majority of cases the equation breaks down when the product of *n* and the molality exceeds about 10 or 15. This is to be expected, as there are only 55.51 moles of water altogether for *m* moles of salt, and the effects of "competition" between neighboring ions of the same sign must become noticeable. To proceed to higher concentrations we would have to use an *n* which was a suitably decreasing function of concentration. It is important to note that when equation (10) begins to fail by more than 1% or so, the predicted γ values are *higher* than the experimental values, as a natural consequence of the use of too large an *n* value. The only exceptions to this last statement occur in the case of the rubidium halides, where the predicted γ values become too *low* above 2 *M*. Here of course the relation between *n* and $\mathring{a}$ is being stretched to rather absurd lengths, in treating the ions as spherical with such small *n* values as are needed. The activity coefficients of the cesium halides cannot be reconciled with equation (10); they are equally difficult to fit with the conventional equation (2), requiring $\mathring{a}$ values substantially *less* than the radius sums.

One cannot claim that the accuracy of fit obtainable with the one-parameter equation (10) is quite as good as can be done with equation (9) using two parameters; but it is at least able to predict activity coefficients within about twice the experimental error, and with an accuracy nearly always better than 1% up to remarkably high concentrations.

The simplicity of the physical model makes its success the more striking. Though there are many obvious criticisms which can be made, the empirical value of the one-parameter equation is clear from the figures, and is sufficient to justify the decidedly *ad hoc* arguments used in its development.

II. Water Activities in Very Concentrated Electrolyte Solutions.—In the course of isopiestic measurements on very concentrated calcium nitrate solutions it was found that, while the solution is saturated at 8.4 *M* at 25°[15] it readily supersaturates. These supersaturated solutions, on further concentration (by isothermal evaporation at 25°) pass into semi-solid gels. The transition from a freely flowing solution to a transparent, rigid gel is marked by no visible discontinuity, and the vapor pressure–concentration curve is also continuous. The measurements were extended to 21 *M*, at which concentration the clear homogeneous gel broke down into a striated form. Vapor pressure measurements were not made on these striated gels, because equilibrium was not reached sufficiently rapidly. These phenomena suggested the possibility that at high concentrations the system could be treated as an adsorbent (calcium nitrate)–adsorbate (water) system.

As in Table II the $\mathring{a}$ values in parentheses are not parameters but are computed from n and the apparent ionic volumes.

Experimental

Calcium nitrate from British Drug Houses, Limited, was recrystallized twice from water. Solutions, analyzed for calcium as carbonate, were equilibrated against sulfuric acid by the isopiestic method.[16] From the experimental results, given in Table IV, the osmotic and activity coefficients were evaluated (Table V) with the aid of the data

(16) R. A. Robinson and D. A. Sinclair, THIS JOURNAL, **56**, 1830 (1934).

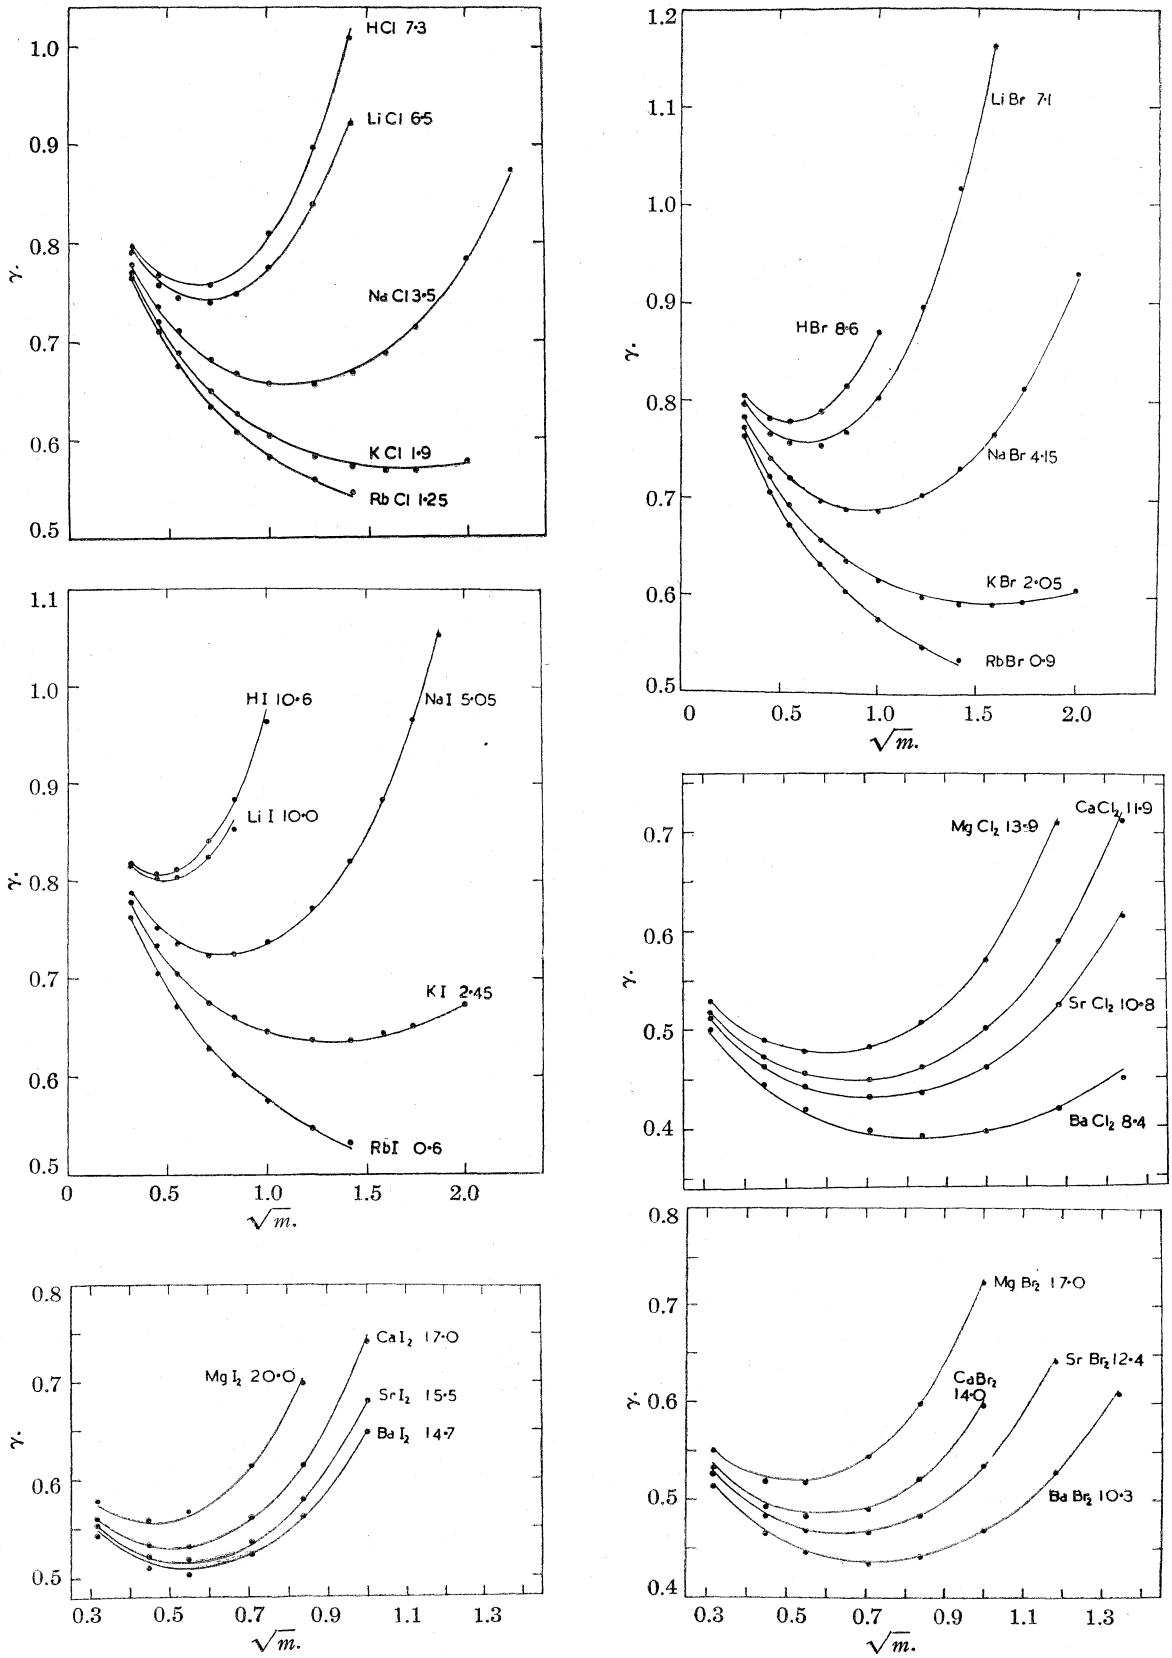

Fig. 1.—Comparison of experimental activity coefficients with those predicted by the one-parameter equation (10). The full curves are calculated from equation (10), using the value for the "hydration parameter" n following the formula of each salt. The circles give the experimental values. Diameter of circles equals 0.004 in γ.

for sulfuric acid.[17,18] Previous values[19] at concentrations up to 3 M have been recalculated to conform to more recent standards. Compared with such salts as calcium chloride low γ values are obtained for calcium nitrate over the whole concentration range. Thus at 6 M we find $\gamma_{Ca(NO_3)_2} = 0.592$, $\gamma_{CaCl_2} = 11.11$. This is consistent with the general behavior of bivalent metal nitrates, and is probably to be explained in terms of Bjerrum's ideas of ion-pair formation. It seems quite likely that at high concentrations the salt would be better formulated as $(CaNO_3)^+ \cdot NO_3^-$.

In the case of calcium nitrate and other highly soluble salts it would be futile to attempt any form of extension of the Debye–Hückel treatment, into the very concentrated solutions. We have only to note that in an 18 molal solution there are only about 3 molecules of water per molecule of solute, to realize the hopelessness of such an approach. Another important point is that at these concentrations there can be little left of the normal coordinated structure of water; for in a solution with say 5 moles of a 2:1 electrolyte per liter, there are $(15 \times 6.023 \times 10^{20})$ ions per cc., so that the average distance between an ion and its nearest neighbors can be only about 5 Å. Clearly there can be in such a solution no water molecules which are not subject to quite large electrical forces from the ionic field. It is in fact rather surprising that the Debye–Hückel treatment as extended in Part I of this paper gives such reasonable results as it does in the case of say 5 M sodium chloride. In very dilute solutions the ion–ion forces are dominant, and the simple Debye–Hückel treatment is applicable. In moderate concentrations, the ion–ion and ion–solvent forces become of comparable importance, and the method of Part I provides a satisfactory treatment. We believe that at very high concentrations the ion–solvent forces are the dominant factor, and shall therefore develop as a first approximation a treatment which ignores the ion–ion forces, or rather assumes that they are little affected by concentration in the range to be discussed. There is some justification for this: (a) the Debye–Hückel function $[A\sqrt{c}/(1 + \mathring{a}B\sqrt{c})]$ flattens out with rising concentration, approaching the limit $A/\mathring{a}B$. (b) From an entirely different viewpoint, we might treat the solution as a somewhat irregular ionic lattice with interspersed water molecules, a view supported by the X-ray data of Beck,[20] for example, on concentrated solutions of lithium chloride and bromide and rubidium bromide. The ion–ion energy on this picture might reasonably be expected to be proportional to the inverse cube root of the volume–concentration, so that again it should vary rather slowly with concentration.

The behavior of concentrated calcium nitrate "solutions," described above, raised the question of whether we could obtain a relation between molality and water activity by the application of an adsorption isotherm. Though calcium nitrate is the only electrolyte which we have found to form gels, we have obtained vapor pressure data for a number of other electrolytes at equally high concentrations, and there would seem to be nothing to prevent the application of the same idea to these also. We may picture a concentrated solution as containing ions in various stages of hydration, some with a complete hydration shell forming a monomolecular layer round the ion, others with incomplete shells, and others with more than one layer, the second and higher layers being of course much less strongly bound. All these would be in equilibrium, the relative amounts of each varying with concentration. Now this model bears a strong resemblance to that from which the adsorption isotherm derived by Brunauer, Emmett and Teller[21] was derived. Modifying the notation of these authors to suit the present case, we may write their equation as

$$\frac{ma_w}{55.51(1 - a_w)} = \frac{1}{cr} + \frac{c - 1}{cr} a_w \qquad (11)$$

where: a_w is the water activity of the solution; m its molality; r is the number of molecules of water in the monomolecular hydration layer *when complete;* and c is a constant related to the heat of adsorption E of the molecules in the layer by the approximate relation $c = \exp(E - E_L)/RT$, E_L being the heat of liquefaction of pure water. Equation (11) may be tested by plotting the left-hand side (determined from the experimental m and a_w) against a_w. We find that good straight lines are obtained from the following electrolytes in the concentration range where $a_w < 0.3$: calcium nitrate, calcium chloride,[11] calcium bromide,[22] lithium chloride,[23] lithium bromide,[22] zinc chloride,[11] zinc bromide,[11] perchloric acid,[24] hydrochloric acid,[25] and sodium hydroxide.[26] Table VI gives the best values of the parameters c and r for these electrolytes, obtained by a least-squaring process. Also recorded are the average deviations of the water activity observed from that required to reproduce the experimental molality with equation (11) rewritten in the form

$$m = \frac{55.51(1 - a_w)}{a_w}\left\{\frac{1}{cr} + \frac{c - 1}{cr}a_w\right\} \qquad (11a)$$

The accuracy of fit is on the whole surprisingly good; it should be remembered that the experimental accuracy of vapor pressure measurements at these high concentrations is in the majority of cases not much better than 0.0010 in a_w. It is immediately noticeable that the r values for the 1:1 electrolytes are between 3 and 4, while those of calcium chloride and calcium bromide are about twice as large. Zinc chloride and bromide have r values similar to those of 1:1 electrolytes, which is to be explained on the grounds that concentrated solutions of these salts should really be formulated as Zn $(ZnCl_4)$ and Zn $(Zn\ Br_4)$[27] so that only half the zinc is in the form of ions free to undergo hydration. The free zinc ions then have r values similar to those of calcium in calcium chloride and bromide. In the case of calcium nitrate if we adopt the formulation $CaNO_3^+ \cdot NO_3^-$ it is reasonable that the r value should be in the range characteristic of 1:1 electrolytes. The values of the parameter c are also reasonable, corresponding to $E - E_L = 1$ to 3 kcal. per mole of water adsorbed. An unsatisfactory feature of equation (11) is that it demands the non-integral r values of Table VI. These can scarcely correspond to any physical reality, and have more likely arisen as a result of approximations in the B–E–T. theory and its application to this case. The most drastic of these approximations is that of treating all water molecules beyond the first layer as held by ordinary liquid forces, with a heat of liquefaction E_L. Anderson[28] has deduced a modification of the B–E–T equation in which the subsequent layers (up to about the tenth) have a heat of adsorption less than that of water by d. This has the effect of multiplying a_w, wherever it occurs in (11), by a factor $K = e^{-d/RT}$ leading to the equation

$$\frac{ma_w}{55.51(1 - Ka_w)} = \frac{1}{cKr} + \frac{c - 1}{cr}a_w \qquad (12)$$

We shall now investigate whether this equation, with r fixed at 4.000 or 8.000 according to the salt considered, will represent the observed relation between m and a_w by an appropriate choice of the two constants c and K. To make the test we rewrite (12) in the form

$$c = \left\{\frac{1}{K} - a_w\right\} \Big/ \left\{\frac{rma_w}{55.51(1 - Ka_w)} - a_w\right\}$$

and find by trial a value of K which lends to a reasonably constant c over the widest possible range of molality. The c and K values found for the nine electrolytes are listed in Table VII. The range of validity of equation (12) is somewhat wider than that of equation (11), extending in most cases up to $a_w = 0.5$. The average deviations are on the whole slightly greater, though there would be little difference if equation (12) were restricted to the same range of water activities as equation (11).

TABLE VI

CONSTANTS OF EQUATION (11)

Electrolyte	r	c	Range fitted	Average deviation in a_w
LiCl	3.64	17.2	$12M$–$29M$	0.0008
LiBr	3.82	43.0	$11M$–$20M$	.0015
HCl	3.50	19.1	$12M$–$16M$	.0009
$HClO_4$	3.93	59.0	$10M$–$16M$	.0017
$Ca(NO_3)_2$	3.86	9.40	$12M$–$20M$	.0007
$ZnCl_2$	3.69	22.6	$12M$–$22M$	.0017
$ZnBr_2$	4.01	19.8	$11M$–$20M$	.0008
$CaCl_2$	6.73	9.50	$7M$–$10.5M$	.0004
$CaBr_2$	7.06	42.6	$6M$–$9M$	.0031
NaOH	3.20	19.3	$14M$–$29M$	.0011

The c parameter of equation (12) ranges from 9.0_4 to 58.2, corresponding to values of $E - E_L$ of 1.3 to 2.4 kilocalories per mole of water. These magnitudes seem reasonable enough. The K parameter range corresponds to $d = 0$ to 150 cal./mole of water in the second and subsequent layers. This relatively small energy might easily correspond to a weak ordering effect on the water molecules concerned. It would however clearly be unwise to go too far in attempting to attach an exact physical meaning to K in terms of the model. It is sufficient to have shown that with an integral r value of 4 or 8, and a c corresponding to a reasonable "energy of adsorption," equation (12) is applicable over the remarkably wide ranges of con-

centration given in Table VII. The K parameter can then be regarded as a convenient carry-all for such effects as ordering in the second and higher layers and the otherwise neglected variation in the ion–ion energy with concentration. In view of the approximate nature of the treatment, the accuracy with which the molality can be related to the water activity by equations (11) and (12) is more than satisfactory.

TABLE VII

CONSTANTS OF EQUATION (12)

Electrolyte	r	c	K	Range fitted	Average deviation in a_w.
LiCl	4.00	15.84	0.860	$8M$–$20M$	0.0006
LiBr	4.00	42.0	0.890	$8M$–$20M$	.0018
HCl	4.00	14.38	0.850	$7M$–$16M$	.0019
$HClO_4$	4.00	58.2	0.950	$9M$–$16M$	.0024
$Ca(NO_3)_2$	4.00	9.04	0.960	$9M$–$20M$	.0010
$ZnCl_2$	4.00	20.5	0.880	$10M$–$22M$	.0025
$ZnBr_2$	4.00	20.0	1.000	$11M$–$20M$	.0009
$CaCl_2$	8.00	9.24	0.775	$4M$–$10.5M$	.0016
$CaBr_2$	8.00	34.1	0.770	$4.5M$–$9M$	.0007

In the case of hydrochloric acid, the data available[24] cover the temperature range 0–50°, so that an interesting test of these ideas is possible. Table VIII gives the values of the K and C parameters, taking $r = 4$, for hydrochloric acid at various temperatures. The variation in C is considerable, but corresponds to a practically constant value of $E - E_L$ in the equation

$$C = \exp (E - E_L)/RT$$

This is consistent with the idea of strong electrostatic forces causing the "adsorption." The K values on the other hand do not correspond to a constant value of d; but the various effects covered by the introduction of K are not clearly enough defined to justify the expectation that it would be constant.

TABLE VIII

CONSTANTS OF EQUATION (12) FOR HYDROCHLORIC ACID AT VARIOUS TEMPERATURES

$r = 4.00$ in each case. $c = \exp (E - E_L)/RT$. Range fitted 10 M–16 M at each temperature

Temp., °C.	K	c	$(E - E_L)$, kcal.	Average deviation in a_w.
0	0.870	18.28	1.58	0.0010
10	.861	16.52	1.58	.0020
20	.852	14.98	1.58	.0020
25	.850	14.38	1.58	.0019
30	.843	13.68	1.58	.0016
40	.834	12.45	1.57	.0016
50	.825	11.29	1.56	.0013

We consider that the ideas put forward in this section are worth developing further, perhaps by an attempt to evaluate the ion–ion energies in the quasi-lattice of the concentrated solution. If these energies could be included the treatment should find a firmer theoretical basis. The ideas put forward in the two sections of this paper are not self-contradictory. In Part I we have shown that the introduction into the Debye–Hückel equation of the concept of ion–solvent molecule interaction will account for observed activity coefficients up to a total ionic strength of about 4. In part II we have accounted for vapor pressure data at concentrations above about 12 M by assuming that ion–solvent molecule interaction occurs by a mechanism similar to that of the Brunauer–Emmett–Teller theory. Between these concentrations the hydration number, n, is diminishing and the ions are tending to a quasi-crystalline structure with some of the water molecules imbedded in the remnants of the crystal lattice (adsorbed water) and some present as "free" solvent. There is nothing contradictory in these two methods of approach; rather do we regard them as limiting cases of a more general theory which would cover the entire concentration range.

Summary

Part I: By superimposing on the Debye–Hückel treatment an allowance for the ion–solvent interaction in terms of a hydration model, a two parameter equation for activity coefficients is obtained. This has a range of validity greater than that of the usual Hückel equation. When dealing with the class of the chlorides, bromides and iodides of hydrogen and the alkali metals, the two-parameter form can be reduced to a one-parameter equation by the assumption that the anion can penetrate a distance of 0.7 Å. into the hydration sheath of the cation. A closely similar one-parameter equation holds for the alkaline-earth halides and other normally dissociated bivalent metal halides, the "penetration distance" for this class being 1.3 Å. Within each class only the single parameter n, the effective hydration number of the cation, is required to represent the observed activity coefficients, usually up to an ionic strength of about 4.

Part II: An approximate treatment of the water activity of very concentrated electrolyte solutions is based on the application of the adsorption isotherms of Brunauer, Emmett and Teller and of Anderson. The resulting equations apply with surprising accuracy to nine electrolytes which have recently been studied at very high concentrations. The parameters of the equations are listed and their physical significance discussed.

Polarographic Behavior of Phenolphthalein

BY I. M. KOLTHOFF AND D. J. LEHMICKE[1,2]

In the course of a polarographic study of the reduction of various acid–base indicators, phenolphthalein was found to exhibit such unusual characteristics that a thorough investigation was made of its polarographic behavior under conditions of varying *p*H, solvent and temperature. A unique current–voltage curve was found in 25% alcohol at a *p*H of about 7, the curve showing a typical diffusion current plateau, the diffusion current then decreasing to a minimum value close to zero at a potential about half a volt more negative than the half-wave potential. The normal diffusion current in 25% ethanol was found to decrease almost to zero when the water in the solvent was being replaced by ethanol. An interpretation of the observed phenomena is given in the discussion section.

In a subsequent paper it will be shown that the polarograph is very suitable, not only to follow the fading of phenolphthalein in alkaline medium, but also to determine the rate of reaction of the colorless carbinol form with hydrogen ions in acid medium, which is not easily followed colorimetrically.

Experimental

Apparatus.—Unless otherwise stated the current–voltage curves were determined using a type VIII Heyrovsky polarograph. Exact data of diffusion currents and sometimes of half wave potentials were obtained with a manual apparatus. The galvanometer had a unit sensitivity of 3.19×10^{-3} microamperes per millimeter.[3] Two capillaries were used with the following characteristics. Capillary 1: droptime, $t = 3.55$ sec., $m = 2.93$ mg./sec., $m^{2/3}t^{1/6} = 2.52$. Capillary 2: $t = 2.96$, $m = 1.427$ and $m^{2/3}t^{1/6} = 1.52$. Unless otherwise noted capillary 2 was used.

The electrolysis cells consisted of 50-ml. Erlenmeyer flasks with side-arms for the admission of nitrogen and for connection with the saturated calomel electrode, which as a rule served as a reference electrode. All the potentials are referred to the saturated calomel electrode (S.C.E.). Several runs were made with a pool of mercury on the bottom of the electrolysis cell as anode. In these instances the anode potential was measured against the S.C.E. All diffusion currents as measured from the polarographic records were corrected for the residual current. In case two diffusion currents were found, their relative values were referred to the same value of $m^{2/3}t^{1/6}$.[4]

The electrolysis experiments were carried out in a thermostat at 25 ± 0.01°.

Materials. Phenolphthalein.—A National Aniline Company product with a melting point of 262–264° (cor.) (Beilstein, XVIII, 143 reports 254° uncor.).

Phenolphthalin.—This substance was prepared by reduction of phenolphthalein with zinc dust in 2 *N* sodium hydroxide according to the directions of Baeyer.[5]

Basic Fuchsine.—A National Aniline product; a 0.1% solution of the dye in water was prepared which served to eliminate maxima.

Nitrogen.—Tank nitrogen, purified by passing through a train consisting of acid chromous chloride solution, sodium hydroxide solution, mercuric chloride solution and water. In all polarographic experiments air was replaced with nitrogen.

Other chemicals were reagent grade. Standard acid and base solutions were prepared and standardized by conventional methods.

Buffer Solutions.—In the range of *p*H between 1 and 10 Clark and Lubs buffer solutions were used. The *p*H was checked with the aid of a glass electrode. The *p*H data refer to water as a solvent and not to solvents containing alcohol. Solutions with a *p*H higher than 10 were prepared using 0.1 *N* sodium carbonate (*p*H 11), 0.01 *N* sodium hydroxide (*p*H 12) and 0.1 *N* sodium hydroxide (*p*H 13).

Medium.—Except where the alcohol content was varied 25% ethanol by volume was present. In other instances the ethanol content is also expressed in per cent. by volume. In general, the concentration of phenolphthalein was 0.001 *M*. In order to work at this concentration it was necessary to have 25% ethanol in the solvent.

The test solutions contained 50% by volume of buffer solution and 0.001% of basic fuchsine. In the absence of the dye pronounced maxima in current–voltage curves were usually found. In addition, the solutions were usually 0.1 *N* in potassium chloride.

Results

Experiments in 25% Ethanol. Effect of *p*H.—Polarograms were run of 0.001 *M* solutions of phenolphthalein in 25% ethanol over the *p*H range between −0.6 and 13. Four different types of curves were obtained as shown in Figs. 1 and 2.

In solutions with a *p*H less than about 3.5 a single wave of the normal type was observed (Fig. 1). In the *p*H range between 4 and 8.5 one step reduction waves were observed, with well defined diffusion currents. The polarogram at a *p*H of 7.4 has quite an abnormal appearance (Fig. 1). The diffusion current remains practically constant in a potential range between about −1 and −1.2 volt, it decreases very slightly between −1.2 and −1.4 volt and then drops suddenly to attain a minimum value at a potential of about −1.6 volt. The minimum value remains constant to a potential of about −1.75 volt, whereupon the wave yielded by the supporting electrolyte appears. At a *p*H of 4.7 the decrease in the diffusion current starts at a potential of about −1.1 volt; however, before a flat minimum as at a *p*H of 7.4 is attained the wave of the supporting electrolyte appears. In still more acid medium (*p*H < 3.5) no decrease of the diffusion current is observed, as the hydrogen wave appears before the decrease of the diffusion current occurs. In the *p*H range corresponding roughly to the color-change inter-

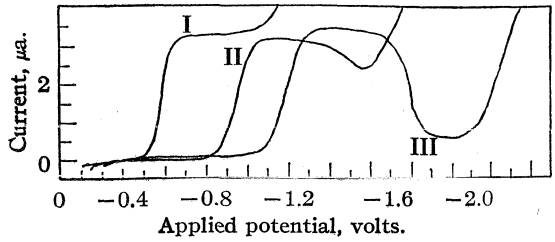

Fig. 1.—Current-voltage curves of millimolar phenolphthalein in 25% ethanol: I, solution is 3.8 N in HCl and 0.001% in basic fuchsine; II, biphthalate buffer, pH 4.73; III, phosphate buffer, pH 7.40. Abscissa scales for curves II and III start 0.1 and 0.2 volts, respectively, to the right of curve I.

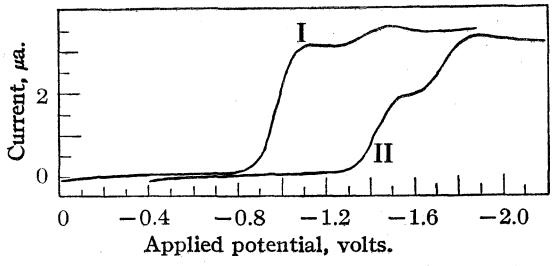

Fig. 2.—Current-voltage curves of millimolar phenolphthalein in 25% ethanol solution: I, in borate buffer, pH 9.55; II, in borate buffer, pH 10.25. Abscissa scale for curve II starts 0.4 volt to the right of curve I.

val of phenolphthalein two waves are observed. At a pH of about 9 the first diffusion current is almost equal to the total diffusion current found at lower pH, the second wave comprising only a few per cent. of the total current. In more alkaline medium the second wave increases at the cost of the first one (Fig. 2), the total current remaining the same. At a pH of 10.25 (Fig. 2) and at higher pH two waves of equal height are found. It is interesting to note that no decrease of the total diffusion current with increasing negative potential is found at a pH greater than 9.

The "apparent" diffusion currents (constant value before the dip) found at a pH of 7 and in more acid medium, and the total diffusion currents in alkaline medium are all of about the same value, indicating that these currents represent true diffusion currents. The polarograms in strongly alkaline medium must be taken immediately after preparation of the solutions, as the diffusion currents decrease slowly as a result of carbinol formation.

In order to provide further evidence that the apparent diffusion currents at a pH of 7 or smaller are true diffusion currents, their variation with concentration was determined. It was found that the diffusion current is proportional to the concentration. A few values of $K = i_d/c$ in a phosphate buffer of pH 7 in the presence of 0.1 N potassium chloride are: 0.50×10^{-3} M phenolphthalein, $K = 3.94$; 0.001 M, $K = 3.90$; 0.0015 M, $K = 3.90$.

In the phosphate buffer of pH 7 the apparent diffusion current is hardly affected by the concentration of electrolyte. However, the decrease in the current and the appearance of the well-defined minimum (Fig. 1) depend on the total electrolyte content of the solution. Experiments were carried out in which the polarograms were determined in a buffer solution of pyridine and pyridinium hydrochloride, the total chloride concentration being 2.4×10^{-4} M, the pyridine concentration 2×10^{-3} M and the phenolphthalein concentration 1×10^{-3} M (pH 6.85). The polarogram had a normal appearance, and the diffusion current did not decrease at more negative potentials. It remained constant until the wave of the supporting electrolyte appeared. When the solution was made 2.8×10^{-4} M in potassium chloride the dip came into evidence, and it became more pronounced as more potassium chloride was added. The non-appearance of the minimum in the pyridine buffer without salt, therefore, cannot be attributed to an increasing pH at the surface of the dropping mercury during the reduction (two hydrogen ions are consumed in the reduction), as the pH would change in a similar way in the presence of the potassium chloride. The effect of the potassium chloride must be a typical "electrolyte effect."

The appearance of the dip at pH values between 4 and 8 is a matter of practical consequence, when dealing with a mixture of phenolphthalein and a substance which is reduced at more negative potentials. This is demonstrated in Fig. 3, giving the polarogram of a 0.0015 M phenolphthalein and 0.001 M cobalt solution in 26% ethanol containing ammonium acetate as a buffer and fuchsine as an eliminator of maxima. First the diffusion current of phenolphthalein is observed; however, just before the diffusion current of cobalt is attained the dip in the phenolphthalein manifests itself and the current decreases to a fairly constant value, this value being equal to the sum of the diffusion current of cobalt and the small minimum current of phenolphthalein.

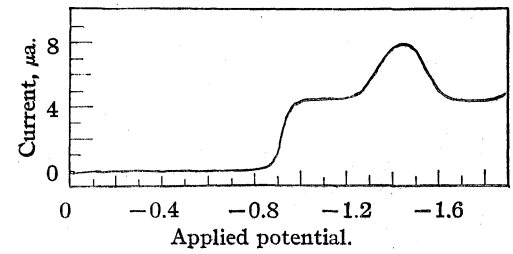

Fig. 3.—Current-voltage curve of millimolar cobalt acetate in the presence of 1.5×10^{-3} molar phenolphthalein in 26% ethanol. Solution is 0.2 M in ammonium acetate and contains 0.001% basic fuchsine.

When the solution contains in addition to phenolphthalein a substance which is reduced at more positive values than phenolphthalein the

polarogram is simply interpreted, the phenolphthalein wave being superimposed upon the previous wave. This was shown to be true in the electrolysis of a mixture of benzoquinone and phenolphthalein.

Two-step Reduction in Alkaline Medium.—Apparently the red form of phenolphthalein (Fig. 2) gives a two-step reduction, whereas the colorless forms give only a single wave. In Table I are given the values of i_{d_1} (i_1) and i_{d_2} (i_2) at varying pH obtained with a 0.001 M phenolphthalein solution in 25% ethanol. In all instances the values of i_{d_1} have been corrected to the same value of $m^{2/3}t^{1/6}$ as prevailed at the potential at which i_t was measured ($i_{d_2} = i_t - i_{d_{1corr.}}$). The pH in the mixture was measured with the glass electrode.

TABLE I

VALUES OF i_{d_1} AND i_{d_2} IN MICROAMPERES OF PHENOLPHTHALEIN IN ALKALINE MEDIUM

i_t = total diffusion current uncorrected for $m^{2/3}t^{1/6}$

pH	i_1 (uncor.)	i_t	i_2	$i_2/^1/_2i_t$
9.18	2.99	3.05	0.13	0.08
9.55	2.91	3.15	.33	.21
9.79	2.59	3.14	.61	.39
9.96	2.28	3.11	.90	.58
10.18	2.09	3.22	1.18	.73
10.25	1.70	3.11	1.45	.93
(13.0	1.33	2.51	1.20	.96)
(13.3	1.34	2.61	1.29	.99)

It is seen that the total diffusion current is found reasonably constant, except in the last two solutions which were 0.1 and 0.2 N in sodium hydroxide, respectively. In these solutions part of the red form was transformed into the carbinol form which does not give a reduction wave under the above conditions. At a pH of 10.3 the two waves become of equal height and remain of equal height with increasing pH.

When the ratio of $i_2/^1/_2i_t$ is plotted against pH, a curve is obtained which has the appearance of a dissociation curve of an acid. The curve is almost identical with the curve obtained on plotting the fraction of phenolphthalein in the red form against pH, as determined by Michaelis and Gyemont.[6] The fact that the two curves practically superimpose indicates that the rate of transformation of the red form into the colorless reducible one is relatively small. If the dissociation equilibrium of the phenolphthalein in buffer solutions with pH between 9 and 10.5 were established very rapidly only one wave corresponding to that of the colorless form would have been observed.

Half-wave Potentials.—The half-wave potentials in 25% ethanol at varying pH are summarized in Table II.

Reduction of Phenolphthalin.—Solutions of phenolphthalin in 25% ethanol were electrolyzed at the dropping electrode in a pH range between 0 and 13. No reduction waves were observed.

TABLE II

HALF-WAVE POTENTIALS AS FUNCTION OF pH

pH	−0.06	0	1	2.5	3.5	4.7	5.8	6.9
$-(\pi^{1/2})_1$	0.49	0.53	0.60	0.67	0.71	0.75	0.80	0.86
$-(\pi^{1/2})_2$								
pH	7.4	8.2	9.6	10.06	12	13	13.3	
$-(\pi^{1/2})_1$	0.89	0.93	0.98	1.01	(.84)	(.82)	(.81)	
$-(\pi^{1/2})_2$			1.35	1.33	1.33	1.23	1.24	

Effect of Ethanol Concentration on Current–Voltage Curves in Neutral Medium.—The experiments were carried out with a 0.001 M phenolphthalein solution, except in 10% ethanol. The concentration in this medium was 0.0005 M, as a 0.001 M solution was supersaturated. All solutions contained a phosphate buffer of pH 7, and were 0.001% in fuchsine and 0.1 M in potassium chloride. Column II of Table III lists the diffusion currents. The value of i_{d_0} in water was found by graphical extrapolation.

Abnormally small values of the diffusion current were found at alcohol concentrations greater than 40%. In order to be quite sure that these small values of the diffusion current were typical for phenolphthalein and not due to a general effect of the solvent, diffusion currents of benzoquinone were determined at the same ethanol concentrations. Column III of Table III lists for phenolphthalein the ratio of the value of i_d in solutions of varying alcohol content to the (extrapolated) value in water (i_{d_0}). Column IV lists the same values for quinone, and Column V the ratio of the values in Columns II and IV.

TABLE III

EFFECT OF ETHANOL CONCENTRATION ON DIFFUSION CURRENT

Ethanol concn., %	$i_{d_{phpht}}$	$(i_d/i_{d_0})_{phpht}$	$(i_d/i_{d_0})_{quinone}$	Column III / Column IV
0	(4.17)	(1.00)	1.00	1.00
10	3.97	0.95	0.90	1.05
20	..	..	.75	..
25	3.29	.79	.69	1.14
30	2.66	.64	.65	0.99
35	1.84	.44	.62	.71
40	0.97	.23	.60	.38
50	0.24	.06	.59	.10
70	0.04	.02	.63	.03

As an illustration Fig. 4 shows the current–voltage curve at an ethanol concentration of 40%.

From the last column in Table III it is seen that up to an alcohol concentration of 30% the diffusion currents of phenolphthalein and quinone are affected in about the same way. At higher alcohol concentrations the diffusion current of phenolphthalein is decreased much more than that of quinone. At an ethanol concentration of 70% the phenolphthalein diffusion current has become vanishingly small.

Assuming that the electroreduction of phenolphthalein involves two electrons it is possible to calculate its diffusion coefficient in water from the

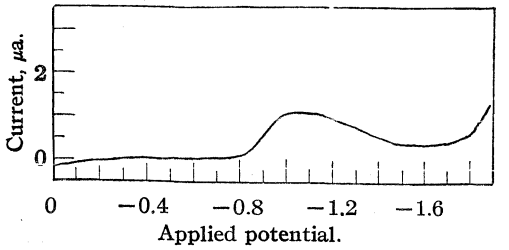

Fig. 4.—Current–voltage curve of millimolar phenolphthalein in 40% ethanol. Solution contains phosphate buffer; *p*H 7.

extrapolated value of the diffusion current with the aid of the Ilkovic equation

$$i_d = 605nD^{1/2}m^{2/3}t^{1/6}$$

The value of $m^{2/3}t^{1/6}$ at −1.0 volt, at which i_d was measured was 1.51 mg.$^{2/3}$ sec.$^{-1/2}$ and i_d in 0.001 *M* solution was 4.17 microamperes. This yields a value of $D = 5.2 \times 10^{-6}$ sq. cm./sec. at 25°. For benzoquinone a diffusion coefficient of $8.6 \pm 0.2 \times 10^{-6}$ was calculated at 25°.[7] The values for phenolphthalein and benzoquinone are of the same order of magnitude, showing conclusively that the reduction of phenolphthalein at the dropping electrode involves two electrons.

Effect of the Temperature on the Current–Voltage Curves in 25% Ethanol in Neutral Medium.—All experiments were carried out with the same solution which was 0.001 *M* in phenolphthalein, 25% in ethanol, 0.1 *M* in potassium chloride, 0.001% in basic fuchsine and which contained 50% of a phosphate buffer of *p*H 7. Experiments at 0° were carried out in an ice-bath, and at temperatures above 25° in a water-bath, the temperature of which was controlled manually. In these experiments the temperature was constant within 2°.

The diffusion current was found to increase with increasing temperature in a predictable fashion, but the current at the minimum of the c.–v. curve showed a relative increase at temperatures above 25°, which was many times greater than that of the diffusion current. This is demonstrated in Table IV in which i_{min} denotes the current at the minimum in the c.–v. curve.

TABLE IV

EFFECT OF TEMPERATURE ON CURRENT–VOLTAGE CURVES OF 0.001 *M* PHENOLPHTHALEIN IN 25% ETHANOL IN PRESENCE OF PHOSPHATE BUFFER

Temp., °C.	i_d, microamperes	i_{min}, microamperes	i_{min}/i_d
0	2.00	0.14	0.06
25	3.29	0.24	.07
50	4.77	1.15	.24
75	6.41	3.49	.56

Figure 5 illustrates the c.–v. curve at 75°.

A run was also made at 85°, within two degrees of the boiling point of the 25% ethanol solution. At this temperature the diffusion current varied somewhat irregularly (about 7.2 microamperes), but the current–voltage curve did not show a dip. Hence the minimum had practically disappeared.

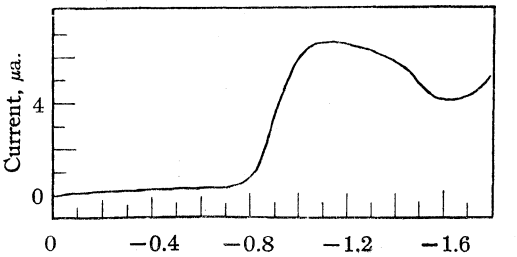

Fig. 5.—Current–voltage curve of millimolar phenolphthalein in 25% ethanol at 75°. Solution contains phosphate buffer; *p*H 7.

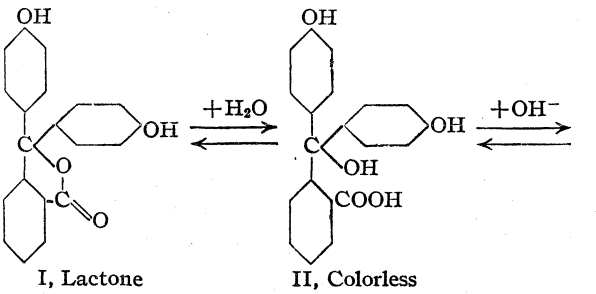
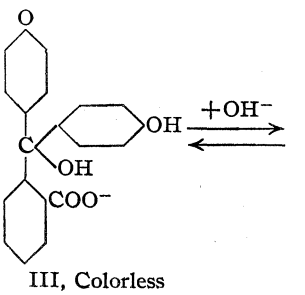
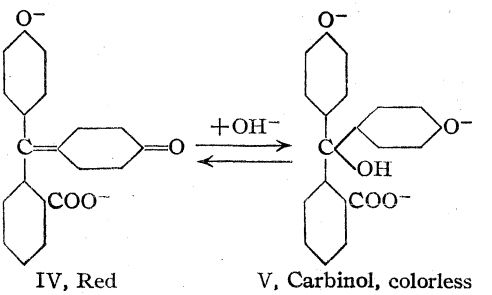
Discussion

1. Phenolphthalein in solution can exist in different forms, which are in equilibrium. Representing the various forms by the classical formulas we have







At a *p*H smaller than 8 practically all of the phenolphthalein is present in the lactone form I. It is estimated that the concentration of II is

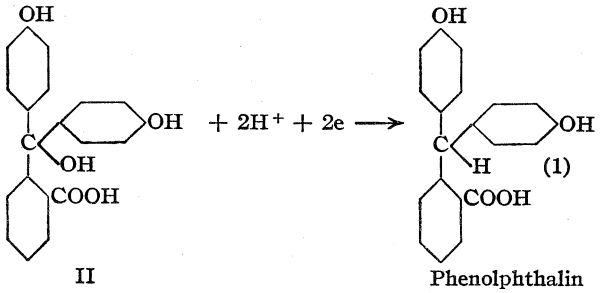
(7) I. M. Kolthoff and E. F. Orlemann, THIS JOURNAL, **63**, 664 (1941).

less than 0.01% of that of I.[8] For reasons mentioned below it is concluded that form II is reducible at the dropping electrode, but form I is not, at least at potentials more positive than that at which the wave of the supporting electrolyte used appears. Both forms II and III give a single reduction wave. The red form IV gives a two step reduction, both waves being of equal height. The colorless carbinol form V formed in strongly alkaline medium does not give a reduction wave, at least not at potentials more positive than that at which the sodium wave appears. When a strongly alkaline solution of phenolphthalein is permitted to stand the color fades and a corresponding reduction of the diffusion current is observed.

In the region of *p*H between 0 and about 10 the half wave potential varies according to

$$\pi^{1}/_{2} = -0.54 - 0.046pH$$

The reduction which is irreversible can be represented by the equation



II Phenolphthalin

This mechanism is supported by the following facts.

The diffusion current corresponds to a transfer of two electrons as shown in the experimental part. It also has been shown that phenolphthalin does not yield a reduction wave at the dropping electrode.

The reduction of form III can be represented by a similar equation as that of form II. The reduction of the red form IV, however, occurs in two steps. The first wave could correspond to the formation of the trivalent anion of phenolphthalin. As shown in the experimental part, the first wave of the red form is identical with the wave of form III. It does not seem plausible that the quinone form would be reduced at the same potentials as form III. However, it is peculiar that the half wave potential of form III varies with *p*H, whereas the half wave potentials of both waves of form IV appear to be independent of *p*H (Table II). Accepting the dipolar structure[9] of forms III and IV the coincidence of the reduction wave of III and of the first wave of IV becomes more reasonable.

Although the final reduction product is VIIa, form VII is formed intermediately at the surface of the electrode. The reduction of the colorless form III is found at higher hydrogen ion concentrations

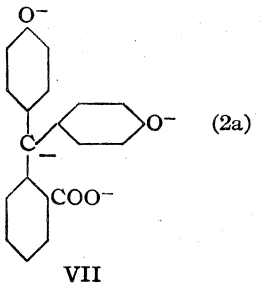
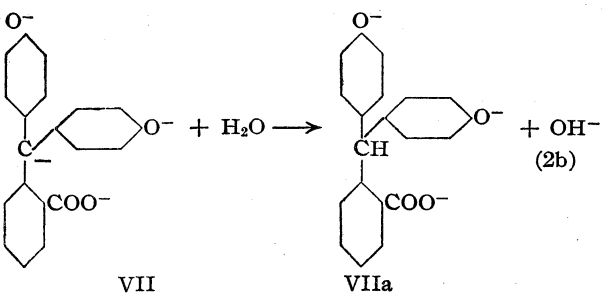
IVa, Red VI

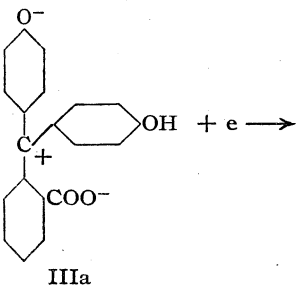


VII

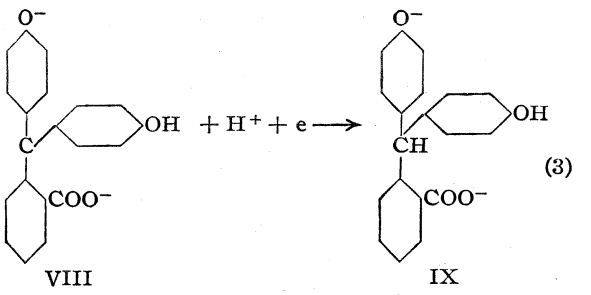


VII VIIa

than that of form IV. The reduction of III can be represented by



IIIa



VIII IX

The first steps in the reductions of IVa and IIIa are comparable, but the form corresponding to VII is not formed in the reduction of VIII or if it would be formed it would react instantaneously with hy-

drogen ions with formation of IX. The potential of reduction of VIII to IX becomes dependent upon the hydrogen ion concentration, and the second wave coincides with the first one.

2. From Table II it is seen that up to 30% ethanol the diffusion currents of phenolphthalein (*p*H 7) and benzoquinone are affected in the same way by the alcohol. This is mainly a viscosity effect. When the ethanol concentration becomes greater than 30% the diffusion current of phenolphthalein decreases much more than that of the quinone and in 70% ethanol the diffusion current of phenolphthalein becomes almost vanishingly small. This can be explained if it is assumed that form II, but not form I, is reducible. In the transformation of I into II the concentration of water becomes rate-determining. The experimental results indicate that at concentrations of less than 25% ethanol the rate of formation of II is so large that it is reformed from I immediately at the surface of the electrode when it is reduced. Therefore, at ethanol concentrations of 25% or less the apparent diffusion current corresponds to the true diffusion current of phenolphthalein. When the alcohol concentration increases the concentration of water decreases and the rate of transformation of I into II decreases. The apparent diffusion current now decreases and becomes partly diffusion and partly rate controlled. At alcohol concentrations greater than 50% the current becomes so small that it is practically entirely rate controlled. Under these circumstances the current should become independent of the height of the mercury in the reservoir.[10]

At the higher alcohol concentrations the polarographic behavior of phenolphthalein becomes comparable to that of some reducing sugars, like glucose and lactose in aqueous medium. As shown by Wiesner[11] the small "apparent" diffusion currents of these sugars are determined entirely by

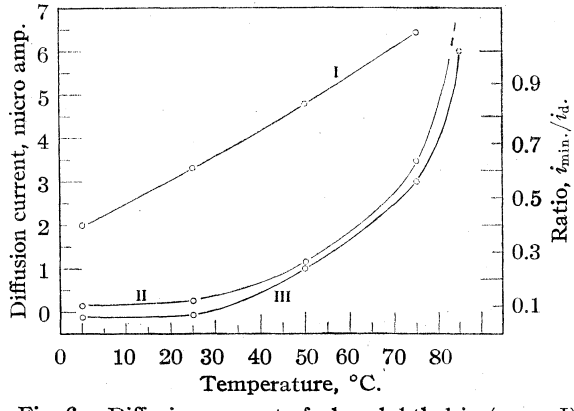


Fig. 6.—Diffusion current of phenolphthalein (curve I), minimum current (curve II) and ratio of minimum current to diffusion current (curve III) *versus* temperature.

(10) Comp. K. Wiesner, *Z. Elektrochem.*, **49**, 164 (1943); R. Brdicka and K. Wiesner, *Coll. Czechoslov. Chem. Commun.*, **12**, 138 (1947).

(11) K. Wiesner, *ibid.*, **12**, 64 (1947).

the rate of transformation of the non-reducible form of the sugars into the reducible form.

3. In 25% ethanol and in the presence of a phosphate buffer (*p*H 7) the diffusion current varies with the temperature in a normal way (see Fig. 6). From the slope of curve I in Fig. 6 it is calculated that the diffusion current increases by about 1.8% per one degree increase of temperature. This value is of the same order of magnitude as that of normal diffusion currents.[12] However, the effect of temperature on the minimum value of the current is quite different. Curve III in Fig. 6 gives the change of the ratio of $i_{min.}/i_d$ with the temperature. At temperatures between 0 and 30° i_d and $i_{min.}$ vary in about the same way, but at temperatures higher than 30° $i_{min.}$ increases much more than i_d.

First, we tried to explain the occurrence of the unprecedented minimum (see Fig. 1) by assuming that phenolphthalein is reduced only in the adsorbed state and that at potentials corresponding to that of the minimum current the phenolphthalein is desorbed. However, several phenomena are contrary to this interpretation. In general, the adsorption at the surface of the mercury decreases with increasing temperature. If phenolphthalein were reduced only in the adsorbed state the minimum current should decrease rather than increase with increasing temperature. The opposite is found. Another fact of significance is that at a *p*H of 9 a normal polarogram is observed. At this *p*H the second wave is negligibly small, and the (first) diffusion current retains its normal value until the wave of the supporting electrolyte occurs. At a *p*H of 9 little of the non-reducible form I is present, most of the phenolphthalein being in form III, and there is no indication that this form is being reduced in the adsorbed state. If it were reduced in the adsorbed state a desorption would be expected at more negative potentials, before the sodium wave (of the supporting electrolyte) appears. This would be accompanied by a decrease of the diffusion current, which has not been observed.

We attribute the occurrence of the minimum to a decreased rate of transformation of I into II *at the surface* of the electrode. The very large effect of the temperature upon $i_{min.}$ strongly suggests that we are dealing with a process which is rate controlled. If our interpretation is correct the rate of tranformation of I into II at the interface mercury–water should decrease with increasing potential. This is not strange, if it is realized that the structure of the double layer at the interface mercury–water varies in a complicated manner with the potential, and the type and concentration of electrolyte in the solution. Quite generally, strongly adsorbable organic compounds are being completely desorbed in the presence of electrolyte at negative potentials of the order of −1.5

(12) Comp. I. M. Kolthoff and J. J. Lingane, *Chem. Rev.*, **24**, 37 (1939).

volt. Similarly the orientation of water molecules at and in the interface changes with the potential of the mercury, thus affecting the rate of hydration of I. When the electrolyte content in the solution is small, as was the case in our experiment with a very dilute pyridine–pyridinium hydrochloride buffer, the structure of the double layer, especially at more negative potentials, is quite different from that in 0.1 *M* potassium chloride solution, which was the normal salt content in our experiments. In the very dilute buffer no dip in the current–voltage curve and no minimum were observed. Although the exact mechanism of the decreasing rate of the reaction I + $H_2O \rightarrow$ II with increasing negative potential needs further study, there is no doubt that the occurrence of the minimum, as in Fig. 1 (curve III), must be attributed to a decreasing rate of the above reaction at the electrode surface with increasing negative potential.

Summary

1. The polarographic behavior of phenolpthalein has been investigated under widely varying conditions. In 25% ethanol phenolphthalein gives a one-step reduction wave in a *p*H range between 0 and 9. In this range the half-wave potential changes according to $\pi^1/_2$ (*vs.* S.C.E.) = 0.54 − 0.046 *p*H. The red form of phenolphthalein yields two waves of equal height, each wave giving a well-defined diffusion current. The sum of the two diffusion currents is equal to that of the single wave observed at lower *p*H. The polarographic reduction of phenolphthalein to phenolphthalin is accompanied by a transfer of two electrons.

2. In the presence of a phosphate buffer of a *p*H of 7 the diffusion current decreases abnormally when the ethanol concentration is increased. In 60% ethanol the "apparent" diffusion current becomes extremely small at 25°. It is concluded that the lactone form of phenolphthalein is not reduced, but its hydrated form is. At alcohol concentrations of 25% or less the rate of hydration at the surface of the electrode is so large that a normal diffusion current is observed. At high alcohol concentrations the "apparent diffusion current" becomes entirely rate- and not diffusion-controlled. Experiments carried out at various temperatures substantiate this interpretation.

3. In 25% ethanol in the presence of a buffer of *p*H 7 the diffusion current remains constant in a potential range between −1.0 and −1.2 volt; it decreases slightly between −1.2 and −1.4 volt and then drops suddenly to attain a small minimum value at a potential of about −1.6 volt. Experimental evidence has been given substantiating the interpretation that the occurrence of the minimum is to be attributed to a decreased rate of transformation of the lactone form into the reducible hydrated form at the surface of the dropping electrode.

Polarographic Behavior of Nitrosophenylhydroxylamine[1]

BY I. M. KOLTHOFF AND A. LIBERTI[2]

The ammonium salt of nitrosophenylhydroxylamine, called cupferron, is a well-known analytical reagent, which precipitates a great number of metal ions in acid medium. In connection with a study of the use of cupferron as a reagent in amperometric titrations, the polarographic behavior of nitrosophenylhydroxylamine has been investigated over a wide range of *p*H.

Experimental

Materials Used: Cupferron.—Eastman Kodak Co. and G. F. Smith Chemical Co. products were recrystallized from ethanol. The crystals had the appearance of silver-white leaflets (m. p. 163–164°). The solid product was stored in a dark bottle over solid ammonium carbonate to prevent decomposition. A stock solution (0.02 *M*) in water was found to be stable for more than two weeks when kept in the dark in a cool place. The solution is not stable in acid medium, as the phenylnitrosohydroxylamine decomposes. The rate of decomposition increases with decreasing *p*H. When polarograms were determined in acid medium at a *p*H smaller than 3, a measured volume of an air-free stock solution of cupferron was added to a suitable volume of air-free buffer solution in the cell and the current-voltage curve was determined soon after mixing. In some experiments the lithium salt of nitrosophenylhydroxylamine was used, which was prepared from cupferron and lithium hydroxide.

Buffer Solutions.—In the *p*H range between 1 and 5.6 Clark and Lubs buffers served to adjust the *p*H. In the range between *p*H 3 and 10 the universal buffers of Britton and Robinson[3] were used. The buffer mixtures were prepared by addition of lithium hydroxide to a solution which was 0.04 *M* in phosphoric, 0.04 *M* in acetic and 0.04 *M* in boric acids. In addition, Clark and Lubs buffers, prepared from boric acid and lithium hydroxide and lithium chloride, were used in the *p*H range between 8 and 10.

Tetramethylammonium Hydroxide Solution.—An Eastman Kodak Co. product of the bromide of this base was purified by repeated recrystallizations from ethanol–water mixtures. A stock solution of the hydroxide was prepared from the purified bromide with silver hydroxide as described by Peracchio and Meloche.[4] Buffer solutions prepared from tetramethylammonium hydroxide and phos-

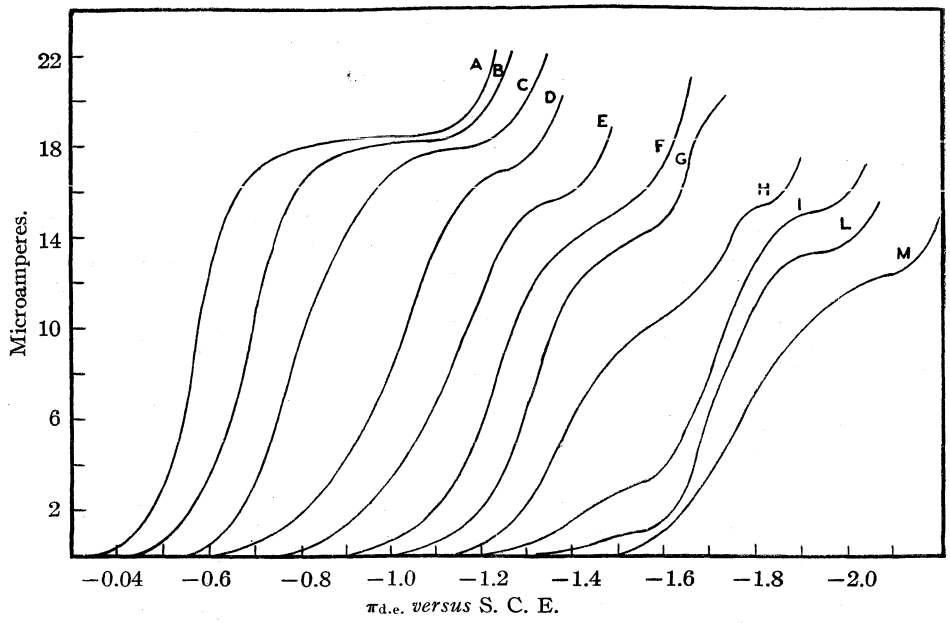

Fig. 1.—Polarograms of cupferron (8×10^{-4} *M*) in buffer solutions at the following *p*H values: A 1.2, B 2.1, C 3.1, D 4.4, E 5.2, F 5.9, G 6.6, H 7.2, I 7.9, L 8.8, M 12.5.

phoric acid or boric acid were prepared. Polarograms obtained with these buffers gave poorly reproducible and irregular currents near the potentials at which the cupferron waves appeared. For this reason these buffers could not be used in the present polarographic work. On the other hand, well defined waves were obtained in tetramethylammonium hydroxide solutions.

Gelatin Solution.—A 0.1% gelatin solution in water was stored under a layer of toluene to prevent decomposition. When used in a concentration of the order of 0.01%, gelatin was found to eliminate maxima in the polarograms at a *p*H smaller than 3. At a *p*H greater than 3 no maxima were observed even in the absence of gelatin.

Determination of Polarograms.—Both the manual polarograph[5] and the automatic Heyrovsky instrument, Model XI, have been used in this work. In all the experiments an outside saturated calomel electrode (S.C.E.) served as the reference electrode. All the potentials refer to the S.C.E.

Under the experimental conditions the capillary had a drop time *t* of 3.00 seconds at zero applied e.m.f. and the mass of mercury *m* flowing out per second was 2.37 mg. The values of *m* and *t* were determined in the potential range between 0 and 2 volts. The values of the diffusion current could thus be referred to the same value of $m^{2/3}t^{1/6}$. The reported values of diffusion or limiting currents are corrected for the residual current and refer to a $m^{2/3}t^{1/6}$ value at a potential of 0.5 volt.

The electrolysis cell was provided at the bottom with an inlet tube for purified nitrogen. Another inlet tube through the stopper of the cell served for the introduction of nitrogen to the gas phase above the solution during the measurements. All the experiments were carried out in a thermostat at 25.0 ± 0.1°.

Experimental Results

As an illustration some representative polarograms in the *p*H range between 1 and 12.5 are given in Fig. 1. Without correction for the residual current many of the limiting currents appear poorly defined. For this reason the polarograms represented in Fig. 1 give the currents found with the manual apparatus, corrected for the residual current and referred to a constant value of $m^{2/3}t^{1/6}$. Since at a *p*H between 1 and 3 the decomposition of phenylnitrosohydroxylamine is rapid, 24 ml. of the supporting buffer solution was made air-free in the cell, 1 ml. of standard air-free cupferron solution was added and the current-voltage curve determined immediately after mixing. The determinations were well reproducible.

Only one wave was found in acid medium, up to a *p*H of 6.6. The apparent diffusion or limiting current decreased with increasing *p*H, the change becoming very pronounced when the *p*H became greater than 6. At *p*H values between 3 and 6 the limiting current was found to be proportional to the concentration of cupferron added to the buffers. This is illustrated in Fig. 2.

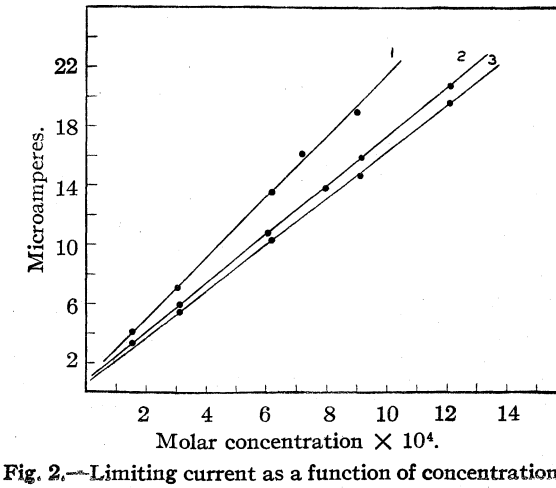

Fig. 2.—Limiting current as a function of concentration at: 1, *p*H 2.9; 2, *p*H 5.2; 3, *p*H, 6.6.

(5) J. J. Lingane and I. M. Kolthoff, THIS JOURNAL, 61, 825 (1939).

A plot of the values of log $i/(i_d - i)$ *versus* the potential at a *p*H of 1 yields a straight line with a slope of 182 mv. This indicates that the reduction is irreversible; as it seems impossible that a reversible reduction would involve three electrons.

In the *p*H range between 7 and 9 two waves were observed. The first wave was poorly defined (see Fig. 1 and 3); its limiting value was estimated by the tangent method (see Fig. 3). The second wave appeared to attain a constant value at a *p*H greater than 8.

Only one wave due to reduction of the cupferronate was observed at a *p*H greater than 9, its height remaining unchanged when the *p*H was raised to 12.5.

Some of the experimental data are summarized in Table I.

TABLE I

WAVE HEIGHTS AND HALF WAVE POTENTIALS IN 8×10^{-4} *M* SOLUTIONS OF CUPFERRON AT VARYING *p*H AT 25°

*p*H	Supporting electrolyte	Height first wave in μA	$-(\pi_{1/2})_1$	Height second wave in μA	$-(\pi_{1/2})_2$
1.1	Clark and Lubs; HCl–KCl	18.5	0.672		
1.4	Clark and Lubs; HCl–KCl	18.4	.71		
2.1	Clark and Lubs; Phthalate	18.3	.785		
3.0	Clark and Lubs; Phthalate	17.8	.89		
4.4	Clark and Lubs; Phthalate	16.6	1.10		
5.2	Clark and Lubs; Phthalate	15.5	1.22		
5.9	Britton and Robinson	14.6	1.32		
6.6	Britton and Robinson	13.2	1.405		
7.2	Britton and Robinson	9.0	1.46	6	1.79
7.9	Britton and Robinson	3.8	1.53	11.2	1.81
8.3	Britton and Robinson	2.8	1.56	12.2	1.81
8.8	Britton and Robinson	1.0	1.57	12.2	1.82
10.0	Boric acid–lithium hydroxide	..	..	12.2	1.85
12.5	Tetramethylammonium hydroxide	..	..	12.2	1.86

The half wave potential of the first wave was found to depend greatly upon the *p*H. The plot of the half wave potential against the *p*H yields a straight line with a slope of 128 mv. per *p*H unit. Thus, the half wave potential $-\pi_{1/2}$ is found to vary with the *p*H according to $-\pi_{1/2} = -\pi^0_{1/2} - 0.128$ *p*H in which $\pi^0_{1/2} = -0.58$ v. (*versus* the S.C.E.) at 25°.

This relation expresses that the half wave potential varies with the square of the hydrogen ion concentration, which is a very unusual relation. The half wave potential of the second wave appears to be practically independent of the *p*H. Its value was found to be −1.80 v.

For reasons given in the discussion section the height of the first and of the second waves at a *p*H of 8.25 were determined as a function of the height, *h*, of the mercury in the reservoir. In these experiments the lithium salt of nitrosophenylhydroxylamine was used instead of cupferron in order to eliminate the ammonium wave. The experiments were carried out in boric acid–lithium hydroxide buffers. The measured values of the limiting currents were corrected again for the residual current and referred to a constant value of $m^{2/3}t^{1/6}$. The results are given in Table II.

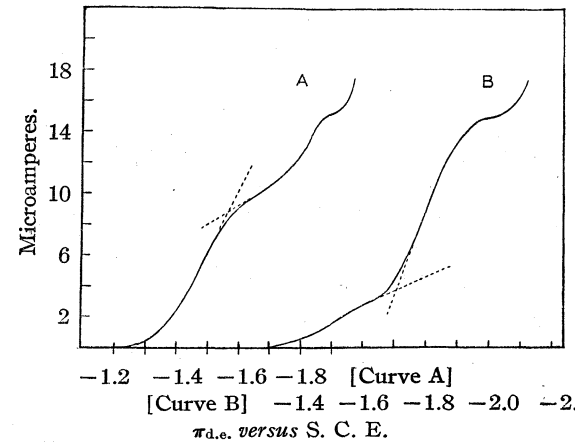

Fig. 3.—Polarograms of 8×10^{-4} *M* cupferron at *p*H 7.2 (curve A) and *p*H 7.9 (curve B).

TABLE II

VALUES OF THE FIRST (i_1) AND THE SECOND (i_2) LIMITING CURRENTS AT *p*H 8.25 AS FUNCTION OF THE HEIGHT OF MERCURY IN THE RESERVOIR

Height *h* of mercury in reservoir in cm.	Drop time *t* in seconds	i_1	i_2	$i_2/h^{1/2}$
94	2.4	2.80	13.55	1.40
75	3.0	2.80	12.20	1.41
56	4.2	2.76	10.64	1.42
39	6.3	2.70	8.60	1.37

It is seen that the height of the first wave is not affected by the height of the mercury in the reservoir, while that of the second wave is proportional to the square root of the height of the mercury. Therefore, the height of the second wave is diffusion controlled, like that of an ordinary diffusion current.

Discussion

(1) From the fact that in the *p*H range between 7 and 9 two reduction waves are observed it is evident that the acid form of nitrosophenylhydroxylamine and its anion are reduced at different potentials. However, in the acid range at a *p*H greater than 3 the height of the wave of the acid form is much greater than corresponds to the concentration of the undissociated acid in the bulk of the solution. Only at a *p*H smaller than 2 does the limiting current correspond to the true diffusion current of the undissociated acid. From the work of Hantzsch[6] and of Pyatnitokii[7] it is estimated that the ionization constant K_a of phenylnitrosohydroxylamine at 25° is equal to 5.3×10^{-5}. Assuming that the limiting value of the current of 18.5 μ in 8×10^{-4} *M* cupferron solution at *p*H 1 is the true diffusion current of the

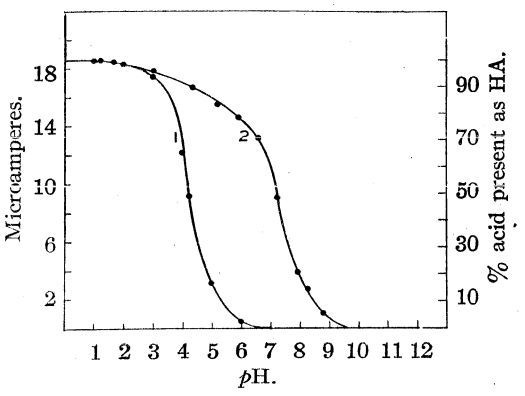

Fig. 4.—Curve 1, dissociation curve of nitrosophenylhydroxylamine; curve 2, change of the limiting current of the acid form of nitrosophenylhydroxylamine.

acid, the values of i_d at higher pH can be calculated. Plotting the calculated values against pH yields curve 1 in Fig. 4. Curve 2 represents the limiting currents due to the acid form observed at varying pH. It is seen that the mid-way point is shifted 3 units to a higher pH. The reason for this shift is that upon reduction of the free acid at the surface of the electrode, more acid is formed as a result of the association of hydrogen ions with the anions A^- of the acid

$$H^+ + A^- \longrightarrow HA \qquad (1)$$

From Fig. 4 it is seen that at a pH greater than 6 the current due to the equilibrium concentration of HA is negligibly small and that the limiting current is determined entirely by the rate of formation of HA at the surface of the electrode. This current may be called the kinetic current. The polarographic behavior of nitrosophenylhydroxylamine in acid medium is very similar to that of pyruvic acid and of phenylglyoxalic acid discussed by Brdička and Wiesner.[8] These authors derived the following expression for the limiting value of the kinetic current $(i_k)_l$

$$(i_k)_l = \frac{\mu k[H^+]acK_a}{(K_a + [H^+])(\mu k[H^+] + a\cdot 10^3/nFyq)} \qquad (2)$$

in which k is the rate constant of reaction (1), μ is the thickness of the layer around the electrode where the association takes place, a is the constant in the Ilkovič equation $i_d = ac$, c is the total concentration (dissociated plus undissociated) of the acid with ionization constant K_a, n is the number of electrons involved in the reduction, Fy the faraday, and q the average surface of mercury per drop.

When the concentration of HA in the bulk of the solution is not negligibly small the total current i_t due to the reduction of the acid form becomes

$$i_t = (i_d)_{HA} + i_k \qquad (3)$$

in which $(i_d)_{HA}$ is the diffusion current of the acid corresponding to the reduction of the undissociated acid present in the bulk of the solution. It can be shown[8] that when i_t is equal to one half of the maximum value of $(i_d)_{HA}$ (in our case found at pH of 1)

$$\mu k = \frac{K_a - [H^+]}{(K_a + [H^+])[H^+]} \times \frac{a\cdot 10^3}{nFyq} \qquad (4)$$

Under our experimental conditions, a had a value of 0.0230 and q of 0.0189. Using these figures in equation (3) a value of μk of 3.34×10^4 is found. Brdička and Wiesner estimate that μ is of the order of 10^{-7} cm. Using this value, a rate constant k (equation 1) of the order of 3.3×10^{11} is found. This value is only an approximation, because equation (2) has been derived on the basis of some simplifying assumptions. A highly mathematical and more exact treatment is given by Koutecky and Brdička.[9]

Using the above value of μk it is possible to calculate the limiting kinetic currents at various pH. The values thus obtained are plotted in Fig. 5 and are compared with the experimental values found by subtracting the calculated values of $(i_d)_{HA}$ from i_t (equation 3). Considering that equation (2) is only approximately valid the agreement between the calculated and experimental values is satisfactory.

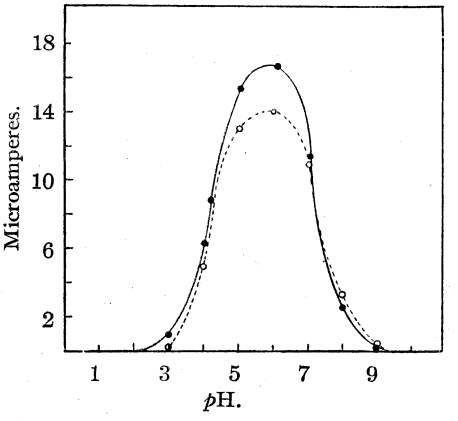

Fig. 5.—Change of the kinetic current at varying pH. The dotted curve shows the experimental values and the drawn curve the calculated values.

The correctness of the interpretation of the polarograms in acid medium is supported by the effect of the height of mercury in the reservoir upon the first and the second waves at a pH of 8.25. At this pH $(i_d)_{HA}$ is equal to zero and the height of the first wave is equal to $(i_k)_l$. Moreover, at this pH, $a\cdot 10^3/nFyq$ is much greater than $\mu k\,[H^+]$. Hence, at this pH

$$i_1 = (i_k)_l = \frac{\mu k[H^+]acnFyq}{(K_a + [H^+])\,a\cdot 10^3} \qquad (5)$$

It is seen that a cancels in equation (5) and that the height of the first wave becomes proportional

(8) R. Brdička and K. Wiesner, *Coll. Czechoslov. Chem. Commun.*, **12**, 138 (1947).

(9) J. Koutecky and R. Brdička, *Coll. Czechoslov. Chem. Commun.*, **12**, 337 (1947).

to q. Since the surface of the mercury is proportional to $m^{2/3}t^{2/3}$ the height of the mercury in the reservoir should not have any effect on i_1 at a pH of 8.25. Indeed, it is seen from Table II that the pressure of the mercury does not affect i_1. On the other hand i_2 is diffusion controlled; therefore, i_2 varies with the square root of the height of the mercury in the reservoir.

(2) It has been mentioned that the limiting current measured at a pH of 1 corresponds to the true diffusion current of the nitrosophenylhydroxylamine. Assuming that the diffusion coefficient of this acid is equal to that of the benzoate ion, it is possible to calculate the number of electrons n involved in the reduction. From the Ilkovič equation it is found that

$$n = \frac{i_d}{0.605\, cD^{1/2}m^{2/3}t^{1/6}}$$

In 8×10^{-4} M cupferron solution at a pH of 1, i_d was found equal to 18.5 microamperes, while $m^{2/3}t^{1/6}$ was 2.14. Taking D equal to 8.81×10^{-6} yields a value of 6.0 for n. Hence six electrons are involved in the reduction of nitrosophenylhydroxylamine.

On the other hand in alkaline medium where we are dealing with the reduction of the anion the diffusion current was found to be equal to two thirds of that at a pH of 1. Hence the reduction of the anion involves four electrons.

Various structures have been suggested for nitrosophenylhydroxylamine. Angeli[10] proposed the structure $C_6H_5-N(=O)-NOH$, while Hantzsch[11] prefers $C_6H_5-N(-OH)-NO$. Diehl[12] suggested that the two forms are in tautomeric equilibrium. Considering the relatively strong acid character of nitrosophenylhydroxylamine G. Fieser and M. Fieser[13] assume that there is an equilibrium between the nitrosohydroxy form, a, and the more strongly acid amine oxide form, b

$$C_6H_5-N(-OH)-N=O \rightleftharpoons C_6H_5-N^+(-O^-)=NOH$$

a b

The reduction of nitro- and nitroso- compounds occurs in steps. In acid medium, in which the reduction at the dropping electrode involves six electrons the final reaction product must be the phenylhydrazine

$$C_6H_5N(NO)-OH + 2H^+ + 2e \longrightarrow C_6H_5N(NHOH)-OH$$

$$+ 2H^+ + 2e \longrightarrow C_6H_5N(NH_2)-OH$$

$$+ 2H^+ + 2e \longrightarrow C_6H_5N(NH_2)-H$$

In alkaline medium the reduction involves four electrons and the anion $C_6H_5N(N=O)-O^-$ (Hantzsch) or $C_6H_5-N^+(O^-)=NO^-$ (Fieser and Fieser) apparently is reduced to $C_6H_5-N(NH_2)-O^-$.

Summary

1. Nitrosophenylhydroxylamine solutions at a pH of 1 yield a diffusion current corresponding to a reduction which involves 6 electrons. At a pH greater than 9 the anion of the acid gives a diffusion current corresponding to an electron transfer of 4. The half wave potential of the acid wave varied with the pH: $\pi_{1/2} = -0.58 - 0.128$ pH *vs.* S.C.E.; the half wave potential of the alkaline wave is -1.80 v. and does not vary with the pH.

2. Only one wave is found in acid medium up to a pH of about 6.6, two waves are found in the pH range between 6.6 and 9.0; at higher pH only one wave is found.

3. In the acid range at a pH greater than 3 the height of the wave is much greater than corresponds to the concentration of the undissociated acid in the bulk of the solution. This is explained by the fact that the current is partly controlled by the rate of formation of acid at the surface of the electrode: $H^+ + A^- \rightarrow HA$. Using Brdička and Wiesner's[8] formulation a rate constant of the order of 3.3×10^{11} is calculated. When the kinetic current is very small with regard to the diffusion current the former becomes independent of the height of the mercury in the reservoir. This is found to be true at a pH of 8.25, where the height of the first wave (kinetic current) is independent of the height of mercury in the reservoir, while the second wave is diffusion controlled.

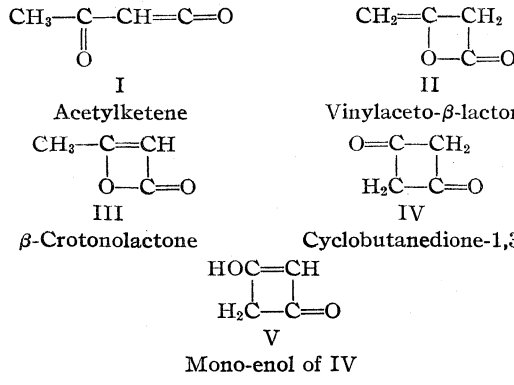
Diketene: Infrared Spectrum and Structure

BY FOIL A. MILLER* AND STANLEY D. KOCH, JR.†

The structure of the ketene dimer, $(CH_2{=}C{=}O)_2$, has been in question ever since its discovery in 1908. Five possible forms have been seriously considered at various times:



I Acetylketene

II Vinylaceto-β-lactone

III β-Crotonolactone

IV Cyclobutanedione-1,3

V Mono-enol of IV

The present status of the problem has been well summarized by Boese[1] and by Hanford and Sauer.[2] Chemical reactions appear to have been of little help in elucidating the structure, for some indicate one form and some another. It is very difficult to evaluate such evidence critically because of the considerable possibility of rearrangements. Since the problem is to establish the structure of the ground electronic state of diketene, it seems undesirable to argue from evidence that involves also an unknown activated state. One is therefore inclined to discount such evidence and to rely on physical measurements made only on the ground state if possible. These, however, have also led to contradictions. The non-zero dipole moment[3,4] eliminates the possibility that the structure may be symmetrical form IV alone. The Raman spectrum has been obtained for the liquid,[5,6,7] and the infrared spectrum for both liquid and solutions.[8] The absence of any O-H stretching frequency eliminates V, and the many coincidences between the Raman and infrared spectra eliminate again the existence of form IV alone. A further decision between the remaining forms I, II, and III has not yet been made from the data. It is noteworthy that five strong bands are found in the double bond stretching region (1500–2000 cm.$^{-1}$), whereas each of the postulated forms would have only two fundamentals there. (Form I may be an exception, with only one band in this region. The ketene group in this molecule probably would give one band above this range and one below it.) The remaining three (or four) bands must then be explained either as combination tones, or as due to the presence of more than one form. The ultraviolet absorption maximum at 3130 A (ϵ = 2) would seem to favor III.[9] (This too involves an upper electronic state, however.) Electron diffraction studies are said to be compatible with II or III, incompatible with I and IV.[10] Unfortunately none of these data provide unambiguous proof for any one of the possible structures. Because of this it has been suggested several times[2,8] that there may be two (or more) forms in equilibrium.

It occurred to us that the existence of such an equilibrium, Form A $\rightleftarrows$ Form B, might possibly be demonstrated by measuring the infrared spectrum as a function of temperature. The van't Hoff equation, $d \ln K/dT = \Delta H/RT^2$, indicates that if ΔH is sufficiently large the equilibrium constant will change appreciably with temperature. The resulting alteration in the composition of the equilibrium mixture may then be evidenced in the infrared spectrum. Conversely, however, a spectrum which changes with temperature does not indicate the existence of an equilibrium unless other temperature effects are excluded. Two such effects come to mind immediately. (a) An irreversible chemical change. This possibility can be eliminated if the changes in the spectrum are found to be reversed when the sample is brought back to its original temperature. (b) Altered population of the energy levels in accordance with the Boltzmann factor. For a moderate rise in temperature the increased population of the higher vibrational levels will increase the intensity of difference bands, but should not appreciably affect the relative intensities of fundamentals. Hence a very few weak bands may become markedly intensified at higher temperatures, but they should be calculable as difference tones. The effect of increased temperature on the rotational fine structure is one of broadening and flattening the rotational branches. If the width of a vibration–rotation band of an asymmetric rotator is defined as the separation of points on the

band envelope where the intensity has a given value, then the width of the band is proportional to the square root of the absolute temperature.[11] Thus in going from 30 to 180° the band width will increase by a factor of about 1.2. This should not be a confusing effect, as we shall be looking for more marked changes in the spectrum.

Experimental

Diketene was prepared by the dimerization of ketene according to the method of Williams and Krynitsky.[12,13] The spectrum was measured from 3 to 15 μ with a Model 12-B Perkin–Elmer infrared spectrometer equipped with rocksalt optics, a General Motors breaker-type amplifier, and a Brown recorder. A 5-cm. Pyrex cell was used for the vapor. The rocksalt windows were sealed on with glyptal resin, which was found to hold well at temperatures up to 180° if one heats or cools rather slowly to avoid cracking the seal. The cell was heated in a small oven consisting of a sheet metal cylinder closed with endplates of transite that were held together by four tie rods. A window was cut in each piece of transite and closed by clamping over it a polished rocksalt plate. A suitably insulated electrical heating element was wrapped around the metal cylinder. The cell was connected by glass tubing to an external sample reservoir immersed in a water bath. The connecting tube had a small U-type mercury manometer sealed to it so that pressures in the range 0–20 mm. could be read. The primary purpose of the manometer was to indicate any failure in the glyptal seals. The connecting tube and manometer were wrapped with a spiral of resistance wire and heated electrically to a temperature sufficiently high so that no condensation occurred in them. In this manner the reservoir was made the coolest part of the system. The pressure of the vapor was thus determined by the temperature of the liquid reservoir, whereas the temperature of the vapor in the beam was determined by that of the oven.

Spectra were measured at vapor temperatures of approximately 30, 60, 100, 140 and 180°. Experimental conditions for the various determinations were

No.	Temp. of reservoir, °C.	Temp. of cell, °C.
1	28	60
2	29	100 ± 2
3	34	141 ± 2
4	35	182 ± 1
5	< −50	183 ± 2
6	29	102 ± 3
7	28	31 ± 1
8	< −50	30

In runs 5 and 8 the vapor was condensed into the liquid reservoir by cooling with a Dry Ice-bath. These runs thus served as blanks to give the transmission through the empty cell, and to demonstrate that no deposit had formed on the windows. After completion of run 5 vapor was readmitted to the cell at 180°, the cell was slowly cooled to 100°, and the spectrum was remeasured at this temperature. The apparatus was then allowed to stand overnight to reach temperature equilibrium with the room, and run 7 was made with the vapor at 31°. The cell then stood overnight again while the sample reservoir was cooled with a Dry Ice-bath, and blank run 8 was made. It was necessary to wait this long because it was found during blank runs 5 and 8 that about 3 mm. of residual permanent gas was present in the system. This impeded the diffusion of vapor back into the reservoir. We believe that this gas was air which degassed from the system during heating, for it gave no infrared absorption.

Another experiment was performed for the purpose of locating very weak bands. In this case a dish of liquid diketene was placed within the smaller or source housing of the spectrometer. This provided a path length of 40 cm. at a vapor pressure of about 13 mm.

Finally, the spectra of solutions of diketene in carbon tetrachloride and carbon disulfide were obtained to get a comparison between our samples and those used by Whiffen and Thompson.

Results

In brief, the spectrum was found to change markedly with temperature, and these changes were reversed on cooling.

Table I summarizes our results at 30°, and gives for comparison the data reported by Whiffen and Thompson[8] for the pure liquid and for solutions. The agreement is reasonably satisfactory. We observed the same change in the relative intensities of certain bands in the 1700–1900 cm.$^{-1}$ region upon change of solvent that was noted by these authors. Our bands in the 3000 cm.$^{-1}$ region are accurate to only about ±15 cm.$^{-1}$ because of poor dispersion, but the spectrum was scanned to 3600 cm.$^{-1}$ to confirm the absence of hydroxyl groups in the vapor. It is noteworthy that the very intense band of ketene monomer at 2153 cm.$^{-1}$ is not present in any of our spectra at any temperature.

It is necessary to point out at this time that the intensities reported in this paper are only qualitatively correct for the following two reasons. First, our procedure was to record a radiation curve through an empty cell, and then to use this in calculating transmission for all the other determinations. (Run 8 was used for this purpose.) Many of the experimental conditions varied slightly from run to run—amplifier gain, energy output from the globar, atmospheric water vapor in the air path, and so on—so the runs are not strictly comparable. Secondly, the concentration of the vapor molecules in the beam was not quite the same at the various temperatures. Assuming an ideal gas, the concentration is proportional to P/T. We hoped to measure the pressure with the little manometer, and to adjust it by changing the temperature of the reservoir in such a manner as to keep P/T constant for the vapor. However, because of the permanent gas alluded to earlier, there was an error in all the pressure measurements. Since the vapor pressure was of the order of 15 mm., a 3 mm. error was relatively large. Hence the amount of sample in the beam was not the same for the various runs. For these two reasons it is evident that we will not be justified in comparing absolute intensities. Nevertheless a comparison of the relative intensities of two bands in one spectrum with the relative intensities of the same two bands in another spectrum will be meaningful. In this connection it should be remembered that the intensity of a band is to be measured by the area under the band envelope

rather than by the position of maximum absorption, because a band will flatten and broaden as the temperature increases.

Figure 1 compares the two 100° spectra (runs 2 and 6). Although the two curves are not quantitatively identical, the general agreement is good except for the two bands at 1133 and 1838 cm.$^{-1}$. The first of these will be discussed later. The second is apparently due to some extraneous material such as the glyptal lacquer because it is most intense in the first run, weaker in the second, and missing in all the others. The two spectra are sufficiently similar to indicate that reversibility is established.

Figure 2 compares the spectrum at 60° with that at 180° (runs 1 and 4). Examination will reveal several significant differences. Consider first the region 1600–1820 cm.$^{-1}$, which contains the four bands at 1676, 1720, 1776, and 1797 cm.$^{-1}$. At 60°, 1720 is much the strongest, 1776 is very slightly more intense than 1676, and 1797 is completely missing. At 180° the intensity is in the order 1776 $\simeq$ 1720 > 1676, and 1797 has appeared. Figure 3B shows that these changes occur gradually as the temperature is increased. A comparison of 1676 and 1776, for example, shows that the intensity of the 1776 cm.$^{-1}$ band changes from less than that of 1676 at 30° to much more at 180°. The changes are reversible, as indicated by the rerun at 100°, and by the fact that the 30° run (which was made last of all) fits the general trend. This group of four bands thus shows a very definite and reversible change with temperature. The 1797 cm.$^{-1}$ band cannot be explained as any reasonable difference tone.

Similar changes are found in the 1100–1300 cm.$^{-1}$ region, as shown in Fig. 3A. The band at 1133 cm.$^{-1}$ is most intense in the first spectrum measured (60°), and is completely gone at 180°. On cooling back to 100° it reappears, but not as intensely as in the first 100° run. On further cooling to 30° it is still present, but with rather low intensity. Hence this band seems to indicate an irreversible change. Since there is little other evidence for irreversibility in the spectrum, one might attribute the band to some impurity. It is reported by Whiffen and Thompson, but by none of the Raman investigators. On the other hand it does reappear, even though weakly, at the lower temperatures. We have no explanation for the behavior. The band at about 1185 cm.$^{-1}$ comes in as temperature increases and goes out again on cooling. It may be the difference tones 1683 − 504(R) = 1179 and 1722 − 531(R) = 1181 (R = Raman band). On the other hand, the 1237-1250 doublet shows the converse behavior, disappearing as the temperature increases. Another band at 1292 cm.$^{-1}$ is present only at the lower temperatures. This band is not reported in any earlier work, and so it may be due to an impurity. Other characteristic changes in the spectrum are noticeable too. For example, as the temperature increases, the intensity of the 1919 cm.$^{-1}$ band relative to that of the 1676–1720–1776 group becomes markedly less. This change is also reversible with temperature.

There can be no doubt, then, that there are real changes in the spectrum as the temperature is increased. We feel that they cannot be due to

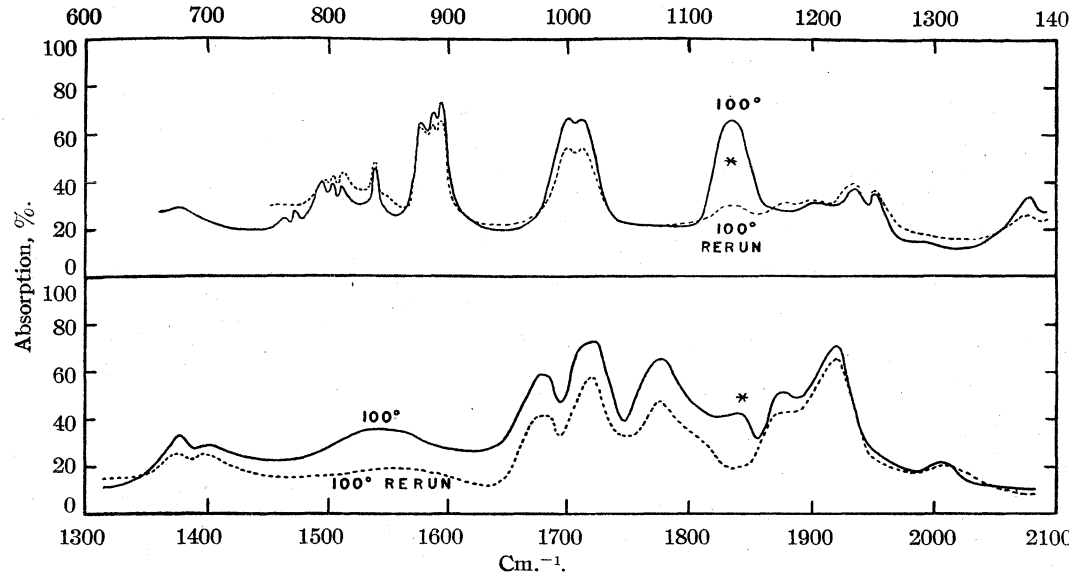

Fig. 1.—Infrared spectrum of diketene vapor at 100° (runs 2 and 6). Bands marked with an asterisk are of questionable origin. See discussion in text.

an irreversible chemical reaction because the original features of the spectrum are recovered on cooling. (The 1133 cm.$^{-1}$ band is an exception to this.) Also the changes are much too marked to be attributed entirely to changes in the population of the vibrational and rotational levels. Hence we feel that the results indicate the existence of an equilibrium between two forms of diketene which co-exist at room temperature.

