The Electrochemical Properties of Mineral Membranes. VI. Clay Membranes for the Determination of Calcium[1]

BY C. E. MARSHALL[2a] AND A. D. AYERS[2b]

Introduction

Three previous papers in this series[3] have dealt with the use of clay membranes in the potentiometric determination of potassium, ammonium, and sodium. In the course of this work it was found that most of the clay membranes prepared were sensitive also to divalent cations. An important and useful exception was provided by membranes prepared from hydrogen montmorillonite (electrodialyzed Wyoming bentonite) previously heated to 450–550°, which were sensitive to monovalent cations but not appreciably to divalent. These were used for the determination of potassium and ammonium. As regards calcium, some preliminary work had shown that quantitative results could be obtained at low concentrations using membranes prepared from Putnam clay (hydrogen beidellite), previously heated to 500–600°.[4] The present work is concerned with the variations in the properties of clay membranes which affect their suitability for the determination of calcium. We have studied two clays, Wyoming bentonite and Putnam subsoil clay, two exchange cations, hydrogen and calcium, and a range of temperatures of pretreatment from 300 to 600°.

Theoretical Considerations

In all our previous work considerable use has been made of the Teorell–Meyer and Sievers theory of porous, charged membranes. As the work has progressed it has become evident, firstly, that certain of its postulates are not fulfilled by clay membranes; secondly, that quantitative departures from its predictions are generally found. Necessary modifications of the theory for the essentially non-porous clay membranes will be dealt with in a later paper. However, the great importance of the charge A, which can be regarded as the thermodynamic activity of the ions associated with the membrane material itself, cannot be denied, and must be taken into account in any modification of the existing theory. The charge A, sometimes known as the selectivity constant, is responsible for the setting up of two Donnan potentials, one near each surface, which have the effect, in the case of a negatively charged membrane, of greatly reducing the anion activity in comparison with cation activity. Hence, the membrane acts as though the anions possess a greatly reduced or negligible mobility. In the limiting case the potential across it can then be calculated according to the Nernst equation, taking the cations only into consideration. In the practical development of membranes suitable for the determination of various cations, it is important in each case to establish the concentration limits over which accurate results can be obtained. The upper limit is chiefly determined by the magnitude of A. The lower limit varies in different cases; it is affected by the hydrolysis of the membrane itself as well as by hydrolysis of salts of weak bases and strong acids at high dilutions. In the case of potassium it was shown that using 490° hydrogen bentonite membranes accurate results could be obtained in the range 0.1–0.0001 molar.

With divalent cations two factors operate in reducing the charge A. Since the Donnan equi-

libria are evaluated in terms of molality, a membrane having a molal charge A in the monovalent case will automatically have a molal charge $A/2$ in the divalent case. Hence, the upper limit at which the Nernst equation is obeyed will correspond to a lower concentration of divalent than of monovalent cations. Secondly, the dissociation of divalent cations from charged surfaces is in general much less than that of monovalent (hydrogen excepted). The charge A can be regarded as the product of the cation exchange capacity and the fraction of cations active or dissociated. It will therefore be greatly lowered in cases where the cations are only slightly dissociated from the membrane surfaces. These factors are illustrated in Fig. 1. The left hand curve is drawn in the conventional manner from the Teorell–Meyer and Sievers equation for the case in which the anion and cation in solution have equal mobilities, $A = 1$; and the cation activities on the two sides of the membrane are in the fixed ratio $a_1/a_2 = 3.000$ throughout. The next curve is that experimentally found for 550° hydrogen beidellite membranes (Putnam clay), using sodium chloride solutions. Transferring to the divalent scale and allowing for the reduction in A to one-half its value gives the third curve. Finally, the curve farthest to the right is the experimental curve for calcium chloride solutions using the same membrane material. Whereas A for sodium chloride solutions is approximately 0.5, the value for calcium chloride is only 0.026. The practical consequence of this, as may be seen from the figure, is that calcium activities can only be determined with this membrane from 0.002 molar downwards. In order to select the most favorable materials, curves have been obtained for hydrogen and calcium bentonite (montmorillonite) and Putnam clay (beidellite) over a range of pretreatments from 300 to 620° (see below).

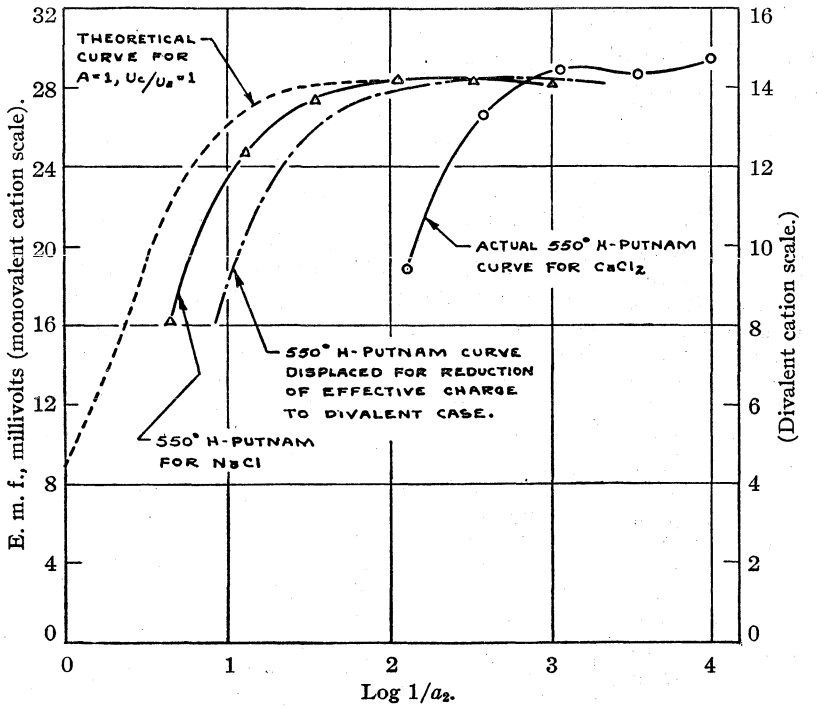

Fig. 1.

The relative behavior of porous membranes as regards different cations can be expressed in terms of mobility ratios. In this formulation the membrane is treated as the limiting case of a liquid junction in which the anions have zero mobility. By application of the Henderson or Planck equations, the potential across the membrane can then be expressed as a function of the activities of the two cations concerned, together with their cationic mobility ratio within the membrane. By measuring the potential when the membrane separates two different salt solutions of known cationic activities, the mobility ratio of the cations can be determined. The equations applicable to different cases have been discussed by Marshall.[5] Once the mobility ratios have been determined it then becomes possible to devise procedures for the analysis of mixtures of cations.

If clay membranes are treated as non-porous then a more rigorous alternative theory (to be discussed in a later paper), relates the potentials observed with different salts to the differential heats of adsorption of the cations concerned. This theory does not as yet facilitate the solution of analytical problems involving mixtures of cations. Hence, in this and the following paper dealing with magnesium, we shall continue to use mobility ratios.

The formulas used for the determination of mobility ratios in the three cases, monovalent–monovalent, divalent–divalent, and monovalent–divalent were derived from the Henderson equation for a liquid junction and are as follows:

Sodium salt on one side of the membrane, potassium salt on the other

$$E = \frac{RT}{F} \ln \frac{a_K^I}{a_{Na}^{II}} \frac{U_K}{U_{Na}} \qquad (1)$$

Calcium salt on one side, magnesium salt on the other

$$E = \frac{RT}{2F} \ln \frac{a_{Ca}^I}{a_{Mg}^{II}} \frac{U_{Ca}}{U_{Mg}} \qquad (2)$$

Potassium salt on one side, calcium salt on the other

(5) C. E. Marshall, *J. Phys. Chem.*, **48**, 67 (1944).

$$E = \frac{RT}{F}\left\{\frac{-a_K^I + \frac{U_{Ca}}{U_K}a_{Ca}^{II}}{-a_K^I + 2\frac{U_{Ca}}{U_K}a_{Ca}^{II}}\right\}\ln\frac{a_K^I}{2\frac{U_{Ca}}{U_K}a_{Ca}^{II}} \quad (3a)$$

As it stands, this equation does not readily lend itself to the determination of U_{Ca}/U_K except by the use of successive approximations. However, if a_K^I is small compared with $U_{Ca}/U_K \times a_{Ca}^{II}$ then we have

$$E = \frac{RT}{F}\frac{1}{2}\ln\frac{a_K^I}{2\frac{U_{Ca}}{U_K}a_{Ca}^{II}} \quad (3b)$$

The way in which mobility ratios so determined can be used may be illustrated by examples which have arisen in investigations of the titration curves of clay acids with bases. Thus in the monovalent–monovalent case we encounter systems comprising a standard potassium salt on one side of the membrane and a clay system containing both hydrogen and potassium ions on the other. Knowing U_H/U_K, a_H^I and a_H^{II} (from a glass electrode measurement) it is possible to calculate the unknown a_K^{II} by applying the equation

$$E = \frac{RT}{F}\ln\frac{a_K^I}{a_K^{II} + \frac{U_H}{U_K}a_H^{II}} \quad (4)$$

Similarly in a calcium–hydroxide titration with a standard calcium solution on one side and a mixture of calcium and hydrogen ions on the other we have

$$E = \frac{RT}{F}\left\{\frac{a_{Ca} - a_{Ca}^{II} - \frac{U_H}{U_{Ca}}a_H^{II}}{2(a_{Ca}^I - a_{Ca}^{II}) - \frac{U_H}{U_{Ca}}a_H^{II}}\right\}\ln\frac{2a_{Ca}^I}{2_{Ca}^{II} + \frac{U_H}{U_{Ca}}a_H^{II}} \quad (5)$$

Substitution of the known quantities E, a_{Ca}^I a_H^{II} and U_H/U_{Ca} does not lead immediately to a solution for a_{Ca}^{II}. This is arrived at by successive approximation, first putting the algebraic quantity before the logarithm equal to one-half and evaluating a_{Ca}^{II}; then using this value to get a better approximation to the quantity before the logarithm; finally using this to calculate an improved value of a_{Ca}^{II}. These three operations are generally sufficient.

Thus the characterization of membrane materials for analytical use involves both the determination of the range of activities over which the Nernst equation is obeyed and a series of mobility ratios. Good methods for the analysis of mixtures can only be developed in cases where the mobility ratio shows reasonable constancy over a sufficiently wide range of concentrations.

Experimental Methods

These were essentially the same as those described in earlier papers dealing with potassium[3a] and sodium.[3c] Since the membranes sensitive to calcium have relatively low resistances (<50,000 ohms) a galvanometer with a sensitivity of 0.025 microamp. per scale division could be used without amplifier in measuring to 0.1 millivolt. The cell measured was Hg, Hg_2Cl_2 Saturated KCl/Solution I/Membrane/Solution II/Saturated KCl Hg_2Cl_2 Hg, the calomel electrodes being of the special type previously described with upturned capillary tip containing saturated potassium chloride in a potassium agar gel. For accurate results fresh calomel electrodes were used whenever the calcium concentration in II was changed. This is important, since if an electrode of this type is transferred from one solution to another, liquid junction potentials which persist for some time can be set up between that part of the first solution which diffused into the capillary tip and the second solution employed. Corrections were applied for the asymmetry potential of the membranes (only those membranes were employed whose asymmetry potentials were less than 1 millivolt) and for the small differences between different calomel electrodes. All results were finally corrected to 25°.

Since the membranes themselves were of relatively low resistance in most cases, the concentrations of the two solutions had a measurable influence upon the total resistance of the cell. A considerable increase in total resistance was noticed in proceeding from $M/1000$ to $M/10{,}000$ solutions of calcium salts.

In membranes prepared from the same sheet of evaporated clay and subsequently treated similarly, individualities still persist, due probably to variation in film structure caused by differences in the rate of evaporation in different parts. They show themselves chiefly in the more concentrated solutions where the theoretical Nernst potential is not attained. Where different salts are employed on the two sides, the mobility ratios are affected and considerable departures from the average value are sometimes encountered. These differences in mobility ratio values are more marked for the monovalent–divalent cases than for monovalent–monovalent or divalent–divalent.

As in previous work, the membranes were first selected for uniformity of thickness and freedom from cracks. They were then mounted and were soaked twenty-four to forty-eight hours—sometimes up to five days—in a calcium chloride solution more concentrated than those employed in measurements. A selection was then made of those with asymmetry potentials below 1 millivolt. The results reported below are averages of from 6–12 membranes so chosen.

In characterizing membranes in their behavior toward calcium ions a series of calcium chloride solutions was required, so adjusted that the calcium ion activities were, for successive pairs, in the fixed ratio 3.000 to 1. The calculations from the activity coefficients of the salt involve two non-thermodynamic assumptions; (1) that in potassium chloride solutions the anion and cation contribute equally to the total activity; (2) that in potassium chloride and calcium chloride solutions of equal ionic strength the chloride ion activities are the same. The primary data used were those of Shedlovsky and MacInnes[6] on potassium chloride and those of McLeod and Gordon[7] on calcium chloride. At any given value of the ionic strength, the following relationship holds.

$$\gamma_{Ca^{++}}^{+} = \frac{(\gamma_{CaCl_2}^{\pm})}{(\gamma_{KCl}^{\pm})^2}$$

where $\gamma_{Ca^{++}}^{+}$ is the activity coefficient of the calcium ion alone, $\gamma_{CaCl_2}^{\pm}$ is the mean activity coefficient of the calcium chloride, and $\gamma_{KCl}^{\pm}$ is that of the potassium chloride. Thus the data are assembled from which a final plot of the activity of the calcium ion against the molality of the calcium chloride could be made. Several such curves were drawn to cover the whole range from 0.1 to 0.0001 molal in suitable steps. Table I presents the data as used for making up standard calcium chloride solutions.

TABLE I

Calcium ion activity, $a_{Ca^{++}}$	Calcium chloride molality, m	G. $CaCl_2$ per 1000 g. H_2O
0.0001	0.000108	0.01198
.0003	.000350	.03884
.0009	.001150	.12763
.0027	.004250	.47167
.0081	.017300	1.91996
.0243	.077000	8.54546

The Effects of Heat Treatments upon Membrane Potentials.—For the four clays used, hydrogen and calcium bentonite (montmorillonite, fraction <200 mμ), and hydrogen and calcium Putnam clay (beidellite, fraction <200 mμ) the relationships are apparent from Figs. 2–5.

(a) **Hydrogen Bentonite (Fig. 2).**—Only membranes pretreated at temperatures below 450° gave reproducible results for calcium. This is in line with the fact previously discovered,[3a] that 490° hydrogen bentonite membranes were sensitive to monovalent cations, but not to divalent. Membranes pretreated at 300, 350 and 400° were closely alike and gave theoretical results for calcium ion activities below 0.0081.

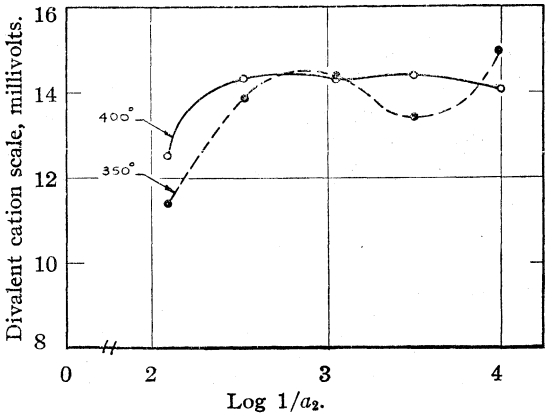

Fig. 2.—Hydrogen bentonite with $CaCl_2$.

(b) **Calcium Bentonite (Fig. 3).**—Between 300° and 600°, increase in the temperature of pretreatment afforded only slight improvement in the electrochemical properties. The 550–600° membranes gave potentials less than 1 millivolt below the theoretical value of 14.1 millivolts even for the 0.0243 and 0.0081 $a_{Ca^{++}}$ solutions. Thus calcium activities below 0.02 extending down to 0.0001 can readily be determined with these membranes.

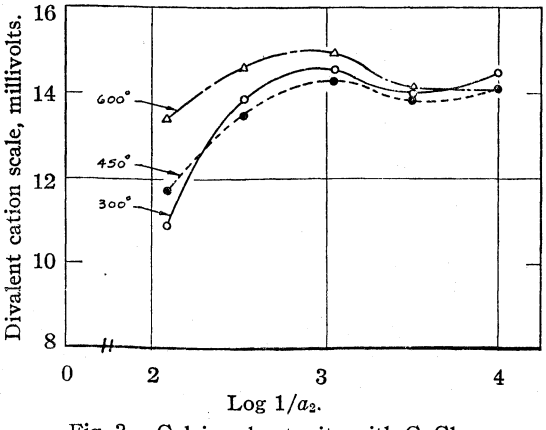

Fig. 3.—Calcium bentonite with $CaCl_2$.

(c) **Hydrogen Putnam Clay (Fig. 4).**—A steady improvement in electrochemical properties with increasing temperature of pretreatments may be seen. None are as good as the corresponding calcium bentonite membranes.

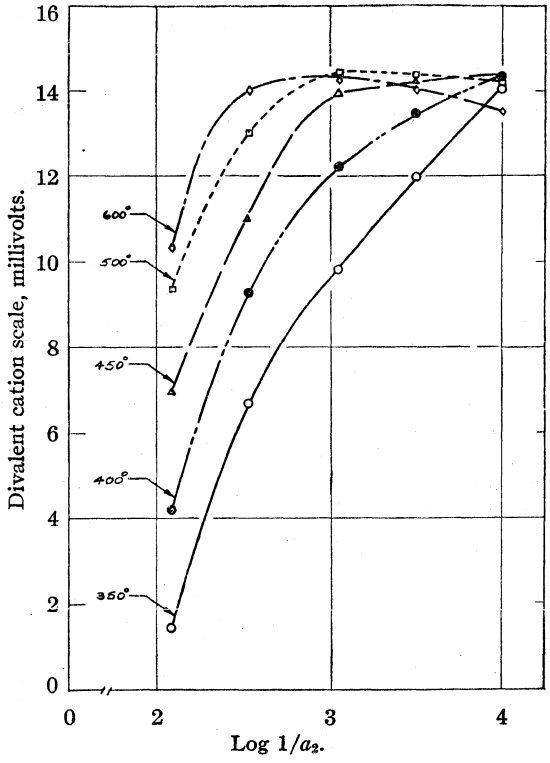

Fig. 4.—Hydrogen Putnam with $CaCl_2$.

(d) **Calcium Putnam Clay (Fig. 5).**—These membranes were consistently a little better than those from hydrogen Putnam clay and in the range 500–600° were very similar to one another, and to the corresponding calcium bentonite membranes. However, at the highest concentration used the latter are somewhat better.

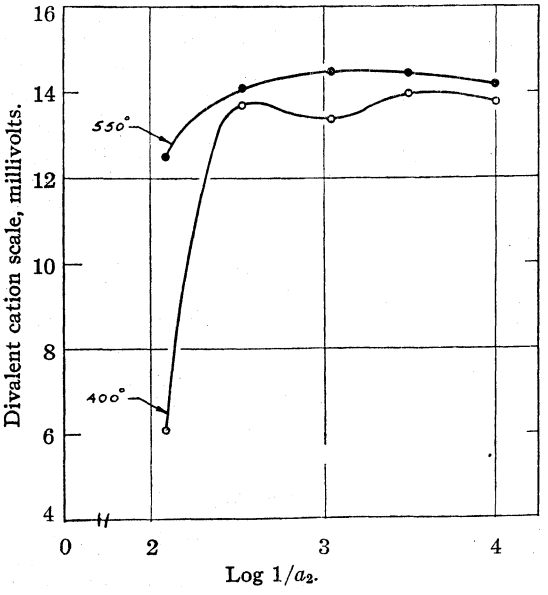

Fig. 5.—Calcium Putnam with $CaCl_2$.

The over-all accuracy of calcium ion determinations in the activity range 0.02–0.0001 using the best membranes is thus around 2–3%. Comparisons of calcium ion activities which are closely alike can be made somewhat more precisely than this, but even here deviations up to 2% are not uncommon.

Cationic Mobility Ratios in Relation to Pretreatment.—More time was needed to establish reproducible potentials with two different cations than where the same cation was present on both sides of the membrane. This was especially true for the monovalent/divalent ratios and in some instances constant values could only be obtained after six to twelve hours contact, with several renewals of the two solutions.

The range of concentrations which can be used in investigating monovalent/divalent mobility ratios is distinctly circumscribed by the fact that if equation 3b is to be used the activity of the monovalent ion must be small compared with the activity of the divalent ion multiplied by the mobility ratio divalent cation/monovalent cation.

As will be evident from the data, monovalent/divalent mobility ratios vary in most cases considerably with concentration. Varying temperatures of pretreatment affect this variation, but not consistently, and change in a somewhat erratic manner the magnitude of the ratio. Table II illustrates the experimental technique for two cases, one of wide variability with concentration and one showing reasonable constancy.

(1) **Calcium–Hydrogen Mobility Ratios.**—In Table III the minimum and maximum values obtained in experiments similar to those of Table II are assembled for clay membranes pretreated at various temperatures. In utilizing these data in the selection of membranes best suited for quantitative work with calcium and hydrogen it must be remembered that if U_{Ca}/U_H is very small, then a_H is multiplied by a large number (U_H/U_{Ca}) and variations in a_H may cause more change in the total potential than variations in a_{Ca}. Other conditions being favorable, the best membranes for this case are those for which U_{Ca}/U_H comes closest to unity.

TABLE II

Membrane material	$a_{Ca^{++}}$	a_{H^+}	Mean mobility ratio, U_{Ca}/U_H
615° Calcium	0.0081	0.000549	0.052
putnam	.0081	.000229	.099
	.0081	.000091	.138
	.0027	.000549	.313
	.0027	.000229	.085
	.0027	.000091	.172
615° Calcium	.0081	.000549	.457
bentonite	.0081	.000229	.545
	.0081	.000091	.466
	.0027	.000549	.674
	.0027	.000229	.615
	.0027	.000091	.496

Hydrogen bentonite membranes pretreated at temperatures between 350 and 420° afford reasonably constant values of U_{Ca}/U_H not far removed from unity. Above 450° these membranes, as previously noted, become insensitive to Ca^{++}.

Calcium bentonite membranes pretreated at 350 and 465° give somewhat lower values, but for 615° membranes the mobility ratio U_{Ca}/U_H varies less with concentration and rises to a value similar to those of the 350 and 415° hydrogen bentonite membranes discussed above.

Hydrogen Putnam membranes show considerable variation with concentration and U_{Ca}/U_H is low, although it rises somewhat with increasing temperature of pretreatment.

Calcium Putnam membranes also show unfavorable properties and the variation with concentration is very marked for those pretreated at 615°.

Thus in work involving mixtures of calcium and hydrogen, such as potentiometric titrations, the most favorable conditions are afforded by the 350–415° hydrogen bentonite and the 615° calcium bentonite membranes. The hydrogen ion activity is first measured using the glass electrode, and by applying equation 5 the calcium ion activity can be computed.

(2) **Calcium-Potassium Mobility Ratios.**—Table III summarizes the minimum and maximum values obtained with calcium chloride and potassium chloride solutions in experiments similar to those with hydrogen chloride. Two calcium activities, 0.0081 and 0.0027, were employed, and three potassium activities, 0.001, 0.00033 and 0.00011. The 360° hydrogen bentonite membranes gave the highest calcium/potassium mobility ratios of any tested, with a moderate degree of variability with concentration.

The 350° calcium bentonite membranes showed considerable variation in mobility ratios, some values being higher than unity and some lower. However, the 615° membranes were much more uniform and closely resembled the 360° hydrogen bentonite membranes in actual values. It is interesting to note that a close similarity exists between 350° hydrogen bentonite and 615° calcium bentonite membranes in their calcium/hydrogen mobility ratios.

The hydrogen Putnam membranes showed extreme variation with concentration at low temperatures of pretreatment, but became much more constant beyond 450° where U_{Ca}/U_K became greater than unity. For the lower temperatures values of U_{Ca}/U_K markedly less than unity were found. Around 450° a considerable change occurs in the electrochemical properties of the hydrogen Putnam membranes. It is much less evident in the calcium/hydrogen series discussed above.

The 465° calcium Putnam membranes showed some variability, but the 615° membranes were relatively constant in their Ca/K mobility ratios.