Discussion

If one accepts the existence of such an equilibrium, it becomes much easier to understand the anomalous behavior of diketene which has been so puzzling heretofore. For example, one chemical reaction may proceed through one form, and another reaction through the other form. It is also now reasonable to find five strong bands in the double bond stretching region. Four (or three) fundamentals are to be expected, leaving only one (or two) to be explained as a combination tone.

The question as to which forms comprise the equilibrium mixture now presents itself. The spectroscopic evidence has been thoroughly discussed by Whiffen and Thompson.[8] We feel that

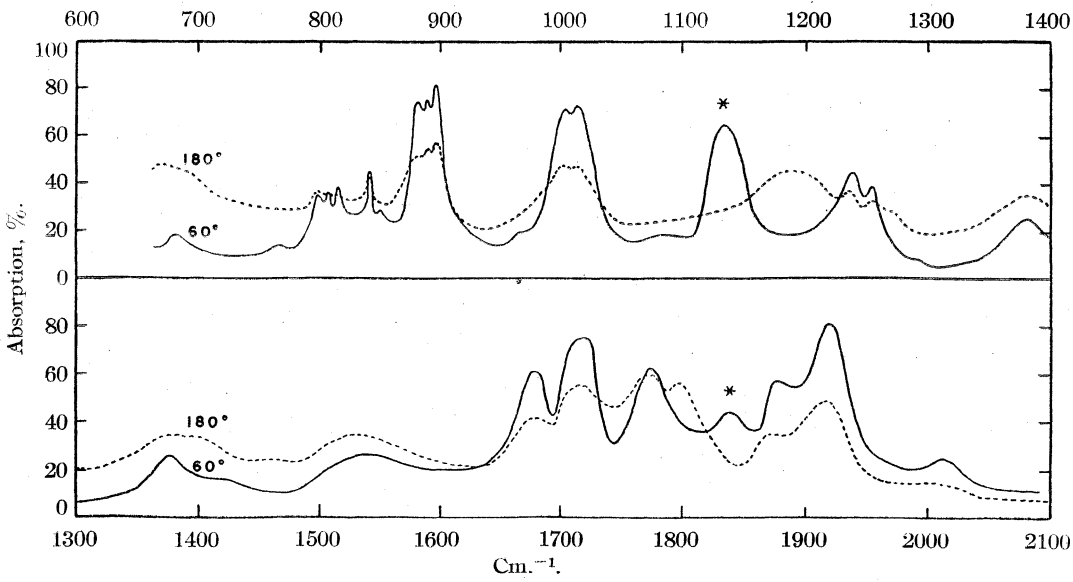

Fig. 2.—Infrared spectrum of diketene vapor at 60° and 180° (runs 1 and 4). Bands marked with an asterisk are of questionable origin. See discussion in text.

their reason for eliminating the acetylketene structure (I)—the lack of a ketene group band near 2150 cm.$^{-1}$—is very compelling. It is our opinion that if as much as 2–4% of the material were in Form I, a band would have been observed in the region 2100–2200 cm.$^{-1}$. This elimination of Form I receives further support from the electron diffraction results cited earlier.[10] Forms II and III seem to be adequate to explain all the observations on diketene—chemical reactions, electron diffraction, ultraviolet absorption, vibrational spectrum, dipole moment. There remains the possibility that Form IV (cyclobutanedione-1,3) may be one of the components of the mixture. It has been amply proved that this structure alone cannot represent diketene, but it is not so easy to prove that it is not present in the equilibrium mixture. However, if there are only two components, it seems probable that they would be II and III rather than either one of these with IV. The conversion between II and III is accomplished by transfer of a proton and the shift of a double bond. Changes of this type are fairly common. On the other hand the conversion of IV into either II or III involves breaking and reforming the four-membered ring, and one would expect the activation energy to be higher for this process than for the former one. Some chemical evidence can also be adduced to support the elimination of IV. It has been shown that diketene does not react with sodium metal, with acetyl chloride, nor with phenyl isocyanate.[14] These reagents are sensitive to the presence of hydroxyl groups, and so it is apparent that diketene contains neither hydroxyl groups nor a potential enolic structure. Judging by analogy with other compounds, Form IV would be expected to enolize sufficiently to show some reaction with these reagents. The fact that no such reaction has been detected indicates that Form IV is not present. This argument is not by itself convincing, because of its speculative nature, but it does add some support to the conclusion reached above.

To summarize, then, it seems that diketene is probably an equilibrium mixture of Forms II and III (vinylaceto-β-lactone and β-crotonolactone).

We have been unable to decide which form is favored by increasing the temperature. One can say, however, that certain of the vibrational bands belong to the high temperature form and certain others to the low temperature form. One thus has an experimental method for following the separation of the two forms.

Summary

1. The infrared spectrum of diketene vapor has been measured at five temperatures ranging from 30 to 180°.

2. The spectrum changes with temperature in such a manner as to indicate an equilibrium mixture of two (or more) kinds of molecules.

3. The equilibrium is probably between two of the three structures: vinylaceto-β-lactone, β-crotonolactone, and cyclobutanedione-1,3. The first two seem most likely; they are capable of accounting for all the experimental observations on diketene.

o-Methoxy-, p-Benzyl-, o-Fluoro-, and o-Cyano-styrenes. Further Examples of the Disproportionation of Phenylmethylcarbinols to Ethylbenzenes[1]

BY C. S. MARVEL AND D. W. HEIN

In connection with the study of a variety of substituted styrenes as substitutes for styrene in GR-S, the syntheses of *o*-methoxy-, *p*-benzyl-, *o*-fluoro-, and *o*-cyano-styrenes have been accomplished by routes not previously described.

o-Methoxystyrene

o-Methoxystyrene has been prepared by a number of methods[2] which need not be enumerated. We first applied the hot tube cracking process of Mowry, Renoll and Huber[3] to 1-(*o*-methoxyphenyl)-ethanol which was prepared both from *o*-methoxybenzaldehyde and methylmagnesium iodide and from *o*-methoxyphenylmagnesium bromide and acetaldehyde. In the first of these processes there was obtained along with the carbinol, a considerable amount of bis-[1-(*o*-methoxyphenyl)-ethyl] ether. This ether cleaved readily over hot alumina to give the desired *o*-methoxystyrene in 75% yields.

The *o*-methoxystyrene produced by catalytic dehydration of 1-(*o*-methoxyphenyl)-ethanol or its ether did not copolymerize well in standard GR-S recipes. Examination of the styrene showed that it contained about 10% of *o*-ethylphenol and a lesser proportion of *o*-ethylanisole. Presumably the *o*-ethylanisole was produced by a disproportionation reaction similar to the one observed in the attempted dehydration of *m*-N-methylaminophenylmethylcarbinol.[4] The *o*-ethylphenol was undoubtedly produced by cleavage of the ether group of *o*-ethylanisole. The other fragment of the disproportionation reaction is undoubtedly the substituted acetophenone since Hunter and Groombridge[5] have observed the formation of acetophenone during the dehydration of phenylmethylcarbinol over alumina.

Even after the removal of the phenolic impurities the sample of *o*-methoxystyrene prepared from the α-arylcarbinol was not satisfactory for polymerization studies. A very good sample of *o*-methoxystyrene was obtained by the conversion of *o*-methoxyphenylmagnesium bromide to 2-(*o*-methoxyphenyl)-ethanol by the action of ethylene oxide and the dehydration of this alcohol over hot potassium hydroxide. The styrene was obtained in good yield and the polymerization rates were satisfactory but the starting material was somewhat difficult to obtain.

Finally *o*-methoxystyrene was prepared by the method of Walling and Wolfstirn.[2g] After the *o*-methoxystyrene thus prepared had been washed with alkali it copolymerized satisfactorily. The yields are less satisfactory than in the preceding preparation but *o*-methoxybenzaldehyde is a more readily available starting material than *o*-bromoanisole.

1-(*o*-Methoxyphenyl)-ethanol.—This alcohol was prepared by the reaction of methylmagnesium iodide with *o*-methoxybenzaldehyde by procedures which have been described.[6] We obtained in every run a by-product boiling at 109° at 0.05 mm., m. p. 93.5°, which appears to be the ether formed by dehydration of the carbinol.

Anal.[7] Calcd. for $C_{18}H_{22}O_3$: C, 75.44; H, 7.75. Found: C, 75.37; H, 7.58.

This by-product was not described in the earlier reports. In one experiment a yield of crude carbinol amounting to 82% was obtained, but on distillation it was found to contain about 30% of the ether.

From *o*-methoxyphenylmagnesium bromide (from 187 g. of *o*-bromoanisole) and acetaldehyde, a 70% yield of the above alcohol was obtained. No ether was isolated in this run.

2-(*o*-Methoxyphenyl)-ethanol.—To an ether solution of *o*-methoxyphenylmagnesium bromide (from 100 g. of *o*-bromoanisole) was added an ether solution of 44 g. of ethylene oxide and the reaction was carried out in the usual manner. The product amounted to 54.5 g. (67%) and boiled at 79–80° at 0.26 mm. pressure, $n^{20}D$ 1.5391, d^{20}_4 1.0889.

Anal. Calcd. for $C_9H_{12}O_2$: C, 71.03; H, 7.95. Found: C, 70.61; H, 7.64.

The phenylurethan was prepared in the usual manner and after recrystallization from ethanol melted at 76°.

Anal. Calcd. for $C_{16}H_{17}O_3N$: C, 70.83; H, 6.32; N, 5.16. Found: C, 71.05; H, 6.42; N, 5.11.

***o*-Methoxystyrene.**—Dehydration of 150 g. of 1-(*o*-methoxyphenyl)-ethanol over (Alorco) activated alumina at 310° at 30–40 mm. pressure gave 102 g. of product boiling at 73–75° at 10 mm., $n^{20}D$ 1.5530. This refractive index is lower than most of the values recorded previously for this styrene. In a redistillation it was observed that there was considerable variation in the refractive index at different stages of distillation although the boiling point was unchanged.

By-products in *o*-Methoxystyrene from 1-(*o*-Methoxyphenyl)-ethanol.—A solution of 153 g. of *o*-methoxystyrene made as above in 1 liter of low boiling petroleum ether was repeatedly washed with 500-cc. portions of 2% aqueous sodium hydroxide. The alkaline extracts were combined and acidified with hydrochloric acid and extracted with ether. After evaporation of the ether, the residual oil was distilled under reduced pressure. Redistillation of the main fraction gave about 11 g. of material, b. p. 48° at 0.05 mm., $n^{20}D$ 1.5367, d^{20}_4 1.0283.

Anal. Calcd. for $C_8H_{10}O$: C, 78.65; H, 8.25. Found: C, 78.71; H, 7.91.

This material had a strong creosote-like odor, absorbed bromine in carbon tetrachloride, decolorized 1% aqueous potassium permanganate solution and gave a violet blue color with ferric chloride in alcohol. These properties agree with those of *o*-ethylphenol as reported by Behal and Choay.[8] To confirm the identification the phenol was converted to *o*-ethylphenoxyacetic acid which is reported to melt at 141°.[9] The product we obtained melted at 134° and a sample made from an authentic specimen of *o*-ethylphenol ($n^{20}D$ 1.5335) melted at 137–138°. A mixture of the two materials melted at 136–137°.

Careful distillation of the *o*-methoxystyrene which had

been washed with alkali to remove phenol showed that it also was not a homogeneous material. The material was divided into five fractions as follows: (1) 9 g., b. p. 33–35° at 0.6 mm., $n^{20}D$ 1.5282.; (2) 21.6 g., b. p. 32–35° at 0.4–0.55 mm., $n^{20}D$ 1.5390; (3) 26.7 g., b. p. 33–36° at 0.35 mm., $n^{20}D$ 1.5500; (4) 47.6 g., b. p. 34° at 0.3 mm., $n^{20}D$ 1.5582; (5) 20.3 g., b. p. 34° at 0.25 mm., $n^{20}D$ 1.5592.

Fractions 1 and 2 were combined and redistilled at a reflux ratio of 5 to 1. About 1.5 g. of distillate boiling at 72° and 13 mm. was collected, $n^{20}D$ 1.5169. The residue was heated in the distillation apparatus under total reflux for two hours to polymerize any *o*-methoxystyrene and then distillation was continued. Seven grams of product boiling at 73° under 14 mm. pressure, $n^{20}D$ 1.5142 were obtained.

Anal. Calcd. for $C_9H_{12}O$: C, 79.37; H, 8.88. Found: C, 79.58; H, 8.67.

Klages and Eppelsheim[2b] have reported a boiling point of 70–71° at 11 mm., and $n^{20}D$ 1.512 for *o*-ethylanisole.

Further confirmation that this product was *o*-ethylanisole was obtained by conversion to a tribromide by bromination with excess bromine in carbon disulfide with a trace of iodine as a catalyst. The product was recrystallized to a constant melting point from 95% alcohol and melted at 108–109°.

An authentic specimen of *o*-ethylanisole was similarly brominated to give a product which melted at 109°. A mixture of the two tribromo derivatives melted at 108–109°.

Anal. Calcd. for $C_9H_9OBr_3$: C, 28.99; H, 2.43; Br, 64.29. Found: C, 28.81; H, 2.28; Br, 64.24.

The dinitro derivative was prepared from the *o*-ethylanisole isolated from the *o*-methoxystyrene and also from authentic *o*-ethylanisole. After recrystallization from 95% alcohol the sample from the *o*-ethylanisole isolated from the styrene preparation melted at 67°, the authentic specimen at 67.5° and the mixture of the two at 67°.

Anal. Calcd. for $C_9H_{10}O_5N_2$: C, 47.79; H, 4.46; N, 12.39. Found: C, 47.98; H, 4.58; N, 12.37.

o-Methoxystyrene from 2-(*o*-Methoxyphenyl)-ethanol.—In a 500-cc. round-bottomed flask fitted with a dropping funnel and a distilling tube with receiver, was placed 150 g. of U.S.P. potassium hydroxide pellets. A very small amount of picric acid was introduced to act as a polymerization inhibitor. The apparatus was pumped out to about 12 mm. pressure, the reaction flask heated to 225° and after the water had distilled out of the potassium hydroxide, 54.5 g. of 2-(*o*-methoxyphenyl)-ethanol was added dropwise at the rate of 15–20 drops per minute. To the distillate was added 100 cc. of low boiling petroleum ether, the water separated and the solvent distilled. The residue was distilled to yield 33.3 g. (69.4%) of quite pure *o*-methoxystyrene boiling at 35° under 0.20 mm. pressure, $n^{20}D$ 1.5595.

o-Methoxystyrene from *trans*-*o*-Methoxycinnamic Acid.—The procedure was that of Walling and Wolfstirn[2g] except that it was found necessary to wash the substituted styrene with sodium hydroxide solution to remove traces of phenolic compounds and unchanged acid. The major portion of this product boiled at 36–37° under 0.2 mm., $n^{20}D$ 1.5600.

p-Benzylstyrene

The synthesis of *p*-benzylstyrene from diphenylmethane was effected by the usual methods of acetylation, reduction and dehydration. The general procedure of Mowry, Renoll and Huber[3] for the preparation of alkylacetophenones was followed for the acetylation of diphenylmethane and as a by-product some bis-(*p*-acetylphenyl)-methane was obtained. This was converted to the new bis-(*p*-vinylphenyl)-methane which was characterized.

The *p*-benzylstyrene which resulted from the dehydration of 1-(*p*-benzylphenyl)-ethanol was found to contain small amounts of *p*-benzylethylbenzene. This is further evidence that the disproportionation of phenylmethylcarbinols over alumina[4,5] is a general reaction.

***p*-Benzylacetophenone.**—When the general procedure of Mowry, Renoll and Huber[3] was followed, 425 g. of diphenylmethane gave 413 g. of *p*-benzylacetophenone, m. p. 39° (lit.[10], 39°), and 60 g. of higher boiling residue.

Bis-(*p*-acetylphenyl)-methane.—Three hundred and five grams of high boiling residues from the above preparation was distilled at 180° and 0.05 mm. and the distillate was recrystallized from 95% alcohol. The yield of diketone was 210 g., m. p. 90–92°. Duval[10] reported a melting point of 93°.

1-(*p*-Benzylphenyl)-ethanol.—A solution of 170 g. of *p*-benzylacetophenone in enough absolute alcohol to make 510 cc. of solution was treated with Raney nickel catalyst at the boiling point for two hours; the nickel was removed by filtration; fresh catalyst was added and reduction with hydrogen was carried out at 75° and 1600 p.s.i. The catalyst was removed by centrifuging, the alcohol was distilled and the product purified by distillation. The yield was 147.5 g., b. p. 125–130° at 0.1 mm., m. p. 43–45°. A small sample was redistilled and it boiled at 114° at 0.06 mm. and melted at 46°.

Anal. Calcd. for $C_{15}H_{16}O$: C, 84.86; H, 7.60. Found: C, 84.69; H, 7.88.

***p*-Benzylstyrene.**—Dehydration of 150 g. of 1-(*p*-benzylphenyl)-ethanol over (Alorco) activated alumina at 310° at 30–40 mm. pressure gave 114 g. (83.3%) of *p*-benzylstyrene, b. p. 76–78° at 0.06 mm., $n^{20}D$ 1.5949; d^{20}_4 1.0011.

Anal. Calcd. for $C_{15}H_{14}$: C, 92.74; H, 7.26. Found: C, 92.88; H, 7.28.

One cubic centimeter of the above styrene was treated with bromine in glacial acetic acid until the color of bromine persisted. It was then warmed on a steam cone a few minutes and diluted with water. The solid which separated on cooling was recrystallized from methanol. The product melted at 92–93°.

Anal. Calcd. for $C_{15}H_{14}Br_2$: C, 50.87; H, 3.99. Found: C, 51.17; H, 3.96.

A sample of 58 g. of the crude *p*-benzylstyrene was heated under total reflux for two hours and distilled to give 30 g. of product b. p. 83–90° at 0.2 mm., $n^{20}D$ 1.5806. This product was treated with bromine in glacial acetic acid until no more bromine was absorbed and then diluted with water. The oil was collected in ether and the solvent evaporated. The residue was crystallized from alcohol to remove most of the *p*-benzylstyrene dibromide. The alcoholic mother liquors were then distilled under reduced pressure to yield 2 g. of a product which boiled at 89–96° at 0.08 mm. pressure, $n^{20}D$ 1.5622. Another distillation gave a purer product, $n^{20}D$ 1.5620.

Anal. Calcd. for $C_{15}H_{16}$: C, 91.78; H, 8.22. Found: C, 91.57; H, 8.19.

Walker[11] reported that *p*-benzylethylbenzene boils at 294–295° at 754 mm. but gave no refractive index. A small sample of *p*-benzylstyrene was reduced over Raney nickel catalyst to give *p*-benzylethylbenzene which boiled at 85° at 0.2 mm., $n^{20}D$ 1.5616.

Bis-[*p*-(1-hydroxyethyl)-phenyl]-methane.—A solution of 210 g. of bis-(*p*-acetylphenyl)-methane in 1500 cc. of alcohol was first treated with Raney nickel catalyst and then reduced with hydrogen over fresh catalyst at 75° and 1600 p.s.i. The catalyst was removed by filtration, the solution evaporated and a crude residue of 200 g. was obtained. Most of this material was used directly for dehydration. Five grams of the crude product was purified by twice recrystallizing from a 1:2 mixture of low boiling petroleum ether and benzene to yield a product, m. p. 85–86°.

Anal. Calcd. for $C_{17}H_{20}O_2$: C, 79.65; H, 7.87. Found: C, 79.85; H, 7.81.

The diphenylurethan prepared by the usual procedure was washed with carbon tetrachloride and low boiling

(10) Duval, *Compt. rend.*, **146**, 341 (1908); *Bull. soc. chim.*, [4] **7**, 796 (1910).

(11) Walker, *Ber.*, **5**, 686 (1872).

petroleum ether and then recrystallized from 95% alcohol. The product melted at 149–150°.

Anal. Calcd. for $C_{31}H_{30}O_4N_2$: C, 75.28; H, 6.11; N, 5.67. Found: C, 75.37; H, 6.27; N, 5.73.

Bis-(*p*-vinylphenyl)-methane.—The crude dicarbinol (134 g.) obtained above, dehydrated as described under *p*-benzylstyrene at 310° and 12 mm., gave 89 g. of crude product. Attempts to distil part of the product produced polymer in the distilling flask even when an inhibitor such as picric acid was added. By dissolving the product in ethyl alcohol at room temperature and cooling in a Dry Ice-bath and filtering at low temperature, pure hydrocarbon melting at 32° was obtained.

Anal. Calcd. for $C_{17}H_{16}$: C, 92.62; H, 7.32. Found: C, 92.80; H, 7.18.

The tetrabromide was made by adding bromine in glacial acetic acid to glacial acetic acid solution of 2 g. of the hydrocarbon. The product was precipitated with water and recrystallized from a mixture of 20 cc. of methanol and 10 cc. of benzene; m. p. 146°.

Anal. Calcd. for $C_{17}H_{16}Br_4$: C, 37.81; H, 2.99. Found: C, 38.09; H, 2.97.

o-Fluorostyrene

o-Fluorostyrene has been prepared by Brooks.[12] We have applied the general styrene synthesis of Walling and Wolfstirn[2g] to *o*-fluorobenzaldehyde and found the method very satisfactory.

o-Fluorotoluene.—When the general procedure described for the preparation of fluorobenzene[13] was used, 574 g. of *o*-toluidine hydrochloride gave 207 g. of *o*-fluorotoluene.

o-Fluorobenzaldehyde.—When the general procedure described for the preparation of *p*-bromobenzaldehyde[14] was followed, 127.6 g. of *o*-fluorotoluene gave 100 g. (71.3%) of *o*-fluorobenzaldehyde. Brooks[12] used chlorination in place of bromination in this preparation and obtained a 48% yield.

o-Fluorocinnamic Acid.—When the general procedure of Walling and Wolfstirn[2g] was used, 100 g. of *o*-fluorobenzaldehyde gave 101 g. of the corresponding cinnamic acid, m. p. 177–178°. Kindler,[15] who prepared this acid by a different route reports it as melting at 175°.

o-Fluorostyrene.—The general procedure of Walling and Wolfstirn[2g] was used for the decarboxylation and from 95 g. of the cinnamic acid 45.6 g. (65.6%) of *o*-fluorostyrene, boiling at 46° at 32 mm., $n^{20}D$ 1.5201, was obtained. Brooks[12] reports $n^{20}D$ 1.5197.

o-Cyanostyrene

o-Cyanostyrene was prepared from *o*-tolunitrile by oxidation to *o*-cyanobenzaldehyde, followed by condensation with malonic acid and subsequent decarboxylation of the substituted cinnamic acid. The polymerization of this substituted styrene has not been studied.

o-Cyanobenzaldehyde Diacetate.—The procedure described for the conversion of *p*-nitrotoluene to *p*-nitrobenzaldehyde diacetate[16] was used. From 84.2 g. of *o*-toluonitrile there was obtained 58.2 g. (34.6%) of the *o*-cyanobenzaldehyde diacetate, m. p. 94–95° after recrystallization from 95% alcohol.

Anal. Calcd. for $C_{12}H_{11}O_4N$: C, 61.79; H, 4.76. Found: C, 61.95; H, 4.69.

o-Cyanobenzaldehyde.—Hydrolysis of the above diacetate was carried out as described for the corresponding *p*-nitro compound.[16] From 58.2 g. of diacetate there was obtained 26.7 g. (81.6%) of *o*-cyanobenzaldehyde which melted at 103–104° after recrystallization from alcohol. Blicke and Pobelski[17] prepared this aldehyde from the corresponding benzal dibromide and reported the melting point at 108–109°.

o-Cyanocinnamic Acid.—The *o*-cyanobenzaldehyde, m. p. 103–104°, was converted to the cinnamic acid by the procedure of Walling and Wolfstirn[2g] except the reaction mixture was heated for five hours. From 48.5 g. of aldehyde there was obtained 39.5 g. (61.7%) of *o*-cyanocinnamic acid, m. p. 253–254°. This agrees with the melting point (255°) reported in the Bayer Company patent.[18]

Anal. Calcd. for $C_{10}H_7O_2N$: C, 69.36; H, 4.07; N, 8.09. Found: C, 69.42; H, 3.80; N, 8.07.

o-Cyanostyrene.—The general method of Walling and Wolfstirn[2g] was modified for the decarboxylation of *o*-cyanocinnamic acid by using more quinoline and distilling more slowly than they recommend. Twenty-three grams of the cinnamic acid, 5 g. of copper bronze powder and 275 g. of quinoline were used. About five-sixths of the material distilled in ninety minutes. Redistillation gave 5 g. (28.9%) of product, b. p. 53° at 0.15 mm., $n^{20}D$ 1.5756.

Anal. Calcd. for C_9H_7N: C, 83.69; H, 5.46. Found: C, 84.55; H, 5.61.

o-Cyanostyrene has been described as boiling at 96–100° at 9 mm., $d^{29}{}_{15}$ 1.012.[19]

o-Cyanostyrene Dibromide.—Addition of excess bromine to a glacial acetic acid solution of *o*-cyanostyrene followed by dilution with water gave a solid dibromide. After recrystallization from alcohol it melted at 86–86.5°.

Anal. Calcd. for $C_9H_7NBr_2$: C, 37.40; H, 2.44; Br, 55.31. Found: C, 37.65; H, 2.51; Br, 55.15.

Polymers of the New Styrene Derivatives.—Two cubic centimeters of monomer was placed in a quartz tube and placed under a 500-watt ultraviolet lamp until a solid polymer had formed. The time varied from two to four days for different monomers. The polymer was dissolved in 50 cc. of benzene and precipitated by dropping the solution into 500 cc. of vigorously stirred methanol. The powder thus obtained was dried in a vacuum desiccator at 0.03 mm. pressure.

Poly-*p*-benzylstyrene softened in a melting point tube at 105° and shrunk to a soft mass at 110°. It was slightly soluble in benzene, $[\eta]$ 0.91.

Anal. Calcd. for $C_{15}H_{14}$: C, 92.74; H, 7.26. Found: C, 91.84; H, 7.51.

Poly-bis-(*p*-vinylphenylmethane) did not soften visibly below 250°. It was insoluble in benzene, chloroform, nitromethane, carbon disulfide and other common solvents.

Anal. Calcd. for $C_{17}H_{16}$: C, 92.68; H, 7.32. Found: C, 91.65; H, 7.74.

Poly-*o*-methoxystyrene softened at 125° and turned to a soft mass at 130°. It was very soluble in benzene, $[\eta]$ 0.57.

Anal. Calcd. for $C_9H_{10}O$: C, 80.56; H, 7.51. Found: C, 80.45; H, 7.40.

Poly-*o*-fluorostyrene softened at 105° and shrunk to a soft mass at 110°. It was very soluble in benzene, $[\eta]$ 0.36.

Anal. Calcd. for C_8H_7F: C, 78.86; H, 5.78. Found: C, 77.88; H, 6.07.

The copolymerization of these styrenes with butadiene will be described later.

Summary

p-Benzylstyrene and bis-(*p*-vinylphenyl)-methane and their polymers are described for the first

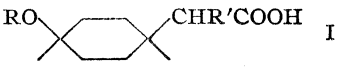
The Hydrogenation of Phenolic Acids

BY HERBERT E. UNGNADE AND FRANCIS V. MORRISS

The catalytic reduction of phenolic acids has been investigated in the hope of obtaining a reasonably simple method for the preparation of acids of the type (I).



I

Previous attempts to prepare the methoxy acid (I, R = CH_3, R′ = H) by catalytic reduction of the corresponding aromatic acid with platinum catalyst have been unsuccessful.[1] In numerous other investigations the catalytic reduction of phenolic acids has been reported to give low yields of hydroxycyclohexane acids due to side reactions. Low pressure hydrogenation, particularly in acid medium, causes considerable hydrogenolysis of the carbon–oxygen linkage with resultant loss of the hydroxyl group[2,3,4] whereas high pressure hydrogenation with nickel catalyst leads largely to decarboxylation[5] regardless of whether the acids or their sodium salts are reduced.[4] The hydrogenolysis reaction in the low pressure hydrogenation with platinum can be repressed by reducing in the presence of alkali. Good yields of 4-hydroxycyclohexanecarboxylic acid have thus far been reported only for the hydrogenation of *p*-hydroxybenzoic acid in ethyl acetate over palladium-on-strontium carbonate under high pressure.[4]

It has been shown in the present investigation that phenolic acids can be reduced smoothly to the hexahydro compounds by high pressure hydrogenation of their esters in alcoholic solution with W-2 Raney nickel catalyst[6] in the presence of approximately 0.3 mole % of the sodium salts of these compounds. The reduction products are pure substances which consist of mixtures of *cis*- and *trans*-isomers and which are formed in nearly quantitative yield. A direct separation of the isomers is rather difficult. A partial separation can be effected by adsorption of the esters on alumina. The *trans*-isomer is more strongly adsorbed.

The best method for the preparation of the pure *cis*- and *trans*-isomers consists in the reduction of the keto acids by specific reduction methods. Sodium and alcohol or sodium amalgam gives fairly pure *trans*-alcohols while the catalytic reduction with Raney nickel at room temperature yields predominantly *cis*-isomers.[3]

Experimental[7,8]

The phenolic acids used in this investigation were commercial products with the exception of α-(*p*-hydroxyphenyl)-butyric acid which was prepared according to Wilds and Biggerstaff.[9,10]

The ethyl esters of the phenolic acids were prepared by esterification of the acids with ethyl alcohol and sulfuric acid or by the method of Thielepape.[11] They were distilled under reduced pressure prior to reduction.

Hydrogenation of the Phenolic Esters.—The phenolic esters (0.2–1.0 mole) were dissolved in 100 cc. of absolute ethyl alcohol containing 0.3 mole % (on the basis of phenolic ester) of sodium ethoxide. Raney nickel (3–6 g.) was added and the mixture was immediately hydrogenated at between 160–220° (240–270 atm.) until the pressure remained constant. The catalyst was filtered off, the solvent was removed and the residue was distilled under reduced pressure. The constants of the products are given in Table I.

Preparation of the Keto Acids.—The hydroxycyclohexane esters described above were hydrolyzed by refluxing for two hours with four volumes of 10–20% aqueous sodium hydroxide solution and one volume of ethyl alcohol. The resultant solution was acidified with hydrochloric acid and extracted continuously with benzene. Most of the water and benzene were removed by distillation from a water-bath, the last traces under reduced pressure. The residual acids were used for the preparation of the keto acids without further purification. The mixtures of the isomeric acids were oxidized with chromic anhydride in aqueous acetic acid below 15°. Ethyl 4-hydroxycyclohexanecarboxylate was oxidized without previous hydrolysis. The resulting keto ester was purified through its bisulfite addition compound and was hydrolyzed on regeneration. The experimental data are given in Table II.

The keto acids were isolated by dilution of the reaction mixture with water and continuous extraction of the resultant solution with ether. The ether was removed by

***cis*-4-Hydroxycyclohexaneacetic Acid.**—The keto acid (0.45 g.), dissolved in 11 cc. of 1 *N* aqueous sodium hydroxide solution, was reduced with 1.5 g. of Raney nickel under 50 mm. of hydrogen. The calculated amount of hydrogen was taken up in thirty-five minutes. The solution was filtered from the catalyst, acidified with concentrated hydrochloric acid and extracted continuously with ether for fourteen hours. The residue obtained after removing the solvent was dried by distillation with benzene. The remaining solid material (0.46 g.), m. p. 115–123°, was purified by crystallization from ethyl acetate. The pure acid melted at 133.5–134°.

Anal. Calcd. for $C_8H_{14}O_3$: C, 60.47; H, 9.09. Found: C, 60.64; H, 9.14.

***trans*-4-Hydroxycyclohexaneacetic Acid.**—Sodium amalgam (75 g., 4%) was added in small pieces over a period of two hours with stirring to a solution of 2.3 g. of 4-ketocyclohexaneacetic acid in 140 cc. of 2 *N* aqueous sodium carbonate solution. The mixture was allowed to stand for fifteen hours. Sodium bicarbonate (10 g.) was then added to the mixture with stirring and stirring was continued for six hours. The mercury was removed by decantation and the aqueous solution was acidified with hydrochloric acid. Continuous extraction of the water solution with ether gave 2.4 g. of crude acid, m. p. 134–136°, which melted at 139.5–140° after repeated crystallization from ethyl acetate. The mixture with the *cis*-acid melted at 110–120°.

Anal. Calcd. for $C_8H_{14}O_3$: C, 60.74; H, 9.09. Found: C, 60.48; H, 9.08.

***cis*-α-(4-Hydroxycyclohexane)-butyric Acid.**—The catalytic reduction of the keto acid (0.4 g.) was carried out as described for *cis*-4-hydroxycyclohexaneacetic acid. The crude product (0.4 g., m. p. 102–107°) was crystallized from ethyl acetate. The pure hydroxy acid melted at 110.5–111°.

Anal. Calcd. for $C_{10}H_{18}O_3$: C, 64.50; H, 9.72. Found: C, 64.47; H, 9.95.

***trans*-α-(4-Hydroxycyclohexane)-butyric Acid.**—The mixture of isomeric hydroxy esters (3.73 g.) from the high pressure hydrogenation of ethyl α-(*p*-hydroxyphenyl)-butyrate was adsorbed on alumina from Skellysolve A solution. The less strongly adsorbed *cis*-isomer was eluted with the same solvent, the *trans*-compound was eluted with benzene. A portion of the benzene eluate (0.82 g.) was refluxed for three hours with 25 cc. of 10% aqueous sodium hydroxide solution and 10 cc. of ethyl alcohol. The solution was acidified with hydrochloric acid and extracted with ether in a continuous extractor. The ether was displaced with benzene, the latter removed by distillation, the last traces under reduced pressure. The residue (0.62 g.) solidified on standing and melted at 93–107°. Three crystallizations from benzene–Skellysolve B mixtures raised the melting point to 123.5–124°. The substance depressed the melting point of the *cis*-isomer.

Anal. Calcd. for $C_{10}H_{18}O_3$: C, 64.50; H, 9.72. Found: C, 64.35; H, 9.75.

Summary

The ethyl esters of the three hydroxybenzoic acids, *p*-hydroxyphenylacetic acid and α-(*p*-hydroxyphenyl)-butyric acid, have been reduced in good yield to the hexahydro compounds by high pressure hydrogenation over Raney nickel catalyst in alcoholic solution containing 0.3 mole % of sodium ethoxide. A method has been described for the conversion of these reduction products to the corresponding keto acids. The *cis*- and *trans*-isomers of 4-hydroxycyclohexaneacetic acid and α-(4-hydroxycyclohexane)-butyric acid have been prepared.

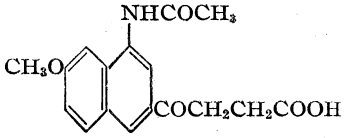
The Succinoylation of 1-Acetylamino-7-methoxynaphthalene

BY LEONARD E. MILLER AND EDWIN F. MORELLO[1]

The reaction of 1-acetylamino-7-methoxynaphthalene with succinic anhydride in nitrobenzene in the presence of aluminum chloride has been found to give β-(1-acetylamino-7-methoxy-3-naphthoyl)-propionic acid (I).



I

The structure of (I) was established by hydrochloric acid hydrolysis, diazotization and deamination using hypophosphorous acid to give the known β-(2-methoxy-6-naphthoyl)-propionic acid (II).[2] The melting points of this acid and its methyl ester were in agreement with those reported. In addition, an alkaline hypochlorite oxidation of (II) produced the known 2-methoxy-6-naphthoic acid (III). Demethylation of (III) with hydrobromic acid in acetic acid gave the known 2-hydroxy-6-naphthoic acid.

Since under similar conditions of reaction the 6-position of 2-methoxynaphthalene is the most reactive one,[2] it may be concluded that the directive influence of the methoxyl group plays the predominant role in the succinoylation of 1-acetylamino-7-methoxynaphthalene in nitrobenzene.

Experimental[3]

1-Acetylamino-7-methoxynaphthalene.—Using Cleve's acid-1,7, this material was prepared by the method of Bachmann and Horton.[4] The procedure used was similar to that given in detail by Wilds and Close[5] for the 1,6-isomer. After distillation at 147° (0.05 mm.), the material crystallized from methanol (Norite) as fine colorless needles, m. p. 160–161°.[4]

β-(1-Acetylamino-7-methoxy-3-naphthoyl)-propionic Acid.—A mixture of 37.6 g. (0.175 mole) of 1-acetylamino-7-methoxynaphthalene and 17.0 g. (0.170 mole) of succinic anhydride was added in small portions to a mechanically stirred, ice-cold solution of 80 g. (0.595 mole) of powdered, anhydrous aluminum chloride in 200 ml. of nitrobenzene. This addition required approximately one hour. After stirring for seventeen hours at 0°, the mixture was poured on 200 g. of ice containing 3 ml. of concentrated hydrochloric acid. The nitrobenzene was distilled off with water vapor at 37° (22 mm.). The solid residue was separated on a filter. The filtrate was heated under reduced pressure once more to remove the residual nitrobenzene. The combined solid residues were treated then with aqueous sodium carbonate. The insoluble material, consisting of starting material and aluminum hydroxide, was removed on a filter. It was treated further with a mixture of ether and aqueous sodium carbonate and was separated on a filter. The combined alkaline filtrates were washed with ether. On acidification with dilute hydrochloric acid, the solid which separated was collected on a filter and permitted to dry in air. It was crystallized from 40% acetic acid to give small colorless needles, m. p. 202–203°; the yield was 45.1 g. (84%). From the ether extracts 1.8 g. of pure starting material was isolated. The yield calculated on the basis of 1-acetylamino-7-methoxynaphthalene consumed was 86%.

Anal. Calcd. for $C_{17}H_{17}O_5N$: C, 64.8; H, 5.4; N, 4.4. Found: C, 64.7; H, 5.7; N, 4.6.

β-(2-Methoxy-6-naphthoyl)-propionic Acid.—A mixture of 43.5 g. of β-(1-acetylamino-7-methoxy-3-naphthoyl)-propionic acid, 150 ml. of water and 300 ml. of concentrated hydrochloric acid was heated under reflux for one hour. On cooling in an ice-bath, the hydrochloride crystallized and was collected on a filter. After one recrystallization from dilute hydrochloric acid, it was used without further purification in the following reaction. The yield was 40.4 g. (94.5%).

Anal. Calcd. for $C_{15}H_{16}O_4NCl$: N, 4.5. Found: N, 4.6.

A mechanically stirred mixture of 10.9 g. (0.035 mole) of the hydrochloride, 100 ml. of glacial acetic acid and 75 ml. of concentrated hydrochloric acid was cooled in an ice-water-bath to 0°. To this suspension of the hydrochloride, 2.9 g. of sodium nitrite in 14 ml. of water was added dropwise very slowly (two hours). At this time 0.5 g. of urea in 5 ml. of water was added to destroy the excess nitrous acid; the mixture was stirred for an additional hour. To the stirred solution at 0°, 87 ml. of ice-cold 50% hypophosphorous acid was added over a fifteen minute period. After being stirred for an additional two hours, the mixture was placed in a refrigerator for thirty-eight hours. After heating on a steam cone for ten minutes, the liquids were removed at 32° (22 mm.). The solid residue was dissolved in aqueous sodium carbonate, filtered and then acidified with dilute hydrochloric acid. After collection on a filter, it was treated with an ethereal solution of diazomethane for a short time (five minutes). The ether solution was washed with cold 2% sodium hydroxide and was dried over magnesium sulfate. After removal of the ether, the residue was evaporatively distilled at 190–195° (0.02 mm.). It crystallized from methanol in long needles, m. p. 97–97.5°.[2]

A solution of 1.8 g. of the methyl ester of β-(2-methoxy-6-naphthoyl)-propionic acid and 4.0 ml. of 10% sodium hydroxide in 100 ml. of methanol was heated under reflux for two hours. On evaporation of the methanol, the solid residue was dissolved in 100 ml. of water. Upon acidification with dilute hydrochloric acid, the free acid precipitated. It crystallized from methanol in shiny colorless plates, m. p. 149.5–150.5°.[2] The yield was 1.6 g. (17.7% based on amine hydrochloride).

2-Methoxy-6-naphthoic acid was prepared from (II) according to Short, Stromberg and Wiles.[2] After five recrystallizations from ethyl acetate colorless needles were isolated, m. p. 200–202° (reported, 205°).

2-Hydroxy-6-naphthoic acid was prepared by the method of Knowles, Kuck and Elderfield[6] from 110 mg. of the methoxynaphthoic acid after heating under reflux for two and one-half hours with 1 ml. of acetic acid, 1 ml. of 48% hydrobromic acid and 1 ml. of acetic acid saturated with hydrogen bromide. It was recrystallized from water (Norite) three times; m. p. 240–242° (reported, 240–241°,[7] 242–244°,[8] 245–248[7]).

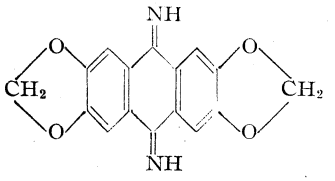
[COMMUNICATION NO. 1141 FROM THE KODAK RESEARCH LABORATORIES]

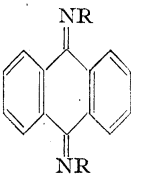
The So-Called "Anthraquinonediimines"; Symmetrical Trisubstituted Triazines

BY C. V. WILSON

Some years ago Brown and Robinson[1] treated 3,4-methylenedioxybenzonitrile with chlorosulfonic acid in chloroform and obtained a substance that was sparingly soluble in the usual solvents, but dissolved in sulfuric acid to give a deep crimson solution. The color of the solution resembled those which are obtained with methoxyanthraquinones and sulfuric acid. On reduction with hydriodic acid followed by zinc dust distillation and subsequent oxidation a product was obtained which gave a positive color test in the oxanthranol reaction. This was interpreted as indicating the presence of anthracene. From these properties and the analysis of the compound, and despite the recorded fact that the substance was unchanged by boiling hydrochloric acid, Brown and Robinson assigned to it the structure I.



I



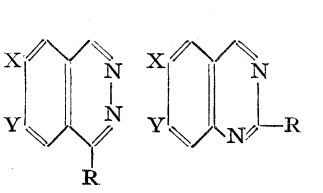
II

Later Keffler[2] attempted a molecular weight determination on the substance but found it so insoluble that he was unable to accomplish his purpose. However, he synthesized two closely related products from veratronitrile and 3-methoxy-4-ethoxybenzonitrile and found them sufficiently soluble in thymol to make possible molecular weight determinations by the cryoscopic method. On the basis of the results he concluded that the products were dimerides of the related nitriles and that the Brown and Robinson formulation was correct.

However, the properties recorded for these substances do not resemble those of 9,10-diiminoanthracene (II, R = H). The latter is prepared from the corresponding diamino compound with silver oxide, is soluble in ether, and is easily changed to anthraquinone with aqueous acids.[3] The latter property is also observed for the substituted diiminoanthracenes (II, R = C_6H_5, $CH_3C_6H_4$, etc.).[4] The great stability of the compounds reported by Keffler[2] toward concentrated hydrochloric acid is not compatible with the properties of the simple, unsubstituted 9,10-diiminoanthracene (II, R = H). It is difficult to believe that the substituents would alter this property of the diimine so markedly.

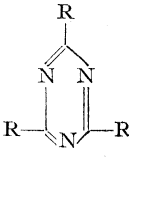
Since substituted anthraquinones that should be obtainable from these diiminoanthracenes were required in connection with another problem in these Laboratories, they were investigated further. A Zerewitinoff determination on the "piperonitrile dimer," prepared as described by Keffler,[2] showed no active hydrogen. This is not in agreement with the proposed structure, which should show two active hydrogens.

It is possible for the nitriles to polymerize in other ways. Thus they may dimerize by the diene synthesis to give phthalazines (III) or quinazolines (IV), or they may trimerize to triazines of structure V. Unlike the diiminoanthracene structure (I) these compounds would have no active hydrogen.

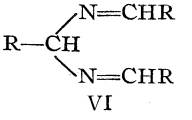


III

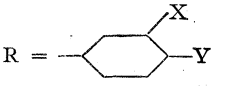
IV



V



VI



where X = Y = OCH_3, or X + Y = 
A literature survey revealed that the triazine (V, X + Y = —OCH_2O—) has been prepared by two different methods, and, surprisingly enough, the melting points recorded were the same as those given by Robinson[1] and Keffler[2] for the so-called dimer. In one of these methods[5] nitro-

gen tetrasulfide (N_4S_4) was digested with piperonal for forty-six hours and the triazine (m. p. 266°) was obtained, along with the sulfate of 3,4-methylenedioxybenzamidine. In the other method[6] "piperhydramide" (VI, X + Y = O—CH_2—O—) was prepared[7] and oxidized with iodine and sodium carbonate to form the triazine (m. p. 265°). In this work the triazine was prepared by the latter method and, after recrystallization from pyridine, melted at 270°, and showed no depression of the melting point when mixed with the compound obtained by Robinson's procedure.

This established the identity of the two compounds. There still remained the question of molecular weight which led Keffler to report the compounds as dimers. As the author pointed out, molecular weight determinations were made difficult because of the insolubility of the substances in most solvents. Since the methoxy derivative is the most soluble of the compounds under consideration, it was used in this work for molecular weight determinations. Use of the cryoscopic method proved unreliable so attention was turned to the ebullioscopic method.

The molecular weight of a closely related product obtained by the action of nitrogen sulfide on *p*-methoxybenzonitrile has been determined by the ebullioscopic method and the results are in agreement with the trimeric formula.[8] This method was applied to the compound in question using pyridine as a solvent. The values obtained for the molecular weight show that the compound is trimeric. There can be little doubt, therefore, that the so-called "anthraquinonediimines" of Keffler and Robinson are in reality trisubstituted triazines.

Since Keffler's molecular weight determinations had indicated that the compounds were dimeric, two possible dimeric substances were synthesized prior to investigating a trimeric form: the phthalazine (III, X + Y = —O—CH_2—O—) and the quinazoline (IV, X + Y = —O—CH_2—O—). The phthalazine was synthesized by condensing piperonoylhydrazine[9] with piperonal followed by ring closure with hydrogen chloride in amyl alcohol.[10] The quinazoline was prepared by treating the product from 6-aminopiperonal[11] and piperonoyl chloride with ammonia under pressure. An attempt to cyclize the Schiff base from piperonal and 6-aminopiperonitrile was abandoned when the quinazoline was obtained by the method described above.

The mechanism of the formation of a triazine is doubtful, but it can be accounted for by an extension of the ideas of Alder[12] and Kilpatrick.[13]

Experimental

1,3,5-Tri-(3′,4′-methylenedioxyphenyl)-*s*-triazine (V, X + Y = —O—CH_2—O—).—The so-called "2,3,6,7-dimethylenetetraoxyanthraquinonediimine" was prepared by the procedure described previously.[1,2] On recrystallization from pyridine it melted at 270°.

The triazine was also prepared by oxidizing "piperhydramide" (VI, X + Y = —O—CH_2—O—),[7] with iodine and potassium carbonate, as described by Robin.[6] The product obtained was recrystallized from pyridine, melted at 270°, and showed no depression of the melting point when mixed with the substance obtained by Robinson's procedure.

1,3,5-Tri-(3′,4′-dimethoxyphenyl)-*s*-triazine was prepared by Keffler's procedure.[2] It melted, when recrystallized from pyridine, at 263°. A molecular weight determination by the cryoscopic method with *p*-bromophenol as a solvent gave the following results: 0.2 g. of the polymeric nitrile in 10 g. of *p*-bromophenol gave a depression of 0.68°, from which the molecular weight is 329 (calcd. for a dimer 326), the constant for *p*-bromophenol being 11.2. However, the substance gave a deep yellow solution in *p*-bromophenol indicating that some change had occurred. As a result other solvents were investigated. Cyclopentadecanone has a fairly high constant (21.3),[14] but the triazine crystallized from it above the setting point at a dilution of 1.4 parts per 100. With 2-aminopyridine the same difficulty was experienced. It is entirely possible that this crystallization above the setting point may be taking place also with the phenolic solvents, thymol and *p*-bromophenol. With camphor as a solvent it was found difficult to obtain consistent results.

When the ebullioscopic method was applied, pyridine was used as the solvent. The constant (K_{1000}) was determined using acetanilide, *p*-amino-N-ethylacetanilide, and *p*-nitrophenylacetonitrile as reference compounds. The average of the values thus obtained, 2.65, 2.68 and 2.63, respectively, was used as the constant. With this value 0.5115 g. of the methoxy derivative in 44.8380 g. of pyridine gave a boiling point elevation of 0.070° from which the molecular weight is 488; similarly, 1.0027 g. of the methoxy derivative in 46.7087 g. of pyridine gave a boiling point elevation of 0.115° from which the molecular weight is 494. Since the calculated value for a trimer is 489 the conclusion that the compounds are triazines is inevitable.

Piperonal-β-(3,4-methylenedioxybenzoyl)-hydrazone was made by condensing piperonal with piperonoylhydrazine,[9] as described for an analogous compound[10]; 5.4 g. of piperonal and 6 g. of the hydrazine were refluxed for two hours in 60 ml. of alcohol containing 1 ml. of 40% sodium hydroxide (later it was found that the alkali was unnecessary). The solid that separated on cooling was collected and washed with alcohol. The yield was 9.7 g.; m. p. at about 210–220°, with preliminary darkening at about 205°. A sample recrystallized from alcohol melted at 193–196°, but if the melting-point tube was inserted in a bath preheated to 150°, there appeared to be decomposition. The substance reacted similarly when recrystallized from propanol, acetic acid, or ethyleneglycolmonomethyl ether. For analysis, the material recrystallized from alcohol was dried in a vacuum oven at 110°.

Anal. Calcd. for $C_{16}H_{12}N_2O_5$: C, 61.5; H, 3.8; N, 8.9. Found: C, 61.3; H, 3.9; N, 8.8.

1-(3′,4′-Methylenedioxyphenyl)-6,7-methylenedioxyphthalazine.—The hydrazone (4 g.) was added to 50 ml. of amyl alcohol which had been saturated at 10–15° with hydrogen chloride. The mixture was heated for one hour on the steam-bath and a further hour with a free flame. The resulting mixture was transferred to a beaker and the solvent allowed to evaporate spontaneously. When almost dry, the residue was digested with benzene and filtered. The remaining solid was shaken with 50 ml. of 10% sodium hydroxide, filtered, washed with water, and dried. One crystallization from alcohol gave 0.5 g.

(14) Giral, *Anales soc. espan. fis. quim.*, **33**, 438 (1935) [*C. A.*, **29**, 6489 (1935)].

of a buff-colored product melting at 203–204°. It was recrystallized from a small volume of ethyl acetate.

Anal. Calcd. for $C_{16}H_{10}N_2O_4$: C, 65.3; H, 3.4; N, 9.5. Found: C, 64.6, 64.9; H, 3.4, 3.8; N, 9.5.

When the reaction was run in chloroform with phosphoryl chloride as the condensing agent, an imidchloride, which is probably an intermediate, was obtained. It melted at 166–167° after recrystallization from benzene.

Anal. Calcd. for $C_{16}H_{11}ClN_2O_4$: C, 58.2; H, 3.3; N, 8.5. Found: C, 58.0; H, 3.2; N, 8.6.

Veratroylhydrazine.—A mixture of 10 g. of methyl veratrate, 12 ml. of ethyl alcohol, and 10 ml. of 80% hydrazine hydrate was refluxed for two hours. The product was isolated by dilution with water and cooling; it was collected and recrystallized from alcohol. The yield was 6.7 g., m. p. 145°.

Anal. Calcd. for $C_9H_{12}N_2O_3$: N, 14.3. Found: N, 14.5.

Veratral β-(3,4-Dimethoxybenzoyl)-hydrazone.—A solution of 6.7 g. of veratroylhydrazine and 6 g. of veratral in 50 ml. of alcohol was treated with 1 ml. of 40% sodium hydroxide and refluxed for two hours. The clear, colored solution was allowed to cool (overnight) and the solid that formed collected on a filter. The solid was digested with 200 ml. of alcohol and again filtered. The yield was 6.5 g.; m. p. 198–205°. Recrystallization of the material from acetic acid or ethyleneglycolmonomethyl ether gave products that still showed indefinite melting points. The crude material was analyzed.

Anal. Calcd. for $C_{18}H_{20}N_2O_5$: C, 62.7; H, 5.8; N, 8.1. Found: C, 61.5; H, 5.8; N, 8.1.

1-(3′,4′-Dimethoxyphenyl)-6,7-dimethoxyphthalazine.—The hydrazone (5 g.) was placed in 50 ml. of amyl alcohol saturated with hydrogen chloride and heated under reflux for one hour on the steam-bath and for one hour at the boiling point. The cooled mixture was filtered and the solid shaken with 50 ml. of 10% sodium hydroxide. The solid was separated by filtration, washed with water, and recrystallized from alcohol. The yield of yellow crystals was 1.6 g.; m. p. 193–194°.

Anal. Calcd. for $C_{18}H_{18}N_2O_4$: C, 66.3; H, 5.5; N, 8.6. Found: C, 66.2; H, 5.9; N, 8.2.

6-Piperonoylaminopiperonal.—A mixture of 3.3 g. of 6-aminopiperonal,[11] 3.7 g. of piperonoyl chloride, 1.6 g. of pyridine, and 75 ml. of xylene was refluxed for one hour. The solution was filtered from a small amount of gummy material and the required product separated from the filtrate. The yield was 3.2 g.; m. p. 221°.

Anal. Calcd. for $C_{16}H_{12}NO_6$: C, 61.3; H, 3.5; N, 4.5. Found: C, 61.6; H, 4.0; N, 4.6.

This material was also prepared from the aminoaldehyde and the acid chloride in acetic acid containing sodium acetate. The yield was not as good.

2-(3′,4′-Methylenedioxyphenyl)-6,7-methylenedioxyquinazoline.—6-Piperonoylaminopiperonal (3 g.) was placed in a small pressure bottle, 125 ml. of ethanol added, and the mixture saturated with ammonia. The bottle was sealed and shaken for two and one-half hours at 80–85°. The mixture was cooled and filtered to recover the solid that separated. The yield was 2.5 g.; m. p. 248–249°. The solid was dissolved in xylene; the solution was decolorized and filtered. On cooling, yellow crystals of melting point 248–249° were obtained.

Anal. Calcd. for $C_{16}H_{10}N_2O_4$: C, 65.3; H, 3.4: N, 9.5. Found: C, 65.7; H, 3.8; N, 9.8.

6-Aminopiperonitrile.—6-Nitropiperonitrile[2] (20 g.) was added in portions to a solution of 100 g. of stannous chloride dihydrate in 100 ml. of hydrochloric acid. The temperature was maintained between 40–50° by cooling when necessary. When complete solution had resulted, the mixture was chilled in ice and treated slowly with sodium hydroxide solution until an excess had been added. During the addition, the temperature was maintained below 40°. The solid was collected on a filter, dried, and extracted with boiling methanol. On dilution with water, the methanol filtrate deposited, on cooling, 14 g. of pale yellow crystals; m. p. 142°.

Anal. Calcd. for $C_8H_6N_2O_2$: C, 59.3; H, 3.7; N, 17.3. Found: C, 59.2; H, 3.6; N, 17.0.

Schiff Base from 6-Aminopiperonitrile and Piperonal.—A solution of 8.7 g. of 6-aminopiperonitrile and 8.5 g. of piperonal in 170 ml. of alcohol was refluxed for one hour. The addition of a drop of sulfuric acid caused immediate formation of a precipitate. The mixture was allowed to reflux for one hour and then cooled. The solid was collected, washed with alcohol, and ether. The yield was 14 g., 88%. A small sample was recrystallized from alcohol; m. p. 184°.

Anal. Calcd. for $C_{16}H_{10}N_2O_4$: C, 65.3; H, 3.4; N, 9.5. Found: C, 65.9; H, 3.5; N, 9.4.

6-Aminoveratronitrile was prepared by a procedure very similar to that just described for 6-aminopiperonitrile. It was obtained in 82% yield and melted at 99–100°. McKee, McKee and Bost[15] record a melting point of 92–93.5° for the compound.

Summary

1. It has been shown that the so-called "anthraquinonediimines" obtained from certain nitriles are in reality triazine derivatives; the reaction is a trimerization rather than a dimerization, as originally reported.

2. The synthesis of certain quinazolines and phthalazines is described.

3. A procedure for the preparation of 6-aminopiperonitrile is given.

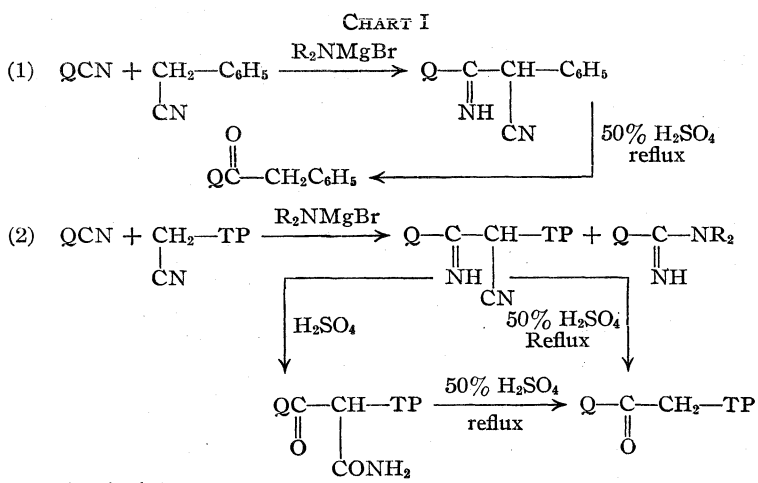
The Reaction of Halogenomagnesium Dialkylamides with Nitriles. The Preparation of N,N-Disubstituted Amidines

BY EMIL LORZ AND RICHARD BALTZLY

The 4-acyl quinolines required for a variety of syntheses are usually prepared by Claisen-type condensations of ethyl cinchoninate or its derivatives with the appropriate aliphatic esters. Since cinchoninic acid is most conveniently obtained by the hydrolysis of 4-cyanoquinoline it seemed likely that a more economical synthesis would be provided by a Ziegler type condensation of 4-cyanoquinoline itself with the desired nitrile using lithium or halomagnesium dialkylamides as the condensing agents. This expectation was realized in a model experiment, phenylacetonitrile and 4-cyanoquinoline reacting in the presence of bromomagnesium dibutylamide to give in 66% yield of α-phenyl-β-(4-quinolyl)-β-imidopropionitrile from which 4-phenacetylquinoline was obtained by refluxing with sulfuric acid (50% by volume). The course of these reactions is shown by equation 1.

CHART I



Q = 4-quinolyl
TP = 4-tetrahydropyranyl

When, however, 4-tetrahydropyranacetonitrile was used in place of phenylacetonitrile the principal product obtained was a basic substance that survived refluxing with 50% sulfuric acid and which was eventually shown to be N,N-di-*n*-butylquinoline-4-carboxamidine. This substance had evidently been produced by an addition of the bromomagnesium dibutylamide to 4-cyanoquinoline, a reaction that was not anticipated since Ziegler and Ohlinger[1] reported that the metal derivatives of secondary amines did not add to nitriles. Ziegler operated exclusively with aliphatic nitriles and it would appear from examination of his procedures and comparison with our own that the addition reaction must proceed much more rapidly with aromatic nitriles than with aliphatic. Addition does take place with aliphatic nitriles, however, since in a later experiment using bromomagnesium di-*n*-amylamide, 4-cyanoquinoline and tetrahydropyranacetonitrile, a small amount of N,N-di-*n*-amyltetrahydropyran-4-acetamidine was obtained. Since the properties of this type of amidine are unfavorable for isolation it is to be presumed that homologous substances were formed in traces in other experiments also. A recent paper by Hullin, Miller and Short[2] on the synthesis of amidines by the addition of magnesium amides to nitriles lends support to this belief as these authors report the formation of N,N-diethylvaleramidine in 26% yield by the reaction of bromomagnesium diethylamide with valeronitrile.

Further investigation showed that under suitable conditions, 40–50% yields of α-tetrahydropyranyl-β-(4-quinolyl)-β-imidopropionitrile could be obtained but that 4-quinoline-N,N-dialkylcarboxamidines were also formed in comparable amounts. This finding and subsequent transformations of the imidonitrile are represented by equation 2. This picture was not significantly altered by the use of lithium dialkylamides and, after this was ascertained, the more convenient magnesium compounds were used exclusively. Since amidines were being obtained in any case, a number of preparations of the imidonitrile were made using available secondary amines in the condensation, the corresponding amidines being isolated as by-products.

The amidines XII, XIV, XVI and XVII were tested for anti-plasmodial action, of which they proved to be devoid. General pharmacological screening, however, showed the presence of local anesthetic activity. When the antimalarial program was suspended it appeared advisable to investigate the addition of halomagnesium dialkyl amides to nitriles as a preparative method and a program was initiated with the object of learning the limitations and utility of the method and also of studying the pharmacology of the amidines produced. This report is concerned primarily with the first part of the program.

During the preparation of this paper the publication of Hullin, Miller and Short[2] appeared. It

(1) Ziegler and Ohlinger, *Ann.*, **495**, 84 (1932).

(2) Hullin, Miller and Short, *J. Chem. Soc.*, 394 (1947).

deals largely with the same subject, but while our findings are in general agreement with theirs we are able to augment and extend their experiments in some respects.

Hullin, Miller and Short found this amidine preparation to be most useful when an aromatic nitrile reacted with a magnesium dialkylamide. The yield was somewhat less when the magnesium amide was derived from methylaniline and the reaction failed with bromomagnesium diphenylamide. This is in agreement with our own experiments. It would appear that the metal–nitrogen bond acquires more of a salt-like character as the acidity of the amine increases and that this sets a limit on the ability of the metal amide to behave as a nitrogen–Grignard reagent. The British authors also found the magnesium amides obtained from aniline and benzylamine to add less readily to aromatic nitriles than bromomagnesium diethylamide. This seems inconsistent with the work of Ziegler and Ohlinger in which amidine formation was prominent when bromomagnesium ethylamide reacted with dialkyl acetonitriles but was absent when bromomagnesium diethylamide was used. Each group of workers operated with nitriles of restricted variety, however, and it is probable that further investigation will resolve this inconsistency.

While we are in agreement with Hullin, Miller and Short that the addition of halomagnesium dialkylamides to aliphatic nitriles is of small preparative value, we have had somewhat more favorable experience with aromatic nitriles, the yields in such cases being generally good. In one respect this reaction is considerably superior to the classical Pinner[3] method. As might be predicted from Kadesch's[4] discussion of steric hindrance in aromatic ketones, this addition is little subject to hindrance. Whereas the Pinner method is reported to fail with *o*-tolunitrile and α-naphthonitrile[5] amidines have been prepared from both by the present procedure in satisfactory yield. Furthermore, both 2-methoxyl-1-naphthonitrile and cyanomesitylene react with bromomagnesium di-*n*-butylamide with no apparent difficulty.

If halomagnesium dialkylamides be supposed to act in essentially the same manner as a Grignard reagent, they should add to some at least of the functions characteristically vulnerable to ordinary Grignard reagents. Most of the products to be expected from such reactions, however, would be either unstable or more readily accessible by other methods. It did seem possible that the reaction $R'R^2NMgBr + RX \rightarrow RR'R^2N + MgBrX$ would be of value in the preparation of tertiary amines. This possibility was explored by refluxing *n*-butyl bromide in ethereal solution with bromomagnesium benzyl-*n*-butylamide. After three hours less than 10% of tertiary amine had been formed showing that reaction in the expected fashion was not rapid and that consequently selective alkylation was improbable.

Experimental

Physical and analytical data on the amidines prepared are shown in Table I. All melting points are corrected.

General Procedure for the Addition Reactions.—To a solution of ethylmagnesium bromide containing about 50% excess Grignard reagent (on the basis of the nitrile to be used) was added gradually a slight excess of the secondary amine. Evolution of ethane generally continued for about thirty minutes.[1] The solution was then refluxed fifteen to twenty minutes further and the nitrile was added, usually in ethereal solution, but in some cases dissolved in benzene (for reasons of solubility). After the solutions had been refluxed for two to three hours or occasionally longer (as indicated in Table I), the reaction mixtures were decomposed with ice and ammonium chloride solution and worked up further according to three general procedures.

Method A.—The total material from the hydrolysis of the reaction mixture was made strongly alkaline. The amidine base and remaining secondary amine were taken into ether, dried, and separated by distillation *in vacuo*. This procedure was preferred for the more volatile amidines.

Method B.—The material from the hydrolysis of the reaction mixture was steam distilled, thereby removing unreacted nitrile and secondary amine. It was usually necessary to add some strong alkali in order to ensure volatilization of secondary amine. The residual material was then made strongly alkaline and the remaining bases were taken into ether. When quite involatile secondary amines were employed (di-octylamine) it was advantageous to extract the ethereal layer with successive inadequate amounts of dilute hydrochloric acid, a separation being thus obtained of stronger from weaker bases. The aqueous extracts were made acid to congo paper, evaporated separately *in vacuo* and the residues were crystallized from suitable solvents.

Method C.—In certain cases, the amidine base precipitated during the hydrolysis of the reaction mixture with ammonium chloride solution. The bulk of the product could thus be filtered off at this stage. It was usually necessary to partition it between dilute sodium hydroxide solution and benzene in order to free the base of small amounts of magnesium salts. The bases could then be acidified with ethanolic hydrogen chloride solution and crystallized as the hydrochlorides.

All the amidines here reported crystallized readily as the hydrochlorides though seldom in characteristic form. Most of the crystals appeared to be stubby prisms or rhombs. The acridine derivative (XI) and the dibenzylbenzamidine (XIII) were crystallized from absolute ethanol; the piperazine derivative XXIV, was crystallized from 95% ethanol. All the others were purified by crystallization from ethanol–ether mixtures.

α-Phenyl-β-(4-quinolyl)-β-imidopropionitrile.—Preliminary experiments using benzonitrile and benzyl cyanide had indicated that the best conditions for condensation were obtained when the two nitriles were added simultaneously.

To a solution of ethylmagnesium bromide prepared from 3.7 g. of magnesium and 16.5 g. (0.15 mole) of ethyl bromide in 200 cc. of ether was added 20 g. (0.155 mole) of di-*n*-butylamine. The solution was refluxed fifteen minutes after addition and a solution of 12 g. (0.1 mole) of benzyl cyanide and 15.5 g. (0.1 mole) of 4-cyanoquinoline dissolved in a mixture of benzene and anisole was added gradually. There was considerable heat of reaction and a red color appeared followed by precipitation of an orange solid. The mixture was refluxed for five hours and allowed to stand overnight. The orange precipitate was filtered off and washed with benzene. The filtrate and precipitate were hydrolyzed separately with ammonium chloride solution, the former eventually yielding 1.5 g. of the condensation product. The precipitate on hydrolysis

[l] After addition of the nitrile the solution was allowed to stand for sixteen hours at room temperature and refluxed five hours longer. Allowing for recovered cyanomesitylene, the yield was 93%.

changed to a sandy solid which was washed successively with methanol and ether, wt. 16.5 g. This substance after crystallization from alcohol formed cream-colored prisms, m. p. 189–190°.

Anal. Calcd. for $C_{18}H_{13}N_3$: C, 79.67; H, 4.83, Found: C, 79.80; H, 5.15.

4-Phenacetylquinoline.—On addition of 5.5 g. of the imidonitrile to a solution of 25 cc. of concd. sulfuric acid and 25 cc. of water an orange-red solid (presumably a sulfate) precipitated. The mixture was heated cautiously at first as there was considerable frothing. The red color faded gradually being succeeded by a deep yellow. After four hours of refluxing the solution was cooled and basified with sodium carbonate. A yellow oil separated which solidified and was recrystallized first from dilute methanol, then from ether–hexane mixture. It then formed colorless rectangular plates melting at 89–89.5°.

Anal. Calcd. for $C_{17}H_{13}ON$: C, 82.53; H, 5.30. Found: C, 82.62; H, 5.50.

α-(4′-Tetrahydropyranyl)-β-(4-quinolyl)-β-imidopropionitrile.—To a solution in 200 cc. of ether of ethylmagnesium bromide prepared from 10 g. of magnesium and 43.6 g. (0.4 mole) of ethyl bromide was added 51.6 g. (0.4 mole) of di-*n*-butylamine. The solution was refluxed for one-half hour and a solution in 400 cc. of 50% anisole–benzene of 30.8 g. (0.2 mole) of 4-cyanoquinoline and 25.2 g. (0.203 mole) of tetrahydropyran-4-acetonitrile was added rapidly. The reaction mixture was refluxed one-half hour (longer reaction times affected the yield adversely) and poured into a solution of 40 g. of ammonium chloride in 200 cc. of ice water. At this stage a faint but definite odor of hydrogen cyanide could be noted. A considerable amount of solid (the imidonitrile) separated at this point and was filtered off and washed with water and ether. The combined filtrates and washings were steam-distilled and the residue was extracted with ether. A further portion of imidonitrile separated during this extraction and was added to the earlier crop. The ethereal extract was dried over potassium carbonate and yielded, on acidification with ethanolic hydrogen chloride, 20 g. of crude N,N-di-*n*-butyl cinchoninamidine hydrochloride (XVI).

The imidonitrile obtained from the hydrolysis of the reaction mixture (weight, 28.6 g.) was not free of magnesium, was very high-melting and virtually insoluble in organic solvents. When dissolved in iced 3 *N* hydrochloric acid and cautiously basified it could be obtained substantially pure.

Anal. Calcd. for $C_{17}H_{17}N_3O$: C, 73.07; H, 6.14. Found: C, 72.79; H, 6.43.

α-(4′-Tetrahydropyranyl)-β-(4-quinolyl)-β-oxopropionamide.—Five grams of the imidonitrile was allowed to stand overnight at room temperature with 8 cc. of concd. sulfuric acid and 2 cc. of water. In the morning the resultant solution was poured onto ice. A light yellow pre-

cipitate formed which was collected and crystallized from absolute ethanol, m. p. 211° (dec.).

Anal. Calcd. for $C_{17}H_{19}N_2O_3 \cdot H_2SO_4$: C, 51.36; H, 5.33; N, 7.06. Found: C, 51.30; H, 5.19; N (Dumas), 6.99.

4-Quinolyl-4'-tetrahydropyranylmethyl Ketone.—Twenty-eight grams of the crude imidonitrile was allowed to stand for two days with 100 cc. of concd. sulfuric acid. The solution was then diluted with 100 cc. of water and the whole was refluxed five hours. The mixture was cooled, diluted and basified with sodium carbonate. The precipitated oil was taken into ether, dried over potassium carbonate and acidified with 48% hydrobromic acid. The hydrobromide crystallized from absolute ethanol as yellow plates melting at 214° (dec.).

Anal. Calcd. for $C_{16}H_{18}NO_2 \cdot HBr$: C, 56.97; H, 5.68. Found: C, 56.75; H, 5.73.

In our hands the bromination of both 4-phenacetyl quinoline and the corresponding tetrahydropyranyl ketone proved quite unsatisfactory. A number of products were isolated but their identity was dubious and they proved valueless for synthetic purposes.

Acknowledgment.—The authors wish to express their gratitude to Messrs. Walter S. Ide and Samuel W. Blackman for the micro-analyses here recorded.

Summary

1. The condensations of 4-cyanoquinoline with benzyl cyanide and tetrahydropyrane-4-acetonitrile using halomagnesium dialkylamides as condensing agents have been studied. While feasible, these condensations appear inferior to the more usual ester condensations, a marked complication being amidine formation between the condensing agent and the aromatic nitrile.

2. The additions of halomagnesium dialkyl or alkyl aryl amides to aromatic nitriles proceed readily and with good yields, thus constituting a useful synthesis of N,N-disubstituted amidines. A particular advantage of the reaction is its relative independence of steric hindrance.

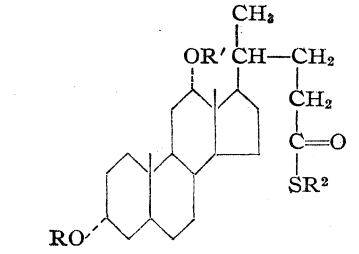
Steroid Acids and Their Transformation Products. II. Desulfurization of Thiol Esters of Desoxycholic Acid[1a]

BY GEORGE B. SPERO, A. VERN MCINTOSH, JR., AND ROBERT H. LEVIN

The preparation of a number of thiol esters of steroid acids, including ethyl 3(α),12(α)-diformoxythiolcholanate (Ia),[1b] was reported recently.[2] According to the literature desulfurization of thiol esters with Raney nickel catalyst may yield alcohols[3] or aldehydes.[4] In our laboratory the course of the desulfurization of I was found to be dependent on the character of the Raney nickel catalyst. Using freshly prepared standard Raney nickel[5] the ethyl thiol ester (Ia) was converted to the cholane alcohol (III) and traces of the cholanic aldehyde (II). These results were obtained with 60 to 90% alcohol as a solvent, reflux times of one to five hours, and a ratio of 5 to 20 g. of catalyst per gram of thiol ester. When the more active W-4 Raney catalyst[6] was used, the thiol ester (Ia) was rapidly and quantitatively reduced and desulfurized to the alcohol (III). Karabinos[7] has suggested that if the reaction is interrupted immediately after the thiol ester has disappeared (as tested by odor after acidification) a good yield of



Ia, R = R' = $\overset{O}{\overset{\|}{C}}$—H; $R^2 = C_2H_5$

aldehyde may be obtained. This method was not practical for us, apparently because even our standard Raney Nickel[5] was more active than the catalyst used by Wolfrom and Karabinos,[4,8] and also because of the small quantities of high molecular weight esters with which we were working.

However, we have been able to produce the cholanic aldehyde (II) in good yields by partially deactivating the standard Raney nickel. Two deactivation procedures were tried. Heating the catalyst with an inert solvent while passing a stream of nitrogen through for twenty-four hours did not give sufficient deactivation. Refluxing with acetone for two hours under standardized conditions was found to give reproducible results, and the aldehyde could then be obtained by adding the thiol ester in acetone–water and refluxing for an additional hour. The aldehyde (II) from ethyl 3(α),12(α)-diformoxythiolcholanate (Ia) was isolated in 60–80% yields as the crude semicarbazone, apparently a mixture of the mono- and diformoxy compounds. Separation of the pure diformyl compound as the semicarbazone by recrystallization could only be accomplished in low yield. The 2,4-dinitrophenylhydrazone of the crude aldehyde (II) was also prepared. The hydrochloric acid used in the dinitrophenylhydrazone preparation apparently caused the hydrolysis of both formyl groups. Benzyl 3(α),12(α)-diformoxythiolcholanate, (Ib) prepared by the previously described methods[2] but not crystallized, was similarly desulfurized to give the C-24 aldehyde. The free aldehyde was isolated from the crude reaction mixture via its bisulfite addition complex according to the procedure developed in this laboratory for the 3-substituted bisnor-Δ^5-cholenic aldehyde.[9] Hydrolysis of the formyl groups occurred during the process. Crystallization from dilute acetic acid and chloroform–hexane gave 3(α),12(α)-dihydroxycholan-24-al (IIc). The experimental data indicate that the desulfurization to produce the aldehyde takes place to the extent of 60–80%, but that the choice of a diformyl derivative has made the isolation of pure products difficult in this instance.

As previously noted,[2] the formoxy groups at positions 3 and 12 are not firmly bound. During the refluxing of ethyl 3(α),12(α)-diformoxythiolcholanate with W-4 Raney nickel in 80% ethanol there was complete deformylation at position 3 and partial deformylation at position 12, giving a mixture of 3(α),24-dihydroxy-12(α)-formoxycholane (IIIa), m. p. 185–186.5°, and 3(α),12(α),24-cholanetriol (IIIb), m. p. 90–125°, which could be separated by fractional crystallization. A better method of separation was chromatography over alumina which gave 60% of the triol monoformate (IIIa), and 40% of the triol (IIIb). When the monoformate (IIIa) was rechromatographed it was recovered unchanged, further indicating that deformylation at position 12 was not due to the alumina. Saponification of IIIa gave the triol (IIIb); however, the compound was difficult to purify to constant m. p. because it formed various hydrates. Acetylation with acetic anhydride and pyridine gave 3(α),12(α),24-triacetoxycholane (IIIc), which crystallized beautifully and gave good analyses. Saponification of the triacetate (IIIc) again gave a triol of unsharp m. p. and variously hydrated.

The structure of the monoformoxy triol (IIIa) was postulated as 3(α)-hydroxy,12(α)-formoxy because of the well-known greater ease of hydrolysis of 3-esters as compared to 12-esters in desoxycholic acid. To prove the correctness of this structure, the monoformate (IIIa) was oxidized with chromic acid in acetic acid at room temperature. The resulting 3-keto acid (IV) was not crystallized, but on hydrolysis followed by esterification gave a good yield of the known methyl 3-keto-12-(α)-hydroxycholanate (V).[10]

This series of reactions was repeated on the crude aldehyde (II) to give a 55% yield of methyl 3-keto-12(α)-hydroxycholanate (V). There remained the possibility that our conditions of oxidation might have caused deformylation and then a partial oxidation of the 3,12-dihydroxy compound to the 3-keto-12-hydroxycholanic acid. Accordingly, using the same experimental conditions, the cholantriol (IIIb) was oxidized to dehydrodesoxycholic acid and methyl diformyldesoxycholate (VI) was recovered substantially unchanged. Methyl diformyldesoxycholate, which apparently has not been recorded previously in the literature, was prepared by direct formylation of methyl desoxycholate. The diformyl compound (VI) was selectively deformylated in the 3-position using the chromatographic technique previously developed,[2] and the resulting 3-hydroxy com-

(8) In a check experiment we reduced ethyl thiol benzoate with standard Raney nickel catalyst following the directions of Wolfrom and Karabinos[4] and obtained just a trace of benzaldehyde. It is possible that the aldehyde is not even an intermediate in the formation of the alcohol from the thiol ester. Thus, in desulfurization experiments with ethyl 3(α),12(α)-diacetoxy-*nor*-thiolcholanate (to be reported shortly) we were able to obtain a good yield of alcohol, recovery of most of the remaining material as thiol ester, and just a trace of aldehyde, isolated as the semicarbazone.

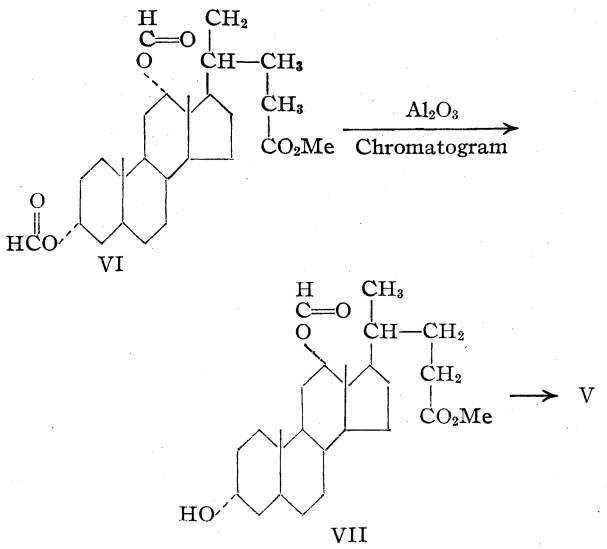
pound (VII) was converted to methyl 3-keto-12-(α)-hydroxycholanate (V).



Experimental[11,12]

Desulfurization of Ethyl 3(α),12(α)-Diformoxythiolcholanate (Ia) with Deactivated Raney Nickel. Aldehyde Formation.—Standard Raney nickel[5] (20 g.) was added to 60 ml. of acetone and heated under reflux with mechanical stirring for two hours. A solution of 2 g. (0.004 mole) of the thiol ester (Ia) in 40 ml. of acetone and 40 ml. of water was then added and refluxing was continued for an additional hour. The catalyst was separated by filtration and the filtrate concentrated *in vacuo* to a volume of 50 ml., then extracted with 100 ml. of ether. The ether was washed in portions with 100 ml. of cold 1% sodium hydroxide, 100 ml. of 1 *N* hydrochloric acid and 300 ml. of water. After drying over anhydrous sodium sulfate and evaporating to dryness *in vacuo*, 1.8 g. of crude aldehyde was obtained as a colorless oil.

Anal. Calcd. for the diformoxy aldehyde (IIa) $C_{26}H_{40}O_5$: C, 72.19; H, 9.32. Calcd. for the monoformoxy aldehyde (IIb) $C_{24}H_{40}O_4$: C, 74.21; H, 9.97. Calcd. for the dihydroxy aldehyde (IIc) $C_{24}H_{40}O_3$: C, 76.54; H, 10.71. Found: C, 72.94, 73.06; H, 9.39, 9.59.

The **semicarbazone** was prepared from the crude aldehyde from the desulfurization of 2 g. of thiol ester. This was dissolved in 80 ml. of 3A alcohol[13] and a solution of 2 g. of semicarbazide hydrochloride and 3 g. of sodium acetate in 20 ml. of water was added. The resulting solution was heated under reflux for two hours, cooled, and the product precipitated by the addition of 200 ml. of water; yield 1.8 g., m. p. 170–185°. Several crystallizations from methanol gave a product melting at 217–220°.

Anal. Calcd. for the diformoxy semicarbazone $C_{27}H_{43}O_5N_3$: C, 66.23; H, 8.85; N, 8.58. Calcd. for monoformoxy semicarbazone $C_{26}H_{43}O_4N_3$: C, 67.64; H, 9.39, N, 9.10. Calcd. for diol semicarbazone $C_{25}H_{43}O_3N_3$: C, 69.24; H, 10.00; N, 9.68. Found: C, 66.44, 66.39; H, 8.49, 8.48; N, 8.36, 8.30.

The **2,4-dinitrophenylhydrazone** was prepared by dissolving 860 mg. of the crude aldehyde in 70 ml. of 3A alcohol and adding 560 mg. of 2,4-dinitrophenylhydrazine. The solution was heated to boiling and 1 ml. of hydrochloric acid added. After refluxing for twenty-five minutes the solution was concentrated to half volume and allowed to cool, giving 520 mg. of product, m. p. 105–140°. An additional 120 mg. of product was obtained by concentrating the mother liquor. These fractions were combined and recrystallized from methanol to give pure 2,4-dinitrophenylhydrazone, m. p. 157–158°.

Anal. Calcd. for the diformoxy derivative $C_{32}H_{44}O_8N_4$: C, 62.72; H, 7.24; N, 9.15. Calcd. for the monoformoxy derivative $C_{31}H_{44}O_7N_4$: C, 63.68; H, 7.59; N, 9.58. Calcd. for the dihydroxy derivative $C_{30}H_{44}O_6N_4$: C, 64.72; H, 7.97; N, 10.06. Found: C, 64.32, 64.48; H, 8.22, 8.23; N, 10.22, 10.29.

3(α),12(α)-dihydroxycholan-24-al (IIc) was obtained by treating the crude reaction product from the desulfurization of 3 g. of ethyl thiol ester (Ia) with sodium bisulfite and subsequent decomposition of the aldehyde bisulfite complex with sodium carbonate.[9] The yield of aldehyde material was 1.12 g. (49%). Saponification of the formyl groups occurs during this decomposition. The aldehyde was crystallized from 50 ml. of dilute acetic acid and then repeatedly from chloroform–hexane, giving 0.27 g. (12%), m. p. 155.5–156.6°.

Anal. Calcd. for $C_{24}H_{40}O_3 \cdot H_2O$: C, 73.05; H, 10.73. Found: C, 73.38; H, 10.22.

Benzyl 3(α),12(α)-diformoxythiolcholenate (1b), prepared from 4.5 g. (0.01 mole) of 3,12-diformoxydesoxycholic acid and 2.4 g. of lead benzyl mercaptide, but not crystallized, was similarly desulfurized using 40 g. of deactivated nickel in 160 ml. of acetone and 80 ml. of water to yield 3.72 g. of aldehyde fraction. Portions of this crude aldehyde were converted to the identical semicarbazone and 2,4-dinitrophenylhydrazone derivatives described above.

Treatment of Ethyl 3(α),12(α)-diformoxythiolcholanate (Ia) with W-4 Raney Nickel. Alcohol formation.—To 2.0 g. (0.004 mole) of the thiol ester (Ia) in 40 ml. of 3A alcohol was added 10 g. of W-4 Raney nickel catalyst[6] and 10 ml. of water. The mixture was heated under reflux for one hour and the catalyst was separated by filtration and washed with 20 ml. of 3A alcohol. The filtrate was diluted with 200 ml. of water and extracted with 3 100 ml. portions of ether. The ether phase was washed with 100 ml. of 0.15 *N* sodium hydroxide, 300 ml. of water, dried over anhydrous sodium sulfate, and evaporated to dryness. The residue, which weighed 1.7 g., was dissolved in warm alcohol and water added to incipient cloudiness. On cooling, 0.7 g. of oil settled out and was separated by decantation. The mother liquor was diluted with water and cooled, giving 0.47 g. of crystalline material, m. p. 143–160°. Three crystallizations from alcohol–water

(11) All analyses and rotations by the Upjohn microanalytical group.

(12) All m. p.'s are corrected unless otherwise indicated.

(13) 3A alcohol is commercial 95% alcohol denatured by the addition of 5% methanol.

gave pure 3(α),24-dihydroxy-12(α)-formoxycholane (IIIa), m. p. 185–186.5°; $[\alpha]^{25}D$ + 86.6° (100.5 mg. in 10 cc. chloroform; 1 dcm. tube; α, +0.87°).

Anal. Calcd. for $C_{25}H_{42}O_4$: C, 73.84; H, 10.41. Found: C, 73.91; H, 10.46.

Further dilution of the mother liquor, after separation of (IIIa), yielded 0.37 g. of 3(α),12(α),24-trihydroxycholane (IIIb), m. p. 90–110°. We were unsuccessful in purifying this compound to a sharp m. p. because of its tendency to solvate. It crystallized nicely from acetone–benzene, m. p. 105–125°, and from alcohol–water, m. p. 106–118°. However, it formed a beautiful triacetoxy compound, m. p. 79.5–80.5°, which will be described below.

Although IIIa and IIIb could be separated by fractional crystallization, chromatography over alumina[14] proved to be a much better method. A portion of the crude reaction product (850 mg.) was dissolved in 150 ml. of benzene and the solution was run through 39 g. of alumina contained in a column 2 cm. in diameter. The column was eluted with three 33-ml. portions each of benzene, benzene and 0.4% methanol, benzene and 1% methanol, benzene and 2% methanol, benzene and 4% methanol, and benzene and 8% methanol. Two separate fractions were obtained. In the benzene and 4% methanol there was 538 mg. of compound IIIa, m. p. 182–186°, and in the benzene and 8% methanol there was 232 mg. of the triol (IIIb), m. p. 90–120°.

The monoformoxy compound (IIIa) (115 mg.) was dissolved in 30 ml. of benzene and chromatographed over 9.7 g. of alumina in a column 1.2 cm. in diameter. The column was eluted with 7 ml. portions of solvent as outlined above. The benzene and 4% methanol fraction contained 107 mg. of unchanged 3(α),24-dihydroxy-12(α)-formoxycholane, m. p. 185–186.5.

Saponification of 3(α),24-Dihydroxy-12(α)-formoxycholane (IIIa). The monoformoxy compound (IIIa) (300 mg.) was dissolved in 10 ml. of 5% methanolic sodium hydroxide solution and heated under reflux for ninety minutes. After cooling the solution was diluted with 30 ml. of water and extracted with ether. The ether extract was washed until neutral, dried over anhydrous sodium sulfate and evaporated to dryness. Crystallization of the residue from 3A alcohol and water gave 290 mg. of 3(α),12(α),24-cholantriol (IIIb), m. p. 90–102°.

3(α),12(α),24-triacetoxycholane (IIIc) was formed by acetylating 1 g. of the triol (IIIb) with 15 ml. of acetic anhydride and 15 ml. of pyridine under reflux for two and one-half hours. After three recrystallizations from 3A alcohol and water 640 mg. of product was obtained, m. p. 79.5–80.5°; $[\alpha]^{25}D$ +93.6° (99.4 mg. in 10 ml. chloroform; 1 dcm. tube; α, +0.93°).

Anal. Calcd. for $C_{30}H_{47}O_6$: C, 71.39; H, 9.59; CH_3CO, 25.59. Found: C, 71.43; H, 9.46; CH_3CO, 26.96.

Saponification of 500 mg. of pure 3(α),12(α),24-triacetoxycholane (IIIc), m. p. 79.5–80.5°, yielded 350 mg. of triol, m. p. 100–110°, after repeated crystallizations.