Thus in selecting membranes for determinations of calcium and potassium in mixtures the 615 calcium Putnam membranes are superior to the others. With some attention to concentration limits, the 360° hydrogen bentonite,

TABLE III

THE RANGE OF MOBILITY RATIOS FOR CALCIUM–HYDROGEN AND CALCIUM–POTASSIUM MEMBRANES PREHEATED TO VARIOUS TEMPERATURES

Membrane material	U_{Ca}/U_H, at temp. 350°	415°	465°	615°
H-bentonite	0.49–0.73	0.35–0.71	.....	
Ca-bentonite	0.13–0.35	.....	0.11–0.28	.46–0.67
H-Putnam	0.021–0.094	.....	0.057–0.13	.46–0.17 (595°)
Ca-Putnam	.....	.....	0.039–0.085	.052–0.31
	U_{Ca}/U_K			
H-bentonite	2.9–5.7 (360°)	.....	.....	.....
Ca-bentonite	0.43–1.81	.....	.....	2.8–5.0
H-Putnam	0.018–0.33	0.026–0.48	0.80–1.86	1.02–1.86 (595°)
Ca-Putnam	.....	.....	0.59–1.70	2.03–2.61

615° calcium bentonite and 595° hydrogen Putnam membranes are probably usable. For the potassium determinations alone, membranes insensitive to calcium, such as the 490° hydrogen bentonite membranes previously described, are required.

(3) **Calcium-Sodium Mobility Ratios.**—Only the 615° calcium bentonite and 615° calcium Putnam membranes were examined. As would be expected, the ratios U_{Ca}/U_{Na} were somewhat greater than the corresponding U_{Ca}/U_{K} values. They showed also more variability with concentration.

(4) **Calcium-Magnesium Mobility Ratios.**—A limited series was determined using high temperature membranes. Much greater constancy was found than with the monovalent–divalent series. These results will be discussed in the succeeding paper, which deals with the determination of magnesium.

Summary

Membranes prepared from hydrogen and calcium bentonite (montmorillonite) and hydrogen and calcium Putnam clay (beidellite), preheated to various temperatures, were examined as to their suitability for the determination of calcium. Hydrogen bentonite membranes heated to 300–415° are suitable; at 450° and higher these are insensitive to divalent cations, but sensitive to monovalent. Calcium bentonite membranes are suitable and are improved only slightly by pretreatment between 300° and 550°. Hydrogen Putnam clay membranes showed great improvement with increasing temperature of pretreatment, but even the 600° membranes were somewhat inferior to the 600° calcium bentonite membranes. The calcium Putnam membranes throughout were better than the hydrogen Putnam, but in the range 500–600° were still slightly inferior to the 500–600° calcium bentonite membranes.

Mobility ratios for calcium–hydrogen, and calcium–potassium were also determined. In many cases this ratio varied greatly with concentration. However, the 350–415° hydrogen bentonite and the 615° calcium bentonite membranes showed reasonable constancy for U_{Ca}/U_{H} and could be employed for the analysis of mixtures containing calcium and hydrogen ions. For calcium–potassium the 615° calcium Putnam membranes were the most favorable.

The Electrochemical Properties of Mineral Membranes. VII. Clay Membranes for the Determination of Magnesium[1]

BY C. E. MARSHALL[2a] AND L. O. EIME[2b]

The theoretical and experimental considerations which have been discussed in the preceding paper of this series[3,4] apply in large measure to the determination of magnesium. The same membrane materials were under investigation and no change was needed in the experimental techniques.

The magnesium chloride solutions employed were arranged in a series according to the calculated magnesium ion activities, adjacent members being in the fixed ratio 3.00. The calculations employed for this purpose were precisely similar to those described for calcium. The basic data were taken from Landolt–Börnstein,[5] and because the activity coefficients of magnesium chloride solutions only extend down to 0.05 molal, a more extensive extrapolation to low concentrations was required than for calcium chloride. Table I gives the activities and concentrations employed. The latter were checked by gravimetric determination of the magnesium as pyrophosphate.

TABLE I

Magnesium ion activity, $a_{Mg^{++}}$	Magnesium chloride molality, m	Grams $MgCl_2$ per 1000 g. water
0.0001	0.000106	0.0101
.0003	.000330	.0314
.0009	.001152	.1098
0027	.00398	.379
.0081	.01490	1.419
.0243	.05600	5.340

The Effects of Heat Treatments upon Membrane Potentials.—Figures 1–4 illustrate the general situation for the four clays hydrogen bentonite, calcium bentonite (montmorillonite), hydrogen Putnam clay, and calcium Putnam clay (beidellite). One marked difference is apparent in all cases between these curves for magnesium and those previously given for calcium. In the case of magnesium the curves fall off more or less sharply after attaining the maximum value. This greatly restricts the range over which accurate determinations of magnesium ion activities can be made.

(a) **Hydrogen Bentonite.**—As in the case of calcium, the three curves for 300, 350 and 400° membranes lie very close together. They attain the theoretical e.m.f. at a slightly lower activity of magnesium than of calcium. Down to 0.0003 $a_{Mg^{++}}$ they give good values, but beyond it the

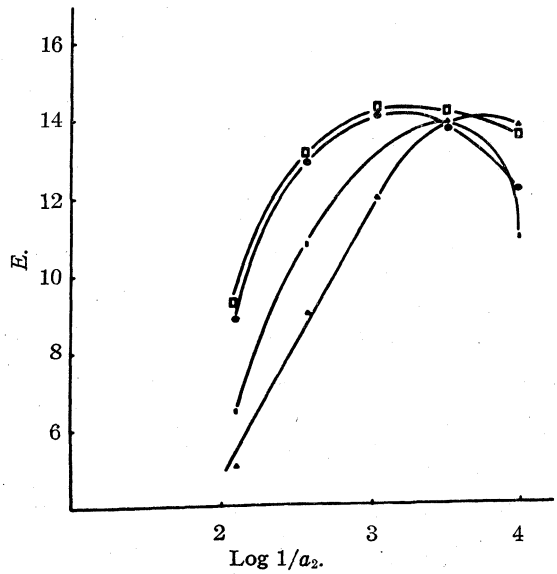

Fig. 1.—Characteristic curves for hydrogen bentonite (montmorillonite) membranes in magnesium chloride solutions: △, 400°; •, 465°; ●, 500°; □, 600°.

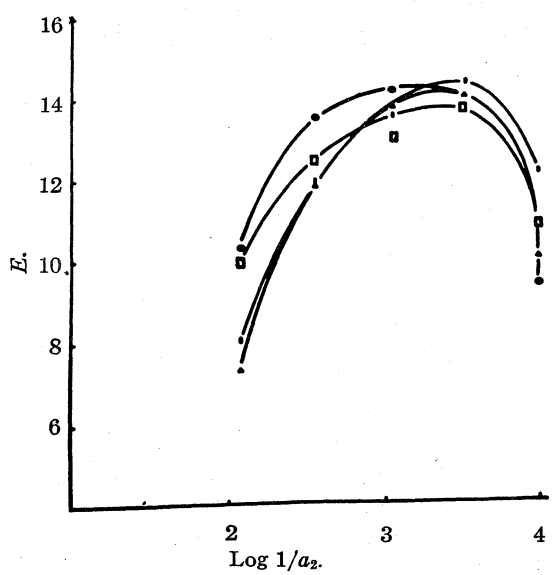

Fig. 2.—Characteristic curves for calcium bentonite (montmorillonite) membranes in magnesium chloride solutions: △, 405°; •, 455°; ●, 500°; □, 550°.

potential shows a rapid falling off. The pair of solutions 0.0003/0.0001 gives only about 10 millivolts instead of 14.1. Thus the range where good accuracy can be secured runs only from about 0.003 to 0.0003.

(b) **Calcium Bentonite.**—These membranes showed considerable improvement with increasing temperature of pretreatment. The 500 and 550° membranes were distinctly superior to the hydrogen bentonite membranes and the usable range of magnesium activities extended from about 0.008 to 0.0003.

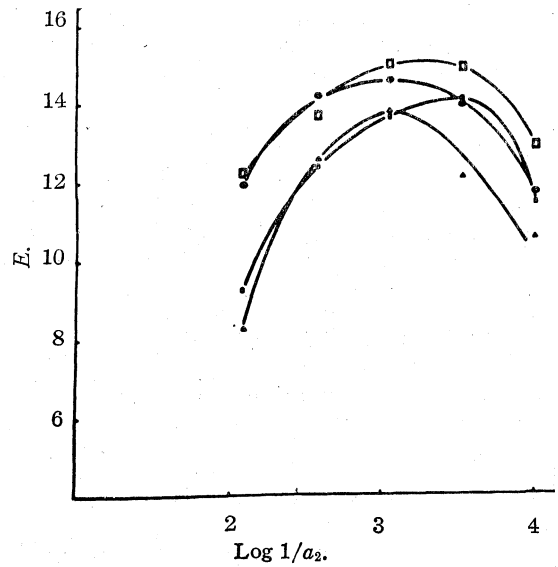

Fig. 3.—Characteristic curves for hydrogen Putnam clay (beidellite) membranes in magnesium chloride solutions: ■, 405°; •, 455°; ●, 500°; □, 550°.

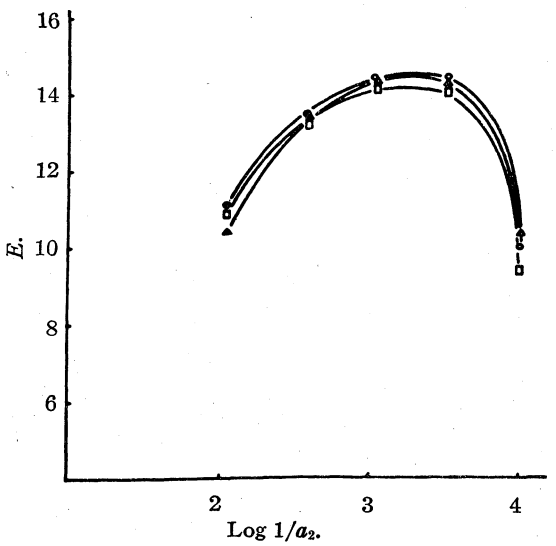

Fig. 4.—Characteristic curves for calcium Putnam clay (beidellite) membranes in magnesium chloride solutions: □, 300°; △, 350°; O, 400°.

(c) **Hydrogen Putnam Clay.**—The properties were considerably improved by higher temperatures of pretreatment. The 600° membranes showed a less marked falling off in potential beyond 0.0003 $a_{Mg^{++}}$ than any of the bentonite membranes. However, the curves were less favorably placed with regard to the higher activities and the usable range runs from about 0.004 to 0.0001.

(d) **Calcium Putnam Clay.**—These membranes were very similar to the corresponding hydrogen Putnam series at the higher activities, but their potentials fell off more below 0.0003.

It can be seen from the curves that the final decline in potential with increasing dilution is general, but that it varies greatly in extent. The basic cause would seem to be hydrolysis, with production of ions such as $(MgOH)^+$. These ions would also affect the membrane potentials, and the preliminary heat treatments would presumably determine to what extent they are potential determining. Unfortunately, the data in the literature on the activity coefficients and equivalent conductivity of magnesium chloride solutions do not extend to sufficiently high dilutions to throw any clear light on their hydrolysis. The same membranes, it should be noted, gave only a very slight indication of a falling off in potential at high dilutions when calcium chloride was used.

One further slight irregularity should be mentioned. There is a tendency for somewhat high potentials to arise at intermediate concentrations, generally with the 0.0027/0.0009 $a_{Mg^{++}}$ pair of solutions. The departure from the theoretical is always less than 1 millivolt, generally around 0.1–0.4 millivolt, but it appears to be real with a given set of membranes. Some of the results with sodium showed similarly high potentials, whereas with potassium and calcium the results were very close to the theoretical.

In consequence, the conditions for the accurate determination of magnesium are distinctly less favorable than for calcium. In the restricted range of magnesium ion activities from 0.008 to 0.0003 using 550° calcium bentonite and 400° hydrogen bentonite membranes, and from 0.004 to 0.0001 using 600° hydrogen Putnam membranes an over-all accuracy of 5% could be relied upon with selected membranes. Comparisons of closely similar magnesium ion activities could be made with greater precision than this.

Cationic Mobility Ratios in Relation to Pretreatment.—The conditions under which divalent–divalent and monovalent–divalent mobility ratios may be determined have been examined in the preceding paper dealing with calcium. The experimental details were essentially the same both for calcium and magnesium.

(1) **Calcium–Magnesium Mobility Ratios.**—When ions of the same valence are employed, the equilibrium potentials are more quickly established and there is less individual variation amongst membranes than for the monovalent–divalent series. Table II gives typical experiments for a series of concentrations; these may be compared with Table II of the preceding paper.

The complete results are summarized in Table III. The variation is much less than for monovalent–divalent ratios. In almost every case where the calcium ion activity is kept constant and the magnesium ion activity decreased, a perceptible fall in the mobility ratio U_{Ca}/U_{Mg} is found. It may be seen that the range of variation is narrow, except for the calcium bentonite and the hydrogen and calcium Putnam membranes heated to around 400°. Excluding these, the range covered is surprisingly similar for the different clays, exchange cations and temperatures of pretreatment. It would not be possible to select from these two sets of membranes with widely different U_{Ca}/U_{Mg} values, which might be used to determine both calcium and magnesium in a mixture by solving two simultaneous equations.

TABLE II[a]

Membrane material	$a_{Ca^{++}}$	$a_{Mg^{++}}$	Mean mobility ratio U_{Ca}/U_{Mg}
615° Calcium Putnam	0.0081	0.0081	1.54
	.0027	.0081	1.59
	.0027	.0027	1.54
	.0009	.0027	1.52
	.0009	.0009	1.33

[a] Determinatons by A. D. Ayers.

(2) **Magnesium–Hydrogen Mobility Ratios.**—Table IV summarizes the range of values obtained with magnesium chloride and hydrochloric acid solutions. The activity of the magnesium ion was held constant at 0.0027 and that of the hydrogen ion ranged downwards from 0.00069. The simplified equation which presupposes that a_H is small compared with a_{Mg} was employed in calculating U_H/U_{Mg} (equation similar to 3b of the preceding paper). Some membranes gave reasonably constant values. In general, the higher temperatures of pretreatment gave the more consistent results. By comparing with Table III of the preceding paper it is apparent that the membranes showing the greatest constancy in U_{Ca}/U_H values are the best also in respect of U_{Mg}/U_H. The actual values of U_{Mg}/U_H are slightly higher than for U_{Ca}/U_H in most cases. The best membranes for use with mixtures of magnesium and hydrogen ions are evidently the

TABLE IV

THE RANGE OF MAGNESIUM–HYDROGEN AND MAGNESIUM–POTASSIUM MOBILITY RATIOS FOR VARIOUS TEMPERATURES OF PRETREATMENT

Membrane material				
H bentonite	Pretreatment at	300°	360°	400°
	U_{Mg}/U_H	0.137–0.201	0.70–0.85	0.81–0.99
Ca bentonite	Pretreatment at	405°		455°
	U_{Mg}/U_H	0.063–0.262		0.250–0.266
H Putnam	Pretreatment at	415°	510°	595°
	U_{Mg}/U_H	0.065–0.139	0.142–0.203	0.126–0.216
Ca Putnam	Pretreatment at	550°		
	U_{Mg}/U_H	0.067–0.24		
H bentonite	Pretreatment at	300°	360°	400°
	U_{Mg}/U_K	0.061–0.602	0.174–0.920	1.60–2.97
Ca bentonite	Pretreatment at	405°	455°	
	U_{Mg}/U_K	0.021–0.236	0.012–0.185	
H Putnam	Pretreatment at	415°	510°	595°
	U_{Mg}/U_K	0.036–0.128	0.239–0.285	0.185–0.201
Ca Putnam	Pretreatment at	500°		
	U_{Mg}/U_K	0.333–0.389		

hydrogen bentonites pretreated at 360 and 400° since these gives ratios of good constancy relatively close to unity. The high temperature calcium bentonite membranes also give good constancy.

(3) **Magnesium–Potassium Mobility Ratios.**—These were also determined under conditions such that a_{K^+} was small compared with $a_{Mg^{++}}$. The latter comprised two values, 0.0081 and 0.0027, and a_K varied from 0.001 to 0.00011. From Table IV it can be seen that U_{Mg}/U_K can be either greater or less than U_{Mg}/U_H for the same membrane, the greater values predominating. On comparing with the ratios U_{Ca}/U_K in Table III of the preceding paper, almost without exception U_{Mg}/U_K is less than U_{Ca}/U_K for the same membrane material. Those showing the greatest constancy in U_{Mg}/U_K are 510° and 595° hydrogen-Putnam, and the 500° calcium-Putnam membranes.

Summary

Using membranes of hydrogen and calcium bentonite (montmorillonite) and hydrogen and calcium Putnam clay (beidellite) preheated over a range of temperatures from 300–600° the conditions most favorable for the determination of the magnesium ion activity have been examined.

Owing probably to the hydrolysis of highly dilute magnesium salt solutions the range was somewhat restricted as compared with calcium. Where magnesium ions alone were concerned, the 400° hydrogen bentonite and 550° calcium bentonite membranes could be used from 0.008 to 0.0003, and the 600° hydrogen Putnam membranes from 0.004 to 0.0001.

Good constancy of the mobility ratio U_{Ca}/U_{Mg} was found with a variety of pretreatments and with the two clays and two exchange cations employed. It was not possible to select membranes with sufficiently widely different values of U_{Ca}/U_{Mg} to make a potentiometric determination of both Mg and Ca in a mixture feasible.

The magnesium–hydrogen and magnesium–potassium mobility ratios were generally variable with concentration. Fortunately, the 400° hydrogen bentonite and 455° calcium bentonite membranes showed reasonable constancy, so that magnesium ions may be determined in the presence of hydrogen ions. The 595° hydrogen Putnam membranes showed the greatest constancy in the magnesium–potassium mobility ratio.

Kinetics, Mechanism, and Activation Energy of the Cobaltous Ion Catalyzed Decomposition of Ozone[1]

BY GEORGE RICHARD HILL

The rate of decomposition of ozone in an aqueous solution containing hydrogen peroxide and perchloric acid has been investigated by Taube and Bray.[2] The catalytic effect of cobaltous ion on the disappearance of ozone and hydrogen peroxide was noted and the rate constants determined. The purpose of the present investigation has been to study in detail the catalysis by cobaltous ion of the decomposition of ozone in the absence of hydrogen peroxide in order to determine the mechanism of the reaction.

The experimental evidence on the homogeneous catalysis by cobaltous ion is consistent with the mechanism

$$Co^{++} + O_3 + H_2O \longrightarrow CoOH^{++} + O_2 + HO \quad (1)$$
$$HO + O_3 \longrightarrow HO_2 + O_2 \quad (2)$$
$$HO_2 + CoOH^{++} \longrightarrow Co^{++} + H_2O + O_2 \quad (3)$$

Experimental

In each of the experiments, one liter of a solution containing cobaltous sulfate and perchloric acid at known concentrations was saturated with ozone at 0° by bubbling a stream of ozonized oxygen through the container. After a steady state had been achieved, samples of the solution were siphoned through a side arm of the container into calibrated 65 ml. reaction bottles and placed in a constant temperature bath. To each fourth sample was added immediately 3 ml. of a 0.2 *N* buffered potassium iodide solution and the iodide oxidized by the ozone titrated with standard 0.01 *N* thiosulfate.[3] The initial concentration of ozone was computed for each container from these data. The concentration of ozone remaining in the individual reaction vessels after different time intervals was determined using exactly the same procedure. In none of the ozone analyses did the concentration of cobalt ion exceed 1% of the total oxidizing agent present so no correction for oxidation of iodide by cobaltic ion was made.

The concentration of cobaltous ion in the stock solution was determined by amperometric titration with α-nitroso-β-naphthol.[4] C. P. grades of perchloric, acetic and sulfuric acids and of cobaltous sulfate were used. Water, redistilled from Pyrex, was used in all experiments. The ozone was prepared by discharge of a 15,000-volt transformer across a battery of eight Berthelot tubes in series.[5]

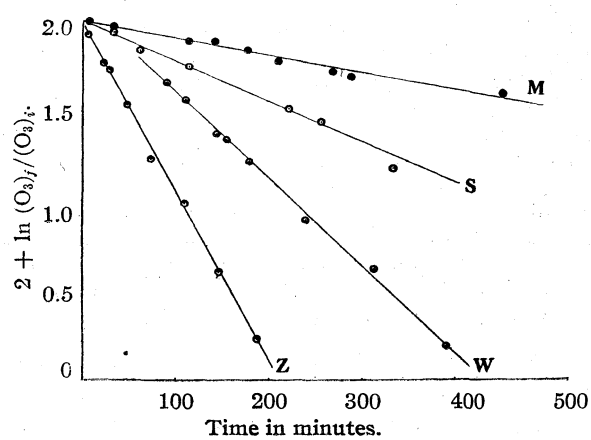

Fig. 1.—The decrease in concentration of ozone at different cobaltous sulfate concentrations: O, S, $(Co^{++})_0 = 6 \times 10^{-5}$ *M*; ●, M, $(Co^{++})_0 = 12 \times 10^{-5}$ *M*; ◒, W, $(Co^{++})_0 = 18 \times 10^{-5}$ *M*; ◓, Z, $(Co^{++})_0 = 36 \times 10^{-5}$ *M*.

Data and Discussion

The reaction was first order with respect to ozone as is shown in Fig. 1. The linear curves are plots of $\ln (O_3)_f/(O_3)_i$ *vs.* time at different concentrations of cobaltous ion. The data for the upper curve on the graph include 8 additional co-linear points determined at longer times.

The reaction was proved homogeneous by experiments in which a 2.3-fold increase in surface area did not change the rate of the reaction appreciably. The reaction rate did not change with substitution of sulfuric acid for perchloric acid as the source of hydrogen ion.

The rate of reaction is independent of hydrogen ion for solutions more acid than *p*H 1.6. From *p*H 1.6 to 3.5 the rate of reaction increases; at the higher value a sol, believed to be $Co(OH)_3$, forms and a heterogeneous reaction no longer first order with respect to ozone ensues. The increased rate with decreasing hydrogen ion can be explained by assuming that the species $CoOH^+$, produced by hydrolysis of Co^{++} in solutions of low acidity, has a higher specific rate of reaction with ozone than does the unhydrolyzed ion.

The rate expression for the disappearance of ozone in acid solution is obtained from equations (1) through (3) as follows

$$-d(O_3)/dt = k_1(O_3)(Co^{++}) + k_2(O_3)(HO)$$

At the steady state

$$\frac{d(Co^{++})}{dt} = \frac{d(HO)}{dt} \backsimeq 0$$

Therefore

$$k_1(O)_3(Co^{++}) = k_2(O_3)(HO) = k_3(CoOH^{++})(HO_2)$$

Since $(Co^{++})_0$, (total cobalt ion) $= (Co^{++}) + (CoOH^{++})$

$$(Co^{++}) = (Co^{++})_0/1 + \frac{k_1(O_3)}{k_3(HO_2)}$$

and

$$\frac{-d(O_3)}{dt} = \frac{2k_1(O_3)(Co^{++})_0}{1 + \frac{k_1(O_3)}{k_3(HO_2)}} = \frac{2k_1(O_3)(Co^{++})_0}{1 + \frac{(CoOH^{++})}{(Co^{++})}}$$

(1) Presented before the Pacific Division of the American Chemical Society meeting in conjunction with the American Association for the Advancement of Science at San Diego, California, June 16–22, 1947.

(2) Taube and Bray, THIS JOURNAL, **62**, 3357 (1940).

(3) Treadwell and Hall, "Analytical Chemistry, Volume II, Quantitative Analysis," 8th ed., John Wiley and Sons, Inc., New York, N. Y., 1935, p. 620.

(4) Kolthoff and Langer, THIS JOURNAL, **62**, 3172 (1940).

(5) L. E. Smith, *ibid.*, **47**, 1844 (1925).

This expression will give first order dependence on initial cobaltous ion concentration and on ozone concentration if the second term in the denominator does not change appreciably during a given experiment. The value of $2k_1/1 + [(CoOH^{++})/(Co^{++})]$ at 0° as determined from a plot of rate *vs.* cobalt ion concentration is 28 mole^{-1} min.$^{-1}$. Spectrophotometric rate measurements leading to the explicit evaluation of k_1 are now being undertaken.