Conversion of 3(α),24-Dihydroxy-12(α)-formoxycholane (IIIa) to Methyl 3-Keto-12(α)-hydroxycholanate (V).—To 100 mg. of IIIa was added 8 ml. of a solution of 1% chromic acid in 95% acetic acid and the resulting solution was allowed to stand at room temperature for thirty minutes. It was then diluted to 40 ml. with water and extracted with 50-ml. of ether, in portions. The ether phase was washed with water and was extracted with 80 ml. of 1% sodium hydroxide solution. The basic extract was acidified with 10% hydrochloric acid and was extracted with 50 ml. of ether. After washing with water and drying over anhydrous sodium sulfate, the ether was removed by evaporation to yield 103 mg. of 3-keto-12(α)-formoxycholanic acid as an oil which was not crystallized.

The oil was dissolved in 20 ml. of 2% ethanolic sodium hydroxide and the solution was refluxed for thirty minutes, cooled, acidified with 10% hydrochloric acid, diluted to four times its volume with water and extracted with 70 ml. of ether. The ether extract was washed with water, dried and evaporated to dryness. The residue, 84 mg., was dissolved in 10 ml. of methanol and 0.2 ml. of acetyl chloride was added. After standing for sixteen hours at room temperature, the solution was diluted to four times its volume with water and extracted with 50 ml. of ether. The ether phase was washed with 30 ml. of 1% sodium hydroxide solution and with water, dried and evaporated to dryness. The residue crystallized on scratching. The yield of methyl 3-keto-12(α)-hydroxycholanate (V) was 72 mg., m. p. 124–139°. Recrystallization from acetone and water, and from acetone and petroleum ether, gave a pure product, m. p. 142–145°. The mixture melting point with an authentic sample showed no depression.

Using the above series of reactions, the following additional conversions to known compounds were made: 100 mg. of the crude aldehyde (probably a mixture of IIa and IIb) gave 59 mg. of V. 221 mg. of methyl 3(α)-hydroxy-12(α)-formoxycholanate (VII) gave 163 mg. of V. 100 mg. of 3(α),12(α),24-trihydroxycholane (IIIb) was oxidized as above to yield 86 mg. of dehydrodesoxycholic acid, m. p. 170–178°. Recrystallized twice from alcohol and water, m. p. 180–184°. An admixture with an authentic sample showed no m. p. depression.

Methyl 3(α),12(α)-Diformoxycholanate.—A solution of 5.0 g. of methyl desoxycholate was heated with 50 ml. of 87% formic acid at 55° for five hours. After diluting with water and working up as usual, crystallization from 170 ml. of 80% alcohol gave 2.8 g. of product, m. p. 78–81°. Two additional crystallizations from the same solvent yielded 2.0 g. of methyl diformyldesoxycholate, m. p. 81.5–82.5°; $[\alpha]^{25}D$ +99° (100 mg. in 10 ml. chloroform, αD, +0.99).

Anal. Calcd. for $C_{27}H_{42}O_6$: C, 70.10; H, 9.15. Found: C, 70.03; H, 9.15.

A 250-mg. sample of methyl diformoxycholanate was dissolved in benzene and passed over alumina. The main fraction, consisting of 221 mg. of material, was eluted with benzene +4% methanol and gave an $[\alpha]^{25}D$ of +74°. It was used directly for the oxidation described above.

Summary

1. The Raney nickel desulfurization of thiol esters of desoxycholic acid can be controlled to produce either the corresponding aldehyde or alcohol in good yield.

2. The structures of the resulting products were confirmed by their conversion into known keto derivatives of desoxycholic acid.

3. 3(α),12(α)-Dihydroxycholan-24-al, 3(α),12(α),24-trihydroxycholane, and various derivatives have been characterized.

KALAMAZOO, MICHIGAN RECEIVED DECEMBER 31, 1947

The Preparation and Dienone-Phenol Rearrangement of 2-Bromo-1,4-androstadien-17-ol-3-one 17-Hexahydrobenzoate

BY CARL DJERASSI AND CAESAR R. SCHOLZ

In 1944, Huang-Minlon and co-workers[1] described the dienone–phenol rearrangement of bromosantonin to bromodesmotroposantonin. In connection with our work on such rearrangements in the steroid series,[2,3] we have studied the preparation and rearrangement of a brominated dienone, 2-bromo-1,4-androstadien-17-ol-3-one-17-hexahydrobenzoate (IV).[4] A recent report of such a rearrangement in the dihydronaphthalene series[5] prompts us to record our results at this time.

The Δ^1-2-bromo derivative II, required as starting material, has been prepared previously by dehydrobromination of the corresponding 2,2-dibromo-3-ketosteroid.[2,3,6] For comparison purposes, and also as an alternate synthesis for compounds of type II, we have studied the bromination of Δ^1-testosterone hexahydrobenzoate (I). With either bromine or pyridine hydrobromide perbromide[7] in glacial acetic acid, the ketone I took up one mole of bromine with the simultaneous evolution of hydrogen bromide. Since the reaction product was the Δ^1-2-bromo ketone II, it is evident that the primary phase was addition of bromine to the double bond, followed by spontaneous loss of hydrogen bromide. By comparison, the bromination of the Δ^1-2-bromo-3-ketone II proceeded at a very much slower rate and resulted in the stable substitution product III. The structure of the Δ^1-2,4-dibromo ketone III was proven by dehydrobromination with collidine, which led in 80% yield to the desired 2-bromo-1,4-androstadien-17-ol-3-one 17-hexahydrobenzoate (IV).[8] In the bromination of II leading to III, the net result is one of substitution rather than addition, but the reaction may also have occurred through primary addition to the double bond to form a 1,2,2-tribromo-3-ketone which rearranged to the unstable 1,2,4-tribromo isomer, followed by spontaneous loss of hydrogen bromide to yield ultimately III.

The dienone–phenol rearrangement of the brominated dienone IV occurred readily in acetic anhydride–sulfuric acid solution with the formation of 1-methyl-2-bromoestradiol (V),[9] which was purified in the form of its diacetate (Vb). 1-Methylestradiol (VI),[2] on monobromination should lead either to Va or the isomeric 1-methyl-4-bromoestradiol. Bromination of VI with pyridine hydrobromide perbromide[7] was found to proceed rapidly, resulting in a good yield of a monobromophenol, which was found to be identical with Va[10] prepared from IV by the dienone–phenol rear-

(4) We are refraining at this time from assigning a configuration to the 17-hydroxyl group of the compounds described in this paper, which are all derived from dihydrotestosterone. In our earlier papers (ref. 2 and 3), the (α) configuration was employed, but recent work summarized by Miescher ("Recent Progress in Hormone Research," Vol. III, in press) seems to indicate that the 17-hydroxyl group possesses the (β) configuration (*cis* to the C-13 methyl group).

(8) An examination of the ultraviolet absorption spectra of the three unsaturated ketones II, III and IV (Fig. 1) shows that introduction of a bromine atom in II shifts the maximum from 255 to 261 mμ (III), but that this bathochromic shift is nullified in converting III to the dienone IV, which again shows a maximum around 255 mμ.

(9) On the basis of the reaction conditions and considering the reaction mechanism (ref. 5), it is unlikely that rearrangement of the 2-bromo substituent to the 4-position should have occurred during the migration of the angular methyl group. Our rearrangement product, therefore, very probably has the assigned structure V. It should be noted, however, that in the two examples of the rearrangement of an α-bromo dienone recorded in the literature (refs. 1 and 5), the alternate position corresponding to C-4 in IV was blocked.

(10) The ultraviolet absorption spectra (Fig. 2) of Va and Vb showed the characteristic differences established previously (see ref. 3) for phenols and their acetates, but the presence of the bromine atom resulted in a bathochromic shift of 5 mμ for the acetate and 7 mμ for the phenol. For comparison the spectra of 1-methylestradiol (VI) and its diacetate are also reproduced.

rangement, thus establishing a connecting link between the two series.

Experimental[11]

Bromination of Δ^1-Androsten-17-ol-3-one 17-Hexahydrobenzoate (I) (Δ^1-Testosterone Hexahydrobenzoate).—A solution of 100 mg. of the ketone I[3,6] in 2 cc. of C. P. glacial acetic acid was treated with 80 mg. of pyridine hydrobromide perbromide and the reaction mixture was warmed slightly until all the reagent dissolved. Decolorization was almost instantaneous and was accompanied by evolution of hydrogen bromide. After standing at room temperature overnight, the crude product was precipitated with water. Although it showed a single maximum at 254.5 mμ, characteristic for the Δ^1-2-bromo ketone II, the compound was seemingly contaminated by some dibromo derivative (Found: Br, 21.30). The crude product was purified readily by chromatographing over alumina, yielding 50 mg. (42%) of **Δ^1-2-bromoandrosten-17-ol-3-one 17-hexahydrobenzoate (II)**, which was shown to be identical with authentic material[2,3] by comparison of the melting points, rotations, absorption spectra and analysis (Calcd.: Br, 16.76, Found: Br, 16.37).

Δ^1-2,4-Dibromoandrosten-17-ol-3-one 17-Hexahydrobenzoate (III).—To a solution of 1.2 g. of the Δ^1-2-bromo ketone II[2,3,6] in 50 cc. of pure, fractionated glacial acetic acid (containing 13 mg. of water/10 cc. of acid; see ref. 3) was added 3 drops of 4 *N* hydrogen bromide in acetic acid followed by 6.25 cc. of a standard solution of bromine in acetic acid (1.6 g. of bromine in 25 cc. of pure acetic acid) and the reaction mixture was allowed to stand overnight. Decolorization was nearly complete after six hours. The solution was poured into cold water, the crude product was collected, washed well with water, dried and recrystallized from ethanol to yield 1.08 g. (77%) of Δ^1-2,4-dibromo ketone III of m. p. 143.5–146°, $[\alpha]^{24}D$ + 16.5°. The analytical sample crystallized from ethanol as colorless, prismatic needles with m. p. 147–148°, $[\alpha]^{24}D$ + 11.3°, maximum at 261 mμ, log E = 3.81, minimum at 230.5 mμ, log E = 3.27 (Fig. 1).

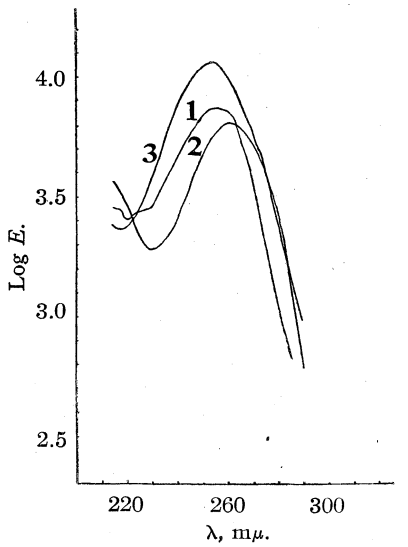

Fig. 1.—Ultraviolet absorption spectra (in 95% ethanol): curve 1, compound II; curve 2, compound III; curve 3, compound IV.

Anal.[12] Calcd. for $C_{26}H_{36}O_3Br_2$: C, 56.12; H, 6.52; Br, 28.73. Found: C, 56.14; H, 6.69; Br, 29.24.

Pyridine hydrobromide perbromide[7] could be substituted for bromine to effect bromination in the 4-position.

2-Bromo-1,4-androstadien-17-ol-3-one 17-Hexahydrobenzoate (IV).—Dehydrobromination of the dibromo ketone III was effected by refluxing 0.5 g. of the ketone with 2.5 cc. of collidine[13] for one-half hour. The amount of collidine hydrobromide (0.17 g.), isolated by dilution with ether, filtering and washing with the same solvent, corresponded to 93% of the calculated quantity. The ether solution was washed several times with 5% hydrochloric acid solution, water, 5% sodium hydroxide solution, and again water, dried over sodium sulfate and the solvent was removed in a current of air. Trituration of the residue with hexane gave 0.35 g. (82%) of nearly colorless dienone of m. p. ranging from 132–137° to 139–142° which was satisfactory for the next step (Found: Br, 16.76). The compound crystallized from hexane as rosets of colorless, prismatic needles which retained solvent very tenaciously. When dried at 55° and 30 mm., the material melted at *ca.* 105–111° (turbid), resolidified and melted at 142–144°. The solvent was removed completely on drying at 130° and 0.1 mm. for five hours (m. p. 144°). The rotations of three different, dry samples were: $[\alpha]^{25}D$ +7.4°, 8.1°, 12.9°. The absorption spectrum is shown in Fig. 1, and exhibited a maximum at 254.5 mμ, log E = 4.06, and a minimum at 218 mμ, log E = 3.36.

Anal. Calcd. for $C_{26}H_{35}O_3Br$: C, 65.68; H, 7.42; Br, 16.81. Found: C, 65.76, 65.85; H, 7.73, 7.60; Br, 16.49.

1-Methyl-2-bromoestradiol-3,17-diacetate (Vb). (a) By Dienone–Phenol Rearrangement of 2-Bromo-1,4-androstadien-17-ol-3-one 17-Hexahydrobenzoate (IV).—The

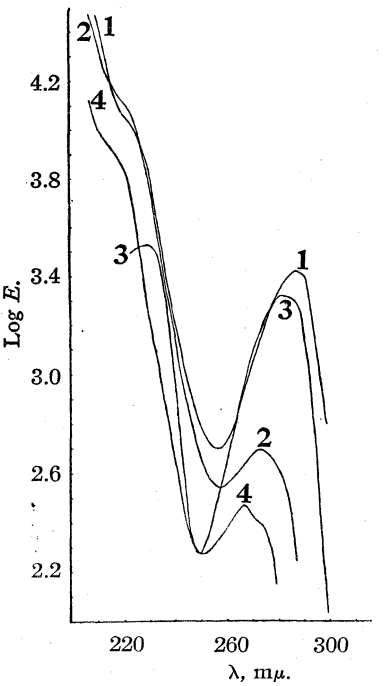

Fig. 2.—Ultraviolet absorption spectra (in 95% ethanol): curve 1, 1-methyl-2-bromoestradiol (Va); curve 2, 1-methyl-2-bromoestradiol diacetate (Vb); curve 3, 1-methylestradiol (VI); curve 4, 1-methylestradiol diacetate.

(11) All melting points are corrected. The optical rotations were determined on 5–10 mg. of sample in 1.2 cc. of chloroform using a 1-dcm. tube of 1-cc. capacity. The ultraviolet absorption spectra measurements were carried out in 95% ethanol solution using a Beckman Quartz Photoelectric Spectrophotometer; $E = 1/c \log I_0/I$ for a 1 cm. cell, where c is the concentration in moles per liter.

(12) All microanalyses were carried out by Mr. Joseph Alicino, Metuchen, N. J., and Mr. George L. Stragand, Microchemical Laboratory, University of Pittsburgh.

(13) The γ-collidine used for the dehydrobromination was Eastman Kodak Co. white label product, which was fractionated before use.

dienone–phenol rearrangement was carried out by treating 0.26 g. of the 2-bromodienone IV in 5 cc. of acetic anhydride with 0.09 g. of concentrated sulfuric acid and allowing the solution to stand at room temperature for five hours. The mixture was poured into water, swirled to hydrolyze most of the acetic anhydride and the product was extracted with ether. After saponification by refluxing with 5% methanolic potassium hydroxide for seventy-five minutes, the crude 1-methyl-2-bromoestradiol was acetylated by means of acetic anhydride and pyridine, and the diacetate was precipitated by dilution with 5% hydrochloric acid. After recrystallization from ethanol, the colorless crystals (0.13 g., 53%) melted at 185–191°, $[\alpha]^{25}D$ + 126°. The analytical sample crystallized as colorless rosets of shiny needles and had the following constants: m. p. 192.5–194°, $[\alpha]^{25}D$ + 128°, maximum at 273 mμ, log E = 2.67, minimum at 256.5 mμ, log E = 2.44 (Fig. 2).

Anal. Calcd. for $C_{23}H_{29}O_4Br$: C, 61.47; H, 6.51; Br, 17.78. Found: C, 61.66; H, 6.58; Br, 18.10.

(b) By Bromination of 1-Methylestradiol (VI).—When a solution of 55 mg. of 1-methylestradiol (VI)[2] in 1.4 cc. of glacial acetic acid was warmed with 63 mg. of pyridine hydrobromide perbromide for *ca.* thirty seconds, decolorization resulted with evolution of hydrogen bromide. After standing for a few minutes, the product was precipitated by the addition of water, filtered, and acetylated as in (a) to give 60 mg. (70% over-all yield) of the diacetate of m. p. 188–192°. Further recrystallization led to crystals melting at 193–194.5°, $[\alpha]^{25}D$ + 125°, which gave no depression in m. p. when mixed with a sample prepared according to (a). The ultraviolet absorption spectrum was also practically identical with that shown for the above sample (method a), maximum at 272.5 mμ, log E = 2.70, minimum at 257.5 mμ, log E = 2.54.

1-Methyl-2-bromoestradiol (Va).—Sixty milligrams of the diacetate Vb on saponification with methanolic potassium hydroxide gave 40 mg. of 1-methyl-2-bromoestradiol (Va) of m. p. 166–167.5°. Recrystallization from hexane or dilute ethanol raised the m. p. to 167.5–169°, $[\alpha]^{24}D$ + 189°, 185°, maximum at 288.5 mμ, log E = 3.42, minimum at 257 mμ, log E = 2.70 (Fig. 2). The same material was obtained from samples of the diacetate prepared according to (a) and (b) above.

Anal. Calcd. for $C_{19}H_{25}O_2Br$: C, 62.47; H, 6.90; Br, 21.88. Found: C, 62.81; H, 7.05; Br, 21.63.

The authors are greatly indebted to Jean Rogers and Helen Dudek for assistance in the experimental work.

Summary

It has been shown that while the bromination of Δ^1-androsten-17-ol-3-one 17-hexahydrobenzoate (I) proceeded rapidly with the formation of the corresponding Δ^1-2-bromo-3-ketone II, the latter reacted only slowly with bromine to form Δ^1-2,4-dibromoandrosten-17-ol-3-one 17-hexahydrobenzoate (III). The dibromo compound was dehydrobrominated with collidine yielding a 2-bromo-1,4-dienone IV, which underwent the dienone–phenol rearrangement to 1-methyl-2-bromoestradiol (V). The latter was also obtained on direct bromination of 1-methylestradiol (VI), thus establishing a link between the two series.

Optical Activity of the 4,5-Phenanthrene Type: 4-(1-Methylbenzo[c]phenanthryl)-acetic Acid and 1-Methylbenzo[c]phenanthrene[1]

BY MELVIN S. NEWMAN AND WILLIAM B. WHEATLEY[2]

The theoretical considerations leading to the prediction of optical activity in compounds of the 4,5-dimethylphenanthrene type have been presented.[3] The structural feature necessary for this type of optical isomerism (called optical activity of the 4,5-phenanthrene type) involves the substitution in the 4 and 5 positions of phenanthrene of groups large enough to prevent their existence in the same plane as that of the aromatic rings. The preparation and resolution of one compound of this type, 4,5,8-trimethyl-1-phenanthrylacetic acid, have been described.[3b,c] In order to obtain an additional example of compounds exhibiting this type of optical activity we undertook the synthesis and resolution of 4-(1-methylbenzo[c]phenanthryl)-acetic acid, I. This has been successfully accomplished and is herein reported. We have also synthesized 1-methylbenzo[c]phenanthrene, II, the last monomethyl derivative of the parent hydrocarbon which remained to be prepared.[4] This compound is to be tested for carcinogenic activity.

The optical activity in I is undoubtedly due to the fact that the methyl group is forced out of the plane of the aromatic rings.[3c] The hydrocarbon, II, should also be capable of resolution but no suitable resolving agent for hydrocarbons is known. We hope to prepare such a resolving agent in the future. We are also planning to synthesize compounds with larger interfering groups so that more accurate studies on the rates of racemization can be made.

The synthetic methods used are outlined in the chart.

The mixture of unsaturated esters resulting from the Reformatsky reaction of ketone III and ethyl α-bromopropionate was dehydrogenated

(1) The material herein presented was taken from the Ph.D. Thesis of W. B. W., The Ohio State University, June, 1947, and was presented before the Division of Organic Chemistry of the ACS, New York, September, 1947.

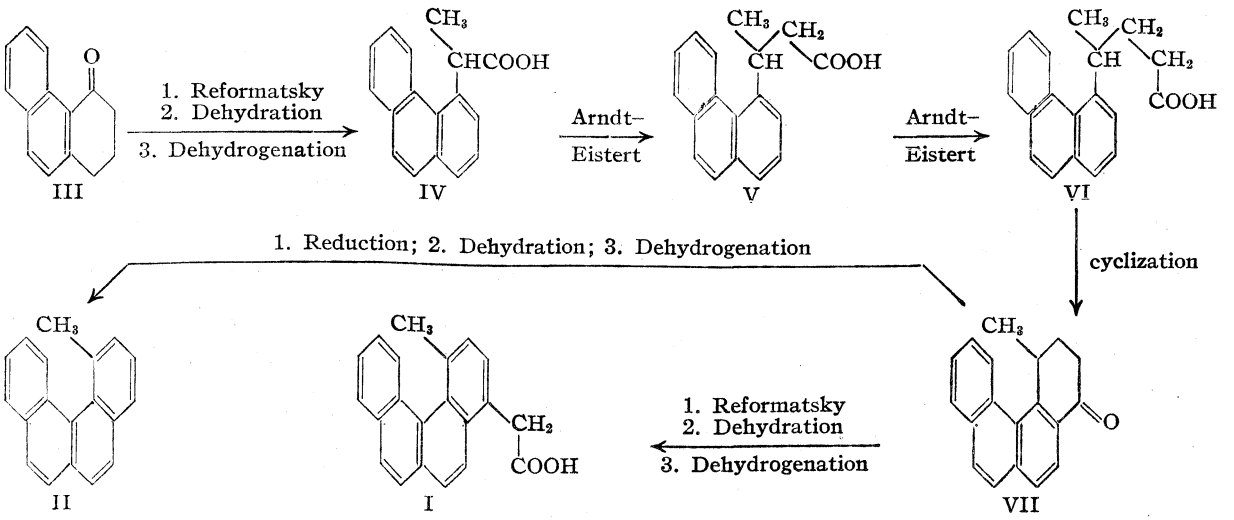
(4) 2-, 3- and 4-isomers, Hewett, *J. Chem. Soc.*, 1286 (1938); 5-isomer, Hewett, *ibid.*, 596 (1936); 6-isomer, Hewett, *ibid.*, 293 (1940).



over palladized charcoal to yield the acid, IV. As in the similar stage of the synthesis of 1,4,5-trimethylphenanthrene[3c] considerable cleavage to phenanthrene occurred during this step. The remaining steps occasioned no particular difficulty.

Two properties of the hydrocarbon, II, are of interest: its high melting point of 141.4–141.9° and its failure to yield a picrate. Since the melting point is higher than that of the parent benzo[c]phenanthrene or the other five monomethyl derivatives, which range from 54 to 81°, it was suspected that I might have been further cyclodehydrogenated into 1,12-methylenebenzo[c]phenanthrene, m. p. 134–135°, a compound previously synthesized from pyrene.[5] However, a comparison of physical and chemical properties indicated that our compound was decidedly different from that reported by Vollmann.[5] The failure to yield a picrate was surprizing in view of the fact that benzo[c]phenanthrene and the 2-, 3-, 4-, 5-, and 6-methylbenzo[c]phenanthrenes all give picrates. We were able to prepare a trinitrofluorenone[6] derivative.

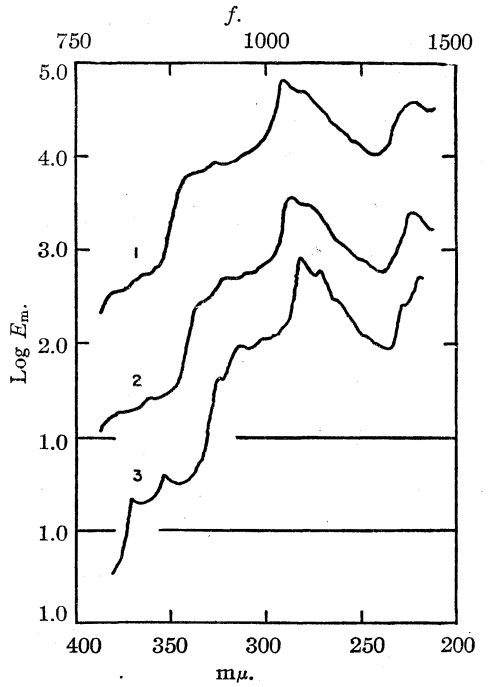


Fig. 1.—Ultraviolet absorption spectra: 1, 4-(1-methylbenzo[c]phenanthryl)-acetic acid; 2, 1-methylbenzo[c]phenanthrene; 3, benzo[c]phenanthrene. Curves 2 and 3 are dropped one and two log E_m units, respectively, to avoid undue overlapping with Curve 1.

The ultraviolet absorption spectra of I and II are given in Fig. 1 where they are compared to that of benzo[c]phenanthrene.[7] It is easily seen that they resemble the parent hydrocarbon but that there is some loss of fine structure.

The resolution of the acid I was not accomplished without much trouble. We were not able to find a suitable salt of I with an alkaloid. By treating the acid chloride of I with *l*-menthol we were able to obtain a quantity of *d*-acid which had evidently not been esterified.[8] On recrystallization this acid gave specific rotations which varied from +1.0 to +2.1°. On standing the rotation gradually disappeared. In this respect, this acid behaved quite the same as that previously reported, 4,5,8-trimethyl-1-phenanthrylacetic acid.[3c]

We would like to take this opportunity to acknowledge a grant-in-aid from a special fund donated by the Ohio State University Research Foundation and administered by the Graduate School.

Experimental[9]

α-4-Phenanthrylpropionic Acid, IV.—A solution of 70 g. (0.357 mole) of ketone III[10] and 75 g. (0.415 mole) of ethyl α-bromopropionate in 400 cc. of dry benzene was added dropwise with stirring to 27 g. (0.415 mole) of hydrochloric acid-washed granular zinc. The reaction started easily upon the addition of a few crystals of iodine, and portions of iodine were added three times during the course of the reaction. Refluxing was maintained by external heating during the addition of the ketone–ester solution, which required about an hour, and for an additional two hours. After cooling, the reaction mixture was hydrolyzed with ice and hydrochloric acid and the organic matter taken into benzene and washed with saturated sodium bicarbonate solution. On removal of the last of the benzene, spontaneous dehydration of the crude hydroxy-ester occurred. Distillation *in vacuo* yielded 86 g. of an orange-red oil, which was saponified by refluxing one hour with dilute methanolic potassium hydroxide and the resulting mixture worked up into neutral and acidic fractions. The neutral fraction yielded 22.4 g. (32%) of recovered ketone, III; the acidic fraction was esterified in the usual manner with methanol and dry hydrogen chloride. Distillation gave 55.7 g. (59%, or 86% based on ketone consumed) of ester, a yellow oil boiling at 163–165 (1 mm.). The ester crystallized in part and on crystallization from low boiling petroleum ether, colorless stout needles, m. p. 67–72°, were obtained.

Anal. (d) Calcd. for $C_{18}H_{18}O_2$: C, 81.2; H, 6.8. Found: C, 80.7; H, 6.9.

The acid obtained from this ester was crystallized from benzene until it melted at 176.6–177.2° dec.

Anal. (c) Calcd. for $C_{17}H_{16}O_2$: C, 80.9; H, 6.4. Found: C, 81.0, 81.1; H, 6.0, 6.2.

In the best of many experiments 160 g. (0.6 mole) of the above crude ester in four equal batches was dehydrogenated by heating with 20% palladium-on-charcoal catalyst for forty-five minutes at 280–320°; 40% of the theoretical quantity of hydrogen was collected during this time. The reaction product was worked up into neutral and acidic fractions. The neutral fraction, which amounted to 11.3 g., (10.5%) was identified as phenanthrene. Recrystallization of the crude acid from benzene gave 63.9 g. (43%) of acid melting above 215.8° and almost as much non-crystalline acid. By esterifying and further dehydrogenation more crystalline acid could be obtained from these non-crystalline fractions. A sample of acid recrystallized several times melted at 218.1–218.6°. *Anal.* (c) Calcd. for $C_{17}H_{14}O_2$: C, 81.6; H, 5.6. Found: C, 81.1; H, 5.8. Longer heating of the dihydroester with the catalyst caused more hydrogen to be evolved, but lower yields of crystalline acid were obtained, along with greater amounts of neutral material. Dehydrogenation with sulfur gave similar but inferior results.

β-4-Phenanthrylbutyric Acid, V.—A solution of 52.5 g. (0.21 mole) of acid IV, 30 cc. of purified thionyl chloride and 5 drops of pyridine in 750 cc. of dry ether was stirred for three hours at room temperature. Removal of solvent and excess thionyl chloride under reduced pressure left a solid residue which on recrystallization from benzene gave 41.1 g. (73%) of acid chloride. A solution of 32.5 g. (0.12 mole) of the above acid chloride in 400 cc. of dry ether was added dropwise over a period of three hours to a dry ethereal solution of diazomethane, prepared from 63 g. of N-nitrosomethylurea,[11] stirred vigorously and maintained at below 5° by an ice-bath.

After stirring overnight, during which time the solution came to room temperature, the ether was removed under reduced pressure. The solid yellow residue was suspended in 250 cc. of methanol and 75 cc. of dioxane and the suspension heated to 55°. Portions of freshly prepared silver oxide were added at ten-minute intervals to this diazoketone suspension and, after two hours of heating at 55°, the theoretical amount of nitrogen had been collected. After refluxing for an hour, the reaction mixture was filtered; the filtrate stripped and distilled *in vacuo*, yielding 27.3 g. of reddish oil which was saponified and worked up into neutral and acidic fractions. The neutral fraction, a dark red viscous oil, was discarded. The acidic fraction was recrystallized from benzene to give 16.3 g. (51%) of acid V, m. p. 143–145°. An analytical sample crystallized in colorless prisms, m. p. 145.8–146.5°.

Anal. (a) Calcd. for $C_{18}H_{16}O_2$: C, 81.8; H, 6.1; neut. equiv., 264. Found: C, 82.1, 81.9; H, 6.4, 6.5; neut. equiv., 263, 266.

γ-4-Phenanthrylvaleric Acid, VI.—An Arndt–Eistert synthesis was carried out on acid V in a manner similar to that described above. In this case, the rearrangement of the diazoketone proceeded more rapidly so that the theoretical amount of nitrogen was evolved in forty-five minutes. There was obtained by crystallization of the acid fraction from benzene a first crop of crystalline acid VI, m. p. 136.0–137.8° (57%) and a second crop melting at 135.6–137.2° (6%). An analytical sample melted at 138.4–139.0°.

Anal. (a) Calcd. for $C_{19}H_{18}O_2$: C, 82.0; H, 6.5; neut. equiv., 278. Found: C, 82.5, 82.1; H, 6.8, 6.4; neut. equiv., 280, 278.

4-Keto-1-methyl-1,2,3,4-tetrahydrobenzo[c]phenanthrene, VII.—To a well-stirred, ice-cold solution of the acid chloride of VI, prepared from 9.0 g. (0.00524 mole) of acid VI by treatment with thionyl chloride and pyridine as described above, in 100 cc. of anhydrous *sym*-tetrachloroethane was added rapidly 10 cc. of fuming stannic chloride. A yellow complex separated almost immediately. After thirty minutes the mixture was hydrolyzed with dilute hydrochloric acid and the solvent removed by steam distillation.

After vacuum distillation there was obtained 7.9 g. (95%) of ketone VII as a viscous yellow oil which solidified on standing a few weeks. An analytical sample, recrystallized from Skellysolve B, melted at 80.2–81.2°.

Anal. (b) Calcd. for $C_{19}H_{16}O$: C, 87.7; H, 6.2. Found: C, 87.6, 87.9; H, 6.3, 6.4.

The 2,4-dinitrophenylhydrazone of VII melted at 300–302° uncor. dec.

Anal. (b) Calcd. for $C_{25}H_{20}O_4N_4$: C, 68.2; H, 4.6; N, 12.7. Found: C, 68.2, 68.1; H, 4.6, 4.7; N, 12.5, 12.6.

1-Methylbenzo[c]phenanthrene, I.—After aluminum isopropoxide–isopropyl alcohol reduction of 4.87 g. (0.019 mole) of VII, dehydration of the resulting carbinol by heating to 215°, and vacuum distillation there was obtained 4.22 g. (92%) of a light yellow oil. A mixture of 4.10 g. (0.017 mole) of this oil and 0.525 g. (0.016 mole) of sulfur was heated for one hour at 205–225°, then immediately vacuum distilled, yielding 3.39 g. of light green oil. This oil was dissolved in petroleum ether b. p. 35–40° (Skellysolve F) and absorbed on a column of −80 mesh alumina. Elution with petroleum ether, b. p. 95–100° (Skellysolve C), followed by several recrystallizations of the crystalline material so obtained, gave 0.81 g. (20%) of colorless 1-methylbenzo[c]phenanthrene (I), m. p. 141.4–141.9°.

Anal. (b) Calcd. for $C_{19}H_{14}$: C, 94.2; H, 5.8. Found: C, 94.2, 94.2; H, 6.0, 6.1.

In contrast to the yellow hydrocarbon, m. p. 134–135° of Vollman,[5] I is colorless and gives a violet color in concentrated sulfuric acid rather than a yellow color with green fluorescence.[5] Furthermore, on chromic acid oxidation, no trace of the quinone mentioned by Vollman was obtained.

While several attempts to prepare the picrate I were unsuccessful, a derivative with 2,4,7-trinitrofluorenone was obtained in the following manner; equivalent amounts of

(9) Analyses marked (a) by Arlington Laboratories, (b) by W. J. Polglase, (c) by S. Olsen, and (d) by D. Mowry. All melting points corrected unless otherwise noted.

the hydrocarbon and trinitrofluorenone were dissolved in hot benzene. On standing in an ice box overnight, the solution deposited light yellow crystals, apparently the hydrocarbon. After several weeks in the ice box, a number of bright red clusters were present. These were picked out, washed in turn with benzene, acetone, and Skellysolve C, then dried *in vacuo;* m. p. 130.6–131.4°.

Anal. (b) Calcd. for $C_{32}H_{19}O_7N_3$: C, 68.9; H, 3.4; N, 7.5. Found: C, 68.7, 68.7; H, 3.5, 3.6; N, 7.6, 7.6.

4-(1-Methylbenzo[c]phenanthryl)-acetic acid, II.—To a solution of 11.12 g. (0.043 mole) of ketone VII in 150 cc. of dry benzene was added 6.0 g. (0.036 mole) of ethyl bromoacetate, 2.4 g. (0.036 mole) of granular zinc and a pinch of iodine. After fifteen minutes of refluxing, the reaction began. Five more like quantities of ester, zinc and iodine were added at half-hour intervals, during which time refluxing was maintained by external heating. Following hydrolysis with dilute hydrochloric acid, the benzene layer was separated and the aqueous layer washed twice with benzene. The combined benzene extracts were evaporated, the residual oil heated ten minutes at 190–200° to effect dehydration, and then distilled *in vacuo*. The distillate was saponified and the resulting product worked up to give a neutral fraction of 1.60 g. (14%) of recovered ketone and an acid fraction which was esterified with methanol–hydrogen chloride, yielding 8.57 g. (63%) of distilled ester.

A mixture of 7.08 g. (0.022 mole) of the above ester and 0.71 g. (0.022 mole) of sulfur was heated for one and one-half hours at 220°, then distilled *in vacuo*. The distillate was saponified, the acid fraction dissolved in acetone and passed through a column of charcoal (Norite A). There was obtained 3.86 g. (57%) of acid II melting above 208°. An analytical sample, colorless prisms from benzene–acetone, melted at 210.1–210.6°.

Anal. (b) Calcd. for $C_{21}H_{16}O_2$: C, 84.0; H, 5.4; neut. equiv., 300. Found: C, 83.7, 83.8; H, 5.3, 5.5; neut. equiv., 297, 300.

The amide of II, recrystallized from benzene–acetone, melted at 234.5–235.5° uncor.

Anal. (b) Calcd. for $C_{21}H_{17}ON$: C, 84.3; H, 5.7; N, 4.7. Found: C, 84.4, 84.4; H, 6.1, 5.9; N, 4.7, 4.7.

Resolution of II.—A solution of the chloride of acid II, prepared by treatment of 1.54 g. (0.0041 mole) of II with thionyl chloride and pyridine, in 50 cc. of dry benzene was added dropwise to a well-stirred ice-cold solution of 0.80 g. (0.0051 mole) of *l*-menthol ($[\alpha]_D$ −49.8°, *c*, 2 in absolute ethanol) in 25 cc. of dry benzene. After being stirred for an hour, during which time it came to room temperature, the reaction mixture was hydrolyzed. The benzene layer was separated, washed in turn with dilute hydrochloric acid, water, saturated sodium bicarbonate solution and then dried. Evaporation of the benzene under reduced pressure left an orange oil, which gave 0.39 g. of crystalline material on trituration with Skellysolve F. This material, after five recrystallizations from chloroform–Skellysolve F, melted at 185.5–187.0° and showed a specific rotation of +1.4 ± 0.2° (*c*, 1 in chloroform). Although it was at first believed that this material was the *l*-menthyl ester of II, the analysis indicated that it was impure.

Anal. (b) Calcd. for $C_{31}H_{34}O_2$ (ester): C, 84.9; H, 7.8. Calcd. for $C_{21}H_{16}O_2$ (acid): C, 84.0; H, 5.4. Found: C, 84.9, 84.9; H, 5.4, 5.4.

The five-times recrystallized material was shaken with alcoholic potassium hydroxide for ten minutes, the mixture then diluted with a large quantity of water and extracted repeatedly with ether. Acidification of the aqueous layer precipitated the acid, which was extracted with ether. Evaporation of the ether from the combined extracts left light tan crystals of acid II, m. p. 208.8–209.6°, alone and when mixed with an authentic sample of II. A solution of 0.1053 g. of this acid in 5 cc. of acetone gave an observed rotation of +0.09 ± 0.02°; $[\alpha]^{25}_D$ +2.1 ± 0.4°. No rotation could be observed the following day. Two other resolutions were carried out in the manner described above, giving samples of acid with specific rotations of +1.6 and +1.0°. The acetone solutions of both of these samples displayed no optical activity after standing for twelve hours at room temperature.

Summary

The synthesis of 1-methylbenzo[c]phenanthrene is described. This synthesis completes the series of methylbenzo[c]phenanthrenes, as the other five isomers have been previously described.

The synthesis of 4-(1-methylbenzo[c]phenanthryl)-acetic acid is described, and the dextrorotatory form of this acid has been isolated. The isolation of this optically active acid provides another instance of optical activity of the 4,5-phenanthrene type.

Vinyl Aromatic Compounds. V. Ortho-, Meta- and Para-Isopropenylbiphenyls[1]

BY DAVID T. MOWRY, JOACHIM DAZZI, MARY RENOLL[2] AND ROBERT W. SHORTRIDGE[3]

In a preceding paper[4] the synthesis of ortho-, meta- and para-vinylbiphenyls from the corresponding xenylmethylcarbinols has been described. The present work deals with the preparation of the corresponding isopropenyl derivatives of biphenyl.

In general, the methods employed resembled those used in the earlier work. *o*-Aminobiphenyl was converted to *o*-iodobiphenyl, which by means of its Grignard reagent with acetone gave dimethyl-*o*-xenylcarbinol. This was dehydrated catalytically in the vapor phase over alumina to give *o*-isopropenylbiphenyl in 83% yield. It is interesting to note that under these conditions the reaction takes a different course from that reported by Anchel and Blatt[5] who dehydrated the same carbinol in the liquid phase with sulfuric acid or a mixture of acetic acid and hydrogen chloride to give nearly quantitative yields of 9,9-

dimethylfluorene. No dimethylfluorene was detected in the product from the vapor phase dehydration, although it is possible that minor amounts may have been formed.

p-Acetylbiphenyl was treated with methylmagnesium bromide to give a 78–85% yield of dimethyl-*p*-xenylcarbinol. This was dehydrated in a similar fashion to *p*-isopropenylbiphenyl.

m-Bromobiphenyl was prepared in four steps from *o*-aminobiphenyl as previously described.[4] The Grignard reagent from the bromide was treated with acetone to give crude dimethyl-*m*-xenylcarbinol which could not be distilled without decomposition and could not be induced to crystallize. This behavior was to be expected since several previously described meta derivatives of biphenyl are reported to freeze to non-crystalline glasses on cooling.[4] Consequently the crude material was dehydrated by refluxing with acetic anhydride to give *m*-isopropenylbiphenyl in 57% yield based on the *m*-bromobiphenyl.

Experimental

Dimethyl-*o*-xenylcarbinol.—*o*-Iodobiphenyl was prepared in 83% yield from *o*-aminobiphenyl by the Sandmeyer method according to the procedure of Gilman, Kirby and Kenney.[6] Four hundred sixty-seven grams of this product, b. p. 145–147° (6 mm.), was converted to the Grignard reagent, using 44 g. of magnesium in 750 cc. of anhydrous ether. The solution was cooled to 5° and 97 g. of dry acetone in 100 cc. of ether was added with stirring during ninety minutes, keeping the temperature below 20°. After standing overnight, a solution of 250 g. of ammonium chloride in 1200 cc. of water was added and the ether layer separated and evaporated. The crystalline residue was recrystallized twice from hexane to give 122 g. (34%) of fluffy needles, m. p. 69.5–70.5°; mixed melting point with biphenyl, 46–48°. Anchel and Blatt[5] report m. p. 73° for a sample prepared from the methyl Grignard reagent and methyl *o*-phenylbenzoate.

o-Isopropenylbiphenyl.—A solution of 231 g. of dimethyl-*o*-xenylcarbinol in 275 cc. of dioxane was passed over activated alumina at 275° and 90–100 mm. pressure using the technique and apparatus that has been described previously.[7] Two distillations gave 176.5 g. (83%) of *o*-isopropenylbiphenyl, b. p. 107–109° (2 mm.), $n^{25}D$ 1.5925 which freezes to a glass at about −40°. A bromide–bromate analysis[8] indicated that the material was 98.5% pure.

(6) Gilman, Kirby and Kenney, THIS JOURNAL, **52**, 2252 (1929).

(7) Mowry, Renoll and Huber, *ibid.*, **68**, 1105 (1946).

(8) Mulliken and Wakeman, *Ind. Eng. Chem., Anal. Ed.*, **7**, 59 (1935).

Anal.[9] Calcd. for $C_{15}H_{14}$: C, 92.73; H, 7.26. Found: C, 92.59; H, 7.29.

Dimethyl-*p*-xenylcarbinol.—An ethereal solution of the Grignard reagent prepared in the usual manner from 48.6 g. of magnesium (2.0 moles) and methyl bromide was treated with 371 g. (1.84 moles) of *p*-acetylbiphenyl dissolved in 1.5 l. of benzene during the course of one hour. After standing overnight the material was hydrolyzed with dilute sulfuric acid. The organic layer was separated, washed with water and evaporated to give 330 g. (85%) of crude dimethyl-*p*-xenylcarbinol. Another similar run gave a 78% yield. The material after recrystallization from a mixture of benzene and hexane melted at 92–93°.

Anal. Calcd. for $C_{15}H_{16}O$: C, 84.86; H, 7.60. Found: C, 85.22; H, 7.62.

***p*-Isopropenylbiphenyl.**—A 30% solution of dimethyl-*p*-xenylcarbinol in dioxane was dehydrated in a manner similar to that described for the ortho isomer. A 79–84% yield of the hydrocarbon, b. p. 122–124° (1 mm.) was obtained. After recrystallization from dilute ethanol, the material melted at 119.0–119.5°. When mixed with a sample of *p*-vinylbiphenyl[4] (m. p. 120°) the melting point was markedly depressed. The material showed 100.1% unsaturation by the bromide–bromate titration.

Anal. Calcd. for $C_{15}H_{14}$: C, 92.72; H, 7.26. Found: C, 92.60; H, 7.25.

***m*-Isopropenylbiphenyl.**—*m*-Bromobiphenyl was prepared from *o*-aminobiphenyl in 62% over-all yield by the four-step synthesis previously described.[1] The improvement in yield (51% was formerly reported) was due to a modification in the deamination step where the crude *m*-bromobiphenyl resulting from decomposition of the diazonium solution was extracted with benzene and washed free of sulfuric acid before distillation. The Grignard reagent was prepared from 150 g. of the bromide (0.64 mole) in the usual fashion and treated with a 20% excess of dry acetone in ether. After standing overnight, the material was hydrolyzed with dilute hydrochloric acid, separated, washed with water and evaporated to give 124 g. (92%) of crude oily dimethyl-*m*-xenylcarbinol which could not be purified by crystallization or distillation.

Two hundred forty-three grams of this crude product was refluxed with an excess (280 g.) of acetic anhydride for three hours. The acetic acid and excess anhydride were removed under vacuum and the product fractionated to give 29 g. of biphenyl and 141 g. of *m*-isopropenylbiphenyl, b. p. 160–161° (12 mm.); $n^{25}D$ 1.6128. A bromide–bromate titration indicated a purity of 99.6%.

Anal. Calcd. for $C_{15}H_{14}$: C, 92.72; H, 7.26. Found: C, 92.23; H, 7.50.

Summary

Ortho-, meta- and para-isopropenylbiphenyl have been synthesized by dehydration of the appropriate dimethylxenylcarbinols.

1,4-Dimethyl-3-alkylcarbostyrils

BY D. J. COOK AND WILLIAM C. LAWALL[1]

Recently the preparation of various 3-alkyl-4-methylcarbostyrils has been reported.[2] Since the preparation of several N-alkyl-4-methylcarbostyrils has been described,[3] it was of interest to prepare a series of 1,4-dimethylcarbostyrils with alkyl substituents in the 3 position. As intermediate products the corresponding N-methyl-α-alkylacetoacetanilides have also been prepared. Ring closure of these compounds with concentrated sulfuric acid gave the corresponding 1,4-dimethyl-3-alkylcarbostyril. The properties of the substituted acetoacetanilides are given in Table I and the data for the 1,4-dimethyl-3-alkylcarbostyrils are recorded in Table II.

In treating N-methyl-α-allylacetoacetanilide with concentrated sulfuric acid not only did the condensation take place to give the carbostyril, but also the sulfuric acid treatment hydrated the unsaturated bond in the allyl side chain to give the secondary alcohol 1,4-dimethyl-3-(propanol-2)-carbostyril.

This alcohol was characterized by the preparation of the phenylurethan.

It is to be noted that even though the N-methyl-α-benzylacetoacetanilide could be prepared, ring closure of this compound to the corresponding carbostyril could not be accomplished.

(3) Kaslow and Cook, *ibid.*, **67**, 1969 (1945).

Experimental[4,5]

N-Methylacetoacetanilide.—This starting material was prepared as described by Kaslow and Cook.[3]

The preparations of N-methyl-α-methylacetoacetanilide and 1,3,4-trimethylcarbostyril can be used as general methods to describe the preparation of the series of N-methyl-α-alkylacetoacetanilides and 1,4-dimethyl-3-alkylcarbostyrils.

N-Methyl-α-methylacetoacetanilide.—To 300 ml. of absolute alcohol in a 3-necked, round-bottomed flask equipped with a reflux condenser, stirrer and dropping funnel was added slowly 4.6 g. (0.20 mole) of sodium metal. When the sodium had reacted completely, 38.2 g. (0.20 mole) of N-methylacetoacetanilide was added to the mixture and the solution then heated on the steam-bath with constant stirring. To the refluxing solution 28.4 g. (0.20 mole) of methyl iodide was added dropwise and the refluxing continued for twelve hours. The alcohol was then removed under vacuum and the residue extracted with 300–400 ml. of ethyl ether. The ether was removed and the product then recovered by distillation under vacuum. After a small forerun, the product distilled at 136–137° (1 mm.); yield 16.8 g. (41%).

The other N-methyl-α-alkylacetoacetanilides were prepared in an analogous manner using ethyl, *n*-propyl, *n*-butyl and allyl bromides and benzyl chloride.

N-Methyl-α-alkylacetoacetanilide 2,4-Dinitrophenylhydrazone.—The 2,4-dinitrophenylhydrazones of the N-methyl-α-alkylacetoacetanilides were prepared according to the directions given by Shriner and Fuson.[6] These derivatives were purified by recrystallization from alcohol.

1,3,4-Trimethylcarbostyril.—To 50 ml. of concentrated sulfuric acid was added 12.8 g. (0.062 mole) of N-methyl-α-methylacetoacetanilide at such a rate as to maintain the temperature at 75°. During the addition the mixture was stirred continuously. After the addition was complete, the mixture was heated on a steam-bath for ten to fifteen minutes. The mixture was then cooled and poured with vigorous stirring into 500 ml. of a 50:50 mixture of ice and water. The solution was then neutralized with a solution of sodium hydroxide. After standing overnight, the white precipitate was recovered by filtration and dried at 70–75°. The crude product weighed 11.3 g. (96.5%) and melted at 100–101°. One gram of the product was recrystallized by dissolving it in 6–8 ml. of hot alcohol, filtering and adding water to faint turbidity. Upon cooling and scratching the inside of the flask, white needles formed, m. p. 106.5–107.5°.

The other 1,4-dimethyl-3-alkylcarbostyrils were prepared in an analogous manner by ring closure of the corresponding N-methyl-α-alkylacetoacetanilide.

1,4-Dimethyl-3-(propanol-2)-carbostyril.—This compound was prepared in a manner analogous to the preparation of 1,3,4-trimethylcarbostyril by treating 12.0 g. (0.052 mole) of N-methyl-α-allylacetoacetanilide with 50 ml. of concentrated sulfuric acid. White needles were obtained upon dilution with water and subsequent neutralization with sodium hydroxide. The yield was 6.7 g. (60%). The product when recrystallized from alcohol–water gave a m. p. of 140–140.5°. This compound did not change upon drying at 90° in a vacuum oven. It would not add bromine and gave no iodine number. The analysis as given in Table II corresponds to the alcohol and not the allyl substituted carbostyril. The prepara-

(4) All melting points were taken on a Fisher–Johns melting block.

(5) Microanalyses were carried out by Mr. Lorne MacBeth.

tion of the phenylurethan is proof of the secondary alcohol being the compound.

The Phenylurethan of 1,4-Dimethyl-3-(propanol-2)-carbostyril.—This derivative was prepared as described by Shriner and Fuson.[7] The compound was recrystallized from carbon tetrachloride. The m. p. was 178–179°.

Anal. Calcd. for $C_{21}H_{22}N_2O_3$: N, 8.00. Found: N, 8.28, 7.93.

Summary

1. Several N-methyl-α-alkylacetoacetanilides have been prepared by condensation of N-methylacetoacetanilide with the corresponding alkyl halide.

2. Ring closure of the N-methyl-α-alkylacetoacetanilides with concentrated sulfuric acid resulted in the formation of the 1,4-dimethyl-3-alkylcarbostyrils.

3. N-Methyl-α-allylacetoacetanilide when subjected to the sulfuric acid treatment gave the hydrated product, 1,4-dimethyl-3-(propanol-2)-carbostyril.

Trimethylsilylcellulose

BY H. A. SCHUYTEN, J. W. WEAVER, J. DAVID REID AND J. F. JURGENS

Silicon tetrachloride and aryl- and alkylhalosilanes react easily and rapidly with organic hydroxyl groups,[2,3,4] to yield hydrogen chloride and silicic esters. A number of patents have been issued dealing with the treatment of cellulose with organosilicon halides to impart water repellency.[5,6,7] In one case[5] a surface reaction either with adsorbed moisture or with hydroxyl groups of the cellulose was postulated. However, the amount of product formed was too small to be measured or analyzed. Jullander[8] has studied the reaction of silicon tetrachloride with nitrocellulose and reports the formation of gels due to cross linkage. The present investigation concerns the reaction of some organo-silanes with cellulose, particularly to obtain trimethylsilylcellulose.

It was found that halosilanes will react with cellulose in the presence of pyridine to form relatively stable compounds. The reaction will take place slowly at room temperature and rapidly at reflux temperatures. A group substitution as high as 2.75 trimethylsilyl groups per glucose unit was attained with cotton linters (Fig. 1). With partially substituted cellulose acetate, the total substitution approached 3.0 (Table I).

TABLE I

REACTIONS OF ALKYLCHLOROSILANES WITH CELLULOSE ACETATE

[b] Assumed.

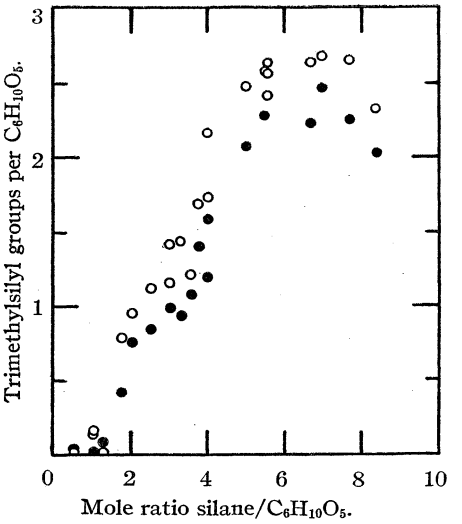

Fig. 1.—Change in trimethylsilyl substitution of cellulose with change in mole ratio of reactants: O, calculated from gain in weight; ●, calculated from silicon content.

Trimethylsilylcellulose is stable in dry air at room temperature but at elevated temperatures or in the presence of atmospheric moisture will decompose slowly. The compound is insoluble in the usual organic solvents and in mixtures of solvents such as are used in dissolving cellulose acetate and other cellulose derivatives.

Materials.—The trimethylchlorosilane used was commercial grade and the acetoxysilanes were prepared according to the method of

Schuyten, Weaver and Reid.[9] Other silanes were prepared by the usual methods.

Analyses.—All silicon analyses were carried out by fusion of the silylcellulose in a Parr bomb followed by the usual gravimetric procedure. Ashing before fusion was impractical because of loss of silicon as trimethylsilanol or similar compounds.

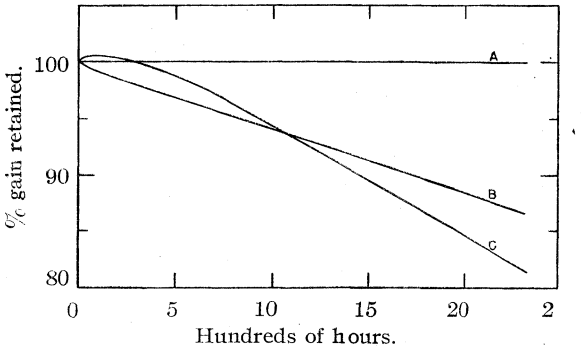

Fig. 2.—Deterioration of trimethylsilylcellulose: A, desiccated (P_2O_5); B, heated (105°); C, conditioned (see text).

Experimental

Trimethylsilylcellulose.—Two grams of oven-dried, low-viscosity cotton linters was suspended in a small amount of anhydrous pyridine in a 500-ml., round-bottom flask provided with a reflux condenser and mercury-sealed stirrer. Trimethylchlorosilane was added from a stock solution in anhydrous pyridine containing 0.05 g. of silane per ml. of solution. The mole ratio of silane per glucose unit of cellulose was varied as indicated in Fig. 1 and the total volume of pyridine was adjusted to 250 ml. The mixture was refluxed and after about one hour the cellulose assumed a dispersed and almost invisible condition. This was undoubtedly due to the nearly identical refractive indices of the compound and pyridine.

After three hours the mixture was cooled and filtered. Washing was done on different runs with both organic solvents and with water; no apparent difference in results were obtained. The samples were vacuum-dried and weighed. Trimethylsilyl group substitution was calculated from gain in weight by

$$\text{Groups} = \frac{\text{Gain in wt.} \times 162.1}{\text{Sample wt.} \times 72.16}$$

and from silicon content by

$$\text{Groups} = \frac{\%\ \text{Si} \times 162.1}{2806 - (72.16 \times \%\ \text{Si})}$$

Other monofunctional group substitutions may be calculated by inserting (group weight—1.008) in place of 72.16.

The correlation of results obtained by these two methods is reasonably good. The difference between results may be due to retention of solvent; it is difficult to remove the last traces of material of this type from cotton.

Other Silanes.—Various other silanes were employed with similar results as recorded in Table II.

Trimethylsilylcellulose Acetate.—Samples of cellulose acetate were dissolved in pyridine and treated as above. The products were soluble in the solvent and were precipitated by pouring into cold water. They were then filtered and washed with water, vacuum-dried, weighed and analyzed. The number of acetyl groups per glucose unit showed little change. The results are given in Table I.

Formation of Trimethylsilylcellulose at Room Temperature.—A sample of cotton linters was treated with trimethylchlorosilane in a mole ratio of 5.58 for four-hundred hours at room temperature. The gain in weight of the cellulose was equivalent to 1.73 groups substitution as compared to 2.53 groups with a similar mole ratio when refluxed for three hours in the pyridine mixture.

(9) H. A. Schuyten, J. W. Weaver and J. David Reid, THIS JOURNAL, **69**, 2110 (1947).

TABLE II

REACTIONS OF VARIOUS SUBSTITUTED SILANES WITH CELLULOSE

Reagent	Weight cellulose, g.	Mole ratio[a]	Gain in weight, g.	Si, %	Silyl groups per glucose by weight	by %, Si
$(C_2H_5)_3SiCl$	2.154	6.06	2.007	11.55	1.32	1.27
$(CH_3)_2SiCl_2$	1.786	5.84	0.202	2.47	[b]	[b]
n-$C_8H_{17}SiCl_3$	1.960	4.01	0.030	1.33	[b]	[b]
$CH_3Si(OAc)_3$	1.904	3.95	0.080	1.16	[b]	[b]

[a] Ratio of moles of silane to glucose unit. [b] Not calculated because of the possibility of cross linkage.

Decomposition of Trimethylsilylcellulose.—Trimethylsilylcellulose may be decomposed by boiling with water or with dilute acid or base. No quantitative results were obtained but boiling with dilute acid yielded a volatile liquid product which burned and deposited silica and was assumed to be trimethylsilanol. Accordingly samples of trimethylsilylcellulose containing 2.6 trimethylsilyl groups per glucose unit were placed in open containers under three sets of conditions: (1) Desiccated over phosphorus pentoxide; (2) dried in an oven at 105°; and (3) conditioned at 70°F. (21.1°) and 65% relative humidity. The samples were weighed at intervals and the per cent. retention of added weight was plotted against time. The results are shown in Fig. 2. The inflection at the beginning of the curve for the conditioned sample is due to increase in moisture content at 65% relative humidity.

Solubility of Trimethylsilylcellulose.—A 0.1-g. sample of trimethylsilylcellulose (2.42 groups per glucose unit) was placed in 5 ml. of solvent in a small tube and tumbled on a wheel for twenty-four hours at room temperature. When the major portion of the material remained undissolved as determined by visual inspection, it was considered insoluble. In some cases (designated below by "sw") the sample particles showed a tendency to swell. No noticeable amount dissolved in the following solvents: acetone, benzene, carbon tetrachloride, chloroform, diethylformamide, ethyl acetate, ethyl alcohol, ethylene dichloride, ether (sw), methylene chloride, methyl ethyl ketone (sw), nitromethane, nitropropane, pyridine (sw), *s*-tetrachloroethane and xylene. The material was not soluble in the following mixtures: acetone (80%), ethanol (15%), ethyl acetate (5%) (sw); toluene (80%), ethanol (20%) (sw); ethylene dichloride (90%), methyl alcohol (10%); and benzene (66%), ethylene dichloride (34%) (sw).

Summary

Trimethylchlorosilane and other chloro- and acetoxysilanes react with cellulose to yield products which by gain in weight and silicon content show a group substitution as high as 2.75 groups per glucose unit. Determination of change in weight of samples of trimethylsilylcellulose over a period of time indicates that it is stable in dry air at room temperature but decomposes at elevated temperatures or in the presence of atmospheric moisture. It may be readily hydrolyzed with boiling water or with dilute acids or alkalies.

The halosilanes react only with the unreacted hydroxyl groups in partially substituted cellulose acetate.

These data indicate the formation of definite compounds of cellulose with substituted silanes.

Wall Effects in the Oxidation of Boron Triethyl Vapor. Ignition of *n*-Butane[1]

BY RICHARD S. BROKAW, ELMER J. BADIN AND ROBERT N. PEASE

In a recent paper on the oxidation of zinc dimethyl vapor at room temperature,[2] it was shown that the reaction is autocatalytic, becoming explosive if the pressure of zinc dimethyl exceeds 12–15 mm.; and that it will induce the ignition of *n*-butane. Somewhat similar data on boron triethyl vapor are presented here. Particular attention has been given to the effect of solid products and surface treatment on the oxidation.

Experimental

The apparatus was similar to that used for the oxidation studies of zinc dimethyl.[2] Spherical reaction bulbs with inside diameters of 4.6, 6.6, 7.4, 9.8 and 12.7 cm. were used. Both the reaction bulb and the oxygen storage bulb were maintained at 0°. The tubing between them was 6 mm. i.d. rather than capillary to permit rapid mixing of reacting gases. Pressures were measured on a direct reading manometer and small McLeod gage designed to read pressures over a range of 0.01–15.0 mm.

Reaction bulbs were cleaned by treatment with boiling concentrated nitric acid followed by rinsing with distilled water. Drying was carried out in an oven at 135°. Coatings were applied after this standard cleaning procedure. Boron triethyl vapor was first admitted to the reaction bulb at the desired pressure. The reaction bulb was then closed off by its stopcock. Oxygen was admitted to the reservoir in an amount sufficient to give the desired final pressure when the connecting stopcock was opened and the gases allowed to mix. Experiments were carried out in a darkened room in order to make observation of faint flashes. Flashes occurred immediately on opening the stopcock, without measurable induction period.

Boron triethyl was prepared from the Grignard reagent and boron trichloride etherate. As a final purification step, 125 g. was fractionated in a helium atmosphere through a 20-plate column. A third fraction of 20 g. (b. p. 95.0°) was used for all experiments. Oxygen and *n*-butane (C. P.) were high purity tank gases.

Results and Discussion

Boron triethyl vapor ignites instantly on admission of oxygen at substantially lower pressures than does zinc dimethyl. A series of runs in clean dry bulbs of diameters between 4.6 and 12.7 cm. diameter gave values as low as 0.10 mm. of boron triethyl in a 5 volume % mixture with oxygen (stoichiometric mixture for combustion to boron trioxide, carbon dioxide and water: 8.70 vol. %). Data are presented in Table I and Fig. 1.

The product of pressure and bulb diameter was found to be approximately constant, as would be expected if reaction chains start in the gas phase and end on the wall.[3]

TABLE I

MINIMUM IGNITION LIMITS FOR 5 VOLUME % BORON TRIETHYL IN OXYGEN, TEMPERATURE, 0°.

Bulb diameter, *d*, cm.	Limit pressure, *p*, mm.	Partial pressure $B(C_2H_5)_3$, mm.	$p \times d$
Clean dry bulbs			
4.6	7.5	0.38	34
6.6	4.3	.22	28
7.4	4.1	.21	30
9.8	3.1	.16	30
12.7	2.1	.11	27
Bulbs self-coated with products			
4.6	10.7	0.54	49
6.6	9.0	.45	59
7.4	7.3	.37	54
9.8	4.7	.24	46
12.7	3.6	.18	46

A coating of reaction products demands a higher limiting pressure (Table I and Fig. 1), indicating that the solid products are somewhat more effective than the clean Pyrex surface in breaking chains before branching (and ignition)

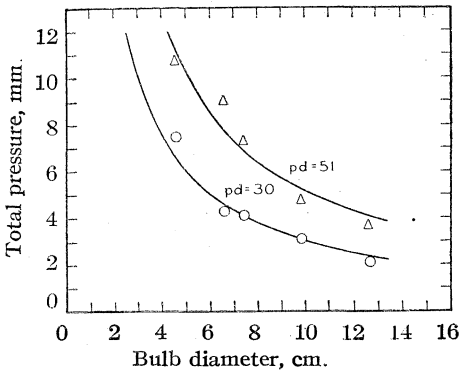

Fig. 1.—Variation of explosion limit with bulb diameter for the oxidation of boron triethyl: △, surface self-coated with reaction products: O, clean "dry" Pyrex surface.

occurs. This would seem to suggest that other surface coatings might likewise be better chain-breakers than Pyrex. It was therefore somewhat puzzling to find that washing out the clean reaction bulb with solutions of boric acid, potassium hydroxide, potassium chloride, hydrochloric acid or paraffin (1% in pentane) gave substantially the same lower limit as clean Pyrex (4.1–5.1 mm. in 6.5 cm. bulb).

No real evidence was obtained of an upper pressure limit such as might be expected of a branched-chain explosion. However, it was observed that the bright green flash due to ignition was somewhat less intense at higher pressures

(3) *Cf.* C. N. Hinshelwood, "Kinetics of Chemical Change," Oxford University Press, 1940, p. 15. Similar results have been obtained for, *e. g.*, the phosphine–oxygen reaction, Dalton and Hinshelwood, *Proc. Roy. Soc.* (*London*), **125A**, 294 (1929).

(~100 mm.), especially with rich mixtures, though this probably only represents more effective quenching of chemi-luminescence. It was also noted that the radiation emitted by mixtures just above the lower limit was more bluish and much less intense. This recalls Frankland's observation[4] that a slow current of boron triethyl (or trimethyl) vapor issuing into air burned with a faint blue flame—"the temperature of which is so low that a finger may be held in it for some time without much inconvenience." Evidently, cool flame phenomena are involved near the limit. It was interesting to find that with the coated reaction bulb this cool flame was no longer observed. The bright green flash was observed right down to the limit which, as already stated, was correspondingly higher.

We have no evidence to present regarding the reaction below the low pressure limit, except that there was no pressure-change or detectable deposit in 1,000 seconds. Experiments of Bamford and Newitt[5] on the oxidation of boron trimethyl and tri-*n*-propyl, by slowly admitting oxygen to the vapor at about 1 mm., indicate a very rapid absorption up to the equivalent of $R_3B:O_2$, with no separation of a condensed product. According to Frankland,[4,6] the slow admission of oxygen or air to liquid boron triethyl produces ethane-boronic diethyl ester, $C_2H_5B(OC_2H_5)$. In any event, there is no evidence of the separation of a solid at these low pressures until the ignition limit is passed.

(6) See also Krause, *et al.*, *Ber.*, **61**, 271 (1928); **63**, 934 (1930); a similar observation on boron tri-*n*-butyl by Johnson and Van Campen, THIS JOURNAL, **60**, 121 (1938).

This is in contrast to the oxidation of zinc dimethyl vapor where a white mist begins to form immediately on mixing with oxygen.

Finally, a few experiments on the induced ignition of *n*-butane by means of boron tri-ethyl have been carried out, by admitting a stoichiometric mixture of oxygen and *n*-butane (13.3 vol. %) to a bulb containing boron triethyl vapor, the total pressure being 100 mm. With 1 mm. of boron triethyl there was no reaction, but with 3 mm. of boron triethyl there was a violent explosion which travelled back through 6 mm. i. d. tubing to the reservoir flask. However, with 5 or 10 mm. of boron triethyl there was only a faint flash, which was much weaker than that in absence of *n*-butane, and a negligible pressure change.[7] There thus appear to be sharp pressure limits to this induced oxidation.

Summary

1. Boron triethyl vapor ignites spontaneously in oxygen at partial pressures below 1 mm. in a Pyrex bulb held at 0°.

2. The product of minimum pressure and bulb diameter is constant, indicating that chains start in the gas phase and end on the wall. When the glass surface is coated with reaction products, the minimum pressure is greater.

3. There is evidence of a cool flame phenomenon.

4. Boron triethyl will ignite a *n*-butane–oxygen mixture within narrow pressure limits.

(7) The 3 mm. mixture produced a large pressure decrease, presumably due to condensation of water vapor formed by the combustion.

Analogs of Pteroylglutamic Acid. I. N^{10}-Alkylpteroic Acid and Derivatives

BY DONNA B. COSULICH AND JAMES M. SMITH, JR.

The structure of pteroylglutamic acid[1] has been demonstrated and several methods of synthesis have been described.[1,2]

This factor of the vitamin B complex is identical with the liver *L. casei* factor[3] and apparently is related to a number of other substances[4] isolated from natural sources. All are necessary for the normal growth and development of certain animals and microörganisms. The question immediately arises as to what the biological effect will be when variations are introduced into the structure of the vitamin by chemical methods of synthesis. There is always the possibility of enhancing the desirable effects of the vitamin, and also of producing new compounds which can be used in treating other syndromes. The use of pteroylglutamic acid antagonists in the treatment of blood dyscrasias, leukemia for example, has been suggested by Franklin, Stokstad, Belt and Jukes.[5a]

Variations of the structure and study of the relationship between structure and biological activity have already received the attention of workers in the field. Dibromobutyraldehyde has

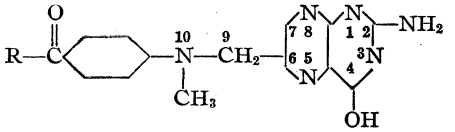
been substituted for dibromopropionaldehyde in the synthesis of pteroylglutamic acid[2a] to give a product which is an antagonist for pteroylglutamic acid.[5] The proof of structure of the active material has not been reported, but the crude has been designated as "7-methylfolic acid."[5b] Pteroylaspartic acid has been synthesized in pure form and shows pteroylglutamic acid antagonist activity on a number of species.[6] The derivative of pteroylglutamic acid in which the 4-hydroxyl group is replaced by an amino group has been reported by Seeger, Smith and Hultquist.[7a] It is a powerful antagonist for pteroylglutamic acid. 2,4-Diaminopteridines having antagonist action have been investigated by other workers.[7b]

The present paper describes the synthesis of a series of N[10]-substituted derivatives of pteroylglutamic acid which are antagonists, as for example N-[4-{N-[(2-amino-4-hydroxy-6-pteridyl)-methyl]-N-methylamino}-benzoyl]-glutamic acid, (I) hereafter designated as N[10]-methylpteroylglutamic acid.



I, R is $HOOCCH_2CH_2CH(COOH)NH-$
II, R is HO—

N[10]-Methylpteroic acid (II) is the simplest member of the series, and also one of the most active antagonists. It was prepared from dibromopropionaldehyde, 2,4,5-triamino-6-hydroxypyrimidine, and *p*-methylaminobenzoic acid, and purified by the methods described for the synthesis and purification of pteroylglutamic acid.[2a] The other compounds reported in this series were all prepared in a similar manner, only those showing significant activity in the crude being purified.

Alkaline permanganate oxidation of N[10]-methylpteroic acid yielded 2-amino-4-hydroxypteridine-6-carboxylic acid, which was identical with that obtained by the alkaline aerobic oxidation of pteroylglutamic and pteroic acids.[1a] This shows that the point of attachment of the side chain is the 6-position. However, alkaline aerobic oxidation of N[10]-methylpteroic acid under conditions which cleaved pteroylglutamic and pteroic acids yielded only the unchanged material.

It was necessary to obtain pure secondary amines to preclude the presence of pteroic and pteroylglutamic acids which would mask the growth inhibiting properties of the N[10]-alkylated derivatives. As a consequence, useful methods for the preparation of pure monoalkylated *p*-aminobenzoic and *p*-aminobenzoylglutamic acids were devised. These included the treatment of the corresponding iodo compounds with alkyl amines, methylation of aminobenzoic acid by the zinc–alkali reduction of the amino acid and formaldehyde, and the reaction of alkyl iodides with sodium ethyl *p*-formamidobenzoate followed by hydrolysis of the formyl group.

The biological properties of the N[10]-alkylpteroic acid derivatives have been examined by Dr. E. L. R. Stokstad and Dr. B. L. Hutchings of the Lederle Laboratories Division, American Cyanamid Company, Pearl River, New York. For N[10]-methylpteroylglutamic acid the inhibition ratio for half-maximum inhibition of the growth of *Streptococcus faecalis R* was 2.0 at a concentration of pteroylglutamic acid of 0.1 microgram per 10 ml. See also Table I.

The details of the biological work will be published elsewhere.

Experimental[8,9]

p-**Methylaminobenzoic Acid.**[10]—Sixty grams of *p*-aminobenzoic acid was dissolved in 90 ml. of water and 17.5 g. of sodium hydroxide. The resulting solution, and 66 g. of 40% formaldehyde solution, were added simultaneously over a two to three-hour period to a slurry of 90 g. of zinc dust in 205 g. of 50% sodium hydroxide solution and 100 ml. of water. The temperature was maintained at 90–95°. Heating at this temperature was continued while 40 g. more of 40% formaldehyde was added. The total heating time was five to seven hours. Excess zinc was removed by filtration, and the filtrate was allowed to stand several days. The sodium salt of *p*-methylaminobenzoic acid crystallized out. It was filtered off, dissolved in water, and the acid precipitated by adjusting the solution to *p*H 3. This was essentially pure *p*-methylaminobenzoic acid; m. p. 158–161.5°. A mixture melting point with a sample prepared by the method of Houben and Schottmüller[10] gave no depression.

N-Methylanthranilic acid[11] was prepared in a similar experiment.

N[10]-**Methylpteroic Acid.**—This compound was synthesized by the method of Waller, *et al.*,[2a] except that *p*-methylaminobenzoic acid was substituted for *p*-aminobenzoylglutamic acid. A mixture of 12.6 g. of crude N[10]-methylpteroic acid, 9 g. of lime, and 1750 ml. of water, was heated at 60° for forty minutes. After the addition of 25 g. of Hyflo-Supercel the mixture was filtered and the cake washed with 750 ml. of water at 60°. The filtrate and washing were adjusted to *p*H 3 with hydrochloric acid and cooled to 20°. After the addition of 25 g. of Hyflo-Supercel, the mixture was filtered. The cake was washed with water and then slurried in 1 liter of water and sodium hydroxide was added to obtain *p*H 11–12. After heating at 80° for ten minutes, the *p*H of the solution was adjusted to 7, and the mixture then cooled to 20° and filtered. The filtrate was treated with hydrochloric acid to *p*H 3–4. The precipitated material was separated by filtration with Hyflo, slurried in water to give 0.75 g./liter concentration and enough magnesium oxide to obtain about *p*H 9 at 80°, and filtered hot with 0.5 g. of charcoal. The filtrate at 80° was adjusted to *p*H 3–4 with hydrochloric acid and cooled to 20°. Yellow rosets of N[10]-methylpteroic acid crystallized out and were purified for analysis by dissolving (at 0.25 g./l.) in hot dilute sodium hydroxide (*p*H 8–9), clarifying with Hyflo filter-aid, and adjusting the filtrate to *p*H 3–4 while at 90°. On cooling analytically pure yellow microcrystalline material was isolated which had an ultraviolet absorption curve quite similar to that predicted from consideration of data on the ultraviolet curves of pteroic acid, *p*-methylaminobenzoic acid, and *p*-dimethylaminobenzoic acid. [a] See footnote to Fig. 1. [b] An arbitrary value of 100 is assigned for the antagonist activity of N^{10}-methylpteroylglutamic acid, for half-maximum inhibition of the growth of *Streptococcus faecalis R.* Values for other compounds are reported in terms of the standard. [c] Estimated by ultraviolet absorption.

biological and ultraviolet absorption data. The analytical sample was dried at 100° and 1 mm. for seven to eight hours.

Anal. Calcd. for $C_{15}H_{14}N_6O_3$: C, 55.2; H, 4.29; N, 25.75. Found (corrected for 2.71% ash): C, 55.3; H, 4.56; N, 25.4.

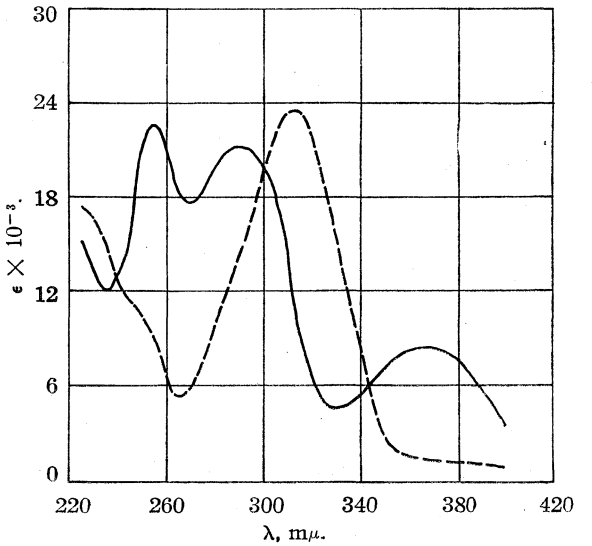

Fig. 1.—Ultraviolet absorption spectra[a] of N^{10}-methylpteroic acid: ——— in 0.1 *N* sodium hydroxide; ---------- in 0.1 *N* hydrochloric acid.

Permanganate Oxidation of N^{10}-Methylpteroic Acid.—A hot solution of 730 mg. of N^{10}-methylpteroic acid in 250 ml. of 1 *N* sodium hydroxide was treated with 2% potassium permanganate solution until the solution maintained a dark green color. After adding sodium sulfite to destroy this color, manganese dioxide was filtered off and the filtrate adjusted to *p*H 3–4 with dilute hydrochloric acid. The mixture was cooled, and centrifuged. The crude moist product was purified by adding a few drops of 5 *N* sodium hydroxide to dissolve, and then 4.4 g. of sodium hydroxide pellets to the 22 ml. of solution to give a 5 *N* caustic solution. On cooling, the disodium salt separated out, was filtered off, and precipitated as the free acid by dissolving in water and adjusting to *p*H 3–4. The disodium salt was isolated a second time to give material which was shown to be 2-amino-4-hydroxypteridine-6-carboxylic acid by comparison of the ultraviolet absorption curve with that of an authentic sample.

Attempted Alkaline Aerobic Oxidation of N^{10}-Methylpteroic Acid.—A solution of 500 mg. of N^{10}-methylpteroic acid in 25 ml. of *N* sodium hydroxide was heated at 100°

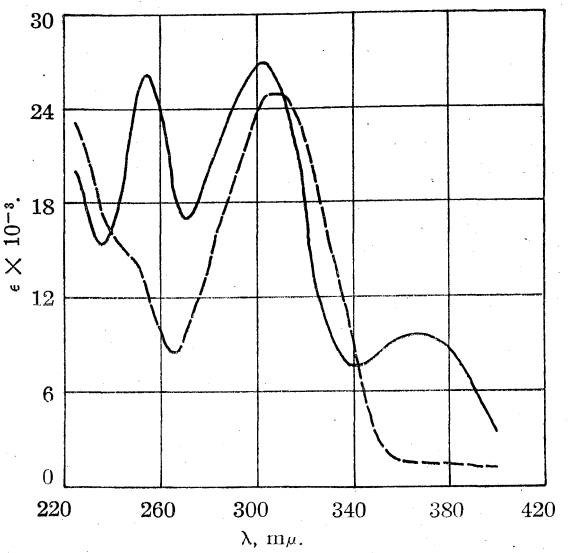

Fig. 2.—Ultraviolet absorption spectra[a] of N^{10}-methylpteroylglutamic acid monohydrate: ——— in 0.1 *N* sodium hydroxide; ---------- in 0.1 *N* hydrochloric acid.

[a] *E* is the molecular extinction coefficient as defined by $I = I_0 10^{-Ecl}$ where *c* is the concentration in moles/liter and *l* is the cell length in centimeters. Transmittancy (I/I_0) measurements of 10 mg./l. solutions were made in 1-cm. cells at 5mμ intervals on a Model DU Beckman spectrophotometer using a solvent filled cell in the reference position. Additional data were obtained at 2 mμ intervals at maxima, minima and points of inflection.

for six hours with a rapid stream of oxygen bubbling through. After cooling and clarifying with 0.5 g. of charcoal, the filtrate was adjusted to 5 *N* by adding 4 g. of sodium hydroxide pellets. When cooled in the icebox overnight, yellow crystals separated, which were filtered and dissolved in water. The yellow solution, after clarifying with 0.2 g. of charcoal, was adjusted to *p*H 3–4 with hydrochloric acid, whereupon an orange substance precipitated. This was isolated by centrifugation and shown to be unchanged N^{10}-methylpteroic acid by comparison of its ultraviolet absorption curve with an authentic sample.

Sodium Ethyl *p*-Formamidobenzoate.—A solution of 82.54 g. of ethyl *p*-aminobenzoate in 578 ml. of ether was treated with 12.5 g. of sodium, added in small pieces. To this was added slowly 37 g. of ethyl formate and the mixture was allowed to stand overnight. The product, isolated as a fine yellow powder, had a neutralization equivalent of 235.4 (theoretical for $C_{10}H_{10}NO_3Na$, 215). A sample was converted to ethyl *p*-formamidobenzoate by neutralization of an aqueous solution with acetic acid; the melting point, 146–149°, agreed with the literature value.[12]

***p*-Ethylaminobenzoic Acid.**[13]—A mixture of 21.5 g. of sodium ethyl *p*-formamidobenzoate, 15.6 g. of ethyl iodide, 125 ml. of ethyl alcohol and 13.4 g. of potassium hydroxide (86%), was refluxed for one hour. Then 25 ml. of water was added and the solution was poured into cold water and neutralized with acetic acid. The crude material was easily purified by two reprecipitations from sodium hydroxide solution to give *p*-ethylaminobenzoic acid. The melting point, 177.9–178.9°, agreed with that obtained by the method of Houben and Freund.[13]

p-Ethylaminobenzoic acid was also prepared from *p*-iodobenzoic acid[14] and ethylamine in a sealed tube in a manner analogous to that described below for the preparation of *p*-methylaminobenzoylglutamic acid.

N^{10}-Ethylpteroic Acid.—This compound was prepared according to the procedure described by Waller, *et al.*,[2a] except that *p*-ethylaminobenzoic acid was substituted for *p*-aminobenzoylglutamic acid. It was purified by a process similar to that described above for N^{10}-methylpteroic acid (see Table I).

N^{10}-Butylpteroic Acid.—This was prepared from *p*-butylaminobenzoic acid[15] and purified as indicated for the N^{10}-ethyl compound above (see Table I).

Ethyl N-(4-Carbethoxyphenyl)-glycinate.—A mixture of 12.25 g. of ethyl chloroacetate and 33 g. of ethyl *p*-aminobenzoate was heated at 130–140° for five to six hours. It was cooled, slurried in ether and filtered. The filtrate was freed of ether by evaporation and the residue was distilled at 215° at 8–11 mm. pressure. The distillate was dissolved in ether and extracted with a small amount of 0.5 *N* hydrochloric acid. Evaporation of the washed and dried ether layer gave the ester which was purified further by recrystallization from aqueous alcohol; m. p. 62.5–62.9°.

Anal. Calcd. for $C_{13}H_{17}NO_4$: C, 62.1; H, 6.77; N, 5.8. Found: C, 62.1; H, 6.87; N, 5.73.

This compound is soluble in acetone, ether, alcohol, isopropyl acetate, carbon tetrachloride and petroleum ether; insoluble in water and carbon disulfide.

N-(4-Carboxyphenyl)-glycine.—The ester above (8.8 g.) was boiled three to four hours in 5 *N* sodium hydroxide solution. On diluting, cooling and acidifying, the pure acid separated out; m. p. 245.7–247.1°, neut. equiv. 98.8 (the theoretical value is 97.5 for $C_9H_9O_4N$).

N^{10}-Carboxymethylpteroic Acid.—This was prepared as a crude as described for other N^{10}-pteroic acids, from N-(4-carboxyphenyl)-glycine.

Other N^{10} Derivatives of Pteroic Acid.—In similar experiments N^{10}-phenacylpteroic acid and N^{10}-benzylpteroic acid were prepared as crudes from *p*-phenacylaminobenzoic acid[16] and *p*-benzylaminobenzoic acid.[1b]

***p*-Iodobenzoylglutamic Acid.**—A solution of 26.5 g. of *p*-aminobenzoylglutamic acid in 50 g. of 35% hydrochloric acid and 150 ml. of water was cooled to 5–10° and 8.5 g. of sodium nitrite in 40 ml. of water was added, until the solution gave a blue spot on starch–iodide test paper. Then 25 g. of potassium iodide in 50 ml. of water was added and the mixture was allowed to stand overnight. It was warmed to 50°, cooled, washed by decantation, and filtered. The crude product was purified by recrystallization from dilute alcohol; m. p. 173.7–176.1°; $[\alpha]^{26}D$ + 16.32 (1 *N* sodium hydroxide).

Anal. Calcd. for $C_{12}H_{13}NO_5I$: C, 38.1; H, 3.44; N, 3.7; I, 33.6. Found: C, 37.7; H, 3.21; N, 3.93; I, 33.6.

***p*-Methylaminobenzoylglutamic Acid.**—A solution of 7.6 g. of *p*-iodobenzoylglutamic acid in 8 ml. of water and sodium hydroxide to give *p*H 8–9 was treated with 8 ml. of aqueous methylamine (24.15 g./100 ml.) and 0.02 g. of fine copper powder in a sealed tube at 125° for three hours. The insolubles were removed by filtration and the excess methylamine was removed by evaporation under vacuum. The sirupy residue was diluted with alcohol to give the disodium *p*-methylaminobenzoylglutamate. The free acid was obtained as an oil by acidification of an aqueous solution of the sodium salt.

Diethyl *p*-Methylaminobenzoylglutamate.—The diethyl ester was obtained by dissolving 3.5 g. of the disodium salt above in 60 ml. of alcoholic hydrogen chloride (20 g./100 ml.) and allowing it to stand three days. After diluting with water and clarifying, the ester was precipitated by the addition of ammonium hydroxide to *p*H 7–8. The crude ester was purified by recrystallization from dilute alcohol; m. p. 89.8–91.0°; $[\alpha]^{25}D$ −21° (1 *N* HCl).

Anal. Calcd. for $C_{17}H_{24}N_2O_5$: C, 60.7; H, 7.14; N, 8.33. Found: C, 60.3; H, 7.09; N, 8.48.

N^{10}-Methylpteroylglutamic Acid.—Synthesis was by the method of Waller, *et al.*[2a] The purification was accomplished as indicated above. The pure material was obtained as yellow spherulites (see Table I). The material, dried at 100° and 1 mm. for eight hours, was a monohydrate.

Anal. Calcd. for $C_{20}H_{21}N_7O_6 \cdot H_2O$: C, 50.8; H, 4.86; N, 20.55. Found: C, 50.8; H, 5.06; N, 20.6.

***p*-Phenacylaminobenzoylglutamic Acid.**—*p*-Aminobenzoylglutamic acid (133 g.) was dissolved in water (500 ml.) by the addition of sodium carbonate (60 g.). The solution was heated to 85° and 75 g. of phenacyl chloride was added in three portions of 25 g. of each fifteen minutes apart. Sodium carbonate was added as necessary to keep the solution slightly alkaline. Heating was continued at 90–95° for three hours. On acidification of the cooled solution the product precipitated out. It was purified by recrystallization from alcohol. The yield was 32 g. of material; m.p. 100–104°.

Anal. Calcd. for $C_{20}H_{20}N_2O_6$: C, 62.5; H, 5.21; N, 7.3. Found (corrected for 4.2% ash): C, 63.5; H, 5.85; N, 7.35.

N^{10}-Phenacylpteroylglutamic Acid.—This compound was prepared in crude form by the method of Waller, *et al.*[2b] See Table I.

Acknowledgment.—We are indebted to Mr. Richard L. Shepard for technical assistance in the preparation of certain of these compounds, and to Miss Ruth Abbott for the ultraviolet absorption data.

Summary

1. N-[4-{N-[(2-Amino-4-hydroxy-6-pteridyl)-methyl]-N-methylamino}-benzoyl]-glutamic acid and 4-{N-[(2-amino-4-hydroxy-6-pteridyl)-methyl]-N-methylamino}-benzoic acid, called herein

N^{10}-methylpteroylglutamic acid and N^{10}-methylpteroic acid, have been synthesized in pure crystalline form, and found to be antagonists for pteroylglutamic acid.

2. The purified N^{10}-ethyl- and butyl-, and crude N^{10}-carboxymethyl-, benzyl-, and phenacylpteroic acids and N^{10}-phenacylpteroylglutamic acid have also been prepared. These have a lower order of antagonist activity.

3. Convenient methods of obtaining pure N-monosubstituted aminobenzoic and aminobenzoylglutamic acids have been devised.

The Synthesis of Thymine Nucleosides[1,2]

BY DONALD W. VISSER,[3] IRVING GOODMAN AND KARL DITTMER

A method for the synthesis of pyrimidine nucleosides was described by Hilbert and Johnson[4] who prepared 1-glucosyluracil by the reaction of 2,4-diethoxypyrimidine with acetobromoglucose followed by hydrolysis. By this method these and other investigators prepared the uracil nucleosides of D-ribose,[5] L-arabinose,[6] D-xylose,[6] D-glucose[4] and D-galactose.[6] However, the literature contains no conclusive report of the synthesis of thymine nucleosides. The syntheses of the D-ribose, D- and L-arabinose, D-glucose and D-galactose nucleosides of thymine by a modification of this procedure are reported in this paper.

When Schmidt–Nickles and Johnson[7] treated 2,4-diethoxy-5-methylpyrimidine with D-acetobromoglucose at 50° for seven days, they obtained a small amount of a crystalline substance which melted at 316°. We repeated this reaction under similar conditions and isolated a small amount of material which, when crystallized from water, melted at 326° and proved to be thymine. Since no other product was isolated from this reaction mixture, various modifications of the original procedure were studied.

It seemed desirable to provide conditions which would enhance the removal of ethyl bromide, a by-product, which might enter into undesirable side reactions.[7] For this reason the reaction between the acetobromoglucose and 2,4-diethoxy-5-methylpyrimidine was carried out at a pressure of 2 mm. for four days at 50°. Since ethyl bromide was collected in a Dry Ice trap, it was assumed that the desired product was formed, even though it could not be isolated. The complete reaction mixture was then hydrolyzed with dry hydrogen chloride in absolute methanol. After the solvents were removed *in vacuo*, glucosylthymine was crystallized from absolute ethyl alcohol.