Determination of Activation Energy.—In order to evaluate the heat, entropy, and free energy of activation for the reaction, additional experiments were undertaken at 17.4°, 24.1° and 30.6°. It was found that the spontaneous decomposition of ozone was important at these temperatures and the rate of that reaction determined. The uncatalyzed reaction was found to be of the same order with respect to ozone as the catalyzed reaction.[6] In Table I are given the values for total rate of ozone decomposition, the rate of the uncatalyzed reaction, and the rate of and rate constant for the catalyzed reaction. From a plot of the rate constants (divided by the frequency factor kT/h) *vs.* reciprocal temperature, the following data were obtained: $\Delta H^{\ddagger} = 9{,}000$ cal., $\Delta S^{\ddagger} = -19$ E. U., $\Delta F^{\ddagger}_{298.1} = 14{,}700$ cal. The constants in terms of the Arrhenius equation are: $E_{exp} = 9{,}600$ cal. and $A = 2 \times 10^8$.

TABLE I

RATE CONSTANT DATA FOR OZONE SOLUTIONS CONTAINING 0.0 AND 1.4×10^{-4} *M* $CoSO_4$

Temp., °C.	Total rate of decomposition (ln (O_3)/time)	Rate of uncatalyzed decomposition	$k'(Co^{++})_0$, rate of catalyzed decomposition	k'
0	3.3×10^{-3}	0	3.3×10^{-3}	28
17.4	9.7×10^{-3}	0.02×10^{-3}	9.68×10^{-3}	69
24.1	17.5×10^{-3}	1.0×10^{-3}	16.5×10^{-3}	118
30.6	28.7×10^{-3}	4.1×10^{-3}	24.6×10^{-3}	176

Reaction in the Presence of an Inhibitor, Acetic Acid.—The reaction remains very nearly first order with respect to ozone—in a particular run the rate increases slightly as the ozone concentration becomes low. The data in Fig. 2 show that the rate of decomposition of ozone decreases with increasing acetic acid concentration to a limiting value of 8 mole^{-1} min.$^{-1}$ at 0°. The concentration of perchloric acid and of cobalt sulfate were the same as in the uninhibited reactions. A ratio of acetic acid to cobaltous ion of 2:1 effects a decrease in the rate to 10 mole^{-1} min.$^{-1}$. These data suggest that in the equilibrium $CoOH^{++} + HAc \rightleftarrows CoAc^{++} H_2O$, whose constant is very large, the cobalti–hydroxide complex is converted to cobalti–acetate complex and that the latter is reduced more slowly by HO_2 than is the hydroxide complex. The rate expression for decomposition of ozone in the solution containing acetic acid is

$$-\frac{d(O_3)}{dt} = \frac{2k_1(O_3)(Co^{++})_0}{1 + \frac{(CoAc^{++})}{(Co^{++})}[1 + 1/K(HAc)]}$$

A decrease in the ratio $(CoAc^{++})/(Co^{++})$ during the run would account for the observed increase in rate at low ozone concentrations.

(6) Sennewald, *Z. physik. Chem.*, **A164**, 305–317 (1933).

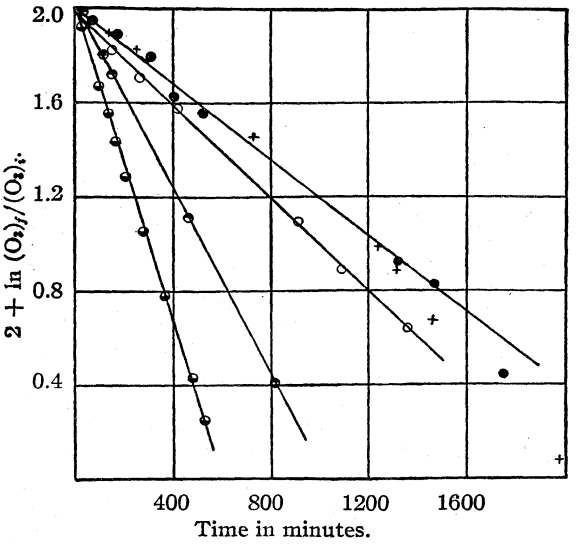

Fig. 2.—Decrease in concentration of ozone at different concentrations of acetic acid: ●, (HAc) = 56×10^{-4} *M*; +, (HAc) = 5.6×10^{-4} *M*; ○, (HAc) = 2.8×10^{-4} *M*; ◒, (HAc) = 0.28×10^{-4} *M*; ◒, (HAc) = 0.0 *M*. $(Co^{++})_0 = 1.4 \times 10^{-4}$ *M* and $(H^+) = 0.2$ *M* in each run.

Summary

1. The heat, entropy, and free energy of activation have been determined for the cobaltous ion catalyzed decomposition of ozone in acid solution.

2. A mechanism involving HO and HO_2 radicals and cobaltous and cobaltic ions is proposed to account for the observed rate dependence of the homogeneous catalyzed reaction on the concentrations of ozone, cobaltous ion and hydrogen ion.

3. The effect of acetic acid in inhibiting the cobaltous ion catalyzed reaction is explained and the rate of the reaction determined at 0°.

4. Differential equations have been obtained which represent the rates of the reactions in the presence and in the absence of acetic acid.

SALT LAKE CITY, UTAH RECEIVED SEPTEMBER 26, 1947

[CONTRIBUTION NO. 147 FROM THE GOODYEAR TIRE & RUBBER CO. RESEARCH LABORATORY]

Kinetics of the Hydrolysis of Ethyl Thiolacetate in Aqueous Acetone[1]

BY JOHN R. SCHAEFGEN

A study of the kinetics of the hydrolysis of ethyl thiolacetate at ordinary temperatures was undertaken in order to compare the behavior of thiolesters with esters and to gain further insight into the mechanism of hydrolysis.

Recorded information concerning thiolesterification and the hydrolysis of thiolesters is limited to qualitative observations and some equilibria and rate studies at elevated temperatures.[2] The data reported in this paper give rate constants and activation energies for the acid catalyzed and the alkaline hydrolysis of ethyl thiolacetate in aqueous acetone solutions containing 24.6, 43.0, and 62.0% acetone by weight. Aqueous acetone was selected as the reaction medium because both thiolester and sodium hydroxide were sufficiently soluble for rate studies in such a mixture over a wide range of composition, and, in addition, a comparison with ester kinetic studies in the same medium was possible.[3]

Experimental

Ethyl thiolacetate was prepared in 77% yield (b. p. 112–115°) by treating ethyl mercaptan with acetyl chloride. The thiolester was purified by fractionally distilling it from anhydrous potassium carbonate through a short packed column. A center constant boiling fraction (113.5° (735 mm.)) was used in the rate studies. This fraction had a refractive index $n^{20.6}D$ 1.4583 and a density d^{20}_4 0.9792. The saponification equivalent was somewhat erratic giving both high and low values depending on the solvent and the length of time allowed for complete hydrolysis. The average value was close to the theoretical, however.

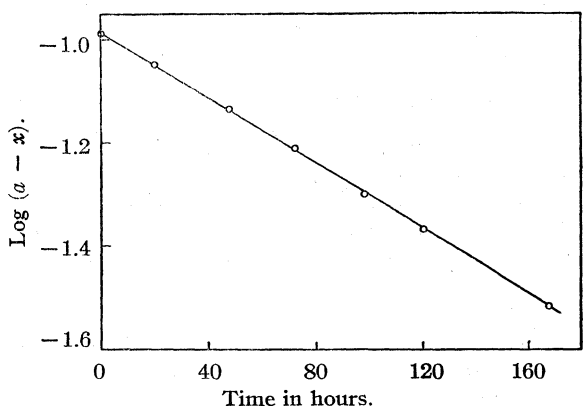

Fig. 1.—The acid catalyzed hydrolysis of ethyl thiolacetate at 40° in 24.6% acetone–water solution: thiolester, 0.1034 *M*; HCl, 0.0985 *M*.

(1) Presented before the Division of Physical and Inorganic Chemistry of the American Chemical Society at the New York Meeting, September, 1947.

(2) W. Michler, *Ann.*, **176**, 177 (1875); E. E. Reid and co-workers, *Am. Chem. J.*, **43**, 489 (1910); THIS JOURNAL, **38**, 2746 (1916); **39**, 1930 (1917).

(3) G. Davies and D. P. Evans, *J. Chem. Soc.*, 339 (1940).

The water–acetone mixtures were made up by weight from boiled distilled water and C. P. acetone dried over and distilled from anhydrous potassium carbonate.

Acid Catalyzed Hydrolysis.—The thiolester solutions were prepared by diluting a weighed quantity of ethyl thiolacetate with aqueous acetone of the desired composition in a volumetric flask. The initial concentration was calculated using the theoretical molecular weight. Appropriate quantities of thiolester and of hydrochloric acid solutions (also in aqueous acetone) were mixed at zero time and the initial concentration of acid was determined by titrating a 10-ml. aliquot with standard 0.1 *N* sodium hydroxide. Additional 10-ml. samples were withdrawn from time to time and titrated to follow the reaction. The mercaptan formed in the reaction interferes with the end-point. Therefore, air freed of carbon dioxide was bubbled through the solution for ten to fifteen minutes to remove mercaptan before a final end-point was determined. The reaction mixture was maintained at constant temperature by means of a thermostat. In some solutions, mainly those high in water content, the mercaptan formed by the hydrolysis separated out as the reaction proceeded. This would tend to make the rate constants low in these cases if much thiolester dissolved in the mercaptan layer.

Alkaline Hydrolysis.—Thiolester solutions were made up the same as for acid catalyzed hydrolysis. Base solutions were prepared by diluting the desired quantity of aqueous carbonate-free sodium hydroxide with acetone until the desired composition was obtained, and making up to volume with aqueous acetone. Appropriate volumes of thiolester and of base solutions were pipetted into separate arms of an inverted Y reaction tube which was partially immersed in a thermostat. The solutions were mixed at zero time by tilting the tube. Samples (10 ml.) were withdrawn from time to time by means of a calibrated free-flowing pipet and were delivered into a slight excess of 0.02 *N* hydrochloric acid solution to stop the reaction. The time of the sample was taken as the time of half delivery. The samples were then back-titrated with 0.02 *N* carbonate-free base solution until a faint phenolphthalein end-point was reached. Air freed of carbon dioxide was bubbled through the solution for ten to fifteen minutes to remove mercaptan before the final end-point was determined just as in acid catalyzed hydrolysis.

Discussion and Results

Acid Catalyzed Hydrolysis.—The rate of the acid catalyzed hydrolysis was found to be first order with respect to thiolester concentration in accord with the rate equation

$$dx/dt = k(a - x)[H^+] \qquad (1)$$

where a is the original concentration of thiolester and x is the amount of thiolester hydrolyzed in time t. On integration equation (1) becomes

$$2.303 \log (a - x) = -k[H^+]t + C$$

Graphs of log $(a - x)$ *vs.* t were prepared (such as shown in Fig. 1) to obtain the values of $k[H^+]$. The data for acid catalyzed hydrolysis are summarized in Table I. The lower value of the rate constant observed in the solution 0.2952 *M* in thiolester may be attributed to the decrease in water content of the solution as the hydrolysis proceeds, and to solution of the thiolester in the mercaptan layer formed during the reaction. The rate of the

reaction is directly proportional to the hydrogen ion concentration (*i. e.*, initial hydrochloric acid concentration), k therefore being independent of the hydrogen ion concentration. The lower value of the rate constant observed in the case of the 0.2808 *M* hydrochloric acid solution is probably due to experimental error since there is no trend in the values of k with increasing hydrochloric acid concentration.

The activation energy computed from the Arrhenius equation is independent of the composition of the reaction medium within the accuracy of the measurements.

TABLE I

RATE CONSTANTS AND ACTIVATION ENERGIES FOR THE ACID CATALYZED HYDROLYSIS OF ETHYL THIOLACETATE IN AQUEOUS ACETONE SOLUTIONS

Wt. % acetone	Temp. °C. ±0.03	Initial concn. (m./l.) Thiol-ester	HCl	$k[H^+] \times 10^5$ l./m./min.	$k \times 10^4$ l./m./min.	E, cal./mole
24.6	30.00	0.1050	0.0995	4.81	4.83	17,500
	40.00	.1034	.0985	12.1	12.3	
43.0	30.00	.1030	.1025	2.60	2.54	18,000
	30.00	.0986	.2808	6.04	2.15	
	30.00	.0986	.4700	11.5	2.44	
	30.00	.2952	.0998	2.10	2.10	
	40.00	.0975	.1006	6.54	6.50	
62.0	30.00	.0995	.1009	1.35	1.34	18,000
	40.00	.0985	.1007	3.52	3.49	

Alkaline Hydrolysis.—The rate of the alkaline hydrolysis of ethyl thiolacetate in aqueous acetone solution was found to be second order and to proceed according to the equation

$$\underset{a-x}{CH_3COSC_2H_5} + \underset{b-2x}{2OH^-} \longrightarrow \underset{x}{CH_3COO^-} + \underset{x}{C_2H_5S^-} + H_2O$$

Integrating the rate expression

$$dx/dt = k(a - x)(b - 2x) \qquad (2)$$

leads to

$$[2.303/(2a - b)] \log [(a - x)/(b - 2x)] = kt + C \qquad (3)$$

A graph of log $[(a - x)/(b - 2x)]$ is linear with t in agreement with theory up to 60–70% completion of the hydrolysis, as shown in Fig. 2. If $b = 2a$, equation (2) on integration gives

$$1/(a - x) = 2kt + C' \qquad (4)$$

Accordingly, $1/(a - x)$ is linear with t in this case (Fig. 3).

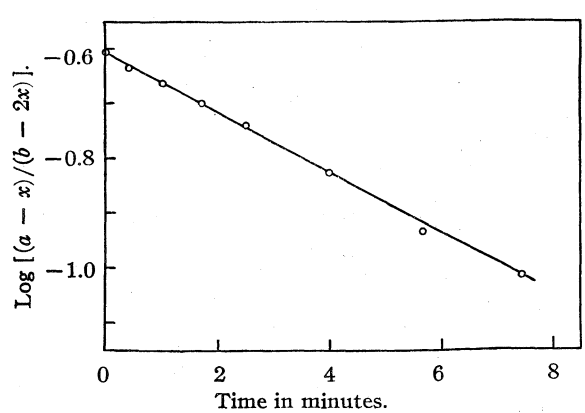

Fig. 2.—The alkaline hydrolysis of ethyl thiolacetate at 20° in 43.0% acetone–water solution: thiolester, 0.0321 *M*; NaOH, 0.1287 *M*.

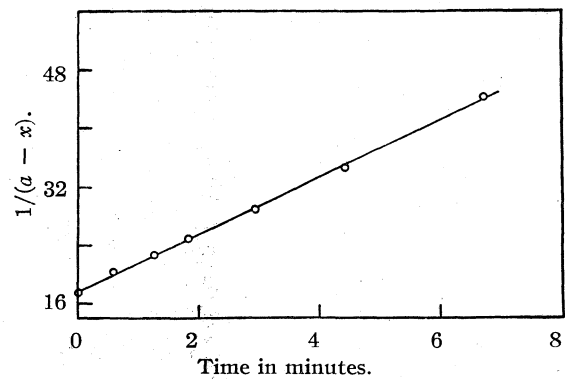

Fig. 3.—The alkaline hydrolysis of ethyl thiolacetate at 20° in 43.0% acetone–water solution: thiolester, 0.0574 *M*; NaOH, 0.1150 *M*.

The data for alkaline hydrolysis are summarized in Table II. The plots from which the energy of activation was determined are shown in Fig. 4. Values of log PZ were calculated from the Arrhenius equation. The rate constant is shown to be independent of thiolester and base concentrations over the small ranges of concentration investigated.

TABLE II

RATE CONSTANTS AND ACTIVATION ENERGIES FOR THE ALKALINE HYDROLYSIS OF ETHYL THIOLACETATE IN AQUEOUS ACETONE SOLUTIONS

Wt. % acetone	Temp. °C. ±0.03	Initial concn. (m./l.) Thiol-ester	NaOH	k (av.)[a] l./mole/min.	E, cal./mole	$\log_{10} PZ$
24.6	10.00	0.0319	0.0637	1.25	13,000	10.2
	20.00	.0369	.0735	2.80		
	30.00	.0319	.0636	5.82		
43.0	10.00	.0570	.1148	0.86	13,800	10.6
	20.00	.0290	.0581	1.91		
	20.00	.0286	.1150	1.98		
	20.00	.0574	.1150	1.98		
	30.00	.0301	.0601	4.39		
62.0	10.00	.0401	.0810	0.638	14,400	10.9
	20.00	.0401	.0802	1.54		
	30.00	.0394	.0795	3.45		

[a] Each of these values is the average of two experiments, the maximum deviation of any value from the mean being 3%.

Comparison with Ester Hydrolysis.—The hydrolysis of ethyl thiolacetate in 62.0% acetone solution is compared to that of ethyl acetate in the same medium in Table III. The rate constant for the acid catalyzed hydrolysis of ethyl acetate at 30° is about thirty times as great as that for ethyl thiolacetate. This difference in k can be attributed almost entirely to the small difference in observed activation energy since the log

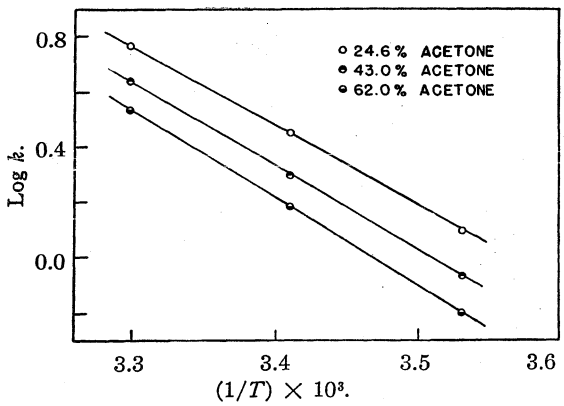

Fig. 4.—The alkaline hydrolysis of ethyl thiolacetate in aqueous acetone. The change of rate constant with temperature.

PZ factor is approximately the same in each case. This would indicate that similar configurational transformations are followed in the acid catalyzed hydrolysis of esters and of thiolesters.

The rate constants for the alkaline hydrolysis of ethyl acetate and of ethyl thiolacetate at room temperature are approximately the same. However, both the activation energy and the log *PZ* factor are much higher for alkaline thiolester hydrolysis than for alkaline ester hydrolysis, indicating that different mechanisms are followed in these two reactions.

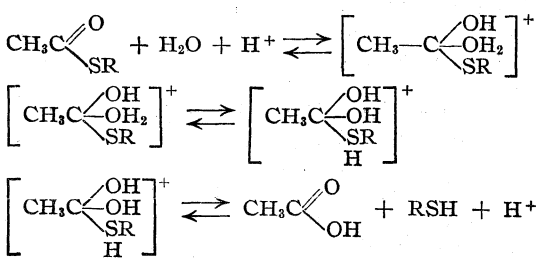
	$\log_{10} PZ$	7.6	10.9

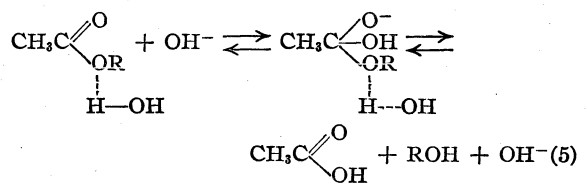
[a] From the data of Davies and Evans, ref. 3.

The mechanism for the acid catalyzed hydrolysis of ethyl thiolacetate is undoubtedly similar to that postulated for ester hydrolysis and may be formulated[4] thus



It should be noted that the addition of the nucleophilic oxygen of the water molecule in the rate controlling first step is favored by polarization of the carbon to sulfur bond; however, the corresponding carbon to oxygen linkage in esters is relatively more polar and the activation energy would therefore be expected to be somewhat lower in the case of ester hydrolysis, in accord with observation (see Table III).

A number of mechanisms have been proposed for alkaline ester hydrolysis, all of which involve an addition of hydroxyl ion at the carbonyl carbon atom in the rate controlling first step with,[5] or without,[6] the aid of a molecule of water to produce the intermediate complex. In the former case the complex then yields the carboxylic acid and the alcohol in a simple decomposition; whereas in the latter case the acid and the alkoxy ion are formed, followed by a second fast reaction with water to produce the alcohol. In view of the work of Kendall,[7] who has demonstrated that solvated ester molecules exist in aqueous solutions of the simple esters, the former mechanism seems more likely, and may be written as follows



The solvated ester complex, formed by hydrogen bonding as shown, reacts with hydroxyl ion in the rate controlling step to produce the intermediate complex which then decomposes to give the observed products. The addition of hydroxyl ion is aided by the small positive charge induced at the carbonyl carbon atom by the added water molecule. The stretching of the C–OR linkage preparatory to rupture is favored by both addition of hydroxyl ion and the electrophilic attack of the hydrogen atom of the water molecule. Thus the activation energy of the reaction, which may be thought[8] of as the energy necessary to add an hydroxyl ion against a negative environment plus a bond stretching energy necessary to break the C–OR linkage, will be much lower by this mechanism than by one in which the coöperation of a water molecule was not involved.

On the other hand, it is quite unlikely that similar solvated thiolester molecules exist in aqueous solution because of the relative weakness of the S---H—O bond compared to the O---H—O bond.[9]

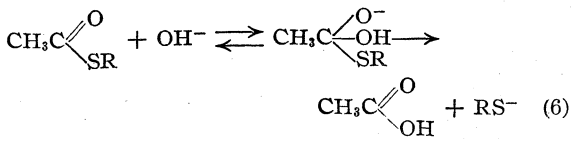
Therefore the preferred mechanism for alkaline thiolester hydrolysis is



(6)

The activation energy for thiolester hydrolysis by mechanism (6) should be appreciably greater than for ester hydrolysis by mechanism (5) for two reasons: firstly, the coöperation of a water molecule lowers the energy necessary to add hydroxyl ion and to split off alcohol, as pointed out in the preceding paragraph; and secondly, the relatively greater polarization of the C–OR bond in esters compared to the C–SR linkage in thiolesters further lowers the energy necessary for hydroxyl ion addition and bond rupture. The latter reason alone, it should be noticed, is insufficient in itself to account for the large observed difference in activation energies (Table III), since its numerical value will amount to only about 1.6 kcal. as a comparison of acid catalyzed hydrolysis of ester and thiolester reveals (same Table). The steric hindrance to the hydrolysis reaction will be greater for esters (mechanism 5) than for thiolesters (mechanism 6) owing to the shielding effect of the water molecule, thus making the log PZ factor lower for ester than for thiolester hydrolysis, also in accord with observation. On the other hand, the alkaline hydrolyses of ester and of thiolester are similar in that E and log PZ for each reaction both increase with increase in acetone content of the reaction medium[10] (see Table II). The increase of activation energy with change in acetone concentration of the reaction medium is in the expected direction, since a decrease in the dielectric constant of the medium would be expected to decrease the ease of addition of hydroxyl ion at the carbonyl carbon atom.

Acknowledgment.—The author wishes to express his sincere thanks to Dr. Paul J. Flory for his valuable suggestions pertaining to this problem, and to Mr. Daniel Fouser for his assistance in part of the experimental work.

Summary

A kinetic study of the acid catalyzed and the alkaline hydrolysis of ethyl thiolacetate in aqueous acetone has been made. The acid catalyzed hydrolysis is first order with respect to thiolester and with respect to hydrogen ion concentration. The basic hydrolysis is second order. The activation energies are as follows: acid catalyzed hydrolysis 17,800 cal./mole; alkaline hydrolysis 13,000 cal./mole (24.6% acetone solution), 13,800 cal. (43.0% acetone), and 14,400 cal. (62.0% acetone).

A comparison of thiolester and ester hydrolysis has been made, and the mechanisms of hydrolysis have been discussed in view of the results obtained.

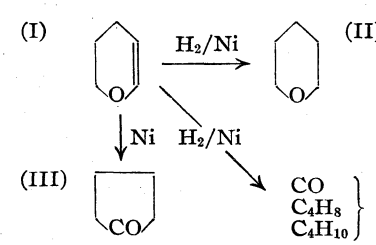
Reactions of Furan Compounds. IX. Catalyzed Rearrangement of 2,3-Dihydropyran into Cyclopentanone[1]

BY CHRISTOPHER L. WILSON

Experiments described in the present paper have shown that 2,3-dihydropyran (I) can be reduced in good yield to tetrahydropyran (II) by passing the vapor with hydrogen over a nickel catalyst at 100°. This confirms an earlier observation.[2] When the temperature was raised to 200° or above, however, two other reactions were noticed. One was ring fission to butane, butene and carbon monoxide and the other rearrangement to cyclopentanone (III). These two reactions have not been recorded before although reference has been made[2] to the formation of unidentified materials of "high molecular weight." Catalysts of nickel or cobalt and mixtures of each of these with copper were effective. On the other hand, copper chromite failed to induce any change whatever.