In a similar manner the other thymine nucleosides were formed, although each behaved differently. The acetoarabinosylethoxythymine crystallized directly in the reaction mixture. Ribosylthymine did not crystallize upon hydrolysis of the reaction mixture. Therefore, an impure intermediate was isolated by fractional precipitation at low temperatures before hydrolysis. Hydrolysis of this intermediate yielded ribosylthymine.

Experimental

2,4-Diethoxy-5-methylpyrimidine.—The 2,4-diethoxy-5-methylpyrimidine was prepared from thymine (commercial source) according to the directions given by Schmidt–Nickles and Johnson.[7]

D-Acetobromoribose.—The directions of Levene and Tipson[8] were followed for the preparation of D-acetobromoribose except that petroleum ether was not used to facilitate crystallization of the product. The ether solution of the acetobromoribose, after treatment with Norite, was slowly concentrated *in vacuo* to about one-third of its original volume. The large colorless crystals were washed with a small amount of cold, dry ether, and dried over phosphorus pentoxide in a vacuum desiccator. Contact with moisture was avoided throughout the procedure. If the proper precautions were not taken, the acetobromcribose began to decompose within ten to fifteen minutes. Unless it was redissolved in dry ether, treated with Norite and recrystallized, complete decomposition took place within a few hours.

D-Acetobromoarabinose.—This compound was prepared according to the directions of Anderson and Snell.[9]

D-Acetobromoglucose.—D-Acetobromoglucose was prepared by a method similar to that described by Karjala and Link.[10]

D-Acetobromogalactose.—A modification of the method of Levene and Raymond[11] was used for the synthesis of D-acetobromogalactose. One hundred grams of glacial acetic acid was saturated with dry hydrogen bromide and cooled to 0°. To this solution 25 g. of dry, finely-powdered D-galactosepentaacetate was added and anhydrous hydrogen bromide was passed through the suspension at 0–10° with stirring until all the galactosepentaacetate had dissolved. The flask was loosely stoppered and allowed to stand for one hour at room temperature. The hydrogen bromide was removed under vacuum, and the product isolated as described for the preparation of acetobromoribose.

1-D-**Ribosylthymine.**—Eight grams (0.044 mole) of 2,4-diethoxy-5-methylpyrimidine was heated with 8.1 g. (0.024 mole) of D-acetobromoribose in an oven at 50° for four days at 3–4 mm. pressure. To the cloudy, viscous sirup was added 50 ml. of anhydrous ether, and the solution was kept at −10° for three days. A white crystalline material (1.7 g.) was filtered and recrystallized from 50% aqueous ethanol, m. p. 126°. Hydrolysis of this compound in anhydrous methanol and hydrogen chloride yielded thymine. This compound was believed to be 2-D-acetoribosido-4-ethoxy-5-methylpyrimidine. The isolation, purification and properties of this compound will be reported elsewhere. The filtrate was cooled in a Dry Ice–acetone-bath, and the material (3.0 g.) which separated was filtered in a funnel cooled with Dry Ice and acetone. The white amorphous material was hydrolyzed for three days with hydrogen chloride in methanol, and the solvent completely removed *in vacuo*. The residue was dissolved in 10 ml. of absolute ethanol and cooled overnight. The 1-D-ribosylthymine, 0.5 g. (yield 8.1%), was filtered and recrystallized from absolute alcohol, m. p. 252°. The specific rotation was $[\alpha]^{25}D$ −110° (*C*, 2 in water).

Anal. Calcd. for $C_{10}H_{14}O_6N_2$: C, 46.52; H, 5.46; N, 10.82. Found: C, 47.10; H, 5.78; N, 11.02.

1-D-**Arabinosylthymine.**—Ten grams (0.055 mole) of 2,4-diethoxy-5-methylpyrimidine was heated with 10.5 g. (0.031 mole) of D-acetobromoarabinose at 50° for four days at 3–4 mm. pressure. Crystals separated at the end of the first day and a solid cake was formed in the bottom of the reaction flask after the fourth day. Twenty milliliters of anhydrous ether was added and the mixture stirred thoroughly and cooled to 0°. The white needles were filtered and recrystallized from 50% aqueous ethanol. The yield of 1-D-acetoarabinosyl-4-ethoxy-5-methylpyrimidine was 4.5 g. (43%), m. p. 181°. The specific rotation was $[\alpha]^{29}D$ −93.6° (*C*, 3 in 95% ethanol).

The 1-D-acetoarabinosyl-4-ethoxythymine was hydrolyzed with anhydrous hydrogen chloride in methanol. From 3.50 g. of the intermediate, 1.42 g. of 1-D-arabinosylthymine was obtained, m. p. 250–251°. The specific rotation was $[\alpha]^{25}D$ −69° (*C*, 3 in water).

Anal. Calcd. for $C_{10}H_{14}O_6N_2$: C, 46.52; H, 5.46; N, 10.82. Found: C, 45.72; H, 5.93; N, 10.92.

1-L-**Arabinosylthymine.**—According to the procedure just described the 1-L-arabinosylthymine was prepared in yields identical with those obtained in the preparation of the 1-D-arabinosylthymine. The 1-L-acetoarabinosylthymine, m. p. 181°, had a specific rotation, $[\alpha]^{29}D$ + 93.5° (*C*, 3 in 95% ethanol). When this intermediate was hydrolyzed, the 1-L-arabinosylthymine was obtained, m. p. 250–251°; $[\alpha]^{25}D$ + 69° (*C*, 3 in water).

Anal. Calcd. for $C_{10}H_{14}O_6N_2$: C, 46.52; H, 5.46; N, 10.82. Found: C, 46.75; H, 5.52; N, 10.80.

When equal amounts of 1-L-arabinosylthymine and 1-D-arabinosylthymine were mixed and crystallized from water, 1-DL-**arabinosylthymine** was obtained, m. p. 238–239°; it did not rotate polarized light and was considerably less soluble in water than the optical isomers.

1-D-**Glucosylthymine.**—Fifteen grams (0.082 mole) of 2,4-diethoxy-5-methylpyrimidine was heated with 15 g. (0.037 mole) of recrystallized acetobromoglucose at 50° for seven days at 2–3 mm. pressure. The sirup was dissolved in 375 ml. of absolute methanol containing 13 g. of dry hydrogen chloride. The flask was stoppered and allowed to stand at room temperature. After three days the solvents were completely removed *in vacuo*, and the residue was dissolved in 50 ml. of hot absolute alcohol and placed in the cold overnight. The product was filtered and a second crop obtained from the filtrate. The combined yield was recrystallized from an alcohol and water mixture giving 4.6 g. (43%) of 1-D-glucosylthymine, m. p. 271°. The specific rotation was $[\alpha]^{25}D$ + 14.6° (*C*, 2 in water).

Anal. Calcd. for $C_{11}H_{16}O_7N_2$: C, 45.83; H, 5.60; N, 9.72. Found: C, 45.90; H, 5.69; N, 9.53.

1-D-**Galactosylthymine.**—Seventeen grams (0.041 mole) of D-acetobromogalactose was heated with 17 g. (0.093 mole) of 2,4-diethoxy-5-methylpyrimidine as described for the synthesis of glucosylthymine. The light yellow reaction mixture was hydrolyzed and the solvents removed as previously described. The sirupy residue was taken up with an equal weight of hot absolute alcohol and 3 volumes of hot chloroform were added. Upon cooling the solution, a white material was deposited which was collected by filtration and washed several times with chloroform before it was allowed to dry. The material collected on the funnel was dissolved in absolute alcohol and treated with Norite. To the hot filtrate was added 3 volumes of chloroform. The material separating from the solution was filtered and washed first with chloroform and then with ether. The product, 5.7 g. (yield 48%) was a white powder having an indefinite melting point.

Anal. Calcd. for $C_{11}H_{16}O_7N_2$: N, 9.72. Found: N, 8.74.

Ultraviolet Absorption Spectra of Thymine Nucleosides.—The ultraviolet absorption spectra of the D-ribose, D-arabinose and D-glucose thymine nucleosides were determined with a Beckman spectrophotometer with a hydrogen discharge tube as the source of light. The concentration used for all the measurements was 25 mg. in a liter of distilled water. The maximum and minimum absorption values of the thymine nucleosides are recorded in Table I. The absorption spectrum of glucosylthymine is shown in Fig. 1.

TABLE I

THE MAXIMUM AND MINIMUM ULTRAVIOLET ABSORPTION OF THYMINE NUCLEOSIDES

	Maximum, Å.	Minimum, Å.
1-D-Ribosylthymine	2660	2340
1-D-Arabinosylthymine	2640	2320
1-D-Glucosylthymine	2640	2340

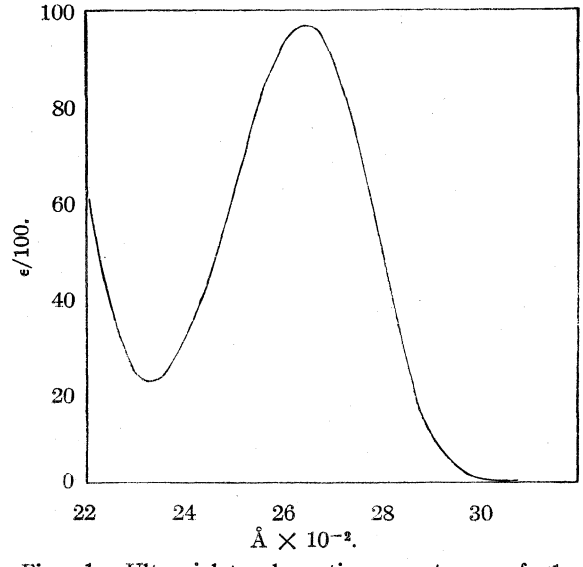

Fig. 1.—Ultraviolet absorption spectrum of 1-D-glucosylthymine. The wave length is plotted against the molecular extinction, ε (ε = $E \times$ mol. wt./cd) where E = extinction, mol. wt. = molecular weight of compound, c = concentration in g. per liter, and d = cell thickness in cm.

Acknowledgment.—The authors are greatly indebted to Dr. J. A. Aeschlimann of the Hoffmann–La Roche Company and to the Chemical

Foundation for generous gifts of thymine and D-ribose. The authors also wish to express their appreciation to Mr. Jack Fox for technical assistance.

Summary

The synthesis of 1-D-ribosyl-, 1-D-arabinosyl-, 1-L-arabinosyl-, 1-D-glucosyl- and 1-D-galactosyl-thymine nucleosides are described. These nucleosides were prepared by reactions between 2,4-diethoxy-5-methylpyrimidine and the proper acetobromo sugar.

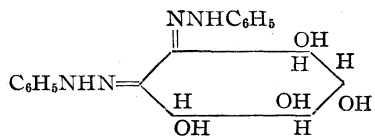
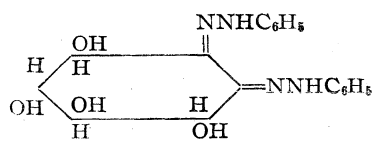
The Action of Periodic Acid on a Cyclohexose Osazone[1]

BY BORIS MAGASANIK[2] AND ERWIN CHARGAFF

It has been shown in a preceding communication[3] that the cyclohexose osazones isolated following the oxidation of *l*- and *d*-inositol by *Acetobacter suboxydans* each consumed three moles of periodic acid per mole of substance. Structure Ia represents the osazone derived from *l*-inositol, Ib that from *d*-inositol.[4]



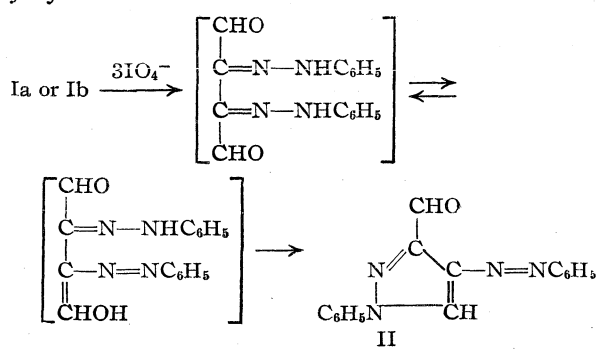
Ia



Ib

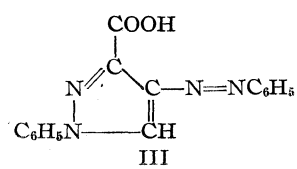
When the oxidation with periodic acid was carried out in a slightly alkaline alcoholic solution, a compound (II) was isolated in a yield of almost 80% whose analytical composition deviated from that of the 2,3-bis-phenylhydrazone of diketosuccinaldehyde, expected by analogy to the behavior of glucose phenylosazone,[5] by the lack of the elements of one molecule of water. The same substance was obtained, though in a lower yield, when the oxidation took place in acidic alcohol. The compound gave the Schiff test and could be oxidized by silver oxide under alkaline conditions to a monocarboxylic acid (III). With semicarbazide it yielded the corresponding semicarbazone.

Compound II appears, therefore, to be derived from the 2,3-bis-phenylhydrazone of diketosuccinaldehyde by the removal of one molecule of water and the concomitant suppression of one aldehyde function. The cyclodehydration of an enolic intermediate would account for the formation of 1-phenyl-4-phenylazo-3-pyrazolecarboxaldehyde (II) from the cyclohexose osazones. This reaction is analogous to the well known formation of 1-phenylpyrazoles from β-diketones and phenylhydrazine.[6]



II

The oxidation of II results in the formation of 1-phenyl-4-phenylazo-3-pyrazolecarboxylic acid (III).



III

The investigation of the absorption spectra of compounds II and III and of IIIa, the sodium salt of compound III, gave results favoring the structures discussed here (see Figure 1). The spectra of II and of the sodium salt IIIa were very similar, showing the low intensity "R band" (molecular extinction ϵ1060 and 940, at wave lengths of 425 and 435 mμ, respectively, obtained by graphical interpolation), and the high intensity "K band" in the ultraviolet, as found characteristic of phenylazo compounds.[7] The free acid III exhibited a slightly different spectrum, probably

(1) This work was supported in part by a grant from the American Cancer Society on the recommendation of the Committee on Growth of the National Research Council.

(2) This report is from a dissertation to be submitted by Boris Magasanik in partial fulfilment of the requirements for the degree of Doctor of Philosophy in the Faculty of Pure Science, Columbia University.

(3) E. Chargaff and B. Magasanik, *J. Biol. Chem.*, **165**, 379 (1946); B. Magasanik and E. Chargaff, *ibid.*, **174**, 173 (1948).

(4) The enantiomorphic osazones originating from *l*- and from *d*-inositol, *i. e.* compounds Ia and Ib, yielded, of course, the same oxidation product with periodic acid.

reflecting contributions by the various tautomeric forms.

The reasons for the readiness with which the pyrazole was formed in the course of the oxidation of the cyclic osazone are not certain. A previous study from this Laboratory[5] has shown the action of periodic acid on the open-chain glucose phenylosazone to result in the production of the 1,2-bis-phenylhydrazone of mesoxalaldehyde; there, an aldehyde group vicinal to an osazone structure was stable. It is possible that the farther-reaching transformation encountered in the present work had its origin in the cyclic nature of the osazone cleaved by periodic acid.

Experimental

1-Phenyl-4-phenylazo-3-pyrazolecarboxaldehyde (II).—A solution of 1.08 g. (3 millimoles) of compound I in 400 cc. of absolute ethyl alcohol was cooled to room temperature and treated with 2.06 g. (9 millimoles) of paraperiodic acid in 300 cc. of 1% aqueous sodium bicarbonate. After one hour the mixture, diluted with one liter of water, was three times extracted with ether. The crystalline evaporation residue of the combined ethereal extracts was recrystallized from aqueous alcohol when *compound II* was obtained as 650 mg. of long orange needles (78% of the theoretical yield). The substance melted[8] at 131°; it gave the Schiff test, was insoluble in water, alkali, and acid, soluble in organic solvents.

Anal. Calcd. for $C_{16}H_{12}ON_4$ (276.3): C, 69.5; H, 4.4; N, 20.3. Found: C, 69.2; H, 4.2; N (Dumas), 20.1.

When the oxidation with periodic acid was carried out in the absence of sodium bicarbonate, the pyrazole II was obtained in a yield of only 18%.

The semicarbazone of II, after several recrystallizations from ethanol–benzene and from ethanol, formed yellow needles, melting at 188–189° (dec.).

Anal. Calculated for $C_{17}H_{15}ON_7$ (333.4): C, 61.2; H, 4.5; N, 29.4. Found: C, 61.5; H, 4.2; N, 29.5.

1-Phenyl-4-phenylazo-3-pyrazolecarboxylic Acid (III).—To a mixture of 555 mg. of silver nitrate in 40 cc. of water and 415 mg. of compound II (1.5 millimoles) in 30 cc. of ethanol, 5 cc. of *N* potassium hydroxide was added dropwise with constant stirring in the course of ninety minutes.[9] The acidification of the filtrate brought about the separation of 280 mg. of the crude acid (64% yield). *Compound III,* following recrystallization from absolute ethanol, formed orange needles, melting at 196–197° (dec.), insoluble in water, soluble in warm aqueous sodium bicarbonate.

Anal. Calculated for $C_{16}H_{12}O_2N_4$ (292.3): C, 65.7; H, 4.1; N, 19.2; neut. equiv., 292. Found: C, 65.6; H, 3.8; N, 19.2; neut. equiv., 288.

(8) The melting points, reported without correction, were determined with an electrically heated stage (Fisher–Johns).

(9) M. Délépine and P. Bonnet, *Compt. rend. Acad. Sci.*, **149**, 39 (1909).

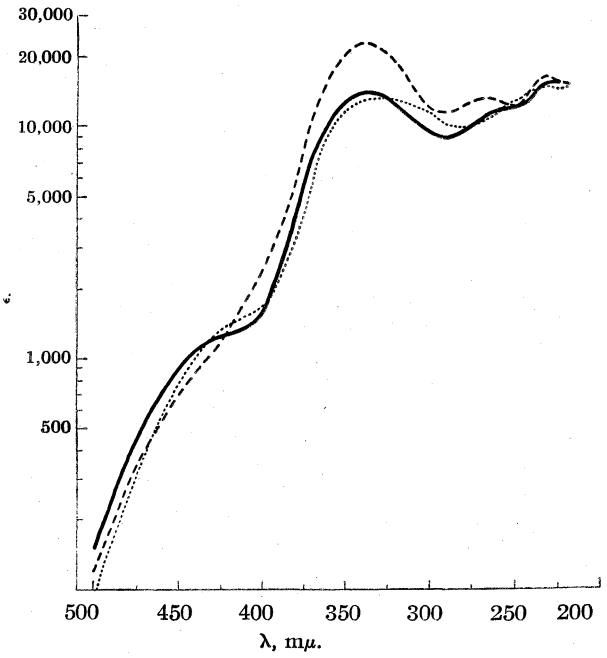

Fig. 1.—Absorption spectra (in absolute ethanol) of compounds II, III and the sodium salt IIIa: ———, IIIa Na salt; — — — — —, III; ..... II.

Absorption Spectra (Fig. 1).—The spectra of compounds II and III and of the sodium salt IIIa (prepared by the exact neutralization of III) were measured by means of a Beckman photoelectric quartz spectrophotometer. About 0.5 and 0.05 millimolar solutions in absolute alcohol were used for visual and ultraviolet spectroscopy, respectively.

The authors are grateful to Mr. W. Saschek and Miss R. Rother for the microanalyses.

Summary

The action of periodic acid on the cyclohexose osazones derived from *l*- and *d*-inositol leads to the formation of 1-phenyl-4-phenylazo-3-pyrazolecarboxaldehyde. Derivatives of this substance (semicarbazone and carboxylic acid) are described. The results of a study of the absorption spectra of these compounds bear out the structures assigned to them.

The Preparation of *o*-Hydroxyphenylacetic Acid

BY JOSEPH LEVINE, T. E. EBLE AND HENRY FISCHBACH

A number of methods have been described for the preparation of *o*-hydroxyphenylacetic acid.[1] In general, the procedures require expensive reagents and usually produce low yields.

The procedure of Czaplicki, *et al.*,[2] entails simultaneous hydrolysis, reduction, and demethylation of *o*-methoxybenzaldehyde cyanohydrin with hydriodic acid. Modification of this procedure for the preparation of the cyanohydrin has now increased the yield from 44 to 95%. Conversion of the cyanohydrin to *o*-methoxyphenylacetic acid was effected in 90% yield with stannous chloride–hydrochloric acid[3] in the presence of a small amount of hydriodic acid. A 75% yield of the pure hydroxy acid was obtained by demethylation with acetic acid–hydrobromic acid mixture containing a small amount of hydriodic acid. In each of the two final steps the use of hydriodic acid resulted in a significant decrease in tar formation.

Methyl *o*-hydroxyphenylacetate, prepared by esterification of the acid with methanol and sulfuric acid, melted at 71°–72°. This compound was reported by Nozu, *et al.*,[4] as melting at 122–124°. From their method of preparation it is evident that their compound is actually the methyl ether, rather than the ester.

Experimental

***o*-Methoxybenzaldehyde** was prepared in 92% yield from salicylaldehyde according to the procedure given in "Organic Syntheses" for the preparation of veratraldehyde.[5] Recrystallized from petroleum ether, it melted sharply at 37°,[6a] as reported by Voswinckel.[6]

***o*-Methoxybenzaldehyde Cyanohydrin.**—To 99 g. of melted *o*-methoxybenzaldehyde was added a saturated solution of 104 g. (1.5 equivalents) of sodium metabisulfite. Upon stirring heat was evolved and the entire mixture solidified. Water was added to obtain a thick suspension, which was covered with ether and cooled. An ice-cold saturated solution of 99 g. of sodium cyanide was added with stirring, and a further 10 g. of sodium bisulfite added, stirring until most of the product was dissolved in the ether. The aqueous layer was diluted with water, extracted with ether, and the combined ether solutions washed with bisulfite solution and then with water. The ether was distilled off and the residue dissolved in benzene and dried azeotropically by refluxing with a water trap. Upon cooling, crystals of the cyanohydrin separated. Petroleum ether was added to effect complete separation. A yield of 113 g. (95%) of granular crystals, m. p. 71–72°, was obtained. Recrystallization from benzene gave a m. p. of 73–74° (Buck[7] reported 73°).

***o*-Methoxyphenylacetic Acid.**—A hot solution of 50 g. of crystalline stannous chloride in 50 ml. of acetic acid, 50 ml. of concentrated hydrochloric acid, and 5 ml. of hydriodic acid (sp. gr. 1.7) was added to 25 g. of *o*-methoxybenzaldehyde cyanohydrin, and the resultant solution heated three hours on a steam-bath. After cooling the solution was filtered to remove stannic chloride which separated during the reaction, diluted with water, and extracted to exhaustion with carbon tetrachloride. The combined extracts were washed with water and evaporated to dryness. A yield of 23 g. (90%) of *o*-methoxyphenylacetic acid was obtained. A portion recrystallized from benzene melted at 124°, the value reported by Pschorr, *et al.*[8]

***o*-Hydroxyphenylacetic Acid.**—Twenty-three grams of *o*-methoxyphenylacetic acid (used directly as obtained above), 70 ml. of glacial acetic acid, 70 ml. of 48% hydrobromic acid, and 7 ml. of hydriodic acid (sp. gr. 1.7) were refluxed sixteen hours. The cooled solution, after dilution with water and addition of a small amount of sodium bisulfite, was extracted first with chloroform and then with ether. The ether extract was washed with water and evaporated; acetic acid in the residue was removed by evaporation with toluene on a steam-bath in a stream of air. The residue was dissolved in ether and sufficient petroleum ether (Skellysolve C) added to form a cloudy solution, from which a small amount of colored gummy material was deposited. The colorless supernatant liquid was decanted and additional petroleum ether added; 15.8 g. (75%) of large snow-white crystals of *o*-hydroxyphenylacetic acid, m. p. 146°–147°, separated; upon recrystallization in the same manner, the m. p. was raised to 149–150° (Czaplicki, *et al.*,[2] reported 147°).

Methyl *o*-Hydroxyphenylacetate.—A solution of 2.0 g. of *o*-hydroxyphenylacetic acid in 20 ml. of methanol and 2 ml. of concentrated sulfuric acid was refluxed for two hours. The cooled solution was diluted with water and extracted with ether. The ether solution, after extraction with sodium bicarbonate solution to remove unreacted acid, was evaporated to dryness. The ester crystallized from petroleum ether as plates (yield, 1.6 g.); upon recrystallization, m. p. 71–72°.

Anal. Calcd. for $C_7H_7OCOOCH_3$: OCH_3, 18.65; sapon. equiv., 166.2. Found: OCH_3, 18.55; sapon. equiv., 163.8.

Summary

o-Hydroxyphenylacetic acid was prepared from *o*-methoxybenzaldehyde (64% over-all yield), *via* the cyanohydrin and *o*-methoxyphenylacetic acid. The methyl ester was prepared.

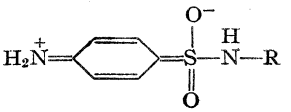
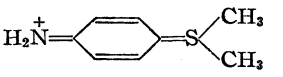
p-Aminophenyldimethylsulfonium β-Naphthalenesulfonate and Antibacterial Activity[1]

BY PHILIP E. WILCOX,[2] JOHN H. OWEN[3] AND MARK A. STAHMANN

Kumler and Daniels[4] have proposed that the anti-*p*-aminobenzoic acid activity of sulfonamides is essentially due to the contribution of the resonant form



to the structure of these compounds. Accordingly it might be expected that a compound such as a *p*-aminophenyldimethylsulfonium salt would exhibit activity of the sulfonamide type since the positive sulfur should readily accept an electron pair from the ring. This would result in the resonant form



which would make a large contribution to the structure of the molecule. Furthermore, from the steric point of view, the *p*-aminophenyldimethylsulfonium cation resembles *p*-aminobenzoic acid and might possess anti-*p*-aminobenzoic acid activity in accordance with the general theory of metabolic antagonists.

Another theory of sulfonamide activity, which has been proposed by Bell and Roblin,[5] and Klotz,[6] correlates the activity of these compounds with their respective acid dissociation constants. From this point of view, it would not be expected that *p*-aminophenyldimethylsulfonium salts would show activity of the sulfonamide type.

In any case, sulfonium compounds are of interest entirely apart from their possible relation to sulfonamides since certain sulfonium compounds do have remarkable physiological activities.[7,8]

Although a great many variations of the sulfonamide structure have been studied, derivatives in which the sulfur appears in the form of a sulfonium group have not been reported. This communication describes the preparation and preliminary microbiological assay of such a compound, *p*-aminophenyldimethylsulfonium β-naphthalenesulfonate. The results furnish supplementary data on the question of the chemical structures which are essential for antibacterial activity of the sulfonamide type.

Many sulfonium compounds are unstable because of the ease with which they undergo dismutation and dealkylation or dearylation. Therefore, it was decided that the synthesis would have the greatest chance for success if the final step was the catalytic reduction under mild conditions of a stable *p*-nitrophenyldimethylsulfonium salt. Preliminary experiments on the hydrogenation of *p*-nitrophenyldimethylsulfonium methyl sulfate with palladium on activated carbon showed that the compound must be reduced in acid solution in order to prevent excessive reduction with the absorption of more than three molar equivalents of hydrogen. On the other hand, in acid solution never more than 80% of the theoretical amount of hydrogen was absorbed even though the catalyst was still active. This reduced solution proved to be quite unstable. The rather insoluble picrate could be isolated if picric acid was added immediately, but attempts to isolate other salts more suitable for antibacterial testing gave only mixtures or oils.

It was found, however, that a more stable solution could be obtained if the reduction was carried out in methanol–water in the presence of an excess of β-naphthalenesulfonic acid. When ether was added to this solution, the desired *p*-aminophenyldimethylsulfonium β-naphthalenesulfonate separated as long needles. Since the β-naphthalenesulfonate anion proved to have no activity in the microbiological tests, this salt was satisfactory for testing.

The structure assigned to the product, namely, *p*-aminophenyldimethylsulfonium β-naphthalenesulfonate, is based on the elementary analysis, the method of synthesis, the fact that the compound is quite soluble in polar solvents, but insoluble in non-polar solvents, and the fact that it gives a strong positive test for a free, primary amino group with glutaconic aldehyde. The instability of some of the sulfonium salts and the greater stability of the same cation in other salts is in conformity with the observations of other investigators, particularly those of Ray and Levine.[9]

p-Aminophenyldimethylsulfonium β-naphthalenesulfonate was tested for anti-*p*-aminobenzoic acid activity against *Staphylococcus aureus* H in a medium which has been described by McIlwain.[10] The compounds involved in the tests were dissolved in sterile water and added aseptically to the sterile medium just before inoculation. Each

tube was inoculated with one drop of a 24-hour culture which had been diluted thirty times. The *p*H of the medium was 6.9 and, after twenty-four hours of incubation at 37°, the growth was determined by measuring the turbidity with an Evelyn colorimeter. For comparison, sulfanilamide was tested in parallel with the sulfonium salt. The activity of each compound was also tested in the presence of *p*-aminobenzoic acid at concentrations of 10 micrograms and 200 micrograms per milliliter.

TABLE I

THE ANTIBACTERIAL ACTIVITY OF *p*-AMINOPHENYLDIMETHYLSULFONIUM β-NAPHTHALENESULFONATE (I), SULFANILAMIDE (II), AND THE EFFECT OF *p*-AMINOBENZOIC ACID

Compound I or II	*p*-Aminobenzoic acid micrograms/ml.	Bacterial growth, expresesd in Evelyn units in the presence of I or II at the following concentrations, and *p*-aminobenzoic acid Micrograms per ml. 1000	500	250	125	62.5	31.7	0
I	0	0	0	5	11	25	28	30
I	10	0	4	13	15	22	24	32
I	200	0	13	18	25	25	26	29
II	0	0	0	0	1	1	12	30
II	10	8	12	19	23	26	28	29
II	200	8	15	22	25	26	28	30

The results of representative tests are presented in Table I. This table shows that sulfanilamide produced almost complete inhibition of growth at a concentration of 62.5 micrograms per ml., and that the addition of either 10 or 200 micrograms of *p*-aminobenzoic acid per ml. allowed almost full growth at 250 micrograms and only partial growth at 1000 micrograms of sulfanilamide per ml. *p*-Aminophenyldimethylsulfonium β-naphthalenesulfonate produced complete inhibition of growth at 500 micrograms per ml. and partial growth at 125 micrograms per ml. The addition of *p*-aminobenzoic acid allowed almost full growth at 125 and partial growth at 500 micrograms per ml. Sodium β-naphthalenesulfonate showed no antibacterial action at a concentration of 2000 micrograms per ml.

These results show that the *p*-aminophenyldimethylsulfonium ion has a low order of antibacterial activity and that this activity is slightly reduced by *p*-aminobenzoic acid. Since it is probable that this ion possesses a resonant form with a quinoidal structure and a positive nitrogen, its low activity indicates that such a resonant form is not sufficient for high action of the sulfonamide type. Apparently, for high anti-*p*-aminobenzoic acid activity, it is necessary to have a negative group comparable to the carboxylate group in the position para to the amino group. However, it must be recognized that the cationic nature of the sulfonium ion may prevent the compound from reaching the points where it could act against a bacterium.

Although sulfonium compounds with a long alkyl chain have high antibacterial activity, the aryl sulfonium group in itself has but a low order of antibacterial activity.[7] In this connection, Freedlander and French[11] have recently shown that methyldiphenylsulfonium nitrate shows no antibacterial activity against *E. coli*, *Staph. aureus*, *B. proteus*, or the tubercle bacillus. Our results would suggest that the introduction of a para amino group into an aromatic sulfonium salt increases the antibacterial activity.

Experimental

Di-*p*-nitrophenyl Disulfide.—This compound was prepared according to the method described for the ortho analog by Bogert and Stull.[12]

***p*-Nitrophenylmethyl Sulfide.**—The disulfide was converted into *p*-nitrophenylmethyl sulfide, according to Brand,[13] in a yield of 61% by the reduction of di-*p*-nitrophenyl disulfide with alkaline sodium sulfide and subsequent direct methylation with methyl sulfate. The product melted sharply at 72.0 to 72.5° in agreement with the literature.

***p*-Nitrophenyldimethylsulfonium Methyl Sulfate and Picrate.**—*p*-Nitrophenylmethyl sulfide was methylated with methyl sulfate according to the method of Brand and Stallmann.[14] The product was recrystallized once from hot methanol and again by the addition of ethyl ether to a methanol solution to give a yield of 84%, m. p. 157.0 to 158.5° (dec.). The picrate was produced in a yield of 95% by the addition of a saturated solution of sodium picrate to an aqueous solution, m. p. 135° to 136° as compared to 137° as reported by Baker and Moffett.[15]

***p*-Aminophenyldimethylsulfonium Picrate.**—Palladium catalyst on activated carbon, prepared according to Hartung,[16] was used for the hydrogenation of *p*-nitrophenyldimethylsulfonium methyl sulfate (3.0 g., 10 millimoles) dissolved in 100 ml. of 90% methanol which contained 20 millimoles of sulfuric acid. The hydrogenation stopped abruptly after 24 millimoles of hydrogen had been absorbed (80% of theory). When this solution is allowed to stand, it became yellow and no crystalline sulfonium salt could be isolated. However, when 3.0 g. (13 millimoles) of picric acid in 100 ml. of water was added immediately to the filtered solution, 3.2 g. (79% yield) of orange prisms separated, m. p. 152 to 153°.

Anal. Calcd. for $C_8H_{12}NS \cdot C_6H_2N_3O_7 \cdot H_2O$: C, 42.0; H, 4.0; N, 14.0; S, 8.0. Found: C, 42.3, 42.3; H, 3.8, 3.7; N, 14.1, 14.1; S, 7.9.

When a methanol solution of this picrate was refluxed for a few hours, long needles of some different, much less soluble picrate separated. This derived compound melted at 165.0 to 165.5° and had an elementary analysis (C, 43.6; H, 3.1; N, 14.5) which indicated that the conversion may have been a reduction.

***p*-Aminophenyldimethylsulfonium β-Naphthalenesulfonate.**—*p*-Nitrophenyldimethylsulfonium methyl sulfate (4.25 g., 14 millimoles) and β-naphthalenesulfonic acid (3.60 g., 17 millimoles) were dissolved in 75 ml. of methanol containing 5% water, and the solution was hydrogenated with palladium catalyst on activated carbon. A total of 30 millimoles of hydrogen was absorbed or 72% of theory. The slightly yellow solution was filtered and 100 ml. of ethyl ether was added immediately. After cooling at 0° for two hours, 3.9 g. (68% yield) of nearly colorless needles of the monohydrate were collected. The product was recrystallized by dissolving it in 120 ml. of absolute methanol, removing the insoluble material by filtration, adding 250 ml. of 30–60° ligroin, and cooling at 0°. The final yield of material was 3.1 g. or 54%, m. p.

(16) Hartung, THIS JOURNAL, **50**, 3370 (1928).

130° (dec.). The product was dried at 80° for four hours for analysis.

Anal. Calcd. for $C_8H_{12}NS \cdot C_{10}H_7O_3S \cdot H_2O$: C, 56.9; H, 5.5; N, 3.7; S, 16.9. Found: C, 56.9, 56.7; H, 5.6, 5.8; N, 3.6, 3.7; S, 16.7.

Further recrystallization did not raise the melting point, but seemed to cause deterioration. The salt was soluble in water, methanol, ethanol, and acetic acid, but was insoluble in ether, chloroform, and benzene. Aqueous base causes the salt to decompose with the formation of an orange color and water insoluble material.

Test for Free Primary Aromatic Amino Group.—Both the *p*-aminophenyldimethylsulfonium picrate and β-naphthalenesulfonate yielded a color characteristic of substances containing a primary aromatic amino group when treated with 4-pyridylpyridinium chloride hydrochloride.[17] On the other hand, the second picrate derived from the initial picrate by heating in methanol gave a completely negative test, indicating that the primary amino group had been destroyed.

Summary

A new compound, *p*-aminophenyldimethylsulfonium β-naphthalenesulfonate, has been synthesized. The picrate of the sulfonium cation has also been prepared.

Microbiological tests showed that the sulfonium sulfonate has a low order of antibacterial activity which is slightly reversed by *p*-aminobenzoic acid.

The activity of the sulfonium salts has been related to the problem of the mode of action of sulfonamides.

MADISON, WISCONSIN RECEIVED NOVEMBER 3, 1947

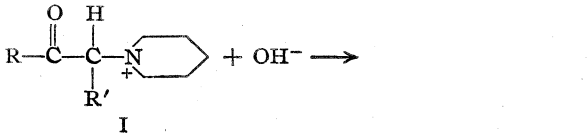
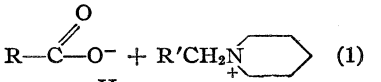
Mechanism of the Alkaline Cleavage of β-Ketoalkylpyridinium Salts[1]

BY RALPH G. PEARSON AND ROBERT L. DILLON

The alkaline hydrolysis of β-ketoalkylpyridinium salts to give the corresponding acid and a simpler alkylpyridinium salt[2] according to equation (1) was studied in some detail by Kröhnke.[3]

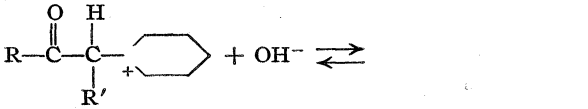


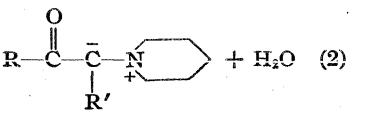
I



II (1)

He showed by kinetic methods that in the presence of excess alkali the reaction was first order and that the stronger the acid, II, formed by the reaction, the greater the rate of hydrolysis. Furthermore, he showed[4] that the initial reaction of the cation, I, with alkali is a typical acid–base equilibrium in which the cation acts as an acid

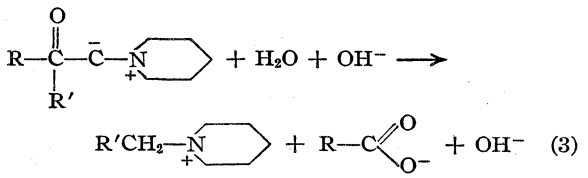




III (2)

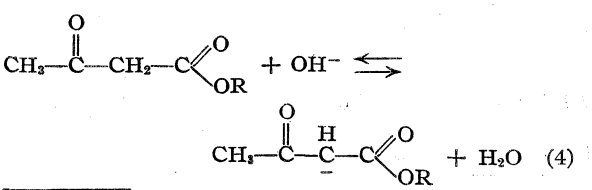
He proposed the name "enol-betaine" for the isolable compound III, writing its structure with the double bond between the two carbon atoms. The enol-betaines in general are highly colored, soluble in organic solvents and not stable in air.

The mechanism that he assumed for the cleavage included the rapid establishment of equilibrium (2) and the subsequent rate-determining reaction of the enol-betaine with excess hydroxide ion and water. If reaction (2) goes well to the right then pseudo first order kinetics will be obtained since hydroxide ion is not used up in (3). However, Kröhnke worked with only one set of concentrations for all of the compounds which he investigated and it can readily be shown that there are several other mechanisms which will turn out to be first order in excess alkali.



(3)

For example in the formally similar hydrolysis of acetoacetic ester by dilute alkali, Goldschmidt and Oslan[5] showed that the reaction was first order under a variety of conditions and the mechanism included an acid-base equilibrium and a rate-determining reaction between hydroxide ion and the unneutralized acetoacetic ester



(4)

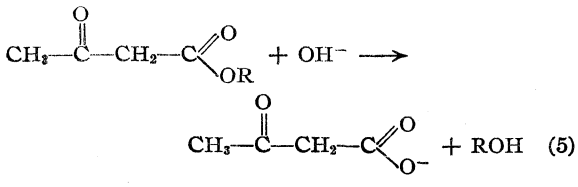
(1) Based on the M.S. thesis of Robert L. Dillon.

(2) (a) Bamberger, *Ber.*, **20**, 3344 (1887); (b) Babcock, Nakamura and Fuson, THIS JOURNAL, **54**, 4407 (1932); (c) Babcock, and Fuson, *ibid.*, **55**, 2946 (1933).

(3) Kröhnke, *Ber.*, **70B**, 864 (1937).

(4) Kröhnke, *ibid.*, **66B**, 604 (1933); **68B**, 1177 (1935).

(5) Goldschmidt and Oslan, *ibid.*, **32**, 3390 (1899); **33**, 1140 (1900).



(5)

Accordingly it seemed advisable to repeat part of Kröhnke's work and to vary the ratios of reactants in such a way as to establish a unique mechanism for the hydrolysis. At the same time the effect of temperature on the rates was investigated and the effect of substituents on the rate constants and the energies of activation determined. The salts selected for this work were phenacylpyridinium iodide and *p*-bromo- and *m*-nitrophenacylpyridinium iodides, all three of which Kröhnke had previously studied as the bromides. The solvent used was distilled water whereas Kröhnke used a mixture of alcohol and water to keep some of the enol-betaines in solution.

Methods and Materials.—The salts used were of high purity[6] and were recrystallized from water–alcohol just before use. The melting points were determined as follows: phenacylpyridinium iodide, 218–219°; *p*-bromophenacylpyridinium iodide, 233–235°; *m*-nitrophenacylpyridinium iodide, 202–203°. Stock solutions made up in distilled water were used within two or three days of preparation.

The extent of reaction was followed by titration of the excess alkali and unreacted enol-betaine. (The enol-betaine is strongly basic.) Selected volumes of solutions of the above salts and carbonate-free standard sodium hydroxide were mixed at the reaction temperature and the zero time recorded. Temperature was controlled to ±0.02° over a range from 13 to 35°. From time to time samples were withdrawn, added to excess acid to stop the hydrolysis and back-titrated. Phenolphthalein indicator was used. A sample was titrated after the reaction was completed also and it was verified that one mole of alkali was used up as in (1). The completion of the reaction could be seen by the disappearance of the intense green-yellow color of the enol-betaine.

As a check on the above method of analysis the kinetics were followed in a few cases with a Beckman photoelectric spectrophotometer. At a wave length of 4400 A. the enol-betaines absorb strongly while the salts themselves and the products do not absorb at all. In this procedure samples were withdrawn from the thermostat into an absorption cell and the transmission measured within a few seconds after withdrawal. The amount of reaction occurring during measurement was negligible.

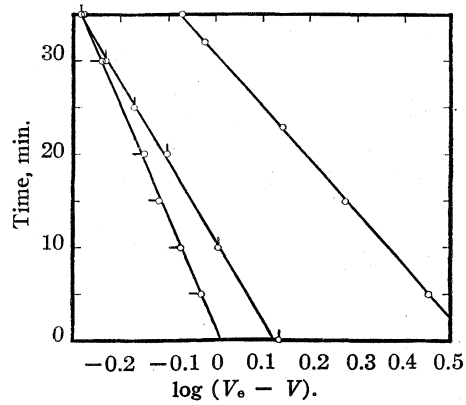


Fig. 1.—O, plot of 0.00714 *M* *p*-bromophenacyl- and 0.01013 *M* NaOH 25.2°; Ọ, 0.00380 *M* *m*-nitrophenacyl- and 0.00482 *M* NaOH 20.0°; O-, 0.00714 *M* phenacyl- and 0.01015 *M* NaOH 25.2°.

(6) Kindly supplied by Dr. L. C. King and prepared by the methods described by him, THIS JOURNAL, 66, 894 (1944), *et seq.*

Calculations and Results

It will be convenient to introduce a list of abbreviations at this point.

- PP^+ = the phenacylpyridinium (substituted or unsubstituted) cation
- $PP^{\pm}$ = the corresponding enol-betaine
- a = concentration of limiting reactant
- $a + b$ = concentration of reactant in excess
- x = concentration of products
- k' = experimental rate constant
- k = corrected rate constant
- K_h = hydrolysis constant for reaction (2)
- V_0 = volume of base needed to back-titrate a sample at time $t = 0$
- V = volume of base needed to back-titrate a sample at time $t = t$
- V_e = volume of base needed to back-titrate a sample at time $t = \infty$

If the acid strength of PP^+ is great enough then (2) goes to completion and $[PP^{\pm}] = (a - x)$ and in solutions where alkali is in excess $[OH^-] = b$ and is constant. When PP^+ is in excess we must solve for $[OH^-]$ from the equilibrium $K_h = [PP^+][OH^-]/[PP^{\pm}]$ so that $[OH^-] = K_h (a - x)/b$, putting in the values of $[PP^{\pm}] = (a - x)$ and $[PP^+] = b$.

In terms of experimental quantities, the volumes of base needed to back-titrate given samples, a is proportional to $(V_e - V_0)$ and $(a - x)$ is proportional to $(V_e - V)$. Accordingly plots of log $(V_e - V)$ against the time were made and straight lines were obtained as shown in Fig. 1 with slopes equal to $k'/2.303$. As Table I brings out the experimental rate constant k' varies with the excess hydroxyl ion concentration so that k'/b is essentially constant.

TABLE I

PHENACYLPYRIDINIUM IODIDE + EXCESS NaOH AT 31.5°

Excess $[OH^-]$ mole/liter	Slope	(Slope) (2.3/$[OH^-]$)	k liters/mole-min.
0.00384	0.01790	10.70	12.2
.00258	.01130	10.00	12.0
.00201	.00840	9.60	12.1
.00062[a]	.00201	7.46	13.8

[a] Spectrophotometric.

In solutions where the salt was in excess $1/(V_e - V)$ was plotted against the time and the results showed a change to second order kinetics in these solutions. Figure 2 presents the type of curves

TABLE II

NaOH + EXCESS PHENACYLPYRIDINIUM SALT

Salt	Temp., °C.	(Slope) $(V_e - V_0)(b/a)$	K_h
Phenacyl-	31.5	5.40×10^{-3}	5.40×10^{-4}
m-Nitrophenacyl-	25.5	1.68×10^{-3}	2.83×10^{-5}
p-Bromophenacyl-	25.2	2.46×10^{-3}	1.87×10^{-4}

that were obtained. Furthermore, the slopes multiplied by $(V_e - V_0)(b/a)$ were constant for a given salt at constant temperature. Table II summarizes the results for solutions where PP^+ was in excess.

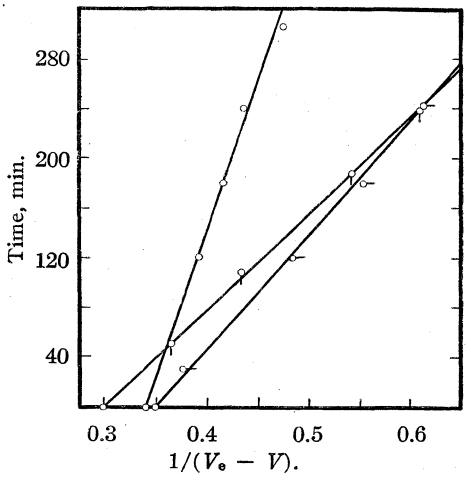

Fig. 2.—O, 0.00882 *M* *m*-nitrophenacyl- and 0.00373 *M* NaOH 25.5°; ○, 0.00833 *M* *p*-bromophenacyl- and 0.00529 *M* NaOH 25.2°; O-, 0.00882 *M* phenacyl- and 0.00373 *M* NaOH 31.5°.

The use of the spectrophotometer has been referred to as a means of following the rate. Here the optical density, *D*, is proportional to $(a - x)$, the concentration of unreacted enol-betaine. So a plot of log *D* *versus* the time should be linear with a slope of $k'/2.3$. Figure 3 shows the results obtained.

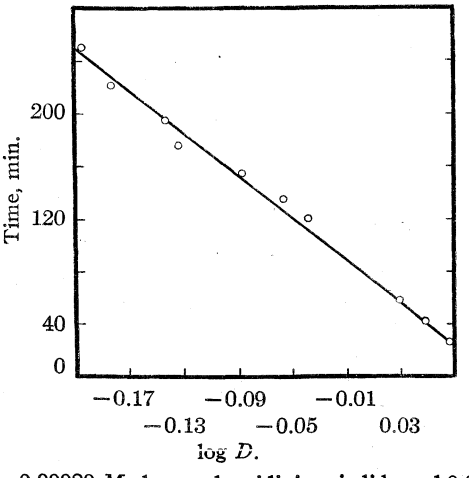

Fig. 3.—0.00080 *M* phenacylpyridinium iodide and 0.00142 *M* NaOH at 25.2°.

Runs were made at least in duplicate at three different temperatures for all three salts. The plot of log *k* against the reciprocal of the absolute temperature gave good straight lines from which the Arrhenius activation energy was computed. Table III gives this information for the three salts.

TABLE III

Salt[a]	Temp., °C.	k,[b] liters/mole-min.	$E_{Arr.}$ kcal.
Phenacyl-	31.5	12.0	13.2
	25.2	7.22	
	20.0	5.00	
m-Nitrophenacyl-	34.0	155	19.7
	25.5	61.2	
	20.0	26.7	
p-Bromophenacyl	34.0	30.1	15.8
	25.2	14.7	
	20.0	8.28	

[a] The salt concentrations were 0.005 to 0.008 *M*; the excess alkali 0.001 to 0.003 *M*. Similar concentrations were used for the same salt at different temperatures. [b] A single value of the hydrolysis constant was used to correct *k* at all three temperatures. While the hydrolysis constant probably changes with temperature, it is used to make only a minor correction and the error introduced is not large.

Discussion

There are two mechanisms consistent with the experimental results. The first is Kröhnke's as shown in (2) and (3) which gives as a rate expression

$$dx/dt = k_1[OH^-][PP^+] \quad (6)$$
$$= k_1 b(a - x) \text{ excess alkali}$$
$$= \frac{k_1 K_h}{b}(a - x)^2 \text{ excess salt} \quad (7)$$

The second is a reaction of the phenacylpyridinium ion with two hydroxyl ions[7] so that

$$dx/dt = k_2[OH^-]^2[PP^+] \quad (8)$$
$$= k_2 K_h b(a - x) \text{ excess alkali}$$
$$= \frac{k_2(K_h)^2}{b}(a - x)^2 \text{ excess salt} \quad (9)$$

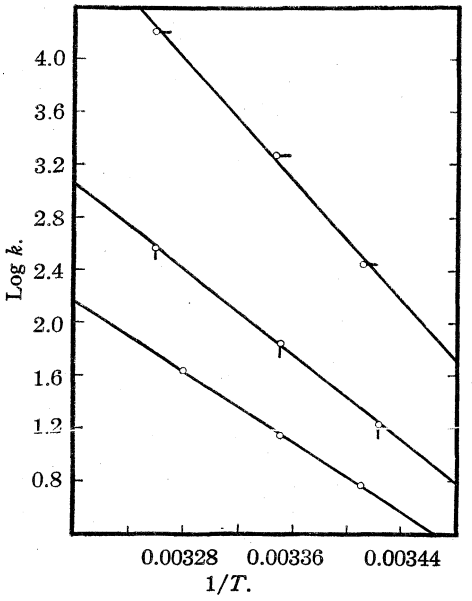

Fig. 4.—O, Phenacyl-; ○, *p*-bromophenacyl-; O-, *m*-nitrophenacyl-.

(7) The authors are indebted to one of the referees for pointing out this possibility of explaining the kinetic data.

Both of these predict correctly pseudo-first order kinetics in excess alkali with a slope varying with the excess alkali and a change to second order kinetics in solutions containing excess salt.

Since for both mechanisms the rate constants in excess alkali and in excess salt differ by a factor of K_h it is possible to evaluate the hydrolysis constant of reaction (2) by dividing (Slope)$(V_s - V_0)(b/a)$ in Table II by k'/b obtained from alkaline solutions at the same temperature. These values are listed in Table II also and it is possible to check the original assumption that $[PP^{\pm}] = (a - x)$. Actually it can be shown that $[PP^{\pm}] = (a - x)[OH^-]/(K_h + [OH^-])$ which reduces to the assumed form when $[OH^-] >> K_h$. The rate constants can be corrected for the small amount of hydrolysis by multiplying them by $(K_h + [OH^-])/[OH^-]$. This has been done for all of the rate constants finally recorded. The magnitude of the effect is seen in Table I where the column (slope)(2.3)/$[OH^-]$ gives the uncorrected rate constant and the last column gives the corrected value. This rate constant k is equal to either k_1 or k_2K_h depending upon which mechanism is correct.

It is interesting to compute the values of K_a, the acid ionization constant of the quaternary ammonium cation, from the values of K_h, the hydrolysis constant. Dividing into the ionization product of water at the temperatures indicated we obtain K_a equal to 3.08×10^{-11}, 5.94×10^{-11}, and 39.6×10^{-11} for the phenacylpyridinium, *p*-bromophenacylpyridinium and *m*-nitrophenacylpyridinium cations, respectively. These values are in the same relative order as the corresponding acidities of the substituted benzoic acids.

Summary

1. The alkaline cleavage of enolizable β-ketoalkylpyridinium salts is shown to be pseudo-first order in excess alkali and second order in the presence of excess salt.

2. The mechanism involves either the reaction of a hydroxyl ion with the enol-betaine or the reaction of two hydroxyl ions with the quaternary cation.

3. The rate constants have been determined for the *m*-nitro-, *p*-bromo- and unsubstituted phenacylpyridinium iodides at several temperatures and the activation energies computed.

The Reaction of Metallic Copper with Titanium(IV) Chloride

BY DONALD E. KOONTZ AND DOUGLAS G. NICHOLSON

During the course of an investigation of the nature of the reaction(s) taking place in the decolorization of commercial titanium(IV) chloride by metallic copper,[1] it was observed that clean dry metallic copper would react with chemically pure titanium(IV) chloride at room temperature. Accordingly, a detailed study was conducted on the interaction of these substances.

Loose rolls of copper foil made from sheets approximately $4 \times 6 \times 0.0127$ cm. were heated to remove carbonaceous matter, cooled, rinsed in dilute hydrochloric acid, then water, and dried. They were then inserted in Pyrex test-tubes containing 5–8 ml. of titanium(IV) chloride, which were tightly closed with lead foil-covered corks.

The purplish-black scale which became evident after two or three hours could be shaken or jarred off, but on continued exposure the bright copper surface again became coated with the scale. After three to five weeks of exposure, the titanium(IV) chloride had entire disappeared, and an appreciable residue of dry, purplish-black material and flakes of unreacted copper remained. Using dry powdered (150 mesh) copper, the process was complete in twenty to thirty hours, but the residue tended to form a hard cake which, because of its expansion, sometimes cracked the tubes.

The rate of scale formation was not appreciably increased by heating the reaction tubes to approximately 100°, unless the metal surface was re-exposed. It appeared that the scale tended to protect the metal surface from further action.

Small samples of the dry scale, with adhering flakes of metallic copper, were subjected to the tests and analyses described below.

(a) Exposure to atmospheric oxygen showed a gradual color change, becoming progressively gray, tan, and greenish-blue. The material was hygroscopic.

(b) Treatment with distilled water produced an immediate white turbidity which gradually (five to ten minutes) became reddish-brown in color. The interior surface of the retaining vessel became coated with a very thin mirror-like copper-colored deposit. This coating was insoluble in dilute hydrochloric acid, but was readily soluble in nitric acid or ammonia water–hydrogen peroxide mixture, yielding solutions which gave positive tests for copper(II) ion but negative tests for titanium(IV). The initial water solution gave a positive test for titanium(III) ions.

(c) Treatment with 6 *N* hydrochloric acid produced a clear purplish-pink solution containing

(1) From a thesis submitted to the Graduate School of the University of Pittsburgh by Donald E. Koontz in partial fulfillment of the requirements for the Master of Science degree, January, 1948.

suspended flakes of copper. This solution gave a positive test for titanium(III) ions. After filtering to remove the suspended copper, samples of this solution were analyzed to determine the copper:titanium ratio present. This was done as follows: (1) atmospheric oxidation for twenty-four hours; (2) titanium was determined by double precipitation by ammonia water followed by ignition of the precipitate to the dioxide; (3) after removal of ammonia from the combined titanium filtrates, copper present was precipitated by the addition of sodium hydroxide, followed by ignition to the oxide. Analyses of solutions of five different scale samples gave an average weight ratio of the elements copper:titanium of 1.39:1.00. Theoretical weight ratio of these elements (based on one atom of each) is 1.33:1.00. It thus appeared that the black residue was composed of compounds of copper and titanium whose metallic ratio contained one atom of each.

(d) Samples of the metal-free, 6 *N* hydrochloric acid solution of the scale become a pale bluish-green color after exposure to atmospheric oxygen for approximately twenty hours.

A sample of freshly prepared copper(I) chloride was added to a solution of titanium(III) chloride, prepared by electrolytic reduction of aqueous titanium(IV) chloride. A water-clear purplish-pink solution resulted. On standing several minutes after dilution with a 4–5 fold excess of distilled water, the initial color of the solution faded and an adherent copper-like deposit coated the interior surfaces of the vessel. This deposit exhibited the same characteristics as that produced when a sample of purplish-black residue was added to distilled water (b, above).

Discussion

Based on the above-described tests and observations, it appears that the purplish-black scale is a mixture and/or a compound containing a ratio of one atom each of titanium(III) and copper(I) chlorides. Either or both of the following reactions are postulated as the means by which the scale is produced.

$$(1)\quad TiCl_4 + Cu \longrightarrow \underset{\text{black scale}}{CuCl} + TiCl_3$$

$$(2)\quad TiCl_4 + Cu \longrightarrow CuTiCl_4$$

The white precipitate produced immediately on addition of the scale to distilled water was probably copper(I) chloride (a product in reaction (1), or produced by aqueous decomposition of $CuTiCl_4$ formed in reaction (2)) in a solution of titanium(III) chloride hexahydrate.

The gradual color change which took place (with passage of time) in the aqueous mixture of titanium(III) and copper(I) chlorides was probably due to either or both of the two reactions

$$(3)\quad TiCl_3 + CuCl \longrightarrow \underset{\text{copper deposit}}{Cu} + TiCl_4$$

$$(4)\quad 2CuCl \longrightarrow Cu + CuCl_2$$

Of these two equations, (3) and (4), reaction (3) appears to be more probable since reaction (4) indicates that one-half of the total copper initially present would be in solution after the reaction was complete. Tests conducted on the residue and filtrate indicated that only a very small fraction of the total copper initially present was soluble in 6 *N* hydrochloric acid.

It is interesting to note that reaction (3), in aqueous solution, is the reverse of reaction (1) in non-aqueous medium.

The solubility of the purplish-black scale in 6 *N* hydrochloric acid producing a clear purplish-pink solution can be explained by either or both of the following equations

$$(5)\quad \underset{\text{black scale}}{CuCl} + TiCl_3 + HCl \longrightarrow HCuCl_2 + TiCl_3$$

$$(6)\quad CuTiCl_4 + HCl \longrightarrow HCuCl_2 + TiCl_3$$

Conclusions

A detailed study of the reaction of metallic copper with titanium (IV) chloride has been undertaken. This reaction produces a purplish-black scale which contains copper (I) and titanium(III) ions.

A Comparative Study of the Three Stereoisomeric 1,4-Diphenylbutadienes

BY J. H. PINCKARD, B. WILLE AND L. ZECHMEISTER

It was recently shown, in collaboration with A. Sandoval,[1] that the maximum extinction in the spectrum of ordinary *trans-trans*-1,4-diphenylbutadiene, $C_6H_5CH{=}CHCH{=}CHC_6H_5$, decreased to about half of the original value upon illumination under certain conditions. However, almost entire restoration of the original extinction curve by iodine catalysis proved that no irreversible destruction had taken place. Further experiments for the identification of the chromatographically homogeneous product were announced.

As is known, Straus[2] prepared two stereoisomers of diphenylbutadiene by reduction methods; one was crystalline (m. p. 70.5°, compared to 152–153°, cor., of the *trans–trans* form) and the other was oily. We were able to confirm Straus' data concerning the crystalline compound but have observed by chromatography that the oily sample contains a number of impurities. After their elimination on the Tswett column, this isomer was found to be identical with that obtained photochemically.[1] Of course, illumination is a simpler method of preparing this oily isomer than the reduction of *trans*-diphenylbutenine.[2]

It was observed in the field of the carotenoids[3] that a single *trans* → *cis* rotation shifts the position of $\lambda_{max.}$ by about 7.5 mμ toward shorter wave lengths (*e. g.*, lycopene, in hexane, measured in the Beckman spectrophotometer). We noticed a similar shift when the extinction curves of the three diphenylbutadienes were compared in hexane solution; however, in this case one *trans* → *cis* step causes a wave length difference of 14–15 mμ:

trans–trans form (m. p. 152–153°), $\lambda_{max.}$ at 328 mμ
cis–trans form (oily), $\lambda_{max.}$ at 313 mμ
cis–cis form (m. p. 70.5°), $\lambda_{max.}$ at 299 mμ

These data compare well with those referring to *trans*- and *cis*-stilbene (difference in $\lambda_{max.}$, 15 mμ)[4] and they also agree with the assignment of configurations to stereoisomeric diphenylbutadienes as given by Straus. An absolute structure determination of *cis–cis*-diphenylbutadiene is not yet available.[2a]

The extinction curve of *trans-trans*-diphenylbutadiene shows definite fine structure while the two other isomers are characterized by smooth curves which are rather similar in this respect (Figs. 1–2).

When petroleum ether is used as a developer, the chromatographic sequence on alumina from top to bottom is: *trans-trans*-, *cis-trans*-, and *cis-cis*-diphenylbutadiene. The zone of the *trans-trans* form can be located by its intense bluish fluorescence in ultraviolet light. The presence of one or two *cis* double bonds, however, destroys this power to fluoresce, in adsorbate as well as in solution. On the other hand, zones of the *cis-trans* and *cis-cis* forms, when either is present in appreciable quantity, may be located on the column by the moderate quenching of the weak fluorescence of the alumina itself. Like *cis*- and *trans*-stilbene zones,[5] those of the three diphenylbutadienes are also detected by brushing with permanganate.

A sharp separation of the *cis-trans* and *cis-cis* forms can be accomplished by means of the liquid chromatogram procedure. The detection of either isomer in the successive fractions of the filtrate is carried out by treating small samples of each fraction with catalytic amounts of iodine followed by a brief illumination. Thus, either of these two stereoisomers is converted into the *trans-trans* form, whereupon fluorescence appears in the solution when inspected in ultraviolet light. The limit of detection is 0.5–1.0 milligram per liter or a few micrograms in a 2-ml. test sample. The recovery of each of the three stereoisomers from artificial mixtures was practically quantitative in such resolutions.

Having chromatographically pure samples of all stereoisomeric diphenylbutadienes, a comparison of their behavior under various conditions was made; the result may be summarized as follows.

In petroleum ether, at 4°, and in the absence of light any of the three configurations can be preserved for several months. When hexane solutions are refluxed in all-glass apparatus, in darkness, for forty-five minutes, the three stereoisomers behave identically: their extinction curves were practically unchanged. The isomers showed only a limited difference when kept in the molten state at 205° for ten minutes, with the exclusion of air and light. The *trans-trans* and *cis-trans* configurations were practically unaffected; *cis-cis*-diphenylbutadiene underwent moderate isomerization whereby the amount of the *trans-trans* compound formed did not exceed 5%.

In order to test the relative photo-stabilities, we conducted two series of experiments under very different conditions: (*a*) illumination of the hexane solution (20 mg. per liter) in Pyrex flasks with a 250-watt light bulb for several hours, and

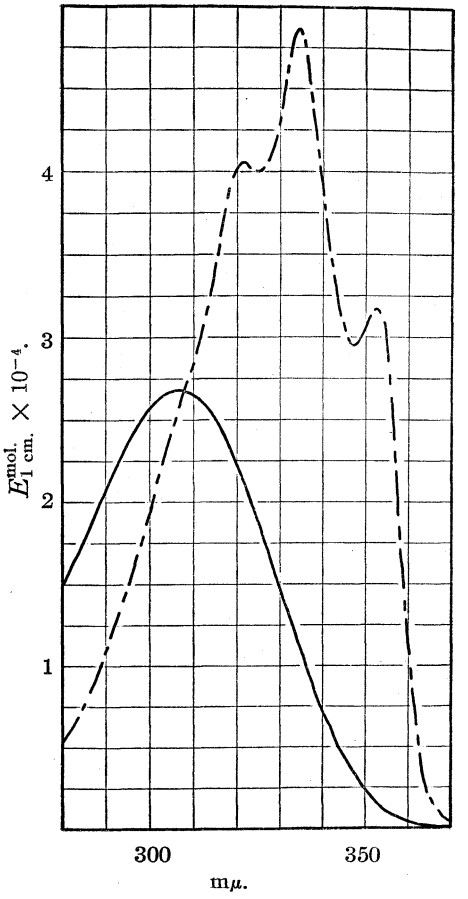

Fig. 2.—Molecular extinction curve of *cis–cis*-diphenylbutadiene in benzene: —, fresh solution; – – – –, after iodine catalysis.

(*b*) insolation, *i. e.*, exposure of more dilute solutions (3–4 mg. per liter) to intense sunshine, in transparent quartz tubes, for one to ten minutes.

In the (*a*) series it was found that the extinction curve of *cis-trans*-diphenylbutadiene was practically unchanged, even after seventeen hours of illumination; the two other isomers underwent almost quantitative rearrangement, and at the end of the irradiation period also showed very nearly the spectral curve of the *cis-trans* form (Figs. 3–4). The *trans-trans* isomer required only one to two hours to reach this state but the *cis-cis* compound as long as thirteen to fourteen hours.

During the insolation as shown by Fig. 5, the fine structure of the *trans-trans* curve had almost entirely disappeared after one minute and the extinction curve approached closely that of the *cis-trans* isomer after ten minutes. The *cis-cis* configuration underwent a similar rearrangement essentially to the *cis-trans* form (Fig. 6), while no appreciable change in the extinction curve was noticed after *cis-trans*-diphenylbutadiene had been insolated for ten minutes.

Whether or not irreversible processes also take place besides photo-isomerization, is revealed by subsequent iodine catalysis and brief illumination with a daylight lamp. If the molecular extinction coefficient at $\lambda_{max.}$ is then found to be smaller than the value established earlier by a similar catalytic treatment of the *trans-trans* form, then the deficit is a fair measure of photochemical destruction. In the experiments with artificial light such losses were smaller than 1–2% of the starting material; however, they amounted to about 8–10% after ten minutes of insolation.

Special experiments showed that upon iodine catalysis in light (like the carotenoids) the stereoisomeric diphenylbutadienes yield practically identical mixtures which in this case contain about 97% all-*trans* form. However, if iodine is added in darkness to the solution, none of the diphenylbutadienes shows a detectable spectral change within half an hour. A subsequent exposure of the *cis-cis* compound even for as little as twenty seconds to the daylight lamp caused noticeable rearrangement. Figure 7 shows, both in the fundamental band and in the secondary maximum near 230 mμ, that the main process in the first stages is a stepwise conversion, *cis-cis* → *cis-trans* → *trans-trans*. If a direct *cis-cis* → *trans-*

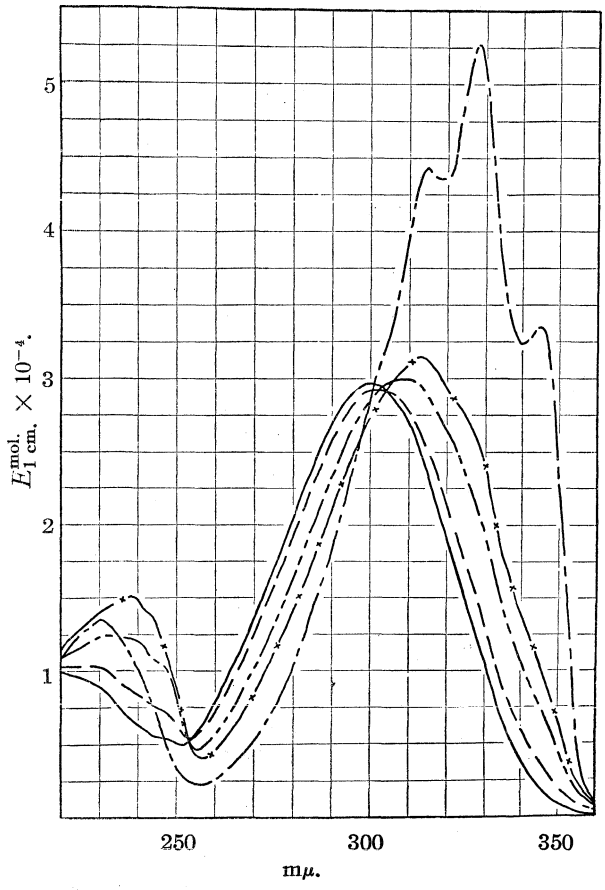

Fig. 3.—Molecular extinction curve of *cis–cis*-diphenylbutadiene in hexane, and its gradual shift toward the curve of the *cis–trans* form during illumination with a 250-watt bulb: —, fresh solution of the *cis–cis* compound; — — —, after forty-five minutes; — — — —, three hours and forty-five minutes; and — x — x —, seventeen hours of illumination; — — — —, after iodine catalysis at the end of seventeen hours of illumination.

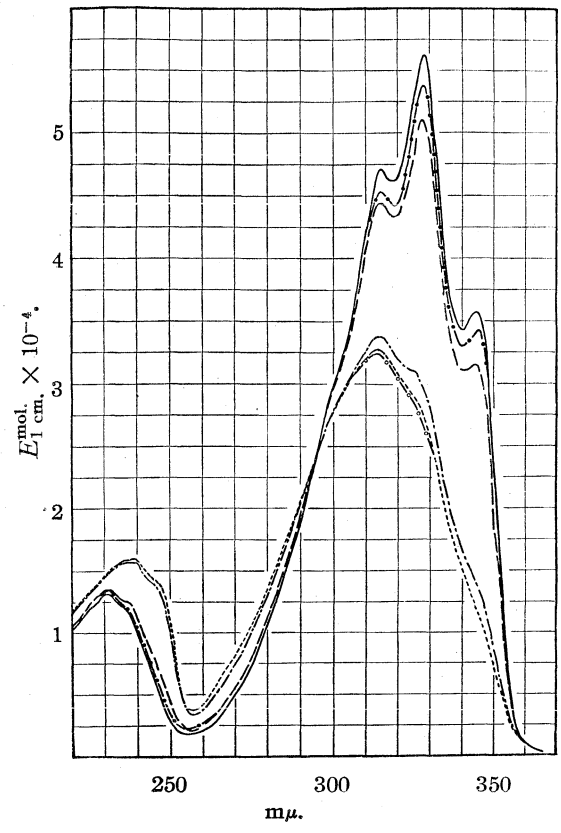

Fig. 4.—Molecular extinction curve of *trans–trans*-diphenylbutadiene in hexane, and its gradual shift toward the curve of the *cis–trans* form during illumination with a 250-watt bulb (strictly parallel experiment to that represented in Fig. 3): —, fresh solution of the *trans–trans* compound; — — — —, after fifteen minutes; — · — ·, forty-five minutes; — — — —, one hour and forty-five minutes; — O — O —, eight hours illumination; —●—●—, after iodine catalysis at the end of seventeen hours of illumination.

trans rearrangement took place, one would expect the appearance of some fine structure in early stages of the illumination; even the presence of 5% *trans-trans* form gives rise to recognizable bulges in the extinction curve, especially around 328 mμ and 344 mμ (in hexane). On the other hand, after illumination for twenty-five minutes the curve in Fig. 7 is essentially that of *trans-trans*-diphenylbutadiene.

The height of $E_{max.}$ also indicates that only a spatial change and no destruction took place. In contrast, when the addition of iodine is followed by excessive illumination, irreversible processes also occur, for example to the extent of 30% during a six-hour exposure to the 250-watt bulb. In the absence of iodine there is no destruction under the same conditions.

Finally, the stability of the three isomers in the absence of solvents was investigated. The oily *cis-trans* compound has the tendency, even in almost complete darkness, to rearrange and deposit crystals of the *trans-trans* isomer; in strong light such crystals appear within a minute.[6,2] Although the oil was handled cautiously, its crystallization tendency was always found to be inferior to its inclination for the spatial change. So far we have failed to obtain *cis-trans*-diphenylbutadiene in crystalline form.

The present study should show that, from the viewpoint of the practical chemist, no one of the three configurations of diphenylbutadiene is the most stable under all conditions. While photochemically the *trans-trans* and the *cis-cis* forms proved to be labile and changed their configuration to *cis-trans*, the latter is much less stable than the others in the absence of solvents. Under none of the conditions tested was the *cis-cis* form the most stable. However, at room temperature the stability of its crystals compared well with the crystalline *trans-trans* compound, and these two forms show no great difference even at 205°.

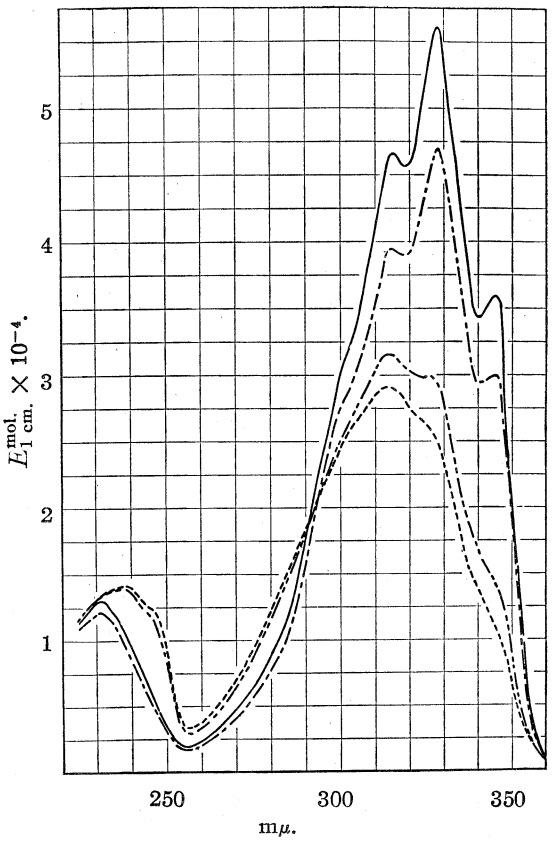

Fig. 5.—Molecular extinction curve of *trans–trans*-diphenylbutadiene in hexane, and its shift toward the curve of the *cis–trans* form during exposure to sunshine: —, fresh solution; — — — —, after one minute; – – – –, ten minutes of insolation; — · — ·, after iodine catalysis at the end of ten minutes of insolation.

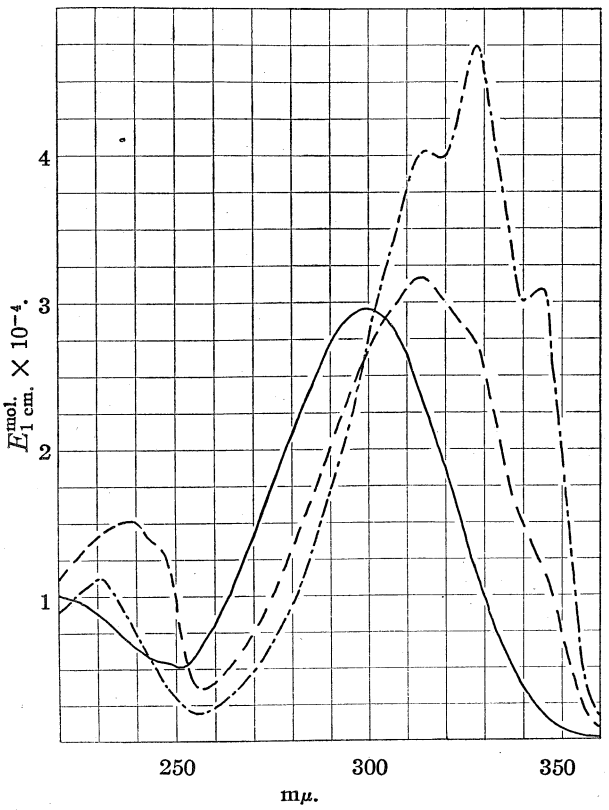

Fig. 6.—Molecular extinction curve of *cis–cis*-diphenylbutadiene in hexane, and its shift toward the curve of the *cis–trans* form during exposure to sunshine: —, fresh solution; – – – –, after ten minutes of insolation; — · — ·, after iodine catalysis at the end of ten minutes of insolation.

Some distinctly individual features of *cis-trans*-diphenylbutadiene as compared to its stereoisomers are also revealed by an inspection of the three models. The dotted lines in Fig. 8 which connect the ends of each resonating system, demonstrate the essentially linear shape of the *trans-trans* and *cis-cis* molecules while the *cis-trans* form shows the pattern of a widely open V. Comparable forms of carotenoids would be[7]: lycopene, neolycopene A, and poly-*cis*-lycopene "IV" (or another poly-*cis*-lycopene).[8] Neolycopene A is characterized by lability of its configuration in the absence of solvents, lack of crystallization tendency (without rearrangement), and by its high *cis*-peak. Although no clearly differentiated *cis*-peak appears in the relatively compressed spectral curve of *cis-trans*-diphenylbutadiene, its extinction at 230 to 240 mμ is the highest of all three stereoisomers. Furthermore, its maximum is located at a 9 mμ longer wave length than the corresponding maximum of the *trans-trans* compound. On the other hand, *cis-cis*-diphenylbutadiene can be compared with a poly-*cis*-lycopene: both show a flat section of the extinction curve in the (potential) *cis*-peak region.

Although extinction areas are more characteristic than the height of maxima, the following data show the very great decrease in $E_{\text{max.}}$ when several *cis* double bonds are formed by rearrangement; and they also indicate that the first *trans* → *cis* step is responsible for the major part of this effect: Relative heights of $E_{\text{max.}}$ in hexane (per cent.): all-*trans*-lycopene, 100; neolycopene A (a central mono*cis* lycopene), 66; poly-*cis*-lycopene "IV," 56; *trans-trans*-diphenylbutadiene, 100; *cis-trans*, 54; and *cis-cis*, 53.

The lack of fine structure in the extinction curve of *cis-trans* or *cis-cis*-diphenylbutadiene parallels to a certain extent the recent observation that all poly-*cis*-lycopenes known at the present time show a very limited fine structure when compared to that of the all-*trans* form.[8]

Experimental

Adsorbents and Solvents.—"Silicic acid" means Merck reagent silicic acid plus 20% celite. Commercial alumina (Alorco, Grade F, ground to −200 mesh) was used mixed with 25% celite. On such columns 0.5% permanganate is a suitable color reagent for the location of diphenylbutadiene zones by brushing.[5] The petroleum ether was Skellysolve B, b. p. 60–70°. The hexane was prepared from Phillips commercial brand by repeated treatment with fuming sulfuric acid.

Light Sources and Conditions of Illumination.—Chromatograms were inspected in the light of a General Electric Purple X bulb using a moulded Corning light filter No. 5840, 0.25 inch thick; "Mineralight Q31" was less satisfactory due to its different light filter. The conditions for the illumination of iodine catalyzed solutions with a Mazda daylight lamp were described in detail recently.[1] Under the same conditions benzene solutions should be illuminated for an hour. For artificial illumination of iodine-free solutions a 250-watt Mazda clear projection lamp bulb (Code −250 T 14/3 −120V) encased in a water jacket was used (distance from filament to center of Pyrex volumetric flask, 10 cm.). Transparent quartz test-tubes were found satisfactory for insolation experiments (end temperature, 20–25°). The values for each extinction curve, taken in the Beckman photoelectric spectrophotometer, are based on the average of at least two independent determinations.

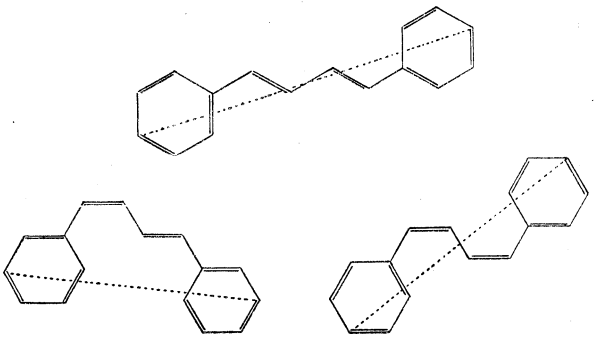

Fig. 8.—Models of *trans–trans*- (top), *cis–trans*- (bottom, left), and *cis–cis*-diphenylbutadiene (bottom, right). (Values: C=C, 1.33 Å.; C—C, 1.46 Å.; and C=C—C angle, 124° 20′. The dotted lines connect the ends of each resonating system.)

Thermal Treatment.—Refluxing of hexane solutions (5–20 mg. per liter) was carried out in darkness, in a slow stream of carbon dioxide. In the melt experiments, 4–12 mg. weighed samples, in evacuated and sealed capillary tubes, were submerged in a dibutyl phthalate bath (205–210°), in darkness. After ten minutes the tubes were rapidly cooled in water and their contents examined without delay.

trans-**Diphenylbutenine,** $C_6H_5CH{=}CHC{\equiv}CC_6H_5$, was prepared (in a crude state) from phenylacetylene–copper according to Straus.[2] Purification: a solution of 8.5 g. of brownish, crude crystals in 100 ml. of petroleum ether was developed with the same solvent on a silicic acid column, 22 × 4.8 cm. (The figures on the left designate thickness of the zones in mm.; fl. means fluorescence or fluorescent in ultraviolet light):

30 several brown zones (in daylight)
30 white fl. (1 g. oil)
7 brown (in daylight)
8 interzone, no fl.
50 white fl. (1 g. oil)
80 column-fl. quenched: main product
Filtrate: no fl.

The main zone was cut out, eluted with ethanol, transferred into petroleum ether, dried with sodium sulfate and completely evaporated *in vacuo*. A solution of the slightly colored crystals (5.5 g.) in 50 ml. of hot methanol deposited 3 g. of white needles in the cold room; m. p. 96°, cor. An additional 1 g. can be obtained by chromatographing the mother liquor as above.

cis–trans-**Diphenylbutadiene from** *trans*-**Diphenylbutenine.**—In an all-glass apparatus (with mercury-sealed stirrer) the solution of 3 g. of the butenine in 250 ml. of alcohol was refluxed in darkness with 2 g. of zinc–copper dust (from copper sulfate and zinc, washed with ethanol) and another 2 g.-portion of the metals was introduced after thirty hours. The sharp extinction maximum (originally at 306 mμ., in petroleum ether) gradually disappeared and, after one hundred and ten hours of refluxing, the smooth maximum of *cis–trans*-diphenylbutadiene was observed in a small sample. Then 250 ml. of petroleum ether and 1 liter of water were added to the filtered liquid; the aqueous layer was re-extracted and the total petroleum ether solution was repeatedly washed and dried. The following chromatogram, obtained with the same solvent, on a 28 × 8 cm. alumina column, refers to one third of the crude solution:

30 several, partly fl. zones
25 blue fl.: *trans-trans*-diphenylbutadiene
140 fl. of alumina quenched: crude *cis-trans*

When the bottom of the lowest zone was 7 cm. from the end of the column, the quenched section was cut out in two halves of which the upper one contained unchanged butenine (its extinction curve was not influenced by iodine). The bottom half of the quenched zone showed the spectroscopic character of *cis-trans*-diphenylbutadiene, and a sample yielded (after iodine catalysis in light) the fine structure of the *trans-trans* form. This fraction was rechromatographed as above.

In order to eliminate the last impurities, especially for optical observations, 3 mg. of the *cis-trans* compound (in 3 ml. of petroleum ether) was adsorbed on a 20 × 1.9 cm.-column and washed with the same solvent. Each 10-ml. portion of the (non-fluorescing) filtrate was tested as follows: A few drops were catalyzed with one drop of iodine solution (0.3 mg./ml.) and the test-tube exposed to the 250-watt lamp from a 10 cm. distance for one to two minutes. If the sample showed fluorescence in ultraviolet light, the fraction was kept, otherwise rejected. This test was positive between the fractions 17–29. Fractions 18–28 were found spectroscopically to contain pure *cis-trans* compound; 3 g. of the butenine yielded 0.75 g. of the purest product.

The molecular extinction coefficients were given earlier.[9]

Anal. Calcd. for $C_{16}H_{14}$: C, 93.16; H, 6.84. Found: C, 92.73, 92.89; H, 6.84, 6.88.

***cis-cis*-Diphenylbutadiene** was prepared by catalytic reduction of diphenyldiacetylene, $C_6H_5C{\equiv}CC{\equiv}CC_6H_5$, by Kelber and Schwarz as well as by Ott and Schröter[2] in yields of 8–32%, depending on the catalyst. Although our yields remained between these limits (for example, 24%), we recommend the following isolation which is based on spectroscopic control of the reduction process and chromatographic purification of the product. During the reaction the triple bonds are reduced not only to double, but in part also to single bonds. These competing processes can be followed by the changing extinction curve. The sharp and high peaks of diphenyldiacetylene at 306 and 326 mμ. (in hexane) gradually disappear and the much lower, smooth maximum of *cis-cis*-diphenylbutadiene at 300 mμ. then makes the main contribution to the curve. A satisfactory amount of the latter compound is clearly indicated if a small sample (diluted with hexane) is examined in the spectrophotometer before and after iodine catalysis (in light). The new maximum (now at 328 mμ.) should be at least 1.5 times higher than $E_{max.}$ was before this catalytic treatment.

Fig. 9.—Crystals of *cis–cis*-diphenylbutadiene (from methanol).

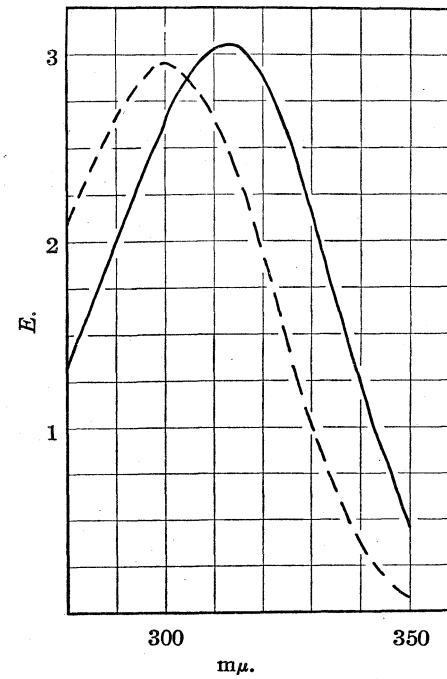

Fig. 10.—Extinction curves (main maxima only) of *cis–cis*- and *cis–trans*-diphenylbutadiene in petroleum ether as obtained by the resolution of their mixture in a liquid chromatogram experiment: ———, *cis–cis*- and ——, *cis–trans*-diphenylbutadiene.

The following operations should be carried out in dim light. A solution of 1 g. of diphenyldiacetylene in 100 ml. of 95% ethanol was shaken with 0.25 g. of palladium–barium sulfate[10] until roughly 350 ml. of hydrogen was taken up within one quarter to one half hour. After filtration, the material was transferred with water into petroleum ether and the aqueous phase re-extracted. The combined petroleum ether solution, after washing, drying and concentrating to 50 ml., was developed on an alumina column (30 × 7.5 cm.) with about 2 liters of the same solvent:

6	dark (in uviol. light)
8	greenish fl.
20	blue fl.: *trans-trans*-diphenylbutadiene
16	non-fl. interzone
60	column-fl. quenched: *cis-trans*-diphenylbutadiene
26	interzone (borders blurred)
50	column-fl. quenched: *cis-cis*- diphenylbutadiene
110	empty section

The location of the *cis-cis* compound possibly could be improved by using a strongly fluorescent column as proposed by Sease.[11]

The *cis-cis* zone was cut out, eluted with ethanol, transferred into petroleum ether, washed, dried and completely evaporated *in vacuo*. The oily residue was then transferred into a small centrifuge tube and dissolved in a minimum amount of warm 95% ethanol. Crystallization was observed at room temperature, whereupon the tube was kept at 4° overnight. Yield, after recrystallization, was 243 mg. of *cis-cis*-diphenylbutadiene which showed distinctly different crystal forms (Fig. 9) from those of the *trans-trans* isomer.[12] The extinction coefficients are given in Table I.

(9) Reference 1, p. 555, Table I; the term "chromatographically homogeneous *cis* form" should now be replaced by "*cis-trans*-diphenylbutadiene." The "All-*trans* form" in the same table refers to *trans-trans*-diphenylbutadiene.

Small-Scale Separation of the Three Stereoisomeric Diphenylbutadienes.—A solution which contained 1 mg. of each isomer in 10 ml. of petroleum ether was developed with the same solvent on alumina (20 × 2 cm.); the developer was forced through the column by nitrogen pressure in order to avoid partial evaporation of the filtrate. The fluorescent *trans-trans* compound remained near the top. Small samples of each fraction collected from the filtrate were submitted to the iodine-catalysis and fluorescence test as described. The first 120 ml. of the flow were found to be free of substance; subsequent 5-ml. fractions were tested with the following result ("*cis-cis*" or "*cis-trans*" refer to the configuration before iodine catalysis):

No. 1–7, strong fl.: *cis-cis*
8–9, weak fl.: *cis-cis*
10–12, almost no fl.: traces
13–21, very strong fl.: *cis-trans*
22–26, strong fl.: *cis-trans*
27–30, weak fl.: *cis-trans*
31, no fl.

The fractions were also tested spectroscopically; the extinction curves of fractions 3 and 16 are given in Fig. 10.

Summary

A comparative study of the *trans-trans-*, *cis-trans-*, and *cis-cis-* forms of 1,4-diphenylbutadiene is presented. The relative stability of the respective configurations depends on the nature of the photochemical or thermal treatment. Data characterizing the spectroscopic and chromatographic behavior are given, and the stereoisomeric diphenylbutadienes are compared with some spatial types of the carotenoids.

Isopiestic Measurements on the Primary Sodium and Potassium Salts of Malonic, Succinic and Adipic Acids at 25°

BY JEAN M. STOKES[1]

The order of the activity coefficient curves for the alkali formates, acetates, and hydroxides is Li < Na < K, a reversal of the usual order K < Na < Li which holds for the halides and many other salts. To account for this, Robinson and Harned[1a] have advanced an hypothesis of "localized hydrolysis," according to which anion and cation are "associated" through interaction with a polarized water molecule, an effect which may be expected to depend on the proton-accepting power of the anion. In order to study this effect for salts of acids of different strengths, the primary sodium and potassium phosphates have been investigated.[2] It was found, however, that these two salts had very low activity coefficients and ionic association probably occurred to a marked extent. Indeed, the primary phosphate ion seems to belong to what Scatchard[3] has termed the second class of anions, in which he included the nitrate, chlorate and perchlorate ions and to which recent measurements[4] indicate the bromate ion should be added.

Measurements are now reported on the salts of three acids of dissociation constant ranging from 10^{-3} to 10^{-5}.

Experimental

Solutions of the sodium and potassium salts of malonic, succinic and adipic acid were prepared by (a) half neutralization of the purified acid with hydroxide in aqueous solution and (b) precipitation of solid salt from alcoholic solutions of acid and base, digestion with alcohol and subsequent solution in water. The two methods gave similar results but the experimental points did not lie on a smooth isopiestic curve as well as other salts that have been investigated. This may be due to sensitivity to the exact composition of the alkali hydrogen salt or to the *p*H of the solution; high accuracy is not claimed for these results, but they are probably accurate to 1% and the order and position of the activity coefficient curves is therefore significant. The molalities of isopiestic solutions are given in Table I and the osmotic and activity coefficients calculated with the aid of the data for the reference salt, sodium chloride,[5] are given in Table II.

Discussion

The activity coefficient curve of sodium hydrogen adipate is close to that of potassium iodide while the potassium salt resembles potassium bromide; sodium and potassium hydrogen succinate are comparable with rubidium chloride and cesium bromide, respectively; sodium hydrogen malo-

If the reversal of order of the activity coefficient curves of the acetates, etc., is associated in any way with the strength of the acid from which the salt is derived, since the dissociation constants of malonic, succinic and adipic acid are 1.6×10^{-3}, 6.7×10^{-5} and 3.6×10^{-5}, respectively, a reversal of order might be expected with the succinates and adipates but not with the malonates. Figure 1, in which the activity coefficients are plotted, along with those for the acetates, shows that there is no reversal of order with these salts, although the difference between the curves for sodium and potassium hydrogen succinate and adipate is small compared with that found for the halides. This plot, however, does show that there is a difference

between salts of the type $COOH(CH_2)_nCOONa$ and $CH_3(CH_2)_nCOONa$, a difference which is marked in spite of the anomalous behavior of sodium caproate[6] at high concentration (probably due to micelle formation). Along with this difference between the two types of salts are to be noted the very low values of the activity coefficients of the salts now under investigation, suggesting that the hydrogen malonate, succinate and adipate ions belong to the same category as the nitrate, chlorate and primary phosphate ions. Thus, although "localized hydrolysis" may be a factor resulting in decreasing dispersion of the curves of the sodium and potassium salts as we proceed from the malonate to the adipate, there must be another factor of larger magnitude which lowers the curves of both the sodium and the potassium salts. It is difficult to explain this effect for the nitrate ion and it is equally difficult to understand why it should occur with ions of the hydrogen malonate type; furthermore, it is difficult to find a common factor between nitrates and malonates apart from their low activity coefficients.

I wish to thank Professor N. S. Bayliss for his kind permission to use the facilities of his department.

Summary

Isopiestic measurements have been made on solutions of the primary sodium and potassium salts of malonic, succinic and adipic acid and the osmotic and activity coefficients calculated.

Although these salts are derived from weak acids, their activity coefficient curves are in the order Na > K; in this respect they differ from the sodium salts of monobasic fatty acids. Moreover, their activity coefficients are very low and have an unexpected resemblance in this respect to sodium and potassium nitrate and the primary phosphates.

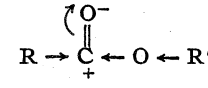
Effect of Structure on Reactivity.[1] I. Ammonolysis of Esters with Special Reference to the Electron Release Effects of Alkyl and Aryl Groups

BY MAXWELL GORDON,[2] JOHN G. MILLER AND ALLAN R. DAY

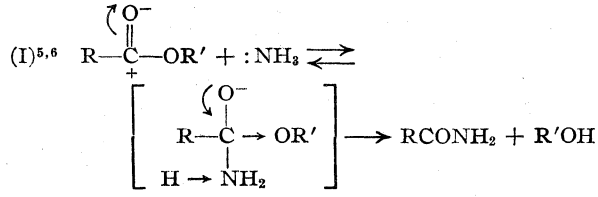
In the interest of augmenting present knowledge of the effect of structure on reactivity, it was decided to measure the rates of ammonolysis of several homologous series of esters. Although several reports have appeared in the literature on the effect of structural variations on the rate of ammonolysis of esters, they have embraced only limited numbers of esters, the possibility of ester interchange in working in alcoholic solution was often overlooked, no calculations of rate constants or activation energies were made in many cases, and the conclusions derived from these studies were, in some instances, conflicting. Most of the references in the literature on this subject have been discussed by Gorvin.[3] Additionally it has been shown by Komatsu and Nakayama[4] that ethyl phenylacetate reacts with ammonia fifteen times as rapidly as does ethyl benzoate.

The present study of the ammonolysis of esters was undertaken in an effort to show the effect of various R and R′ groups in the ester RCOOR′, with special emphasis on tracing the electron release effects in various homologous series. Most of the mechanisms which have been postulated for ammonolysis or hydrolysis of esters[5] indicate that the reactivity of the ester depends on the polarization of the carbonyl group in the ester which then provides the center for nucleophilic attack at the carbon of the carboxyl group. From this representation it may be seen that the greater



the electron release of the R or R′ group, the slower should be the rate of ammonolysis of the ester since the positive charge on the carbonyl carbon would be reduced in magnitude.

One may consider two possible mechanisms for the ammonolysis of esters



Betts and Hammett[7] suggested that both the am-

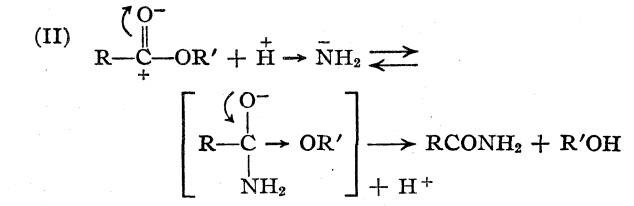
monia amide ion and molecular ammonia are the attacking reagents in ammonolysis.



Both mechanisms involve the addition of a nucleophilic agent to the carbonyl carbon atom. The fact that the presence of a polar (ionizing) solvent is necessary for ammonolysis to occur readily suggests that (II) is more probable than I. It is not necessary to postulate free amide ions $(NH_2)^-$ although they may exist to some extent. It is possible that through hydrogen bonding the polarization of the H—NH_2 bond may be increased to the point that it simulates ionization.

Experimental

It was originally hoped to carry out the ammonolysis of esters in anhydrous media, but preliminary experiments showed that ammonolysis of most esters will not proceed at a useful rate in anhydrous dioxane or methanol. This result confirms the work of Grant and Hinshelwood[8] and others.[9]

As Gorvin[3] has noted, aqueous ammonia is not suitable for accurate kinetic studies owing to the complicating factors introduced by the low solubility of the ester. This difficulty may be overcome by the use of suitable organic diluents in the reaction mixtures. The principal solvent employed in this study was 1,4-dioxane. This compound was used for all series of esters except where all of the esters of a series contained the same alcohol component, in which case that alcohol was used as the diluent. Alcohol was used as a diluent where possible because ammonolysis proceeds roughly twice as rapidly in primary alcohols as in dioxane, provided water is present in each case. Dioxane was selected for use as a result of a process of elimination. Alcohols, generally speaking, were unsatisfactory due to the possibility of ester interchange. There was no method immediately evident for ascertaining the extent of this side reaction. Other solvents react with either the esters or ammonia, or interfere with the subsequent titrations of the reaction mixtures, or are not soluble in water.

In the establishment of conditions for this study three major experimental factors had to be considered: (1) the kinetics of the reaction, which involves making the rate of reaction great enough to minimize the experimental errors involved in the measurements; (2) miscibility of the components, which means adjusting concentrations so that the entire series of reaction mixtures is kept homogeneous; (3) stability of ammonia solutions, which involves addition of sufficient water to avoid loss of ammonia in the course of the manipulations of the study. Since the above three factors are more or less mutually exclusive, it was only on the basis of a great deal of trial and error that a satisfactory set of conditions was arrived at that would hold for substantially all of the esters employed.

The dioxane used, a product of Carbide and Carbon Chemicals Corp., was purified by distillation from sodium metal. Alcohols used were freed from water by the method of Lund and Bjerrum.[10] Most of the esters used[11] were available commercially with the exception of methyl isobutyrate, methyl trimethylacetate, *n*-propyl benzoate, *t*-butyl benzoate, *t*-butyl acetate, β-naphthyl acetate, and *t*-butyl lactate. These esters were synthesized by a variety of methods, all of which have been described in the literature. Of special interest is the method of Richard[12] for esterifying sterically hindered acids. This procedure is seldom encountered in contemporary chemical literature.

An azeotrope of methanol and methyl trimethylacetate was encountered which is believed not to have been hitherto described. Its composition was 12.8% of ester by weight; b. p. 65.0° at 760 mm.

The esters, whether synthesized or obtained commercially, were dried over magnesium sulfate and fractionated in all-glass apparatus using an efficient column. The high boiling esters were distilled under reduced pressure. Refractive indices were used to ascertain final purity of esters employed.

Boiling points or melting points and refractive indices (D line) of the esters used were as follows: methyl acetate, b. p. 57.1° at 755 mm., $n^{20}D$ 1.3610; ethyl acetate, 77° at 760 mm., 1.3728 at 20°; *n*-propyl acetate, 101–101.5° at 750 mm., 1.3844, 20°; isopropyl acetate, 88.5–89.0° at 750 mm., 1.3771, 20°; *n*-butyl acetate, 126.5° at 750 mm., 1.3938 at 20°; isobutyl acetate, 116.5–117.0° at 750 mm., 1.3900 at 20°; *s*-butyl acetate, 112.0–112.5° at 755 mm., 1.3885 at 20°; *t*-butyl acetate, 97.5–98.0° at 755 mm., 1.3860 at 20°; *n*-amyl acetate, 148.0–148.5° at 755 mm., 1.4025 at 20°; benzyl acetate, 93° at 7 mm., 1.5020 at 20°; phenyl acetate, 78° at 10 mm., 1.5033 at 20°; vinyl acetate, 69–70° at 755 mm., 1.3941 at 20°; α-naphthyl acetate, m. p. 44–45°; β-naphthyl acetate, m. p. 68°; methyl benzoate, 85° at 10 mm., 1.5170 at 20°; ethyl benzoate, 90° at 10 mm., 1.5058 at 20°; *n*-propyl benzoate, 101.0–101.5° at 9 mm., 1.5000 at 20°; isopropyl benzoate, 94° at 10 mm., 1.4947 at 20°; *t*-butyl benzoate, 105° at 16 mm., 1.4896 at 25°; phenyl benzoate, m. p. 70°; benzyl benzoate, 110° at 0.5 mm., 1.5685 at 20°; methyl formate, 31.5° at 760 mm., 1.3438 at 20°; methyl propionate, 79° at 750 mm., 1.3770 at 20°; methyl isobutyrate, 92.0–92.5° at 755 mm., 1.3840 at 20°; methyl trimethylacetate, 99.5–100.5° at 760 mm., 1.3908 at 20°; methyl crotonate, 119–120° at 755 mm., 1.4250 at 20°; methyl phenylacetate, 79° at 5 mm., 1.5090 at 16°; methyl lactate, 50° at 17 mm., 1.4140 at 20°; ethyl lactate, 54° at 12 mm., 1.4131 at 20°; *n*-propyl lactate, 71° at 20 mm., 1.4170 at 20°; isopropyl lactate, 51° at 8 mm., 1.4102 at 20°; *n*-butyl lactate, 77° at 13 mm., 1.4215 at 20°; isobutyl lactate, 58° at 3.5 mm., 1.4184 at 20°; *s*-butyl lactate, 42° at 1 mm., 1.4168 at 20°; *t*-butyl lactate, 40° at 6 mm., 1.4085 at 30°; *n*-amyl lactate, 66° at 1 mm., 1.4261 at 20°; allyl lactate, 55° at 3 mm., 1.4369 at 20°; *n*-butyl hydracrylate, 69° at 0.5 mm., 1.4288 at 20°.

Phenyl acetate,[a] 0.5 hr., ammonalysis 86.6%, const. 2.02

Vinyl acetate,[a] 0.5 hr., ammonalysis 75.3%, const. 1.34

[a] Ammonolysis was too rapid for a satisfactory rate study, time, 0.5 hour.

In carrying out the ammonolyses, equivalent molar quantities of the various esters were measured into 10-ml. glass ampoules by means of a 1-ml. glass syringe graduated in 0.01 ml. subdivisions and fitted with a #16 gage 3-inch stainless steel needle. The use of the above device made possible the introduction of the esters into the ampoules without wetting the necks of the containers. It was found by a series of control experiments that the quantities of ester delivered by this method were reproducible with an error of less than one-tenth of one per cent. In the case of the volatile esters the opening of the ampoule was tightly closed by means of half a gelatin capsule of appropriate size, then the needle was pushed through the top of the capsule into the ampoule. In all cases the ampoules were closed off by means of intact capsules after the introduction of the esters and were then chilled in ice.

Reproducible results were obtained in the manipulation of the aqueous dioxane–ammonia solutions only by filling eight ampoules from each 100-ml. buretful of solution, using the first and last 10 ml. of each buretful as controls. These control portions of ammonia solution were run into 4% boric acid solution and titrated directly with half-normal hydrochloric acid using methyl red as the indicator. Following the introduction of both ester and ammonia the ampoules were again cooled in ice and then rapidly sealed off in a hot flame, first removing the gelatin closure. This chilling procedure cut down the loss of ammonia during the sealing operation and reduced the likelihood of leaks developing in the sealed ampoules. The ampoules were then shaken thoroughly and placed in a constant temperature bath.

A series of duplicate reaction mixtures was started for each ester. At intervals the ampoules were removed from the thermostat and again chilled. The ampoules were then opened, rinsed into 4% boric acid solution, and titrated directly with standard acid as in the case of the blank runs. The accuracy of the method was ascertained by setting up a series of reaction mixtures and titrating them at intervals as before, but omitting the ester. These blank runs showed that the error in the rest of the method was less than that involved in titrating the solutions.

The amount of competing hydrolysis occurring in the ammonolysis of the acetates was determined by the method of Pucher[13] as modified by French.[14] Results of this direct analytical method corroborated the results obtained in estimating ammonia consumed by difference.

(13) Pucher, Vickery and Leavenworth, *Ind. Eng. Chem., Anal. Ed.*, **7**, 152 (1935).

(14) French, Johnson and Ratekin, THIS JOURNAL, **58**, 1346 (1936).

Determination of activation energies for methyl acetate and the lactates was carried out by setting up parallel reaction mixtures of the various esters and running half of them at 25° and the rest at 30 or 35°. Determination of the activation energies for the benzoates, for the methyl esters other than acetate and formate, and for the acetates above methyl, was omitted because their low reaction velocity made the accurate measurement of temperature coefficients impossible. The ammonolysis of methyl formate proceeded too rapidly for the determination of activation energies with any accuracy.

Sources of Error

A major consideration in working with aqueous ammonia solutions is the possibility of simultaneous hydrolysis and ammonolysis of the ester. This matter will be discussed after presentation of the data.

The possibility of reversibility of the reaction was eliminated when it was found that acetamide will not react with alcohols in aqueous dioxane-ammonia solutions at the temperatures of the experiments. Other side reactions such as the formation of amines or double amides have been ruled out by various investigators. This aspect of the problem has been fully discussed by Betts and Hammett.[7] The possibilities for manipulative error were discussed in the description of the experimental method employed, and it is believed that the maximum error for any single determination is about 2%. The over-all errors persisting in any of the rate constants obtained graphically probably amount to less than 5%.

Results

The values found for the second order rate constants in the ammonolysis of esters of acetic acid at 25° are listed in Table I. Also tabulated are the percentages of total reaction for the times indicated. The amount of ester employed in all of the reaction mixtures of this investigation was 0.007 mole per 10 ml. reaction vessel, or 0.7 mole per liter. The ammonia concentration in every

α-Naphthyl acetate	.0473	.0458	.0429

[a] Reaction has gone to completion by the time 100 hours is reached, but this ester is included for purposes of comparison.

TABLE III

BIMOLECULAR REACTION RATES FOR AMMONOLYSIS OF BENZOATES AT 25°

Ester	Rate constant	Comparative rate
Phenyl benzoate[a]	0.0620	376
Methyl benzoate	.000165	1.00
Benzyl benzoate[b]	.000087	0.527
Ethyl benzoate	.000084	.509
n-Propyl benzoate	.000065	.391
Isopropyl benzoate	.000056	.341
t-Butyl benzoate	.000019	.116

[a] Owing to the high molecular weight of this ester only 0.467 mole/l. was used. Any greater amount led to separation of layers. Reaction time in this case was twenty-four hours. [b] 0.467 mole/l. of this ester was used.

case was between 2.5 and 2.8 moles/liter. All of the reaction mixtures contained ten moles of water/liter. The diluent used for this series was 1,4-dioxane. The rate constants are bimolecular and are expressed in liters/mole/hour.

Table II lists the relative rate constants for the acetates. All of the rate constants have been divided through by the corresponding rate for methyl acetate so that the latter always has the value unity in the tabulation, and the comparative rates of the other esters may be seen accordingly.

The ammonolysis of benzoic acid esters proceeded so slowly that, in most cases, a satisfactory kinetic study was impractical. The differences in ammonia content found on successive titrations over a period of several days were often so small as to be within the limits of experimental error of the method. Accordingly, only one titration was carried out on each ester after reacting with aqueous dioxane–ammonia for 618.5 hours. Dioxane was used as the diluent. Bimolecular rate constants and comparative rates of ammonolysis of the benzoates are given in Table III.

Second order rate constants and percentages of total reaction in the ammonolysis of lactic acid esters at 30° are listed in Table IV. The diluent for this series was dioxane.

The values found for the second order rate constants and the percentages of total reaction in the ammonolysis of the methyl esters of various acids at 25° are listed in Table VI. The diluent used for this series was absolute methanol.

The compilation in Table VIII is taken from Tables II, III and V in an effort to determine what correlation may be found between structure and reactivity.

The extent of ammonolysis and hydrolysis of acetic acid esters is shown in Table IX.

From the temperature coefficients of ammonolysis an approximate evaluation of the activation energies was possible using the integrated form of the Arrhenius equation. Calculations of PZ factors from the equation $k = PZe^{-A/RT}$ showed that errors in the values of activation energies were too great to permit the use of entropy changes to show the validity of structure–reactivity correlations.

methyl acetate and the lactates are listed in Table X.

Discussion

While the comparative rates for similar esters of different acids (Table VIII) show that the correlation of structure and reactivity is still far from quantitative, they do show that the relative magnitude of effects may be determined. The variations in reaction rates of most of the esters studied are at least qualitatively predictable from the known electronegativity of the groups attached. While it is true that probably both steric and polarization effects contribute to the variations in rate constants among the reactions of this study, the fact that, except for the case of the naphthyl esters to be discussed later, an explanation based on polarization effects has been found to be adequate has led to the emphasis on the latter. The relative rates for the ammonolysis of the different esters agree in the main with published values obtained in alkaline and acid hydrolysis of esters.[15]

In all of the ester series where the acid component was held constant, we noted that the reactivity of the ester toward ammonia decreased with increase of the molecular weight of the alcohol

component, and, to an even greater extent, with increased branching of the alcohol. Generally speaking, esters of primary alcohols ammonolyze more readily than those of secondary alcohols, and the latter in turn react with ammonia more rapidly than the esters of tertiary alcohols: $CH_3 > C_2H_5 > CH_3CH_2CH_2 > (CH_3)_2CH > (CH_3)_3C$. These results are in accord with accepted electron release effects of alkyl groups.

In the acetate series we found that vinyl acetate had several hundred times the reactivity of ethyl acetate. Writing the resonance forms for vinyl acetate, we see that the positive charge on the oxygen tends to make the carbonyl carbon more

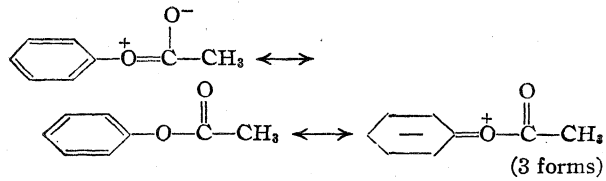
$$CH_2{=}CH{-}O{-} \longleftrightarrow {}^{-}CH_2{-}CH{=}O^{+}{-}$$

electrophilic, which in turn greatly enhances the reactivity of this carbon toward a nucleophilic

$$^{-}CH_2{-}CH{=}O^{+} \leftarrow \overset{+}{C}(=O){-}CH_3$$

attacking species. The latter, in this case, is probably either the ammonia amide ion or a hydrogen bonded water–ammonia complex.

The very great reactivity of phenyl acetate toward ammonia, compared to the other acetates, is likewise attributable to resonance, in this case mainly between the benzene ring and the oxygen bound to it. Writing the various resonance forms we see that all of the charged structures have a positively charged center adjoining the carbonyl carbon. The effect of this charge concentration



(3 forms)

on the reactivity of phenyl acetate is the same as that discussed above for vinyl acetate.

On the basis of resonance it might further be anticipated that the naphthyl acetates would have similarly enhanced reactivities. However, these esters react very slowly with ammonia. This phenomenon can be partly attributed to the large size of the naphthyl groups. Atomic models indicate the reduced susceptibility of the carbonyl carbon to attack due to steric hindrance. In the forms of phenyl acetate in which there is resonance with the benzene ring, there is the spatial requirement that the carbonyl carbon be coplanar with the ring. The decreased likelihood of this restriction being complied with in the naphthyl acetates may further account for their low reactivity toward ammonia.

It was noted that benzyl acetate ammonolyzed twice as rapidly as ethyl acetate and allyl lactate reacted with ammonia five times as rapidly as did *n*-propyl lactate. From these results it must be concluded that the benzyl group is less electron releasing than the ethyl, and the allyl less than the *n*-propyl. These relationships would seem to be at odds with the well-known behavior of the halides of these compounds. For example, benzyl chloride is known to be more reactive than ethyl chloride and this phenomenon is popularly attributed to the greater polarization of the carbon–halogen bond in the benzyl chloride, from which one would have to conclude that the benzyl group is more electron releasing than the ethyl. Similarly the greater reactivity of allyl chloride over *n*-propyl chloride would lead one to believe that the allyl group is more electron releasing than the *n*-propyl.

However, reference to dipole moments shows that precisely the reverse is true. The relative dipole moments of ethyl bromide[16] and benzyl bromide[17] are 2.12 (in benzene) and 1.85 (in benzene), respectively, indicating that the carbon–halogen bond is less polarized in the latter, and that the electron release effect of the benzyl group must be less than that of the ethyl group. Similarly the relative dipole moments of *n*-propyl bromide[16] and allyl bromide[18] are 2.00 (in benzene) and 1.79 (in benzene), respectively, again leading to a conclusion supporting the results of this investigation, namely, that the allyl group is relatively less electron releasing than the *n*-propyl.

The usual high reactivity attributed to allyl halides, alcohols, etc., in unimolecular displacements, when compared to the corresponding saturated

(16) Daily, *Phys. Rev.*, [ii] **34**, 548 (1929).

alkyl compounds, is due to stabilization of the carbonium ion through resonance. However, only after ionization does this stabilizing influence

$$CH_2{=}CH{-}CH_2{-}X \longrightarrow CH_2{=}CH{-}CH_2^+ + X^- \quad \updownarrow \quad {}^+CH_2{-}CH{=}CH_2$$

operate, so that while the allyl compound is in the un-ionized form it is perfectly consistent to say that the polarization of the carbon–halogen bond in allyl halides is lower than in *n*-propyl halides.

There is abundant evidence in the literature, well summarized by Branch and Calvin,[19] to show the great effect of resonance stabilization by cations such as allyl and benzyl groups in bimolecular (S_N2) displacements.

The fact that the reactivity of benzyl halides is greater than that of ethyl halides is due to the presence of the allylic system in the former. So we see that the influence on reactivity attributed to the allyl and benzyl groups in this investigation is not incompatible with the normal behavior of these compounds in displacement reactions, since in ammonolysis there is no cleavage of the alkyl–oxygen bond.

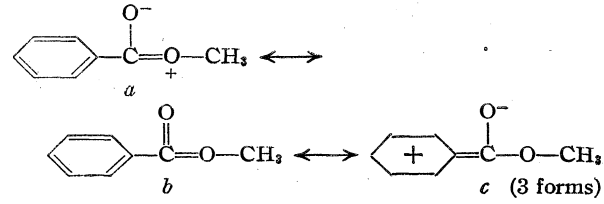
In the case of the saturated aliphatic esters of benzoic and lactic acids the same generalizations apply as in the case of the acetates. The high reactivity of allyl lactate, as compared to *n*-propyl lactate, was noted above. The rate for vinyl esters is much greater than that of allyl esters due to the absence of resonance in the un-ionized form of the latter. *n*-Butyl hydracylate is less than one-fourth as reactive as *n*-butyl lactate because the electron attracting hydroxyl group is farther removed, in *n*-butyl hydracrylate, from the reactive center of the molecule. In general, all of the lactates have from ten to twenty times the reactivity toward ammonia that is exhibited by the corresponding acetates. Here again the difference is due, in part, to the presence of an electron attracting group in the lactic acid esters. Furthermore, to the extent that it occurs, hydrogen bonding in the lactates and hydracrylates could contribute to the electrophilic activity of the carbonyl carbon atom since it assists in the polarization of the carbonyl carbon–oxygen bond. However, hydrogen bonding of the hydroxyl hydrogen to the carbonyl oxygen probably reduces the inductive effect of the hydroxyl group, so that the over-all contribution of hydrogen bonding to the

$$CH_3{-}CH \leftarrow {}^+C{-}O{-}R \quad \downarrow \quad O{-}H\cdots O$$

rate of ammonolysis of the lactates is open to question.

The methyl esters of the various acids show that the variation of R groups in the ester RCOOR′ results in a change in reactivity analogous to that obtained by varying the R′ groups as discussed earlier. However, methyl trimethylacetate has a much lower rate, compared to methyl acetate, than *t*-butyl acetate has compared to methyl acetate. The greater retardation effect of the R_3C grouping in methyl trimethylacetate can be attributed to the closer proximity of that group to the carbonyl carbon than is the case in *t*-butyl acetate. The oxygen, due to its unshared electrons, is probably an efficient conductor of inductive forces, but since the inductive effect falls off rapidly with distance, replacing a given R group in the ester RCOOR′ by any given radical will have greater effect on the rate of ammonolysis of the ester than replacing the corresponding R′ group by the same radical.

In methyl benzoate, unlike phenyl acetate, the conjugation of the carbonyl group with the benzene ring decreases the reactivity toward ammonia. It should be noted that the oxygen attached to the methyl group of methyl benzoate is less positive than that of methyl acetate due to resonance with the ring in the former ester. Writing the resonance structures of methyl benzoate we can see the reasons for the reduced electrophilic nature of the carbonyl carbon atom. Methyl acetate has only the forms corresponding to *a* and *b* above and would therefore be expected to ammonolyze more rapidly than methyl benzoate.



a *b* *c* (3 forms)

In the reaction of methyl crotonate Morsch[20] reported predominantly 1,4-addition of ammonia to give methyl 3-aminobutyrate, which he isolated. In this laboratory these results were confirmed by titrating starting mixtures and reaction products by the bromate–bromide method, whereby about 96% of the product was found to be saturated. These results probably account for the rise in reaction rate constants observed with this ester, as compared with the downward drift in the purely ammonolytic reactions.

In the ammonolysis of methyl formate it was found that the competing hydrolytic reaction may account for as much as 40% of the ester consumed, but nevertheless the ammonia reaction was still several hundred times as rapid as in the case of methyl acetate. Work which had been planned with other formic acid esters was dropped due to the great amount of competing hydrolysis. Another objection to the use of formates was the fact that reaction with ammonia was so rapid as to make accurate kinetic studies exceedingly difficult.

(20) Morsch, *Monatsh.*, 60, 50 (1932).

The amount of hydrolysis found in the case of esters of acetic acid has been given in Table IX. It should be appreciated that hydrolysis figures presented represent extreme upper limits in view of the length of reaction time. These extreme periods of time were specifically employed because the amounts of hydrolysis obtained over periods of time comparable to those used in the ammonolytic studies were of the same order of magnitude as the experimental error of the method and hence meaningless. Since the extent of hydrolysis in all cases tabulated could not be evaluated for periods comparable to those used in the ammonolytic determinations, we were unable to apply any correction to the calculations for the rates of ammonolysis in order to account for the side reaction. In view of the original objectives of this study, an additional expenditure of time on the further study of the hydrolysis of esters was considered unwarranted.[21]

The relative extent of hydrolysis in these experiments, even for extreme periods of reaction time, is well below that encountered by other investigators[14,22] owing to the lower concentrations of water (18%) employed in this Laboratory.

From the foregoing remarks it should be clear that, for the periods of time used in ammonolysis in this study, the amount of hydrolysis is within the limits of experimental error and hence not significant in its effect on the structure–reactivity correlations.

The second order rate constants for the ammonolysis of esters have been found to drift downward with time. The only exception was the case of methyl crotonate, in which, as discussed earlier, the principal reaction was not ammonolysis. The downward drift of rate constants is attributable to two causes; first, to the accumulation of ammonium ions from the competing hydrolytic reaction, the ammonium ions acting to retard the principal reaction and, second, to the fact that reactions were carried out in concentrated solutions in which we would expect to find considerable deviation from ideality.

(21) Results of unpublished work show that the same qualitative structure-reactivity correlations are obtained by working in anhydrous ethylene glycol–ammonia, in which hydrolysis is improbable, as are reported in this paper for aqeuous solutions.

Summary

The rates of ammonolysis of several series of esters have been determined and have been found to be regulated by the electron release effects of both the R and R′ groups in the ester RCOOR′, with variations of R having the greater effect due to the rapid falling off of the inductive effect with distance.

A kinetic study has revealed the following order of reactivity of acetates with aqueous ammonia: phenyl > vinyl > methyl > benzyl > ethyl > *n*-propyl > *n*-butyl > *n*-amyl > isopropyl > isobutyl > *s*-butyl > *t*-butyl > β-naphthyl > α-naphthyl.

A study of the reactivity of benzoates indicated the following order: phenyl > methyl > benzyl > ethyl > *n*-propyl > isopropyl > *t*-butyl.

The following order of reactivity in the ammonolysis of lactates was observed: methyl > allyl > ethyl > *n*-propyl > *n*-butyl > *n*-amyl > isobutyl > isopropyl > *s*-butyl > *t*-butyl.

By utilizing a series of methyl esters of different acids the effects of structural variations on the acid side of the ester molecule were observed. The following order of ammonolysis of methyl esters was obtained: formate > lactate > acetate > phenylacetate > propionate > benzoate > isobutyrate > trimethylacetate.

In general the relative rates of ammonolysis obtained by varying the alcohol and acid components of the ester follow the anticipated electron release effects and confirm the results obtained by other investigators in the acid and alkaline hydrolysis of esters.

An azeotrope of methanol and methyl trimethylacetate has been described.

9,9-Difluorofluorene

BY FRANCIS EARL RAY AND CLARENCE E. ALBERTSON

Only the following fluorine derivatives of fluorene have been prepared: 4-fluoro-5-nitro-1-methylfluorene,[1] 2-fluorofluorenone and its oxime,[2,3] 2-fluoro-9,9-dichlorofluorene and several 9,9- condensation products, and perfluorofluorane ($C_{13}F_{22}$).[4]

Since the 9-position in fluorene has aliphatic properties and has never been fluorinated independently of the rest of the molecule, it seemed of interest to attempt the preparation of 9,9-difluorofluorene. The difluoro compound was selected because it seemed doubtful if the allylic character of the 9-carbon[5] would permit the preparation of 9-monofluorofluorene.

Little difficulty was expected in the preparation of 9,9-difluorofluorene because Henne and Leicester[6] had reported the preparation of diphenyldifluoromethane in yields of 60%.

We treated 9,9-dichlorofluorene with hydrogen fluoride in the presence of mercuric oxide. To reduce the violence of the reaction, toluene or chlorobenzene was used as a diluent. The products that were obtained from the reaction were fluorenone, tolylmercuric chloride and mercuric chloride.

It is not clear whether the formation of fluorenone is the primary reaction. It is possible that hydrogen fluoride reacted with mercuric oxide to produce water and that 9,9-dichlorofluorene was subsequently hydrolyzed to fluorenone.

$$2HF + HgO \longrightarrow H_2O + HgF_2$$

$$\begin{matrix} C_6H_4 \\ | \\ C_6H_4 \end{matrix}\!\!>\!CCl_2 + H_2O \longrightarrow \begin{matrix} C_6H_4 \\ | \\ C_6H_4 \end{matrix}\!\!>\!CO + 2HCl$$

Other catalysts such as antimony tri- and pentafluoride and zinc fluoride also gave fluorenone or intractable tars as did the use of uncatalyzed hydrogen fluoride.

Impure 9,9-fluorochlorofluorene may have been present in some of these products. The monofluorochloro derivatives are generally less stable than the difluoro compounds.[7]

Despite the fact that hydrous mercuric fluoride was entirely unsuitable as a catalyst, Henne[8] later found that it was not necessary to isolate mercuric fluoride but simply passed a stream of hydrogen fluoride into the mixture of mercuric oxide and the substance. This was the first method tried and it led to the formation of fluorenone.

The inconvenient preparation of mercuric fluoride from mercuric chloride and fluorine and the bad effects of mercuric oxide in the second method might both be avoided by passing hydrogen fluoride into a mixture of mercuric chloride and the substance to be fluorinated. Daudt and Youker, U. S. Patent 2,005,707, disclose the use of mercuric chloride in vapor phase hydrofluorination at elevated temperatures but give no experimental details.

On carrying out this experiment at 70°, we obtained the desired 9,9-difluorofluorene in addition to some of the unstable material obtained previously and thought to be 9,9-fluorochlorofluorene.

An attempt to increase the yield by operating at 100 pounds pressure produced a sponge-like rubbery hydrocarbon mass of approximately 2800 molecular weight.

9,9-Difluorofluorene formed white crystals that melted at 47–48° and analyzed correctly for fluorine and had the required molecular weight. After standing for two weeks in a desiccator evidence of decomposition was apparent.

It is thus seen that mercuric chloride and hydrogen fluoride form a fluorinating agent that is especially useful in the conversion of the less stable halides to fluorides or in the preparation of the less stable fluorides.

Experimental

9,9-Dichlorofluorene.—Fluorenone was prepared by the method of Huntress, Hershberger and Cliff[9] except that the acetic acid was reduced from 20 moles to 13 moles. This makes the preparation of large amounts more convenient and slightly improves the yields. From 200 g. of fluorene there was obtained some 148 g., 68%, melting at 82.8 to 83.1°. Fluorenone was converted to 9,9-dichlorofluorene by the following modification of Smedley's[10] method.

To 15 g. (0.1 mole) of phosphorus oxychloride in 60 cc. of toluene are added 90 g. (0.5 mole) of fluorenone and 114 g. (0.55 mole) of phosphorus pentachloride. The mixture was heated for three hours on the water-bath and agitated intermittently. The phosphorus pentachloride had disappeared at the end of the first hour and the mixture became dark brown in color. The reaction mass was subjected to vacuum distillation (25 mm.) to remove most of the phosphorus compounds. The residue was dissolved in benzene, washed twice with ice water and dried over calcium chloride. The benzene was removed under reduced pressure and the residue recrystallized from glacial acetic acid. A 66% yield of almost colorless crystals melting at 102.9 to 103.1° was obtained. Smedley[10] gives m. p. 103°. The pure product is quite stable if protected from moisture. Samples of impure material decomposed within a week to give a sticky green-yellow mass with the sharp odor of hydrogen chloride.

9,9-Difluorofluorene.—Most of the experiments were carried out in a stirred copper reactor with a thermometer well and a copper inlet tube. In general runs using about 0.5 mole of 9,9-dichlorofluorene were made. An excess

of 10–28% of mercury salt and 50–60% of hydrofluoric acid was used. Some runs employed 0.25 mole of the chloride and as much as 200% excess hydrofluoric acid. The successful preparation of 9,9-difluorofluorene is described in detail below.

Five-tenths mole (117 g.) of 9,9-dichlorofluorene was dissolved in 200 cc. of chlorobenzene and 0.37 mole (100 g.) of mercuric chloride was now added. Hydrogen fluoride next was bubbled into the stirred solution at a temperature of 30°. After thirty minutes no apparent reaction had occurred so the temperature was raised. At 70° the solution turned a very dark green but in contrast to the large amount of heat liberated when mercuric oxide and hydrofluoric acid are used this reaction showed little evidence of heat evolution. The temperature did not exceed 81° and the time of reaction was one and one-half hours.

The solution was washed with water and sodium carbonate solution, treated with Darco and distilled at 1–5 mm. The first fraction 55–115° (5 mm.), weighed 6 g. and was chlorobenzene. The second fraction, 115–130° (3 mm.), weighed 20 g. It was a light yellow, viscous oil. The third fraction, 125–135° (3 mm.), weighed 13 g. and came over as a yellow oil that solidified in the receiver. On standing overnight fraction 2 had changed to a thick tarry mass with gas bubbles and yellow crystals held in suspension. Some pressure was evidenced and fumes of hydrogen chloride and hydrogen fluoride were evolved when the container was unstoppered. A somewhat similar but much less pronounced effect was observed in fraction 3.

The yellow crystals were separated and recrystallized from ligroin, m. p. 47–48°. They contained fluorine but no chlorine.

Anal. Calcd. for $C_{13}H_8F_2$: F, 18.8; mol. wt., 202.2. Found: F, 17.9; mol. wt., 195.

From the decomposed material, fluorenone was isolated. Probably unstable 9,9-fluorochlorofluorene was the principal product in fraction 2.

Summary

9,9-Difluorofluorene has been prepared by treating 9,9-dichlorofluorene with hydrogen fluoride in the presence of mercuric chloride. It is somewhat unstable. Evidence has been found for the transitory existence of 9-chloro-9-fluorofluorene.

Mercuric chloride and hydrogen fluoride form a fluorinating agent that is especially useful in the preparation of the less stable fluorides.

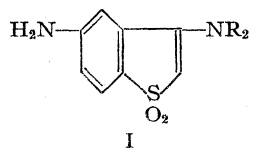
Studies in the Thianaphthene Series.[1] II. Aminothianaphthene-1-dioxides[2]

BY F. G. BORDWELL AND C. J. ALBISETTI, JR.[3]

In a previous paper[4] the synthesis of a sulfanilamide vinylog in which the sulfamyl group was separated from the aromatic ring by a vinyl group was described. As an extension in our synthesis of molecules with chemical characteristics similar to sulfanilamide, but with different stereochemical relationships of the functional groups, the synthesis of 3,5-diaminothianaphthene-1-dioxide (I, R = H) was undertaken. This molecule is a vinylog of sulfanilamide in which the sulfonyl and amino portions of the sulfamyl group have been separated by a vinyl group. It is also noteworthy because of its relationship to bis-(4-aminophenyl) sulfone, a compound which has aroused considerable interest because of its high bacteriostatic activity. Recently 2,8-diaminodibenzothiophene-5-dioxide and 2,8-diaminothiaxanthene-5-dioxide, which are closely related to I, have been synthesized for pharmacological testing.[5]



I

The simplest approach to I appeared to be nitration of 5-nitrothianaphthene, oxidation of the sulfur atom and reduction of the nitro groups.

The preparation of 5-nitrothianaphthene by decarboxylation of 5-nitro-2-thianaphthenecarboxylic acid[6] has been described by Fieser and Kennelly.[7] Our yields of 5-nitro-2-thianaphthenecarboxylic acid from crude 2-chloro-5-nitrobenzaldehyde were about 25%; which compares well with the 28% yield reported by Fieser and Kennelly[7] using pure 2-chloro-5-nitrobenzaldehyde, but is considerably lower than the maximum yield of 45% reported by Fries and his co-workers.[6] The decarboxylation was carried out by a slight modification of the method of Fieser and Kennelly,[7] which was found to be more convenient.

Nitration of 5-nitrothianaphthene to give a pure dinitrothianaphthene was not easy, since it was found that a third nitro group entered the molecule almost as readily as did the second nitro group. By carrying out the nitration with an equivalent amount of potassium nitrate in sulfuric acid at 0–5° for one hour a dinitrothianaphthene, m. p. 171°, was isolated in 46% yield. This compound is very probably 3,5-dinitrothianaphthene since the 3-position is known to be the most active

position in the thianaphthene nucleus toward ordinary substitution.[8]

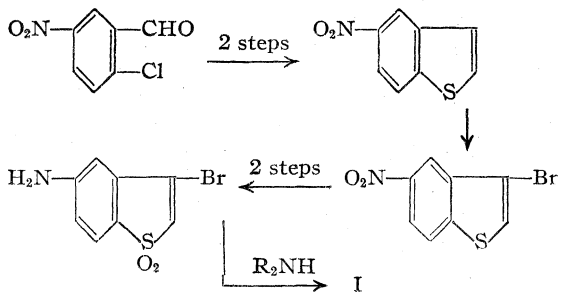
The sulfur atom in 3,5-dinitrothianaphthene was not oxidized by either 30% hydrogen peroxide in acetic acid–acetic anhydride or by sodium dichromate and sulfuric acid. The electron withdrawing effect of the 3-nitro group is responsible for the resistance of the sulfur atom to oxidation, since 5-nitrothianaphthene was readily oxidized to 5-nitrothianaphthene-1-dioxide by 30% hydrogen peroxide in acetic acid–acetic anhydride, but 3-nitrothianaphthene and 3,5,7-trinitrothianaphthene[9] were not oxidized under similar conditions.

No difficulty should be experienced in oxidizing the sulfur atom in 3,5-diacetamidothianaphthene, but attempts to obtain this compound were unsuccessful. In reductions of 3,5-dinitrothianaphthene using palladium on charcoal in the presence of acid the requisite hydrogen was absorbed but no pure products could be isolated. Similar results were obtained in attempted reductive acetylations using hydrogen and palladium catalyst and acetic anhydride in benzene solution. Reduction with tin and hydrochloric acid gave a crystalline tin salt, but attempts to liberate the amine from this salt or to acetylate it according to the method of Hemmecke[6] gave impure materials. Hemmecke[6] was unable to prepare 3-aminothianaphthene in a pure state. Apparently the 3-aminothianaphthenes, like the aminothiophenes, exist to a considerable extent in the imino form, and are very susceptible to oxidation and hydrolysis.

No difficulty is encountered in isolating and purifying aminothianaphthenes in which the amino group is in the benzenoid ring.[6] The nitro group in 5-nitrothianaphthene was reduced by the method of Fieser and Kennelly[7] and the 5-aminothianaphthene produced was converted to 5-(2-diethylaminoethylamino)-thianaphthene for pharmacological testing.[10] In a similar manner 5-aminothianaphthene-1-dioxide was prepared from 5-nitrothianaphthene-1-dioxide.

Synthesis of molecules of type I was finally accomplished by an alternate route. The bromine atom in 3-bromothianaphthene-1-dioxide has been found to be readily replaced by alkylamino groups[1]; therefore, 5-nitrothianaphthene was brominated to 3-bromo-5-nitrothianaphthene and the latter oxidized to 3-bromo-5-nitrothianaphthene-1-dioxide. The bromination of 5-nitrothianaphthene required considerably more vigorous conditions than are necessary for bromination of thianaphthene itself; a 64% yield of 3-bromo-5-nitrothianaphthene was obtained by treating 5-nitrothianaphthene with excess bromine in a refluxing carbon tetrachloride solution for seventy-two hours. The structure of the bromination product was proved by removal of the nitro group by reduction and deamination. The resulting bromothianaphthene was shown to be the 3-derivative by oxidation to 3-bromothianaphthene-1-dioxide.

Refluxing 3-bromo-5-nitrothianaphthene-1-dioxide in alcoholic solution with excess piperidine for thirty minutes gave a 94% yield of 3-(1-piperidino)-5-nitrothianaphthene-1-dioxide. A 94% yield of 3-diethylamino-5-nitrothianaphthene-1-dioxide was obtained in a similar reaction using diethylamine instead of piperidine. Reduction of the nitro group in these compounds could not be accomplished in acid solution without hydrolysis of the 3-alkylamino group.[1] It was, therefore, found to be more convenient to prepare compounds of type I by reduction of 3-bromo-5-nitrothianaphthene-1-dioxide to 3-bromo-5-aminothianaphthene-1-dioxide, which was then coupled with the desired amine. By this procedure 3-diethylamino-5-aminothianaphthene-1-dioxide (I, R = Et) was obtained in good yield. The preparation of 3,5-diaminothianaphthene-1-dioxide I(R = H) could no doubt be accomplished by the reaction of 3-bromo-5-aminothianaphthene-1-dioxide with ammonia according to the procedure used for 3-aminothianaphthene-1-dioxide,[1] but it was felt that 3-diethylamino-5-aminothianaphthene-1-dioxide would serve as well for pharmaceutical testing.



Acknowledgment.—We wish to express our appreciation to the du Pont Company for the fellowship which supported this work. A generous supply of *o*-chlorobenzaldehyde was furnished by the Heyden Chemical Corporation; the 60% sodium sulfide was furnished by the Hooker Electrochemical Company; and the thianaphthene was donated by the Texas Company.

Experimental[11,12]

5-Nitrothianaphthene-2-carboxylic Acid.—This compound was prepared from 2-chloro-5-nitrobenzaldehyde

(8) Fries and co-workers (ref. 6) reported the isolation of a dinitrothianaphthene, m. p. 171°, and a trinitrothianaphthene, m. p. 196°, by nitration of 3-nitrothianaphthene. At present we have under way an investigation of the nitration of thianaphthene, and we hope to be able to isolate the compounds reported by Fries, *et al.*, for comparison with those melting at the same temperature which were obtained by nitration of 5-nitrothianaphthene.

(9) The structure of this compound was not established, but its preparation by nitration of 5-nitrothianaphthene leaves little doubt as to the orientation of the nitro groups.

(10) Block, Lehr and Erlenmeyer, *Helv. Chim. Acta.*, **28**, 1406 (1945), have recently reported 5-aminothianaphthene to be one of the most active of the thirty-seven compounds tested *in vitro* against the tubercle bacillus.

(11) Microanalyses were by Mrs. Margaret Ledyard, Mrs. Nelda Mold and Miss Patricia Craig.

(12) All melting points were taken on a Fisher melting point block and are uncorrected.

essentially by the procedure described by Hemmecke[6] and by Fries, *et al.*,[6] except that the sodium disulfide was prepared and added in a 50% alcoholic solution.

5-Nitrothianaphthene.—A well-stirred mixture of 80 g. (0.36 mole) of 5-nitrothianaphthene-2-carboxylic acid, 400 ml. of quinoline and 20 g. of copper powder was gradually heated to the reflux temperature and the solution was stirred and allowed to reflux for thirty minutes. The mixture was cooled, poured onto 2 kg. of crushed ice and acidified with 18% hydrochloric acid. The suspension was cooled overnight and filtered. The air-dried solids were extracted with one 1.5-liter portion and three 500-ml. portions of boiling acetone (in one experiment a soxhlet extraction apparatus was used). The acetone was clarified with 5 g. of carbon (Norit A) and concentrated to 300 ml. by distillation. On cooling 43 g. (66.7%) of 5-nitrothianaphthene separated from the solution as a light tan powder, m. p. 149–150°.

5-(2-Diethylaminoethylamino)-thianaphthene.—This compound was prepared from 5-aminothianaphthene[7] by a procedure similar to that used by Gilman and Avakian[13] for the attachment of the γ-diethylaminopropylamino side chain on 2-aminodibenzothiophene. The product, obtained in 57% yield, was a yellow oil, b. p. 168–171° at 0.5 mm., which darkened on exposure to air.

Anal. Calcd. for $C_{14}H_{20}N_2S$: C, 67.70; H, 8.12. Found: C, 67.87; H, 7.90.

5-Nitrothianaphthene-1-dioxide.—To a warm mixture of 18.0 g. (0.1 mole) of 5-nitrothianaphthene in 100 ml. of acetic acid, 70 ml. of 30% hydrogen peroxide was added at such a rate as to keep the reaction from becoming too vigorous. A further 20 ml. of 30% hydrogen peroxide in 100 ml. of acetic acid was then added and the reaction mixture heated on the steam-bath for three hours. The hot solution was diluted to the point of turbidity and allowed to cool. The product was separated by filtration and purified by crystallization from 300 ml. of alcohol. There was obtained 13.8 g. (65.5%) of material melting at 164°. Further crystallization from alcohol raised the m. p. to 166°.

Anal. Calcd. for $C_8H_5NO_4S$: C, 45.48; H, 2.39. Found: C, 45.71; H, 2.62.

5-Aminothianaphthene-1-dioxide.—This compound was prepared in 44% yield from 5-nitrothianaphthene-1-dioxide by the procedure described by Fieser and Kennelly for reducing 5-nitrothianaphthene. After several crystallizations from 60% alcohol the material melted at 178°.

Anal. Calcd. for $C_8H_7NO_2S$: C, 53.02; H, 3.90. Found: C, 52.96; H, 4.12.

3,5-Dinitrothianaphthene.—To 120 ml. of concd. sulfuric acid stirred at 0–5° was slowly added 10.8 g. (0.06 mole) of carefully purified 5-nitrothianaphthene. To this was added, dropwise, a solution of 6.06 g. (0.06 mole) of potassium nitrate in 120 ml. of sulfuric acid. After being stirred for one hour at 0–5°, the mixture was poured onto ice. Crystallization of the product from 1 l. of a 1:1 benzene–Skellysolve C mixture gave 6.2 g. (46%) of 3,5-dinitrothianaphthene, m. p. 163–166°. Several crystallizations from alcohol gave pale yellow needles, m. p. 171°.

Anal. Calcd. for $C_8H_4N_2O_4S$: C, 42.87; H, 1.80. Found: C, 42.95; H, 1.89.

Unless carefully purified 5-nitrothianaphthene was used in the above method the conversion to 3,5-dinitrothianaphthene was low. 5-Nitrothianaphthene was essentially unchanged when 9.0 g. in 60 ml. of acetic acid was treated with a mixture of 5 ml. of water and 5 ml. of fuming nitric acid (d. 1.49) and the solution boiled for twenty minutes and diluted. This method has been used by Fries and Hemmecke[14] for the preparation of 3-nitrothianaphthene from thianaphthene. Similarly, treatment of a solution of 4.5 g. of 5-nitrothianaphthene in 40 ml. of acetic acid (d. 1.47), stirring the mixture at 40° for two hours and allowing to stand at room temperature for eighteen hours, did not bring about nitration. Except for the longer length of time and the more dilute reaction mixture used in the present experiment, these are the conditions used by Cullinane, Davies and Davies[15] for the successful nitration of dibenzothiophene.

3,5,7-Trinitrothianaphthene.—In another attempt to prepare 3,5-dinitrothianaphthene 1.8 g. (0.01 mole) of 5-nitrothianaphthene was added slowly to 36 ml. of fuming nitric acid at 0–5° over a period of thirty minutes. The mixture was held at this temperature and stirred for two hours and was then diluted. There was obtained 0.9 g. (33%) of material, m. p. 195–196°. After crystallization from 1-butanol the material melted at 196°.

Anal. Calcd. for $C_8H_3N_3O_6S$: C, 35.70; H, 1.12. Found: C, 35.73; H, 1.29.

Dinitration of 5-nitrothianaphthene also occurred by reaction at about 0° when 10 g. of material was added to a cold mixture of 100 ml. of concd. sulfuric acid and 100 ml. of fuming nitric acid (d. 1.49) and the mixture stirred while cold for two hours and diluted.

Attempted Oxidation of 3-Nitrothianaphthenes.—An attempt to oxidize 3,5-dinitrothianaphthene with sodium dichromate in the presence of sulfuric acid in acetic acid solution, according to the method described for dibenzothiophene[16] was unsuccessful. Hydrogen peroxide (30%) in acetic acid had no effect on 3,5-dinitrothianaphthene, and a refluxing solution of 30% hydrogen peroxide, acetic acid and acetic anhydride was likewise ineffective in attempts to convert 3-nitro-[14] and 3,5,7-trinitrothianaphthenes to the corresponding 1-dioxides.

3-Bromo-5-nitrothianaphthene.—A mixture of 7.2 g. (0.04 mole) of carefully purified 5-nitrothianaphthene, 19.2 g. (0.12 mole) of bromine and 800 ml. of chloroform was refluxed for seventy-two hours. The cooled solution was washed with aqueous sodium carbonate, dried over anhydrous sodium carbonate and concentrated. A total of 7.8 g. of material was obtained in three crops. On purification from ethanol 6.6 g. (64%) of material melting at 170–171° was obtained. A sample purified for analysis separated from ethanol in short, pale-yellow needles, m. p. 170.5–171°.

Anal. Calcd. for $C_8H_4NO_2SBr$: C, 37.22; H, 1.56. Found: C, 37.41; H, 1.87.

5-Amino-3-bromothianaphthene.—Reduction of 5-nitro-3-bromothianaphthene with stannous chloride and concd. hydrochloric acid was effected in 75% yield. The product was purified by crystallization from Skellysolve B, the last trace of pink color being removed with the aid of activated alumina. The compound was obtained as fine colorless needles, m. p. 84°.

Anal. Calcd. for C_8H_6NSBr: N, 6.14. Found: N, 6.18.

Proof of Structure of 5-Amino-3-bromothianaphthene.—Deamination was accomplished by diazotization and treatment with ethanol in the presence of copper powder.[17] Steam distillation of the product from an alkaline solution gave a yellow oil, which was oxidized with 30% hydrogen peroxide in acetic acid–acetic anhydride solution to a yellow solid. The purified compound melted at 181–182°, and a mixed melting point with 3-bromothianaphthene-1-dioxide[1] showed no depression.

3-Bromo-5-nitrothianaphthene-1-dioxide.—Oxidation of 3-bromo-5-nitrothianaphthene was accomplished in 74% yield by the method used for the preparation of 3-bromothianaphthene-1-dioxide.[1] The product was a cream-colored solid, m. p. 185–187°. Crystallization from ethanol gave material melting at 190–191°.

Anal. Calcd. for $C_8H_4NO_4SBr$: C, 33.12; H, 1.39. Found: C, 33.09; H, 1.53.

3-(1-Piperidino)-5-nitrothianaphthene-1-dioxide.—A 94% yield of this compound was obtained within thirty minutes by the reaction of 3-bromo-5-nitrothianaphthene-1-dioxide with a two molar excess of piperidine in refluxing ethanol solution. After crystallization from ethanol it melted at 197–198° (with dec.).

Anal. Calcd. for $C_{13}H_{14}O_4N_2S$: N, 9.53. Found: N, 9.29.

In a similar manner a 94% yield of **3-diethylamino-5-nitrothianaphthene-1-dioxide**, m. p. 210°, was obtained.

Anal. Calcd. for $C_{12}H_{14}O_4N_2S$: N, 9.92. Found: N, 9.74.

3-Bromo-5-aminothianaphthene-1-dioxide.—Reduction of 3-bromo-5-nitrothianaphthene-1-dioxide in ethanol solution was brought about in 81% yield using stannous chloride and concd. hydrochloric acid, according to the method of Fries, *et al.*[6] The product, m. p. 233°, was obtained as yellow needles by crystallization from ethanol.

Anal. Calcd. for $C_8H_6O_2NSBr$: N, 5.38. Found: N, 5.46.

3-Diethylamino-5-aminothianaphthene-1-dioxide.—By refluxing a mixture of 0.65 g. (0.0025 mole) of 3-bromo-5-aminothianaphthene-1-dioxide, 0.55 g. (0.0075 mole) of diethylamine and 10 ml. of ethanol for one hour, there was obtained 0.44 g. (70%) of a cream-colored solid, m. p. 180–184°. Purified four times by crystallization from ethanol, the material melted at 194°.

Anal. Calcd. for $C_{12}H_{16}O_2N_2S$: C, 57.11; H, 6.39. Found: C, 56.65; H, 6.43.

Summary

1. 3-Bromo-5-nitrothianaphthene was obtained in the bromination of 5-nitrothianaphthene. From the nitration of 5-nitrothianaphthene a dinitro- and trinitrothianaphthene were isolated, which are believed to be 3,5-dinitro- and 3,5,7-trinitrothianaphthene.

2. The electron attracting power of a nitro group in the 3-position of several thianaphthenes was found to be strong enough to prevent oxidation of the sulfur atom under the usual conditions.

3. 3-Diethylamino-5-aminothianaphthene-1-dioxide, which is a vinylog of N,N-diethyl sulfanilamide, and is closely related to bis-(4-aminophenyl)-sulfone has been prepared.

The Decomposition of Dibutylchloramine

BY GEORGE F WRIGHT

It has recently been found that aliphatic secondary amines can be nitrated in organic acid anhydrides when a chloride catalyst is present[1]; further, that the formation of the nitramine proceeds *via* the chloramine. Unsatisfactory yields of certain nitramines have been attributed to the instability of this intermediate.[2] It thus seemed worthwhile to re-investigate the stability of chloramines. Dibutylchloramine, which was chosen for this study, has been found to decompose to complex mixtures. Partial identification of these mixtures indicates that extensive intramolecular chlorination has taken place.

Chlorine, which has been reported as a product when chloramines are treated with excess hydrogen chloride,[3] was obtained in 68% yield from dibutylchloramine, I, in methanol. The expected dibutylammonium chloride, IV, was produced in 55% yield. It is not unreasonable to assume that this decomposition proceeds by formation from I of dibutylchloramine hydrochloride, II, which decomposes spontaneously in excess of hydrogen chloride to dibutylammonium chloride, IV.

The spontaneous decomposition of dibutylchloramine yielded dibutylammonium chloride released by reaction I → V. No chlorine was evolved. A liquid could be distilled out of the tar left when electropositive chlorine had disappeared, but this liquid showed a peculiar instability. Immediately after distillation a hydrochloride began to precipitate, but ceased after a certain amount had appeared. After redistillation the precipitation was resumed approximately to the same extent as before.

This distillate is considered to be a mixture of VI, VIII, X and XI which is formed by the action of chlorine released by initial decomposition of I. It is thought that the mixture loses hydrogen chloride until the basicity is reduced by hydrochloride formation, and that this loss is resumed after removal from the hydrochloride by distillation. The aldimine structure of the mixture has been confirmed by alkaline decomposition in presence of *p*-bromobenzenesulfonyl chloride to give the bromosulfonyl derivatives of monobutylamine.

Monobutylamine as its hydrochloride also was formed when the hydrochloride of the mixture was treated with methanol. The aldehydic fraction remaining after precipitation of the salt with ether was unstable, so it was treated with phenylhydrazine hydrochloride in ethanol. A distinctive blood-red color appeared which faded when the hydrochloride of ethylglyoxal precipitated. The color change is remindful of that which occurs when dichloroacetaldehyde is converted to glyoxal osazone.[4] Since the color change does not occur when ethylglyoxal is treated with phenylhydrazine, this hydrochloride, which is convertible to the known osazone,[5] is probably formed from

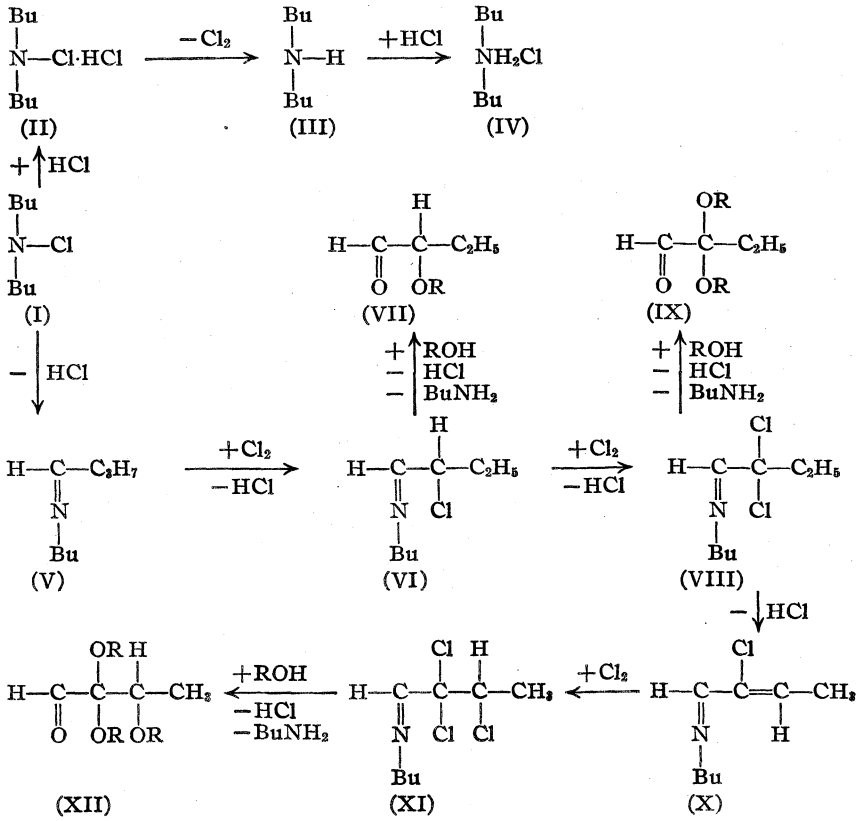
2,2-dichlorobutanal. On this basis the mixture must consist largely of VIII, and its analysis approximated that expected for VIII.



This analysis must, however, have been fortuitous, because in hot ethanol–hydrochloric acid a complex mixture of dinitrophenylhydrazones precipitated after a reproducible and characteristic induction period, presumed to involve alcoholysis. The least soluble compound in the complex mixture from dinitrophenylhydrazine treatment was, according to its analysis, the dinitrophenylosazone of ethoxyethylglyoxal, XII (R = Et, shown as its diethyl ketal). Substantiation for the constitution of XII was obtained when methanolic dinitrophenylhydrazine produced the homologous methyl ether (R = Me). Out of the remaining mixture only the most soluble compound could be identified by analysis; it was the 2,4-dinitrophenylhydrazone of 2-ethoxybutanal, VII. Thus evidence is at hand for three compounds in the postulated mixture, VI, VIII, X and XI.

The reactions I → IX seem to occur in one operation when dibutylchloramine is decomposed during fourteen hours in boiling ethanol. From the solution could be isolated (on the mole for mole basis) a 23% yield of monobutylamine, a 48% yield of dibutylamine, a 9% yield tentatively identified as *n*-butyl-N-butyramide; and finally ethylglyoxal was identified as its osazone. The ethylglyoxal must have been present as such or as its diethylketal, IX, since the red color was not observed during osazone formation.

The decomposition of dibutylchloramine in acetic acid was very slow at 25° but could be accelerated to completion (negative test for electropositive chlorine) in one hour by reaction at 90°. A 39% yield of dibutylammonium chloride was formed, as well as two distillable fractions. Neither of these was N-*n*-butylpyrrolidine.[6] The lower boiling of the two fractions was undoubtedly dibutylacetamide. The other fraction does not undergo the characteristic delayed precipitation with ethanolic dinitrophenylhydrazine.

The decomposition of dibutylchloramine in acetic anhydride was even more extensive than in the solvents recorded above. Reaction in this anhydrous medium was much more rapid than in acetic acid or ethanol, and was violent at 65°. A low yield of dibutylammonium chloride was produced when one or two equivalents of the anhydride were employed, but none was found when three equivalents were used.

The distillate from the residue was unstable. Partial separation provided a 21% yield of butyl butyramide,[2] at least 20% of dibutylacetamide, and two aldehydic fractions from which phenylhydrazine derivatives of ethylglyoxal were obtained.

Aid from the Canadian National Research Council is gratefully acknowledged.

Experimental[7a]

Dibutylchloramine with Hydrogen Chloride.—Five grams (0.0316 mole) of dibutylchloramine in 12 cc. of methanol was cooled to 0° while hydrogen chloride was passed through until saturation. The chlorine which was evolved amounted to 0.023 mole (68%). The residual salts remaining after evaporation of the solvent weighed 3.8 g. and after neutralization with alkali were identified by distillation as 0.02 g. of butylamine, 2.30 g. (55%) of dibutylamine and 0.04 g. of an oil which contained combined chlorine. Aldehydic material was lost during the evaporations, but a remaining trace gave a derivative with dinitrophenylhydrazine melting at 234°. According to its mixed melting point this was identical with the ethoxyethylglyoxal dinitrophenylosazone which is discussed later.

(6) G. H. Coleman and G. E. Goheen, THIS JOURNAL, **60**, 730 (1938).

(7a) All melting points have been corrected against known standards.

Dibutylchloramine with Sulfuric Acid–Water.—When 42.3 g. (0.26 mole) of dibutylchloramine was added to a mixture of 80 cc. (1.5 mole) *concd.* sulfuric acid and 30 cc. (1.67 mole) of water it was necessary to cool the mixture slightly. It was heated one day at 90° with strong evolution of chlorine, but at the end of this time, the electropositive chlorine test was negative. The whole was poured into ice and extracted with ether to remove a little oil which was discarded. The cooled aqueous layer was made basic with 135 g. of sodium hydroxide and was then extracted with ether and this solution dried with sodium hydroxide. Distillation yielded 20.3 g., b. p. 42–51° (11 mm.), $n^{25}D$ 1.4327, of N-butylpyrrolidine in 61% of the theoretical yield. This was redistilled at 155–157° (754 mm.) to free it from contamination with an impurity which contained chlorine. The distillate, which had the same refractive index, was identified by precipitation of N-butylpyrrolidine picrate from hydrochloric acid solution with saturated picric acid, m. p. 123–124.5°, after crystallization from 95% ethanol.[7]

Dibutylchloramine in Ethanol.—A solution of 16.3 g. (0.1 mole) of dibutylchloramine in 50 cc. of absolute ethanol became very dark after boiling for fourteen hours until a negative electropositive chlorine test was obtained. The ethanol was removed under 150 mm. pressure, the residue taken up in 2% hydrochloric acid and extracted three times with ether. This ether solution, dried with magnesium sulfate, was distilled to yield 1.79 g. boiling at 35–42° (0.25 mm.); $n^{25}D$ 1.4484. This was redistilled to remove a small first fraction, then a second fraction at 74–76° (10 mm.). When this main distillate was treated with phenylhydrazine and a little acetic acid in ethanol and then diluted with water, a precipitate (m. p. *ca.* 110°) appeared. This melted at 115° after crystallization from petroleum ether (b. p. 60–70°) and was the osazone of ethylglyoxal.[5]

Anal. Calcd. for $C_{16}H_{18}N_4$: C, 72.2; H, 6.84; N, 21.0. Found: C, 71.8; H, 7.04; N, 20.7.

The aqueous liquor from which were obtained the acid insoluble fractions described above, was made basic to release an amine fraction. Upon distillation, this yielded 1.7 g. of monobutylamine $n^{25}D$ 1.3643, b. p. 78–80° (754 mm.), (23% of theoretical), and then 6.3 g. of authentic dibutylamine, b. p. 32° (0.25 mm.), $n^{25}D$ 1.4156 (48% of theoretical) and 1.3 g. of material, b. p. 70–78° (0.01 mm.), $n^{25}D$ 1.4413, m. p. −10°. According to boiling point and refractive index this fraction may be N-butylbutyramide. It would not react with dinitrophenylhydrazine in dilute ethanolic hydrochloric acid but on treatment of 0.2 g. overnight with 1 g. of *p*-bromobenzenesulfonyl chloride in 7 cc. of 10% alkali, it yielded 0.1 g. of *n*-butyl bis-*p*-bromobenzenesulfonimide, m. p. 107–114°. After crystallization from ethanol, this melted without depression at 115° when mixed with the authentic material.[8]

Thermal Decomposition of Dibutylchloramine.—It required six weeks at 38° before 4.5 g. (0.028 mole) of dibutylchloramine no longer gave an electropositive chlorine test. The brown residue was suspended in ether and filtered to remove 2.25 g. of dibutylammonium chloride (49% of theoretical) which was identified as its styphnate, m. p. 91.4–91.9°. The ether filtrate was distilled, finally at 0.01 mm. to yield 0.93 g., b. p. 40–47°, $n^{25}D$ 1.4534. This distillate precipitated a small amount of salt. It was redistilled *in toto* at 50° (0.006 mm.) $n^{25}D$ 1.4539.

Anal. Calcd. for $C_8H_{15}NCl_2$: C, 49.2; H, 7.75; N, 7.19. Found: C, 49.8; H, 8.05; N, 7.76.

When 0.489 g. (0.0025 mole) of this material was treated with 1.53 g. (0.006 mole) of *p*-bromobenzenesulfonyl chloride and 19.2 cc. (0.012 mole) of 5% aqueous sodium hydroxide at 0° and then shaken two hours at 25° a solid formed which was filtered off after neutralization of the alkali. It weighed 0.16 g. and melted at about 60°. Several crystallizations from hot ethanol raised this to 115.3°. The identical material could be prepared from the salt remaining after the N-butyldichlorobutaldimine was distilled under reduced pressure. This is evidently identical with the *n*-butyl-*bis*-bromobenzenesulfonimide reported with melting point of 116°.[8]

Anal. Calcd. for $C_{16}H_{17}NO_4S_2Br_2$: C, 37.6; H, 3.36; N, 2.74. Found: C, 37.9; H, 3.64; N, 3.26.

The compound designated above as N-butyldichlorobutanaldimine (5.72 g. 0.029 mole) was dissolved in 25 cc. of dry ether and treated with hydrogen chloride. No chlorine was evolved. After evaporation of the ether, the residue weighed 6.8 g. (quantitative yield). No satisfactory melting point of this material could be obtained. When it was dissolved in 17 cc. of methanol to which 250 cc. of dry ether was added a new precipitate appeared in smaller quantity (2.98 g.). It melted at 213–213.5° and according to analysis was butylammonium chloride in 97% yield.

Anal. Calcd. for $C_4H_{12}NCl$: C, 43.8; H, 11.03. Found: C, 43.4; H, 10.80.

This was identified by treatment of 1 g. (0.0092 mole) of salt with 3 g. (0.012 mole) of bromobenzenesulfonyl chloride and 40 cc. (0.05 mole) of 5% aqueous sodium hydroxide in the cold. This yielded 2.56 g. (97%) of N-butyl-*p*-bromobenzenesulfonamide, m. p. 56–57°, and was contaminated with the 116° compound described above. This was washed with carbon tetrachloride and crystallized twice from 1:4 benzene–petroleum ether (b. p. 60–70°) to melt at 54–54.5°. Since this is lower than that previously reported[7] (58°), the compound was identified by analysis.

Anal. Calcd. for $C_{10}H_{14}NSO_2Br$: C, 41.2; H, 4.84. Found: C, 41.5; H, 4.89.

When the methanol–ether solution, from which the butylammonium chloride was isolated, was evaporated to a small volume and diluted with water, a water-insoluble phase separated. Its ether solution, dried and distilled, yielded 0.37 g., b. p. 43–45° (12 mm.), $n^{25}D$ 1.4515. When this substance was treated with phenylhydrazine hydrochloride in ethanol, the suspension first turned yellow, then after five minutes was blood-red. This color disappeared by the next day to leave yellow crystals melting at 162°. This crop was crystallized from ethanol and then ground in dioxane to melt at 169–170.6°. It was slightly soluble in dilute hydrochloric acid. The compound was evidently a hydrochloride.

Anal. Calcd. for $C_{16}H_{19}N_4Cl$: C, 63.6; H, 6.36; N, 18.5. Found: C, 63.7; H, 6.57; N, 18.5.

When this compound was dissolved in ethanol and treated with aqueous sodium hydroxide and water, the precipitate melted at 110°. Crystallization from petroleum–ether (b. p. 60–70°) raised this to 114–115°. A mixed melting point with the osazone of ethylglyoxal was not lowered.

Crude "N-Butyl Dichlorobutaldimine" with Dinitrophenylhydrazine.—A suspension of 1.45 g. (0.0073 mole) of 2,4-dinitrophenylhydrazine in 150 cc. of ethanol and 3 cc. of concentrated hydrochloric acid was boiled with 1.18 g. (0.006 mole) of crude N-butyldichlorobutanaldimine. After one minute the clear solution became cloudy and a yellow precipitate began to appear. After fifteen minutes, this had become red. The suspension was filtered hot to remove 0.88 g. of orange-red precipitate, m. p. 232–234°. This was crystallized from dioxane (80 cc. per g.) as dark red prisms which melted at 241.1–241.6°. It contained no chlorine and is thought to be the osazone of 3-ethoxyethylglyoxal.

Anal. Calcd. for $C_{18}H_{20}N_8O_9$: C, 44.3: H, 3.69; N, 22.8. Found: C, 44.4; H, 3.67; N, 22.4.

When the ethanol solution (from which this osazone was filtered) was cooled, an orange precipitate weighing 0.25 g., m. p. *ca.* 200°, was obtained. This obvious mixture was crystallized thrice from dioxane (20 cc. per g.) to melt at 227.5–228°. The precipitate contained

(8) Ssolonina, *J. Russ. Phys.-Chem. Soc.*, **31**, 640 (1899).

chlorine. The analysis conformed most closely with that expected for 3-chlorobutanal 2,4-dinitrophenylhydrazone.

Anal. Calcd. for $C_{10}H_{11}N_4O_4Cl$: C, 42.0; H, 3.85; N, 19.5. Found: C, 42.7; H, 3.70; N, 18.9.

The ethanolic filtrate from which this compound was isolated when diluted with water, precipitated 0.17 g. of yellow material, m. p. *ca.* 85°, which was dissolved in hot ethanol to give a first crop, m. p. 185–187°, not further investigated. Further cooling yielded 0.05 g., m. p. 92.8°. This melting point was not raised by further crystallization from ethanol. The compound contained no chlorine.

Anal. Calcd. for $C_{12}H_{16}N_4O_5$: C, 48.6; H, 5.45; N, 18.9. Found: C, 48.1; H, 5.46; N, 19.1.

When this process with dinitrophenylhydrazine was carried out in methanol instead of ethanol, the hot methanol-insoluble precipitate melted at 234°. It was crystallized from boiling nitromethane (40 cc./g.), then extracted with boiling chloroform and finally recrystallized from nitromethane to melt at 242–244°. A mixed melting point of this dinitrophenyl osazone of 3-methoxyethylglyoxal with the ethoxy analog melted at 227°.

Anal. Calcd. for $C_{17}H_{16}N_8O_9$: C, 42.8; H, 3.28. Found: C, 43.1; H, 3.41.

When the thermal decomposition of dibutylchloramine was effected at higher temperatures the reaction was complete in ten days at 58° and in one day at 95°. The yield of dibutylammonium chloride was lower (40–37%) but the products were essentially the same.

Dibutylchloramine in Acetic Acid.—A solution of 70.6 g. (0.434 mole) of dibutylchloramine $n^{25}D$ 1.4348 in 86 cc. of acetic acid showed no tendency toward salt formation in one day, but when heated to 90°, the electropositive chlorine was consumed in one hour. The solvent was removed under 15 mm. pressure and the residue made alkaline with cold 15% aqueous sodium hydroxide. The oil which separated was taken up in ether, dried with magnesium sulfate and distilled to yield 22 g. (39% of theoretical) of dibutylamine, b. p. 30–36° (0.35 mm.), $n^{25}D$ 1.4162 (identified as the styphnate, m. p. 93°) and then 17 g., b. p. 88–92° (0.05 mm.), $n^{25}D$ 1.4500.

This fraction contained no N-butylpyrrolidine, since its dilute hydrochloric acid extract gave no picrate. When it was shaken with saturated sodium bisulfite, dried under vacuum, and redistilled, it first yielded 4.58 g., b. p. 120–5° (12 mm.), $n^{25}D$ 1.4480, which was evidently impure dibutylacetamide. The characterization of this compound was effected by one-day reflux with an equal weight of sodium methoxide in 5 volumes of methanol which yielded, on distillation, dibutylamine in 20% yield, b. p. 45–50° (12 mm.), $n^{25}D$ 1.4150. This was converted to dibutyl *p*-bromobenzenesulfonamide, m. p. 58–59°, for complete identification by mixed melting point.[9] In addition to this amine, purified dibutylacetamide, $n^{25}D$ 1.4436, b. p. 119–121° (12 mm.), was recovered.

The second and main fraction from this redistillation of the 17-g. portion boiled at 127–130° (12 mm.), $n^{25}D$ 1.4513. The compound contains chlorine. The analysis could not be correlated with any reasonable structure.

Anal. Calcd. for $C_9H_{18}NCl$: C, 61.6; H, 10.3; N, 7.97. Found: C, 61.1; H, 10.1; N, 7.88.

This product did not react with 2,4-dinitrophenylhydrazine in boiling dilute ethanolic hydrochloric acid. Some early fractions after removal of the dibutylamine in the initial distillation did, however, give ethoxyethylglyoxal dinitrophenylosazone, m. p. 238–240°, when treated under the same conditions.

Dibutylchloramine with Acetic Anhydride.—When a mixture of 48.9 g. (0.3 mole) of dibutylchloramine and 91.8 g. (0.9 mole) of acetic anhydride had reacted together for four hours a solid began to appear. After seven days, no more electropositive chlorine could be detected. The whole was poured into 500 g. of ice and neutralized with 140 cc. of 50% aqueous potassium hydroxide and extracted with ether. This ether solution was extracted with 35 cc. of 12% hydrochloric acid, then with aqueous sodium chloride solution, and was dried with magnesium sulfate for distillation. The acid washing liquor was made basic to yield 2.50 g. of oil, b. p. 109° (7 mm.), $n^{25}D$ 1.4439, but no dibutylamine.

The dried ether solution was distilled first at 7 mm. to yield 4 g. of chlorinated material, not identified, $n^{25}D$ 1.1456, and then at 0.5 mm. The principal distillate boiled at 78–95° and weighed 40 g. Although it was contaminated with material which contained halogen, its density at 20° (0.9) and its refractive index, $n^{25}D$ 1.4445, showed that it was essentially halogen-free. By contrast, final fractions of 4.4 g. (b. p. 95–98°) and 7.1 g. (b. p. 128°) were rich in halogen according to their refractive indices, $n^{25}D$ 1.4564 and $n^{25}D$ 1.4729, respectively.

The principal yield of 40 g. was refractionated with difficulty because of continual decomposition. From it was obtained 8.27 g., b. p. 73° (0.02 mm.), $n^{25}D$ 1.4407 melting at −8 to −10°. A mixed melting point with N-butylbutyramide, m. p. −7 to −6° was not lowered. This yield, 21% of theoretical, represents a minimum of the compound which actually was present. The remainder of the 40 g. of product was not positively identified but its refractive index, $n^{25}D$ 1.4437, indicated that it was dibutylacetamide.

Decomposition occurred during all of these distillations and these decomposition products, caught in a trap chilled to −75°, weighed 8.8 g. Fractionation of the material was very unsatisfactory owing to a tendency toward separation into two phases when the liquid was warmed above 60°. The second phase disappeared when the distillation temperature reached 94°. The distillation yielded two main fractions boiling at 90–92° (750 mm.), wt. 2.2 g. and 1.13 g., b. p. 115–125° (750 mm.). The first of these fractions, $n^{25}D$ 1.4580, could not be recognized by its analysis (32.1% carbon, 5.82% hydrogen) but it must have been largely ethylglyoxal since it gave a 60% yield of the monophenylhydrazone when it was treated with 1.1 equivalent of phenylhydrazine in ethanol. This compound, m. p. 133–136°, was purified by crystallization from ethanol and isopropyl ether to melt at 134.5–135.5°. It was then halogen-free.

Anal. Calcd. for $C_{10}H_{12}N_2O$: C, 68.3; H, 6.88; N, 15.9. Found: C, 68.6; H, 7.10; N, 15.9.

When 0.3 g. of this ethylglyoxal phenylhydrazone was treated in boiling ethanol solution with 0.3 g. of phenylhydrazine and then filtered, after treatment with Darco decolorizing charcoal, an oil appeared after dilution with water and acetic acid. When hydrochloric acid was added, this solidified to a crystal mass melting at 158–159°. Crystallization from hot ethanol–chloroform mixture yielded the phenylosazone hydrochloride of ethylglyoxal, m. p. 168°. This was identified by mixed melting point.

The aldehydic fraction boiling at 115–125° contained chlorine but no nitrogen, $n^{25}D$ 1.3773, m. p. −8 to 0°. According to its analysis it might be 1-acetoxy-2-chloro-1,2-dihydroxybutane.

Anal. Calcd. for $C_6H_{11}O_4Cl$: C, 39.6; H, 6.1. Found: C, 39.4; H, 6.5.

When this material was treated with excess phenylhydrazine in ethanol plus a trace of acetic acid, it yielded the osazone of ethyglyoxal, m. p. 112–114°, authenticated by mixed melting point.

When 0.18 g. of this aldehydic distillate was treated with 0.18 g. of 2,4-dinitrophenylhydrazine in boiling ethanolic hydrochloric acid only a slight precipitate of ethoxyethylglyoxal 2,4-dinitrophenylosazone appeared. The main product, *ca.* 0.1 g., was precipitated by addition of water to melt at 155–175°. Repeated crystallization from boiling ethanol (30 cc./g.) raised this melting point to 194.5°. The compound contained chlorine, and is believed to be the hydrochloride of ethylglyoxal 2,4-dinitrophenylosazone.

Anal. Calcd. for $C_{16}H_{15}N_3O_3Cl$: C, 40.0; H, 3.14; N, 23.3. Found: C, 39.9; H, 3.16; N, 23.3.

Summary

1. The spontaneous decomposition of dibutylchloramine yields dibutylammonium chloride and a distillable fraction believed to be a mixture of N-*n*-butyl mono-, di- and trichlorobutanaldimines with the second of these compounds predominating. Other compounds seem to be present, but phenyl and dinitrophenylhydrazones and osazones of these three have been isolated.

2. Decomposition of dibutylchloramine in alcohols follows the same course, but hydrolysis of the aldimines occurs to give monobutylammonium chloride and ethylglyoxal.

3. Decomposition of dibutylchloramine in acetic acid or its anhydride gives also dibutylacetamide and, in the latter reagent, N-*n*-butylbutyramide.

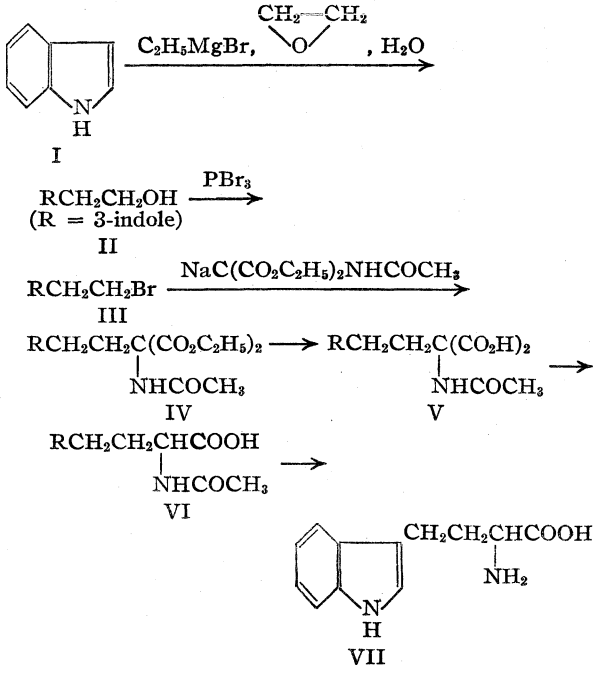
A Synthesis of *dl*-Homotryptophan

BY H. R. SNYDER AND FREDERICK J. PILGRIM

Homotryptophan [α-amino-γ-(3-indole)-butyric acid, VII] has been synthesized to permit physiological studies of the substance, particularly with reference to its possible action as an antimetabolite. The reactions employed in the synthesis are shown in the accompanying diagram.



Tryptophol (II) was prepared from indole (I) by the method of Oddo and Cambieri[1] which consists in the treatment of indole-magnesium bromide with ethylene oxide. Phosphorus tribromide was employed to convert tryptophol to the corresponding bromide (III) as described previously.[2] Alkylation of ethyl sodioacetylaminomalonate[3] by III was found to take place readily and in good yield (about 60%). The alkylation product, ethyl α-acetamino-α-carbethoxy-γ-(3-indole)-butyrate (IV), as obtained directly from the reaction mixture was of sufficient purity for conversion to V. Saponification of IV to the corresponding malonic acid, V, was effected by refluxing a mixture of IV with dilute sodium hydroxide solution; an almost quantitative yield of V was obtained.

Decarboxylation of the substituted malonic acid was brought about by refluxing an aqueous suspension of the material for several hours. *dl*-N-Acetylhomotryptophan (VI) was isolated from the mixture as the monohydrate. It was found convenient to purify the substance as the monohydrate; deacetylation of the pure monohydrate by hot dilute sodium hydroxide produced *dl*-homotryptophan (VII) in a state of high purity and in almost quantitative yield.

Experimental[4,5]

Ethyl α-Acetamino-α-carbethoxy-γ-(3-indole)-butyrate (IV).—To a solution prepared from 75 ml. of absolute ethanol and 0.58 g. of sodium were added 5.44 g. of ethyl acetaminomalonate and 5.50 g. of β-(3-indole)-ethyl bromide[2] (III). The reaction mixture was refluxed for fifteen hours with mechanical stirring. The hot mixture was filtered, the insoluble material on the filter was washed with 50 ml. of hot absolute ethanol, and the combined filtrate and washings were concentrated under reduced pressure to a small volume (about 20 ml.). The residue was cooled to 5° and filtered. The light yellow crystals on the filter were washed with 50 ml. of cold absolute ethanol to give a white product (IV), m. p. 161–163°; yield, 4.8 g. Concentration of the mother liquor to a few milliliters and addition of 30 ml. of anhydrous ether to the residue yielded a precipitate, mainly sodium bromide. Extraction of this precipitate with small portions of warm water left a residue of crude IV (0.3 g.), m. p. 153–156°. A dark oily residue was obtained when the mother liquor from the second crop of crude product was evaporated to dryness under reduced pressure. No additional product was isolated from the oily residue. The over-all yield of IV, sufficiently pure for conversion to V, was 5.1 g. (57.6%). A sample of pure IV, prepared for analysis by recrystallization from 95% ethanol, melted at 163–164°.

Anal. Calcd. for $C_{19}H_{24}O_5N_2$: N, 7.77. Found: N, 7.74.

(5) Microanalyses by Miss Theta Spoor and Mr. Howard Clark.

α-Acetamino-α-carboxy-γ-(3-indole)-butyric Acid (V).—A reaction mixture consisting of 4 g. of IV, 2.2 g. of sodium hydroxide and 25 ml. of water was refluxed for four hours. The hot mixture was treated with Darco, filtered hot and the filtrate was then cooled to 5°. The addition of 5.7 ml. of cold concentrated hydrochloric acid to the filtrate caused precipitation of slightly pink crystals of V. The mixture, after standing fifteen hours at 5°, was filtered. The solid was washed with 50 ml. of ice-water and dried for two hours at 60°; m. p. 140–141°; yield 3.3 g. (97.5%) of material suitable for conversion to VI.

A sample of pure V, recrystallized from 30% ethanol, melted at 153–154°.

Anal. Calcd. for $C_{15}H_{16}O_5N_2$: N, 9.21. Found: N, 8.94.

α-Acetamino-γ-(3-indole)-butyric Acid (*dl*-N-Acetylhomotryptophan) (VI).—Decarboxylation of the substituted malonic acid V was readily effected by refluxing a suspension of 3.0 g. of V in 25 ml. of water for three hours. The homogeneous reaction mixture was cooled to 5° and made acidic (congo red paper) by the careful addition of 18% hydrochloric acid. The acetyl derivative (VI) separated from the acidic solution as an oil which slowly crystallized. The mixture was filtered and the crude product (2.0 g.) was recrystallized from 40% ethanol. The product isolated from this recrystallization was the monohydrate of VI, m. p. 112–113°; yield, 1.60 g. (58.3%).

Anal. Calcd. for $C_{14}H_{16}O_3N_2 \cdot H_2O$: N, 10.05. Found: N, 10.12.

For the above analysis the crystals were dried for two hours at 25° under 2 mm. pressure. When the crystals were finely pulverized and dried for an additional two hours at the same temperature and pressure the hydrate apparently decomposed to anhydrous VI.

Anal. Calcd. for $C_{14}H_{16}O_3N_2$: N, 10.77. Found: N, 10.53.

α-Amino-γ-(3-indole)-butyric Acid (*dl*-Homotryptophan) (VII).—Recrystallized *dl*-N-acetylhomotryptophan monohydrate (VI, 1.60 g.), sodium hydroxide (1.00 g.) and water (10 ml.) were combined and the solution was refluxed for twenty hours. The hot reaction mixture was treated with Darco, filtered and the filtrate was cooled to 5°. Glacial acetic acid (1.50 g.) was added to the filtrate which was then allowed to stand at 5° for twelve hours to ensure complete precipitation of the amino acid VII. The reaction mixture was filtered and the white solid was found to be almost pure *dl*-homotryptophan, m. p. 306–310°; yield 1.21 g. (96.5%). It was recrystallized from a large volume of 50% ethanol. The glistening platelets of pure VII melted sharply at 308° with decomposition.

Anal. Calcd. for $C_{12}H_{14}O_2N_2$: C, 66.0; H, 6.47; N, 12.84. Found: C, 66.15; H, 6.51; N, 13.16.