(1) This paper was presented before the Organic Division at the New York meeting of the American Chemical Society in September, 1947.

(2) British Patent 565,175, Bremner, Jones and Taylor.



The yield of cyclopentanone, calculated on consumed dihydropyran, under favorable circumstances attained almost 30% but the reaction was always accompanied by fission. Replacement of added hydrogen by nitrogen suppressed to some extent both fission and reduction but the rearrangement was only affected to a minor extent. Thus hydrogen does not appear to be essential for this reaction. On the other hand, the catalyst to be active must be so for all three processes and deterioration toward one reaction is accompanied

by inactivation in the other two. These features are illustrated by Tables I and II.

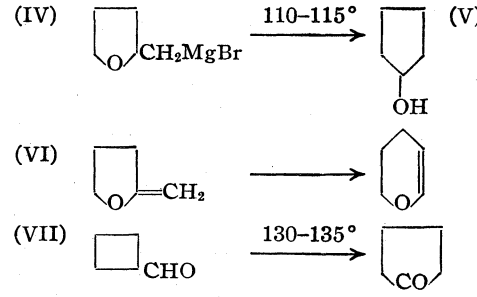
There appears to be no recorded parallel with the reaction leading to cyclopentanone, but certain observations of significance have been made previously. Cyclopentanone is present in the higher ketone fractions from the destructive distillation of wood or lignite which may suggest a connection with furan compounds. Furthermore Paul[3] obtained what he thought was a small amount of cyclopentanol (V) by heating the magnesium derivative of tetrahydrofurfuryl bromide (IV). Later[4] he drew attention to the fact that thermal rearrangement of methylenetetrahydrofuran (VI), which may be made by the elimination of hydrogen bromide from tetrahydrofurfuryl bromide, would be expected to give rise to cyclopentanone if the usual mode of vinyl ether rearrangement was followed.[5] His experiments gave, however, only a poor yield of dihydropyran. At temperatures higher than those Paul used, dihydropyran is known to split into acrolein and ethylene, and it has already been pointed out that if the usual mode of vinyl ether rearrangement obtained here the initial product would be cyclobutane aldehyde.[6] This compound, however, could not be detected but its intervention was not disproved. It has since been noted that cyclobutane aldehyde (VII) on heating in the presence of certain acidic substance rearranges to cyclopentanone.[7] Since this ketone was absent from the pyrolytic products from dihydropyran the intervention of the cyclic aldehyde would appear to be excluded. The catalysed rearrangement of course might proceed in quite another manner, and cyclobutane aldehyde might intervene here before being transformed into cyclopentanone.



The formation of cyclopentanone from dihydropyran offers an explanation of the hitherto unaccountable presence of the cyclic ketone in the products from the reaction of tetrahydrofurfuryl alcohol over a nickel catalyst.[8] It is, however, necessary to suppose the intermediate formation of some dihydropyran which although not detected with a nickel catalyst has since been shown to form using a cobalt catalyst.

The function of the catalyst in the rearrangement is obscure. Activated adsorption involving the C–O links, and particularly the weaker one remote from the carbon double bond, might be expected to be the first step in ring fission and loss of carbon monoxide. On the other hand, adsorption by attachment of the carbon double bond must be an important step in reduction. The type of activation necessary for rearrangement is not so clear but it may be that the second variety which leads to reduction, if hydrogen is also present, might also be responsible for a loosening of the α-hydrogen atom of the double bond. This kind of effect has been recognized ever since it was shown[9] that the rate of hydrogen-isotope exchange with an olefin under the influence of a metallic catalyst is much more rapid than the rate of hydrogen addition to the double bond. If this is so it should be possible to find a catalyst which will cause rearrangement and reduction rather than fission.

Experimental

Catalysts.—These were used in the form of granulated (4–16 mesh) sintered powders. They were placed in the

catalyst chamber consisting of a Pyrex glass tube, 1.7 in. diameter, and heated electrically. The metal was activated by oxidation in a stream of air at 500° followed by slow reduction below 300° with hydrogen. The weight of each catalyst and the amount of water produced at the first reduction was as follows, pure nickel (2500 g., 250 cc.), pure cobalt (2300 g., 359 cc.), nickel–copper (50% of each, 2500 g., 607 cc.) and cobalt–copper (50% of each, 2500 g., 425 cc.). Copper chromite (750 g.) prepared by the usual precipitation method was inactive at 225° and 350°. The catalysts were reactivated by oxidation and reduction as above.

Isolation and Analysis of Products.—Dihydropyran was prepared by dehydration of tetrahydrofurfuryl alcohol over aluminum silicate at 350°. After drying over solid sodium hydroxide it had b. p. 86–88°.

The product issuing from the catalytic chamber containing the active metals was passed through a trap at −78° and the condensed portion distilled at atmospheric pressure. Material, b. p. below 20°, consisted of C_4-hydrocarbons. Bromine was added at −78° until addition was complete and the volatile unreacted butane distilled off into a graduated tube where its volume at 0° was measured. The involatile bromide was weighed and the amount of butene to which it corresponded was calculated. The bromide had b. p. 159–160° and would therefore appear to consist essentially of the symmetrical butene dibromide. The boiling point of the 1,2-compound is recorded as 166°.

The fraction of the products collected between 20 and 100° boiled mainly between 70 and 90°. It appeared to contain only di- and tetra-hydropyrans in addition to a little water. The organic substances were estimated in one of three ways depending on the accuracy desired, each method being checked using authentic mixtures. The most accurate was to weigh the precipitated δ-hydroxyvaleraldehyde 2,4-dinitrophenylhydrazone formed by adding a weighed sample to excess of a saturated solution of the hydrazine in hydrochloric acid (2 *N*); the accuracy was 1% with a mixture of equal amounts of the pyrans. A second method, accurate to 6% with the same mixture of pyrans, was to measure the reduction in weight of a sample (5 cc.) after shaking with hydrochloric acid (2 *N*) saturated with sodium chloride. Shaking and separation were carried out in a micro-separatory funnel. This method was only reliable when the pyrans were present in approximately equal amounts. The third method depended on titration of a sample with bromine (about *M*) dissolved in aqueous acetic acid (50%) containing sodium acetate (5%). The last method was the most rapid but least reliable.

Cyclopentanone was estimated in the material, b. p. above 100°, by measuring the reduction in weight after shaking with excess of saturated sodium bisulfite. The method was accurate to within 5% of the ketone which usually amounted to about half the material. A more accurate method for small quantities depended on precipitation with dinitrophenylhydrazine.

In the experiments with nickel, distillation of the material from the last fraction and insoluble in bisulfite gave a small quantity, b. p. 136–142°, which may have been cyclopentanol. It could not be induced to give a solid dinitrobenzoate and was therefore unidentified.

Experiments with cobalt–copper were carried out over a range of temperatures between 200 and 350°. Cyclopentanone was formed in all the experiments above 250° in amounts similar to those with the cobalt catalyst. Reduction and fission were also observed and the catalyst deteriorated in use.

The nickel–copper catalyst was investigated only at one temperature (275°). Dihydropyran (84 g.) was passed over the catalyst with hydrogen (24 l./hr.) during two hours. The product contained *n*-butane, b. p. 0–2° (6 g.), tetrahydropyran, b. p. 87–89° (44 g.), and cyclopentanone, b. p. 129.5–130.5° (7.5 g.), 2,4-dinitrophenylhydrazone, m. p. 142–143°, m. m. p. with an authentic specimen (m. p. 144–145°) was 142–143°. There was no unsaturated material.

Summary

2,3-Dihydropyran has been shown to undergo three simultaneous reactions when passed with hydrogen over catalysts containing nickel or cobalt at a temperature of 200° or above.

The reactions are (1) reduction to tetrahydropyran, (2) fission to butene, butane and carbon monoxide and (3) rearrangement into cyclopentanone.

The mechanism of the reactions is discussed.

Reactions of Furan Compounds. X. Catalytic Reduction of Methylfuran to 2-Pentanone

BY CHRISTOPHER L. WILSON

Reference was made some years ago[1] to the formation of small amounts of 2-pentanone (II) and 2-pentanol (III) during the gas phase reduction of methylfuran (I) to tetrahydromethylfuran (IV). Experiment has now shown that either tetrahydromethylfuran or 2-pentanone can be the major product depending on conditions. Results obtained using a nickel catalyst at various temperatures are shown in the diagram. At 100° the chief product (86% yield) was tetrahydromethylfuran but as the temperature was raised the quantity decreased and ketone appeared in increasing amounts attaining a maximum (yield 75%) at about 185°. Along with the ketone a small quantity of its reduction product, 2-pentanol, was also formed. Below 150° conversion of methylfuran was complete but surprisingly enough a proportion escaped reaction above this temperature. This coincided with the formation of quantities of gaseous products, with a slight increase in the amount of tetrahydromethylfuran and with a rapid drop in ketone production. No adequate explanation of these variations has yet been found but the reason is undoubtedly connected with complex surface conditions. Furthermore, nuclear hydrogenation of methylfuran might be reversible.

Other metallic catalysts such as cobalt and mixtures of nickel, cobalt or iron with copper as well as copper chromite also gave some ketone but a

(1) French Patent 811,695 (1937).

detailed study of their behavior has not been made.

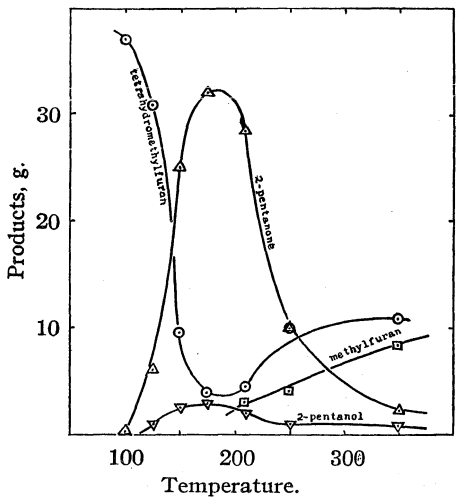

Fig. 1.—Products from methylfuran and hydrogen over a nickel catalyst at various temperatures. Each point corresponds with the passage of 41 g. of methylfuran and 80 liters of hydrogen over the catalyst in two hours.

At present there is little information from which to propose a reaction mechanism. It is particularly uncertain to identify the chemical steps of a catalytic reaction by duplicated experiments with possible intermediates since the conditions on the surface are no longer comparable. Experiment has shown that tetrahydromethylfuran on passage over the catalyst with hydrogen below 200° does not give any ketone. If we ignore the criticism just made of this type of experiment, this fact indicates that ring fission must occur before ring saturation. It may occur therefore either in methylfuran itself or a derived dihydro- compound.

In Part III of this series[2] evidence was presented showing that 2,3-dihydrofuran was much more susceptible to hydrogenative ring fission than either furan or tetrahydrofuran and that the carbon–oxygen bond remote from the carbon double bond was the more readily attacked. Applying these ideas to the reduction of methylfuran would indicate the intermediate formation of an unstable 4,5-dihydromethylfuran (V).

Evidence for the formation of this compound has been presented before[3,4] to account for the formation of some γ-acetopropyl alcohol (VI) during the catalytic reduction of methylfuran in the presence of dilute acid. Presumably dilute acid would hydrolyze 4,5-dihydromethylfuran to acetopropyl alcohol just as it converts 2,3-dihydrofuran into γ-hydroxybutaldehyde.[2]

There still remains the possibility, however, that ring fission occurs in methylfuran itself in the vapor phase by reduction, although the absence of unsaturated products would appear to discount it, and in the experiments in aqueous acid by hydrolysis followed by reduction. In connection with the last point it was shown in the present work during attempts to devise a method for estimating methylfuran that it reacted in the cold with a solution of dinitrophenylhydrazine in dilute hydrochloric acid to give levulinic aldehyde bis-dinitrophenylhydrazone (VII). An analogous reaction is the formation of the dimethylacetal by reaction with methyl alcoholic hydrogen chloride.[5] Levulinic aldehyde might then reduce further to acetopropyl alcohol.

It will be recalled[2] that the reaction of tetrahydrofurfuryl alcohol vapor with a nickel catalyst gave rise to many products including some 2-pentanone. The present work confirms the view then expressed that the ketone arose by fission of methylfuran which was formed from furfuryl alcohol present as an impurity in the commercial tetrahydro-alcohol.

Experimental

Materials.—Methylfuran, b. p. 63–64°, was prepared by reduction of furfuraldehyde using a copper chromite catalyst at 275°. The feed rate was 48 cc. of furfural and 45 liters of hydrogen per hour. The product was distilled, dried over sodium hydroxide and redistilled.

Catalysts.—The description of these excepting iron–copper and pure copper was given in the preceding paper. Iron–copper sintered powder (4% copper, 2200 g., 4–16 mesh) was oxidized at 550° and reduced below 400° giving 64 cc. of water. The pure copper contact material was produced by reducing the granular oxide (1840 g.) below 200°. This metal failed to have any effect on methylfuran either at 280 or 320°. On the other hand, copper chromite gave a 52% yield of 2-pentanone at 340° together with a little pentanol.

Cobalt–copper gave rise to rather more low-boiling materials. The yield of ketone was about 60% at 350°. Iron–copper at 350° gave ketone (4.0 g.), tetrahydro-

(5) Harries, *Ber.*, **31**, 41 (1898).

methylfuran (10.8 g.) and unchanged methylfuran (16.1 g.) from an input of 41 g.

Isolation and Analysis of Products.—The products from the reaction chamber were caught in a trap at −78° and freed from water either by filtering with exclusion of atmospheric moisture through a small sintered glass funnel kept very cold or by using anhydrous magnesium sulfate. Distillation was effected at atmospheric pressure with a 12-plate fractionating column. Methylfuran constituted most of the fraction, b. p. 60–70°. The amount was checked by conversion into the maleic anhydride adduct using benzene as solvent. Tetrahydromethylfuran was present in the fraction b. p. 70–90° (most 79–80°); 2-pentanone distilled mainly between 101 and 103°, the fraction being collected between 90 and 110°. This fraction was shaken with saturated aqueous bisulfite and correction applied for the small amount of non-ketonic material. The distillation residue contained 2-pentanol, usually too little for separation by distillation. The material from several experiments was collected, any ketone removed by bisulfite and the material shown by distillation to contain 80% of b. p. 117–120°. The figures for 2-pentanol are perhaps the least accurate of those recorded.

The 2,4-dinitrophenylhydrazone of 2-pentanone after recrystallization from ethyl alcohol had m. p. 146–147°. The 3,5-dinitrobenzoate of 2-pentanol recrystallized from ligroin, b. p. 90–120°, had m. p. 61–62°.

Reduction of 2-Pentanone.—The ketone (15 g.) was passed with hydrogen (15 l./hr.) during thirty minutes over the nickel catalyst at 100°. The product consisted of unchanged pentanone (20 g.) and 2-pentanol (12.3 g.).

Dehydrogenation of 2-Pentanol.—The alcohol (10 g.) was passed over the nickel catalyst at 225° together with hydrogen (30 l./hr.). The product contained 95% ketone. Similar results were obtained at 250°.

Tetrahydromethylfuran.—The cyclic ether, b. p. 80–81° (30 g.), was passed during one hour together with hydrogen (30 l./hr.) over nickel at 250°. No ketone was produced but there was considerable gas formation. At 100° the compound was recovered unchanged.

Reaction of Methylfuran with Dinitrophenylhydrazine.—Methylfuran (1 g.) and 2,4-dinitrophenylhydrazine dissolved in hydrochloric acid (2 *N*) were shaken for several days. The yellow precipitate (1.3 g.) was filtered off, washed with water and hot ethyl alcohol. It was insoluble in all ordinary solvents but was crystallized from dimethylformamide forming dark red prisms, m. p. 231° (dec.).

Anal. Calcd. for $C_{17}H_{16}O_8N_8$: C, 44.3; H, 3.5; N, 24.2. Found: C, 44.4; H, 3.5; N, 24.2.

Acknowledgment.—The author is indebted to M. J. While for help with the experiments and to Revertex, Ltd., in whose laboratories some of the work described in this and the preceding three papers in this series was carried out.

Summary

The variation of products with temperature in the reaction of methylfuran vapor with hydrogen over a nickel catalyst has been studied. At 100° the main product was tetrahydromethylfuran while above this temperature 2-pentanone was formed in large amounts. The yield of ketone was a maximum at 185°. Along with the ketone small amounts of 2-pentanol were also formed and at the higher temperatures quantities of gaseous materials.

Other catalysts containing cobalt, copper and iron also resulted in ketone formation but a detailed study of their behavior was not made.

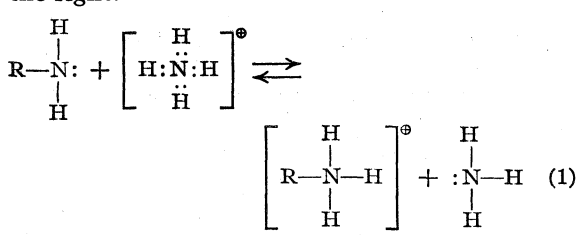
A Low Pressure Reductive Alkylation Method for the Conversion of Ketones to Primary Amines[1]

BY ELLIOT R. ALEXANDER AND ALICE LOUISE MISEGADES[2]

It is well known that carbonyl compounds can be hydrogenated in the presence of ammonia to produce mixtures of primary, secondary, and tertiary amines.[3] Originally the reaction was carried out by the hydrogenation of the carbonyl compound in ethanol, saturated with ammonia, at low pressure over a nickel catalyst.[3a] Better yields and more reproducible results, however, have been obtained over Raney nickel with hydrogen pressures of 20 to 150 atmospheres at temperatures ranging from 40 to 150°.[3b,3c] This technique, while readily carried out, requires high pressure apparatus which is not always available. Accordingly, it was the object of this work to improve Mignonac's low pressure reductive alkylation reaction for the preparation of primary amines.

It appeared that this might be done by taking advantage of the fact that a primary amine is more basic than ammonia. If ammonium ions were introduced into the reaction mixture, the following reaction should occur in which the position of equilibrium should favor the products on the right.



(1)

Since the alkylammonium ion no longer has an electron pair available for combination with the carbonyl group, the process should tend to stop at the formation of primary amines.

(1) Taken from a thesis by Alice Louise Misegades submitted to the faculty of the University of Illinois in partial fulfillment of the requirements for the degree of bachelor of science.

(2) Present address: Albertus Magnus College, New Haven, Connecticut.

Methyl β-naphthyl ketone	1-β-naphthylethyl-[e]	53
Benzophenone	Benzhydryl-	34

[a] Freshly distilled commercial products were used in all cases. [b] Mailhe, *Compt. rend.*, **172**, 693 (1921). [c] The bulk of the product (71%) was dibenzylamine. [d] Reference 3b. [e] Blicke and Maxwell, THIS JOURNAL, 61, 1781 (1939).

It will be observed that the method was only partially successful in preventing the formation of secondary products but that the yields from ketones are quite comparable to those obtained at higher pressures and temperatures.[3b] In the case of isobutyraldehyde, benzaldehyde, methyl isopropyl ketone, cyclohexanone, methyl *n*-amyl ketone, and phenylacetone, considerable amounts of secondary amines were observed. With less reactive ketones such as methyl isobutyl, di-*n*-propyl, diisopropyl, acetophenone, propiophenone, methyl β-naphthyl, and benzophenone there appeared to be very little secondary amine formation. Presumably, the formation of a secondary alcohol was a competing reaction although this point was not investigated.

The improvement ammonium chloride made upon the yield of primary amine can be illustrated with acetophenone and methyl isobutyl ketone. When the reaction was carried out in the absence of ammonium chloride yields of 37 and 49%, respectively, were obtained. Table I shows that yields of 69 and 57–65% were obtained for the same reactions in the presence of ammonium chloride.

Experimental

Reductive Alkylation of Ammonia with Ketones.—An apparatus similar to the one described by Adams and Voorhees[4] was used for the reaction. The carbonyl compounds were all redistilled before use.

In a 300-ml. reduction bottle containing 10 ml. of distilled water, 0.2 g. of platinum oxide[5] was reduced to platinum by shaking in an atmosphere of hydrogen for about ten minutes.[6] The ketone (0.3 mole), ammonium chloride (20.0 g., 0.37 mole), 225 ml. of absolute methanol saturated with ammonia, and 25 ml. of aqueous ammonia were added and the mixture was reduced by shaking with hydrogen at one to three atmospheres. Hydrogenation was continued until a constant pressure reading indicated that reduction had ceased. The shaker was then stopped, The bottle was vented, and the catalyst was allowed to settle. The platinum was removed by filtering the mixture through a Hirsch funnel into a one-liter round-bottomed flask and any salt which collected on the filter was rinsed down with water or methanol. The flask and contents were then removed to a hood and refluxed under a condenser for one hour to remove the excess ammonia.

When the excess ammonia had been removed, the solution was cooled, acidified to congo red paper with concentrated hydrochloric acid, and evaporated to about one-half of its volume under vacuum. Water (200 ml.) was added and the solution extracted with three 25-ml. portions of benzene. The benzene extracts were discarded. The aqueous solution was then made strongly basic with 50% sodium hydroxide solution, the two layers which formed were separated and the water layer was extracted three or four times with ether. The ether extracts and the oily layer were then combined, washed with water and dried over potassium hydroxide. The primary amine was purified by distillation through a 13-cm. column packed with glass helices. The boiling points found agreed well with those recorded in the literature.

In the case of the runs with benzaldehyde, phenylacetone, methyl β-naphthyl ketone, and benzophenone, insoluble salts were formed on acidification. With these compounds the procedure was modified to the extent that the mixture was cooled, the salts filtered with suction and washed thoroughly with water. The filtrate was then extracted with benzene as before and the salts were recombined with it before basing the solution with aqueous sodium hydroxide.

Summary

Experimental conditions have been described for the low pressure hydrogenation of a mixture of a ketone and ammonia to the corresponding primary amine. The reduction was carried out over platinum oxide in methanol saturated with ammonia in the presence of excess ammonium chloride. In general the yields were comparable to those obtained with high pressure equipment.

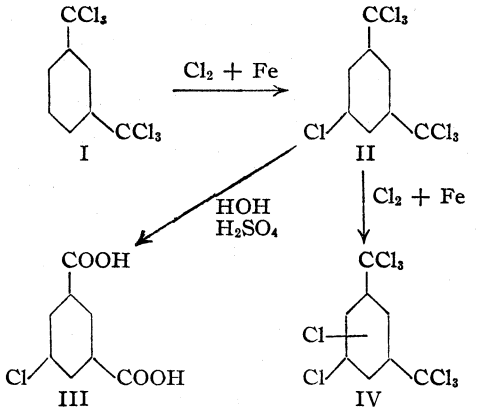
Chloro- and Dichloro-*bis*-(trichloromethyl)-benzenes[1]

BY C. K. BRADSHER, P. M. GROSS, M. E. HOBBS, R. S. KITTILA, L. RAPOPORT,[2] P. TARRANT[3] AND G. WEST[4]

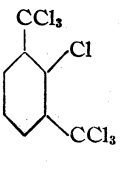
In the course of a program of indirect fluorination carried out in this laboratory, it became necessary to prepare some *bis*-(trichloromethyl)-benzenes containing a chlorinated nucleus. A few such compounds have been mentioned previously, chiefly in the patent literature,[5,6,7,8,9] but with little information as to details of preparation or physical constants. A description of the preparation, physical constants, and, where possible, the proof of structure of some compounds of this class forms the subject of the present communication.

Our investigation followed two general lines, the nuclear chlorination of *bis*-(trichloromethyl)-benzenes and the chlorination of the methyl groups of chloroxylenes. In the nuclear chlorination of 1,3-*bis*-(trichloromethyl)-benzene (I), chlorine enters the position *meta* to the two trichloromethyl groups to yield the new 5-chloro-1,3-*bis*-(trichloromethyl)-benzene (II). Hydrolysis of

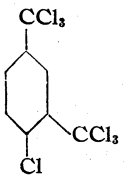


the product yielded the known[10] 5-chloro-isophthalic acid (III).