Summary

dl-Homotryptophan [α-amino-γ-(3-indole)-butyric acid] has been synthesized *via* the sequence: indole, tryptophol, β-(3-indole)-ethyl bromide, ethyl α-acetamino-α-carbethoxy-γ-(3-indole)-butyrate, α-acetamino-α-carboxy-γ-(3-indole)-butyric acid, α-acetamino-γ-(3-indole)-butyric acid, *dl*-homotryptophan.

URBANA, ILLINOIS RECEIVED JANUARY 2, 1948

NOTES

Correlation of Rates of Halogenation of Methylbenzenes

BY FRANCIS E. CONDON

The rate of chlorination of toluene relative to that of benzene is 345[1]; relative to that at only one position in benzene, it is 345 × 6 = 2070. The product has been reported to be 42% *p*- and 58% *o*-chlorotoluene.[2] Hence the partial relative rate of chlorination of toluene at the para position is 0.42 × 2070 = 870; similarly, the ortho partial relative rate is (0.58/2) × 2070 = 600. The meta partial relative rate may be approximated as 5, which seems reasonable in view of the value of 3 found for meta nitration.[3]

If each of the methyls in a polymethylbenzene exerts the same activating influence as the one in toluene, a partial relative rate of chlorination at each available nuclear position may be calculated as a product of two or more partial relative rates, each corresponding to a methyl and its position. The rate for the polymethylbenzene relative to that for benzene is then one-sixth the sum of the partial relative rates for all available positions.

TABLE I

RELATIVE RATES OF HALOGENATION OF POLYMETHYLBENZENES (BENZENE = 1)

	p-Xylene	*o*-Xylene	*m*-Xylene	Mesitylene	Pentamethylbenzene
Calculated	2.0×10^3	2.5×10^3	2.4×10^5	1.6×10^8	13×10^8
Experimental[1]	2.2×10^3	4.6×10^3	4.3×10^5	1.8×10^8	7.8×10^8
	Pseudocumene	Hemimellitine	Durene	Prehnitene	Isodurene
Calculated	7.4×10^5	8.7×10^5	3.0×10^6	4.4×10^7	5.2×10^8

In *p*-xylene, for example, each of the four available positions is influenced by two methyls, one ortho and one meta. The calculated partial rela-

(1) De la Mare and Robertson, *J. Chem. Soc.*, 270 (1943).

(2) Wertyporoch, *Ann.*, **493**, 153–165 (1932); *C. A.*, **26**, 2177 (1932).

(3) Ingold, Lapworth, Rothstein and Ward, *J. Chem. Soc.*, 1959 (1931).

tive rate at each position is therefore 600 × 5 = 3000; and the rate for *p*-xylene relative to that for benzene is 4 × 3000/6 = 2000. Similarly, inasmuch as the single available position in pentamethylbenzene is influenced by one para, two meta, and two ortho methyls, the rate of chlorination of pentamethylbenzene relative to that of benzene is 870 × 5 × 5 × 600 × 600/6 = 1.3 × 10^9. Such calculated relative rates are compiled in Table I, together with available experimental values[1] for chlorination or bromination. The agreement between the calculated and the experimental values, which is good in view of the 350,000-fold range, inspires considerable confidence in the five values for which experimental confirmation is at present unavailable.

A product of relative rates as calculated above is mathematically related to a sum of activation energy differences calculated from Arrhenius-type equations for the individual rate constants

$$k = Ae^{-E/RT}$$

For

$$k_i/k = (A_i/A)e^{(E-E_i)/RT}$$

and

$$\Sigma(E - E_i) = \Sigma RT \ln (k_i/k) - \Sigma RT \ln (A_i/A) = RT \ln \Pi(k_i/k) - RT \ln \Pi(A_i/A)$$

If the several A terms are equal,[4] the relationship simplifies to

$$\Sigma(E - E_i) = RT \ln \Pi(k_i/k)$$

According to the theory of absolute reaction rates[5]

$$k = (KT/h)e^{-F/RT}$$

where K = Boltzmann constant, h = Planck constant, and F = difference in free energy between initial and activated states, or "activation free energy." Consequently, without any assumption of constancy for an A term, or "frequency factor"[5]

$$k_i/k = e^{(F-F_i)/RT}$$

and

$$\Sigma(F - F_i) = RT \ln \Pi(k_i/k)$$

so that a product of relative rates is simply related to a sum of activation free energy differences.

BARTLESVILLE, OKLAHOMA RECEIVED NOVEMBER 28, 1947

Liquid Nitrosyl Chloride as an Ionizing Solvent

BY ANTON B. BURG AND GEORGE W. CAMPBELL, JR.[1]

Liquid nitrosyl chloride is expected to be a fairly effective ionizing solvent, for its dielectric constant (18.2 at 12°)[1a] is comparable to that of liquid ammonia. The acid–base system would be defined by the neutralization equation $NO^+ + Cl^- \rightarrow NOCl$. As in the analogous case of carbonyl chloride,[2] the chloride ion should not be appreciably solvated, for the electronic structure of NOCl (resonance between $:\ddot{O}{=}\ddot{N}^+Cl^-$ and $:\ddot{O}{=}\ddot{N}{-}\ddot{Cl}:$)[1,3] will not be affected by an electron-donor so weak as chloride. In agreement with this prediction, potassium chloride is insoluble in liquid nitrosyl chloride, contributing no conductance effect.

The nitrosyl ion, on the other hand, should be solvated very strongly, on account of the resonance structures $\left[:\ddot{O}{=}\ddot{N}{-}\ddot{Cl}{-}\ddot{N}{=}\ddot{O}:\right]^+$, $\left[:\ddot{O}{=}\ddot{N}{-}\ddot{Cl}:\right]\ :\overset{+}{N}{\equiv}O:$, and $:O{\equiv}\overset{+}{N}:\left[:\ddot{Cl}{-}\ddot{N}{=}\ddot{O}:\right]$. Hence it is expected that nitrosyl salts, many of which have been recognized,[4] should be soluble in liquid nitrosyl chloride, with high electrical conductance.

Experimental Results.—These ideas have been tested in a preliminary investigation of the electrical conductance of solutions of typical nitrosyl salts in liquid nitrosyl chloride. The mononitrosyl salts $NOAlCl_4$, $NOFeCl_4$ and $NOSbCl_6$ are readily soluble strong electrolytes, as demanded by the theory (see Table I). The solvation is indicated by the reaction $NOAlCl_4(s) + NOCl(g) \leftrightarrows NOAlCl_4 \cdot NOCl(s)$, recently discovered in our laboratories by Donald E. McKenzie. The dissociation pressure of the product is approximately 240 mm. at 0°.

Less favorable results were obtained with $(NO)_2SnCl_6$, $(NO)_2TiCl_6$, and $(NOSO_4H)$, all of which appeared quite insoluble and non-conducting. Dinitrosyl pyrosulfate, $(NO)_2S_2O_7$,[5] showed a slight conductance which very slowly passed through a maximum (see Table II). Sulfuric acid was inert.

The inert character of potassium chloride was not changed by an "acid" solution of nitrosyl chloroantimonate, which, by analogy with carbonyl "acids" in carbonyl chloride, should have dissolved it. The reason might be a protective coating of $KSbCl_6$.

In an attempt to establish chloride ions in liquid NOCl, the base-action of water was tried. However, the water only dissolved without conductance and was recovered by evaporating the nitrosyl chloride. The usual hydrolysis reaction $H_2O + 2NOCl \rightarrow NO + NO_2 + 2HCl$ is slow at room temperature and the products are nonconducting in nitrosyl chloride.

Methods and Numerical Results.—All reagents were prepared and handled with complete exclusion of moisture. The nitrosyl chloride was prepared by the usual reaction $NOSO_4H + HCl \rightarrow H_2SO_4 + NOCl$, and purified by means of a helix-packed column. With electrodes of bright platinum wire 1 mm. thick, having 12 mm. exposed length, and 6 mm. apart, polarization effects caused a 15% uncertainty in the evaluation of the cell constant (0.78) by reference to aqueous KCl, but the various NOCl solutions gave results consistent to 1%. These results accordingly are presented in Tables I and II for purposes of comparison.

The Effect of Sulfur Fluorides on the Viscosity of Sulfur

BY R. FANELLI

Recently, it was shown,[1,3] that the halogens, chlorine, bromine, iodine and also hydrogen sulfide and hydrogen persulfides, even when present in minute amounts, reduce the viscosity of sulfur above 160°. The degree of effectiveness decreased, with respect to the halogens, in the order shown. It was also indicated that the increasing viscosity of pure sulfur with rise in temperature might be due to polymerization of sulfur into long straight chains and that reduction of the viscosity was due to the rupture of these chains by the halogens which take up terminal positions of the segments. For example, in the case of chlorine added in the form of sulfur chloride we have

$$S_n(\text{chain}) + S_2Cl_2 \longrightarrow Cl\text{–}S\text{–}S\text{–}S \cdots S\text{–}S\text{–}SCl \text{ and/or } Cl\text{–}S\text{–}S\text{–}S \cdots S\text{–}S\text{–}S.$$

Sulfur mixtures containing 2% chlorine give viscosities under 15 centipoises throughout the entire liquid range, 115–445°. This is in sharp contrast with the maximum viscosity of pure sulfur, 93,200 centipoises, at 186–188°.

Fluorine was not tried in the earlier experiments because of the difficulty in obtaining this element. It was assumed, however, that because of its position in the halogen group it would be much more effective than chlorine. Recently, sulfur hexafluoride became available commercially and it was used in the same manner as sulfur chloride. Because of its high thermal stability, sulfur hexafluoride, if effective, would be an attractive reagent for reducing the viscosity of sulfur.

Experimental

Quantitative data were not obtained as the nature of the work was exploratory. The effect of the sulfur fluorides was determined by visual comparison of the fluidity of the treated sulfur with that of pure sulfur[2] which at 180–195° shows very little or no flow in the space of a few minutes.

Sulfur hexafluoride was bubbled for five and one-half hours through pure sulfur heated to 310° during which period little, if any, decrease in viscosity was noted. On cooling from 310 to 194° with the gas still bubbling through, the sulfur gelled indicating that the sulfur hexafluoride was comparatively ineffective in reducing the viscosity of sulfur. Apparently the stability and inertness of the hexafluoride is such that its reaction with the long sulfur chains is negligible under the conditions of the experiment.

The direct fluorination of sulfur gives in addition to the hexafluoride much smaller and variable concentrations of SF_4, S_2F_2, and (about 1%) S_2F_{10}. As revealed by Schumb,[4] these lower fluorides are removed before the purified hexafluoride is compressed into the cylinders. These lower fluorides are less stable and more reactive than the hexafluoride and might react with the long sulfur chains to appreciably reduce the viscosity.

The effect of the gases SF_4 and S_2F_2 was determined by heating in an electric furnace mixtures of pure sulfur with metallic fluorides in rotating, sealed, heavy-walled Pyrex tubes (free volume about 15 cc.). For the preparation of SF_4 the following reaction, reported to yield this compound,[4–7] was employed

$$4CoF_3 + S \longrightarrow 4CoF_2 + SF_4$$

Under the conditions of this experiment, probably some of the cobaltous fluoride was converted to sulfide. For the formation of S_2F_2 two reactions reported to yield this halide[6,7] were tried

$$2HgF + 3S \longrightarrow Hg_2S + S_2F_2$$
$$2AgF + 3S \longrightarrow Ag_2S + S_2F_2$$

Each tube contained 7 g. of pure sulfur mixed separately with 0.3 g. and 1.0 g. of CoF_3; 0.3 g. and 1.0 g. of HgF; 0.5 g. and 1.0 g. of AgF. At the end of the experiments, all tubes were under fairly high pressure indicating formation of the gases had taken place. Only after prolonged heating (about forty-eight hours at 180–440°) was a slight reduction of the viscosity noted.

These experiments lead to the opinion that the observed failure of the sulfur fluorides to greatly affect the viscosity of sulfur is just one more instance of the abnormal behavior of fluorine and its compounds when viewed in comparison with the other halogens.

The Melting Point of Mustard Gas

BY W. A. FELSING, C. A. HUNTING AND S. D. FELL

Recently du Vigneaud and Stevens[1] reported a study of the preparation and purification of mustard gas (*bis*-(β-chloroethyl) sulfide) and its action on yeast. They purified the mustard by three recrystallizations from absolute ethanol and once from petroleum ether; the product had a melting point of 14.5°. The authors also cite references to other reliable melting point determinations found in relatively recent literature (*i. e.*, 14.4° and 14.5°).

In Chemical Laboratory Report No. 369, Edgewood Arsenal, Edgewood, Md., dated November 29, 1918, the authors of this note reported the purification and the melting point of mustard gas. Crude Levinstein mustard gas, melting at 8–9°, was distilled at 10 mm. pressure, yielding a distillate melting at 13.6°. This material was thrice distilled at pressures below 10 mm. and subjected to partial freezing. It was collected on a Buchner filter and the adhering liquid was removed rapidly by suction. The collected crystals were melted and again the resulting liquid was partially re-frozen and the crystals collected as before. In all, the crystals were partially frozen, drained and remelted seven times. The final product weighed about 750 g. (original volume of distilled mustard gas was about 1 gallon).

The melting point of the purified mustard gas was determined by the usual procedure of taking temperature readings every thirty seconds until every trace of the crystals had disappeared. The melting point was determined graphically from a time–temperature plot. The melting point apparatus and the thermometer were kindly loaned by the Physical Chemistry Division of Johns Hopkins University. The short-range thermometer, whose ice-point was carefully checked and which was calibrated by the Physikalische Technische Reichsanstalt (P.R.T. No. 26260) was calibrated in 0.1° and temperatures could be estimated to 0.02° by the aid of a magnifier. Two series of determinations yielded a melting point of 14.45° and one of 14.44°.

Both of these values agree markedly well with the values given and cited by du Vigneaud and Stevens.

This note was suggested as a historical record by Chemical Corps Technical Command, Army Chemical Center, Md.

The Preparation of *p*-Dimethylaminobenzoic Anhydride

BY WILLIAM S. FONES

In connection with other work under way in this Laboratory it was necessary to prepare *p*-dimethylaminobenzoic anhydride. By heating *p*-dimethylaminobenzoic acid in acetic anhydride V. Meyer and Askenasy[1] isolated a substance (m. p. 109°) that analyzed correctly for an addition complex consisting of one molecule of *p*-dimethylaminobenzoic anhydride and one of acetic anhydride. This work was repeated by Van Der Haar,[2] who reported the complex (m. p. 109°) lost acetic anhydride when heated above its melting point to yield a substance sintering at less than 200° and melting at 218°. He assumed the latter material to be the free anhydride.

This assumption is shown to be in error by the present work. The anhydride was prepared by the action of phosphorus pentoxide on *p*-dimethylaminobenzoic acid in boiling xylene (method A) or by adding phosphorus oxychloride to a solution of *p*-dimethylaminobenzoic acid and triethylamine in chloroform (method B). The product from either reaction upon recrystallization from benzene had a m. p. of 157–159° (cor.); a mixed melting point determination showed no depression. By method A the anhydride was obtained in a yield of 30% based on acid used with a 36% recovery of unreacted acid whereas a 50% yield was obtained by method B but no starting material was recovered.

The pure compound gave the expected analysis and was further characterized by conversion to the known methyl *p*-dimethylaminobenzoate,[3] and *p*-dimethylaminobenzamide[4] through the action of methanol and ammonia, respectively.

Experimental

***p*-Dimethylaminobenzoic Anhydride (Method A).**—To a stirred suspension of 9.1 g. of *p*-dimethylaminobenzoic acid in 450 ml. of refluxing *m*-xylene there was added 8 g. of phosphoric anhydride. Stirring and refluxing were continued for seven hours with an additional 8-g. portion of phosphoric anhydride being added at the end of the first,

(1) V. Meyer and P. Askenasy, *Ber.*, **26**, 1365 (1893).

third and fifth hours. After standing overnight the reaction mixture was heated to boiling and filtered. The filter cake was dissolved in water, made slightly alkaline with dilute sodium hydroxide and acidified with acetic acid to precipitate 3.3 g. (36%) unreacted *p*-dimethylaminobenzoic acid. The xylene filtrate was concentrated and cooled to yield 4.1 g. of crystals, m. p. 147–160°. This material was taken up in chloroform, extracted with sodium bicarbonate solution and dried. Stripping of the solvent followed by recrystallization of the residue from benzene gave 2.6 g. (30%) of *p*-dimethylaminobenzoic anhydride, m. p. 157–159° (cor.).

Anal. Calcd. for $C_{18}H_{20}O_3N_2$: C, 69.3; H, 6.4; N, 9.0. Found: C, 69.6; H, 6.4; N, 8.8.

Method B.—To a solution of 16.0 g. of *p*-dimethylaminobenzoic acid and 60 ml. of triethylamine in 150 ml. of chloroform there was added dropwise 11.7 g. (7.0 ml.) of phosphorus oxychloride. After the initial reaction subsided the solution was heated to reflux for ten minutes and allowed to stand one hour at room temperature. The chloroform solution was extracted with ice-cold dilute sodium hydroxide solution and filtered through anhydrous sodium sulfate. Upon concentration and cooling the chloroform solution deposited 9.6 g. of crystals, m. p. 148–157°. Two recrystallizations of this material from benzene gave 7.5 g. (50%) of *p*-dimethylaminobenzoic anhydride, m. p. 157–159° (cor.), identical with that obtained by method A as evidenced by mixed melting point determination.

Acidification of the alkali extract with acetic acid did not yield any recovery of *p*-dimethylaminobenzoic acid.

Methyl *p*-Dimethylaminobenzoate.—In a sealed tube there was heated for three hours at 100° 0.5 g. of *p*-dimethylaminobenzoic anhydride and 25 ml. of methanol. The reaction mixture was poured into cold dilute sodium hydroxide to dissolve the *p*-dimethylaminobenzoic acid and to precipitate the ester which was collected by filtration. There was thus obtained 0.23 g. (80%) of methyl *p*-dimethylaminobenzoate, m. p. 99–102° (lit. 102°).[3] Acidification of the alkali extract gave 0.18 g. of *p*-dimethylaminobenzoic acid.

***p*-Dimethylaminobenzamide.**—A solution of 0.53 g. of *p*-dimethylaminobenzoic anhydride in 25 ml. of chloroform was saturated with ammonia and then heated in a sealed tube for two hours at 70° and two additional hours at 100°. The chloroform was stripped and the residue recrystallized from water to give 0.21 g. (76%) amide, m. p. 203–206° (lit. 206°).[4]

Preparation of 2-Phenylbenzoxazole

BY LUCAS C. GALATIS

The preparation of 2-substituted benzoxazoles by heating appropriately *o*-substituted anilines with an organic acid is a well-known reaction. In the case of benzoxazole, apparently the reaction has been used only for the preparation of the parent compound from *o*-aminophenol and formic acid.[1] It has now been found that 2-phenylbenzoxazole (I) may be prepared by the general method by heating *o*-aminophenol with benzoic acid. Purification of crude I presents difficulty especially because of the persistence of a highly fluorescent by-product which has been commonly encountered when I was prepared by heating aminophenol with various benzoyl derivatives.[2] By choosing ligroin as a solvent, I could be extracted from the reaction product free from other by-products, except traces of the above mentioned fluorescent substance, which were in their turn eliminated by taking advantage of a difference in basicity between I and the latter. The fluorescent matter accumulated in the residue of the ligroin extraction was then easily separated and identified as triphen-dioxazine, an oxidation product of *o*-aminophenol.[3]

Experimental

In a large test-tube an intimate mixture of 10.9 g. of *o*-aminophenol and 15 g. of benzoic acid is melted in an oil-bath at 160°. The tube is then fitted with a stopper carrying a gas inlet tube and an exit tube bent downward. The temperature is raised to 195° while passing carbon dioxide through the tube, at which temperature rapid evolution of water occurs. After two hours the temperature is raised to 200–205° and held at that point for ten hours. Every two or three hours the sublimate is melted down from the walls of the tube. After cooling to 130° the melt is poured with stirring into cold water. The insoluble material is ground in a mortar with 2 *N* sodium hydroxide. The dark colored residue is warmed with 300 ml. of ligroin (b. p. 80–120°) until extraction of 2-phenylbenzoxazole from contaminating black material is complete. After filtering, the solution which is strongly fluorescent, although it does not contain but traces of the fluorescent matter, is shaken with two drops of concd. hydrochloric acid which removes the fluorescent impurity as a violet-blue solution. The ligroin solution is filtered through a dry gravity filter and shaken with 80 ml. of concd. hydrochloric acid which removes the benzoxazole. The acid extract is diluted with stirring with four or five volumes of cold water yielding 14 g. (72%) of 2-phenylbenzoxazole as a white or slightly green powder melting at 101°. A perfectly white product may be obtained by distillation of the material after the sodium hydroxide treatment with superheated steam (180°) followed by the treatment with hydrochloric acid in ligroin.

In order to isolate the main quantity of the fluorescent substance, the black residue from the ligroin extraction is repeatedly extracted with boiling alcohol for removal of a red contaminant, and then with boiling xylene. On cooling, the intensively fluorescent xylene solution deposits small red brown needles with a metallic cast. This shows all the properties of triphen-dioxazine including the characteristic production of green vapor on heating at 300°.

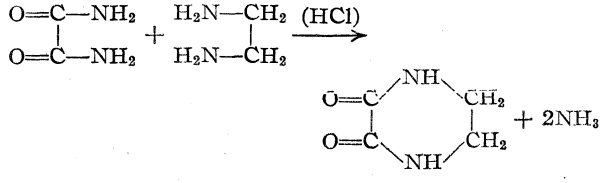
Synthesis of 2,3-Diketopiperazine

BY C. E. GOULDING, JR.,[1] AND C. B. POLLARD

Two prior methods for the preparation of 2,3-diketopiperazine by the reaction between diethyl oxalate and 1,2-ethanediamine[2,3] have been reinvestigated in this Laboratory and found to afford yields of only about 1 and 10%, respectively. A new method involving the reaction of oxamide and 1,2-ethanediamine in 1,4-dioxane was therefore

(1) Present address: Caracas, Venezuela.
(2) Hofmann, *Ber.*, **5**, 247 (1872).
(3) Van Alphen, *Rec. trav. chim.*, **54**, 937 (1935).

undertaken which, using anhydrous reagents and vigorous stirring, has afforded yields of approximately 50%. The reaction is presumably



Procedure.—To 63 g. of finely powdered oxamide in a three-necked flask, 60 g. of anhydrous 1,2-ethanediamine in 250 ml. of anhydrous 1,4-dioxane, and thereafter as a catalyst, 2 ml. of concentrated hydrochloric acid was added. The mixture was heated to reflux and stirred with a collapsible, stainless steel stirrer which swept the sides of the flask for twenty-four hours until ammonia was no longer evolved.

The 1,4-dioxane was removed by evaporation *in vacuo*, the solid material macerated in 3 liters of boiling water and filtered. The filtrate was evaporated on a steam-bath to 300 ml. and the solid 2,3-diketopiperazine removed by filtration. The yield was 41.1 g. (or 50.3%) melting with decomposition at 285°. The product was identified by means of the 1,4-dinitrate-2,3-diketo derivative, m. p. 150°, which, mixed with an authentic sample of the 1,4-dinitrate derivative, melted at 149–150°.

Trifluoroethanol

BY ALBERT L. HENNE, ROBERT M. ALM AND MALCOLM SMOOK

CF_3CH_2OH has been prepared by Swarts[1] by reduction of trifluoroacetic anhydride under pressure, on a platinum catalyst. Although no one has ever voiced any doubt, this reduction has never been successfully repeated, due apparently to Swarts' failure appropriately to describe his catalyst. The reduction of CF_3CONH_2 is also mentioned by Swarts, and has been successfully developed by Gilman[2]; we duplicated Gilman's 77% yield, but had to consume 5 g. of platinum per mole of amide. Scherer[3] has made trifluoroalcohol by treating CF_3CH_2Cl with fused potassium acetate at 225°, and saponifying the resulting acetate. We have repeated this work and found the yields exceedingly sensitive to the reaction temperature, an experience duplicated by other laboratories.

We are now recommending the reduction of a derivative of trifluoroacetic acid (the ester or the acyl halide) with lithium aluminum hydride as the most convenient and efficient way to make the alcohol. Our preferred procedure is given.

Preparation of CF_3COCl.—A two-liter, three-necked flask was fitted with a dropping funnel, a mercury-sealed stirrer and a coiled reflux condenser with outlet leading to a 500-cc. receiver cooled in Dry Ice. The apparatus was thoroughly dried by flaming while sweeping with dry nitrogen; the inlet and outlet were protected by drying tubes. Benzoyl chloride (679 g. or 4.83 moles) was delivered into the flask; then over a one-hour period, trifluoroacetic acid (417 g. or 3.66 moles) was dropped in, with constant stirring. After completing the addition, the dropping funnel was replaced by a thermometer and the mixture heated overnight, up to 150°. The crude trifluoroacetyl chloride distilled through the reflux condenser; its rectification gave 380 g. (2.87 moles = 79%) of pure product, b. p. −27°, and 47 g. (0.41 mole = 11%) of unreacted acid.

Preparation of CF_3CH_2OH.—A five-liter, three-necked flask was fitted with a Dry Ice reflux condenser, a sealed stirrer and a gas inlet tube. The equipment was dried by flaming and sweeping with dry nitrogen. Solid lithium aluminum hydride (54 g. or 1.42 moles) was placed in the flask and covered with three liters of rigorously dried ether; while continuously stirring, CF_3COCl was led into the liquid as fast as the return from the reflux condenser would permit; the addition of 350 g. (2.64 moles) took about three and one-half hours. After this the mixture was refluxed for one more hour on an electric heating mantle. The inlet tube was replaced by a dropping funnel, then 200 cc. of water was slowly added to hydrolyze the excess of hydride. This made a clear solution and a precipitate of white curds. The solution was decanted into 1500 cc. of 6 *N* sulfuric acid containing ice. The ether layer was separated, then used in three portions for extractions of the aqueous layer; the latter was poured back onto the solid residue in the flask, then ether extracted. From the ether extracts, distillation isolated 285 g. of material boiling at 74–75°, which is a mixture of the trifluoroalcohol with 5–10% of water. Distilling from concentrated sulfuric acid gives the desired anhydrous alcohol, CF_3CH_2OH, b. p. 74°. The net yield is 85%.

In later experiments an excess of trifluoroacetyl chloride was used instead of an excess of hydride, because the latter was not readily available; a utilization of about 95% of the hydride was thus obtained, but this procedure is not recommended.

Production of Radioactive Carbon Monoxide and Phosgene from Barium Carbonate

BY J. L. HUSTON[1] AND T. H. NORRIS[1]

Recently Kummer[2] has recommended the preparation of radioactive carbon monoxide by exchanging over a hot tungsten filament the C^{14} in a small amount of carbon dioxide with the inactive carbon in a large quantity of ordinary carbon monoxide. Some time ago we had occasion to prepare radioactive carbon monoxide ($C^{14}O$) as the first step in the preparation of radioactive phosgene which was to be used in biological experiments. Since our procedure involves no dilution of the radioactive carbon, and can be accomplished in less time than Kummer's procedure, we are presenting it at this time.

Our method involved the reduction of carbon dioxide to carbon monoxide by hot zinc, which was discovered by Noack.[3] Although this method was considered the most suitable for our purposes it should be pointed out that carbon monoxide can be prepared in good yield by heating alkaline earth

(1) Present address: Chemistry Department, Oregon State College, Corvallis, Oregon.

(3) E. Noack, *Ber.*, **16**, 75 (1883).

carbonates directly with zinc,[4] and without intermediate conversion to carbon dioxide. The phosgene was then prepared photochemically by the reaction of this carbon monoxide with chlorine. Our preparations were made in the apparatus diagramed in Fig. 1.

Experimental Part

Preparation of Carbon Monoxide.—About 50 g. of reagent zinc was cleaned with dilute acetic acid, washed, dried and placed in tube E. This cleaning was necessary since otherwise the hot zinc would evolve slowly a small quantity of permanent gas (presumably carbon monoxide from decomposition, with reduction, of zinc carbonate). Radioactive barium carbonate (~20 mg. was convenient for our apparatus) was placed in I, and the entire system evacuated. Tube E was surrounded by a small electric furnace and baked out overnight at about 370° (necessary for each fresh batch of zinc only). Temperature was adjusted manually by means of a Variac and read with a thermocouple connected to a millivoltmeter.

With the system open to the high vacuum, radioactive carbon dioxide was next generated by dropping 85% phosphoric acid into I and, after passing through phosphorus pentoxide in H, was trapped in F with liquid air. Stopcock G was now closed and the small quantity of air introduced by the phosphoric acid was pumped off. The temperature of E was raised to 385° and thereafter held within 5° of this temperature: the reaction is too slow at 370° and above 400° there is considerable tendency for the tube E to become plugged, due probably to sublimation and recrystallization of the zinc.

The stopcocks leading to the pumping system were closed; next the liquid air was removed from F and the pressure of carbon dioxide in the system (F and the capillary line extending to, and including, the capillary monometer C) was measured. Carbon monoxide subsequently was stored in the same portion of the apparatus, as it was generated, its pressure thus serving as a measure of the yield.

The two-liter Töpler pump D was now used to pump the carbon dioxide several times, alternately clockwise and counterclockwise, through the hot zinc in E. After each traverse through the zinc, unreacted carbon dioxide was trapped with liquid air in the appropriate spiral S_1 or S_2 while carbon monoxide was pumped into F and its pressure measured with manometer C. The first traverse through the zinc would produce about a 50% yield of carbon monoxide and 5 or 6 more passes made the conversion quantitative within the limit of error in reading the manometer (0.4%). The process, from generation of carbon dioxide to complete conversion to monoxide, required three to four hours.

Preparation of Phosgene.—Bulb B (~500 cc.) contained chlorine (introduced on another gas-handling system) equal in amount to about 2.5 times the stoichiometric quantity required for union with the carbon monoxide. This chlorine was frozen down into the bottom of the bulb with liquid air and the carbon monoxide in F was introduced with the Töpler pump, a small fraction (<2%) remaining in the capillary line. B was then isolated from the line and after removal of the liquid air the gas mixture was irradiated with an ultraviolet mercury vapor lamp. Spiral S_4 was then cooled with liquid air and B was opened to high vacuum *via* this spiral S_4, a small amount of residual carbon monoxide thus being removed from the condensable gases (phosgene and chlorine) which were trapped in the spiral.

The system was again isolated and the mixture of phosgene and chlorine distilled with liquid air to A which contained antimony. Bulb A and spiral S_3 were then closed off from the rest of the system, removed from the line as a unit, warmed to room temperature, and shaken to remove excess chlorine. The antimony appears to react with phosgene to a slight extent to produce a little

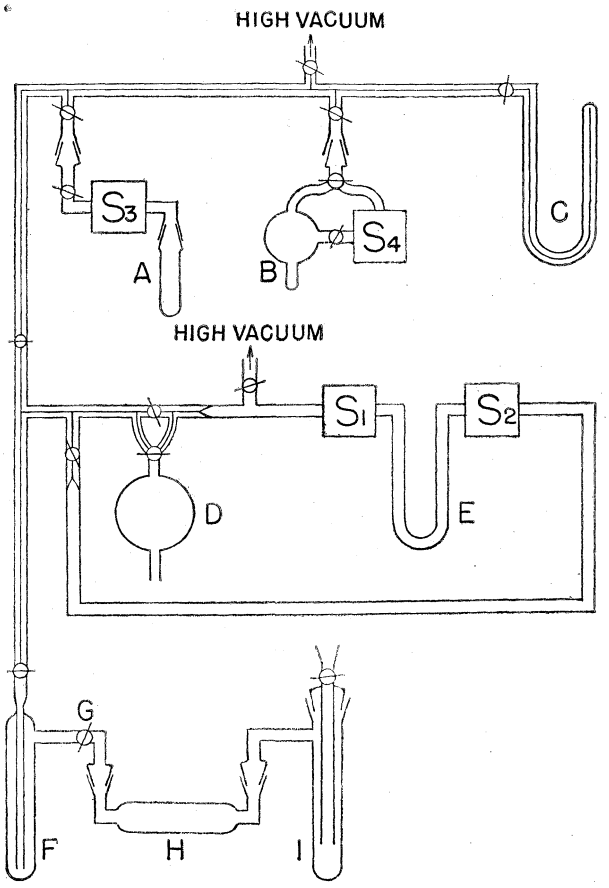

Fig. 1.

carbon monoxide; after A and spiral S_3 were re-attached to the line permanent gas was pumped off while the phosgene was trapped with liquid air in spiral S_3. After distillation to F the pressure of phosgene was read and the yield thus measured. In five runs the yields ranged from 80.0% to 84.5%, based on the original barium carbonate.

It should be noted that since the equilibrium $2CO = C + CO_2$ lies well to the right at these temperatures, reduction to carbon is thermodynamically possible. That our yields of carbon monoxide were quantitative, within the limits of error of our measurements, is in accord with an observation made by Maier and Ralston[5] in their quantitative measurements on the equilibrium $ZnO(s) + CO(g) = Zn(g)$ in the temperature range 500 to 850°. They observed a slight deposition of carbon on molten zinc but estimated that carbon monoxide was thus consumed at about $^1/_{100}$ its rate of formation from carbon dioxide. It should be noted that our procedure was designed to minimize the contact time of carbon monoxide and zinc.

The time required for our procedure could be shortened by substitution of a Dry Ice trap for the drying tube H and the use of molten zinc instead of the solid granular material. Alternatively, if granular zinc is used an automatic Töpler pump could be used to decrease the time required to pump the gases through the zinc. Some of the phosgene was probably absorbed by stopcock grease and its yield could be improved by irradiation in an all-glass container. However, it is doubtful that the labor involved in using this procedure would sufficiently improve the yield to be worth while.

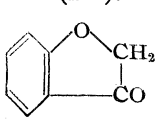
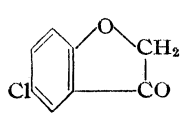
Cyclization of Phenoxyacetic Acid and Some Chlorophenoxyacetic Acids

BY M. L. KALINOWSKI AND L. W. KALINOWSKI*

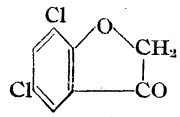
In the course of our studies on the relationship between the chemical structure and the herbicidal activity of organic compounds, such as 2,4-dichlorophenoxyacetic acid, it appeared of interest to prepare coumaran-3-one (I), 5-chlorocoumaran-3-one (II), and 5,7-dichlorocoumaran-3-one (III).



I

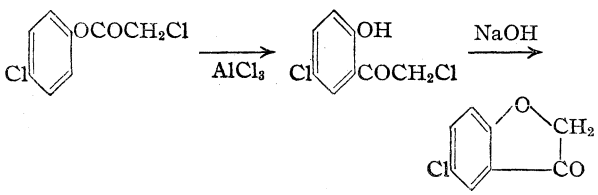


II



III

Three methods of preparation were considered, (1) the cyclization of the corresponding phenoxyacetyl chloride by means of aluminum chloride,[1] (2) the cyclization, by means of dilute alkali, of the corresponding 2-hydroxy-ω-chloroacetophenone,[2] and (3) the cyclodehydration of the corresponding phenoxyacetic acid in benzene solution with phosphorus pentoxide.[3]



Compound (I) was prepared by all three methods; (II) was obtained in traces by methods (1) and (3), and in fair yield by method (2). The disubstituted coumaranone (III) could not be prepared by any of these methods. It appears that the cyclization of phenoxyacetic acid is partially suppressed by chlorine substitution in the 4-position, and apparently completely suppressed by chlorine substitution in the 2,4-positions.

An attempt to effect the Fries rearrangement of 2,4-dichlorophenyl chloroacetate to 3,5-dichloro-2-hydroxy-ω-chloroacetophenone was unsuccessful. This failure of the Fries reaction to take place is not entirely unexpected in view of the work of Tarbell and Fanta.[4] These investigators point out the unreactive character of the phenolic nucleus with two chlorine atoms meta to the position where substitution is to take place, and the further decrease in reactivity by α-substitution in the acetate portion of the molecule.

When 2,4-dichlorophenoxyacetic acid was treated with phosphorus pentoxide the expected 5,7-dichlorocoumaran-3-one was not obtained. However, a good yield of material, m. p. 111.5–112.5°, was isolated which was identified as 2,4-dichlorophenyl-2′,4′-dichlorophenoxyacetate. It appears that cleavage at the ether linkage is effected by phosphorus pentoxide followed by esterification of unreacted 2,4-dichlorophenoxyacetic acid by the phenol fragment. During the reaction, the phosphorus pentoxide acquired a black color, probably due to decomposition products of glycolic acid, and a strong phenolic odor was noted in the crude reaction mixture.

In view of this unexpected reaction of 2,4-dichlorophenoxyacetic acid, the reaction products from the reaction of phenoxyacetic acid and phosphorus pentoxide, and 4-chlorophenoxyacetic acid and phosphorus pentoxide were examined carefully for ester formation. However, in neither case could any ester be found.

In order to have authentic samples of the esters for purposes of identification, phenyl phenoxyacetate, 4-chlorophenyl-4′-chlorophenoxyacetate, and 2,4-dichlorophenyl-2′,4′-dichlorophenoxyacetate were prepared from the phenoxyacetyl chlorides and the appropriate phenols.

Experimental

Cyclization of Acid Chlorides with Aluminum Chloride.—The phenoxyacetyl chlorides were prepared with thionyl chloride. Except that *s*-tetrachloroethane was employed as the solvent in the cyclization reaction, coumaran-3-one, m. p. 99–100°, and 5-chlorocoumaran-3-one, m. p. 114–116°, were prepared according to the procedure given by Stoermer and Atenstadt.[1]

The reaction with 2,4-dichlorophenoxyacetyl chloride in the common Friedel–Crafts solvents under a variety of conditions of temperature and reaction time yielded a resinous product from which no 5,7-dichlorocoumaran-3-one could be isolated.

Cyclization of 2-Hydroxy-ω-chloroacetophenones.—Although this method is indirect, it was found to be the most satisfactory one for the preparation of coumaran-3-one,[5] and 5-chlorocoumaran-3-one.[2]

However, 5,7-dichlorocoumaran-3-one could not be prepared by this procedure. The desired 3,5-dichloro-2-hydroxy-ω-chloroacetophenone was not obtained by heating 2,4-dichlorophenyl chloroacetate with aluminum chloride. Instead a light tan, non-lachrymatory compound, m. p. 135–135.5°, was obtained in 53% yield. This compound was not identified.

Anal. Calcd. for $C_8H_5Cl_3O_2$: Cl, 44.3. Found: Cl, 29.0, 29.7.

The compound 2,4-dichlorophenyl chloroacetate, b. p. 125–130° (1 mm.), has not been reported. The compound was prepared by heating 2,4-dichlorophenol with an excess of chloroacetyl chloride.

Anal. Calcd. for $C_8H_5Cl_3O_2$: Cl, 44.3. Found: Cl, 44.4.

Reaction of the Phenoxyacetic Acids with Phosphorus Pentoxide.—Coumaran-3-one and 5-chlorocoumaran-3-one were prepared by this method according to the procedure given by Stoermer and Bartsch.[3] A reaction time of eight to ten minutes seems to give a maximum yield of coumaranone. For both phenoxyacetic acid and 4-chlorophenoxyacetic acid a longer reaction time of forty-five minutes gave a heavy oil from which no coumaranone or ester could be isolated.

To a solution of 15 g. of 2,4-dichlorophenoxyacetic acid in 125 cc. of anhydrous benzene, 20 g. of phosphorus pentoxide was added. The reaction mixture was stirred and refluxed for forty-five minutes. The phosphorus pentoxide was removed by filtration, the filtrate was washed several times with water, dried over sodium sulfate, and the benzene removed by distillation. A residue of 12 g. of pasty,

brown solid was obtained which had a strong phenolic odor, and from which no 5,7-dichlorocoumaran-3-one could be isolated by steam distillation. The residue was triturated with a small amount of cold methanol, and the solid was recrystallized from Skelly C, m. p. 111.5–112.5° (yield 8.0 g.) A mixed m. p. with an authentic sample of 2,4-dichlorophenyl-2′,4′-dichlorophenoxyacetate showed no depression.

Anal. Calcd. for $C_{14}H_8Cl_4O_3$: C, 45.9; H, 2.18; Cl, 38.8. Found: C, 46.0; H, 2.18; Cl, 40.1.

A shorter reaction time of ten minutes afforded a lower yield of ester, and none of the 5,7-dichlorocoumaran-3-one.

Preparation of the Phenyl Esters of the Phenoxyacetic Acids.—The ester 2,4-dichlorophenyl 2′,4′-dichlorophenoxyacetate was prepared by heating equivalent amounts of 2,4-dichlorophenol and 2,4-dichlorophenoxyacetyl chloride at 130–140° for three hours. The reaction product was recrystallized from Skelly C, m. p. 112–113°.

Anal. Calcd. for $C_{14}H_8Cl_4O_3$: Cl, 38.8. Found: Cl, 38.0.

In a similar manner, 4-chlorophenyl 4′-chlorophenoxyacetate was prepared, m. p. 118–119°.

Anal. Calcd. for $C_{14}H_{10}Cl_2O_3$: Cl, 23.9. Found: Cl, 24.0.

Phenyl phenoxyacetate was prepared in a similar manner, m. p. 54–57° (reported[6] m.p. 58°).

Herbicidal Activity Tests

The various phenoxyacetic acids, cyclized derivatives, and phenyl esters were tested for plant growth regulating activity. Snap beans, grown under field conditions, were used as the test plant. Approximately 40 mg. of a solution of 1% of the compound in lanolin was applied to the pulvinus of the primary leaves when the first trifoliate leaves were expanding. Each of the compounds was applied to two plants, and the treated plants were observed over a period of eight weeks.

Phenoxyacetic acid, coumaran-3-one, and phenyl phenoxyacetate were without action.

The 4-chlorophenoxyacetic acid was very active, as was the 4-chlorophenyl ester. A slight effect was noted within two days after application, and within ten days the stems were badly swollen and the trifoliate leaves were dwarfed. After eight weeks the plants were alive but were very stunted. When 4-chlorophenoxyacetic acid was cyclicized to 5-chlorocoumaran-3-one all herbicidal activity was lost.

As was expected, 2,4-dichlorophenoxyacetic acid was very active. The 2,4-dichlorophenyl ester possessed the same order of activity, but seemed to act somewhat more slowly.

CHICAGO 29, ILLINOIS RECEIVED DECEMBER 31, 1947

Difluoroboron-acetoacetanilide

BY JOSEPH R. KILLELEA

A recent application of the Knorr reaction in this laboratory[1] prompted a study of the use of boron fluoride as the acid catalyst for the cyclization. Small quantities of the expected 4-methylcarbostyril (I) were obtained in some cases. In every case the principal product was difluoroboron-acetoacetanilide (II).[2]

Experimental

Difluoroboron-acetoacetanilide.—To 20 ml. of a 40% solution of boron fluoride in absolute ethanol[3] is added 5.0 g. of acetoacetanilide. The solution is allowed to stand for fifteen minutes and then poured cautiously into an excess of dilute sodium carbonate. The filtered solid is stirred with normal hydrochloric acid to remove inorganic matter and dried over sodium hydroxide. It is dissolved in the minimum volume of dry dioxane, the solution filtered, and the product precipitated by the addition of petroleum ether. The product (5.0 g., 79%) forms fine needles and melts at 154–155°.

Anal. Calcd. for $C_{10}H_{10}O_2NBF_2$: B, 4.8; F, 16.9; N, 6.23. Found: B, 5.2; F, 16.7; N, 6.22.

Properties.—**(a) Hydrolysis.**—One gram of (II) is stirred with 50 ml. of a very dilute ferric chloride solution at room temperature. No color is observed until considerable time (one-half to one hour) has elapsed. The color gradually deepens as hydrolysis proceeds and reaches its maximum after six to eight hours. The solution gives positive qualitative tests for boric acid and fluorides. Nearly the theoretical quantity of acetoacetanilide may be recovered by extraction.

(b) Cyclization.—One gram of (II) is stirred with 3 ml. of concentrated sulfuric acid and the solution warmed to 80–90°. Reaction sets in with the evolution of acidic gases (wet litmus) containing boron (green flame). Nearly the theoretical quantity of (I) may be isolated by the usual method.[1]

(2) Similar compounds from β-diketones have been reported by Morgan, *J. Chem. Soc.*, **125**, 1963 (1924).

(3) The Knorr cyclization was attempted in other solvents and under various conditions. These directions represent a convenient method of preparation of (II).

Isomerization of Alkyl Phosphites. VII. Some Derivatives of 2-Bromoethane Phosphonic Acid

BY GENNADY M. KOSOLAPOFF

The reaction of triethyl phosphite with ethylene bromide readily leads to a very reactive diethyl 2-bromoethane phosphonate. It was felt to be of interest to prepare a number of derivatives of this substance through the reactive halogen atom.

The action of alcoholic potassium hydroxide on this ester was found to give good yields of diethyl vinyl phosphonate, which had been earlier reported by Kabachnik,[1] who used a rather involved reaction sequence for his synthesis.

Dialkylamines react with the bromo compound in aqueous solution to give good yields of the corresponding diethyl 2-dialkylaminoethane phosphonates. As might be expected, the use of a nonpolar solvent leads to dehydrohalogenation and the formation of the above-mentioned vinyl derivative.

Experimental Part

Triethyl phosphite (33.2 g., 0.2 m.) and ethylene bromide (150 g., 0.8 m.) were heated for three hours to 160°

(1) Searles and Lindwall, THIS JOURNAL, **68**, 988 (1946).

(1) Kabachnik, *Izvest. Akad. Nauk. S. S. S. R.*, No. 2, 233 (1947).

in the previously described apparatus.[2] Ethyl bromide evolution amounted to 20 g. (theory, 21.8 g.). The product was distilled with a minimum of superheating by the use of a still equipped with a sealed stirrer. The yield of diethyl 2-bromoethanephosphonate, b. p. 86–87° at 2 mm., $n^{25}D$ 1.4555, was 33 g., 67.5%.

Diethyl Vinyl Phosphonate.—Diethyl 2-bromoethanephosphonate (33 g.) was added in the course of thirty minutes to a stirred solution of 7.5 g. of potassium hydroxide in 250 cc. of absolute ethanol with ice cooling. The mixture was warmed to a gentle reflux for fifteen minutes, cooled and filtered. The precipitated potassium bromide was washed with 50 cc. of absolute ethanol and the combined filtrates were distilled to give 21 g. (95%) diethyl vinyl phosphonate as a colorless mobile liquid, b. p. 50° at 1 mm., $n^{25}D$ 1.4260. It decolorized permanganate instantly in the cold and possessed mildly expressed polymerizability.

Diethyl 2-Diethylaminoethanephosphonate.—Diethyl 2-bromoethanephosphonate (24.5 g., 0.1 m.) was added to 25 g. of diethylamine in 50 cc. of water and the mixture was refluxed for two hours. After cooling, 50 cc. of 20% sodium hydroxide was added and the mixture was extracted with 200 cc. of benzene. Distillation of the organic layer gave 17 g. (72%) diethyl 2-diethylaminoethane phosphonate, as a pale yellow oil, b. p. 106–7° at 3 mm., $n^{25}D$ 1.4380, which forms a methiodide, m. p. 104–106°.

Anal. Calcd.: N, 5.9. Found: N, 5.87, 6.01.

Repetition of the above experiment in dry toluene gave only the above described vinyl compound.

Diethyl 2-Di-*n*-butyl-aminoethane Phosphonate.—Diethyl 2-bromoethane phosphonate (24.5 g., 0.1 m.) was refluxed for four hours with 40 g. of di-*n*-butylamine and 50 cc. of water. Isolation, as given above, gave 21 g. (72%) diethyl 2-di-*n*-butyl-aminoethane phosphonate as a pale yellow oil, b. p. 140–142° at 3 mm., $n^{25}D$ 1.4421.

Anal.: Calcd.: C, 57.5; H, 10.9. Found: C, 57.7, 57.64; H, 10.6, 10.9.

The Preparation of Carboxymethoxylamine Hemihydrochloride

BY MARY HARRIET LOTT

Carboxymethoxylamine has been used frequently as a ketone reagent, for instance in the isolation of α-estradiol from human pregnancy urine.[1] It can be synthesized by the simple procedure of Borek and Clarke[2] whereby acetoxime is condensed with sodium chloroacetate and the resulting acetone carboxymethoxime hydrolyzed with 6 *N* hydrochloric acid. In this Laboratory no difficulty has been encountered in the condensation; however, hydrolysis with 6 *N* hydrochloric acid has not uniformly yielded the desired carboxymethoxylamine hemihydrochloride. Often merely ammonium chloride is obtained. It has furthermore been noted that in the crystallization of the hemihydrochloride from ethanol–ether a fragrant oil often results in the mother liquor. The procedure of Borek and Clarke for hydrolyzing acetone carboxymethoxime has therefore been modified as described below. In this modification the concentration of hydrochloric acid, even after partial evaporation of solvent, is never permitted to become greater than 3.6 normal; isopropyl alcohol is substituted for ethanol under the assumption that esterification with ethanol takes place during crystallization. By the adoption of these modifications it has been possible consistently to obtain carboxymethoxylamine hemihydrochloride in satisfactory yield.

Procedure.—Crude acetone carboxymethoxime is distilled prior to hydrolysis. To a solution of 10.0 g. of acetone carboxymethoxime in 100 cc. of water contained in a 500-ml. wide-mouthed Erlenmeyer flask, 6.0 cc. of concentrated hydrochloric acid is added. The homogeneous solution is then heated on the steam-bath (hood) until the volume of solution is reduced to 20 cc. (approximately three hours time). After having been cooled, this solution is treated with 100 cc. of isopropyl alcohol and 200 cc. of dry, alcohol-free ethyl ether. After a day in the ice-box, the deposited crystals are filtered (Büchner) and washed with cold isopropyl alcohol–ether (1:3). The yield of carboxymethoxylamine hemihydrochloride, after drying, is about 4 g. melting at 150–151° uncor. (with evolution of gas). This material is of sufficient purity for use as a ketone reagent.

The Synthesis of 3,4,9-Trimethoxyphenanthrene

BY S. F. MACDONALD AND A. J. CHECHAK

The significance, in morphine chemistry, of the function of the 9- or 10-hydroxy group in 9-hydroxycodeine and of the structure of Knorr's 9- or 10-acetoxyacetylmethylmorphol, has been indicated by Knorr[1] (in part) and by Holmes.[2] Evidence on these points would definitely locate the position of the nitrogen in morphine, unless the hydroxy group of 9-hydroxycodeine were on 9 and the nitrogen on 10 or 14. The latter publication has led us to report work which we had done to the same purpose, though it is as yet incomplete.

It was pointed out[2] that the 9-hydroxycodeine structure was not consistent with its failure to react as a carbinolamine with malonic acid, etc.; more conclusive evidence to this effect had already been obtained by Knorr,[1] who found that it did not react with hydroxylamine or with semicarbazide, but who failed to interpret the result thus. As codeine N-oxide is known,[3] there would appear to be little justification for the suggestion, made and disposed of by Holmes,[2] that 9-hydroxycodeine is an N-oxide.

The synthesis of 3,4,9-trimethoxyphenanthrene should permit the determination of the structure of Knorr's acetoxyacetylmethylmorphol. Attempts had therefore been made to convert 3,4-

dimethoxy-9-phenanthrylamine into 3,4-dimethoxy-9-phenanthrol.[1,2] This conversion was carried out quantitatively by a modification of the Bucherer reaction wherein sulfur dioxide replaced the usual bisulfite,[4] and the presence of much aqueous dioxane prevented the formation of the diphenanthrylamine derivative. Analogous deaminations have been carried out by other methods in low or in unstated yields.[5] 3,4-Dimethoxy-9-phenanthrol gave the required 3,4,9-trimethoxyphenanthrene on methylation.

Experimental

α-Phenyl-2-nitro-3,4-dimethoxycinnamic Acid.—This was obtained in 75% yield by Pschorr's method[6] or in 90% yield by the following modification. 2-Nitroveratraldehyde, 2.1 g., phenylacetic acid, 1.4 g., triethylamine, 1.0 g., and acetic anhydride, 5 ml., were heated together at 60° for two days. Isolation and purification according to Pschorr gave the product, 3.0 g., m. p. 222.5–223.5° (uncor.).

3,4-Dimethoxy-9-aminophenanthrene.—Prepared according to Knorr,[1] the base was obtained from its hydrochloride with alcoholic potassium hydroxide.

3,4-Dimethoxy-9-phenanthrol.—3,4-Dimethoxy-9-aminophenanthrene, 4.7 g., was dissolved in 50 ml. of dioxane, 50 ml. of water added, the mixture saturated with SO_2 at 0°, and heated in a sealed tube at 100° for one day. Removal of the solvent *in vacuo*, grinding the residue with water, filtering and drying, gave 3,4-dimethoxy-9-phenanthrol, 4.7 g., m. p. 147–152°. The crude product was distilled (1×10^{-4} mm., bath temp. 130°) and crystallized from toluene, giving pale yellow prisms, m. p. 156°.

Anal. Calcd. for $C_{16}H_{14}O_3$: C, 75.57; H, 5.55; OCH_3, 24.4. Found: C, 75.53; H, 5.43; OCH_3, 21.9, 22.4.

3,4,9-Trimethoxyphenanthrene.—3,4-Dimethoxy-9-phenanthrol, 390 mg., was refluxed under nitrogen with water, 10 ml., and *N* sodium hydroxide, 2 ml. Methyl sulfate, 0.5 ml. then 0.4 ml., and *N* sodium hydroxide, 5 ml. then 4 ml., were added alternately. The cooled mixture was extracted with chloroform, the chloroform washed with dilute hydrochloric acid, with dilute sodium hydroxide with water, and dried with sodium sulfate. 3,4,9-Trimethoxyphenanthrene, 330 mg., m. p. 85–95°, was obtained by distilling (1×10^{-4} mm., bath temp. 110°) the residue left on evaporating the chloroform. It was purified by crystallizing from petrol ether (b. p. 60–80°, 20 parts) giving colorless prisms, m. p. 96.5–97.5° after drying.

Anal. Calcd. for $C_{17}H_{16}O_3$: C, 76.10; H, 6.01; OCH_3, 34.70. Found: C, 76.21; H, 6.32; OCH_3, 31.76.

X-Ray Diffraction in Aqueous Systems of Dodecyl Sulfonic Acid

BY SULLIVAN S. MARSDEN, JR., AND JAMES W. MCBAIN

Aqueous systems of lauryl sulfonic acid are especially interesting because their X-ray diffraction shows different kinds of patterns for ordinary isotropic solution, concentrated anisotropic liquid crystalline region, and the highly concentrated anisotropic liquid crystalline, and the pure crystalline acid.

1. The ordinary isotropic liquid solution existing at room temperature exhibits only a very diffuse indication of a long spacing even near the highest concentration (23%) at which it can exist. The phase diagram giving the boundaries of this[1] and the two anisotropic phases was published by M. J. Vold. X-Ray diffraction therefore indicates the absence of any strongly repeating structure such as that found in solutions of potassium laurate, except high angle scattering due to neighboring molecules in the colloidal particles of the sulfonic acid.

However, when 3.6% of benzene is added to 19.0% solution of the dodecyl sulfonic acid the solution is still isotropic but gives a diffraction line corresponding to a single order of Bragg spacing of 63.4 Å. But when the amount of benzene is increased to 6.9% the system becomes anisotropic and gives two long Bragg spacings of 67.0 Å. and 48.4 Å. It is assumed that this structure is lamellar in analogy with the system Triton X-100: water: benzene.[2]

2. Most interesting is the aqueous liquid-crystalline phase existing between 23 and 70% of lauryl sulfonic acid. The colloidal particles apparently consist of *fibers* or long rods or elongated ellipsoids. These lie parallel at a distance from each other in hexagonal arrangement. Such a structure was found for certain aqueous systems of tobacco mosaic virus by Bernal and Fankuchen.[3]

The evidence for this interpretation of the X-ray diffraction patterns follows from: (a) The ratios of the successive Bragg spacings to each other are in the proportions $1:1/\sqrt{3}:1/\sqrt{4}:1/\sqrt{7}$. These correspond to hexagonal indices $10\bar{1}0$, $11\bar{2}0$, $20\bar{2}0$, $21\bar{3}0$, respectively.

(b) Most important, the relative intensities of the various diffractions, which in the order given above are: very strong, strong, weak and very weak, respectively; in a few cases the second and third lines are strong and strong, respectively.

(c) The variation of the inter-particle distance with concentration, which is approximately as the reciprocal of the square root of the concentration.

The thickness or diameter of the fibers seems to be in the neighborhood of the double length of the soap molecule. The short spacings consist of halos at 7–8 Å. and 4.5–4.6 Å., which indicates a liquid arrangement of neighboring molecules within the fibers.

It should be mentioned that this structure is quite different from that of the anisotropic phases of aqueous potassium laurate as is shown by studies in this laboratory by Oscar A. Hoffman being reported elsewhere. He shows that the potassium laurate systems contain a repeating *lamellar* structure such as was first suggested by Hess and his collaborators.

(1) Vold, THIS JOURNAL, **63**, 1427 (1941).

(2) Marsden and McBain, *J. Phys. & Coll. Chem.*, **52**, 110 (1948).

(3) Bernal and Fankuchen, *J. Gen. Physiol.*, **25**, 111 (1941).

3. Up to the present, only two papers have appeared on X-ray diffraction of aqueous anisotropic phases of soaps or detergents. Ross and McBain reported that a *lamellar* structure *expanding continuously with dilution* exists both in the isotropic and anisotropic phases of the system hexanolamine oleate:water.[4] Marsden and McBain[2] found lamellar structures in the isotropic and anisotropic phases in aqueous systems of nonionic detergents, but the variation of long spacing with concentration is different for the two phases.

The aqueous liquid crystalline phase of dodecylsulfonic acid existing in the very high concentrations in the neighborhood of 85% has a *lamellar* structure, but the long spacing does *not* change with concentration. This long spacing appears to be due to the double length of the detergent molecule tilted at an angle β of about 63°. The various orders of this long spacing are in the ratio of 1:2:3 (that is, Bragg spacings in the proportion of $1:1/\sqrt{4}:1/\sqrt{9}$), with no diffraction lines in between; while the side spacings consist again of halos at 7–8 Å. and 4.5–4.6 Å.

4. For comparison with the various aqueous systems just described it may be mentioned that solid dodecyl sulfonic acid exhibits long spacings corresponding to even orders of pairs of molecules of the acid placed end to end but tilted at an angle β of 55°. No diffraction corresponding to that expected for the odd orders has yet been found.

It is clear that quite different colloidal particles exist in the different concentrations and phases of aqueous dodecyl sulfonic acid. It is evident that thorough study of aqueous systems of association colloids, wherein the fundamental chemical unit is definitely known, must throw light upon the study of closely related but less well characterized systems, such as those of proteins and virus.

A New Method of Preparation of Diazomethane

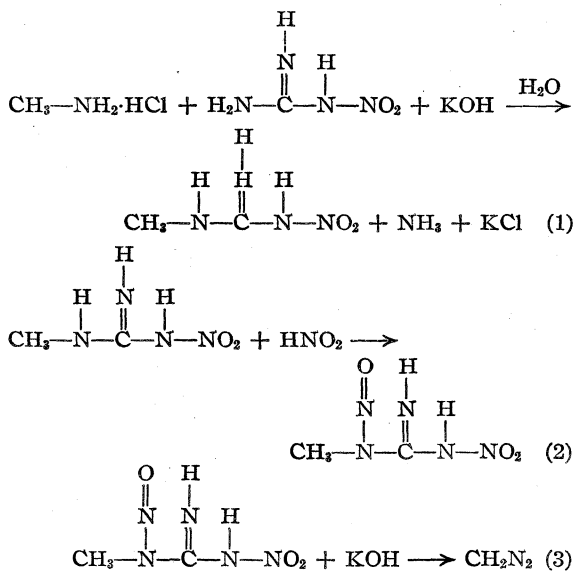
BY A. F. MCKAY

N-Methyl-N-nitroso-N′-nitroguanidine described by McKay and Wright[1] has been found to give diazomethane in 72.6% yield on reaction with aqueous potassium hydroxide.

The available methods[2] of production of diazomethane have disadvantages not encountered in the present method. The chief drawback in the method of Arndt[3] is the instability of methylnitrosourea which limits the production of this compound to 25–50 g. lots. On the other hand N-methyl-N-nitroso-N′-nitroguanidine has been prepared in pound lots and stored in the dark at room temperature for periods of time up to two months without showing signs of decomposition. N-Methyl-N-nitroso-N′-nitroguanidine changes slowly from orange to green in color on exposure to sunlight and loses nitrogen oxides. Moreover, in the purification of this compound it is best to employ an anhydrous solvent, preferably absolute methanol. Prolonged refluxing with 95% ethanol is sufficient to cause partial denitrosation with the production of N-methyl-N′-nitroguanidine.

The only disadvantage noted in handling N-methyl-N-nitroso-N′-nitroguanidine has been a skin irritation. The dermatitis is accompanied by pruritus and a burning sensation. In more severe cases a vesicant action has been noted. These skin reactions were obtained during the nitrosation of N-methyl-N′-nitroguanidine and when using the nitroso compound in other reactions. The simple expedient of performing the reactions in a fume hood eliminated these undesirable effects.

The series of reactions involved in the formation of diazomethane are



The first two reactions have been previously reported,[1] while reaction 3 is described in the experimental section. The diazomethane was characterized by methylating stearic acid. The methyl stearate obtained in quantitative yield melted at 39.0–39.5° alone and on admixture with an authentic sample.

This method is not limited to the production of diazomethane but it has been found to be of general use in the preparation of diazo compounds. The results on the broader application of this method will be published at a later date.

Experimental

Diazomethane.—The procedure used in the preparation of diazomethane from 20 g. (0.13 mole) of N-methyl-N-nitroso-N′-nitroguanidine was the same as the distillation technique described by Arndt[3] in the preparation of diazo-

methane from methylnitrosourea. The solutions in the receivers were combined and diluted to a volume of 250 cc. with anhydrous ether. A 10-cc. aliquot was used in the determination of the yield of diazomethane by the use of benzoic acid as described by Marshall and Acree.[4] The total yield was 4.15 g. or 72.6%.

Characterization of Diazomethane.—To 498 mg. (0.0017 mole) of stearic acid (m. p. 69 ± 0.1°) dissolved in 30 cc. of ether was added 331 mg. (0.0078 mole) of diazomethane in 20 cc. of ether. The ethereal solution was allowed to stand at room temperature for twenty minutes after the evolution of nitrogen had ceased. The excess diazomethane was decomposed with dilute hydrochloric acid solution and the ether fraction separated. After washing the ether solution with water (3 × 40 cc.), it was dried over anhydrous sodium sulfate and evaporated. The colorless residue crystallized on cooling. These crystals melted at 39–39.5° (capillary method) alone and on admixture with an authentic sample of methyl stearate. The yield was 514 mg. or 98.4% by theory.

Acknowledgment.—The author wishes to acknowledge the technical assistance of Mr. W. J. McIntyre.

Volatile Decomposition Products of Sugars in Aqueous Solution

BY LOUIS SATTLER AND F. W. ZERBAN

Enders and his co-workers[1] have published a series of papers purporting to show that methylglyoxal is found in the distillate not only when alkaline solutions of glucose and xylose are distilled at constant volume, but that methylglyoxal is found in distillates of neutral and acid solutions of these sugars as well. They also report the finding of methylglyoxal in the distillates from acid solutions of sucrose, maltose, dextrin and soluble starch.

Their conclusion that methylglyoxal is indeed the volatile material in the distillate, is based upon the following observations: the iodoform reaction, the color reaction with pyrrole, the color test of Denigès,[2] as for example with codeine phosphate, the Ariyama reaction[3] with arsenophosphotungstic acid and the characterization of methylglyoxal as its phenyl and 2,4-dinitrophenylosazones.

These color reactions for methylglyoxal are not specific and the reaction with sodium nitroprusside[4] has its limitations. The isolation of the osazones is not conclusive because acetol also yields the same derivatives. Acetol makes the Ariyama test ambiguous because, as with methylglyoxal, there is a great intensification of the blue color upon the addition of sodium cyanide (1 g.). Unfortunately, the conversion of acetol into 4(5)-methylimidazole[5] does not lend itself to micro quantities.

Baudisch and Deuel[6] have shown that sugars when distilled from a 5% sodium bicarbonate solution, yield acetol. The acetol can be specifically identified[7] by its reaction with *o*-aminobenzaldehyde to form 3-hydroxyquinaldine which can be isolated. This compound crystallizes from acetone and water in the form of colorless needles melting at 260°,[8] and possesses a beautiful blue fluorescence when it is illuminated in very dilute aqueous solution with invisible ultraviolet light.

In view of Enders' claim that methylglyoxal is obtained in the distillates when maltose solutions are distilled ranging over a wide *p*H, from strongly acid to strongly alkaline,[1b] it was deemed desirable to test for acetol because of the obvious conflict of these findings with the observations of Baudisch and Deuel. Pure 20% aqueous solutions of glucose and of maltose were distilled at constant volume. The distillates gave a positive test with Ariyama's reagent, and they yielded the reported osazones. However, with *o*-aminobenzaldehyde, under the conditions described by Baudisch and Deuel,[6] the distillates gave strong positive tests for acetol as observed by fluorescence. Baudisch and Deuel found that 1 g. of methylglyoxal gives only a faint acetol test, as observed by the intensity of the fluorescence, whereas 5 mg. of glucose when distilled with a sodium bicarbonate solution, yields a relatively large amount of acetol.

Pinkus[9] obtained the osazone of methylglyoxal when glucose was treated with strong alkali in the presence of phenylhydrazine. While Nef,[10] Wohl,[11] and Neuberg[12] have expressed beliefs that in alkaline solution methylglyoxal is the initial product formed in the rupture of the sugar molecule, Baudisch and Deuel are of the opinion that acetol is the primary compound which is produced because under their experimental conditions the Cannizzaro reaction is apparently negligible. Thymine, which on treatment with ferrous sulfate and sodium bicarbonate in the presence of air, is oxidized to urea, pyruvic acid and acetol, can be detected in the presence of sugar.[6]

Our finding of acetol in the distillates of aqueous sugar solutions does not rule out the simultaneous presence of methylglyoxal. It does point up the conclusion that Enders' quantitative method for the estimation of methylglyoxal is erroneous and that his opinions regarding the formation of methylglyoxal are open to modification. Of further interest to us is the darkening of these triose solutions when they are distilled from a 5% so-

2-Aryl- and 2-Alkoxycyclohexanols[1]

BY B. C. MCKUSICK[2]

As part of a program to find improved insect-repellents, a number of 2-aryl- and 2-alkoxycyclohexanols were prepared from cyclohexene oxide.

The 2-arylcyclohexanols were obtained by condensing cyclohexene oxide with appropriate aryllithiums[3]; Grignard reagents were not used because the products would have been the isomeric arylcyclopentylcarbinols.[3] The postulated cyclohexanol structure was confirmed for one product, 2-(*p*-tolyl)-cyclohexanol, by oxidizing it to the known δ-*p*-toluylvaleric acid. Yields of cyclohexanols were good except in the case of 2-(*p*-methoxyphenyl)-cyclohexanol, where the low yield is understandable in view of the ease with which the side-reaction of *p*-methoxyphenyllithium with *p*-bromoanisole to give anisole and 5-bromo-2-methoxyphenyllithium is known to occur.[4] Since 2-phenylcyclohexanol prepared from cyclohexene oxide and phenyllithium[3] has been shown to have a *trans*-configuration,[5] it is probable that the present 2-arylcyclohexanols are also *trans*.

The 2-alkoxycyclohexanols were obtained by heating cyclohexene oxide with an excess of the appropriate alcohol in which a trace of sodium had been dissolved.[6] *trans*-1,2-Cyclohexanediol was a by-product of the preparation of 2-(β-phenethoxy)-cyclohexanol and may have been a by-product in other cases.

Experimental

2-Arylcyclohexanols.—The preparation of 2-(*m*-tolyl)-cyclohexanol can be used to illustrate the general procedure. In a 12-liter three-necked flask, 69 g. (20% excess) of lithium in the form of small strips[7] was stirred vigorously in 3 liters of anhydrous ether under nitrogen while 711 g. of *m*-bromotoluene was added at a rate to maintain gentle refluxing of ether. Once reaction set in, the flask was kept immersed in an ice-bath in order to shorten the time necessary for the addition (about one hour). The mixture was heated under reflux for an hour and 408 g. of cyclohexene oxide[8] was added in the same manner. The mixture was cooled in ice and decomposed by the gradual addition of 3 liters of water with stirring. The ether layer was separated, washed with water, dried over magnesium sulfate, and distilled; 655 g. (71% yield) of 2-(*m*-tolyl)-cyclohexanol was collected at 113–114° (1.0 mm.).

The acetate and propionate were obtained by heating 2-(*m*-tolyl)-cyclohexanol at 100° for two hours with 1.5 molar equivalents of acid anhydride and 2 molar equivalents of pyridine and distilling the reaction mixtures under reduced pressure.

sodium hydroxide solution and distilled; 37 g. of a mixture of starting material and the corresponding ketone was obtained. Acidification of the sodium hydroxide extract caused the precipitation of 7.6 g. of *p*-toluylvaleric acid, m. p. 152.5–154°[9] after recrystallization from a benzene–ethanol mixture; neutralization equivalent, 223 (calcd., 220). δ-Benzoylvaleric acid has been obtained from 2-phenylcyclohexanol under similar conditions.[3]

2-Alkoxycyclohexanols.—In a typical experiment, 2-amyloxycyclohexanol was prepared by refluxing for twenty-two hours a solution of 49 g. of cyclohexene oxide[8] in 200 ml. of *n*-amyl alcohol containing 0.5 g. of dissolved sodium. The reaction mixture was distilled and 72 g. (77%) of 2-amyloxycyclohexanol was collected at 100–113° (11 mm.). When alcohols boiling above 200° were used, the solutions were heated at 180–200°.

In the reaction between 35 g. of cyclohexene oxide and 140 ml. of phenethyl alcohol, the first portion of 2-(β-phenethoxy)-cyclohexanol collected on distillation contained *trans*-1,2-cyclohexanediol, 4 g. of which crystallized out on cooling the mixture. It was recrystallized from hexane and identified by its melting point (102–103°),[10a] dibenzoate melting point (91.5–92°),[10b] and composition.

Anal. Calcd. for $C_6H_{12}O_2$: C, 62.0; H, 10.4. Found: C, 62.1; H, 10.4.

The Solubility of Aminoguanidonium Bisulfate in Water and in Sulfuric Acid Solutions[1]

BY JOHN J. PITHA[2] AND G. B. L. SMITH[3]

In the reduction of nitroguanidine in a sulfuric acid solution, the end-product of the reaction is aminoguanidonium bisulfate. In order better to control the recovery of this salt, some investigations were made into the solubility of aminoguanidonium bisulfate in water and in solutions of various sulfuric acid concentrations.

Experimental

The solubility of aminoguanidonium bisulfate was determined by preparing a saturated solution of the salt in the appropriate solvent at a definite temperature. After equilibrium had been established, a sample of the solution was withdrawn and transferred to a tared volumetric flask and weighed. This solution was then diluted to volume and analyzed for aminoguanidine by the method of Smith and Wheat.[4]

These studies were carried out in a specially constructed three-necked flask of 100 ml. capacity. One neck was used to insert a thermometer into the solution, one neck allowed the entry of an all-glass stirrer, and the third neck was used as an addition port. Ground glass joints were used throughout. Solution temperatures from 5 to 40° were measured with an unjacketed thermometer, but higher temperatures were measured with a thermometer suspended within a glass jacket. The bulb of the flask and the lower third of the necks were immersed in a 7.5-gal. water-bath. This thermostat was equipped with both heating and cooling coils and the temperature of the solution in the reaction flask was controlled to ±0.03°.

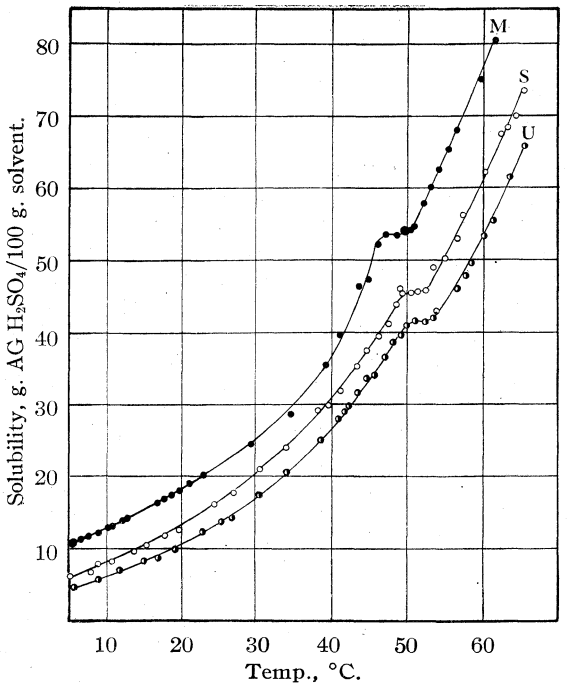

Fig. 1.—M, ●, H_2O; S, ○, 0.7419 *N* H_2SO_4; U, ◑, 1.4088 *N* H_2SO_4.

Saturated solutions of the salt at a particular temperature were prepared by adding an excess of the solute to the solvent and stirring the solution until equilibrium had been established. The attainment of equilibrium was proven by successive sampling and analysis at regular intervals of time until three successive values were in agreement. A half-hour lapse of time after the solution had come to temperature was usually sufficient for equilibrium to be reached. In certain portions of these studies, the equilibrium was approached from both directions in order to establish definitely the values reported.

In order to avoid errors that might occur in the removal and transfer of samples due to crystallization of the salt from the saturated solution while in the sampling tube, pipets used for this purpose were kept in an oven and were used warm. The operation was performed with sufficient speed that no difficulty with crystallization was encountered.

At least three determinations of solubility were made at each temperature, and in the cases where abnormalities were observed sufficient determinations were made to establish the points reported. The accuracy of the analytical procedure was such that an error of 0.1% was average. Precision of results on duplicate sets of samples was of the order of 1 part in 1000 parts. The solubility of aminoguanidonium bisulfate in water, 0.7419 *N* sulfuric acid and 1:4088 *N* sulfuric acid was determined. The results of the solubility determinations are summarized in Fig. 1. Crystals obtained by evaporation at temperatures above and below the inflection temperatures in all cases analyzed 99.5% or better for aminoguanidonium bisulfate, and macro observations of these crystals showed no differences in crystalline form. The nature of the inflection observed in each of the curves is not completely understood, but additional information is being sought and will be reported in a subsequent paper.

Critical Temperature and Pressure of Diborane[1]

BY ARTHUR E. NEWKIRK

In connection with studies of the boron hydrides the critical temperature and pressure of diborane have been measured experimentally by observing the temperature and pressure at which the meniscus between liquid and vapor disappeared on warming. The apparatus was patterned after that of Kay.[2] The temperature was estimated to 0.01° and the pressure to one p.s.i. The sample of diborane was taken from a cylinder and analyzed by low temperature fractional distillation yielding 0.2% of non-condensable gas and 99.8% diborane. The gas used for measurement was therefore vaporized from the cylinder, frozen in a thin layer on the walls of a glass bulb, pumped to remove non-condensable gas and distilled to the capillary. The remainder of the capillary was filled with mercury, attached to the apparatus, and the capillary, its holder and the mercury reservoir placed in a bath at 14°. The bath warmed at the rate of 2° per hour. Several cycles of warming and cooling were made with each run to avoid accidental errors. The results are given in Table I.

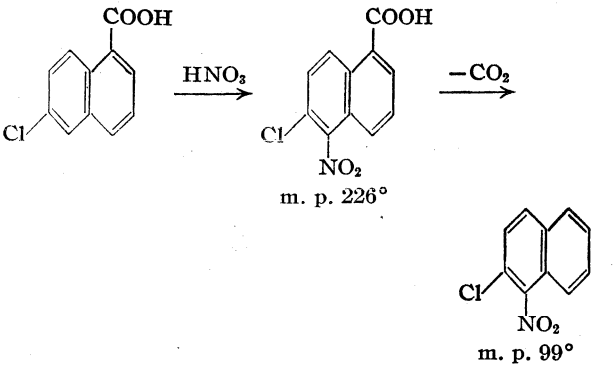
The Nitration of 6-Chloro-1-naphthoic Acid

BY CHARLES C. PRICE, THOMAS J. BARDOS AND HERMAN I. ENOS[1]

In an exploration of possible routes to a heterocyclic ring system analogous to that in morphine[2] but based on the naphthalene rather than the phenanthrene nucleus, we have investigated the nitration of 6-chloro-1-naphthoic acid with the hope that it might produce the 3-nitro derivative. Nitration of the acid, or preferably of its ester, proceeded satisfactorily to give only one product which could be isolated in pure crystalline condition. This material was shown to be the 5-nitro derivative by decarboxylation to 1-nitro-2-chloronaphthalene, identified by mixing melting point with an authentic sample.

(1) Present address: Department of Chemistry, Swarthmore College, Swarthmore, Pa.

(2) Barltrop, *J. Chem. Soc.*, 399 (1947).



Experimental

Preparation of 6-Chloro-1-naphthoic Acid.—The method of Price and Huber[3] was followed in its original form. The ester fraction obtained was hydrolyzed with 15% aqueous sodium hydroxide solution until it dissolved and the acid was precipitated with dilute hydrochloric acid. The total yield of *crude* 6-chloro- and 7-chloro-1-naphthoic acid mixture was 66% (40% from the straight acid fraction and 26% from the ester fraction; the melting points were 183–185° and 171°, respectively). The 6- and 7-chloro isomers were separated through their acid chlorides, following the procedure of Jacobs, Winstein, Seymour and Linden.[4] Methyl 6-chloro-1-naphthoate was obtained (35%, m. p. 66°) and only 8% of the 7-chloro-1-naphthoyl chloride (m. p. 100–104°). The methyl 6-chloro-1-naphthoate was saponified with 20% aqueous sodium hydroxide, and the acid (m. p. 215.5–216°) precipitated.

Nitration of 6-Chloro-1-naphthoic Acid.—An 11-g. sample (0.053 mole) of the pure 6-chloro-1-naphthoic acid was treated with 18 cc. of fuming nitric acid (d. 1.49–1.50). The substance dissolved partly under vigorous evolution of nitrous oxides and of heat. The reaction mixture was warmed for five to ten minutes on the water-bath. After cooling, fine crystals deposited which were collected on a glass filter, washed with some cold nitromethane, and recrystallized from nitromethane. After this first recrystallization, 8.2 g. (62%) of the greenish yellow nitration product was obtained melting in the range of 198–215°. Five more recrystallizations from nitromethane raised the melting point to 224.8–225.5°. The yield of this pure mono-nitro derivative was 3.7 g. (27.5%) obtained as white needles with a greenish tint; neutralization equivalent, 246 (calcd., 251).

Anal. Calcd. for $C_{11}H_6O_4NCl$: C, 52.48; H, 2.41; N, 5.56; Cl, 14.05. Found: C, 52.70; H, 2.21; N, 5.48; Cl, 14.48.

Decarboxylation of the Nitro Acid.—A sample of 0.48 g. of the 6-chloro-nitro-1-naphthoic acid in 1 cc. of redistilled quinoline was heated in an oil-bath to 220–230° until a homogeneous solution was obtained. Then 0.1 g. of hydrogen-reduced copper powder was added. Immediately vigorous carbon dioxide evolution was observed. The temperature was raised to 240° for five minutes and then the mixture was cooled. It was extracted with ether, the ether extract filtered, washed with dilute hydrochloric acid, with 10% aqueous sodium bicarbonate solution and with water. Finally it was treated with some charcoal, filtered and the ether evaporated: large, pale yellow crystals were obtained. This substance was again recrystallized from aqueous ethanol, with charcoal, to yield pale yellow crystals, m. p. 96.5°. After a further recrystallization almost colorless crystals were obtained, m. p. 98.5–99°.

This corresponds closely to the melting point reported for 1-nitro-2-chloronaphthalene. Since the data in the

(3) Price and Huber, THIS JOURNAL, **64**, 2136 (1942).

(4) Jacobs, Winstein, Seymour and Linden, *J. Org. Chem.*, **11**, 292 (1946).

literature are somewhat divergent (Vesely,[5] Colerdi and Moe,[6] Hodgson and Leigh[7]) we synthesized this compound from β-naphthylamine following for the Sandmeyer step the directions of Hodgson and Walker.[8] The 2-chloro-1-nitronaphthalene so obtained had a melting point of 99–99.5°. The mixed melting point with the sample obtained by the decarboxylation of the 6-chloro-nitro-1-naphthoic acid was 98.5–99°. Accordingly our nitro product must be 6-chloro-5-nitro-1-naphthoic acid.

Nitration of Methyl 6-Chloro-1-naphthoate.—A 9.0-g. sample (0.041 mole) of pure methyl 6-chloro-1-naphthoate (m. p. 66°) was treated with 15 cc. of fuming nitric acid (d. 1.49–1.50) and warmed for five minutes on a water-bath. After cooling, a crystalline mass deposited which was collected on a glass filter and washed with a small portion of cold nitromethane. The crystal mass was already almost white, and after one recrystallization from aqueous methanol, pure methyl 6-chloro-5-nitro-1-naphthoate was obtained: yield, 3.3 g. (30%), m. p. 143.5–144°.

Anal. Calcd. for $C_{12}H_8O_4NCl$: C, 54.23; H, 3.03; N, 5.27; Cl, 13.36. Found: C, 54.52; H, 3.23; N, 5.07; Cl, 13.34.

Hydrolysis of the Nitro Ester.—A solution of 0.5 g. of the ester was refluxed in 30 cc. of 20% aqueous potassium hydroxide, to which 4 g. of salt was added. The substance dissolved after one-half hour of vigorous boiling. In acidification, a dark brown precipitate was obtained. This was filtered and twice recrystallized from nitromethane. Greenish-yellow crystals were obtained which melted at 226.5°. A mixed melting point with 6-chloro-5-nitro-1-naphthoic acid above gave 226–226.5°, showing the identity of the two compounds.

Anilide from the Nitro Acid.—A mixture of 0.2 g. of 6-chloro-5-nitro-1-naphthoic acid and 0.5 cc. of thionyl chloride was refluxed for one-half hour. The reaction mixture was treated with 1 cc. of redistilled aniline and dissolved in 15 cc. of benzene. The yellow suspension was washed with water, with dilute hydrochloric acid, with water and with sodium carbonate solution. After evaporation of the benzene, the residue was recrystallized from aqueous ethanol, using charcoal. The slightly greenish crystalline substance had a melting point of 193–193.5°.

Anal. Calcd. for $C_{17}H_{11}O_3N_2Cl$: C, 62.46; H, 3.40; N, 8.57; Cl, 10.85. Found: C, 62.71; H, 3.30; N, 8.68; Cl, 11.10.

Anilide from the Nitro Ester.—(a) A 0.28-g. sample of the ester was treated with three to four-fold excess of anilinomagnesium bromide for ten minutes on the water-bath. (The anilinomagnesium bromide was prepared by addition of 8 g. of aniline to ethylmagnesium bromide, prepared from 2 g. of magnesium and 10 g. of ethyl bromide in 60 cc. of ether, until the very vigorous evolution of ethane ceased.) Ten cc. of dilute hydrochloric acid was added to the mixture and the ether evaporated at room temperature. The dark brown solid residue from the ether layer was separated from the acidic solution by filtration, and it was recrystallized from aqueous ethanol, yielding 0.12 g. of anilide (34%), m. p. 190–191°. This was recrystallized twice (first with charcoal) to give almost colorless crystals, m. p. 193.5–194°, identical with the anilide obtained from the acid.

(b) When 0.3 g. of the ester was heated with 0.2 g. of aniline at 160–170° for twenty minutes, the ester was recovered unchanged, m. p. 143.5–144°.

Amide from the Nitro Acid.—A 0.22-g. sample of 6-chloro-5-nitro-1-naphthoic acid was heated with 1 cc. of thionyl chloride for twenty minutes. The mixture was poured into 10 cc. of ice-cooled 33% ammonium hydroxide. It was cautiously heated on the water-bath for five minutes, then cooled, filtered and recrystallized from aqueous ethanol, m. p. 207–208°.

9,9-Dibromofluorene and Formation of a Dangerous Skin Irritant

BY JOHN R. SAMPEY AND SCOTT J. CHILDRESS

The preparation of 9-bromofluorene by direct photobromination[1] suggested the preparation of 9,9-dibromofluorene by the addition of a second mole of bromine under strong irradiation.

A solution of 16 g. of fluorene in 150 ml. of carbon tetrachloride was placed in a 250 ml. Vitreosil Erlenmeyer flask equipped with reflux condenser. By the use of a six-inch mercury arc close to the flask, the contents were heated to reflux while a solution of 2 moles of bromine in 50 ml. more solvent was added dropwise through the condenser in thirty minutes. Anhydrous conditions were assumed by a calcium chloride tube and irradiation continued thirty minutes after the addition. Evaporation of the solvent yielded a light gray crystalline product recrystallized from acetic acid, *n*-heptane or absolute alcohol. The yield was 45% of material melting at 115° (uncor.). The literature value for 9,9-dibromofluorene is 114°.[2]

Experiments to further identify the 9,9-dibromofluorene were discontinued when two additional workers to those reported previously,[3] were stricken with a severe dermatitis which has spread over large areas of the body, and which is responding slowly to medical treatment. Intense itching, pus formation, and considerable swelling of the hands, arms and face accompany the irritation.

The authors acknowledge with pleasure the interest of Dr. E. Emmet Reid.

Nuclear Substituted 9-(4′-Diethylamino-1′-methylbutylamino)-acridines[1]

BY E. R. SHEPARD AND H. A. SHONLE[2]

At the suggestion of the Committee on Medical Research of the OSRD several years ago, the preparation of a series of nuclear substituted acridines was undertaken. They were prepared in order to study clinically the absorption, excretion and metabolic changes which these materials undergo. In addition, it was of interest to inquire further

(1) Presented before the Division of Medicinal Chemistry at the 109th meeting of the American Chemical Society, Atlantic City, New Jersey, April, 1946.

(2) Deceased, February 24, 1947.

into the relationship of structure and antimalarial activity of the acridines.[3]

The following conclusions can be drawn on the basis of duckling tests[4] on the compounds reported here: (a) A substituent in the 1 position (Fig. 1) appears to be mildly dystherapeutic:

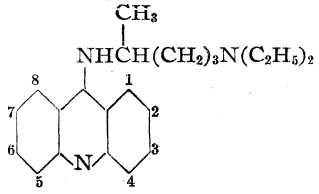

Fig. 1.

(b) One substituent in the 4 or 5 position gives a regular dystherapeutic effect. Since completion of this work, these findings have been supported by Hall and Turner[5] with the amendment that upon substitution in both the 4 and 5 positions, increased activity may be expected.

Experimental

The *o*-chloro-, *o*-bromo and 2,4-dichlorobenzoic acids were obtained commercially. The *o*-chlorobenzoic acid was purified[6] before use.

The anilines with the exception of 2-chloro-4-methoxy and 3,5-dichloroaniline were commercial samples which were distilled or crystallized.

3,5-Dichloroaniline was prepared from 2,6-dichloro-4-nitroaniline by deamination and reduction of the resulting 3,5-dichloronitrobenzene.[7]

2-Chloro-4-methoxyaniline was prepared quite readily in large quantities from technical *p*-anisidine.[8] Phosgene passed into an aqueous solution of pyridine and technical *p*-anisidine gave an 82% yield of N,N'-di-(*p*-methoxy)-phenylurea which was dried and chlorinated in *sym*-tetrachloroethane to give a quantitative yield of the dichlorinated urea. Treatment with 28% ammonium hydroxide at 150–160° for five hours gave a 90–95% yield of 2-chloro-4-methoxyaniline, b. p. 141–144° (25 mm.); N-acetyl derivative, m. p. 113–114.5° (lit.,[8] m. p. 114°).

Diphenylamine-2-carboxylic Acids.—The diphenylaminecarboxylic acids were prepared according to the method of Ullmann.[9] The following more detailed description is typical of the method used for the preparation.

5-Chlorodiphenylamine-2-carboxylic Acid.[10]—One hundred grams (0.52 mole) of 2,4-dichlorobenzoic acid, 60 g. (0.64 mole) of aniline, 82 g. (0.59 mole) of potassium carbonate, 3–5 g. of copper oxide (precipitated powder), and 250 ml. of isoamyl alcohol were refluxed three hours. The hot solution was steam distilled until all of the alcohol and some basic oil came over. The hot residual solution was diluted to 3–4 liters with hot water and decolorized with carbon. The filtrate was acidified with dilute hydrochloric acid, and filtered. The yield was 103–115 g. of crude 5-chlorodiphenylamine-2-carboxylic acid. Since purification was not necessary at this step and would diminish over-all yields, no attempt was made to isolate the pure amino acids.

The crude amino acids were ring closed to the corresponding 9-chloroacridines[11] and these then reacted with excess 5-diethylamino-2-aminopentane in phenol at 100–110° for one to two hours. The reaction mixtures were decomposed with excess sodium hydroxide solution and extracted with ether. The ether layers were washed and extracted with 5% acetic acid. The bases were liberated from the acetate solutions with sodium hydroxide, taken up in ether and heated eventually at 100° at 15 mm. to remove excess 5-diethylamino-2-aminopentane. Dry hydrogen chloride passed into the solutions of the bases in dry ether gave the anhydrous hydrochlorides which were extremely hygroscopic. The melting points of the anhydrous salts varied widely with slight changes in hydrogen chloride content and were therefore meaningless. Table I lists the acridines prepared in this manner.