Introduction of a second chlorine atom into the nucleus of 5-chloro-1,3-*bis*-(trichloromethyl)-benzene (II) or dichlorination of the parent 1,3-*bis*-(trichloromethyl)-benzene (I) alike yielded a viscous liquid which appears to be a dichloro-1,3-*bis*-(trichloromethyl)-benzene (IV). From several of the dichlorination runs there was isolated a small amount of a high melting solid which proved to be 2,5-dichloro-1,4-*bis*-(trichloromethyl)-benzene.[9]



V



VI

The 2-chloro- (V), 4-fluoro-,[11] and 4-chloro-1,3-*bis*-(trichloromethyl)- (VI) and 2-chloro-1,4-bis-(trifluoromethyl)-benzenes were prepared from the corresponding halogenated xylenes by chlorination at elevated temperatures in the presence of a mercury arc, and using the patented technique[6b] of employing a large excess of chlorine in the latter stages. It was found that the 4-chloro-1,3-*bis*-(trichloromethyl)-benzene (VI) obtained from monochlorinated meta-xylene had to be separated from a small amount of the 2-isomer (V). This suggests that nuclear chlorination of the hydrocarbon yields a mixture containing the 2- as well as the 4-isomer, a result that would be predicted by ordinary rules of orientation, but which seems to have escaped earlier workers.[12]

Experimental

5-Chloro-1,3-*bis*-(trichloromethyl)-benzene (II).—A glass reactor was charged with 243 g. of 1,3-*bis*-(trichloromethyl)-benzene[6b] (m. p. 32–36°) and 0.25 g. of iron filings. The reactor was heated to 115–125° and a rapid stream of chlorine bubbled through the liquid for five hours. At the end of this time, the weight increase amounted to 15% more than the theoretical. The fraction distilling at 150–169° (6–7 mm.) amounted to 163 g. and partly solidified on cooling. Recrystallization of the solid portion from alcohol yielded 73 g. of white flakes, m. p. 76–78°. An analytical sample (m. p. 77–78°) gave low values for chlorine, but its identity was established by hydrolysis to 5-chloro-isophthalic acid.

Anal. Calcd. for $C_8H_6Cl_7$: Cl, 71.5. Found: Cl, 71.0.

5-Chloro-isophthalic Acid (III).—The above compound (II) was heated with 100 ml. of 85% sulfuric acid. As the temperature neared the boiling point of the acid,

the evolution of hydrogen chloride commenced and proceeded vigorously for several minutes. After cooling, the mixture was poured into a large volume of water and the solid collected. The acidic material was dissolved in sodium carbonate, treated with charcoal, filtered and reprecipitated by addition of concentrated hydrochloric acid. After drying at 120° the white powder melted at 279–280° (lit.[10] 278°). Neutral equivalent calcd. for $C_8H_5O_4Cl$: 100.3. Found: 105, 104.

The dimethyl ester was obtained as white needles, m. p. 79–80°.

Anal. Calcd. for $C_{10}H_9O_4Cl$: Cl, 15.51. Found: Cl, 15.59.

The ethyl ester melted at 50–51° (lit.[10] 45°).

Dichlorination of 1,3-*bis*-(Trichloromethyl)-benzene.—The chlorination was carried out essentially as described above for the preparation of the 5-chloro-1,3-*bis*-(trichloromethyl)-benzene except that chlorination was continued for ten hours, and the temperature was allowed to go as high as 145°. From 204 g. of *bis*-(trichloromethyl)-benzene, 138 g. of a very viscous liquid was obtained b. p. 184–189° (9 mm.). Essentially the same result was obtained by starting with 5-chloro-1,3-bis-(trichloromethyl)-benzene.

Anal. Calcd. for $C_6H_2Cl_2(CCl_3)_2$: active Cl,[13] 55.9. Found: active Cl, 55.4.

In the dichlorination of *bis*-(trichloromethyl)-benzene prepared from research grade *m*-xylene (E. K. 275), a small quantity of a high melting isomer, m. p. 191–192°, was obtained. This was shown to be **2,5-dichloro-1,4-*bis*-(trichloromethyl)-benzene** (lit.[9] 193°).

Anal. Calcd. for $C_8H_2Cl_8$: Cl, 74.3. Found: Cl, 74.8.

2-Chloro-1,3-*bis*-(trichloromethyl)-benzene (V).—The chlorination of 179 g. of 2-chloro-1,3-dimethylbenzene[14] (b. p. 181.5–183°; $n^{25}D$ 1.5241) was carried out at 120–130° in a glass reactor and in the presence of a mercury arc. After the theoretical quantity of chlorine had been absorbed (fifteen hours), the mixture was cooled and the crude crystals collected, m. p. 115–125°; yield 130 g. (30%). On recrystallization from ethanol, white prisms were obtained, m. p. 136–137°.[15]

Anal. Calcd. for $C_8H_3Cl_7$: Cl, 71.5. Found: Cl, 71.5.

4-Chloro-1,3-*bis*-(trichloromethyl)-benzene (VI).[6b,6c]—The chlorination of 166 g. of 4-chloro-1,3-dimethylbenzene (b. p. 181–184°, $n^{17}D$ 1.5269) under similar conditions to those used in the preparation of the 2-isomer yielded 177.5 g. (50%) of 4-chloro-1,3-*bis*-(trichloromethyl)-benzene as a viscous liquid, b. p. 180–185° (8.5 mm.).

Anal. Calcd. for $C_8H_3Cl_7$: Cl, 71.5. Found: Cl, 71.0, 71.5.

The residue from the distillation of 4-chloro-1,3-*bis*-(trichloromethyl)-benzene yielded a small quantity of solid which was identical with the 2-chloro-1,3-bis-(trichloromethyl)-benzene (VI) described above and gave no depression of melting point when mixed with it.

4-Fluoro-1,3-*bis*-(trichloromethyl)-benzene.—The chlorination of 4-fluoro-1,3-*bis*-(trichloromethyl)-benzene[16] was carried out essentially as described for the chloro compounds above, twenty-eight hours being required. Vacuum distillation gave an 82% yield of a colorless oil, b. p. 157.5–159.5° (11 mm.).

Anal. Calcd. for $C_8H_3Cl_6F$: Cl, 64.3. Found: Cl, 64.4, 64.5.

2-Chloro-1,4-*bis*-(trichloromethyl)-benzene[5] was prepared in 79% yield by side-chain chlorination of 2-chloro-*p*-xylene in the manner described above, the crude chlorination product being purified by recrystallization from ethanol, m. p. 78–80°.

Anal. Calcd. for $C_8H_3Cl_7$: Cl, 71.5. Found: Cl, 71.4.

Summary

Some bis-(trichloromethyl)-benzenes containing nuclear halogen have been prepared, and some evidence has been obtained in support of the assigned structures.

(13) The compound was refluxed for eighteen hours with a mixture of 10 ml. of 15% potassium hydroxide solution and 20 ml. of ethanol. After acidification, the chloride ion was determined by the Volhard method.

(14) U. S. Patent 1,796,108; *C. A.*, **25**, 2441 (1931).

(15) This compound has been prepared previously (ref. 6a) but no constants were given.

(16) Balz and Schiemann, *Ber.*, **60**, 1186 (1927).

Chlorination of 1,3-bis-(Trifluoromethyl)-benzenes[1a,b]

BY CHARLES K. BRADSHER AND RICHARD S. KITTILA

In an investigation of methods for the preparation of *bis*-(trifluoromethyl)-benzenes containing nuclear chlorine,[2] the direct chlorination of *bis*-(trifluoromethyl)-benzenes was studied. Recently McBee, Hass, Weimer, Burt, Welch, Robb and Speyer[3] have reported that chlorination in the presence of conventional catalysts, and at temperatures approaching the boiling point of *bis*-(trifluoromethyl)-benzenes is without effect, and this is confirmed by our observations. While it was stated that chloro-*bis*-(trifluoromethyl)-benzenes could be obtained by reaction in the vapor phase at 500°, it was added that "at this high temperature there was extensive chlorinolysis."[4]

We have found that chlorination of *bis*-(trifluoromethyl)-benzenes may be effected readily by carrying out this reaction in an iron reactor at 150–170° and under a chlorine gage pressure of 300 lb./sq. in.

The material used in the majority of our chlorination experiments was a mixture containing both

(1a) This work was sponsored by the Naval Research Laboratory.

(1b) With the exception of the experiment noted, the material contained in this communication is drawn from a thesis submitted to the faculty of the Graduate School of Arts and Sciences for the degree of Master of Arts, November, 1943.

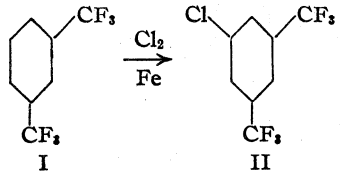
(3) McBee, Hass, Weimer, Burt, Welch, Robb and Speyer, *Ind. Eng. Chem.*, **39**, 387 (1947).

(4) No yields have been mentioned, and it is clear from the text that this process was abandoned as unworkable.

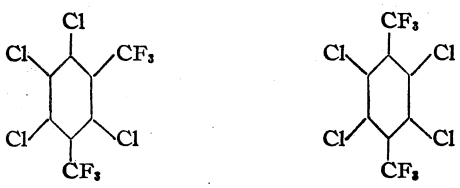
1,3- (I) and 1,4-*bis*-(trifluoromethyl)-benzenes,[5a] but the principal product isolated was 5-chloro-1,3-*bis*-(trifluoromethyl)-benzene[5b] (II), the best yield being 57% (42% conversion).



I II

In each case some material boiling at 170–175° was obtained, and though no chemical individual was isolated with certainty, analysis showed this to consist of dichloro-*bis*-(trifluoromethyl)-benzenes. Similar material could be obtained by the chlorination of either "technical" 4-chloro-[6] or crude 5-chloro-1,3-*bis*-(trifluoromethyl)-benzenes.

Fractionation of the higher boiling material yielded fractions which may have contained trichloro-*bis*-(trifluoromethyl)-benzenes, but no chemical individual other than a crystalline tetrachloro derivative was isolated. The low melting point (47–48°) of the tetrachloro-*bis*-(trifluoromethyl)-benzene suggests that it is 2,4,5,6-tetrachloro-1,3-*bis*-(trifluoromethyl)-benzene (III) rather than the symmetrical 2,3,5,6-tetrachloro-1,4-*bis*-(trifluoromethyl)-benzene (IV).



III IV

The authors are indebted to Dr. Paul M. Gross for his encouragement and many helpful suggestions, to Drs. Marcus E. Hobbs and John H. Saylor for direction of the physical measurements, and to Dr. Carl H. Deal and Miss Virginia Goodbody for most of the physical constants reported.

Experimental

Apparatus.—The reactor used in most of the experiments reported here was made from a 39 in. length of 2.5-in. black iron pipe closed at the bottom by a plate welded on, and at the top by a leaded pipe cap to which was attached a short length of 0.5-in. copper tubing. The copper tubing was connected by flare fittings to a "T" which was provided with a 0–300 lb./sq. in. compressed air gage and a stainless steel exit valve. The gage was protected from the action of the corrosive gas by a coil of 0.25-in. copper tubing, connection being made to the "T" and gage by short lengths of 0.125-in. copper tubing.

General Procedure.—The gage and valve assembly was removed while the reactor was charged through the copper tube at the top with the material to be chlorinated and the apparatus assembled. The end of the tube leading from the exit valve of the reactor was secured to a tank of liquid chlorine and the reactor cooled for one-half to one hour while chlorine distilled into the reactor.

The lower twelve inches of the reactor was next immersed in an oil-bath[7] and the temperature raised. Excess chlorine was valved off until the gage pressure wa 300 lb./sq. in. at the desired bath temperature (usually 150–175°). After heating for a number of hours, the reactor was cooled and the hydrogen chloride and excess chlorine valved off. The gage and valve assembly was removed and the product poured out of the reactor, filtered, washed with dilute acid, dried and distilled.

The reactor was cleaned after each reaction by filling with dilute hydrochloric acid and allowing it to stand for one to three hours. It was rinsed with water and then acetone, and finally dried by evacuation.

5-Chloro-1,3-*bis*-(trifluoromethyl)-benzene.—Using charges of 100–150 ml. of *bis*-(trifluoromethyl)-benzene[5a] and chlorinating for three hours at 150–170°, the best yield of monochloro-*bis*-(trifluoromethyl)-benzene (b. p. 135–145°) obtained under these conditions was 57%, representing a conversion of 42%. Refractionation showed that nearly all of this material boiled at 139–140°, $n^{30}D$ 1.4023, ϵ 3.08. (A sample prepared by the indirect fluorination of 5-chloro-1,3-*bis*-(trichloromethyl)-benzene by the technique of German Patent 575,593 gave: b. p. 138.2–138.3°, $n^{25}D$ 1.4027, ϵ^{23} 3.04.)

Anal. Calcd. for $C_8H_3ClF_6$: Cl, 14.28. Found: Cl, 14.26.

Chlorination of a relatively pure sample of 1,3-*bis*-(trifluoromethyl)-benzene yielded a product boiling at 137.5–138.5°.

Dichloro-*bis*-(trifluoromethyl)-benzene.—(a) By chlorination of *bis*-(trifluoromethyl)-benzene: The chlorination was carried out as in the preparation above except that the reaction was allowed to run longer at slightly higher temperatures. In some cases, the reactor was cooled, the gas pressure released, additional chlorine distilled in, and heating continued for a further period. For example, the chlorination of 280 g. of *bis*-(trifluoromethyl)-benzene for three hours at 175°, recharging with chlorine and heating for an additional four and one-half hours yielded 42% of the dichloro-*bis*-(trifluoromethyl)-benzene (b. p. 167–177°) or a conversion of 39%. This material was refluxed with 6 *M* sulfuric acid to remove hydrolyzable material, washed, dried and redistilled. Most of the material boiled at 173–175°.

(b) By chlorination of "technical" 4-chloro-1,3-*bis*-(trifluoromethyl)-benzene[6]: A small reactor was charged with 67 g. of the 4-chloro-*bis*-(trifluoromethyl)-benzene and chlorinated for two hours at 160–170° to give a 58% yield (45% conversion) of product, b. p. 169–174°.

(c) By chlorination of 5-chloro-1,3-*bis*-(trifluoromethyl)-benzene: Crude 5-chloro-1,3-*bis*-(trifluoromethyl)-benzene (b. p. 135–145°) obtained by chlorination of *bis*-(trifluoromethyl)-benzene was chlorinated for one and one-half hours at 170–185°. The reactor recharged with chlorine and chlorination continued for an additional three hours. An 83% yield (49% conversion) of product (b. p. 168–177°) was obtained.

The material obtained by procedure (a) (b. p. 173–175°) had the properties: $n^{25}D$ 1.4389, ϵ^{27} 2.97, and appeared to be a mixture of isomers.

Anal.[8] Calcd. for $C_8H_2Cl_2F_6$: Cl, 25.06. Found: Cl, 24.75.

(5a) We are indebted to the Hooker Electrochemical Company for this material which is now being manufactured by them on a commercial scale; *cf.* Murray, Beanblossom and Wojcik, *Ind. Eng. Chem.*, **39**, 302 (1947).

(5b) Since this manuscript was submitted but before it was accepted for publication, McBee, Bolt, Graham and Tebbe, THIS JOURNAL, **69**, 947 (1947), have reported some physical properties of 5-chloro-1,3-*bis*-(trifluoromethyl)-benzene; the constants reported are in fairly good agreement with ours. The article referred to indicates that the method of syntheses will be published at a later date.

(6) This material was prepared from monochlorinated technical *meta*-xylene. The low dielectric constant (4.92) suggests that it contains some 2-chloro-1,4-*bis*-(trifluoromethyl)-benzene.

(7) The bath used was made from a larger pipe and was electrically heated by a length of nichrome ribbon insulated with asbestos.

(8) Analysis by Miss Louise Gurney (1947).

Tetrachloro-*bis*-(trifluoromethyl)-benzene.[9]—Chlorination of 238 g. of the dichloro-*bis*-(trifluoromethyl)-benzene obtained above for three hours at 165–215° in the presence of 0.05 g. of aluminum chloride yielded 76 g. of starting material, 55 g. of intermediate fractions (b. p. 180–241°), and finally 31 g. (b. p. 241–244°) which solidified on cooling. Crystallized from ethyl alcohol, it gave colorless crystals, m. p. 47–48°.

(9) Experiment by Jean B. Bond.

Anal. Calcd. for $C_8Cl_4F_6$: Cl, 40.04. Found: Cl, 40.09.

Summary

It has been demonstrated that chlorination of bis-(trifluoromethyl)-benzenes may be effected at elevated temperatures and pressures.

α-Chloro-β-amino Ketones

BY NORMAN H. CROMWELL AND RONALD A. WANKEL

In a previous communication[1] a study was reported concerning the rate of iodine release from acidified potassium iodide solution by α-bromo β-amino ketones prepared from α-bromobenzalacetophenone. These results were compared with those obtained from similar studies with bromobenzylaminobenzylacetophenone hydrobromides prepared by the reactions of 1-benzyl-2-phenyl-3-benzoylethylenimine with wet and dry hydrogen bromide.[1,2] Also recorded was the fact that at room temperature the chlorobenzylaminobenzylacetophenone hydrochlorides, produced by the action of wet or dry hydrogen chloride, gave a slow iodine release. In this latter case no authentic α-halogenated β-amino ketones were available for comparison as had been the case with the bromo series.

Recently considerable interest has been shown in various types of β-chloroethylamines,  .[3] β-Halogenated ethylamines seem to owe some of their unusual chemical and physiological properties to the ability of their solutions to form the very reactive quaternary ethyleneimmonium ions.[4]

In the present investigation certain α-chloro β-amino ketones have been prepared for iodine release studies and for pharmacological investigation.

Piperidine, morpholine and tetrahydroisoquinoline each added readily to both α-chlorobenzalacetophenone and α-chlorobenzalacetone to give the desired α-chloro β-amino ketones. Attempts to add benzylamine or dibenzylamine or tetrahydroquinoline to α-chlorobenzalacetophenone were not successful. These α-chloro β-amino ketones, especially the α-chloro-β-aminobenzylacetophenones, proved to be considerably more stable than the corresponding bromo compounds reported in the previous studies.[4]

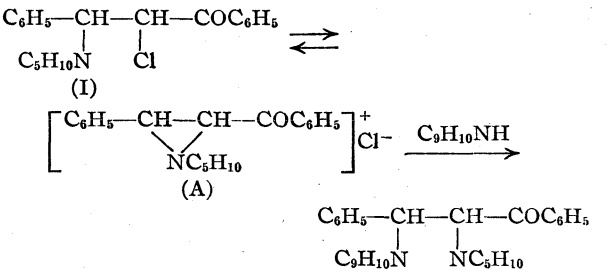
(1) Cromwell and Caughlan, THIS JOURNAL, **67**, 2235 (1945).

(2) Cromwell, Babson and Harris, *ibid.*, **65**, 312 (1943).

(3) For example, the nitrogen mustards, Gilman and Philips, *Science*, **103**, 409 (1946); N,N-dibenzyl-β-chloroethylamine, Nickerson and Goodman, *Federation Proc.*, Feb., 1946, p. 195; N-benzohydryl-β-chloroethylamines, Cromwell and Fitzgibbon, THIS JOURNAL, **70**, 387 (1948).

(4) Cromwell and Cram, *ibid.*, **65**, 301 (1943); Cromwell, *Chem. Rev.*, **38**, 118 (1946).

α-Chloro-β-piperidinobenzylacetophenone (I) was quite stable in absolute alcohol solutions at room temperature, showing little tendency to form the quaternary ethyleneimmonium ion (A), as indicated by the slight reaction of such solutions with silver nitrate after standing fifteen hours. However, this α-chloro β-amino ketone reacted readily with tetrahydroquinoline, as did the analogous bromo ketone,[5] to give a good yield of α-piperidino-β-tetrahydroquinolinobenzylacetophenone.



The hydrochlorides of the α-chloro-β-aminobenzylacetophenones were readily prepared and found to be quite stable in alcohol solution, showing no tendency to rearrange to the β-chloro α-amino ketone hydrochlorides. The hydrochlorides of the α-chloro-β-aminobenzylacetones proved to be too unstable to isolate.

For comparative purposes the reactivity of α,β-dichlorobenzylacetophenone with benzylamine was checked and it was found that the yield of the ethyleneimine ketone was about the same as with dibromo ketones.[6] The molecular weight of this product was determined to eliminate the possibility that this compound might be a piperazine such as

TABLE II

RELEASE OF IODINE BY CHLORO KETONES IN THIRTY MINUTES AT 26° (0.200 G. SAMPLES)

Halogenated ketone	0.0300 *M* $Na_2S_2O_3$, ml. used	required	Per cent. reaction
(III)	1.93	40.40	4.78
(V)	1.35	35.48	3.52
(VI)	0.97	32.38	3.03

As shown in Table II, these various α-chloro β-amino ketones released iodine slowly from acidified potassium iodide solutions at room temperature. At elevated temperatures these compounds reacted with such solutions much more rapidly and at a constant rate. (See Fig. 1 and Table III.) It was also found that the reaction products of 1-benzyl-2-phenyl-3-benzoylethylenimine with wet or dry hydrogen chloride[2] released no iodine under such conditions, and thus both must still be assumed to be β-chloro-α-benzylaminobenzylacetophenone hydrochloride, as was previously decided.[1] This constitutes a method of differentiating between α-chloro β-amino ketones and the very similar β-chloro α-amino ketones.

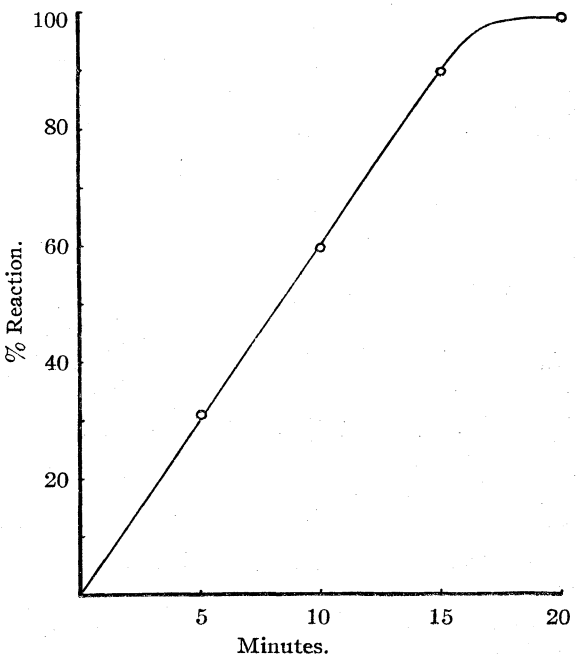

Fig. 1.—Rate of iodine release by (II) at 66°.

Nevertheless, further proof that certain ones of these reaction products of ethylene imine ketones with hydrogen halides actually are β-halogeno α-amino ketone hydrohalides seems to be required. Their very slow reaction with an acidified solution of potassium iodide could conceivably be the result of their being the least reactive of the two possible racemates of the α-halogeno β-amino ketone hydrohalide. This possibility is being investigated.

Experimental[7]

α,β-Dichloro Ketones.—These compounds were prepared by the methods given by Goldschmidt,[8] using an efficient gas–liquid reaction tower, as described by Degering.[9] The yield of α,β-dichlorobenzylacetophenone was the same as previously reported, but the yield of α,β-dichlorobenzylacetone was considerably lower, although the reaction was repeated several times. In a typical experiment, 40 g. (0.274 mole) of benzalacetone was dissolved in 50 ml. of chloroform, cooled to 5° and placed in the glass tower of the chlorination apparatus.[9] Tank grade chlorine gas was bubbled into the solution for one hour. The chloroform was evaporated under reduced pressure to leave an oily solid residue which on recrystallization from absolute alcohol gave 20 g. (33.6% yield) of α,β-dichlorobenzylacetone, m. p. 92–93°. Evaporation of the absolute alcohol solution and vacuum distillation of the residual oil gave 20 g. of α-chlorobenzalacetone, described below.

α-Chlorobenzalacetone.—This compound was obtained in an 83% yield according to the method given by v. Auwers and Brink.[10] The resulting yellow oil distilled at 140–141° at 5 mm. and solidified on cooling in an ice-bath. Recrystallization from petroleum ether (b. p. 60–70°) by cooling to 0° gave large, colorless crystals, m. p. 20–21°.