INDIANAPOLIS 6, INDIANA RECEIVED FEBRUARY 6, 1948

Ethyl Acetoacetate 4-Nitrophenylhydrazone and 1-(4'-Nitrophenyl)-3-methylpyrazolone-5

BY WARD C. SUMPTER AND PHIL H. WILKEN

The interaction of equimolecular proportions of ethyl acetoacetate and 4-nitrophenylhydrazine at steam-bath temperature in either the presence or absence of ethanol as a solvent yields ethyl acetoacetate 4-nitrophenylhydrazone (I), m. p. 118°, and not 1-(4'-nitrophenyl)-3-methylpyrazolone-5 (II), m. p. 218°, as stated in the literature.[1]

The nitrophenylhydrazone (I) was converted into the pyrazolone (II) by refluxing a solution of I in glacial acetic acid for five hours at steam-bath temperature. Heating I at steam-bath temperature for fifteen minutes with concentrated hydrochloric acid accomplished the same transformation. Similarly II was obtained when ethyl ace-

toacetate and 4-nitrophenylhydrazine were refluxed together in equimolecular quantities in glacial acetic acid as solvent. The pyrazolone (II) was also obtained when the condensation of ethyl acetoacetate and 4-nitrophenylhydrazine was carried out in the presence of concentrated hydrochloric acid with or without the addition of ethanol.

The samples of II obtained in these several procedures were identified by comparison with an authentic sample prepared by the nitration of 1-phenyl-3-methylpyrazolone-5 as described in German Patent 61794.[2]

Experimental

Ethyl Acetoacetate 4-Nitrophenylhydrazone (I).—A mixture of 15.3 g. (0.1 mole) of 4-nitrophenylhydrazine and 13.0 g. (0.1 mole) of ethyl acetoacetate with or without the addition of a small quantity of ethanol as solvent was heated under reflux on the steam-bath for several hours. The orange colored crystalline product which separated on cooling was purified by crystallization from 95% ethanol; m. p. 118°.

Anal. Calcd. for $C_{12}H_{15}N_3O_4$: N, 15.84. Found: N, 15.85, 15.76.

1-(4′-Nitrophenyl)-3-methylpyrazolone-5 (II). A.—A sample of ethyl acetoacetate 4-nitrophenylhydrazone (5 g.) was treated with sufficient glacial acetic acid to dissolve it and the resulting solution heated under reflux at steam-bath temperature for five hours. The yellow crystalline product which separated on cooling was purified by crystallization from 95% ethanol from which it separated as light yellow crystals; m. p. 218°. Heating the hydrazone (I) for fifteen minutes at steam-bath temperature with concentrated hydrochloric acid brought about the same transformation.

B.—A mixture of 7.65 g. (0.05 mole) of 4-nitrophenylhydrazine, 6.5 g. (0.05 mole) of ethyl acetoacetate and 25 g. of glacial acetic acid was heated under reflux at steam-bath temperature for five hours. The product which separated on cooling was crystallized from 95% ethanol from which it separated as light yellow crystals; m. p. 218°. The pyrazolone (II) was also obtained when a mixture of ethyl acetoacetate (0.05 mole) and 4-nitrophenylhydrazine (0.05 mole) was heated in the presence of 2 ml. of concentrated hydrochloric acid either with or without the addition of ethanol.

C.—The compound was prepared from 1-phenyl-3-methylpyrazolone-5 by nitration according to the procedure given in German Patent 61794[2]; light yellow crystals; m. p. 218°.

The identity of the samples prepared by procedures A, B and C was established by melting point methods. The melting points reported herein are uncorrected.

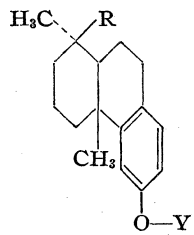
Studies on Resin Acids. III. A Direct Reduction of Podocarpic Acid[1]

BY HAROLD H. ZEISS, CHESTER E. SLIMOWICZ AND VARSENIG Z. PASTERNAK

The constitution of the naturally occurring podocarpic acid (I) has suggested this resin acid as an unusually attractive starting material for the preparation of compounds having structural and perhaps physiological similarity to estradiol. One such compound is the hitherto unknown podocarpinol (II), the preparation of which is described in one step from podocarpic acid in this paper.



I, R = COOH; Y = H
II, R = CH_2OH; Y = H
III, R = COOCH; Y = CH_3
IV, R = COCl; Y = CH_3
V, R = CH_2OH; Y = CH_3

The direct reduction of the carboxylic acid group of the resin acids is usually attended by more or less difficulty, depending upon the configuration of these groups at the C_1 position. The *trans* acids,[2] represented by abietic acid, are less hindered and therefore more easily reduced than the *cis* acids,[2] represented by agathic and podocarpic acids, which are quite resistant to reaction owing to the extremely large effect of steric hindrance. While methyl abietate responds readily to a forced Bouveault-Blanc reduction, the methyl ester of isonoragathic acid is converted to isonoragathenol in very poor yield.[3] Alternately Campbell and Todd[4] have used an indirect method for reducing the O-methyl derivative of podocarpic acid to O-methylpodocarpinol *via* the acid chloride and the aldehyde.

It has been found that lithium aluminum hydride,[5] a compound recently discovered by Schlesinger and co-workers[6] and developed by Nystrom and Brown,[7] converts podocarpic acid directly to podocarpinol in satisfactory yield (56%). Under the same experimental conditions the methyl ester (III) and the acid chloride (IV) of O-methylpodocarpic acid also react with lithium aluminum hydride to give, after hydrolysis of the metal complex, O-methylpodocarpinol (V). The identity of podocarpinol is established by methylation to the known O-methylpodocarpinol.

Although the rate of reaction of lithium aluminum hydride with podocarpic acid is slow, it appears that the reduction of hindered acids with this reagent is not unreasonably limited by steric effects.

Experimental

Podocarpinol (II).—A solution of 8 g. of lithium aluminum hydride in 300 ml. of dry ether was placed in a one-liter flask equipped with dropping funnel, reflux condenser and mercury seal stirrer. All outlets were provided with calcium chloride tubes to exclude moisture during the reaction. To this solution was added dropwise with stirring 7 g. of podocarpic acid (m. p. 194–196°) dissolved in 150 ml. of ether. The mixture was then

allowed to stand for four days with occasional warming. Ice was next introduced to decompose excess hydride reagent and the reaction complex then hydrolyzed with dilute sulfuric acid. The ether layer was removed and the aqueous layer extracted with fresh ether. The combined ether extracts were then washed with water and extracted with dilute sodium carbonate solution to remove unreacted podocarpic acid. After drying over anhydrous potassium carbonate the ether solution was concentrated and hexane added. On cooling transparent cubes of podocarpinol crystallized out of solution; m. p. 177–178.5°. Recrystallization from ether gave 3.7 g. (56%) of pure material; m. p. 178–179°.

Anal.[8] Calcd. for $C_{17}H_{24}O_2$: C, 78.42; H, 9.29. Found: C, 78.09; H, 9.08.

In an earlier run in which the total reaction time was two hours a yield of 4.6% of podocarpinol was obtained.

Methylation of podocarpinol with dimethyl sulfate in the usual manner gave O-methylpodocarpinol (m. p. 90–91°), first prepared by Campbell and Todd.[4] A mixed m. p. with the O-methylpodocarpinol prepared as described below showed no depression.

O-Methylpodocarpinol (V). (*a*) **From O-Methylpodocarpoyl Chloride (IV).**—Reaction between 33 g. of O-methylpodocarpoyl chloride (m. p. 61°) in 1 liter of ether and 10 g. of lithium aluminum hydride in 800 ml. of ether was carried out over a period of four days. The mixture was worked up in the same manner as described above (m. p. 91°) from which 28 g. (92%) of pure O-methylpodocarpinol was obtained after one crystallization from ether–hexane.

(*b*) **From Methyl O-Methylpodocarpate (III).**—Lithium aluminum hydride (8 g.) in 400 ml. of ether was treated with 15 g. of methyl O-methylpodocarpate m. p. 158–159° in 300 ml. of ether as above. From this experiment there was obtained 12.7 g. (93%) of O-methylpodocarpinol; m. p. 91°.

NEW COMPOUNDS

α-Nitrostilbene Analogs

The *alpha*-nitrostilbenes are physiologically active. Also compounds of the *alpha*, *beta*-diphenylethylamine type obtained by further reduction have been reported to have a selective effect in damaging sarcoma cells.[3]

Accordingly we have prepared nitro compounds of this type and submitted them to the National Cancer Institute for testing.

1-α-Thienyl-2-phenyl-2-nitroethylene was prepared by mixing 9.0 g. phenylnitromethane, 8.1 g. 2-thiophenealdehyde[4] and 3 ml. of a 10% solution of methylamine in methanol, warming gently, then shaking for three hours at room temperature. The bright yellow crystals which separated weighed 4.9 g. After triple recrystallization from absolute ethanol the product melted at 123° cor.

Anal. Calcd. for $C_{12}H_9O_2SN$: C, 62.34; H, 3.90; N, 6.06. Found: C, 62.45; H, 3.76; N, 6.06.

(4) Purchased from Aragohes Chemicals, Inc., Boulder, Colo.

1-α-Furyl-2-*o*-chlorophenyl-2-nitroethylene was prepared by mixing 7.82 g. of *o*-chlorophenylnitromethane, 4.36 g. of freshly distilled furfural, and 5.16 cc. of a 16% solution of methylamine in methanol. The crystals which separated on standing three days weighed 3.96 g. The product was dissolved in absolute ethanol and the solution decolorized with activated carbon. After recrystallization from absolute ethanol the melting point was 101.1° cor.

Anal. Calcd. for $C_{12}H_8NO_3Cl$: C, 57.72; H, 3.21; N, 5.61. Found: C, 57.92; H, 3.12; N, 5.53.

1-*m*-Nitrophenyl-2-phenyl-2-nitroethylene was prepared by mixing 3 ml. of phenylnitromethane, 3.0 g. of *m*-nitrobenzaldehyde,[5] 0.5 ml. of 10% methylamine and 6 ml. of methanol. After standing four days the solution was diluted with 25 ml. of petroleum ether and chilled in Dry Ice. The yield of crystals was only 0.4 g. (7.5%). After recrystallization from absolute ethanol the melting point was 112.0° cor.

Anal. Calcd. for $C_{14}H_{10}N_2O_2$: C, 62.22; H, 3.70; N, 10.37. Found: C, 62.60; H, 3.75; N, 10.12.

1-*p*-Nitrophenyl-2-phenyl-2-nitroethylene, reported by Baker and Wilson[6] as melting at 155°, was prepared by us and found to melt at 157.5° cor., after repeated recrystallization.

Acknowledgment.—We wish to acknowledge our indebtedness to Dr. M. J. Shear and Dr. Jonathan L. Hartwell of the National Cancer Institute for suggestions and encouragement, to Mr. Charles A. Kinser and Mrs. Margaret M. Ledyard of the National Institute of Health for carrying out the microanalyses recorded above, and to the National Cancer Institute for financial assistance.

[a] Fractionations were through a five-inch indented Claisen distillation head. [b] For super-cooled liquid. [c] Based on piperonylic acid.

perature did not exceed 16°. The resultant solution stood at room temperature for three days, was neutralized with carbon dioxide, and the alcohol was removed by distillation. The oily layer was taken up in ether and the extract was washed once with a small amount of water, dried with magnesium sulfate and distilled.

2,2-Diethyl-1,3-Propanediol Diacetate.—A solution of 23.5 g. of 2,2-diethyl-1,3-propanediol and 75 ml. of acetic anhydride was heated on a steam-bath for twelve hours with 10 g. of sodium acetate.

2-(*p*-Methoxyphenyl)-5,5-diethyl-*m*-dioxane.—A solution of 21 g. of 2,2-diethyl-1,3-propanediol, 23.8 g. of anisaldehyde, 0.2 g. of *p*-toluenesulfonic acid and 50 ml. of benzene was refluxed overnight in an apparatus which trapped water as formed.

1-Phenyl-1,3-propanediol Dipropionate.—A solution of 30 g. of 1-phenyl-1,3-propanediol,[2] 76 ml. of propionic anhydride and 63 ml. of pyridine was heated at 100° for two hours and distilled.

Piperonylates.—The acid chloride[3] of piperonylic acid[4] was heated at 100° with pyridine and a several-fold excess of suitable alcohol.

***p*-Methoxycinnamates.**—These esters were obtained by transesterification. A solution of ethyl *p*-methoxycinnamate[5] in 3 parts by weight of the appropriate alcohol containing 0.2% of dissolved sodium was slowly distilled through a short Vigreux column.

Hexahydrophthalates.—Dimethyl hexahydrophthalate, b. p. 91–93° (1.3 mm.), $n^{25}D$ 1.4567, was obtained in 92% yield by hydrogenation of dimethyl phthalate over Raney nickel at 175°. It was converted to higher esters by transesterification as described for the *p*-methoxycinnamates.

Benzaldehyde Di-*n*-butyrate.—A drop of 95% sulfuric acid was added to a solution of 25 g. of benzaldehyde in 41 g. of butyric anhydride. Heat was evolved. After the solution had cooled back to room temperature, it was taken up in ether and the ether solution was washed with water, dried, and distilled.

***p*-*n*-Propylphenethyl Alcohol.**—To an ether solution of the Grignard reagent prepared from 50 g. of *p*-bromo-*n*-propylbenzene (Eastman Kodak Co.) there was added with stirring 12 g. (10% excess) of ethylene oxide. A gum precipitated. While stirring continued, the ether was removed by distillation, toluene being gradually added to take its place. The mixture was stirred for an hour at 95° and poured while still hot into aqueous ammonium chloride solution. The oil which separated was taken up in ether and the ether extract was dried over magnesium sulfate and distilled.

N-Cyclohexyl-N-phenylpropionamide.—A solution of 28 g. of cyclohexylaniline (Monsanto Co.) and 47 g. of propionic anhydride was refluxed for eight hours and distilled. The product was recrystallized from hexane.

COMMUNICATIONS TO THE EDITOR

ADSORPTION AT THE DROPPING MERCURY ELECTRODE

Sir:

Despite the large quantity of work which has been carried out with capillary-active substances as maximum suppressors in polarographic analysis, a detailed consideration of their effect on the diffusion current itself has apparently not been made. One may find references in the literature[1,2,3] to interference with the diffusion current, brought about by the use of capillary-active materials, but no satisfactory explanation has been offered.

Polarograms prepared from solutions which contained various concentrations of purified horse albumin at *p*H 8 and which were 1×10^{-4} *M* in the dye *p*-hydroxyphenylazophenylarsonic acid, 0.15 *M* in sodium chloride, and 0.02 *M* in veronal indicated that the diffusion current was suppressed to approximately 90% of its true value at a protein concentration of 1×10^{-6} *M* and to an asymptotic value of about 25% at 1×10^{-5} *M*.

It seems likely that the albumin, a capillary-active substance, is adsorbed on the growing mercury drops, decreasing the surface available for reaction with the reducible molecules or ions and so decreasing the diffusion current. If so, the fractional change of free surface and the consequent fractional change in instantaneous diffusion current should at any stage in the life of the drop be a function of the change in the concentration of protein. At moderately high concentrations of protein, however, a monomolecular layer would be formed and an asymptotic diffusion current would be attained corresponding to the remaining free surface between the adsorbed protein molecules. (Even in closest packing these large molecules might well leave holes large enough to permit the smaller molecules of reducible material to reach the electrode.) These considerations are in qualitative agreement with the experimental results; furthermore, for protein concentrations C_p giving diffusion currents i_d not too close to the asymptotic current for a given constant dye concentration, they lead to a theoretical relation similar to the equation $\log i_d = -k_1 C_p + k_2$ which was found empirically.

As the concentration of a reducible substance is increased beyond a critical value, the "diffusion current constant" decreases and the current approaches a saturation value. It might be expected that an electrode covered over to a given extent, say with a monomolecular layer of adsorbed large molecules, would reach saturation at the same concentration of reducible substance as a normal electrode, but that the saturation current would be reduced; *i. e.*, with a given protein concentration, the diffusion current should be reduced by a constant fraction, which is independent of the dye concentration. A series of polarograms of the same system, this time with the protein absent or held constant at a comparatively high concentration, showed a 70% reduction of the saturation current, in the presence of protein, but no change in the concentration of dye required to reach saturation.

The probable relation of these results to the phenomenon of maximum suppression is being explored. A more detailed account of the work will be published later.

THE INFRARED SPECTRUM OF SPRUCE NATIVE LIGNIN

Sir:

Initial work on an extensive study of the applications of infrared spectroscopy to the problem of lignin structure has resulted in the establishment of the spectrum of Brauns' spruce native lignin by several independent methods of sample preparation. Typical curves (obtained with a Perkin–Elmer Model 12-B recording spectrometer using a sodium chloride prism) are shown in Fig. 1.

The film method of sample preparation warrants a brief description. By filling a shallow cup comprised of a metal ring and salt plate base with ethyl alcohol, adding a small proportion of dioxane solution, and allowing evaporation to take place slowly, the lignin was deposited as a strongly adherent clear film. The films thus obtained were dried for sixteen hours in a vacuum desiccator before use. Of particular value is the fact that dioxane is sufficiently transparent to permit its use as a solvent in the important carbonyl (1650–1850 cm.$^{-1}$) and hydroxyl (3000–3700 cm.$^{-1}$) regions, as shown in Curve A.

Two important points have been established: (1) The infrared spectrum of native lignin in film form is essentially unchanged by as much as ten hours of heating at 100°. (2) The broad band centered at 3350 cm.$^{-1}$ for film and Nujol dispersion and the shift of this band to higher frequency in dioxane solution is indicative of strong hydrogen bonding in lignin. Experiments on dilution and heating effects are planned which should yield valuable evidence as to the nature of this bond.

An investigation of the spectra of related com-

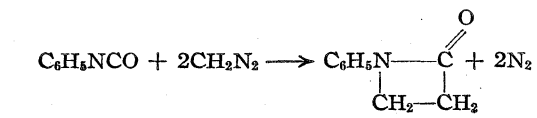
A NOVEL SYNTHESIS OF A β-LACTAM

Sir:

In the course of an investigation of amino acid derivatives, a unique synthesis of the β-lactam of N-phenyl-β-alanine was discovered. The reaction between an isocyanate and diazomethane does not seem to have been studied previously. We have found that in the case of phenyl isocyanate two methylene units are added in a reaction analogous to the formation of cyclobutanone from ketene and diazomethane.[1]



To a solution of 2.38 g. (0.02 mole) of freshly distilled phenyl isocyanate in 25 ml. of anhydrous ether was added 109 ml. of a 0.46 *M* cold ethereal solution of diazomethane (0.05 mole) dried over sodium. Within about two minutes a vigorous reaction commenced with evolution of nitrogen and the simultaneous deposition of an amorphous orange precipitate. After twenty hours at 0–5° the solution was separated from insoluble material (0.9 g.), and concentrated under reduced pressure to a brown, viscous oil (1.8 g.). Evaporative distillation at 80–120° and 1 mm. gave 0.59 g. (20%) of the colorless crystalline β-lactam of N-phenyl-β-alanine, m. p. 74–76°. An analytical sample, recrystallized twice from acetone–isooctane, was obtained as colorless glistening platelets, m. p. 78–79°.

Anal. Calcd. for C_9H_9ON: C, 73.43; H, 6.16; N, 9.52; mol. wt., 147.2. Found: C, 73.20; H, 6.23; N, 9.58; mol. wt., 139 (Rast).

A suspension of the lactam (0.5 g.) in 5 ml. of *N* sodium hydroxide was warmed with shaking to 70–80°. After ten to twelve minutes the solution became completely clear. From the cooled acidified solution crystalline N-phenyl-β-alanine (0.25 g., m. p. 59–60°) was recovered by ether extraction, evaporative distillation, and crystallization from carbon disulfide–ligroin. No depression in melting point was observed for a mixture with authentic N-phenyl-β-alanine (m. p. 58–59°), prepared from aniline and β-iodopropionic acid by the method of Bischoff and Mintz.[2]

This appears to be the simplest β-lactam reported; other known representatives of this class of compounds have at least two substituents on the ring.[3] It is of interest to note the ease of hydrolysis in the present case as compared to more highly substituted β-lactams or normal amides. The reaction between diazomethane and other isocyanates and isothiocyanates has been investigated and will be reported shortly.

We are indebted to Dr. John D. Roberts for valuable suggestions and to Swift and Company for support of a fellowship for one of us (P.T.I.).

ION-EXCHANGE SEPARATION OF THE ALKALI METALS

Sir:

We wish to report preliminary results on the separation of alkali-metal ions by an ion-exchange procedure, using the identical column and resin bed used by Mayer and Tompkins[1] in their 61-Eu separation (1.0 sq. cm. × 10.4 cm. colloidal agglomerates of Dowex-50; 2.83 g. oven-dried resin weight; 8.84 ml. bed solution volume = one V-unit[1]) and a recording counter to assay the relative activity in the effluent solution.

was then begun with 0.15 *N* HCl at a flow rate (*ca.* 0.3 ml./min.) slow enough to permit an approach to equilibrium conditions.[1] The effluent from the column was collected in a number of fractions, each of which was radiometrically analyzed for Na^{24}, K^{42}, Rb^{86}, and Cs^{134}.

The results are shown in Fig. 1. The automatically-recorded curve (normalized) is superimposed upon the block diagram and serves to locate the valley between Na and K and the peak of K, both of which occurred while the column was unattended. The table at the top of the figure shows

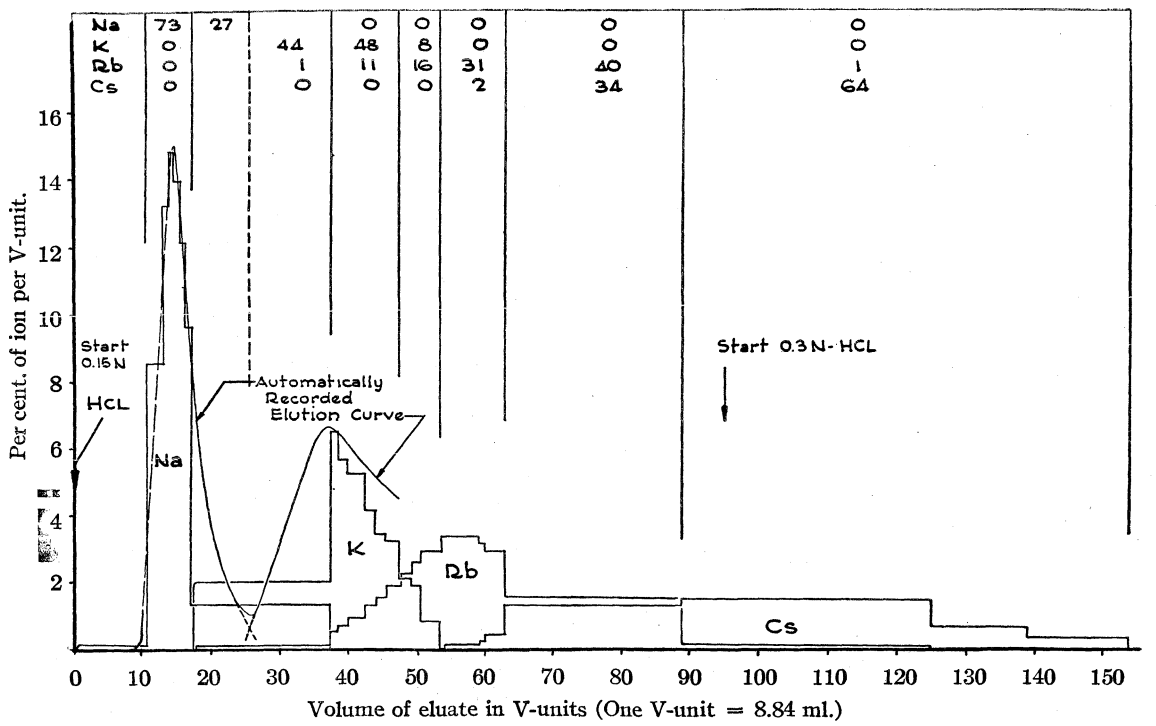

Fig. 1.—The separation of the alkali metal ions by elution from an ion exchanger.

A neutron-activated mixture of 1.0 mg. Na, 10 mg. K, 8 mg. Rb and 13 mg. Cs, in the form of their chlorides, was dissolved in water and absorbed on the hydrogen-form column.[2] Elution

NEW BOOKS

Modern Colloids. An Introduction to the Physical Chemistry of Large Molecules and Small Particles. By ROBERT B. DEAN, Ph.D., Assistant Professor of Chemistry, University of Oregon. D. Van Nostrand Co., Inc., 250 Fourth Ave., New York, N. Y., 1948. xi + 303 pp. 16 × 23.5 cm. Price, $3.75.

As stated in the Preface, this book is designed to serve as an introduction to the behavior of colloidal material. According to the author, colloid chemistry had fallen into bad repute, but much of the dead wood is being cleared away. The reviewer doubts that this book will assist in this process of rejuvenation.

The author's definition of colloids is not up to date and will give the reader an entirely wrong impression of what colloid chemistry stands for. The statement that nearly all of the properties of lyophobic colloids are due to the presence of impurities makes one wonder if the author realizes that this statement is not only incorrect but is a serious affront to the memory of men like Wo. Ostwald, H. Freundlich, and to all those who still are devoting their lives to the study of lyophobic colloids.

Ultramicroscopy by incident light and its applications in research pertaining to lyogels are not mentioned. A more adequate discussion of ultramicroscopes, their construction and application would be far more appropriate than the eulogy of the electron microscope, which also has its limitations, particularly in the study of lyophilic colloids. That solutions of proteins and other high polymers show no Faraday–Tyndall effect is contrary to fact. In the chapter on liquid surfaces, the drop weight, drop number and pendant drop methods are not mentioned. The statement that a thixotropic gel sets only when the particles associate is contrary to experimental evidence. Ebonite, or hard rubber, is not a thermosett, but a thermoplastic resin. The discussion of rubber latex is incomplete because it disregards the most basic colloidal phenomena. The structural diagram of montmorillonite (Fig. 11–7) does not explain cation exchange because it lacks the ion substitutions in the Gibbsite layer necessary for this phenomenon. The explanation as offered is not in line with known facts. When using illustrations copied from other publications, reference should be made to the one in which it originally appeared. The references to scientific and technical books and periodicals are incomplete.

Based on these statements, the reviewer's opinion may now be summarized:

The author deserves credit for his enthusiasm and for his desire to stimulate the interest of others in the multifarious colloidal phenomena in such diverse fields as chemistry, biology, medicine and agriculture. It would be risky, however, to depend upon this book for an introduction to the behavior of colloidal materials, because it disregards many basic phenomena characteristic of this state of matter or offers inadequate explanations; and its organization will confuse the reader more than it will enlighten him.

ERNST A. HAUSER

Autoxidation of Diethyl Ether and its Inhibition by Diphenylamine. A Chemical, Biological and Clinical Study of Some Practically Important Problems Concerning the Protection of Anesthetic Ether against Disintegration. By GUNNAR LINDGREN. P. A. Norstedt and Son, Stockholm, Sweden 1946. 190 pp.

The subtitle of this monograph is rather misleading. Ether does not *disintegrate* or lose its potency, like other delicate *materia medica*. However, as is well known, if ether stands for some time in bottles with access of air from frequent pourings, it forms through oxidation small amounts (seldom greater than 1%) of undesirable impurities, chiefly peroxides, acetaldehyde and acid. Of course, such treatment of ether intended for anesthesia is wisely interdicted by the pharmacopoeias of all nations. It is this familiar but complicated oxidation reaction and its prevention which forms the central theme of this investigation.

It also seems misleading to say (*vide* p. 10) apropos of the experiments of Mendenhall, Knoefel, *et al.* (*vide* p. 83) that "it therefore seems clear that *the existence of autoxidation products in anesthetic ether involves considerable practical inconvenience* . . . . . on account of autoxidated ether containing biologically extremely active substances, which may possibly disturb the course of the anesthesia and also involve an increased risk for the patient," because only through gross carelessness could ether containing 0.05% peroxide and 0.13% of aldehyde find its way into the operating room.

The standards of acceptability for the *freshly* prepared product are now so rigorous that no such amounts of auto-oxidation products could exist in it and one may say without fear of contradiction that anesthetic ether almost the world over is one of the purest substances used in medicine. Furthermore, anesthetic ether of the composition prescribed by the U. S. Pharmacopoeia in the manufacturer's original packages will keep its original purity for long periods of time—amply sufficient for all practical purposes.

The situation is somewhat different in Sweden, however, as the Swedish Pharmacopoeia prescribes for anesthetic purposes and designates as "Aether ad Narcosin" an ether free from alcohol and water (presumably treated with metallic sodium to remove the last traces of water) and put up in bottles of 100 grams capacity. Apparently one of the principal objects of this investigation was to ascertain whether any of the cheaper grades of Swedish ether could be substituted for this expensive product and still retain satisfactory keeping qualities. The author shows how this end may be accomplished by the addition of 0.02% of diphenylamine (one of the many substances known to inhibit the formation of peroxides in ether) to a grade of Swedish ether designated simply as "Aether Ph.S.," which is bottled in dark glass to exclude the actinic rays. The use of inhibitors, however, has not met with favor in America. Here the problem has been solved by the use of a pure ether of a slightly different composition[1] than that made in Sweden, and packaged in specially treated tin containers. The author states that in his stability tests this cheaper grade of Swedish ether, if no diphenylamine was added, acquired peroxides more rapidly than did the specially prepared "Aether ad Narcosin," but points out that one should not conclude that "Aether ad Narcosin" possesses more stability, since the bottles and light exposure were not identical in the two stability tests. It is to be regretted that this interesting grade, namely, "Aether ad Narcosin," was not included for direct comparison.

The author also tested the stability of ether in drums, and on page 48 we find the statement that ether in drums seems less stable than in bottles. The basis for this statement was the fact that the special grade, "Aether ad Narcosin," in bottles had kept almost perfectly for a year, whereas the grade known simply as "Aether Ph.S." in the manufacturer's drums had shown a marked decomposition. Since the grades of ether were entirely different, and the drums were galvanized (zinc being a very undesirable metal in contact with ether), the conclusion seems hardly rigorous; indeed, it is partially retracted on the next page.

(1) "Ether contains from 96 per cent. to 98 per cent. of $C_4H_{10}O$, the remainder consisting of alcohol and water" (U. S. P. XIII).

An excellent summary and criticism of the various methods for the determination of peroxide, acetaldehyde and acid is given in the section on chemistry. In passing we would like to remark that with a little experience an approximation of the amounts of peroxide and aldehyde, sufficient for evaluating the quality of anesthetic ether, can be made instantaneously by simple visible comparisons of the colors obtained with the well known sulfocyanate test for peroxides and Nessler's reagent for aldehyde as against sets of standards.

Under the heading, "Purification of Autoxidated Ether by Potassium Hydroxide," and also in other sections, Lindgren discusses the results obtained in his experiments and, taking cognizance of some similar results of Reimers, he concludes that "with the help of potassium hydroxide it is possible to obtain an ether almost free from peroxide, aldehyde and acid which is rather stable when kept in the dark." Twenty years ago this reviewer, E. Mallinckrodt, THIS JOURNAL, 49, 2655 (1927), in studying the then widely used German Pharmacopoeia (Ph.G.VI) test for aldehyde, which is based upon this reaction, showed that with anhydrous ether to which as much as 0.1% pure acetaldehyde has been added, the formation of brown aldehyde resin on the surfaces of the lumps of potassium hydroxide does not occur unless a small amount of moisture is present in the outer layer of the lumps of solid caustic. Thus, the efficacy of Lindgren's purification procedure when applied to Swedish anesthetic ether which is anhydrous cannot be taken for granted unless the above precautions are taken into account. It should also be noted that he used only about one-third of the proportions of caustic to ether that the German Pharmacopoeia prescribes for the aldehyde test.

In Part II, under the heading, "Experiments on Animals," a considerable point is made of the fact published by Knoefel and Murrell in 1935, and confirmed and continued by Lindgren, that the time required to induce anesthesia in mice is longer if ether containing peroxides and acetaldehyde from long exposure to air and light is used, than if pure ether is administered under otherwise identical conditions. How important this observation of Lindgren and others may be one cannot say, unless one knows why this slowing is present. It would seem that in a work as extensive as this one, a direct attack upon this interesting problem would have been made other than by speculation. If, as seems probable, delay in induction is to be explained by the action of irritant substances reducing the respiratory minute volume, this might have been studied directly and in conjunction with the rate at which the anesthetic blood level of ether was achieved. Larger animals than mice would be required.

In this paper conclusions based upon deductions are sometimes resorted to, where direct examination would have been better and not difficult, as for example, in ascertaining whether an important accumulation of carbon dioxide in the bottles where mice were confined had occurred. It should also be pointed out that the untoward biological effects of ether containing peroxide and aldehyde, cited by the author, were obtained with specimens of ether containing much larger amounts than the various pharmacopoeias allow. It is thus hardly proper to refer to the ether used in Mendenhall and Connolly's investigation on the cilia of oysters, which contained 0.02% peroxides and 0.02% of aldehydes, as a "low percentage of autoxidation products"; this is at least ten and probably twenty times as much as the standard American anesthetic ether is allowed to contain.

In Part III under the heading, "Clinical Study," a tremendous amount of work has been done, but the study is too broad in that too many variables are considered for the number of cases studied. Moreover, important differences appear to have been overlooked and much unimportant data dilute the observations pertinent to the subject. Largely for these reasons, the clinical studies fail to carry conviction.

This study, as the author points out, was concerned wholly with Swedish absolute ether and so has no direct bearing on the anesthetic ether used in this country. Even with this restriction, however, little contribution has been made to an understanding of the auto-oxidation of ether in general.

Based upon its effect on mice, the author concludes that peroxidized ether treated with potassium hydroxide to remove peroxides and aldehyde contains an unknown biologically active principle not revealed by the usual chemical tests for the purity of ether. One must await with interest further evidence substantiating this possibility.

It is gratifying to have this study published in the English language and thus made accessible to a wide circle of readers. There are occasional lapses in clarity and in good usage, and often the results are presented in a curiously circuitous way, which a more careful editing could have eliminated, but the language is indeed commendable for authors whose native language is not English.

Studies of Sulfonates. IX. Transference Numbers and Activity of 1-Dodecanesulfonic Acid in Aqueous Solutions at 40°[1,2]

BY L. L. NEFF,[3] O. L. WHEELER,[4] H. V. TARTAR AND E. C. LINGAFELTER

One of the most important properties for the interpretation of the behavior of solutions is the thermodynamic activity. While many studies have been made of solutions of paraffin-chain salts as colloidal electrolytes, the only activity data are the freezing point measurements of McBain and co-workers[5] and of Ralston and associates,[6] the vapor pressure measurements of McBain and co-workers,[7] and, appearing since the completion of the present study, the electromotive force measurements of Walton.[8]

It was felt that an independent determination of these activities would be desirable. We have therefore determined the activity of 1-dodecanesulfonic acid in aqueous solutions at 40° up to 0.4 *m* by electromotive force measurements. Two types of cells were used. In the concentration range 0–0.02 *m* we have used cells of the type

$$\mathrm{Pt,\ H_2|C_{12}H_{25}SO_3H}(m_1)|\mathrm{C_{12}H_{25}SO_3H}(m_2)|\mathrm{H_2,\ Pt} \quad (1)$$

(concentration cells with liquid junction). In the concentration range 0.01–0.4 *m* we have used cells of the type

$$\mathrm{Pt,\ H_2|C_{12}H_{25}SO_3H}(m)|\mathrm{Hg_2(C_{12}H_{25}SO_3)_2{\cdot}2H_2O(s),\ Hg} \quad (2)$$

(concentration cells without liquid junction).

The transference numbers necessary for the calculation of activities from the measured electromotive force of cells of type (1) were determined by the Hittorf method over the concentration range 0–0.6 *m*.

Experimental

Materials.—The 1-dodecanesulfonic acid was prepared from its sodium salt by the method of Zuffanti.[9] The sodium 1-dodecanesulfonate had been prepared by the action of aqueous sodium sulfite on *n*-dodecyl bromide in a bomb at 160°.

The mercurous 1-dodecanesulfonate for use in the mercury–mercurous electrodes was prepared by precipitation from a solution of either the 1-dodecanesulfonic acid or its sodium salt with an excess of mercurous nitrate. The precipitated salt was washed thoroughly with distilled water and stored until used under 0.1 *m* 1-dodecanesulfonic acid in contact with mercury. Microscopic examination showed the solid to consist of very small, well-formed crystals. Analysis of the solid for mercury by the method of Hager and Hulett[10] gave results in agreement with the composition $Hg_2(C_{12}H_{25}SO_3)_2{\cdot}2H_2O$ (% Hg found: 42.77, 42.99, 43.00; calcd. 42.86).

The solubility of mercurous 1-dodecanesulfonate in water at several temperatures was determined by evaporating to dryness 50-ml. samples of the saturated solutions. At 40° the result obtained was 5.7×10^{-5} *M*.

The mercury used in the preparation of the mercury–mercurous sulfonate electrodes had been washed with nitric acid and distilled twice *in vacuo*.

Commercial tank hydrogen was used for the hydrogen electrodes, the oxygen being removed by passing the gas through a quartz tube filled with granular copper filings heated electrically to about 700°.

Conductivity water from a Barnstead still was used for the preparation of all solutions. The solutions were made up by weight from a stock solution of 1-dodecanesulfonic acid. This stock solution was standardized by weight titration against a sodium hydroxide solution which had been standardized against twice-recrystallized Baker C. P. grade potassium acid phthalate.

Apparatus and Procedure.—The transference numbers were determined in a modified Washburn[11] apparatus con-

structed of 2-cm. Pyrex glass tubing according to the specifications of MacInnes and Dole.[12]

Two silver coulometers, constructed according to the specifications of the U. S. Bureau of Standards,[13] were placed in series with the transference cell, one on either side.

The temperature was held to 40 ±0.03° in a Freas water thermostat. The cathode of the transference cell was a coiled silver wire coated with silver chloride. The anode was of lead (anode reaction, $Pb + 2C_{12}H_{25}SO_3^- = Pb(C_{12}H_{25}SO_3)_2 + 2e^-$) for concentrations of sulfonic acid below 0.05 *m*, and of platinum (anode reaction, $2H_2O = 4H^+ + O_2 + 4e^-$) for concentrations above 0.05 *m*.

In all runs, the transference numbers were calculated from data on both anolyte and catholyte and the two values were averaged. In solutions below 0.05 *m* these two values agreed within 1% in all cases. Above 0.05 *m* the agreement was somewhat less satisfactory, but always within 3%.

The electromotive forces were measured by means of a Leeds and Northrup Type K potentiometer with a Type R galvanometer. The standard cell was checked by means of a White potentiometer against a pair of cells recently standardized by the United States Bureau of Standards.

The temperature was controlled at 40±0.05° by means of an air thermostat.

The cells used were very similar to those described by Tartar, Newschwander and Ness.[14]

Results and Discussion

The transference numbers are given in Table I. The data are quite similar to those obtained by McBain[15] at 20°, although our data indicate no change in transference number below the critical concentration.

The expression of e.m.f. in terms of activities for a cell containing a colloidal electrolyte such as 1-dodecanesulfonic acid is complicated by the transference of micelles, as well as single ions, across the liquid junction. It can be shown, however, that the expression assumes a form identical with that for an ordinary electrolyte.

In calculating and discussing the results, we may make use of an activity coefficient defined as the ratio of the mean ionic activity to the total stoichiometric molality, $\gamma = a_\pm/m$.

The activity coefficients in the concentration range 0–0.02 *m* were calculated from the measured e. m. f. of the cells of type (1) by the method outlined by MacInnes.[16]

Table II gives measured e. m. f. and molality of solution 2, solution 1 being constant at 0.00526 *m*. Table III includes the values of the mean ionic activity of 1-dodecane sulfonic acid at rounded concentrations. The data are plotted in Fig 1.

It was found that the mercury–mercurous 1-dodecanesulfonate electrode was not constant or reproducible in very dilute solutions and measurements in solutions below 0.01 *m* were made with hydrogen electrodes in concentration cells with liquid junction (type 1). In solutions of concentration 0.01 *m* and greater, the mercurous sulfonate electrode functioned satisfactorily and cells without liquid junction (type 2) were used. Their reversibility was proven by the calculation of E^0 in a series of concentrations where the activity coefficients had been determined from the electromo-

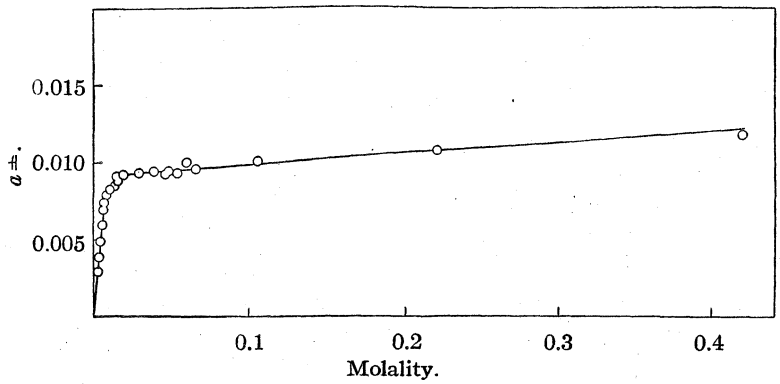

Fig. 1.—Mean ionic activity of 1-dodecanesulfonic acid in aqueous solution at 40°.

tive force of cells with liquid junction; these values of E^0 are shown in Table IV. The average value, 0.386 volt, is identical with the value obtained by Walton[8] at 25°.

The average value of E^0 was used to calculate the solubility of mercurous 1-dodecanesulfonate to check the result obtained analytically; the result obtained was 2.5×10^{-5} mole per liter. This agrees quite well with the analytical value of 5.7×10^{-5} mole per liter. Part of the difference may be due to the value of the standard potential of the mercury–mercurous ion electrode. Since its value was not known experimentally at 40°, an approximation was made from its value and temperature coefficient at 25° assuming that the temperature coefficient was constant from 25 to 40°. This temperature coefficient was calculated from the standard entropy change of the reaction $2Hg + 2H^+ = Hg_2^{++} + H_2$ reported by Latimer, Pitzer and Smith.[17] The analytical value is undoubtedly high because of the nature of the salt; minute crystals were present in the filtrate as shown by a carbon arc and because of the limited solubility these caused a rather large error in the result.

Data from cells of type 2 were used to calculate activities in solutions of 1-dodecanesulfonic acid where the sulfonate electrodes would function. The activity in a reference solution (near 0.01 *m*) was obtained from those determined by means of cells with liquid junction, and the activity in the other solutions calculated from the electromotive force of the above cell. The mean ionic activities are listed in Table V and are plotted in Fig. 1.

It may be seen from Fig. 1 that the behavior to be expected on the basis of the mass law is shown by these solutions. Below the critical concentration the activity of the 1-dodecanesulfonic acid increases with concentration as expected for an ordinary univalent strong electrolyte. Above the critical concentration, the activity is almost constant, rising only very slowly with increasing concentration.

Our results agree very well with those of Walton.[8] The extent of the agreement is indicated by the fact that our data, if plotted on Fig. 2 of his paper, fall almost exactly on the dashed line. Thus the three sets of data, at 0, 25 and 40°, form a consistent body, both with respect to the values of the activities and the position of the critical concentration.

(18) McBain and Bolduan, *J. Phys. Chem.*, **47**, 94 (1943).

cal concentration, ceases to fall in moderate dilution and may even increase. In order to investigate this phenomenon further, we have calculated the osmotic coefficients from our activity data. These results are plotted in Fig. 2 along with the values for potassium laurate from McBain and Bolduan. Although the curve of activity against concentration above the critical shows no discontinuity, or even deviation from a straight line, the osmotic coefficient curve calculated therefrom ceases to fall and even rises more abruptly than that of potassium laurate. Thus this "outstanding property of colloidal electrolytes (*g* ceasing to fall in moderate dilution)" would appear to be due entirely to the nature of the osmotic coefficient, and not to any changes occurring in the solution.

Similarly, the interpretation of the minimum as a "critical concentration for completion of the formation of micelles"[19] is unwarranted.

We do not wish to imply from the above that these data prove that no change does occur, but merely wish to point out that one must be extremely careful in attaching significance to a change in direction of a curve.

Summary

1. Thermodynamic activity of 1-dodecanesulfonic acid in aqueous solution at 40° in the concentration range 0–0.4 *m* has been determined by e.m.f. measurements.

2. The activity of 1-dodecanesulfonic acid in aqueous solution agrees with that expected on the basis of the mass law.

The Electrical Conductance and Density of Solutions of Potassium 9,10-Dihydroxystearate and Potassium Stearate at 60°

BY N. W. GREGORY AND H. V. TARTAR

To determine the effect of substitution of hydroxyl groups in the middle of the carbon chain of a fatty acid soap on electrical conductance and micelle formation, studies have been made on solutions of the potassium salts of stearic and 9,10-dihydroxystearic acids.

A comparison of this type has not been made previously. Data concerning the electrical conductance of solutions of potassium 9,10-dihydroxystearate are not on record. The conductance of solutions of potassium stearate and related compounds has been reported by Bunbury and Martin[1] and by McBain and co-workers.[2,3,4] In these studies, however, any break in the conductance curves, indicating a critical concentration at which micelles are formed, would likely be masked by hydrolysis with the concomitant formation of slightly soluble acid soaps. This difficulty has been obviated in the investigation reported herein by using as a solvent an alkaline solution of sufficient concentration to repress hydrolysis. Measurements were made at 60° because of the slight solubility of potassium stearate at room temperature.

Experimental Part

Preparation of Materials.—The 9,10-dihydroxystearic acid (high melting form) was prepared by the oxidation of oleic acid with alkaline permanganate in dilute solution. Oleic acid (U.S.P. quality) was purified by a treatment modified from the methods described by Brown and Shimarowa[5] and Smith,[6] and conversion of oleic acid to dihydroxystearic acid effected by oxidation in a manner similar to that reported by Smith.[6]

The impure 9,10-dihydroxystearic acid resulting from the oxidation was extracted twice with boiling wate to remove any hexa- or tetra-hydroxy acids, and recrystallized from 95% alcohol. After drying, the acid was extracted with both petroleum and ethyl ethers to remove any stearic acid and the residue recrystallized four times from 95% alcohol. The resulting compound was crystalline and melted at 131.6°. This is in excellent agreement with the melting point reported by Le Sueur–Freundler,[7] and others.[8]

Four hundred grams of oleic acid (U.S.P.) yielded 150 g. of the purified dihydroxystearic acid. The yield from the oxidation was very good and the principal losses incurred were in the purification procedures.

The potassium salt of dihydroxystearic acid was prepared in a manner adapted from the method of preparation of sodium stearate reported by McBain, Vold and Frick.[9] A hot alcoholic solution of dihydroxystearic acid was neutralized with an alcoholic solution of potassium ethoxide using phenolphthalein as an indicator. Upon cooling the resulting solution, the potassium salt separated as a silky crystalline precipitate. The crystals were washed thoroughly with alcohol, dried at 110°, and recrystallized from alcohol. The purity of the salt was checked by regenerating the acid from a small aliquot and determining the melting point.

Potassium stearate was prepared in an analogous manner from stearic acid (U.S.P. stearic acid recrystallized

from alcohol) and was purified as directed by Scheringa.[10] The salt was recrystallized eight times from 66% alcohol. Upon regeneration of stearic acid from an aliquot of the final material, it was found to have a melting point of 69.0°.[11]

The potassium hydroxide solution used as a solvent in the conductivity measurements was prepared in the following manner: a 50% aqueous (conductivity water) solution of potassium hydroxide (analyzed reagent grade) was prepared and the small amount of carbonate present precipitated with dilute barium hydroxide solution. The barium ion concentration of the solution was reduced to a minimum by careful titration against dilute potassium carbonate solution until the two were balanced. The total volume of the solution was 100 ml. and contained 50 g. of potassium hydroxide. Five-tenths ml. of this solution was diluted with conductivity water to a normality of approximately 0.001. Standardization of the dilute solution was effected with potassium acid phthalate, using a weight buret and neutral phenolphthalein. The titrations were carried out in an atmosphere of nitrogen.

Equipment and Procedure.—Conductance measurements were made using a Jones and Josephs-Dike conductivity bridge[12,13] calibrated to an accuracy of 0.02%, with current supplied by an a.c. vacuum-tube oscillator. A two-stage amplifier with telephone formed the detecting circuit. Measurements were made at a frequency of 1000 cycles, occasionally checking at 2000 cycles.

Measurements were made at 60° using an oil-bath with temperature controlled to ±0.001°. The temperature of the bath was determined by means of a platinum resistance thermometer (calibrated by the National Bureau of Standards).

Cells of the Jones and Bollinger type[14] were used for the conductivity measurements. It was found necessary to modify the cells slightly, to permit passage of nitrogen over the liquid in the filling tubes during the measurements, in order to eliminate drifts caused by absorption of carbon dioxide from the air by the alkaline solvent. By the use of nitrogen, drifts in the measured resistance were reduced to less than 0.005% per minute. The lowest resistance measured over a period of ten minutes after thermal equilibrium had been attained was the value used in calculating the conductance of the solution. The two cells used were found to have constants at 60° of 2.6841 and 25.904, respectively.[15]

All solutions were made up by weight. The samples were weighed on an analytical balance with an accuracy of 0.1 milligram, and the solvent on a larger balance (accuracy ± one milligram). The conductance of the stock potassium hydroxide was checked from time to time during the period in which measurements were made and was found not to vary beyond the limits of experimental error. Transfer of solutions was effected in glass systems by applying a pressure of nitrogen and solutions were maintained under nitrogen at all times. The bottles in which the solutions were stored had been carefully aged and paraffined before use.

In the case of the stearate, which is rather insoluble at room temperatures, it was found necessary to fill the conductance cell at 60°. This requirement renders the probable error in the stearate measurements somewhat greater than those for the dihydroxystearate. The latter is sufficiently soluble at room temperature to enable the cells to be filled without difficulty.

The density of the solutions was measured at 60° in a modified Sprengel type pycnometer,[16] which consisted of a 25 ml. pipet with the ends drawn down to capillary dimensions and fitted with ground glass caps. The pycnometer was calibrated with water at 60°. The accuracy of the density measurements is estimated to be ±0.00003.

The authors estimate that values for the conductance of the solutions, except those at very low concentrations, have a maximum probable error of the order of 0.1%.

Results and Discussion

The results of the density and conductance measurements are tabulated in Tables I and II and are illustrated graphically in Figs. 1 and 2. The solvent for all but the values designated *a* for the dihydroxystearate was 0.001317 N_w po-

tassium hydroxide; that for the a values was 0.001038 N_w potassium hydroxide. The latter solvent was used entirely for the potassium stearate measurements. All data were obtained at 60°.

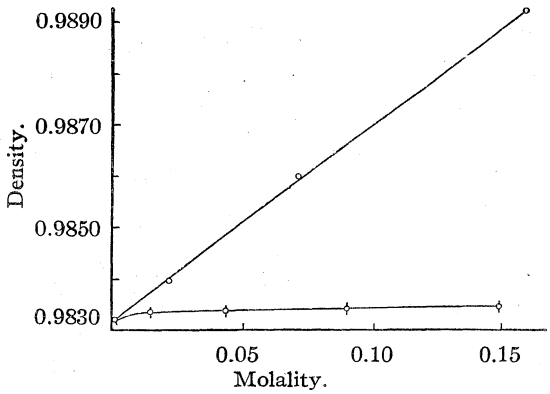

Fig. 1.—Change of density with concentration at 60°: O, potassium 9,10-dihydroxystearate; -O-, potassium stearate.

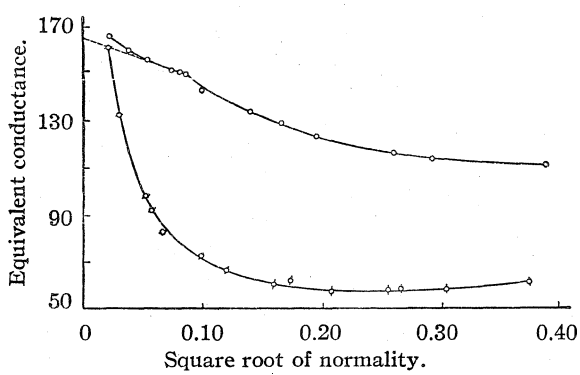

Fig. 2.—Equivalent conductance curves for solutions of potassium 9,10-dihydroxystearate and potassium stearate: O, potassium 9,10-dihydroxystearate; -O-, potassium stearate.

The concentration of potassium hydroxide necessary to repress hydrolysis of the soaps was computed on the basis of an assumed ionization constant for stearic acid. The constant for dihydroxystearic acid was assumed not to be appreciably different from that of stearic acid. Since ionization data for these acids are not available, a constant of 1.5×10^{-5} at 60° was taken, based on the known values of other members of the stearic acid homologous series up to caprylic acid. Using K_w for water as 9×10^{-14} at 60°, a concentration of hydroxyl ion of 0.001 mole/liter was calculated as sufficient to repress the concentration of the acid soap below 10^{-5} mole/liter. That this concentration was sufficient was confirmed by the observation that the more dilute solutions were either clear or only faintly colloidal, indicating negligible formation of acid soaps due to hydrolysis.

The use of the potassium hydroxide solution as the solvent requires a correction to be applied to the measured resistance of the solution, if the true conductance of the soap is to be determined. According to the Onsager theory, the conductance is determined by the total ionic strength of the solution. The concentration of the potassium hydroxide in the solvent remains constant and is sufficiently dilute to be treated by the Onsager equation. The soap has been assumed to be completely ionized at concentrations below that at which formation of micelles is indicated.

On this basis, the Onsager correction for the conductance of the potassium hydroxide, due to changing ionic strength of the solution, has been made up to the concentration at which micelles begin to form. The Onsager correction was computed from the general relation

$$\Lambda = \Lambda_0 - (\alpha\Lambda_0 + \beta)\sqrt{\mu}$$

where

Λ = equivalent conductance
Λ_0 = equivalent conductance at infinite dilution
α = 0.2627, β = 119.6 } Onsager constants at 60°
μ = total ionic strength

Since Λ_0 may be obtained from the measured conductivity of the standard potassium hydroxide by assuming an Onsager slope, the actual specific conductance due to the solvent may be found by calculating the total ionic strength of the solution, and substituting this value in the expression above. This involves the assumptions that the potassium hydroxide and the soap are completely dissociated up to the concentration at which micelles are formed. The difference between the total measured conductance and the value calculated for the solvent yields the value for the conductance of the soap.

In solutions of soaps in micellar form, determination of the ionic strength is not straightforward. Consequently, for lack of a precise method of treatment, a constant correction (the value calculated at the critical concentration) was applied to correct the measured conductance data for the contribution of the solvent. While it is realized that the equivalent conductance values determined on this basis are only approximate, it is doubtful that appreciable errors are involved, and certainly would not be of such a nature to change materially the over-all form of the curve.

Comparison of the two equivalent conductance curves illustrated in Fig. 2 reveals a striking difference. The dihydroxystearate is more soluble than the stearate, as would be expected from the influence of the hydroxyl groups. Its equivalent conductance is considerably greater than that of the stearate over most of the concentration range investigated.

There is a small break in the equivalent conductance curve for the dihydroxy compound occurring at a concentration of approximately 0.0075 N, at which point micelles may be formed. Below this concentration the curve follows an Onsager slope (indicated by the dotted line). The apparent up-

ward trend of the conductance curve in the region of very low concentration is not felt to be real. The conductance of the solution in this region is almost entirely due to the solvent and the value for the soap is obtained only by taking the difference of two relatively large numbers. Neglecting the two values at high dilution, the soap exhibits a behavior characteristic of a strong electrolyte until the critical concentration is reached.

The change in slope in the equivalent conductance curve for potassium 9,10-dihydroxystearate at the critical concentration is not nearly as great as has been observed in the studies of sulfonates and other soaps in which the carbon chain does not contain substituted hydrophilic groups. This would indicate that the micelle formed is possibly somewhat smaller and of a different type as the result of the influence of the hydroxyl groups in the middle of the chain, and hence does not change the ionic characteristics of the soap as markedly.

In studying the conductance curve of potassium stearate, the critical concentration for micelle formation was not established. The soap behaved as a colloidal electrolyte throughout the concentration range investigated. It may be seen from Fig. 2 that the critical concentration must lie very close to 0.0005 N (the lower limit of the concentration range studied), in order that the curve for the stearate intersect the ordinate at a reasonable value of Λ_0. Since measurements were not made below the critical concentration, as an approximation, a constant correction for the conductance of the solvent (the value of the conductance of the pure solvent) was applied in reducing the data.

Qualitative observations of the stearate solutions confirm the colloidal nature of the soap as indicated in the conductance measurements. All solutions were observed to be faintly opalescent whereas those of the dihydroxy compound were clear in dilute solution. The conductance curve obtained for potassium stearate is similar to that given by Bunbury and Martin,[1] if the fact that their measurements were made at 90° without repression of hydrolysis is considered.

While the critical concentration for the formation of micelles may be somewhat different in solutions not alkaline in character, the value indicated by these data is, without question, characteristic of the soap in the solvent used, and serves to evaluate the effect of the hydroxyl groups.

The change in density of solutions of the dihydroxystearate with concentration in the potassium hydroxide solvent presents an interesting contrast with that observed for potassium stearate. The density curves are illustrated in Fig. 1 and re-emphasize the pronounced effect of the hydroxyl groups in the molecule. It seems quite likely that the higher density observed for the potassium dihydroxystearate indicates association of water molecules by the hydroxyl groups.

Summary

1. The electrical conductance and density of solutions of potassium 9,10-dihydroxystearate and potassium stearate in 0.001 N potassium hydroxide have been determined at 60°. A comparison of data for the two compounds reveals that the hydroxyl groups have considerable influence.

2. The critical concentration for the formation of micelles in 0.001 N potassium hydroxide is indicated at 0.0075 N for potassium 9,10-dihydroxystearate. The value for potassium stearate was not established but is probably in the vicinity of 0.0005 N.

The Solubility of Cesium and Rubidium Dichloroiodides in Hydrochloric Acid Solutions

BY PAUL BENDER AND ROGER A. STREHLOW

Introduction

In the usual procedure for the purification of cesium or rubidium salts the repeated recrystallization of the dichloroiodide from hydrochloric acid solution is employed for the elimination of the other alkali metals. The quantity of material to be processed is ordinarily limited and the solubility of the complex salt appreciable, so that the attainment of efficiency in the purification process can be accomplished only through a quantitative knowledge of the solubility relationships involved. The present study was carried out to supply the required data which have not previously been available in the literature.

Experimental

Preparation of Materials.—Cesium chloride of spectroscopic purity was prepared from Pollucite by the method of Wells.[1] Rubidium chloride was prepared from Lepidolite (from Pala, Calif.) essentially as described by Kennard and Rambo.[2] The five-fold recrystallization as rubidium acid tartrate recommended by Archibald[3] was carried out to ensure the removal of cesium. Other reagents employed were of analytical grade.

In the preparation of the dichloroiodides a slight excess of iodine was added to a hot hydrochloric acid solution of the alkali chloride and chlorine gas bubbled through the

(3) E. H. Archibald, "The Preparation of Pure Inorganic Substances," John Wiley and Sons, New York, N. Y., 1932.

solution until the last of the iodine had dissolved. The salt which separated on cooling was recrystallized four times before use. Analysis of the air dried products gave the following result in terms of % ICl: $CsCl_2I$, calcd. 49.11, found 49.19; $RbCl_2I$, calcd. 57.28, found 57.32.

Solubility Measurements.—Standard procedures were followed in the solubility determinations. The thermostat temperature was maintained at 25.00 ± 0.02° and 0.00 ± 0.02° for the two series of measurements; the thermometers employed were calibrated before use. Duplicate determinations were run at each hydrochloric acid concentration to provide a check on the attainment of equilibrium.

Analytical Methods.—Samples of the saturated solutions were transferred to the weighing flasks by air pressure. Glass wool plugs were used as filters in the delivery tubes. Approximately 50-cc. samples of the cesium dichloroiodide solutions were taken, and 25-cc. samples of the rubidium dichloroiodide solutions. The analysis was made by evaporating the weighed sample to dryness, igniting lightly to drive off the ICl, and weighing the residual cesium or rubidium chloride. Due precautions were taken to ensure complete removal of the iodine chloride. Hydrochloric acid solutions used were standardized by means of silver chloride. Calibrated weights were used in all determinations. Weld specific gravity bottles were used in the density measurements required for the conversion of the results to the volume concentration basis.

4.909	17.51	21.50
8.989	10.66	12.98
12.48	8.75	10.83

Results

In Tables I and II are summarized the results of the solubility determinations. The accuracy of the data is estimated at 0.2% for the cesium dichloroiodide, and 0.3% for the rubidium dichloroiodide.

Discussion

Solubility measurements were not carried out at higher temperatures because the high temperature coefficient of solubility permits the volume of solvent employed to be adjusted simply on the basis of convenience in the filtration following crystallization. Precautions must of course be taken to avoid loss of iodine chloride from the hot solutions. The use of approximately nine molal hydrochloric acid as solvent is recommended as giving minimum inconvenience from hydrogen chloride in the vapor while retaining nearly the maximum advantage of the cosolute effect.

Summary

The solubility of cesium and rubidium dichloroiodides in hydrochloric acid solutions has been measured at 0 and 25°.

Potentiometric Titration of +4 and +6 Selenium and Tellurium with Chromous Ion

BY JAMES J. LINGANE AND LEONARD NIEDRACH*

This paper presents the results of a potentiometric investigation of the reduction of selenium and tellurium from the +6 and +4 oxidation states by chromous ion. Tomicek,[1] and Willard and Fenwick,[2] studied the reduction of selenium and tellurium compounds with titanous ion, but titrimetric reduction with chromous ion has not previously been investigated.

This study has led to the development of new methods for the accurate determination of Se(IV) and Te(IV), both separately and in mixtures of these two elements.

Preparation of Materials

Tellurium Dioxide.—This was prepared from U. S. P. elementary tellurium by the method of Schuhmann.[3,4] Finely granulated tellurium was added slowly to excess concentrated nitric acid at 70°. When the metal had all dissolved the solution was allowed to evaporate at 80° until crystallization of the basic tellurium (IV) nitrate, $2TeO_2 \cdot HNO_3$, began. The crystals obtained by cooling were air dried and then ignited strongly in a platinum crucible to convert to TeO_2. The latter was dissolved in concentrated hydrochloric acid, the acidity was adjusted to approximately 10 *M*, and the solution was saturated with sulfur dioxide to precipitate any selenium. Tellurium is not easily reduced at this acid concentration. The solution was then filtered, diluted until the hydrochloric acid concentration was about 2 *M*, and treated again with sulfur dioxide to precipitate elementary tellurium. This was converted to the basic nitrate, and the latter was ignited for four hours in a muffle furnace at 400° to obtain pure TeO_2 which was stored in a desiccator.

When assayed by oxidation to the +6 state with excess potassium dichromate and potentiometric titration of the excess dichromate with ferrous ion, as recommended by Shrenk and Browning,[5] a purity factor of 99.87 ± 0.06% was obtained. Gravimetric assay by precipitation as the element from a boiling hydrochloric acid solution with sulfur dioxide and hydrazine hydrochloride[6] gave a purity factor of 99.90 ± 0.06%.

Since tellurium dioxide is only very slightly soluble in water, standard solutions were prepared in dilute hydrochloric acid.

Telluric Acid.—The method of Meyer and Franke,[7] involving oxidation of elemental tellurium with chloric acid solution, was used. The crystals of orthotelluric acid, H_6TeO_6, obtained by evaporating the solution were purified by two further recrystallizations from water.

A stock solution in water was prepared and standardized by the method of Gooch and Howland[8] which employs the reaction $H_6TeO_6 + 2Br^- + 2H^+ = H_2TeO_3 + Br_2 + 3H_2O$ in dilute sulfuric acid. The bromine produced was distilled with the aid of pure carbon dioxide or nitrogen into an excess of potassium iodide solution, and the liberated iodine was titrated with thiosulfate.

Selenium Dioxide.—This was prepared from U. S. P. elementary selenium by the method described by Biltz, Hall and Blanchard.[9] The finely pulverized selenium was dissolved by treatment with excess concentrated nitric acid, the solution was evaporated to dryness, and the resulting selenium dioxide was sublimed. The sublimate was dissolved in 10 *M* hydrochloric acid and reduced to elementary selenium with sulfur dioxide in the cold. To prevent the formation of Se_2Cl_2 it was necessary to partially neutralize the solution with sodium hydroxide near the end of the reduction. The precipitated selenium was washed free of chloride ion, converted to the dioxide with nitric acid, and the selenium dioxide was finally sublimed.

A stock solution was prepared in water. Acidimetric titration with carbonate-free sodium hydroxide using the glass electrode[5] showed a molarity of 0.05093. A molarity of 0.05097 was found by precipitation as elemental selenium from a tartaric acid solution with hydroxylamine hydrochloride.[10]

Selenic Acid.—Following the procedure outlined by Gilbertson and King[11] selenic acid solution was prepared by oxidizing a solution of the previously purified selenium dioxide with 30% hydrogen peroxide. The solution was standardized by titration with sodium hydroxide, which yielded a molarity of 0.02024, and also by the method of Gooch and Howland[8] which led to a molarity of 0.02026.

Titration Technique

Titrations were performed with standard 0.1000 *M* solutions of chromous sulfate, prepared in either 0.1 or 1 *N* sulfuric acid by the method described by Lingane and Pecsok.[12]

A 250-cc., three-necked balloon flask served as titration vessel.[12] A bright platinum indicator electrode was used, in conjunction with the saturated calomel electrode. The salt bridge contained dilute sulfuric acid. Carbon dioxide or nitrogen, purified by passage through a wash bottle containing chromous sulfate solution, was bubbled rapidly through the solution to remove air for at least ten minutes before a titration was started, and at a slower rate during the titration. Magnetic stirring was employed. The solutions were adjusted to an initial volume of 150 cc.

Potentials were read on a Leeds and Northrup potentiometer in the usual manner.

Results and Discussion

+4 Selenium.—In solutions acidified with hydrochloric or sulfuric acid +4 selenium is reduced to the elemental state by chromous ion, according to

$$H_2SeO_3 + 4Cr^{++} + 4H^+ = Se + 4Cr^{+++} + 3H_2O$$

Typical titration curves for titrations in various concentrations of hydrochloric acid are shown in Fig. 1.

Steady potentials are reached in two or three minutes at room temperature, and somewhat more rapidly at 70°. It was necessary to clean the platinum indicator electrode with concentrated nitric acid before each titration to obtain repro-

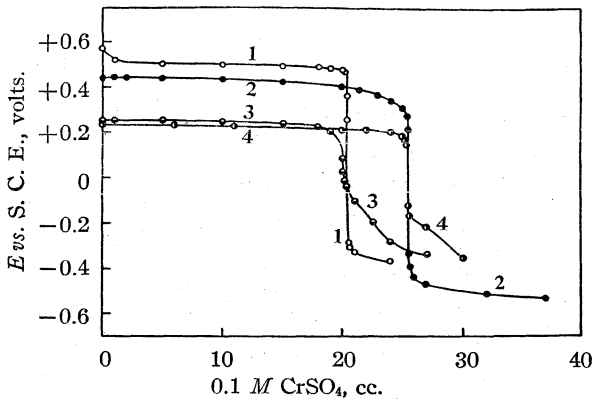

Fig. 1.—Titration of +4 selenium in hydrochloric acid media: (1) 9 *N* acid at 70°; (2) 6 *N* acid at 25°; (3) 0.1 *N* acid at 25°; (4) 1 *N* acid at 25°.

ducible potentials; when this was omitted the potential values before the equivalence point were abnormally low, although the e. p. could be determined without difficulty.

In 0.1 and 1 *N* hydrochloric acid the shape of the curves immediately after the e. p. suggests the partial reduction of Se to hydrogen selenide, and the characteristic odor of this gas could be detected. The formation of H_2Se was most pronounced in titrations in 9 *N* hydrochloric acid at 70°. The standard potential of the half reaction $Se + 2H^+ + 2e = H_2Se$ is −0.36 v. *vs.* N. H. E., which is only slightly more oxidizing than that of the chromic–chromous couple (−0.40 v.) and consequently complete reduction to hydrogen selenide cannot be expected.

From the data in Table I it is seen that titration in 0.1 *N* hydrochloric acid yields low results. In 1 to 9 *N* hydrochloric acid accurate results are

TABLE I

TITRATION OF SELENIUM (IV) WITH CHROMOUS SULFATE

Initial volume of solution was 150 cc. Calculated volume of chromous sulfate required was 25.52 cc. Solutions swept with CO_2

Initial acidity	Temp., °C.	Cr_2SO_4 required	Error, cc.
0.1 *N* HCl	25	25.35	−0.17
	70	25.26	− .26
1.0 *N* HCl	25	25.49	− .03
	70	25.47	− .05
6.0 *N* HCl	25	25.52	.00
		25.45	− .07
		25.57	+ .05
	70	25.48	− .04
		25.56	+ .04
		25.53	+ .01
9.0 *N* HCl	70	25.55	+ .03
		25.55	+ .03
1.0 *N* H_2SO_4	70	25.48	− .04
6.0 *N* H_2SO_4	70	25.48	− .04
		25.52	.00
		25.62	+ .10
		25.67	+ .15

obtained at both 25° and 70°. The higher acid concentrations are preferable because of the very large potential change at the e. p., and because the reaction is more rapid the higher the acidity.

Titration curves in 1 to 6 *N* sulfuric acid are very similar to those in the same concentration of hydrochloric acid. Titration in sulfuric acid solution is not as satisfactory as in hydrochloric acid because the reaction is slower, although it is feasible if the titration is performed at 70°. The data in Table I show a somewhat poorer precision in sulfuric acid than in hydrochloric acid.

+4 Tellurium.—Typical titration curves in various concentrations of hydrochloric and sulfuric acids are shown in Fig. 2. The titration reaction is

$$TeOOH^+ + 4Cr^{++} + 3H^+ = Te + 4Cr^{+++} + 2H_2O$$

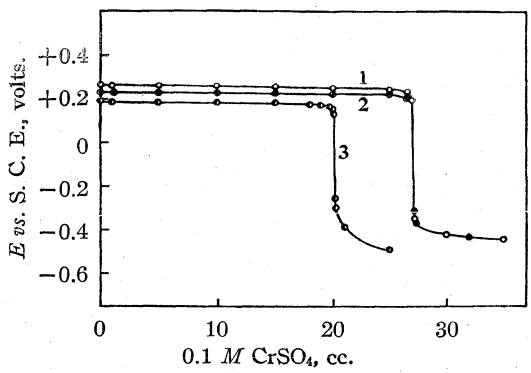

Fig. 2.—Titration of +4 tellurium: (1) 0.3 and 1 *N* hydrochloric acid, and 1 and 6 *N* sulfuric acid, at 25°; (2) 6 *N* hydrochloric acid at 25°; (3) 9 *N* hydrochloric acid at 70°.

The potential change at the e. p., although quite large, is smaller than that in the titration of +4 selenium. This is understandable from the following potential data[13] (referred to the standard hydrogen electrode). The standard potential

$H_2SeO_3 + 4H^+ + 4e = Se + 3H_2O$; $E^0 = +0.74$ v.

$TeOOH^+ + 3H^+ + 4e = Te + 2H_2O$; $E^0 = +0.529$ v.

$TeCl_6^{=} + 4e = Te + 6Cl^-$; $E^0 = +0.55$ v.

of the half reaction $Te + 2H^+ + 2e = H_2Te$ (−0.69 v.) is more reducing than that of the chromic–chromous couple (−0.40 v.), which precludes reduction to hydrogen telluride.

The reduction of +4 tellurium proceeds more rapidly than that of +4 selenium; at 70° establishment of the potential is almost instantaneous.

The data in Table II show that the titration is very accurate in all concentrations of hydrochloric acid between 0.3 and 9 *N*, and in 1 and 6 *N* sulfuric acid.

+6 Tellurium.—The standard potential of the half reaction

$H_6TeO_6 + 3H^+ + 2e = TeOOH^+ + 4H_2O$; $E^0 = +0.96$ v.

is 0.43 v. greater than that of the $TeOOH^+$–Te

TABLE II

TITRATION OF TELLURIUM (IV) WITH CHROMOUS SULFATE

Initial volume of solution was 150 cc. Calculated volume of chromous sulfate required was 26.99 cc. All titrations at room temperature. Solutions swept with carbon dioxide

Initial acidity	Cr_2SO_4 required, cc.	Error, cc.
0.3 *N* HCl	26.94	−0.05
	26.91	− .08
1.0 *N* HCl	26.96	− .03
	26.97	− .02
6.0 *N* HCl	26.98	− .01
	26.96	− .03
	26.96	− .03
	27.03	+ .04
9.0 *N* HCl	26.97	− .02
	27.06	+ .07
1.0 *N* H_2SO_4	26.94	− .05
	26.96	− .03
	27.09	.00
	27.03	+ .04
6.0 *N* H_2SO_4	26.86	− .13
	26.86	− .13
	27.04	+ .05
	26.96	− .03

couple, so that a two stage reduction of telluric acid, first to the +4 state and then to the element, is possible. However, the reduction of telluric acid by chromous ion in either hydrochloric or sulfuric acid medium is so slow that a determination of tellurium based on reduction from the +6 to the +4 state is not feasible.

The first addition of chromous ion produces elemental tellurium which is only slowly reoxidized to the +4 state by the remaining telluric acid. In 6 *N* hydrochloric acid at 70° it is possible to obtain a titration curve with two inflection points if a long time is allowed for establishment of equilibrium between each addition of chromous ion until the first end-point has been reached. However, under these conditions a considerable part of the telluric acid is reduced by chloride ion

$$H_6TeO_6 + 2Cl^- + 3H^+ = TeOOH^+ + Cl_2 + 4H_2O$$

and since much of the resulting chlorine escapes from the solution, too little chromous solution is required. In a typical case, 9.75 cc. of chromous solution was required to reach the first end-point, compared to a theoretical 10.04 cc.

Titration of telluric acid to the elemental state is not feasible in any concentration of either hydrochloric or sulfuric acid up to 6 *N* at room temperature, nor in hot sulfuric acid solutions, because of the slow reduction. Although the reduction of telluric acid to the element proceeds at a more rapid rate in hot hydrochloric acid, the reduction by chloride ion precludes the use of this medium during the first stage of the titration. It is possible to obtain accurate results in the titration to the element by starting the titration in 6 *N* hydrochloric acid at room temperature, gradually heating the solution to 70° over a period of about ten minutes as the chromous solution is slowly added, and finally completing the titration at 70°. About one-half the total required volume of chromous solution should be added during the heating period. In five such titrations the volumes of chromous solution required ranged from 30.09 to 30.22 cc., the average being 30.14 ± 0.04 cc., in good agreement with the theoretical volume 30.13 cc. In this procedure the only oxidized form of tellurium that remains near the end-point is the +4 state, and the titration can be completed quickly.

+6 Selenium.—The titration of selenic acid is more difficult than telluric acid because the reaction is slower. Titration to the elemental state in 6 *N* hydrochloric acid at 70° led to results that were about 5% low, apparently because of partial reduction of the selenic acid by chloride ion. Starting the titration in 6 *N* hydrochloric acid at room temperature, slowly heating to 70° as the chromous solution was added, and finally completing the titration to the elemental state at 70°, yielded results accurate to about 0.5%. However, the titration requires such a long time that it is not practical.

Simultaneous Determination of Selenium and Tellurium.—Since in strongly acid solutions the oxidation potential of the Se(IV)–Se couple is about 0.3 v. greater than that of the Te(IV)–Te couple it is possible to determine both elements by a single titration with chromous ion.

Titration curves of mixtures of +4 selenium and +4 tellurium under various conditions of acidity and temperature are shown in Fig. 3.

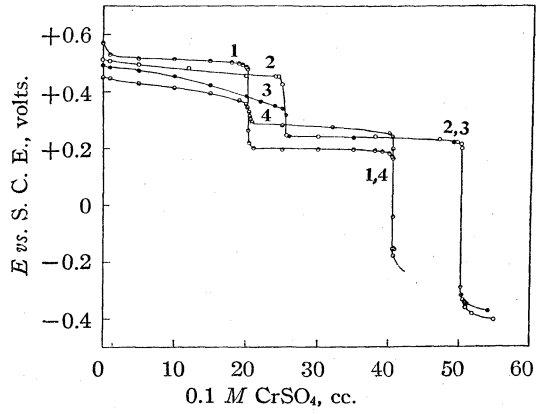

Fig. 3.—Titration of mixtures of +4 selenium and +4 tellurium under various conditions: (1) 9 *N* hydrochloric acid at 70°; (2) 6 *N* hydrochloric acid at 70°; (3) 6 *N* hydrochloric acid at 25°; (4) 6 *N* sulfuric acid at 70°.

In all cases the first inflection point corresponds to the reduction of Se(IV) to the elemental state, and the second occurs after the reduction of Te(IV) to the metal. Since the reduction of Te(IV) by chromous ion is more rapid than that of Se(IV),

addition of chromous ion causes some transient precipitation of elemental tellurium during the selenium stage of the titration, and equilibrium is established via the reduction of Se(IV) by the elemental tellurium.

In 6 *N* sulfuric acid at 70°, and in 6 *N* hydrochloric acid at room temperature the potential change at the selenium equivalence point is small and a long time is required for the attainment of equilibrium. In 9 *N* hydrochloric acid at 60° to 70° the titration is very satisfactory; a large potential break occurs at the selenium e. p. and equilibrium is established quickly. Under these conditions the titration yields accurate results. In three titrations, 25.55 ± 0.05 cc. of 0.1 *M* chromous sulfate solution was required to titrate the selenium, and 25.29 ± 0.09 cc. was used to titrate the tellurium, compared to theoretical values of 25.52 cc. and 25.30 cc., respectively.

Fairly accurate determinations of selenium may also be obtained in the presence of a large amount of tellurium. In two titrations in which 1.2 g. of tellurium (as TeO_2) was present, the selenium titration required 25.64 ± 0.02 cc. of 0.1 *M* chromous sulfate solution, compared to a theoretical 25.52 cc. The amount of selenium present was 6% of the amount of tellurium.

Selenium in Presence of Copper.—Since selenium frequently occurs in association with copper, the possibility of simultaneously determining both elements by titration with chromous ion was investigated.

Titration curves of solutions containing approximately equimolar concentrations of Se(IV) and Cu(II) are shown in Fig. 4. In all cases the Se(IV) is reduced first. In sulfuric acid medium the cupric copper is reduced to the metal, but in hydrochloric acid the copper exists as a chlorocuprate ion (probably $CuCl_4^=$) which is reduced to a chlorocuprite complex (probably $CuCl_2^-$).[12]

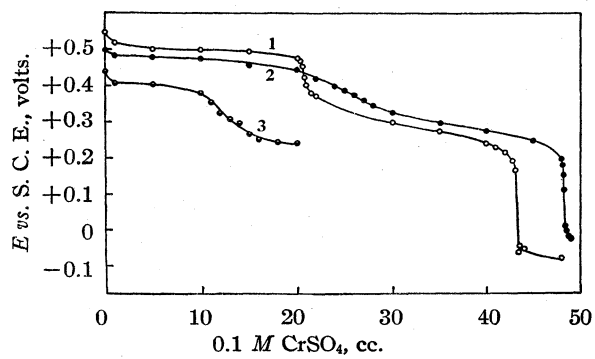

Fig. 4.—Titration of mixtures of +4 selenium and copper: (1) 9 *N* hydrochloric acid at 70°; (2) 6 *N* hydrochloric acid at 25°; (3) 6 *N* sulfuric acid at 70°.

In 6 *N* sulfuric acid at 70° (Curve 1 in Fig. 4) co-reduction of the copper takes place along with the reduction of the Se(IV), and the small gradual inflection in the titration curve occurs when only about half the Se(IV) is reduced.

In 6 *N* hydrochloric acid at room temperature (Curve 2) there is no distinct inflection at the completion of the Se(IV) reduction, although the completion of the reduction of both the Se(IV) and the Cu(II) is marked by a large potential change.

The optimum conditions appear to be 9 *N* hydrochloric acid and a temperature of 70°, as shown by curve 3. Under these conditions a small but distinct potential change occurs when the Se(IV) has been reduced, and both elements can be determined with fair accuracy. In one such titration, 20.8 cc. of 0.1 *M* chromous solution was used to reach the first inflection point, which was 2% greater than the theoretical 20.38 cc., and 22.5 cc. was required to titrate the copper, compared to a theoretical 22.71 cc.

Summary

In solutions acidified with sulfuric or hydrochloric acid Se(IV) and Te(IV) can be titrated accurately with standard chromous solution. The optimum conditions are 6 to 9 *N* hydrochloric acid and a temperature of about 70°. In both cases reduction proceeds to elemental selenium and tellurium.

Although it is quite possible to obtain titration curves for the stepwise reduction of both Se(VI) and Te(VI), first to the +4 states and then to the elements, the slow establishment of equilibrium renders impractical the determination of these elements by titrimetric reduction to the +4 states.

Accurate determinations of Se(IV) and Te(VI) in mixtures were obtained by a single titration with chromous ion in 9 *N* hydrochloric acid at 60° to 70°. A small amount of selenium can be determined accurately in the presence of large amounts of tellurium under these conditions.

Se(IV) and Cu(II), in mixtures containing approximately equal amounts of the two, can be determined with an accuracy of about 2% when the titration is performed in hot 9 *N* hydrochloric acid.

Vapor Pressure of Methyl Sulfoxide from 20 to 50°. Calculation of the Heat of Vaporization

BY THOMAS B. DOUGLAS[1]

For the calculation of bond energies from the previously reported[2] heats of two reactions involving liquid methyl sulfoxide, the heat of vaporization of this substance near room temperature must be known. It seemed that this quantity could be most conveniently determined with the required accuracy by measuring the vapor pressure at several temperatures. There was adopted a modification of the gas-saturation method used by Baxter and co-workers[3] to determine the vapor pressure of iodine. The amount of methyl sulfoxide evaporated was determined by chemical analysis.

Experimental Procedure

Methyl sulfoxide, prepared as previously described,[2] was finally purified in a closed system (J in Fig. 1) by four recrystallizations, the last of which did not appreciably change the freezing point (18.42°). The amount of impurity remaining was estimated to be 0.1 mole %, and the vapor pressure values were corrected accordingly.

Air, entering at A, was purified in train B by successive passage over the solids ferrous sulfate, potassium hydroxide, chromium trioxide, potassium hydroxide, and phosphorus pentoxide. Passing through a thermostat over two layers of liquid methyl sulfoxide C (each layer being 5 mm. wide and 25 cm. long) at a rate of two liters per hour (measured by a flowmeter K) and at a pressure 0.1 mm. below atmospheric, the air then bubbled through mercury (D), which completely prevented contamination of the liquid sulfoxide by backward diffusion of water vapor. The saturated sulfoxide vapor was absorbed in two tubes each containing 15 ml. of water (E). The air then emerging from the thermostat, after being thoroughly redried in the train F, was admitted through a system of capillaries (G) to one or two thirteen-liter highly evacuated glass bulbs (H) whose volumes had been (1) determined by filling with water and (2) checked by admittance of dry air and use of its data of state. The final pressure of the collected air was compared with the barometric pressure by means of a butyl phthalate manometer (L).

The temperatures of the thermostat and the collected air were periodically measured to ±0.01° by single-junction copper–constantan thermocouples,[4] using a calibrated Type K potentiometer and correcting for extraneous potentials. (The five thermocouple wells are designated in Fig. 1 by P.) The thermostat temperature remained constant to ±0.005°, and the total gradient averaged 0.03° at the highest temperatures. The combined absorption solutions produced in each run were withdrawn through tube M (sealed by mercury (N) during runs) and were accurately analyzed for their total content of methyl sulfoxide by the method previously developed,[2] with use of blanks and the other usual precautions.

Experimental Errors.—Tests were made to determine whether certain suspected sources of systematic error appreciably affected the results.

The contamination of the methyl sulfoxide during the series of runs was found to be inappreciable. After the completion of half the runs, involving the passage of 170 liters of air, the freezing point of the remaining sulfoxide was redetermined and found to have changed not more than 0.03°. This result indicated also the lack of appreciable reaction between the sulfoxide and oxygen of the air at the temperatures used. Nor did a removal of appreciable sulfoxide vapor by adsorption seem to occur before it reached the absorber tubes. For the various temperatures were run in random order and no chronological trend of vapor pressure values was detectable after three preliminary runs, each of whose values was about 0.5% low on the basis of the remaining fifteen runs.

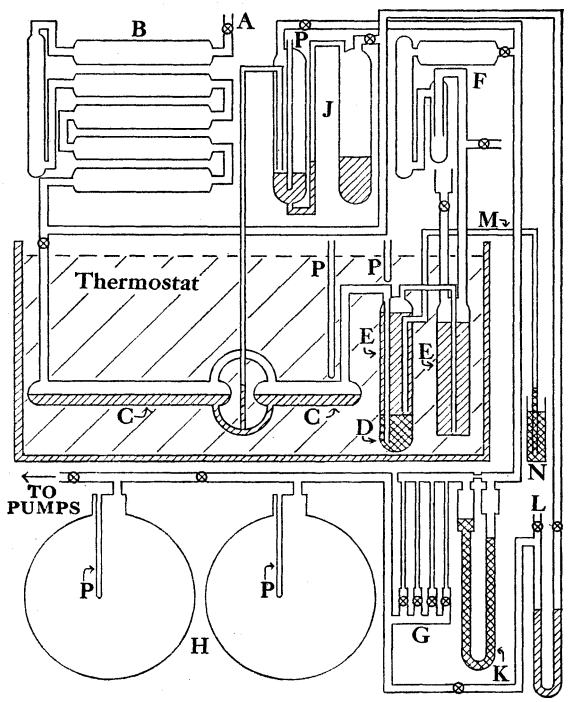

Fig. 1.—Apparatus used for determining the vapor pressure of methyl sulfoxide. No disassembling between runs was necessary. The arrangement permitted the liquid being frozen in J to be stirred by a stream of dry air.

Tests were made to establish whether the normal rate of air flow of two liters per hour was slow enough to permit complete saturation of the air with sulfoxide vapor, and a subsequent complete absorption of the vapor. One extra run at 30° and one at 50° were made at twice[5] the normal rate of air flow, yielding vapor pressure values which were, respectively, 0.1 and 0.3% lower than at the normal rate, which latter thus appears to be sufficiently slow.

Within the experimental error, all the sulfoxide vapor was found to be retained by the first of the two absorber tubes. One extra run at 30° and one at 50° in which water was present in only the first absorber tube gave vapor

(3) Baxter, Hickey and Holmes, *ibid.*, **29**, 127 ff (1907); Baxter and Grose, *ibid.*, **37**, 1061 ff. (1915).

(4) Calibrated at the ice-point, the steam-point, and the transition temperatures of $Na_2SO_4 \cdot 10H_2O$, $NaBr \cdot 2H_2O$, and $MnCl_2 \cdot 4H_2O$ [Richards and Wrede, *Z. physik. Chem.*, **61**, 313 (1907)].

(5) Doubling the rate of flow should provide a more rigorous test than halving it, since the change in observed vapor pressure due to lack of saturation should be much greater in the former case.

pressure values which were respectively 0.1% lower and 0.2% higher than the values obtained using two absorbers. As a check the total water collected from the emerging air from all the runs was found to contain only a mere trace of sulfoxide.

It was feared that some mercury may have been carried into the water absorbing the sulfoxide vapor, causing the subsequent titration of the solution with permanganate to run high. One solution from a 30° run and one from a 50° run were each tested for mercury, which, if present at all, was shown to be insufficient in amount to raise the experimental value of the vapor pressure by more than 0.1%.

The departure of the saturated methyl sulfoxide vapor, mixed with air, from gas ideality is probably small, but seems too uncertain to justify its estimation. During one purification of the sulfoxide a sample was observed to boil at 79° at 16.5 ± 1 mm., whereas extrapolation of the calculated vapor pressure values to this temperature gives 15.5 mm. This comparison indicates that the vapor density does not differ widely from that calculated using the formula $(CH_3)_2SO$. Nor is departure from this formula, through dissociation or association, to be expected on theoretical grounds.

An estimation of individual errors indicated that the experimental vapor pressure values, as represented by the empirical equation below, are probably accurate in the temperature range of the measurements to within ±1%.

Results

Each value of the vapor pressure was calculated from the experimental data by use of the equation

$$p = \frac{0.9977\ P_1}{N\left(\frac{P_2 V_2}{nRT_2}\right) + 1}$$

where p is the vapor pressure of pure methyl sulfoxide, P_1 the average total pressure in the saturator (about 635 mm.), N the estimated mole fraction of methyl sulfoxide in the liquid used, P_2 the pressure of collected air at absolute temperature T_2, V_2 the volume of collected air, n the moles of methyl sulfoxide evaporated (assuming the formula $(CH_3)_2SO$), and R the gas constant. 0.9977, the ratio of the fugacity of liquid methyl sulfoxide at pressure p to its fugacity at pressure P_1,[6] corrects the vapor pressure to the value which should be obtained in the absence of the air. Two independent measurements of vapor pressure were made at each temperature at 5° intervals from 20 to 50°. These duplicates at the same temperature agreed on the average to within 0.15% and the maximum difference was 0.5%.

Using the method of least squares and giving each value of log p equal weight, the following equation was found for the vapor pressure of methyl sulfoxide from 20 to 50°.[7] This equation

$$\log_{10} p = 26.49558 - (3539.32/T) - 6.00000 \log_{10} T \quad (1)^8$$

represented the experimental values of vapor pressure with an average deviation of ±0.15%, the maximum discrepancy being 0.4%. Values calculated from equation (1) in this temperature range are given in Table I.

TABLE I

VAPOR PRESSURES OF METHYL SULFOXIDE AT ROUNDED TEMPERATURES

(Calculated from equation (1))

Temp., °C.	Vapor pressure, mm.	Temp., °C.	Vapor pressure, mm.
20	0.417	40	1.656
25	.600	45	2.27
30	.853	50	3.07
35	1.195		

Equation (1) yields a value of 12.64 kcal. for the molal heat of vaporization of methyl sulfoxide at 25°. This figure was estimated to have an uncertainty of ±0.1 kcal. It is of interest that equation (1) leads to a normal boiling point of 192° and a Trouton constant of 22.9 cal./mole/deg., but these two figures are naturally not highly reliable, because of the wide extrapolations involved.