α-Chlorobenzalacetophenone.—This unsaturated chloroketone was prepared in a 75% yield by the method of v. Auwers and Hügel.[11] The golden yellow oil distilled at 195–200° at 5 mm. and solidified on cooling in an ice-bath. Recrystallization from petroleum ether gave large, colorless crystals, m. p. 29–30°.

Addition of Amines to the α-Chloro Unsaturated Ketones.—Five grams of the α-chloro unsaturated ketone was dissolved in 5 ml. of dry ether and the solution cooled to 0°. A cold solution of an equal molecular amount of the amine in 2 ml. of dry ether and 2 ml. of petroleum ether was added all at once. In five to ten minutes the solution became a solid mass. After standing in the ice-bath for one hour the colorless solid was filtered and washed with petroleum ether. These products were recrystallized by dissolving them in warm petroleum ether and then cooling the solutions to 0°. In this way the α-chloro β-amino ketones (I), (III), (V), (VII), (VIII) and (IX) were prepared (see Table I).

When 0.5 g. of (I) was dissolved in 10 ml. of absolute alcohol and allowed to stand at room temperature for fifteen hours, only a slight precipitate of silver chloride resulted upon addition of alcoholic silver nitrate. The chloro amino ketones (I), (III) and (V) were stable at room temperature for several months, while (VII), (VIII) and (IX) decomposed upon standing for twenty-four hours at room temperature.

Attempts to add benzylamine, or dibenzylamine, or tetrahydroquinoline to α-chlorobenzalacetophenone at various temperatures ranging from −40 to 40° were unsuccessful.

Hydrochlorides of α-Chloro β-Amino Ketones.—Five grams of the α-chloro-β-aminobenzylacetophenone was dissolved in 150 ml. of dry ether and 50 ml. of pure acetone and cooled to 10°. A cold saturated solution of dry hydrogen chloride in dry ether was added slowly with stirring until no further precipitation took place. The colorless solid product was filtered and recrystallized by dissolving in about 40 ml. of alcohol followed by the addition of 120 ml. of dry ether. In this way the hydrochlorides (II), (IV) and (VI) were prepared.

A 0.5-g. sample of (II) was dissolved in 25 ml. of absolute alcohol and allowed to stand at room temperature for forty-eight hours. Addition of 50 ml. of dry ether to this solution gave 0.48 g. of a compound identical with (II) (same m. p. and rate of iodine release).

The hydrochlorides of the α-chloro-β-aminobenzylacetones (VII), (VIII) and (IX) decomposed almost immediately upon isolation from the ether–acetone solutions to give the starting secondary amine hydrochlorides, and thus were not studied.

Reaction of Tetrahydroquinoline with (I).—Three grams (0.00915 mole) of (I) was dissolved in 5 ml. of absolute alcohol and 2.43 g. (0.0183 mole) of tetrahydroquinoline added. This solution was warmed for five minutes on a steam-bath and allowed to stand for forty-eight hours at room temperature. The light yellow product was filtered, washed with water and recrystallized from chloroform and alcohol to give 1.59 g. (41% yield) of yellow crystals, m. p. 166–167°, identical with α-piperidino-β-tetrahydroquinolinobenzylacetophenone,[5] as indicated by a mixed melting point experiment.

Reaction of α,β-Dichlorobenzylacetophenone with Benzylamine.—Nine grams (0.33 mole) of the dichloroketone was mixed with 10 ml. of alcohol and 6 ml. of benzene. This mixture was cooled in an ice-bath and then treated with 10.6 g. (0.097 mole) of benzylamine. Following the previously described procedure,[6] 2.3 g. (23% yield) of a compound, m. p. 107°, identical with 1-benzyl-2-phenyl-3-benzoylethylenimine[2] was obtained.

Mole Weight Determination.—Using 8–12% solutions in benzene and the cryoscopic method, calcd. for $C_{22}H_{19}NO$: 313. Found: 300, 316.

The Determination of Active Chlorine. (a) Reaction with Potassium Iodide at 26°.—Following the directions previously described,[1] the results given in Table II were obtained.

(b) Reaction with Potassium Iodide at 66°.—A mixture of 5 ml. of dry acetone, 5 ml. of absolute alcohol, 0.6 ml. of 3 *N* hydrogen chloride in absolute alcohol, and 16 ml. of 0.2 *N* potassium iodide in 50% absolute alcohol–acetone was brought to reflux temperature in a water-bath. A 0.100-g. sample of the chlorine compound was then dropped into this solution to dissolve immediately. After allowing the solution to reflux for the stated length of time, the flask was removed from the water-bath and 50 ml. of ice-cold water, along with 2 ml. of freshly prepared 2% starch solution was added immediately. The solution was then titrated rapidly with 0.0300 molar sodium thiosulfate until the color changed from blue to colorless (see Table III and Fig. 1).

Summary

1. Piperidine, morpholine and tetrahydroisoquinoline have been found to add readily to both α-chlorobenzalacetophenone and α-chlorobenzalacetone. The stability and reactivity of the resulting α-chloro β-amino ketones have been compared with that of the analogous α-bromo β-amino ketones.

2. The rates of reaction of chloro amino ketones with acidified potassium iodide solution have been studied, and a method of differentiating α-chloro β-amino ketones from β-chloro α-amino ketones proposed.

LINCOLN, NEBRASKA RECEIVED NOVEMBER 24, 1947

(7) All m. p.'s were observed using a strong glass and obtained by placing the sample in the bath about 10° below the m. p. and heating at the rate of 3° per minute. The Isolation of 1,1-Dichloro-2-*o*-chlorophenyl-2-*p*-chlorophenylethane from Technical TDE[1]

BY STANLEY J. CRISTOL[1a] AND H. L. HALLER

The recent discovery of the effectiveness of 1,1-dichloro-2,2-bis-(*p*-chlorophenyl)-ethane (called *p,p'*-TDE or *p,p'*-DDD), as an anopheline larvicide made it desirable to have on hand a supply of its *o,p'* isomer, 1,1-dichloro-2-*o*-chlorophenyl-2-*p*-chlorophenylethane. This compound had been prepared previously by the condensation of chlorobenzene and 2,2-dichloro-1-*o*-chlorophenylethanol,[2] but the synthesis involved a difficultly available reactant, and optimum conditions had not been worked out. Separation of the isomers by fractional crystallization, an operation successful for *o,p'* and *p,p'*-DDT,[2] was also difficult, since both isomers crystallized in similar appearing crystals. The recent successful separation of *o,o'*-DDT from the *o,p'* and *p,p'* isomers,[3] by a procedure making use of the decrease in reactivity toward dehydrochlorination with ethanolic sodium hydroxide caused by the replacement of *para* by *ortho* chlorine atoms, suggested a parallel experiment for the separation of *o,p'*-TDE from *p,p'*-TDE.

A sample of technical TDE was recrystallized, giving pure *p,p'*-TDE. The oil recovered from the mother liquors was treated with ethanolic sodium hydroxide under conditions calculated[4] to effect the dehydrochlorination of substantially all the *p,p'* isomer and expected to leave unreacted most of the *o,p'* isomer. When this mixture of the unreacted *o,p'* isomer and the olefin related to the *p,p'* isomer was treated with chromic anhydride in glacial acetic acid, the olefin was oxidized to *p,p'*-dichlorobenzophenone but the saturated *o,p'*-TDE was not affected. The ketone–ethane mixture was separated by selective adsorption on and elution from activated alumina, the ketone being held more strongly on the column.

The recrystallized *o,p'*-TDE melted at 75.8–76.8°,[2] and was obtained in 7 to 8% yield from the original crude mixture of isomers. Mixed melting points with known samples[2] were not depressed.

Dinitro and tetranitro derivatives of *o,p'*-TDE, m. p. 134–135.5° and 183–185°, respectively, were prepared. Treatment of *o,p'*-TDE with ethanolic potassium hydroxide resulted in elimination of one mole of hydrogen chloride, but the resulting olefin, b. p. 160° (1 mm.), could not be made to crystallize.

The rate constant for the dehydrochlorination with sodium hydroxide of the *o,p'*-TDE was determined in 92.6% (by weight) ethanol at 20.11° (method used same as described earlier),[4] and a value of 0.000144 liter per second per mole (average of two determinations) was obtained. This compares with a value of 0.00567 for the *p,p'* isomer, and again indicates the importance of the steric and/or electrostatic effect of the *ortho* chlorine atom in hindering the elimination reaction.

Experimental

Separation of 1,1-Dichloro-2-*o*-chlorophenyl-2-*p*-chlorophenylethane from its *p,p'*-Isomer.—A two-hundred gram sample of technical TDE was recrystallized from 450 ml. of 95% ethanol. The solid (129 g.) was fairly pure *p,p'*-TDE and was discarded. The solvent was removed *in vacuo*, and the residual oil was taken up in 1200 ml. of 95% ethanol, brought to 20° in a constant-temperature bath, and treated with 800 ml. of 1 *M* ethanolic sodium hydroxide solution at 20° for exactly thirty minutes. The dehydrochlorination reaction was then stopped by the addition of 40 ml. of concentrated nitric acid in 500 ml. of water. Most of the ethanol was removed *in vacuo*, and the resulting mixture was extracted several times with ether. The ether extracts were washed with water, dilute aqueous sodium hydroxide, and saturated salt solution, and were then filtered. The ether was removed by distillation, leaving 60.4 g. of viscous oil.

This oil was taken up in 200 ml. of glacial acetic acid. To the refluxing solution was added 48 g. of solid chromium trioxide in small portions, violent oxidation occurring at each addition, over a period of one to two hours. Refluxing was continued for about fifteen minutes after the addition was complete. The mixture was cooled and poured onto ice. The presence of excess oxidant was shown by testing with potassium iodide–starch paper. The mixture was extracted twice with ether. The combined ether extracts were washed successively with water, dilute base until washings were basic, and saturated salt solution, and were then filtered. Evaporation of the ether left 49.1 g. of a brown solid mixture.

This solid was divided into two portions, and each portion was treated as follows: The solid was dissolved in 200 ml. of petroleum ether (b. p. 60–70°) and adsorbed on an activated alumina column 42 mm. in diameter and 200 mm. high, which had been washed with 200 ml. of petroleum ether. The column was then washed successively with five 200-ml. portions of petroleum ether, two 200-ml. portions of carbon tetrachloride, and two 200-ml. portions of 95% ethanol. The petroleum ether eluates consisted mostly of *o,p'*-TDE, while the later fractions were mostly *p,p'*-dichlorobenzophenone. The combined petroleum ether eluates from both runs weighed 25.0 g. After two recrystallizations from 95% ethanol, 14.8 g. of *o,p'*-TDE, m. p. 75.8–76.8°, was obtained. This is equivalent to 7.4% of the original technical TDE mixture. The melting point of this sample of *o,p'*-TDE was not depressed when mixed with material isolated from technical DDT[2] or obtained by synthesis.[2]

Dinitro-*o,p'*-TDE.[5]—This derivative was prepared by treatment of 500 mg. of *o,p'*-TDE with 5 ml. of fuming

Tetranitro-*o,p'*-TDE.[7]—A mixture of 500 mg. of *o,p'*-TDE, 2.5 ml. of concentrated sulfuric acid, and 2.5 ml. of fuming nitric acid was heated on a steam-bath for one hour. The reaction mixture was cooled and poured onto ice. The resulting solid was recrystallized from acetone–ethanol to constant m. p., 183–185°.

Anal. Calcd. for $C_{14}H_6Cl_4N_4O_8$: N, 11.21. Found: N, 11.14.[6]

***o,p'*-TDE Olefin.**—A solution of 500 mg. of *o,p'*-TDE and 0.4 g. of potassium hydroxide in 20 ml. of ethanol was heated at reflux for three hours. The resulting mixture was poured into water. The mixture was extracted with ether, and the ether extract was washed with water and saturated salt solution and filtered. The ether was evaporated off, leaving a viscous oil. This oil, b. p. 160° (1 mm.), was distilled in a vacuum sublimation apparatus. The product remained as an oil after standing at room temperature for over a year.

Acknowledgment.—We are indebted to the Rohm and Haas Company for a generous supply of technical TDE mixture.

(6) The authors are indebted to Mr. Harlan L. Goering for the nitrogen analyses.

(7) The structure of this compound has not been proved, but it is presumably 1,1-dichloro-2-(2-chloro-3,5-dinitrophenyl)-2-(4-chloro-3,5-dinitrophenyl)-ethane.

Summary

1,1-Dichloro-2-*o*-chlorophenyl-2-*p*-chlorophenylethane (*o,p'*-TDE) has been separated from a mixture with its *p,p'* isomer by a procedure making use of the lowered reactivity with ethanolic sodium hydroxide of the *o,p'* isomer compared with the *p,p'* isomer.

Nitration and dehydrochlorination products of *o,p'*-TDE have been described. The rate constant for the reaction of *o,p'*-TDE with ethanolic sodium hydroxide has been determined.

Lignin. I. Purification of Lignin Sulfonic Acids by Continuous Dialysis

BY QUINTIN P. PENISTON AND JOSEPH L. MCCARTHY

Introduction

Lignin sulfonic acids[1] have several times been separated from sulfite waste liquor and purified by metal or amine salt precipitations.[2] Although dialysis has been employed as a step in some of these procedures, and has been practically considered by Ogland,[3] no detailed study appears to have been made of the degree of purity and extent of recovery of the lignin sulfonic acids attainable by direct continuous dialysis of sulfite waste liquor. This easily conducted procedure was thought worthy of investigation both as a method for laboratory preparation of purified lignin sulfonic acids for research purposes and as a means of characterization of sulfite waste liquor components.

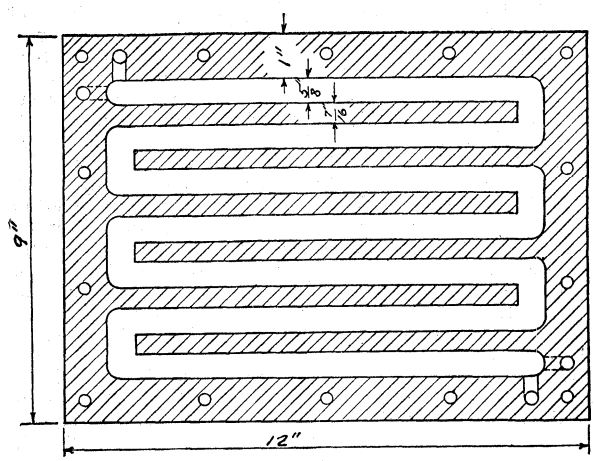

Fig. 1.—Dialyzer plate detail.

Experimental Part

Dialysis Apparatus.—To obtain a high ratio of membrane area to liquor volume and a close approach to true counter-current operation, a multicellular apparatus was constructed from $^1/_8'' \times 9'' \times 12''$ plates of "Plexiglas." This material was chosen for its resistance to chemical attack, dimensional stability in water, workability, and transparency. The last quality is desirable since it aids detection of air blocks or other obstructions to flow. The cells consisted of zig-zag channels $^5/_8''$ wide sawn in the "Plexiglas" plates. Both liquor and water plates were identical except for interplate connections. The design details are indicated in Fig. 1. Fifteen pairs of such plates were used, each pair being isolated by separator plates of $^1/_{16}''$ "Plexiglas." Connections between cells were by means of ports grooved about half through the plates at the ends of the channels. The ports fed into holes which led through membrane and separator to the next appropriate cell. The entire assembly was held between $^1/_4''$ stainless steel plates by means of 14 stainless steel machine bolts.

The total volume of the apparatus amounted to 2780 ml., and the total membrane area to 0.435 square meter. With no bulging of the membrane, the volumes in liquor and water channels were equal.

(3) N. J. Ogland, *Svensk. Papperstidn.*, **47**, 288–291 (1944).

Flows of both sulfite waste liquor and distilled water to the apparatus were from constant head reservoirs through small Alyea[4] flowmeters to open funnel receivers. Pressure on the two channels was independently controlled by adjustment of the height of inlet and outlet tubes. In operation the apparatus was placed with plates horizontal and both channels were filled with water using parallel upflow until all air bubbles were removed. Water was then switched from upflow to downflow and sulfite waste liquor was admitted in upflow in the other channel. Steady state operation was obtained over several days' operation without attention. The addition of small amounts of toluene to the input reservoirs was found effective to prevent growth of microorganisms in the apparatus. These if uncontrolled rapidly caused increase in porosity and failure of the membranes.

The membrane used in these studies was a denitrated nitrocellulose casing produced by the Sylvania Industrial Corporation and obtained from the Brosites Machine Company, New York; sample K 412, thickness (dry) 0.0032 inch.

Sulfite Waste Liquor Samples.—The compositions of sulfite waste liquor samples used in this study are shown in Table I. For sample B the alterations brought about by pretreatment before dialysis are indicated. Important differences between Samples A and B are: the higher amount of total reducing substances and fermentable sugar in Sample A, and the high values for total sulfur and loosely combined sulfur dioxide in Sample B. Both samples were obtained from commercial pulping operations using the same wood source: about 85% Western Hemlock and 15% White Fir. In the production of Sample B a much higher "free sulfur dioxide" concentration was present in the pulping liquor.

TABLE I

COMPOSITION OF SULFITE WASTE LIQUOR SAMPLES

Fermentable sugar, g. glucose/l.[10]	19.05	12.45	...

[a] Sulfated ash. [b] Determined by drying *in vacuo* at 60° on quartz sand.

Method of Calculation of Dialysis Data.—To obtain samples representative of a given set of flow conditions the apparatus was allowed to operate for sufficient time to ensure a steady state condition. Usually a time equivalent to the passage of 2 liters of the more slowly moving fluid was allowed. Samples of dialyzed liquor and dialyzate were then collected over a measured time interval to determine output flow rates. Input flow rates were calculated from a total solids balance. Dialysis rate coefficients and amounts of substances transferred were then calculated from analyses of the effluent samples, the composition of the original liquor and the flow rates established from the total solids balance.

Results and Discussion

The isolation of pure lignin sulfonic acids from sulfite waste liquor by dialysis is dependent on two major factors. Firstly, the non-lignin components, being of relatively low molecular weight, diffuse more rapidly through the pores of the membranes than most of the lignin components, and secondly, the membrane behaves in some degree as an ultra-filter being substantially impermeable to particles above a certain size.

Schwabe and Hasner[11] have shown that for such low molecular weight non-electrolytes, as hexose sugars, the rate of diffusion is determined by Graham's law for certain membranes. With electrolytes in the presence of a high concentration of supporting electrolyte, presumably the dialysis rate is also inversely proportional to the square root of the molecular weight. This relationship has been used by Schwabe and Hasner for estimation of molecular weight of various lignin sulfonic acid preparations. In the absence of extraneous electrolyte, however, potential gradients as well as concentration gradients must be effective in determining the dialysis rate of electrolytic substances. According to Vinograd and McBain[12] the potential gradient in a mixture of electrolytes may be expressed as

$$\frac{d\psi}{dx} = \frac{RT}{F}\left[\frac{\Sigma u_+ G_+/n_+ - \Sigma u_- G_-/n_-}{\Sigma u_+ c_+ + \Sigma u_- c_-}\right]$$

where u_+, u_- are mobilities, G_+ G_- are ionic concentration gradients, c_+, c_- are concentrations and n_+, n_- are valences. An interesting consequence of this relation is that the presence of a high concentration of non-dialyzable high molecular weight lignin sulfonic acid anions should increase the rate of dialysis for low molecular weight anions in the mixture.

In order to aid in the interpretation of dialysis rate coefficients calculated for sulfite waste liquor components, two mixtures of pure substances have been dialyzed under similar conditions using the same dense membrane employed for the sulfite waste liquor experiments. Results with known aqueous mixtures of glucose and sucrose (Table II) dialyzed under four different flow conditions (Experiments 1–4) using newly installed membranes and, again after six weeks of continuous service in sulfite waste liquor dialysis (Experiments 5–8), show (a) that while the free diffusion rate for glucose is 1.37 times that for sucrose,[13] the ratio of dialysis rate coefficients now found for these substances is 1.64 indicating a filtering action by the membrane for molecules as small as sucrose; (b) that apparently the dialysis rate coef-

	$\frac{K_{C_7H_7SO_3Na}}{K_{glucose}}$	1.34	1.43	1.49	1.59

[a] Original mixture: glucose 20.60 g./liter, sodium *p*-toluenesulfonate 22.84 g./liter.

ficients for these non-electrolytes, are not dependent on flow rate, and (c) that only a small change if any occurred in the porosity of the membrane during the entire period.

Similar experiments with known aqueous mixtures of glucose with sodium *p*-toluenesulfonate (Table III) showed that (a) although the two substances are of about the same molecular weight, the electrolyte dialyzed considerably faster than the non-electrolyte and (b) that the dialysis rate coefficient of the electrolyte increases with flow rate.

Since sodium *p*-toluenesulfonate is a salt of a relatively large organic anion, it might be expected that similar effects would occur in dialysis of sodium lignin sulfonates and low molecular weight non-electrolytic substances.

The purification of lignin sulfonic acids by dialysis of sulfite waste liquor Sample A was investigated using five different liquid input flow rates corresponding to five different times for dialysis. Dialyzed liquors and dialyzates were analyzed for total solids, methoxyl, total reducing substances and sulfur. The analytical results and the amounts of each analytically determined constituent dialyzed are shown in Table IV as a function

of the time of dialysis. Limiting values are approached by all constituents which are characteristic of the calcium salts of the purified lignin sulfonic acids. Interpreting the dialysis of methoxyl groups as proportional to that of lignin sulfonic acids, it appears that about 78% of the original lignin sulfonic acids in Sample A are retained by the membrane used irrespective of the time of dialysis. The remainder pass through the membrane at a rate not greatly lower than that for reducing substances and thus are apparently of lower molecular weight. From the above experiments with known substances and from the recent reports by Gralen[14] and by Pennington and Ritter[15] the molecular weight of lignin sulfonic acids pass-

[a] Based on assumption of 35% dialyzable methoxyl.

ing through the membrane is probably not greater than about 2000 and thus these may contain only up to about ten of the structural units postulated by Freudenberg[16] and Hibbert.[17]

The non-dialyzable lignin sulfonic acids may be characterized by a methoxyl equivalent weight (grams of total solids per 31.02 g. of methoxyl). This value for the solids remaining undialyzed was found to decrease with increasing time of dialysis, the data being representable by an equation of the form

$$\text{Methoxyl equivalent weight} = C + A/\text{Time}$$

where A and C are constants. Extrapolation with this relationship of the data to infinite time of dialysis (Fig. 2) suggests a value of about 250 as the methoxyl equivalent weight of the completely purified calcium lignin sulfonate from sulfite waste liquor Sample A. The mole ratio of sulfur, and of the copper reducing value calculated as glucose, to methoxyl in the dialyzed solutions is shown in Fig. 2 as a function of time of dialysis. Both quantities decrease rapidly with increasing purity and approach values of 0.5 mole of sulfur, and less than 0.04 mole of copper reducing groups, per mole of methoxyl, respectively. Thus the nondialyzable lignin sulfonic acids manifest approximately one sulfonic acid grouping for every two structural units. The rate at which the mole ratio of sulfur to methoxyl decreases with increasing purity appears to exclude the possibility that the sulfur-containing impurities can be entirely lignin sulfonic acid salts of higher sulfur content and suggests that they may be, in part, the sulfonic acid derivatives of sugars postulated by Hägglund and Urban[18] and recently studied by Adler.[19]

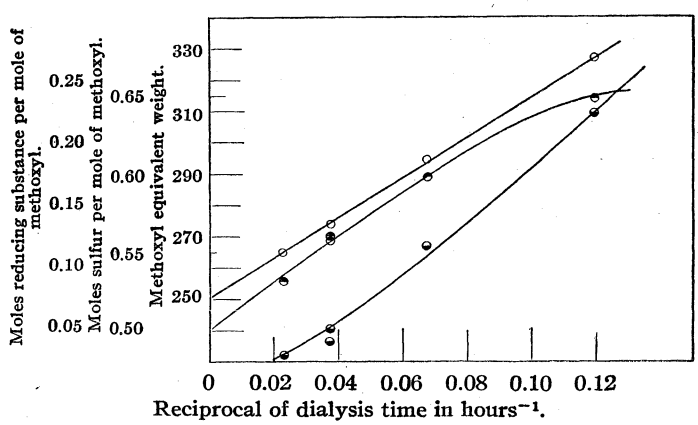

Fig. 2.—Calcium lignin sulfonate composition *vs.* dialysis time: ○, equivalent weight; ◒, sulfur; ◒, reducing substances.

To try to generalize the above trends, a series of experiments was conducted with calcium base sulfite waste liquor Sample B which differs from Sample A in that it was obtained from a separate commercial plant wherein the practice is to use a sulfite pulping liquor very high in concentration of sulfurous acid. In both cases, however, the wood used was the same, namely, about 85%

(19) E. Adler, *Svensk Papperstidn.*, **49**, no. 15 (Aug. 15, 1946).

Western Hemlock and 15% White Fir. Sample B, in its original form, and after conversion by ion exchange to sodium salts (Table I), was dialyzed at various flow rates. The dialyzed solutions were analyzed and dialysis coefficients were computed.

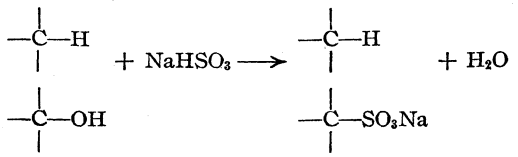
Results (Table V) indicate that dialysis coefficients of electrolyte components of sulfite waste liquor are higher when in the form of sodium salts than as calcium salts. This might be expected from activity considerations.

By extrapolation to infinite time of dialysis of data secured using the sodium salts, it is estimated, on a methoxyl basis, that about thirty-five per cent. of the weight of the original lignin sulfonic acid present in Sample B will dialyze through the membrane, compared to about 22% for Sample A. This evidence for the presence of a larger proportion of lower molecular weight lignin sulfonic acid molecules in the sulfite waste liquor Sample B may correlate with the higher sulfurous acid concentration during the sulfite pulping procedure in this case.

Following completion of these experiments, non-dialyzable sodium lignin sulfonates were prepared by dialyzing Sample B as the sodium salt using a very low flow rate. Also at the conclusion of the above described studies on Sample A, non-dialyzable calcium lignin sulfonates were secured similarly and these were converted to sodium salts by ion exchange. Purified lignin sulfonates A and B were recovered by evaporation to dryness at reduced pressure and then carefully dried under vacuum below 60°. According to Purves[20] erroneous carbon and hydrogen values may result if high temperatures are used. The composition of the two dry samples was found to be

	Sample A (%)	Sample B (%)
Carbon	52.1	50.5
Hydrogen	4.18	3.96
Sulfur	6.66	7.38
Sodium	4.63	4.88
Methoxyl	12.8	12.5

Differences in degrees of sulfonation of these purified non-dialyzable sodium lignin sulfonates can be taken into account to permit comparison of the two samples by calculation of the above analytical data to a sulfur and ash free basis. For such a computation, the mechanism of sulfonation may be postulated either as replacement of one hydroxyl grouping, or else one hydrogen atom, of the lignin for each sulfonic acid grouping becoming attached to the lignin. We have based our calculations on the hydroxyl replacement mechanism, *i. e.*



which yields the following carbon–hydrogen–oxygen–methyl ratios from the experimental data for the average unsulfonated lignin structural unit containing ten carbon atoms

Sample A	$C_{9.00}H_{7.20}O_{2.75}$ $(OCH)_{0.94}$
Sample B	$C_{9.00}H_{7.00}O_{2.84}$ $(OCH_3)_{0.95}$
"Theoretical"	$C_{9.00}H_{7.00}O_{2.75}$ $(OCH_3)_{1.00}$

The "theoretical" ratio given may be secured by assuming that the lignin polymer consists of "*n*" guaiacyl oxygenated propane structural units with the empirical formula $C_{10}H_{10}O_3$ and "3*n*" units with the empirical formula $C_{10}H_{10}O_4$.

Mr. Vincent F. Felicetta's analytical assistance is appreciated.

Summary

1. Lignin sulfonic acids may be isolated in a high degree of purity in about 65 to 80% yield by exhaustive continuous dialysis of sulfite waste liquor.

2. The dialyzable lignin sulfonates are believed to be of molecular weight of less than 2000 and appear to vary in amount depending upon conditions obtaining during the pulping process.

3. Two non-dialyzable lignin sulfonate samples from different commercial sources are found to have nearly the same empirical composition when calculated to a sulfur and ash free basis, and this composition is in agreement with the concept of lignin as a polymer of guaiacyl oxygenated propane structural units.

Lignin. II. Liberation of Phenolic Hydroxyl Groups by Alkaline Cleavage of Lignin Sulfonic Acids

BY QUINTON P. PENISTON AND JOSEPH L. MCCARTHY

The conception of softwood lignin as a polymer of oxygenated guaiacyl propane structural units postulates the occurrence of one phenolic hydroxyl per methoxyl grouping. It has been concluded by most workers within the field that phenolic hydroxyl groupings occur in a free state in at least some structural units of the polymer. Thus, Tomlinson and Hibbert[1] have stated: "The fact that methylated (dimethyl sulfate and alkali) lignin sulfonic acids yield veratric aldehyde affords conclusive proof that the original lignin sulfonic acid contains a free phenolic hydroxyl group," and F. E. Brauns[2] has concluded, from diazomethane methylation studies, that: "...lignin sulfonic acid in addition to the sulfonic group has a free phenolic hydroxyl." Freudenberg and coworkers[3] have suggested that the phenolic hydroxyl group is bound in native lignins by an ether linkage to a secondary aliphatic hydroxyl and that this linkage is broken by sulfonation to yield a sulfonic acid and a free phenolic hydroxyl. From more recent investigations using a technique involving hydrazine reduction of toluene sulfonate esters of phenolic hydroxyl groupings to toluene sulfinate esters, Freudenberg and Plankenhorn[4] have concluded that there are present 0.075, 0.14, and 0.31 free phenolic hydroxyl groups per lignin structural unit in cuproxam lignin, hydrochloric acid lignin, and deacetylated acetic acid lignin, respectively.

To secure further information as to the status of the phenolic hydroxyl groupings in lignin sulfonic acids, conductometric titration studies have now been made of exhaustively dialyzed sulfite waste liquor solutions which, as is established in another communication,[5] consist of salts of lignin sulfonic acids of a high degree of purity.

Experimental Part

Conductometric titrations were conducted in 50% ethanol solution using carbonate-free sodium hydroxide. A 60-cycle Wheatstone bridge circuit with pointer type AC galvanometer was used. The titration cell, of 100-ml. capacity, was constructed with buret delivery tubes and glass stirrer mounted in the lid. This was connected by a ground glass joint to the body containing platinized electrodes. The cell constant was 0.492 cm.$^{-1}$.

Samples from alkali cleavage experiments were adjusted with dilute hydrochloric acid to *p*H 4. A measured excess of standard acid was then added and the samples were boiled to expel carbon dioxide and sulfur dioxide formed by desulfonation of the lignin sulfonic acid. After cooling in stoppered flasks, aliquots were titrated with 0.01 *N* iodine solution to determine residual sulfur dioxide. Weak acids, determined conductometrically on separate aliquots, were corrected for residual sulfite.

Potentiometric titrations were conducted using a Leeds and Northrup glass electrode *p*H electrometer.

Total solids and total sulfur recovery in the fractionation of alkali cleaved lignin sulfonic acid were corrected for sodium sulfate resulting from alkali neutralization by conductometric sulfate[6] determinations.

Other analytical procedures have been described in a separate communication.[5]

Extinction coefficients for the nitroso lignin test were determined using a Coleman Spectrophotometer.

Alkali cleavage experiments were generally conducted in glass apparatus under a reflux condenser using a nitrogen atmosphere. Some experiments were conducted using small stainless steel autoclaves in a constant temperature oil-bath.

The lignin sulfonic acid concentration was generally 20 g. per liter. Free lignin sulfonic acids were prepared from calcium or sodium lignin sulfonate solutions by treatment with an acid regenerated cation exchange resin (Amberlite 1R 100).

Discussion

Typical results with untreated lignin sulfonic acid solutions are illustrated in Fig. 1, which shows comparative conductometric and potentiometric titrations on the same solution of lignin sulfonic acids. From the character of curves obtained, it is clear that only small amounts—certainly less than 0.2 mole per mole of methoxyl of weak acids with *pK* values between 4 and 10—can be contained. Since phenolic hydroxyl groups in lignin sulfonic acids, if free, should fall within this range, the absence, or presence in only low concentrations, of these groupings, is indicated.

However, free phenolic hydroxyl groups do exist in lignin sulfonic acids which have been subjected to an alkaline environment. Such conditions may arise during methylation reactions which have been used to indicate the presence of free phenolic groups[1] and have been found by Karrer and associates,[7] to lead to rapid cleavage of some anthocyanins to simple phenolic substances. Treatment of lignin under more strongly alkaline conditions and at higher temperature yields products which are precipitable with carbon dioxide and thus presumably phenolic in character and under these conditions lignin sulfonic acids yield vanillin and other phenolic substances.

When the lignin sulfonic acid preparation described in Figure 1 was treated with 5% sodium hydroxide at 100° for several time periods, the reaction products showed the conductometric titra-

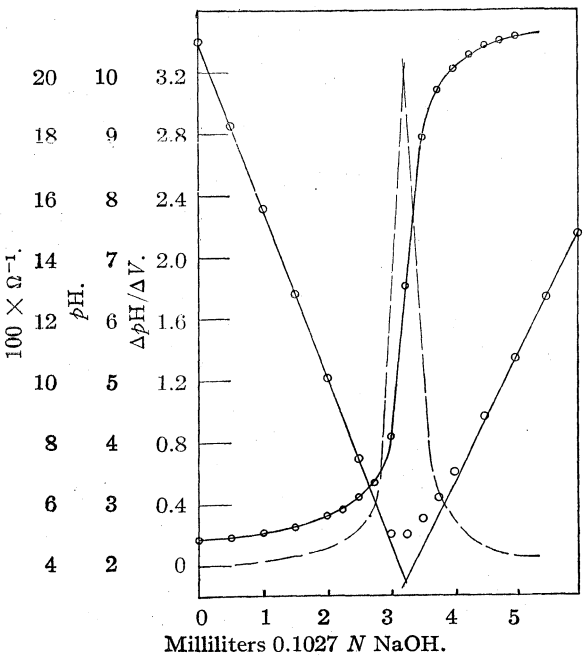

Fig. 1.—Potentiometric and conductometric titrations of lignin sulfonic acid showing low weak acid content: 1.0 ml. NaOH = 0.164 mole of acid per mole of OCH_3.

tion curves given in Fig. 2. After sodium hydroxide addition equivalent to the midpoint of the indicated weak acid lines, all solutions were found to be approximately *p*H 9, indicating that the ionization constants for the acids titrated are in the expected range for phenolic hydroxyl groups. From the above and similar studies on different lignin sulfonic acid preparations, it is concluded that treatment in five per cent. sodium hydroxide solutions at 100°, causes liberation in about two hours of about 0.67 mole of phenolic hydroxyl per mole of methoxyl. Following this there is a more gradual formation of weak acid groups which continues with the time of cleavage.

The rate of the initial phenolic hydroxyl liberation appears to be approximately proportional to the alkali concentration. Thus in aqueous solutions 1% in sodium hydroxide, the rate is found to be roughly one-fifth of that observed in solutions 5% in sodium hydroxide. Also, at the lower alkali concentration, the more gradual acid formation is not discernible. Thus there may be two reactions involved or two different groupings cleaved by the alkaline treatment.

The liberation of phenolic hydroxyl groups in lignin sulfonic acid should result in its increased reactivity in chemical reactions dependent on the presence of active nuclear hydrogen. After alkali treatment there should be evident increased ease of oxidation and of halogenation, increased reactivity in condensation reactions, *e. g.*, with formaldehyde, and in substitution reactions such as coupling with diazonium salts or reaction with nitrous acid. Two such reactions have now been studied in comparison with titration data for the amount of weak acid liberated in alkali cleavage.

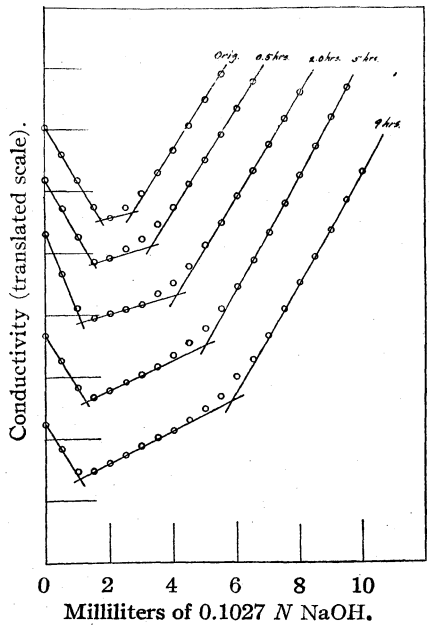

Fig. 2.—Conductometric titrations of L. S. A. after alkali cleavage.

Pearl and Benson[8] have developed a procedure for determination of lignin sulfonic acid in sea water utilizing the color formed by reaction with nitrous acid presumably forming a nitroso lignin. Mr. William G. Westover,[9] in collaboration with H. K. Benson and the authors, has studied the effects of alkali cleavage on the color developed in this reaction.

Pennington and Ritter[10] have recently investigated oxidation of various phenolic substances with periodic acid and have found that substances with guaiacyl nuclei with free phenolic hydroxyl groups are readily oxidized with accompanying demethylation. Dr. Pennington has examined a series of our alkali cleavage samples using the periodate oxidation technique.

Results of the three characterizations of the same series of alkali treated lignin sulfonic acid samples are shown in Fig. 3, in which the conductometric moles of weak acid per mole of methoxyl, the increase in extinction coefficient at 4700 Å. for the nitrous acid reaction product, and the moles of periodate consumed per mole of methoxyl, are each plotted as ordinates against the time of alkali cleavage as abscissa. The three quantities show pronounced increases during the early stages of treatment, indicating an increase in concentration of free phenolic groups. After two hours of treatment, however, there is no further increase in periodate consumption, or in the extinction coefficient, while a continued gradual increase in weak

(8) Pearl and Benson, *Paper Trade J.*, **111**, no. 18, 35–36 (1940).
(9) Westover, B. S. Thesis, University of Washington, 1946.
(10) Pennington and Ritter, THIS JOURNAL, **69**, 187 (1947).

acids is still apparent. It is believed, therefore, that for the experimental conditions used liberation of phenolic groups is substantially complete in two hours, and that generation of other acidic groupings is probably responsible for the subsequent gradual rise in titratable acids. Ritter and Pennington[10] have observed that pure guaiacyl type phenolic substances in general consume three moles of periodate per mole of methoxyl. This would imply that in alkali cleavage under conditions used only two thirds of the potential phenolic hydroxyl groups have been liberated and suggests the possibility that a different type of linkage exists for the remaining third. A similar result is obtained by linear extrapolation to zero time of the gradual weak acid increase. On this basis the amounts of phenolic hydroxyl liberated in the first two hours are in close agreement as determined by periodate consumption or titration (Fig. 3a).

The increase in extinction coefficient for the products of reaction with nitrous acid agrees reasonably well with the assumption that light absorption of the lignin polymer is due to two typical groupings, *i. e.*, structural units with free phenolic hydroxyls, and those remaining as phenolic ethers. The observed extinction coefficient, "K_{obs}," should thus be expressible as a sum of two terms as

$$(C_1 + C_2)K_{obs.} = K_1C_1 + K_2C_2 \qquad (1)$$

where "C_1" and "C_2" represent the molar concentrations of free and combined phenolic hydroxyl groupings per mole of methoxyl, and "K_1" and "K_2" represent the extinction coefficients associated with these respective groupings. If the concentrations of free phenolic hydroxyl found experimentally by periodate oxidation be taken as C_1, then C_2 may be regarded as the difference between unity and C_1. Using values found experimentally by the nitroso technique for the total extinction coefficient, K_{obs}, then the individual extinction coefficients, K_1 and K_2, may be evaluated by simultaneous solution of Equation 1 using data derived from samples hydrolyzed for two different time intervals. Taking K_1 and K_2 as 76 and 20, respectively, calculation of the terms $K_1C_1 + K_2C_2$ as compared to $(C_1 + C_2)K_{obs}$ shows (Table II) satisfactory correlation of the results of the periodate oxidation method with those of the nitroso method except for the original sample in which some phenolic hydroxyl may have been liberated under the alkaline conditions obtaining during the carrying out of the nitroso method.

The liberation of phenolic hydroxyl groups by mild alkaline treatment of lignin sulfonic acid necessarily brings about other changes in molecular structure. If all of the structural units of the lignin polymer are joined together by non-cyclic ether linkages (such as in Formula I), simple cleavage of these ethers would result in conversion of the polymer to the monomer. However, if furan or pyran rings are involved (such as in Formula II), reduction in molecular weight would require not only liberation of the phenolic hydroxyl but also rupture of carbon to carbon bonds.

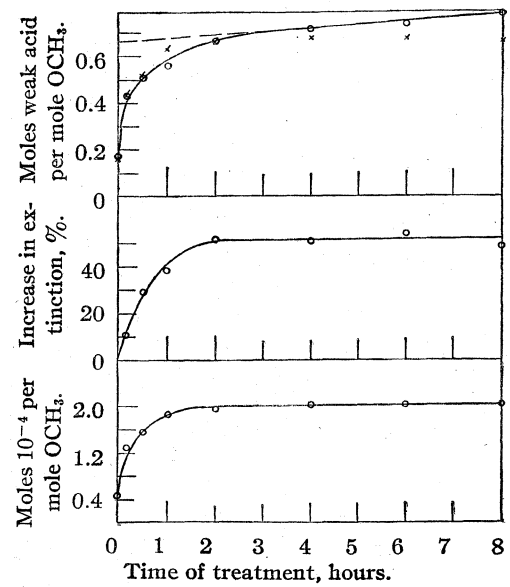

Fig. 3.—Phenolic hydroxyl liberation by alkali cleavage.

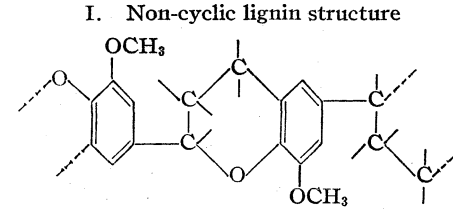
I. Non-cyclic lignin structure



II. Cyclic lignin structure

To investigate alteration in molecular size and other changes associated with the alkaline treatment, a fractionation of lignin sulfonic acid after five hours of treatment with 5% sodium hydroxide solution at 100°, has been conducted. Fraction A, which is first apparent after about three hours of treatment and increases with time of the alkali

reaction, is insoluble in water under neutral conditions and after its separation, the remaining soluble Fraction B was dialyzed exhaustively following the same procedure and with the same membranes initially used for preparation of the lignin sulfonic acids from sulfite waste liquor. The non-dialyzable residue (Fraction B-1), the dialyzate (Fraction B-2), and Fractions A and B were then analyzed to determine total material, methoxyl and sulfur balances.

TABLE II

FRACTIONATION OF ALKALI CLEAVED LIGNIN SULFONIC ACIDS

Fraction	Fraction A	Fraction B	Fraction B-1	Fraction B-2
Per cent. of total material	19.1	68.5	32.4	32.3
Per cent. of total sulfur	10.0	58.5	21.5	31.9
Per cent. of total methoxyl	22.5	72.3	36.0	29.7
Extinction coefficient	43	61	49	73

Although considerable material losses occurred particularly in isolation of the peptizable Fraction A, results (Table II) show insoluble Fraction A to be strongly desulfonated (from about 0.50 in the lignin sulfonic acid before alkaline cleavage, to about 0.22 mole of sulfur per mole of methoxyl in Fraction A). The soluble non-dialyzable residue Fraction B-1 is desulfonated to a lesser degree (0.43 mole of sulfur per mole of methoxyl) while the soluble dialyzable Fraction B-2 retains practically the same proportion of sulfur as the original lignin sulfonic acid (0.54 mole of sulfur per mole of methoxyl). Extinction coefficients indicate that a considerable proportion of the phenolic hydroxyl groups remains combined in Fractions A, B, and B-1, while in the dialyzate Fraction B-2 all phenolic hydroxyl groupings appear to be free. That about one-third of the lignin sulfonic acid is readily dialyzable after alkali cleavage whereas the original material had been isolated as a non-dialyzable residue using the same membrane material, appears to demonstrate a substantial decrease in molecular weight for this fraction. Other indications of reduced molecular weight in cleavage products have been obtained from observations of a reduction in specific viscosity.

The liberation of only two-thirds of the potential phenolic hydroxyl groups of lignin sulfonic acid by alkali treatment and the apparent simultaneous formation of sulfonated fragments of lower molecular weight suggest that more than one type of linkage between structural units must exist in the lignin polymer.

The authors are indebted to Mr. Vincent F. Felicetta for analytical assistance.

Summary

1. Examination of a sample of purified lignin sulfonic acids by conductometric and potentiometric titration methods has indicated the absence, or the presence in only low concentrations, of free phenolic hydroxyl groupings in the material as it exists in sulfite waste liquor.

2. By mild alkaline hydrolysis of purified lignin sulfonic acids, weakly acidic groupings are formed which show a pK value of about 9 and are regarded as phenolic hydroxyl groupings.

3. Periodate oxidation studies, and the extent of "nitroso-lignin" formation, as well as conductometric analyses, indicate phenolic hydroxyl liberation by mild alkaline treatment of lignin sulfonic acids.

4. From periodate oxidation values and also conductometric titrations apparently only about 0.67 mole of phenolic hydroxyl per mole of methoxyl are liberated by alkali treatment under the conditions used. The presumed remaining phenolic groups (0.33 mole per mole of methoxyl) thus appear to be bound in a more stable type of linkage.

5. Alkaline hydrolysis of lignin sulfonic acid brings about a decrease in molecular weight of some fractions of the acids, and this and other evidence indicates that more than one type of bond serves to combine structural units in lignin sulfonic acid.

The Hydrolysis of Some β-Alkoxypropionitriles[1]

BY ROBERT V. CHRISTIAN, JR.,[2] AND R. M. HIXON

The usual method employed heretofore in the preparation of β-alkoxypropionic acids has involved the hydrolysis[3] of an ester[4] of the desired acid. A variation was introduced by Jones and Powers[5] who obtained sodium β-methoxypropionate from the action of excess sodium methoxide upon β-chloropropionic acid. A single reference to β-alkoxypropionitriles as precursors of acids of this type appears as a patent[6] describing the hydrolysis of di-(2-cyanoethyl)-ether as a step in the preparation of esters of di-(2-carboxyethyl)-ether, although the free acid was not characterized. It should be noted, too, that Kilpi[7] carried out kinetic studies on the hydrochloric acid hydrolysis of β-methoxy- and β-ethoxypropionitrile but did not isolate the products of the reactions.

In the present work, some of the now easily available β-alkoxypropionitriles were examined as intermediates for the preparation of acids of the β-alkoxypropionic type.

Experimental[8]

Materials.—1,4-Pentanediol was prepared by hydrogenation[9] of γ-valerolactone. The other alcohols and glycols were commercially available products which were purified by distillation when necessary. The acrylonitrile (Eastman Kodak Co. Practical Grade) was used without further treatment.

β-Ethoxypropionitrile was prepared by the method of Koelsch.[10] Utermohlen's procedure,[11] employing 40% potassium hydroxide as the catalyst, was followed in the synthesis of the other monofunctional nitriles. Those which have not been described heretofore are listed in Table I with pertinent information. The preparation of 1,4-di-(2-cyanoethoxy)-pentane has been described.[12] The other bifunctional nitriles were obtained in accordance with the procedure of Bruson and Riener.[13]

Alkaline Hydrolysis of β-Alkoxypropionitriles.—1,4-Di-(2-cyanoethoxy)-pentane, when refluxed with 10% sodium hydroxide in the usual manner, gave an undistillable and uncrystallizable oil of neutral equivalent 177 (calculated for the expected dibasic acid, 124). Similar treatment of di-(2-cyanoethyl)-ether with 24% sodium hydroxide gave material from which neither di-(2-carbamylethyl)-ether[13] nor the disodium salt of di-(2-carboxyethyl)-ether[14] could be obtained by suitable procedures.