Summary

The vapor pressure of methyl sulfoxide has been determined by a gas-saturation method at 5° intervals from 20 to 50°.

The values found are expressed, with an average deviation of ±0.15%, by the equation

$$\log_{10} p = 26.49558 - (3539.32/T) - 6.00000 \log_{10} T$$

which gives 12.64 ± 0.1 kcal. for the molal heat of vaporization at 25°.

Various sources of error are discussed. It is estimated that correct vapor pressures are given by this equation, in the temperature range of the measurements, to within ±1%.

BOZEMAN, MONTANA RECEIVED JANUARY 30, 1948

(6) Using $(\partial \ln f/\partial P)_T = v/RT$, where v is the molal volume of the liquid, 71 ml. The ratio of fugacities is practically independent of temperature in the range investigated.

(7) Although the constants given are accurately interconsistent, it was first necessary to find by trial a value for the coefficient of log T which would approximately minimize the sum of the squares of the deviations. No value of this coefficient between −8 and −4 produces any particular trend of deviations with temperature.

(8) p in mm., T in deg. absolute, and 0°C. = 273.16°K.

Hydrogen Exchange of Phenols and Phenol Ethers with Deutero-alcohol[1]

BY PHILIP F. TRYON,[2] WELDON G. BROWN AND M. S. KHARASCH

The experiments described herein were performed in an attempt to set up a quantitative basis for the comparison of variously constituted phenols and phenol ethers in respect to the rates of exchange of nuclear hydrogen atoms. Whereas previous investigators have examined the hydrogen exchange of phenol[3] with aqueous alkali, and of anisole with aqueous sulfuric acid,[3a] our work has been done with deutero-ethanol as solvent and reactant, thereby avoiding heterogeneous reaction mixtures. Moreover, although we have used sulfuric acid to promote the exchange of nuclear hydrogens, it has been under such mild conditions, as compared to the above-mentioned experiments on anisole, that the exchange is limited to those positions which are known to be active in ordinary electrophilic substitutions.

Briefly, the significant features of our results are the following. First, it is noted that the partition coefficient for the distribution of deuterium in a nuclear exchange reaction differs appreciably from unity, the deuterium favoring the hydroxyl group of ethanol as might be expected from zero-point energy considerations. Thus the limiting values of the "exchange number" in experiments on mixtures which were allowed to approach exchange equilibrium fall short of the integer representing the number of participating hydrogen atoms by nearly 10%. Such an effect is not observed in exchange reactions involving only the hydroxyl group of phenols (*cf.* Table I).[4]

TABLE I

EXCHANGE OF HYDROXYL HYDROGEN OF PHENOLS WITH DEUTEROALCOHOL[a]

Compound	Obs. exch.
p-Cresol	1.02
β-Naphthol	1.01
3,5-Dimethyl-4-chlorophenol	1.06
3,4-Dimethylphenol	1.09
6-Hydroxytetralin	1.10
5-Hydroxyhydrindene	1.06

[a] Experiments carried out by dissolving 0.008 mole of the phenol in 5 ml. of deuteroalcohol and recovering the alcohol immediately thereafter by vacuum distillation.

Referring next to the naphthols and naphthol ethers, the data presented in Table II show that whereas α-naphthol and its ethyl ether exchange two nuclear hydrogens, β-naphthol and its ether exchange only one. That this is the α-hydrogen is strongly supported by the observation that α-methyl-β-naphthyl ethyl ether exhibits no exchange under comparable conditions. The non-occurrence of exchange at the 3-position of β-naphthol and derivatives is readily explained on the basis of a mechanism similar to that established for the acid-catalyzed exchange reactions of tertiary aromatic amines.[5] Of the two possible transition states which could arise from the attachment of a deuteron at a carbon atom adjacent to the hydroxyl or alkoxyl group, I is fixed in electronic configuration and must correspond to an activation energy several kilocalories higher than II in which a benzenoid ring is preserved.

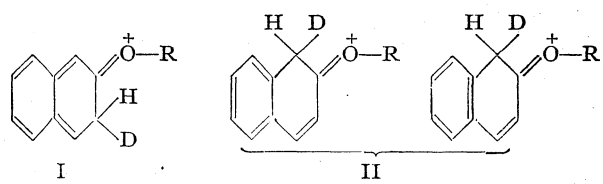

TABLE II

ACID CATALYZED EXCHANGE OF HYDROGEN ATOMS OF PHENOLS AND PHENOL ETHERS WITH DEUTEROALCOHOL AT 110°

α-Methyl-β-naphthyl ethyl ether	142	0.03	0

(1) Abstracted from a Ph.D. thesis by Philip F. Tryon, Chicago, 1939.

(2) Present address: Commercial Solvents Corporation, Terre Haute, Indiana.

(3) (a) Ingold, Raisin and Wilson, *J. Chem. Soc.*, 1637 (1936); (b) Small and Wolfenden, *ibid.*, 1811 (1936); (c) Best and Wilson, *ibid.*, 28 (1938); (d) Munzberg, *Z. physik. Chem.*, **B33**, 23, 39 (1936).

(4) This work was carried out prior to the discovery that significant changes in isotopic composition occur when ethanol is fractionally distilled and that precautions are necessary to avoid errors due to this effect (Brown and Widiger, THIS JOURNAL, **61**, 2453 (1939)). The exchange numbers herein reported, being subject to such errors, may be too high by as much as 5%.

(5) Brown, Widiger and Letang, *ibid.*, **61**, 2597 (1939).

In experiments which were carried out at a lower temperature (Table III), and in which exchange equilibrium was not attained, there is revealed the rather surprising effect of the β-methyl group in ethers of β-methyl-α-naphthol. The lower reactivity of these compounds, in which the hydrogen atoms in the 4-position should still be active, is perhaps an example of a steric effect which should arise in di-*ortho*-substituted phenol ethers because of hindrance to coplanarity in the quinonoid transition state.[6]

TABLE III

ACID CATALYZED EXCHANGE OF HYDROGEN ATOMS AT 60°

Compound	Reaction time, hours	Observed exchange	Active H atoms (theor.)
p-Cresol	15	1.11	
	20	1.15	3
α-Naphthyl methyl ether	70	0.36	
	238	1.15	2
α-Naphthyl isopropyl ether	213	1.18	2
β-Methyl-α-naphthyl methyl ether	238	0.08	1
β-Methyl-α-naphthyl isopropyl ether	213	0.07	1

The results shown in Table IV for phenols having two non-equivalent free ortho positions are of interest in connection with the Mills–Nixon effect. It is clear from these results that each of these substances exchanges two nuclear hydrogen atoms, and if one exchanges faster than the other the differences are not great enough to be readily discernible in the rate curves. These curves are similar in form to that shown by the symmetrical phenol, 3,5-dimethyl-4-chlorophenol, except that the time scale is somewhat more extended for this compound because of its lower reactivity.

Experimental

The experimental procedure employed in this Laboratory for following exchange reactions with deuteroalcohol has been described in previous papers.[7] In all of the experiments here reported the extent of exchange has been determined from the decrease in deuterium content of the alcohol.

The experiments on sulfuric acid catalyzed reactions fall into two groups according to the temperature employed. At 60° the acid is present as ethyl hydrogen sulfate and it was determined that there is no loss of catalyst by further reaction to form diethyl sulfate within a period of eight days. At 110° the loss of catalyst is appreciable within a few hours and the experiments carried out at this temperature therefore do not represent steady conditions with respect to catalyst concentration.

In the presence of small amounts of sodium ethylate, neither α-naphthyl ethyl ether nor β-naphthyl ethyl ether showed any measurable exchange in periods up to twelve days at 110°.

The reaction mixtures generally contained 5 cc. of deuteroalcohol (0.085 mole) and about 0.009 mole of the phenol or ether. Where sulfuric acid was to be used, it was added to the alcohol so as to provide a stock solution containing 10 mg. of sulfuric acid per 5 cc. of alcohol. However, in the series of experiments summarized in Table IV, a more dilute stock solution, containing 0.5 mg. of sulfuric acid per 5 cc. of alcohol, was used and the quantity of phenol was accurately adjusted to 0.00818 mole.

TABLE IV

UPTAKE OF DEUTERIUM FROM DEUTEROALCOHOL, AT 60°, BY 3,4-DIMETHYLPHENOL (I), 5-HYDROXYHYDRINDENE (II), 6-HYDROXYTETRALIN (III) AND 3,5-DIMETHYL-4-CHLOROPHENOL

Time, hours	Exchange number[a] (I)	(II)	(III)	(IV)
0[b]	1.05	1.02	1.06	1.02

342				2.56

[a] For each experiment a solution was prepared containing 0.085 mole of deuteroalcohol (14.77 mole % C_2H_5-OD), 0.001 equivalent of sulfuric acid, and 0.00818 mole of phenol. The exchange numbers were calculated from the analyses on recovered alcohol, taking into account dilution of deuterium by hydrogen from the sulfuric acid. [b] The experimental results entered for zero time were obtained by recovering the alcohol, by distillation, immediately after preparing the mixture. Actually the separations required several minutes to perform. The observed exchange is obviously the exchange of the hydroxyl hydrogen atoms of the phenols.

Except as noted below the materials used were prepared and purified by methods described in the literature.

β-Methyl-α-naphthyl Methyl Ether.—This compound was obtained in 50% yield on treatment of an alkaline solution of β-methyl-α-naphthol[8] with dimethyl sulfate: colorless liquid, b. p. 129–130° at 9 mm., $n^{20}D$ 1.6007, d^{25}_4 1.056. It was characterized by nitration, following a procedure similar to that used by Heermann[9] in the nitration of α-naphthol ether, which furnished a mononitro derivative (1-methoxy-2-methyl-4-nitronaphthalene), light yellow needles, m. p. 104°. *Anal.* Calcd. for $C_{12}H_{11}O_3N$: N, 6.45; Found: N, 6.82.

β-Methyl-α-naphthyl Isopropyl Ether.—A suspension of the sodium salt of β-methyl-α-naphthol in a solution

(6) Further evidence concerning possible steric effects was sought by examining the hydrogen exchange of 2-methylanisole and 2,6-dimethylanisole, but both of these compounds showed some decomposition (positive ferric chloride test) under the conditions of the exchange experiments and the results were therefore inconclusive.

(7) (a) Kharasch, Brown and McNab, *J. Org. Chem.*, **2**, 36 (1937); (b) Brown, Kharasch and Sprowls, *ibid.*, **4**, 442 (1939).

(8) Prepared by the method of Lesser, *Ann.*, **402**, 38–43 (1914).

(9) Heermann, *J. prakt. Chem.*, **44**, 238 (1891).

containing 150 cc. of dioxane, 32 g. of isopropyl bromide, and 2 g. of potassium iodide was refluxed for fourteen hours. After distilling off most of the dioxane, ether and water were added, and the ether layer, after washing with alkali and with water and then drying over calcium chloride, yielded on distillation 13 g. (38% yield) of the desired product; b. p. 147–148° at 12 mm., n^{20}D 1.5764, d^{25}_4 1.017. Nitration yielded a mononitro derivative (1-isopropoxy-2-methyl-4-nitronaphthalene), light yellow needles, m. p. 45°. *Anal.* Calcd. for $C_{14}H_{15}O_3N$: N, 5.71; Found: N, 5.69.

α-Naphthyl Isopropyl Ether.—This was prepared by a procedure similar to the preceding, from the sodium salt of α-naphthol and isopropyl bromide in 21% yield; b. p. 139–140° at 9 mm., n^{20}D 1.5848, d^{25}_4 1.025. On nitration a mononitro derivative was obtained which yielded 4-nitro-1-naphthol on treatment with alcoholic potassium hydroxide for one hour on the steam-bath and is thus identified as 1-isopropoxy-4-nitronaphthalene; dark yellow needles, m. p. 69°. *Anal.* Calcd. for $C_{13}H_{13}O_3N$: N, 6.06; Found: N, 6.15.

Summary

It is shown that hydrogen atoms *ortho* and *para* to the hydroxyl or alkoxyl group in phenols and phenol ethers exchange with deuteroalcohol in the presence of small amounts of sulfuric acid. Exceptions are β-naphthol and derivatives thereof in which exchange occurs only at the α-position. The unsymmetrical phenols, 5-hydroxyhydrindene and 6-hydroxytetralin, which couple at a preferred *ortho* position (Mills–Nixon effect), show two active nuclear hydrogens in the exchange reaction.

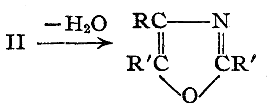
Conversion of α-Amino Acids to Acylamido Ketones and Oxazoles

BY RICHARD H. WILEY AND OLIN H. BORUM[1]

A previous communication[2] described a method for the conversion of α-amino acids (I) to acetamidoketones (II, R′ = CH_3) by reaction with acetic anhydride in pyridine, and of the acetamidoketones to oxazoles (III).

$$\underset{\text{I}}{RCH(NH_2)CO_2H} + 2(R'CO)_2O \xrightarrow{\text{pyr.}}$$

$$\underset{\text{II}}{RCH(NHCOR')COR'} + 2RCO_2H + CO_2$$



III

The present paper describes the anomalous course of this reaction with glycine, the substitution of propionic for acetic anhydride in the formation of a propionamidoketone, and a modified procedure for obtaining yields of 70–90% of the acylamidoketone.

The reaction product obtained on refluxing glycine and acetic anhydride in pyridine can be fractionated to give a principal fraction boiling at 105–108° at 2 mm. The analytical data show that this compound is not acetamidoacetone, the product which would be formed if the reaction were analogous to that with alanine. The data agree with values calculated for an acetyl derivative of acetamidoacetone. This is substantiated by the hydrolysis of this acetyl derivative to acetamidoacetone b. p. 101–105° (0.5 mm.) in 76% yield. The structure of the acetyl derivative cannot be assigned on the basis of the available information. It is noted in this connection that previous attempts to bring about this reaction with glycine[3] were less successful because the reaction is very slow at steam-bath temperatures.

Improved yields of 3-acetamido-2-butanone are obtained by stirring during the reaction period to aid in evolution of carbon dioxide. The preferred procedure, in which the product is separated by fractionation of the reaction mixture, gives 88% of redistilled product as described in the experimental part. Using this procedure aminophenylacetic acid and propionic anhydride give a 75% yield of 1-phenyl-1-propionamido-2-butanone.

Dehydration of the acylamidoketones to oxazoles with potassium bisulfate and other reagents has been accomplished but with no advantage over the previously described[2] sulfuric acid dehydration.

Experimental Part

3-Acetamido-2-butanone (II, R = CH_3, R′ = CH_3).—A mixture of 159 ml. (1.98 moles) of pyridine (J. T. Baker C. P.), 224 ml. (2.35 moles) of acetic anhydride (95% min. assay), and 35.11 g. (0.39 mole) of vacuum-dried alanine (Merck) was heated with stirring on the steam-bath for six hours after solution was complete. The excess pyridine and acetic anhydride were removed at reduced pressure and the residue distilled through a short column to obtain 47.5 g., 93.2% of the theoretical amount of crude 3-acetamido-2-butanone, b. p. 110–125° at 3 mm. On refractionation 88% of the theoretical amount, 45 g., b. p. 102–106° at 2 mm., was obtained, n^{25}D 1.4558.

Anal. Calcd. for $C_6H_{11}NO_2$: C, 55.79; H, 8.59; N, 10.85. Found: C, 55.81; H, 8.48; N, 10.90.

Without stirring the yield dropped to 46%. Reducing the molar ratio of pyridine or anhydride also reduced the yield.

1-Phenyl-1-propionamido-2-butanone (II, R = C_6H_5, R′ = C_2H_5).—A mixture of 60 g. (0.4 mole) of aminophenylacetic acid (E. K. Co.), 250 ml. (2.0 moles) of propionic anhydride (Carbide and Carbon Co.), and 165

(1) The work reported in this paper was taken in part from the Master's Thesis submitted by Olin H. Borum to the Graduate School of the University of North Carolina.

(2) Richard H. Wiley, *J. Org. Chem.*, **12**, 43 (1947).

(3) Dakin and West, *J. Biol. Chem.*, **78**, 91–105 (1928).

ml. of pyridine were heated to solution and then at gentle reflux for one and a half hours. On vacuum distillation a fraction, b. p. 159–162° at 3–4 mm., weighing 66 g., 75% of the theoretical amount of 1-phenyl-1-propionamido-2-butanone, was collected. This fraction solidified on standing and was recrystallized from xylene, m. p. 69.7–70.7 (cor.).

Anal. Calcd. for $C_{13}H_{17}O_2N$: C, 71.20; H, 7.82; N, 6.39. Found: C, 71.33; H, 7.89; N, 6.65.

Acetyl Acetamidoacetone.—A mixture of 1.1 liters (11 moles) of acetic anhydride (95% min. assay), 485 ml. (6 moles) of pyridine (J. T. Baker C. P.), and 75 g. (1 mole) of vacuum-dried glycine (E. K. Co) was refluxed with stirring for six hours. The excess pyridine and acetic anhydride were removed at reduced pressure and the residue distilled to obtain 95 g., 60% of the theoretical amount, of crude acetyl acetamidoacetone, b. p. 118–128° at 3 mm. On refractionation 85 g., 54% of the theoretical amount of purified acetyl acetamidoacetone, b. p. 105–108° at 2 mm., was separated, $n^{25}D$ 1.4668; d^{25}_{25} 1.1275.

Anal. Calcd. for $C_7H_{11}O_3N$: C, 53.49; H, 7.05; N, 8.91. Found: C, 53.54; H, 7.17; N, 9.17.

Acetyl acetamidoacetone reacts immediately with neutral potassium permanganate solution to give a heavy precipitate. Acetamidoacetone does not. Both decolorize bromine in carbon tetrachloride solution.

Acetamidoacetone (II, R = H, R′ = CH_3).—Thirty-two grams of acetyl acetamidoacetone was dropped into 500 ml. of boiling water over a thirty-minute period. The mixture was steam distilled for five hours, the remaining water and acetic acid removed under reduced pressure, and the residue fractionated to give 17.8 g., 76% of the theoretical amount of acetamidoacetone, b. p. 104–109° (1–2 mm.), $n^{25}D$ 1.4600 (supercooled). This fraction solidified to an extremely hygroscopic solid, m. p. 39–41°.

Anal. Calcd. for $C_5H_9O_2N$: C, 52.16; H, 7.88; N, 12.16. Found: C, 51.87; H, 7.92; N, 12.10.

Acetamidoacetone was converted to 2,5-dimethyloxazole by the process previously described.[2] Ten to fifteen per cent. of 2,5-dimethyloxazole, b. p. 116–117°, $n^{25}D$ 1.4365 was obtained. The reported[4] boiling point is 117°.

Anal. Calcd. for C_5H_7ON: N, 14.42. Found: N, 14.60.

2,5-Dimethyloxazole picrate, m. p. 122–122.5°, was prepared in alcohol solution. The reported m. p. is 124°.[4]

Anal. Calcd. for $C_{11}H_{10}O_8N_4$: N, 17.17. Found: 17.34.

Dehydration of 3-Acetamido-2-butanone to 2,4,5-Trimethyloxazole.—Thirty grams of 3-acetamido-2-butanone was dropped over a thirty-minute period onto 87.5 g. of potassium bisulfate in a distilling flask at 220°. A total of 21.10 g. of distillate was collected in the receiver. This material on fractionation gave a total of 17.8 g., b. p. 70–147°. A center cut of 7.8 g., b. p. 141–143°, $n^{25}D$ 1.4280 gave a picrate, m. p. 110–111.5°, which did not lower the m. p. when mixed with a sample of previously prepared[2] picrate. When 11.7 g. of the crude reaction mixture, b. p. 142–150°, was washed with 33% aqueous sodium hydroxide and dried over solid potassium hydroxide 1.7 g. of oxazole, b. p. 133–135°, $n^{25}D$ 1.4391, was obtained. Other pyrolyses with alumina, anhydrous zinc sulfate, lime, boron oxide and phosphorus pentoxide at 200–300°, but not thermal pyrolysis at 500°, dehydrate the ketone to the oxazole in low yields.

Summary

Glycine reacts with acetic anhydride in pyridine to form acetyl acetamidoacetone which is readily hydrolyzed to acetamidoacetone. Improved yields in the conversion of alanine to 3-acetamido-2-butanone, the conversion of aminophenylacetic acid to 1-phenyl-1-propionamido-2-butanone, and a potassium bisulfate dehydration of 3-acetamido-2-butanone to 2,4,5-trimethyloxazole are reported.

Some Chloromethyl Ethers of Nitro Alcohols and the Preparation of Mixed Acetals from Them

BY E. B. HODGE

The reaction between formaldehyde, hydrogen chloride and an alcohol to form a chloromethyl ether was first reported by Henry.[1] Since then, the reaction has become very well known and is frequently used in synthetic work. The chlorine atom in these compounds is quite reactive, and it was thought to be of interest to see if the chloromethyl ethers of nitro alcohols would form. These compounds would make available a new tool in the preparation of derivatives containing aliphatic nitro groups. The aromatic nitro group is known to hinder the chloromethylation reaction.[2]

The success of the chloromethylation reaction as applied to nitro hydroxy compounds was found to vary with the structure of the nitro hydroxy compound. The chloromethyl ethers prepared were mobile liquids with sharp odors. They were soluble in benzene and the usual oxygenated solvents, but were insoluble in petroleum ether and water. On being shaken for a short time with water they decomposed.

Properties and yields of the chloromethyl ethers prepared are listed in Table I. The yields are based on the nitro alcohol.

The chloromethyl ethers prepared were found to react smoothly with sodium phenoxide and alkoxides to give mixed acetals. The nitro group in these could be reduced catalytically to the amino group. Properties and yields of these mixed acetals are given in Table II.

Yields of the nitro acetals and of the amino acetals from phenol are based on the chloromethyl

ether, while the yields of the other amino acetals are based on the nitro acetals.

When the chloromethylation of 2-methyl-2-nitro-1,3-propanediol was attempted, only the acetal, 5-methyl-5-nitro-1,3-dioxane was obtained.[3]

The cyclic acetal was too stable to be split by hydrogen chloride. Support for this hypothesis is given by the fact that bis-(2-methyl-2-nitropropoxy)-methane was found to react with hydrogen chloride and formaldehyde to give 1-chloromethoxy-2-methyl-2-nitropropane.

The effect of structure on the formation of chloromethyl ethers of nitro alcohols is shown by the relative ease of preparation of the chloromethyl ethers. 2-Methyl-2-nitro-1-propanol and 2-methyl-2-nitro-1-butanol reacted smoothly and gave a product which could be distilled at reduced pressure without apparent decomposition. However, the chloromethyl ether of 2-nitro-1-butanol could not be distilled without some decomposition, while no product could be isolated from 2-methyl-2-nitro-3-hexanol.

Experimental

The preparation of the chloromethyl ethers is illustrated by the reaction between hydrogen chloride, formaldehyde and 2-methyl-2-nitro-1-propanol.

(3) The fact that this acetal was formed from the diol while chloromethyl ethers were formed from the monohydroxy compounds suggests that the chloromethyl ethers were formed through the acetals as intermediates and that the cyclic acetal was too stable to be split by hydrogen chloride. Thus the equations might be written to account for the formation of the chloromethyl ethers. Support for this hypothesis is given by the fact that bis-(2-methyl-2-nitropropoxy)-methane was found to react with hydrogen chloride and formaldehyde to give 1-chloromethoxy-2-methyl-2-nitropropane.

$$2ROH + HCHO \xrightarrow{H^+} (RO)_2CH_2 + H_2O$$
$$(RO)_2CH_2 + HCl \longrightarrow ROCH_2Cl + ROH$$

Into a mixture of 238 g. of 2-methyl-2-nitro-1-propanol, 90 g. of trioxymethylene and 175 ml. of concentrated hydrochloric acid in a 1-liter beaker was passed a rapid stream of HCl from a cylinder of liquefied hydrogen chloride. The beaker was in an ice-bath which kept the temperature below 30° during the addition of the hydrogen chloride. The contents of the beaker were stirred vigorously and the hydrogen chloride was added through a disperser of sintered glass. After about one hour the addition was stopped, 50 ml. of benzene was added, and the layers were separated. Dry air was passed through the top layer until no more hydrogen chloride was evolved and then the product was distilled, first at atmospheric pressure and then at 5 mm. to remove the chloromethyl ether. This came off at 90–94°, wt. 228 g.

The preparation of a mixed acetal is illustrated by the following experiment.

One-hundred and sixty grams of methanol was placed in a 500 ml. round-bottomed flask equipped with a sealed stirrer, a dropping funnel and a reflux condenser. One mole (23 g.) of sodium was added slowly and when all had reacted, 145 g. (0.8 mole) of 1-chloromethoxy-2-methyl-2-nitrobutane was added dropwise to the refluxing mixture. After one-half hour of refluxing the mixture was cooled and filtered. Then 500 ml. of water was added and the methanol was stripped off. The oil which separated from the water was distilled. The main cut (81.4 g.) came off at 75° at 1–1.5 mm.

Reduction of the nitro mixed acetals is illustrated by the following experiment.

2-Methyl-2-nitro-4,6-dioxaheptane (78.6 g.) was dissolved in 400 ml. of methanol and reduced with hydrogen in a rocking bomb at 50–60° and 1000 lb. pressure in the presence of 5 g. of Raney nickel. The methanol was stripped off and the product was distilled at 10 mm. The weight of the product was 53.5 g.

Reaction between an acetal and hydrogen chloride was carried out as follows.

To 63 g. (0.25 mole) of bis-(2-nitroisobutoxy)-methane was added 1 mole of formalin. Dry hydrogen chloride was passed into this mixture at room temperature for three hours. The mixture was then extracted with benzene and the high boiling product was rectified under reduced pressure. A middle cut of 27 g. was taken which boiled at 104–106° at 13 mm. and contained 21.5% of chlorine. Theory for 1-chloromethoxy-2-methyl-2-nitropropane is 21.2%.

Summary

The chloromethyl ethers of three nitro alcohols have been prepared.

Evidence suggests that the formation of these chloromethyl ethers takes place through the formal as an intermediate.

Several mixed acetals have been prepared from chloromethyl ethers of nitro alcohols and the nitro groups in these compounds have been reduced to amino groups.

Reactions of Vanillin and its Derived Compounds. VI.[1] The Reaction of Vanillin with Mercuric Oxide[2,3]

BY IRWIN A. PEARL

The high yields of vanillic acid obtained when vanillin is treated with alkali and 0.5 mole of silver oxide in aqueous solution[4,5] and the interesting reactions of vanillin with alkali in the presence of silver oxide and silver metal[6] led to a study of the reaction of vanillin with alkali and other metallic oxides. This paper reports the study with mercuric oxide.

Vanillin gradually reacts with an excess of mercuric oxide in a boiling aqueous solution containing at least two moles of alkali to give a clear alkaline solution which may be treated by various procedures to give several different reaction products. All forms of mercuric oxide are operative, but the more reactive, freshly precipitated forms require less time. The reaction time is also dependent, to a considerable extent, upon the temperature of boiling which, in turn, is dependent upon dilution. The reaction of vanillin with mercuric oxide is much slower than that with silver oxide.

Acidification of the alkaline reaction mixture with a non-reducing acid (such as sulfuric acid) gives a high yield of 5-hydroxymercurivanillin and minor amounts of oxidized mercurated compounds. Acidification with hydrochloric acid yields 5-hydroxymercurivanillin as the chief product, together with minor quantities of 5-chloromercurivanillin and other mercurated compounds, including oxidized and bis derivatives.

Treatment of the alkaline solution with sulfur dioxide, followed by short boiling, decomposes the organic mercury compounds and gives a 60–70% yield of vanillic acid and a 25–35% yield of recovered vanillin. No mercurated products are obtained after the sulfur dioxide treatment, and most of the mercury is recovered as the free metal.

When only one mole of vanillin is employed in the above reaction, the vanillic acid yield is very low, and almost all the initial vanillin is recovered after the sulfur dioxide treatment.

Long boiling of vanillin with technical dry mercuric oxide and excess alkaline solution resulted in considerable decarboxylation of the originally formed vanillic acid to yield 11% of guaiacol. This was an unexpected result, because earlier work[7,8] on the caustic fusion of vanillin to yield protocatechuic acid indicated that the carboxyl group was much more resistant to removal by drastic alkaline treatment than was the methoxyl group. All attempts to oxidize vanillin by means of mercuric oxide without alkali in a non-aqueous solvent were unsuccessful.

5-Hydroxymercurivanillin was identified by converting it successively to 5-acetoxymercurivanillin, 5-chloromercurivanillin, and 5-iodovanillin, which compounds were compared with the corresponding compounds prepared according to Paolini,[9] who obtained acetoxymercurivanillin by treating vanillin with mercuric oxide in boiling glacial acetic acid. Paolini's compound was proved to be 5-acetoxymercurivanillin by Henry and Sharp.[10] 5-Iodovanillin was also compared with the iodovanillin prepared according to Carles[11] which Raiford and Wells[12] proved to be 5-iodovanillin.

Paolini's[9] 5-acetoxymercurivanillin, upon boiling with *N* potassium hydroxide solution and acidifying with hydrochloric acid, yielded 5-chloromercurivanillin, but all attempts to isolate 5-hydroxymercurivanillin from 5-acetoxymercurivanillin failed.

5-Hydroxymercurivanillin possesses remarkable toxicity toward representative microörganisms, such as sporeforming and non-sporeforming aerobic bacteria and molds and compares favorably with such outstanding antiseptics as ethylmercury and phenylmercury derivatives. On the other

hand, 5-hydroxymercurivanillin is much less toxic toward fish than the ethylmercury and phenylmercury compounds and, therefore, its use as a mill disinfectant or slime control agent is indicated. 5-Hydroxymercurivanillin also appears to have medicinal uses.

Experimental

All melting points given are uncorrected.

Reaction of Vanillin with Alkali and Mercuric Oxide.—To a solution of 136 g. of mercuric chloride in 400 cc. of hot water was added a hot solution of 100 g. of sodium hydroxide in 100 cc. of water. The mixture was vigorously stirred and treated with 25 g. of vanillin. The reaction mixture was heated to boiling under a reflux with mercury-sealed stirring for ten hours and allowed to cool.

Acidification with Sulfuric Acid. Preparation of 5-Hydroxymercurivanillin.—The above reaction mixture was filtered and the inorganic precipitate was washed with water. The combined filtrate and washings were acidified with 1:3 sulfuric acid. The thick white precipitate which separated was filtered, washed with water, and dried in a vacuum desiccator. The yield was 40 g. Recrystallization from water, ethanol, methanol, acetone, or dioxane gave colorless needles of 5-hydroxymercurivanillin melting at 235°. 5-Hydroxymercurivanillin is very slightly soluble in the above solvents, but is soluble in dilute alkali, glacial acetic acid, and concentrated sulfuric acid.

Anal. Calcd. for $C_8H_8O_4Hg$: CH_3O, 8.4. Found: CH_3O, 8.4.

A sample was dissolved in the minimum amount of boiling acetic acid. On cooling a fine crystalline powder of 5-acetoxymercurivanillin separated, which melted at 196–198°.

Anal. Calcd. for $C_{10}H_{10}O_5Hg$: CH_3O, 7.56. Found: CH_3O, 7.61.

A suspension of 5-acetoxymercurivanillin in a solution of excess sodium chloride was boiled several hours and cooled. The glistening precipitate was filtered and recrystallized from methanol to yield 5-chloromercurivanillin melting at 242–243° and not depressing a mixed melting point with Paolini's compound.[9]

Anal. Calcd. for $C_8H_7O_3HgCl$: C, 24.8; H, 1.83; Cl, 9.17. Found: C, 24.2; H, 1.89; Cl, 9.2.

5-Chloromercurivanillin was warmed with a solution of iodine in ethanol and cooled. The light yellow crystals were recrystallized twice from water and twice from 50% ethanol to give colorless crystals of 5-iodovanillin which melted at 176° and did not depress a mixed melting point with Carles'[11] authentic 5-iodovanillin.

Acidification with Sulfur Dioxide. Preparation of Vanillic Acid.—A hot solution of 80 g. of sodium hydroxide in 500 cc. of water was treated with stirring with 108 g. of C. P. dry yellow mercuric oxide and then with 25 g. of vanillin. The mixture was boiled under a reflux with mercury-sealed stirring for seven hours and allowed to cool. The precipitate was filtered and washed with water. The filtrate and washings were acidified with sulfur dioxide, which caused the separation of a granular white precipitate. This precipitate was filtered, washed with water, dried, and washed with ether. The filtrate was thoroughly extracted with ether and the combined ether extracts were extracted with 8% sodium bicarbonate solution; the extract yielded 17.9 g. (65%) of vanillic acid melting at 207–208°. Recrystallization from water or ethanol yielded colorless crystals which melted at 209–210° and did not depress a mixed melting point with authentic vanillic acid.[4]

The sulfur dioxide-saturated aqueous solution was acidified with sulfuric acid, aspirated with air, and extracted with ether. The ether was extracted successively with 21% sodium bisulfite, 8% sodium bicarbonate, and 5% sodium hydroxide solutions. No bisulfite extract was obtained. A little more vanillic acid was obtained from the bicarbonate extract. Approximately 30% vanillin was recovered by acidification of the sodium hydroxide extract. The occurrence of vanillin in the sodium hydroxide extract, rather than in the bisulfite extract in this experiment, has not been satisfactorily explained, although it is apparent that the aldehyde group must be protected in some manner until treated with strong alkali.

In an alternate procedure, the original sulfur dioxide-saturated reaction mixture containing the granular white precipitate was boiled for a short while and filtered. The clear solution deposited needles of vanillic acid upon cooling and the rest was secured by ether extraction.

The granular white precipitate appears to be a hydrated mercuric bisulfite or bisulfate. The ether-extracted white crystals, when boiled with water, yielded metallic mercury and sulfur dioxide.

Anal. Calcd. for $Hg(HSO_4)_2 \cdot 2H_2O$: Hg, 46.8; S, 14.8. Calcd. for $Hg(HSO_3)_2 \cdot 4H_2O$: Hg, 46.0; S, 14.8. Found: Hg, 46.20, 46.73; S, 14.83, 14.64.

In a similar experiment employing technical dry mercuric oxide, the sulfited reaction mixture was boiled, cooled, and extracted with ether. The ether was extracted with 8% sodium bicarbonate solution, which was acidified to yield 35.4% vanillic acid. The ether was dried and distilled. The oily residue, on distillation, yielded 11.0% of guaiacol boiling at 203–207°. The benzoate melted at 57° and did not depress a mixed melting point with authentic guaiacol benzoate. The original sulfited aqueous solution yielded 53.3% of recovered vanillin.

Reaction of Vanillin with Mercuric Oxide in Anhydrous Solvent.—A mixture of 15.2 g. of vanillin, 21.6 g. of C. P. dry mercuric oxide, and 250 cc. of dry benzene was boiled under reflux with occasional shaking for seven hours. No reduction of the oxide took place and all the vanillin was recovered.

Reaction of 5-Acetoxymercurivanillin with Alkali.—A mixture of 20 g. of 5-acetoxymercurivanillin and 400 cc. of *N* potassium hydroxide solution was boiled for two hours. The clear solution was filtered from a trace of metallic mercury, cooled, and acidified with sulfur dioxide. The acidified solution was heated to boiling with continued sulfur dioxide introduction for ten minutes. The sulfur dioxide introduction was discontinued, and boiling was continued for ten minutes. The mercury which separated was filtered, and the cooled filtrate was extracted with ether. The ether solution, when dried and distilled, gave 7 g. of vanillin melting at 78–79° and not depressing a mixed melting point with authentic vanillin.

In a similar experiment, the original filtered alkaline reaction mixture was acidified with dilute hydrochloric acid. The white flocculent precipitate was filtered, washed with water, dried, and recrystallized from methanol to yield white crystals of 5-chloromercurivanillin melting at 241°.

Anal. Calcd. for $C_8H_7O_3HgCl$: Cl, 9.2; CH_3O, 8.1. Found: Cl, 9.2; CH_3O, 8.4.

Solution of the 5-chloromercurivanillin in dilute potassium hydroxide and acidification with sulfur dioxide yielded vanillin.

Similar acidification of the 5-acetoxymercurivanillin-potassium hydroxide reaction mixture with dilute sulfuric acid yielded only a yellow brittle solid which contained 8.3% methoxyl and which would not melt. All attempts to isolate 5-hydroxymercurivanillin failed.

Toxicity Studies.—The toxicity of 5-hydroxymercurivanillin was determined for the representative micro-organisms, *Aerobacter aerogenes* (non-sporeforming bacteria), *Bacillus mycoides* (sporeforming bacteria), and *Aspergillus niger* (molds), by the method of Appling and McCoy[13] and compared with commercial samples of Merfenel (phenylmercuric acetate), Lignasan (ethylmercuric phosphate), and Santobrite (sodium

(13) Appling and McCoy, *Paper Trade J.*, **119**, No. 11, 116 (1944).

pentachlorophenate). The results are given in Table I.

TABLE I

INHIBITING CONCENTRATIONS FOR THREE TEST ORGANISMS (IN PER CENT. BY WEIGHT)

	A. aerogenes (increment 0.0001%)	*B. mycoides* (increment 0.0004%)	*A. niger* (increment 0.0004%)
5-Hydroxymercurivanillin	0.0004	0.0002	0.0010
Merfenel[a]	.0001	.00001	.0001
Lignasan[b]	.0010	.00016	.0006
Santobrite[c]	.0225	.0004	.0016

[a] Technical phenylmercuric acetate. [b] Contains 6.25 ethylmercury phosphate. [c] Technical sodium pentachlorophenate.

TABLE II

TOXICITY TOWARD LAKE EMERALD SHINER (*Notropis atherinoides*)

	Critical concn., p. p. m.	Survival period, min.
5-Hydroxymercurivanillin	5–7	600 (7.5 p. p. m.)
Merfenel[a]	0.02	15 (5.0 p. p. m.)
Lignasan[b]	0.8	128 (5.0 p. p. m.)
Santobrite[c]	0.4	16 (5.0 p. p. m.)

[a] Technical phenylmercuric acetate. [b] Contains 6.25 ethylmercury phosphate. [c] Technical sodium pentachlorophenate.

Fish toxicity tests were run according to the method of Van Horn[14] employing the lake emerald shiner (*Notropis atherinoides*) as the test fish. Van Horn has shown this fish to be one of the most sensitive for toxicity studies. The data are given in Table II.

Acknowledgment.—The author is indebted to the Analytical, Biology, and Microbiology Departments of The Institute of Paper Chemistry for the analyses and toxicity tests reported in this paper.

Summary

Reaction of vanillin with excess mercuric oxide and alkali in aqueous solution and acidification of the filtered reaction mixture with sulfur dioxide yields 60–70% vanillic acid. Similar reaction of vanillin with one or more moles of mercuric oxide and acidification with a non-reducing acid yields 5-hydroxymercurivanillin as the chief reaction product. 5-Hydroxymercurivanillin has demonstrated remarkable toxicity toward representative microorganisms, but was found to be much less toxic to fish than other well-known comparable antiseptics. Its use as a mill disinfectant or slime control agent is indicated.

Bromination of Zein

BY W. W. BINKLEY[1]

Investigations of the chemical nature of zein have been largely indirect. Extensive studies have been made of the hydrolytic products of this corn protein.[2] Few reagents are selective enough to reveal any part of the intimate structure of this molecule. Neuberger,[3] using iodine and ammoniacal methanol, prepared an undegraded iodozein which indicated the combination of 0.064 g. atom of iodine with 100 g. of zein. The iodine was shown to be combined with the tyrosine residues in the protein. The halogenation of zein has been extended using chlorine and bromine.

The direct titration of zein with chlorine in acetic acid did not show the formation of a definite compound (Fig. 1). Bromine reacted with zein to form an undegraded or slightly degraded bromozein (Fig. 1). Iodine did not react with zein in the presence of acetic acid.

Dry ethyl ether and 0.25% aqueous sodium chloride were used as the precipitation media for the brominated zein. The product of the ether precipitation was acidic, reacted with sodium hydroxide, silver nitrate, and liberated iodine from potassium iodide; this compound was called bromozein hydrobromide. The other product was neutral, and did not react with sodium hydroxide, silver nitrate or potassium iodide; it was named bromozein.

A total of 0.24 g. atom of bromine was required to brominate 100 g. of zein (Fig. 1). Bromozein hydrobromide possessed 0.20 g. atom of this bromine (Table I).[4] Sodium hydroxide or silver nitrate reacted readily with 0.13 g. atom of the bromine in bromozein hydrobromide, while 0.07 g. atom of the bromine was firmly bound. The amino acids which occur in zein were titrated with bromine in acetic acid. Two of these amino acids reacted under these conditions, *viz.*, tyrosine and histidine (Table II). Folin and Ciocalteu[5] established the presence of 0.033 mole of tyrosine residues in 100 g. of zein. The bromination of these tyrosine residues would produce 0.066 g. atom of the alkali labile bromines and an equal number of the firmly bound bromines in bromozein hydrobromide. Osborne and Liddle[6] found

0.005 g. mole of histidine residues in 100 g. of zein. The bromine uniting with the histidine residues would account for all the firmly combined bromine in bromozein hydrobromide. An amount of 0.037 g. atom of the labile bromines of bromozein hydrobromide liberated iodine from potassium iodide.

TABLE I

DISTRIBUTION OF THE ELEMENTS IN ZEIN, BROMOZEIN AND ITS HYDROBROMIDE[a]

Elements		Zein, g. atoms / 100 g. zein	Bromozein hydrobromide, g. atoms / 100 g. zein residue	Bromozein, g. atoms / 100 g. zein residue	Bromozein from bromozein hydrobromide, g. atoms / 100 g. zein residue
Carbon		4.60		4.32	4.31
Nitrogen	Total	1.15	1.13	1.06	1.06
	Amide	0.33	0.33	0.31	
Bromine			0.20	0.07	0.07

[a] Calcd. as follows

$$\frac{\%\text{ of element present}}{100 - \%\text{ Br present}} \times \frac{1}{\text{at. wt. of element}} \times 100 = \frac{\text{g. atoms element}}{100\text{ g. zein residue}}$$

TABLE II

TITRATION OF THE AMINO ACID RESIDUES WHICH OCCUR IN ZEIN WITH BROMINE IN ACETIC ACID

Amino acid[a]	Bromine consumed, g. atoms / mole of amino acid	Bromide ion formed, g. ions / mole of amino acid	Bromine combined with amino acid, g. atoms / mole of amino acid
Tyrosine	4.1	2.1	2.0
Histidine	2.3	1.2	1.1

[a] The other amino acids which occur in zein had no significant bromine titration.

Bromozein hydrobromide was converted readily into bromozein with silver nitrate or sodium hydroxide. A total of 0.07 g. atom of bromine was found in bromozein (Table I).

The solubility characteristics of the bromozein and its hydrobromide were similar to those of zein itself but, unlike the latter substance, they showed only a slight tendency toward gelation.

Experimental

Materials.—The zein was obtained from the Corn Products Refining Co., Argo, Ill.

Anal. Moisture, 6.6; ash, 0.5; fat, 1.0; N, 14.70 (16.00, cor. for moisture, ash and fat); amide N, 4.58.

Titration of Zein with Chlorine, Bromine and Iodine.—Chlorine was passed into 1 liter of glacial acetic acid in an ambered-colored glass bottle surrounded by an ice-and-water-bath. After the addition of 4–5 g. of chlorine, 25-ml. aliquots of the resulting solution were titrated with 0.1 *N* sodium thiosulfate in the presence of an excess of potassium iodide using starch as the indicator. Four samples, each containing 5 g. of zein in 100 ml. of 90% acetic acid (10% water), were treated with 50, 100, 200, 300 ml., respectively, of the standardized chlorine solution and allowed to stand one hour at room temperature in diffuse daylight. After the addition of an excess of potassium iodide, the solutions were titrated with 0.1 *N* sodium thiosulfate using starch as the indicator.

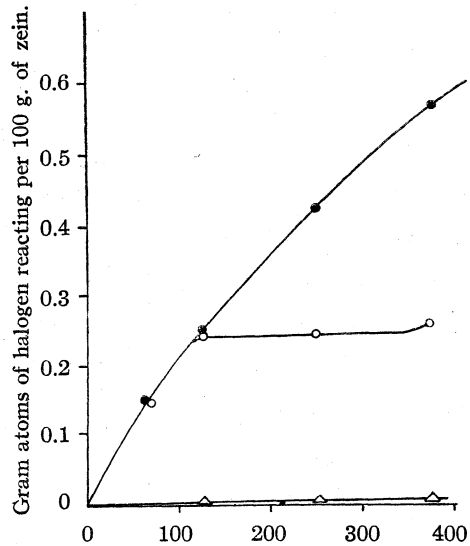

Fig. 1.—Titration of zein with chlorine, bromine and iodine in acetic acid: ●, chlorine; ○, bromine; △, iodine.

An amount of 10 g. of bromine was made up to 1 liter with glacial acetic acid and titrated with 0.1 *N* sodium thiosulfate as previously indicated. Zein was allowed to react with bromine under the conditions already described for chlorine.

An amount of 15.9 g. of iodine was made up to 1 liter with glacial acetic acid and titrated with 0.1 *N* sodium thiosulfate as previously indicated. Zein was treated with iodine under the conditions already described for chlorine. The analytical results are shown graphically in Fig. 1.

Titration of Amino Acids with Bromine.—An amount of 100 mg. of amino acid[7] in 20 ml. of 90% acetic acid was allowed to react with 40 ml. of 0.125 *N* bromine in glacial acetic acid for one hour at room temperature. The excess bromine was titrated with 0.1 *N* sodium thiosulfate as previously indicated.

An amount of 100 mg. of amino acid was allowed to react with bromine as indicated above. The excess bromine in the reaction was reduced to bromide ion with 0.1 *N* sodium bisulfite. This solution was diluted with 100 ml. of water and titrated with 0.1 *N* silver nitrate using eosin as the indicator. Analytical data are collected in Table II.

Preparation of Dibromotyrosine Hydrobromide.—An amount of 100 mg. of tyrosine was allowed to react with bromine as described above. The solvents and excess bromine were removed under reduced pressure with a bath temperature of 50°. The crystalline residue was washed with cold dry ethyl ether; yield, 232 mg. These crystals were recrystallized from ethanol–ethyl ether solution; m. p. 213–215° (dec.). They were soluble in water, ethanol and acetic acid; they were not soluble in ethyl ether. They were acid to methyl red and reacted with aqueous silver nitrate.

Anal. Calcd. for $C_9H_9O_3NBr_2 \cdot HBr$: total Br, 57.11; Br as HBr, 2.38 ml. of 0.1 *N* $AgNO_3$ per 100 mg. Found: total Br, 57.02; Br as HBr 2.40 ml. $AgNO_3$ per 100 mg. These data are summarized in Table II.

Bromination of Histidine.—Histidine dihydrobromide (150 mg.) was allowed to react with bromine as indicated previously. The solvents and excess bromine were removed almost completely under reduced pressure in the presence of carbon dioxide with a bath temperature of 30°.

(7) The amino acids were obtained from the Eastman Kodak Co. Rochester, N. Y.

The residue was poured into 20 ml. of cold, dry ethyl ether with vigorous stirring. The pink precipitate which formed, was collected on a filter, washed with 20 ml. cold, dry ethyl ether and dried in the absence of air at 25°; yield, 150 mg. The brominated histidine decomposed rapidly on exposure to air. It was soluble in water, ethanol and acetic acid, insoluble in ethyl ether. It was acid to methyl red and reacted with aqueous silver nitrate.

Anal. Calcd. for $C_6H_8O_2N_3Br \cdot 2HBr$: total Br, 60.57; Br as HBr, 5.95 ml. 0.1 *N* $AgNO_3$ per 100 mg. Found: total Br, 57.8; Br as HBr, 5.40 ml. 0.1 *N* $AgNO_3$ per 100 mg. These data are summarized in Table II.

Preparation of Bromozein Hydrobromide.—Ten grams of bromine in 500 ml. of glacial acetic acid was added slowly to a solution of 50 g. of zein in 450 ml. of 90% acetic acid. The reaction mixture was allowed to stand twenty-four hours at 25° in diffuse daylight and then poured slowly into 7 liters of dry ethyl ether with vigorous stirring. The white precipitate which formed, was collected on a filter, washed with 3 to 4 liters of dry ethyl ether and dried forty-eight hours at 50°; yield, 55.00 g. This solid was soluble in 90% acetic acid and 70% ethanol. It reacted with sodium hydroxide and silver nitrate in ethanol and liberated iodine from potassium iodide in acetic acid. An accelerated gelation test of bromozein hydrobromide in 70% ethanol showed only a slight tendency toward gel formation.

Anal. Moisture, 5.2; N, 12.90; amide N, 3.96; Br, 13.10; three samples, each of 500 mg., required 5.25 ml. 0.1 *N* NaOH, 5.25 ml. 0.1 *N* $AgNO_3$, and 1.50 ml. 0.1 *N* $Na_2S_2O_3$, respectively.

Preparation of Bromozein.—Zein was allowed to react with bromine as described in the preparation of bromozein hydrobromide. The reaction mixture was poured into 20 liters of 0.25% aqueous sodium chloride with vigorous stirring. The bromozein coagulated readily and the supernatant liquid was removed with a siphon. The product was resuspended in 20 liters of distilled water and allowed to settle. This washing process was repeated twice. The bromozein was collected on a filter and dried forty-eight hours at 50° and two hours at 105°; yield, 47.63 g. It was soluble in acetic acid and 70% ethanol but did not react with sodium hydroxide, silver nitrate, or potassium iodide. An accelerated gelation test of bromozein in 70% ethanol showed only a slight tendency toward gel formation.

Anal. N, 14.10; amide N, 4.06; Br, 5.34; C, 49.10.

The first supernatant liquid from the precipitation of bromozein was concentrated to 200 ml. and filtered. The addition of sodium hydroxide to this concentrate produced ammonia before and after digestion with sulfuric acid.

Conversion of Bromozein Hydrobromide into Bromozein.—An amount of 5 g. of bromozein hydrobromide was dissolved in 500 ml. of 0.05 *N* sodium hydroxide. The addition of 100 ml. of 2.5 *N* acetic acid to this solution resulted in the precipitation of a nearly white solid which was collected on a filter, dissolved in 10 ml. of glacial acetic acid, reprecipitated in dry ether, collected on a filter, washed free of acetic acid and dried forty-eight hours at 50° and two hours at 105°; yield, 4.3 g. It was soluble in acetic acid and 70% ethanol, but did not react with sodium hydroxide, silver nitrate, or potassium iodide.

Anal. N, 14.04; Br, 5.30; C, 49.02.

Control Experiment with Zein.—Five grams of zein was dissolved in 45 ml. of 90% acetic acid, allowed to stand twenty-four hours at 25° in diffuse daylight, and then poured into 2 liters of 0.25% aqueous sodium chloride with vigorous stirring. The zein was washed and dried as described in the preparation of bromozein: yield, 4.51 g.

Anal. N, 16.04.

The first supernatant liquid from the precipitation of zein was concentrated to 100 ml. and filtered. The addition of sodium hydroxide to this concentrate did not produce ammonia before or after digestion with sulfuric acid.

Acknowledgment.—This work was supported by the American Maize-Products Co., and the A. E. Staley Manufacturing Co. Acknowledgment is made of the counsel of Mr. W. L. Morgan.

Summary

1. A bromozein and its hydrobromide have been prepared.

2. Bromozein hydrobromide is acidic, reacts with silver nitrate and liberates iodine from potassium iodide. Sodium hydroxide converts it to bromozein.

3. Bromozein is neutral and does not react with silver nitrate or potassium iodide.

4. Bromozein and its hydrobromide have only a slight tendency toward gel formation.

The Preparation of Stable Ketimines from 2,2,6-Trimethylcyclohexanecarbonitrile

BY H. L. LOCHTE, JOE HORECZY,[1] P. L. PICKARD[2] AND A. D. BARTON[3]

In 1942 Horeczy isolated the very highly hindered 2,2,6-trimethylcyclohexanecarboxylic acid from California petroleum.[4] Shortly thereafter an attempt was made to synthesize the corresponding ketone by reaction of phenylmagnesium bromide with the nitrile of this acid. The usual Grignard synthesis yielded a very stable ketimine instead of the ketone.[5]

Since this ketimine is not hydrolyzed even on prolonged heating with acids or bases either in aqueous or alcoholic solution, and since it possesses other interesting properties, the corresponding methyl ketimine was prepared.[6] This ketimine is equally stable to hydrolysis, thus indicating that the abnormal stability is due mainly to the 2,2,6-

(4) Shive, Horeczy, Wash and Lochte, THIS JOURNAL, **64**, 385 (1942).

(5) The observation that reaction of the nitrile with phenylmagnesium bromide produced a basic compound instead of a ketone was first made by William Shive in this Laboratory.

(6) P. L. Pickard, Ph.D. Dissertation, University of Texas, 1947.

trimethylcyclohexane group, rather than to the combination of the phenyl group and this group.[7]

It was thought that the corresponding aldimine (2,2,6-trimethylcyclohexanecarboxaldimine) might also be stable. Attempts to prepare this aldimine by partial hydrogenation of the nitrile have led only to complete reduction of the nitrile, the corresponding primary amine being the only product isolated.

It seemed possible that the unusual stability of these ketimines might be due to the fact that they possess an ene-amine structure. Accordingly, attempts were made to determine whether these compounds are primary or secondary amines. When treated with nitrous acid, no nitrogen is liberated, and each ketimine yields a neutral liquid compound which contains two atoms of nitrogen per molecule. Although attempts to purify these compounds were unsuccessful, they appear to be nitroso derivatives. Treatment of either ketimine with chloroform, ethanol and sodium hydroxide solution does not produce an isonitrile odor; each ketimine gives a monobenzenesulfonamide derivative which is insoluble in 10% (or more dilute) sodium hydroxide solution. However, since these ketimines are unusually unreactive, and since the hydrochloride of the phenyl ketimine is extremely insoluble in water, the results of the amine tests given above did not appear to be entirely conclusive. Therefore, attempts were made to prepare the corresponding primary amines by reduction of the ketimines.

On hydrogenation in the presence of Adams platinum catalyst, the phenyl ketimine takes up three moles of hydrogen but the reduction product gives the same amine reactions as the starting material. Apparently, only the benzene ring is hydrogenated. The methyl ketimine does not take up hydrogen in the presence of Adams catalyst. In alcoholic solution, neither compound is reduced by 3% sodium amalgam. When treated with sodium in liquid ammonia containing 5% methanol, each ketimine yields a reduction product which reacts as follows: when treated with nitrous acid each reduction product liberates the calculated volume of nitrogen; when treated with chloroform, ethanol and sodium hydroxide solution each gives a characteristic isonitrile odor; but each gives a monobenzenesulfonamide derivative insoluble in sodium hydroxide solution.

On hydrogenation with Adams catalyst or on reduction with sodium in liquid ammonia containing methanol, the nitrile (2,2,6-trimethylcyclohexanecarbonitrile) gives the same reduction product; this reduction product gives the same primary amine reactions as the reduction products of the ketimines.

Since these two ketimines react like secondary amines in the isonitrile and nitrous acid tests before they are reduced and since they yield reduction products which react like primary amines, it is probable that these compound do possess the ketimine structure which is abnormally stable due to steric hindrance.

(7) Quite recently, the preparation of a stable ketimine was reported by Schultz, Robb and Sprague, THIS JOURNAL, **69**, 2454 (1947).

Experimental

2,2,6-Trimethylcyclohexanecarbonitrile.—This nitrile was prepared from the corresponding acid *via* the acid chloride and the amide as described previously.[4]

Phenyl 2,2,6-Trimethylcyclohexyl Ketimine.—Phenylmagnesium bromide was prepared by the addition of 20.4 g. of bromobenzene to 3.15 g. of magnesium in anhydrous ether; 18.6 g. of 2,2,6-trimethylcyclohexanecarbonitrile dissolved in anhydrous ether was added and the mixture was refluxed for twelve hours. When the reaction mixture was poured into cold, dilute sulfuric acid, 22 g. of a solid sulfate salt of a base separated; 9 g. of unreacted nitrile was recovered from the ether layer. When the sulfate salt was treated with dilute sodium hydroxide solution a liquid was obtained which on fractionation yielded 13.2 g. (90% based on nitrile not recovered) of a compound characterized by the following data: b. p. 310° (750 mm.); d^{20}_4 0.9842; $n^{20}D$ 1.5406; MR_D calcd. 72.87; found 73.18.

Anal. Calcd. for $C_{16}H_{23}N$ as a secondary amine: C, 83.83; H, 10.12; N, 6.05; primary amino N, none; mol. wt., 229. Found: C, 83.47; H, 10.21; N, 6.11; primary amino N (Van Slyke), none; mol. wt. (in acetone), 236.

The ketimine dissolved readily in concentrated hydrochloric acid; when the resulting solution was neutralized most of the ketimine separated in the form of a hydrochloride salt which was extremely insoluble in water. The ketimine was liberated very slowly from this salt even in the presence of a strongly alkaline solution.

One drop of the ketimine, 3 drops of chloroform and 5 drops of ethanol were mixed and shaken continuously with 5 ml. of 10% sodium hydroxide solution and heated intermittently on a steam cone for five minutes. Even after the mixture had been allowed to stand for some time, no isonitrile odor was detected.

The benzenesulfonamide derivative was prepared by heating the ketimine with a slight excess of benzenesulfonyl chloride in pyridine solution on a steam cone for two hours. The mixture was then poured into a large volume of water and the material which separated was recrystallized from 50% aqueous alcohol, yielding small colorless needles: m. p. 114.5–116°. All of the benzenesulfonamide derivatives described in this paper are insoluble in 10% or more dilute sodium hydroxide solution.

Anal. Calcd. for $C_{22}H_{27}NO_2S$: N, 3.79. Found: N, 3.76.

The nitroso derivative was prepared by adding an aqueous sodium nitrite solution to a solution of the ketimine in ethanol containing hydrochloric acid. The solution was evaporated and the residue was extracted with ether. The ether extract was washed with dilute aqueous acetic acid and then with water. After the solution was dried with Drierite (anhydrous calcium sulfate) the ether was evaporated and the viscous residue was dried *in vacuo* over calcium chloride. Analysis indicated 8.27% nitrogen, whereas the value calculated for the pure nitroso derivative, $C_{16}H_{22}N_2O$, is 10.64. Although attempts to prepare this nitroso derivative (as well as the nitroso derivative of the methyl ketimine) in pure form were unsuccessful, it is evident that the treatment with nitrous acid introduced a second nitrogen atom into the molecule, whereas the nitrogen atom already present should have been eliminated had the compound been an eneamine.

Methyl 2,2,6-Trimethylcyclohexyl Ketimine.—Methylmagnesium iodide was prepared by the addition of 23.1 g. of methyl iodide to 3.96 g. of magnesium in anhydrous ether; 7.38 g. of 2,2,6-trimethylcyclohexanecarbonitrile in 100 ml. of anhydrous toluene was added, the ether was distilled off and the mixture was heated on a steam cone

for twenty hours. The resulting solution was poured on a mixture of chipped ice and ammonium chloride and was then extracted with ether. The ether layer was extracted with hydrochloric acid and the acid layer was then made strongly basic with sodium hydroxide and extracted with ether. The ether extract was dried and evaporated, leaving a liquid residue which, when distilled, yielded 7.5 g. (94%) of a compound with the following characteristics: b. p. 79–80° (4 mm.); d^{20}_4 0.8957; $n^{20}D$ 1.4730; MR_D calcd. 53.15, found 52.72.

Anal. Calcd. for $C_{11}H_{21}N$ as a secondary amine: N, 8:37; primary amine N, none. Found: N, 8.60; primary amino N, none.

When tested, this ketimine produced no isonitrile odor.

The benzenesulfonamide derivative was prepared by shaking a few drops of the ketimine with a slight excess of benzenesulfonyl chloride in 10% aqueous sodium hydroxide solution. Since the product did not crystallize, it was extracted with ether and the ether extract was washed with dilute acid, then with dilute alkali and finally with water; after the solution was dried, the ether was evaporated and the liquid residue was dried *in vacuo*.

Anal. Calcd. for $C_{17}H_{25}NO_2S$: N, 4.55. Found: N, 4.27.

The picrate of the ketimine was prepared in ethanol solution and recrystallized from aqueous ethanol: m. p. 143–144°.

Anal. Calcd. for $C_{17}H_{24}N_4O_7$: N, 14.06. Found: N, 14.21.

The nitroso derivative was prepared by adding a solution of the ketimine hydrochloride to a solution of sodium nitrite. The red liquid which separated was extracted with ether and the ether solution was washed with dilute acid, then with dilute alkali and finally with water. After the solution was dried and treated with charcoal, the ether was evaporated and the yellow viscous residue was dried *in vacuo*. Analysis indicated 12.12% nitrogen; the value calculated for the pure nitroso derivative, $C_{11}H_{20}N_2O$, is 14.26.

Attempted Hydrolysis of the Ketimines.—Each ketimine was refluxed for eight to ten hours with aqueous hydrochloric acid solution (37%) and with aqueous (33%) and alcoholic (10%) potassium hydroxide solutions without showing any evidence of hydrolysis.

Each ketimine was refluxed for eight hours with 50% aqueous potassium hydroxide solution containing 10% ethanol; each mixture was then steam distilled and the distillate was tested for ammonia with Nessler reagent. In each case the distillate contained some unchanged ketimine but no trace of ammonia was detected.

A small sample of each ketimine was dissolved in concentrated sulfuric acid and heated on a steam cone for one hour. Each solution was then cooled and poured into a large volume of water. The resulting solutions were made strongly alkaline with 50% potassium hydroxide solution and then steam distilled. Each distillate contained some unreacted ketimine but showed no trace of ammonia present when tested with Nessler reagent. The nitrile (2,2,6-trimethylcyclohexanecarbonitrile) was converted quantitatively to the corresponding amide (2,2,6-trimethylcyclohexanecarboxamide) when heated with concentrated sulfuric acid on a steam cone for one hour, and poured into a large volume of water.

Reduction of Phenyl 2,2,6-Trimethylcyclohexyl Ketimine. (a) **Hydrogenation with Adams Catalyst.**—When 317.4 mg. (1.38 millimoles) of phenyl 2,2,6-trimethylcyclohexyl ketimine dissolved in 50 ml. of methanol containing 1 ml. of glacial acetic acid was shaken with 14 mg. of Adams platinum catalyst in an atmosphere of hydrogen at room temperature and pressure, 94.0 cc. (4.20 millimoles) of hydrogen were absorbed. The catalyst was filtered off and the filtrate was evaporated to one fifth of its original volume; 20 ml. of water was added, the mixture was made strongly alkaline with sodium hydroxide and then extracted with ether. One portion of the ether solution was evaporated and the liquid residue was used for the isonitrile test and to prepare the benzenesulfonamide derivative of the reduction product. The other portion of the ether solution was shaken with the calculated quantity of concentrated hydrochloric acid solution. The cyclohexyl 2,2,6-trimethylcyclohexyl ketimine hydrochloride, which separated as a white solid, was washed with ether and with water and was dried *in vacuo*. Analysis indicated no primary amino nitrogen present.

When tested, this catalytic reduction product produced no isonitrile odor.

The benzenesulfonamide derivative of the catalytic reduction product was prepared in pyridine solution. This derivative proved to be a liquid, and it was purified in the same manner as the benzenesulfonamide derivative of methyl 2,2,6-trimethylcyclohexyl ketimine.

Anal. Calcd. for $C_{22}H_{33}NO_2S$: N, 3.73. Found: N, 3.82.

The picrate of the catalytic reduction product was prepared in ethanol solution and recrystallized from aqueous ethanol: m. p. 168–170°.

Anal. Calcd. for $C_{22}H_{32}N_4O_7$: N, 12.06. Found: N, 12.15.

(b) **Reduction with Sodium Amalgam.**—A sample of phenyl 2,2,6-trimethylcyclohexyl ketimine in 95% ethanol was stirred for twelve hours with 3% sodium amalgam. The ketimine was recovered unchanged and there was no evidence to indicate that any of the ketimine had been reduced.

(c) **Reduction with Sodium and Methanol in Liquid Ammonia.**—Reduction by means of sodium in liquid ammonia containing methanol was carried out under the conditions described by Watt, Knowles and Morgan.[8] To 100 ml. of liquid ammonia containing 5 ml. of anhydrous methanol was added 1.0 ml. of phenyl 2,2,6-trimethylcyclohexyl ketimine. Over a period of an hour, approximately 1.5 g. of sodium was added in small pieces and the mixture was stirred continuously. The gummy ketimine slowly disappeared and a copious white precipitate accumulated. The ammonia was allowed to evaporate, water was added and the mixture was extracted with ether. The reduction product and its hydrochloride were obtained in the same manner as the catalytic reduction product of phenyl 2,2,6-trimethylcyclohexyl ketimine.

Anal. Calcd. for α-phenyl-2,2,6-trimethylcyclohexanemethylamine hydrochloride, $C_{16}H_{26}NCl$: primary amino N, 5.23. Found: primary amino N, 5.40, 5.14.

When tested, this reduction product gave a characteristic isonitrile odor.

The benzenesulfonamide derivative was prepared in pyridine solution. The crude product was recrystallized three times from 95% ethanol, yielding small colorless needles: m. p. 193–195°. This sulfonamide, like the others, was insoluble in dilute sodium hydroxide solution.

Anal. Calcd. for $C_{22}H_{29}NO_2S$: N, 3.77. Found: N, 3.94.

On hydrogenation in the presence of Adams catalyst, 60.0 mg. (0.224 millimole) of the reduction product (hydrochloride) absorbed 15.7 cc. (0.70 millimole) of hydrogen, apparently indicating that the benzene ring was not attacked when the phenyl ketimine was treated with sodium in liquid ammonia containing methanol.

Reduction of Methyl 2,2,6-Trimethylcyclohexyl Ketimine. (a) **Hydrogenation with Adams Catalyst.**—When a small quantity of methyl 2,2,6-trimethylcyclohexyl ketimine dissolved in methanol containing acetic acid was shaken with Adams catalyst in an atmosphere of hydrogen at room temperature and pressure, no hydrogen was absorbed.

(b) **Reduction with Sodium Amalgam.**—A small quantity of methyl 2,2,6-trimethylcyclohexyl ketimine was treated with 3% sodium amalgam in the manner described above. The ketimine was recovered unchanged and there was no evidence to indicate that any of the ketimine had been reduced.

(8) Watt, Knowles and Morgan, THIS JOURNAL, **69**, 1657 (1947).

(c) Reduction with Sodium and Methanol in Liquid Ammonia.—Methyl 2,2,6-trimethylcyclohexyl ketimine in liquid ammonia containing methanol was treated with sodium and the reduction product was isolated according to the procedure described above. The ether solution containing the reduction product was washed repeatedly with water, dried with Drierite and evaporated. The liquid residue was dried *in vacuo* over calcium chloride.

Anal. Calcd. for α-methyl-2,2,6-trimethylcyclohexanemethylamine, $C_{11}H_{23}N$: primary amino N, 8.27. Found: primary amino N, 8.31, 7.99.

When tested, this reduction product gave a characteristic isonitrile odor.

The benzenesulfonamide derivative of the reduction product was prepared in 10% sodium hydroxide solution. The solid material which separated was recrystallized twice from 50% aqueous ethanol to yield colorless needles: m. p. 121–122°.

Anal. Calcd. for $C_{17}H_{27}NO_2S$: N, 4.53. Found: N, 4.68.

Reduction of 2,2,6-Trimethylcyclohexanecarbonitrile. (a) Hydrogenation with Adams Catalyst.—2,2,6-Trimethylcyclohexanecarbonitrile was hydrogenated with Adams catalyst and the reduction product and its hydrochloride salt were isolated according to the procedure described above; 156.5 mg. (1.03 millimoles) of the nitrile absorbed 47.4 cc. (2.12 millimoles) of hydrogen.

Anal. Calcd. for 2,2,6-trimethylcyclohexanemethylamine hydrochloride, $C_{10}H_{22}NCl$: primary amino N, 7.31. Found: primary amino N, 7.42, 7.32.

When tested, this reduction product produced an isonitrile odor.

The benzenesulfonamide derivative of the reduction product was prepared in sodium hydroxide solution. The product was recrystallized twice from 50% ethanol, to give colorless needles: m. p. 111–112°.

Anal. Calcd. for $C_{16}H_{25}NO_2S$: N, 4.77. Found: N, 4.74.

Attempts were made to achieve partial hydrogenation of the nitrile by carrying out the hydrogenation in a small volume of methanol containing an excess of concentrated hydrochloric acid. In all cases, the only compounds isolated were the unreacted nitrile and the fully hydrogenated primary amine described above.

(b) Reduction with Sodium and Methanol in Liquid Ammonia.—2,2,6 - Trimethylcyclohexanecarbonitrile in liquid ammonia containing methanol was treated with sodium in the manner described above. The benzenesulfonamide derivative of the reduction product was prepared in 10% sodium hydroxide solution: m. p. and mixed m. p. with the benzenesulfonamide derivative of the catalytic reduction product of 2,2,6-trimethylcyclohexanecarbonitrile, 111–112°, indicating that the two methods give the same reduction product, 2,2,6-trimethylcyclohexanemethylamine.

Summary

1. Phenyl 2,2,6-trimethylcyclohexyl ketimine and methyl 2,2,6-trimethylcyclohexyl ketimine have been prepared by treating 2,2,6-trimethylcyclohexanecarbonitrile with phenylmagnesium bromide and methylmagnesium iodide, respectively. These ketimines are not hydrolyzed even on prolonged heating in the presence of concentrated acid or alkali.

2. It appears that these compound possess the ketimine structure because, before reduction, they react like secondary amines to the isonitrile and nitrous acid tests and they yield reduction products which react like primary amines.

3. It is concluded that the abnormal stability of these compounds is due to steric hindrance.

Secondary and Tertiary Amino Ketones and Alcohols Derived from Desoxybenzoin and 1,2-Diphenylethanol.[1] Ring-Chain Tautomerism of the α-(β-Hydroxyethylamino) Ketones[2]

BY ROBERT E. LUTZ, JAMES A. FREEK[3a] AND ROBERT S. MURPHEY[3b]

This investigation was initiated in the fall of 1942 in connection with the search for new types of antimalarials.[2a] The compounds obtained,[4] however, showed no significant activity against avian malaria. At the instigation of Dr. J. L. Hartwell they were then tested at the National Cancer Institute for activity against mammalian tumors, because of their relationship to the nuclear - substituted 1,2 - diphenylethylamines,[5] $ArCH_2CH(NH_2)Ar$, which had already been under investigation as tumor-necrotizing agents. Two of the new compounds when tested in mice gave evidence,[6] at high dosage, of damage to sarcoma 37; these two compounds were α-[N-ethyl-N-(β-hydroxyethyl)-amino]-desoxybenzoin [supposed at the time to have the open-chain structure (I)],

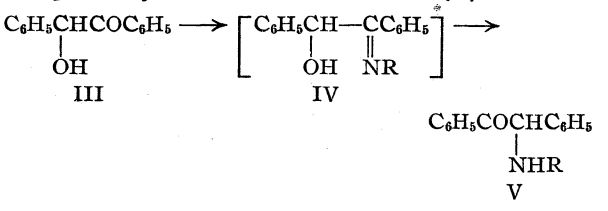
and the related 1,2-diphenyl-2-N-piperidylethanol (II).

Because of these findings the synthetic work in this series was extended. The results are summarized in Tables I and II where the various mono- and disubstituted-amino ketones and alcohols are listed.[7] The discussion of new chemistry incidental to the preparation of these compounds follows. The pharmacological results will be reported elsewhere.[6]

The Reaction between Benzoin and Primary Aliphatic Amines.—This condensation was used to prepare a series of seven monoalkylamino and the *p*-diethylaminoanilino ketones (V).

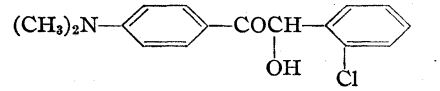


III IV V

It was adapted from the Voigt reaction[8] which up to this time had been applied only to aromatic amines. One attempt had been made to use an aliphatic amine in this reaction,[8b] but it was unsuccessful, perhaps because no catalyst was employed. In the present work phosphorus pentoxide or hydrochloric acid was used as the condensing agent and the reaction appeared to be general and proceeded with good yields.

Two aliphatic N-monoalkylamino desoxybenzoins have already been made in small yields by the palladium-catalyzed hydrogenation of benzil in the presence of cyclohexylamine and 3-aminopentane.[9] The first of these (V, R = cyclohexyl) has now been made in a second way by the Voigt reaction.

Some observations in the present work are pertinent to the mechanism proposed for the Voigt reaction, which involves first the formation of the Schiff base of benzoin (IV) followed by rearrangement to the monoarylamino ketone.[8c,d,e] The highly branched-chain amines, tris-(hydroxymethyl)-methylamine and 2-amino-1,3-dihydroxymethyl-2-methylpropane, do not undergo the reaction under the conditions applicable to ordinary primary amines, presumably because of steric interference with addition at the carbonyl groups.



VI

Furthermore 2′-chloro-4-dimethylaminobenzoin does not undergo this reaction with *n*-butyl and *n*-octylamines under the usual conditions, presumably also because of lowered activity of the carbonyl group, lowered in this case chemically by the *p*-dimethylamino group.

The monoalkylamino ketones are unstable in the form of the free bases and only the hydrochlorides have been isolated. In many cases it was observed that the bases underwent facile

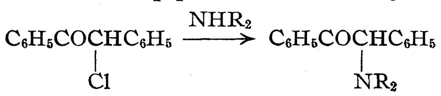
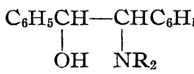
hydrolysis and oxidation during preparation of the hydrochlorides with the resulting formation of the primary amine and benzil. This secondary reaction often caused considerable loss in yield during purifications. The interesting question as to whether this formation of benzil was due to initial oxidation of the amino ketone to the mono-Schiff base of benzil followed by hydrolysis, or to hydrolysis to benzoin followed by oxidation (or to both of these as competing reactions) has not been answered. It is noteworthy, however, that in one case the γ-diethylaminopropylamino ketone [V, R = $NHCH_2CH_2CH_2N(C_2H_5)_2$, obtained as an oil and not characterized, but successfully reduced nevertheless to the diamino alcohol] was hydrolyzed readily by moist ethereal hydrogen chloride to benzoin.

Condensation of Desyl Chloride with Secondary Amines.—Three new dialkylamino desoxybenzoins (VIII) have been made by this method, and also α-piperidyldesoxybenzoin (VIII, NR_2 = piperidyl) which had previously been made by the action of N-chloropiperidine on desoxybenzoin.[10]



VII VIII

The Preparation of β-Mono and Dialkylamino Alcohols by Reductions.—Reductions of the mono- and dialkylaminodesoxybenzoins were accomplished by means of aluminum isopropoxide. In all but one case moderate yields of only one of the two possible diastereoisomeric amino alcohols were obtained. Doubtless the



IX

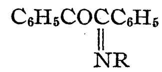
other diastereoisomers were also formed in many of these reductions but escaped detection because they were the minor and the more soluble forms.

The probabilities are that the amino alcohols obtained as the chief products from these reductions, are of the same type-configuration (arbitrarily designated as type-A) because in each of five cases, namely, the butyl, cyclohexyl, dodecyl, benzyl and phenylethylamino, these same compounds were isolated as the sole products, respectively, when *trans* stilbene oxide was condensed with the appropriate amines, and because in two cases studied, namely, the butyl and cyclohexylamino, the stereoisomeric lower-melting amino alcohols were obtained as the sole products, respectively, of the condensations with *cis* stilbene oxide.

Although the platinum-catalyzed reduction of α-piperidyldesoxybenzoin hydrochloride gave chiefly the one stereoisomer-A and appears to be consistent stereochemically with the other reductions described above, the reduction of either the base or the hydrochloride by means of aluminum isopropoxide gave difficultly separable mixtures of the two diastereoisomers. This constitutes the only case in the 1,2-diphenyl series where the B-type stereoisomer has actually been isolated as a reduction product, and the result is to be compared with the reduction of the amino ketone $C_6H_5COCH(CH_3)NHCH_3$ to ephedrine where, however, only a relatively smaller amount of the stereoisomer is formed.[11]

The second and lower-melting stereoisomeric piperidyl alcohol was subsequently obtained as the sole product of condensation of *cis*-stilbene oxide with piperidine.

The methylamino and cyclohexylamino alcohols, which are described in the literature, were made in a second way by platinum-catalyzed hydrogenation of a mixture of benzil and the primary amine.[12] It has been suggested that this reaction proceeds through the monoalkimine (X). It is



X

conceivable however that reduction of benzil to benzoin occurs first, and that this is followed by the formation of the benzoin-alkimine (IV) and/or the alkylamino ketone (the Voigt reaction) and reduction to the alkylamino alcohol. This alternative mechanism is suggested by the fact that the acyloin, $C_6H_5CHOHCOCH_3$, undergoes reductive amination to ephedrine,[13] and it has been tested as follows. The platinum-catalyzed hydrogenation of a mixture of benzil and cyclohexylamine (analogously to Skita's experiment[12a]) gave a cyclohexylamino alcohol corresponding in properties and evidently identical with that obtained by Skita. The product was shown to be of the type-A configuration by synthesis also from *trans*-stilbene oxide. Repetition of this hydrogenation experiment using benzoin in place of benzil, however, produced only *meso* hydrobenzoin in nearly quantitative yield. Therefore benzoin and the Voigt reaction could not have been involved here.

The Preparation of β-Mono and Dialkylamino Alcohols by Condensation of the Stilbene Oxides with Primary and Secondary Amines.—Of the compounds listed in Table II, ten sec-

ondary-amino and eleven tertiary-amino alcohols (*cf.* IX) have been made by condensation of *trans* stilbene oxide (XI) with appropriate amines. Because five of these compounds were identical with the products of reduction of the substituted-amino ketones, all of these compounds which clearly belong to the same stereochemical system are classified as type-A. The five stereoisomeric secondary- and tertiary-amino alcohols made similarly from *cis*-stilbene oxide (XII) have been designated configurationally as type-B.

It is noteworthy that *trans*-stilbene oxide was successfully condensed with three typical 2-substituted piperidines (the 2-methyl, 2-hexyl and 2,4-dimethyl), but that 2,4,6-trimethylpiperidine did not undergo this condensation, presumably because of excessive steric hindrance at the nitrogen.

Incidentally it should be mentioned at this point that the various condensations of β-ethanolamine with the stilbene oxides have been shown actually to involve the NH-group rather than the hydroxyl, as would be expected. The evidence is the fact that in one case the resulting β-(β-ethanolamino) alcohol (IX, NR_2 = $NHCH_2CH_2OH$) is obtainable in a second way by reduction of the α-(β-ethanolamino) ketone (V, NHR = $NHCH_2CH_2OH$) the structure of which is certain from the mode of synthesis from benzoin by the Voigt condensation with ethanolamine.

All of the secondary amino alcohols listed in Table II are new except the two with indicated references. One of these, the benzylamino compound, was first made by a complex reaction from benzaldehyde through the action of sodium nitrite, formic or acetic acid and zinc.[14] The properties reported for this compound, both the free base and the hydrochloride, agree with those of the samples we have prepared from *trans*-stilbene oxide. The configuration therefore appears to correspond to type-A.

For the purpose of comparative tests the two aminohydrins (known[15]) (IX, NR_2 = NH_2) were made in a new way by the ammonolysis of the *trans* and *cis* stilbene oxides. The higher-melting isomer (m. p. 165–166°) obtained from the *trans* oxide, is the one obtained by hydrolysis of the *trans* imine,[16] and is the one obtained in the reductions of aminodesoxybenzoin,[17] the benzilmonoximes[17] and benzoin oxime[18]; it evidently corresponds in configuration to the type-A. The lower-melting isomer (m. p. 127–128°) obtained from the *cis* oxide, is the one obtained by hydrolysis of the *cis* imine[16] and corresponds therefore to type-B. Thus the stereochemical picture here corresponds exactly to that described above for the mono and dialkylamino alcohols.

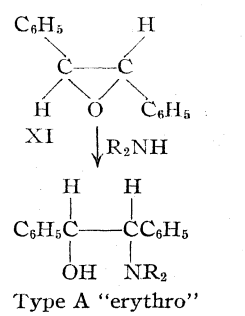
The Assignment of Relative and Specific Configurations to the Amino Alcohols.—The condensations between primary, secondary amines and ammonia, and the *cis* and *trans* stilbene oxides (XI and XII) have proceeded consistently in each case in only one of the two possible stereochemical senses, and in this respect they are comparable with three types of stereochemically consistent reactions (a) the hydrochlorination of the stilbene oxides,[19] (b) the formation of the stilbene oxides from the halohydrins[19] and aminohydrins,[20] and (c) the hydrolysis of the *cis* and *trans* imines.[16] The normal or chief products of reductions in which the two-asymmetric-carbon system is generated correspond in so far as has been tested, to the compounds obtained from the *trans* oxide; and the two synthetic methods therefore serve as independent means of assignment of type-configurations. However, because in one isolated case in this investigation a reduction actually did give simultaneously both of the two possible stereoisomeric products, the synthesis from the stilbene oxides where no such exception has appeared, is clearly the more reliable and is the preferred basis for stereochemical classification. Those compounds obtained in reductions which have not been directly or indirectly related by synthesis to the stilbene oxides are to be regarded as probably of the type-A configuration, and the assignment of configurations in these cases is tentative.

The specific configurations of these products have been assigned tentatively (a) on the assumption that the oxide ring-opening is consistently *trans* as has been demonstrated in the hydrochlorination and hydrolysis[21] of maleic and fumaric acid oxides, and (b) on the basis of analogy to the consistent stereochemical mode of reductions, namely, the catalytic, sodium amalgam or aluminum isopropoxide reductions[22] of benzoin which give chiefly the *meso* hydrobenzoin, and the reduction of benzil dioxime predominantly to *meso*



Type A "erythro"

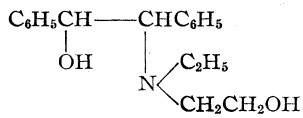
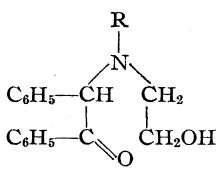
stilbenediamine.[22e] Thus the type-A compounds are presumed to be "erythro" as formulated (XIII) and the type-B compounds are tentatively formulated as "threo" (XIV).

Ring-Chain Tautomerism of the α-(β-Hydroxyethylamino)-desoxybenzoins.—One negative result in the earlier aluminum isopropoxide reductions of the various substituted-amino desoxybenzoins stood out as striking; the reductions had proceeded effectively in all cases except one, namely, α-[N-ethyl-N-(β-ethanol)-amino]-desoxybenzoin (I). This compound either as the base or as the hydrochloride was recovered unchanged after prolonged treatment, yet the corresponding ethylethanolamino alcohol (XV), could easily be made through condensation of *trans*-stilbene oxide with ethylethanolamine.

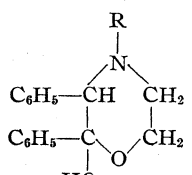


XV ("erythro")

It was of significance that this exceptional compound was the only one of the group of compounds reduced up to that time, which carried a β-hydroxyethyl group on the nitrogen. The unexpected resistance to reduction by the carbonyl-specific reagent, aluminum isopropoxide, suggested that the compound exists in the tautomeric ring form, XVIBa.



XVIA



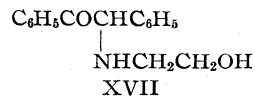
XVIB

(a) R = C_2H_5
(b) R = *n*-butyl
(c) R = CH_2CH_2OH

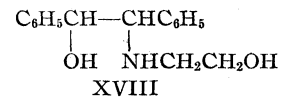
The ability of compounds of this type to function in the tautomeric cyclic sense is already implied in the conversion of one N-benzoyl compound of this type into a dehydromorpholine (dihydro-1,4-oxazine)[23] under the action of alcoholic hydrogen chloride. However, the present results indicate more than this, namely, that the cyclic hemiacetal form of these compounds actually can exist and in some cases is the stable tautomer. This phenomenon, of ring-chain tautomerism, if it has been correctly interpreted, might have been predicated from the probable influence of the α-amine nitrogen atom on the carbonyl group, an influence which should be to some extent analogous to that exerted by the δ-hydroxyl group in the ketone sugars and related compounds where the cyclic structures are the stable ones.

(23) (a) Hill and Powell, THIS JOURNAL, **67**, 1462 (1945); *cf.* also (b) Knorr, *Ber.*, **32**, 729 (1898); (c) Wolff and Marburg, *Ann.*, **363** 169 (1908); (d) Coghill, THIS JOURNAL, **59**, 801 (1937).

In order to explore the β-hydroxyethylamino ketones further in respect to reducibility by aluminum isopropoxide, three other compounds of the type were made. The β-hydroxyethylamino compound itself (XVII) in which the nitrogen is secondary, was reduced, with normal ease, to the dihydroxyamine (XVIII), whereas the tertiary



XVII

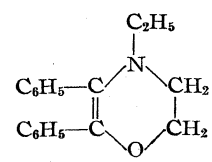


XVIII

N-butyl-N-(β-hydroxyethyl)-amino and di-(β-hydroxyethyl)-amino compounds (XVIBb and c) failed to undergo reduction. It is to be concluded from this that the latter two compounds which carry tertiary nitrogens are cyclic under these conditions like the ethylethanolamino compound (XVIBa), but that the monoethanolamino compound itself, which is secondary with respect to the nitrogen, either is open-chain (XVII) or involves a relatively labile ring-chain tautomerism. It thus seems that cyclization or stability of the cyclic tautomer is favored by N-substituents.

There are, of course, other though unlikely interpretations of these failures of aluminum isopropoxide reductions; for example, some special or peculiar influence of the hydroxyl group located β to the nitrogen and δ to the carbonyl, through chelation, hydrogen-bonding or aluminum-complex formation, perhaps through enolization. However, it should be stressed that many and various of the ordinary N-substituted secondary and tertiary desylamines (of the type V and VIII) have now been made and have been reduced successfully by means of aluminum isopropoxide, and that a close analog which is not represented in Tables I and II, the N,N-diethyl, has been made in the 4,4′-dichlorodesoxybenzoin series and has proved to be readily reducible in this same way.[7] Furthermore the simple monoethanolamino ketone (XVII) is readily reducible by aluminum isopropoxide. In view of these facts, no influence other than ring-chain tautomerism is apparent which might account for the diminished reactivity of these compounds toward aluminum isopropoxide.

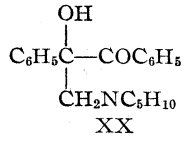
As a consequence of this phenomenon of ring-chain tautomerism it was anticipated that dehydration of the ethanolamino ketones could be accomplished easily (*cf.* ref. 23) by heating these compounds above their melting points. β-(Ethylethanolamino)-desoxybenzoin (XVIBa) at 160° with a trace of acid actually did give the dehydromorpholine (dihydro-1,4-oxazine) (XIX) which was readily hydrolyzed by dilute aqueous acid to regenerate the original compound.



XIX

Further work is in progress in respect to other kinds of evidence dealing with these phenomena,[24] and in exploration of the influence of various structural factors and substituents in this and other series on the tendency to cyclize and on the stability of the cyclic forms.

Products of the Mannich Reaction.—A few Mannich-reaction products were made for comparison with respect to possible tumor-necrotizing activity (see experimental part). One of these of particular interest is the piperidyl hydroxyketone (XX) which was made from benzoin.



XX

There are analogies for this reaction in the Mannich reaction on tartronic acid[25] and in the condensation between formaldehyde and benzoin.[26]

Acknowledgment.—The preparation of the piperidyl alcohol-A (II) was first carried out by Dr. M. T. Clark.

Experimental[27]

The Preparation of the Secondary-Amino Desoxybenzoins (V) (Method 1).—(*cf.* Refs. 8). A mixture of 0.2 mole of benzoin, 0.22 mole of the appropriate amine and 2 g. of phosphorus pentoxide was heated on a water-bath for two to ten hours. The sirupy mixture was cooled, treated with water, stirred until crystallization of the base occurred, and filtered.

The hydrochlorides were prepared in one of the following ways: by dissolving the moist filter-cake in (a) ether or (b) an ether–acetone mixture, and adding ethereal hydrogen chloride; or (c) by triturating the moist filter-cake with dilute hydrochloric acid until the yellow color associated with the free base disappeared, followed by filtering, washing with hot water and then with acetone, and recrystallizing.

(d) In two preparations 2 ml. of concentrated hydrochloric acid was used as the catalyst instead of phosphorus pentoxide. The hydrochloride was precipitated as a resin by means of ethereal hydrogen chloride, digested with water and crystallized. Significant amounts of benzil were recovered from the mother liquors.

(e) In one preparation using diethylaminopropylamine, the reaction mixture (heated for two hours) was dissolved in ether. After washing with 10% sodium hydroxide and then with water, and after drying over sodium sulfate, the amino ketone was obtained as a clear yellow oil which resisted attempts to obtain a crystalline form; it was reduced successfully without purification and was readily hydrolyzed to benzoin by moist ethereal hydrogen chloride.

Preparation of the Tertiary-Amino Ketones (VIII) from Desyl Chloride (VII) (Method 2).—A mixture of desyl chloride and three equivalents of the secondary amine was heated at 60–65°. The resulting brown sirupy product was dissolved in ether and the solution was washed with water and dried over sodium sulfate. The hydrochloride was precipitated by addition of ethereal hydrogen chloride. In the case of the di-(β-ethanol)-amino compound, the crude product was washed with water, digested with a small amount of cold ether and crystallized as the base.