β-Ethoxypropionic acid[3b] could not be identified as a product of the hydrolysis of β-ethoxypropionitrile with 22% sodium hydroxide. Upon distillation of the reaction products under reduced pressure, partial decomposition took place and a colorless distillate was collected. This liquid liberated carbon dioxide from dilute sodium bicarbonate and reduced alkaline 2% permanganate. The substance polymerized upon standing to form a transparent, elastic solid which was insoluble in ethanol or chloroform but dissolved slowly in sodium bicarbonate solution, with evolution of carbon dioxide, to yield a clear solution of unusually high viscosity.

[a] By micro Kjeldahl.

Acid Hydrolysis of β-Alkoxypropionitriles.—The procedure consisted in heating a mechanically stirred mixture of the β-alkoxypropionitrile and twice the calculated quantity of concentrated hydrochloric acid. Only representative experiments are described below. Yields of the liquid acids were based upon the neutral equivalents of the once-distilled compounds. Analytical data and physical constants were obtained upon material purified by fractional distillation using a 20-cm. Vigreux column. The information is summarized in Table II. The yields of the solid acids were determined from the neutral equivalents of the crude products whereas recrystallization to constant melting point furnished analytical specimens. These data are presented in Table III.

The monobasic acids were characterized, when possible, by preparation of solid *p*-bromophenacyl esters (Table IV) in accordance with a standard procedure.[15] Thionyl chloride, followed by cold, concentrated ammonium hydroxide, served to convert the dibasic acids to amides (Table V), of which several have been prepared recently by other methods.[13,16]

β-*n*-Propoxypropionic Acid.—A mixture of 79.1 g. (0.7 mole) of β-*n*-propoxypropionitrile and 140 g. (1.4 moles) of concentrated hydrochloric acid was stirred and heated for three hours at 70–80° and then for thirty minutes at 100°. The reaction mixture was evaporated to dryness *in vacuo* with heating on a water-bath. The product was taken up in acetone (or ether) and filtered. The residual ammonium chloride was washed several times with the solvent. Distillation gave 74 g. of colorless liquid boiling at 117–123° (13 mm.) and having the neutral equivalent 130. This represents a yield of 80%.

The corresponding ethoxy-, isopropoxy-, *n*-butoxy-,

isoamyloxy-, *s*-amyloxy-, and 2-methoxyethoxy-compounds were prepared by this method.

β-Isobutoxypropionic Acid.—β-Isobutoxypropionitrile (76.2 g., 0.6 mole) was stirred with 120 g. (1.20 moles) of concentrated hydrochloric acid for four hours at 75–80°. The cooled reaction mixture was diluted with sufficient water to dissolve the precipitate of ammonium chloride. The organic layer was separated and the aqueous solution was extracted with ether. Distillation gave 63 g. of material boiling at 105–110° (5 mm.). The neutral equivalent, 157, indicated a yield of 67%.

The *s*-butoxy- and allyloxy- derivatives were prepared in a similar fashion.

1,3-Di-(2-carboxyethoxy)-propane.—A stirred mixture of 98 g. (0.54 mole) of 1,3-di-(2-cyanoethoxy)-propane and 216 g. (2.16 moles) of concentrated hydrochloric acid was heated at 70–80° for four hours and then at 100° for thirty minutes. The mixture was evaporated to dryness *in vacuo* and extracted with warm acetone. Evaporation of the acetone solution under reduced pressure gave 118.5 g. of sirup which crystallized to a white solid (melting

point 65–77°) upon standing overnight. The neutral equivalent was 123, indicating a yield of 90%.

Di-(2-carboxyethyl)-ether, 1,2-di-(2-carboxyethoxy)-ethane, and di-(2-[2-carboxyethoxy]-ethyl) ether were prepared by this method.

Acid Hydrolysis of 1,4-Di-(2-cyanoethoxy)-pentane.—A stirred mixture of 40 g. (0.19 mole) of 1,4-di-(2-cyanoethoxy)-pentane and 76 g. (0.76 mole) of concentrated hydrochloric acid was heated for five hours at 80–90°. Extraction with chloroform gave 40.5 g. of uncrystallizable oil of neutral equivalent 199. This material was esterified by refluxing with absolute ethanol containing a trace of dry hydrogen chloride. Upon distillation the principal fraction consisted of 13 g. of colorless liquid which contained chlorine and was shown by the ferric hydroxamate test[17] to be an ester. The physical constants were boiling point 109–112° (2.5 mm.), d^{25}_4 1.0325, and $n^{25}D$ 1.4386.

The presence of chlorine in the product suggested that cleavage at an ether linkage might have occurred during the hydrolysis. Under the conditions of the experiment this would likely lead to the formation of an ethyl β-(chloroamyloxy)-propionate. The analytical data lend support to this hypothesis.

Anal. Calcd. for $C_{10}H_{19}O_3Cl$: MR_D, 56.63; C, 53.9; H, 8.60; Cl, 15.9. Found: MR_D, 56.75; C, 53.6; H, 8.82; Cl, 15.2.

1,4-Di-(2-carbethoxyethoxy)-pentane.—Sixty grams (0.16 mole) of coarsely pulverized 1,4-di-(2-cyanoethoxy)-pentane bis-(ethyliminoester hydrochloride)[12] was added in small portions to 200 ml. of distilled water at room temperature. The addition was carried out over a period of twenty minutes and the mixture was stirred continuously. The solid dissolved readily and no change in temperature was observed, but an oil began to separate at once. The mixture was finally heated at 45° for thirty minutes, cooled, and extracted with ether. Distillation of the dried ether extract gave 28 g. (58%) of colorless liquid of boiling point 142–145° (0.5 mm.), d^{25}_4 1.0174, and $n^{25}D$ 1.4363.

Anal. Calcd. for $C_{15}H_{28}O_6$: sapn. equiv., 152.2; C, 59.2; H, 9.27. Found: sapn. equiv., 151.4, 152.4; C, 59.5; H, 9.54.

Alcoholysis of 1,4-di-(2-cyanoethoxy)-pentane by the methods of Spiegel[18] and Sabetay[19] gave complex mixtures. 1,4-Di-(2-carbethoxyethoxy)-pentane was obtained in 33% yield, however, by a modification of the procedure described by Kimball, Jefferson and Pike[20] for the preparation of ethyl α-phenylacetoacetate.

With a view to characterization of 1,4-di-(2-carbethoxyethoxy)-pentane by conversion to the sodium salt of the corresponding acid, an attempt was made to saponify the ester by gentle warming with the calculated quantity of alcoholic sodium hydroxide. The experiment was abandoned when the reaction mixture began to exhibit a strong odor of ethyl acrylate.

Discussion

The fact that lower yields of β-alkoxypropionitriles were obtained from secondary alcohols is in agreement with the observations of Utermohlen.[11] Furthermore, it was found unnecessary to employ external cooling to hold the reaction temperature below 40° during the addition of *s*-butyl alcohol and *s*-amyl alcohol to acrylonitrile. This suggests a lower reaction rate or a lower heat of reaction for the secondary alcohols.

Failure to obtain the expected products in the three cases in which β-alkoxypropionitriles were treated with aqueous alkali was unexpected, inasmuch as other investigators have successfully employed basic hydrolysis for the conversion of the cyanoethyl derivatives of active methylene compounds,[21] isatin,[22] pyrrole[23] and ammonia[24] to the corresponding acids. It has been established, however, that the base-catalyzed reaction of an alcohol with acrylonitrile produces an equilibrium mixture which contains, in addition to the β-alkoxypropionitrile, appreciable quantities of the reactants.[10] It is suggested that under the conditions of the basic hydrolytic experiments herein described, partial decomposition of the β-alkoxypropionitriles into their generators took place with subsequent formation of complex hydrolysis mixtures. It is deemed significant that one of the products of the basic hydrolysis of β-ethoxypropionitrile exhibited properties suggestive of acrylic acid or one of its derivatives. Hollihan and Moss[25] have reported that acrylonitrile reacts with commercial viscose solutions to form cyanoethyl ethers of cellulose xanthate, and that during the aging process the latter are hydrolyzed by the approximately 3% sodium hydroxide normally present to form carboxyethyl ethers. These hydrolysis conditions are, of course, much less drastic than those employed in the present study.

Although no attempt was made to determine optimum conditions, hydrolysis in acid media appears to be a fairly general method for the conversion of β-alkoxypropionitriles to the corresponding acids. Slightly lower yields were obtained in the preparation of the β-*s*-alkoxypropionic acids and there was a general decrease in yield as the size of the alkyl group increased. No attempt is made to explain the cleavage which apparently took place upon hydrolysis of 1,4-di-(2-cyanoethoxy)-pentane with hydrochloric acid.

The monobasic β-alkoxypropionic acids were colorless liquids having little or no odor. They were all soluble in the common organic solvents. The ethoxy-, isopropoxy-, allyloxy- and 2-methoxyethoxy- derivatives were easily soluble in water whereas β-*n*-propoxypropionic acid was only slightly so. None of the higher homologs were appreciably soluble in water.

The dibasic acids of the β-alkoxypropionic type were very soluble in water, thus displaying, by comparison with acids of similar molecular weight but having a carbon chain uninterrupted by oxygen, the striking effect of the ether linkage upon solubility. These acids were soluble in acetone or ethanol but insoluble in petroleum ether. Di-(2-carboxyethyl)-ether was highly soluble in ether, but insoluble in benzene. 1,2-Di-(2-carboxyethoxy)-ethane was insoluble in ether and slightly soluble in benzene. 1,3-Di-(2-carboxyethoxy)-

propane was insoluble in ether, but easily soluble in warm benzene.

Summary

1. Six hitherto undescribed β-alkoxypropionitriles have been prepared.

2. A reaction mechanism is proposed to account for the fact that alkaline hydrolysis of β-ethoxypropionitrile, di-(2-cyanoethyl)-ether and 1,4-di-(2-cyanoethoxy)-pentane failed to yield the expected β-alkoxypropionic acids.

3. A series of monobasic and dibasic acids of the β-alkoxypropionic type was prepared by acid hydrolysis of the corresponding nitriles. The acids were characterized, when possible, by the preparation of suitable solid derivatives. The dibasic acids and several of the monobasic acids are described for the first time.

4. Hydrolysis of 1,4-di-(2-cyanoethoxy)-pentane with hydrochloric acid yielded a chlorine-containing acid which was isolated as the ethyl ester. The analysis of this ester was in close agreement with that calculated for an ethyl β-(chloroamyloxy)-propionate.

5. Hydrolysis of 1,4-di-(2-cyanoethoxy)-pentane-bis-(ethyliminoester hydrochloride) or ethanolysis of 1,4-di-(2-cyanoethoxy)-pentane at low temperatures gave 1,4-di-(2-carbethoxyethoxy)-pentane.

Decompositions of Di-*t*-alkyl Peroxides. III. Kinetics in Liquid Phase

BY JOHN H. RALEY, FREDERICK F. RUST AND WILLIAM E. VAUGHAN

In the first papers of this set,[1,2] the decomposition of di-*t*-butyl peroxide in the vapor phase was shown to be a clean-cut, first order process, the rate determining step of which was the scission of the peroxy-oxygen linkage. The resultant radicals, *t*-butoxy and the methyl derived therefrom, can react with copresent molecules by steps which follow the generally accepted patterns of chain initiation, propagation and termination. This work has now been extended to a study of decompositions in condensed phases.

It is well established[3a,b,4,5] that the rate of decomposition of benzoyl peroxide varies profoundly with the solvent; further, the first order rate is complicated by higher order processes which become increasingly important at higher concentrations. In contrast, the present work reveals that even in such diverse solvents as cumene, *t*-butylbenzene and tri-*n*-butylamine, the rates of decomposition of di-*t*-butyl peroxide are closely the same and, importantly, nearly equal to that in the vapor phase. Likewise the energies of activation in solution and vapor are approximately equivalent. This implies, obviously, that the same simple dissociation step is rate determining in all cases.

Although these condensed environments do not alter the rate, their differing abilities to donate hydrogen atoms give rise to varying amounts of *t*-butyl alcohol in relation to acetone in the competing steps 2 and 3a

$$(CH_3)_3CO{-}OC(CH_3)_3 \longrightarrow 2(CH_3)_3CO- \quad (1)$$

$$(CH_3)_3CO- + R'H \longrightarrow (CH_3)_3COH + R' \quad (2)$$

$$(CH_3)_3CO- \longrightarrow (CH_3)_2CO + CH_3 \quad (3a)$$

$$CH_3 + R'H \longrightarrow CH_4 + R' \quad (b)$$

Further, in all of the solvents, with increasing temperature the *t*-butoxy radical increasingly dissociates to acetone and methyl (3a). The data permit a rough estimate of the difference in the activation energies of the steps 2 and 3a for the hydrocarbon solvents.

Experimental

Materials

Di-*t*-butyl peroxide, prepared by the method of Vaughan and Rust[6] and vacuum distilled ($n^{20}D$ 1.3890), was used for both the decomposition experiments and calibration of the infrared spectrograph. By titration it analyzed 98% pure. The several solvents were chosen for convenience of boiling points (avoidance of undue pressure build-up in the bombs), obtainability, ease of purification and, importantly, differing abilities as hydrogen donors to free radicals. Commercial **cumene** was carefully distilled and a fraction of b. p. 152° and $n^{20}D$ 1.4912 was collected and stored under nitrogen. ***t*-Butylbenzene** (Eastman Kodak Co.) was similarly treated (b. p. 169°, $n^{20}D$ 1.4922). **Tri-*n*-butylamine** (Eastman) was treated with 3 *N* hydrochloric acid and the water-insoluble impurities removed; the amine was regenerated with aqueous sodium hydroxide, washed, dried, and distilled (b. p. 214°; $n^{20}D$ 1.4291).

Method

The decompositions were carried out in heavy-walled glass bomb tubes (capacity 40 cc.) in an oil-bath regulated to ±0.1°. The seven or more bombs for a given experiment were filled from a stock solution of the peroxide in the particular solvent, chilled, evacuated, sealed, and immersed. After a short equilibration period, they were withdrawn at specified intervals, quenched, and prepared for analysis. They were then opened in an inert atmosphere, the density of the solution determined by pycnometer, and analysis performed by infrared spectrometry. Time "zero" is defined as the time of withdrawal of the first sample. Duplicate experiments were performed in nearly all cases.

Evidence that the decomposition is independent of the

vapor volume in the tubes was obtained from the following pair of experiments. Two sets of bombs were charged with a stock solution of the peroxide in cumene, one set having a vapor volume of 35% and the other 66%. The decompositions were then carried out at 135 ± 0.1° to at least 50% completion. The first order constants were 5.1 and 5.2 × 10^{-5} sec.$^{-1}$, respectively, and the *t*-butyl alcohol–acetone ratios, 1.51/0.49 = 3.1 and 1.41/0.59 = 2.4.

Analysis

Analyses were performed by an infrared spectrometric procedure developed for di-*t*-butyl peroxide and its decomposition products, acetone and *t*-butyl alcohol. The bands utilized in the method are found at the (uncorrected) wave lengths of 11.46 μ, 5.88 μ and 2.925 μ, respectively. Tests showed the method to be applicable in the three solvents studied. Since the spectral procedure yields concentrations in terms of unit volume, the density of the sample was needed for conversion to terms of unit weight. This basis is used for expressing concentrations since the weight rather than the volume or total number of moles remains constant throughout the decomposition. The weight of methane which could escape when the bombs were opened was negligible.

Results

Figure 1 gives an example of the precision of measurement in several runs and Fig. 2 that of the correlation of a set of experiments. The reaction is first order to conversions as high as 85% (Fig. 3). In Table I are summarized all of the data and included therein are corresponding values for the vapor phase for the sake of ready comparison. The small variation of the rates in the four media at a given temperature is striking and argues

strongly for the unimolecularity of the decomposition,[7] especially in light of the large differences in the fate of the *t*-butoxy radicals. There is a slight trend of k with concentration (Table II), but this variation is no greater than that exhibited by the decomposition of nitrogen pentoxide in carbon tetrachloride.[8]

TABLE II

DECOMPOSITION OF DI-*t*-BUTYL PEROXIDE IN CUMENE

Temp. 135.0 ± 0.1°

Initial concentration (moles/kg. soln.)	$k \times 10^5$[a] (sec.$^{-1}$)
0.455	4.9 ± 0.4
0.799	5.2 ± .1
1.62	5.0 ± .2
2.35	5.7 ± .4

[a] Calculated from data for the first 50% decomposition.

The regular behavior in tri-*n*-butylamine is especially interesting in view of Nozaki and Bartlett's[3,9] finding of explosive reactions of benzoyl peroxide in nitrogen-containing solvents. Di-*t*-butyl peroxide does not behave as an oxidizing agent in the usual sense of the expression.

(7) For comparison with the thermal decomposition of N_2O_5 in various solvents, see F. Daniels, "Chemical Kinetics," Cornell University Press, Ithaca, N. Y., 1938, pp. 100–107.

(8) Eyring and Daniels, THIS JOURNAL, **52**, 1472 (1930).

(9) Also private communication from Dr. Nozaki.

The trends in the stoichiometries enable one to calculate roughly the differences in the activation energies of the steps 2 and 3a. The values of $(E_{3a} - E_2)$ are *ca.* 16 kcal. for cumene and 11 for *t*-butylbenzene. It should be mentioned that calculation shows that step 3a is endothermic to the extent of *ca.* 5 kcal.

Acknowledgment.—The authors wish to thank Mr. William R. Harp and Dr. Robert S. Rasmussen of the Spectroscopic Department of this Company for their extensive coöperation, without which the analytical procedures would have been far more complicated and less accurate. Thanks are also due Mr. Charles E. Fuller and Miss Betty J. Benell for their assistance.

Summary

The small variation in the first order rates of decomposition of di-*t*-butyl peroxide in cumene, *t*-butylbenzene and tri-*n*-butylamine solution and in the vapor state is strong evidence that the same process is rate-determining in all cases. This is thought to be unimolecular scission of the peroxy-oxygen linkage. With increasing temperature the *t*-butoxy radicals become more subject to loss of methyl rather than abstraction of hydrogen from solvent molecules.

Effect of Salts on the Solubilization of Insoluble Organic Liquids by Cetylpyridinium Chloride

BY PAUL H. RICHARDS AND JAMES W. McBAIN

Solutions of colloidal electrolytes and of similar non-electrolytic detergents have the power of dissolving otherwise insoluble substances by putting them into or upon the colloidal micelles of the detergent. Salts promote the formation of colloidal micelles of the detergent. Salts promote the formation of colloidal micelles and probably change even their sizes and relative proportions. Therefore they also affect solubilization. Heretofore[1–6] salts have always been reported to enhance solubilization, as well as produce it in solutions of detergents otherwise too dilute to contain colloidal particles.

Materials.—The detergents used in these experiments were cetylpyridinium chloride, obtained in very pure form through the courtesy of Wm. S. Merrell Company, Emulsol 607L (Emulsol Corporation), and Triton X-100 (Röhm and Haas); compare previous publications using these detergents.[3,5,7] The relative effects of a number of detergents with a series of insoluble organic liquids has already been reported.[7]

The organic compounds used were benzene (Kahlbaum "K," thiophene free), *n*-octane (Eastman Kodak Co.) and *n*-octyl alcohol (Eastman Kodak), as well as others previously referred to.[7] The salts employed in the investigation were Kahlbaum sodium and potassium chloride "zür Analyse."

Method.—The method of determining the solubilization of the organic compound by the detergent has been fully described.[7] The turbidimeter was used to detect the saturation or inflection point where solubilization in the clear solution was complete, and any excess of organic liquid began to appear as emulsified droplets. The solutions were shaken in a thermostat maintained at 25° for from ten to twenty hours before readings were taken. The solutions of the detergent and of the salts were prepared at double the desired concentration and 5 cc. of each solution was pipetted

into the reacting bottle to make up a 10 cc. solution of the desired concentration.

As in the previous work, the results were expressed in terms of mole to mole ratio, that is, moles of the organic material solubilized per mole of detergent. The sources of error were the same as previously described. All normalities are volume normalities, N_v.

Results

The initial experiment was to prepare a solution that was 0.1 N in respect to the detergent and 1 N in respect to sodium chloride. It was found that in a few minutes the detergent was precipitated from the solution. This "salting out" of the detergent did not occur when dilute solutions of the salt were used; it began between 0.25 N and 0.5 N sodium chloride with 0.1 N cetylpyridinium chloride. Salting out of detergent depends on its concentration as well as upon that of the salt.[8] Instead of discarding this precipitated solution (1 N sodium chloride, 0.1 N cetylpyridinium chloride), a few drops of benzene were added and the solution was shaken overnight. It was found that the solution had become clear. The turbidimeter reading of this solution was identical with the reading of a 0.1 N detergent solution. This phenomenon is similar to that observed by Lawrence,[9] who found that small amounts of water-insoluble materials cleared up cloudy soap solutions. He called the phenomenon "peptization." However, it is observed that what happens is the spontaneous formation of stable colloidal particles of detergent solubilizing the insoluble benzene, a process that proceeds with positive affinity, that is, diminution of free energy. The benzene promotes the formation of these colloidal particles of detergent which otherwise could not have gone into solution in the presence of the salt. Peptization is merely the separation and protection of aggregates of previously existing particles.

The following results all refer to the solubility of benzene in 100 cc. of aqueous solution. In 0.1 N cetylpyridinium chloride it is 1.88; this includes the small amount, 0.08 cc., molecularly dissolved, but the greater portion of the benzene, 1.8 cc., is solubilized by the detergent. In the same solution, but containing 1 N sodium chloride, 2.5 cc. was dissolved and solubilized. (However, only 0.18 cc. was required to bring the detergent into solution in this mixture. Even the filtrate from a mixture of 1 N sodium chloride and 0.1 N detergent without benzene possesses some solubilizing action because the total solubility of benzene therein was 0.26 cc.)

From the above data it is seen that once the detergent is brought back into solution by the benzene the solubilizing power of the solution with salt, 2.5 cc., exceeds that of the original solution without salt, 1.88 cc.

Table I presents the data for the solubilization of the aliphatic hydrocarbon octane, the aromatic hydrocarbon benzene, and the polar compound octyl alcohol, with and without various additions of sodium and potassium chloride. All results for solubilization in this paper are corrected for the solubility of benzene in pure water (see Table I of ref. 7). For benzene this may be an over-correction in dilute solution because it makes the ratio moles liquid/moles detergent appear to pass through a minimum. The results of Table I are graphically presented in Fig. 1. From the figure it is seen that potassium chloride has the larger effect on the solubilization of benzene in dilute solutions of detergent, and sodium chloride at higher concentrations, but the curves cross at 0.19 N where they are therefore equal. The results also clearly show that the addition of salts increases the solubility of the hydrocarbons, but that it equally definitely, and quite strongly, depresses the solubilization of the octyl alcohol. However, in the case of benzene above a certain concentration of added salt the solubilization begins to be again depressed and there is a slight indication that a similar result might occur with octane in

In Table II the concentration of cetylpyridinium chloride is varied and two concentrations of sodium chloride are added, and again the same effects of enhancing solubilization of the hydrocar-

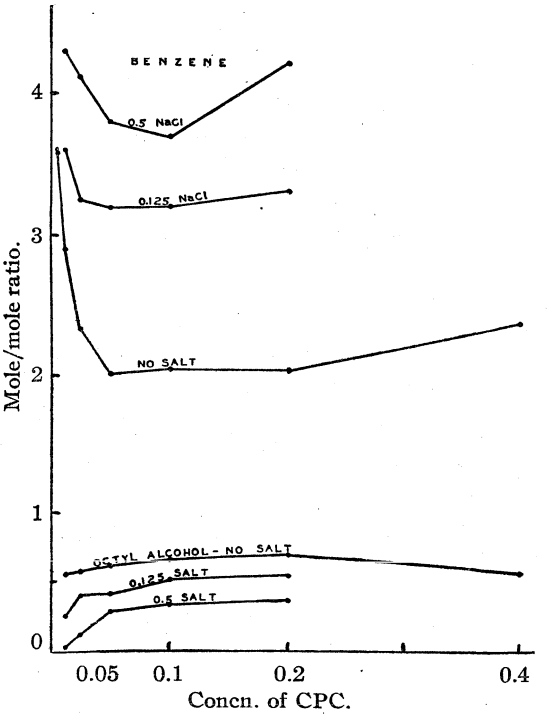

Fig. 2.—Effect of varying concentration of sodium chloride and of cetylpyridinium chloride on the solubilization of benzene and octyl alcohol.

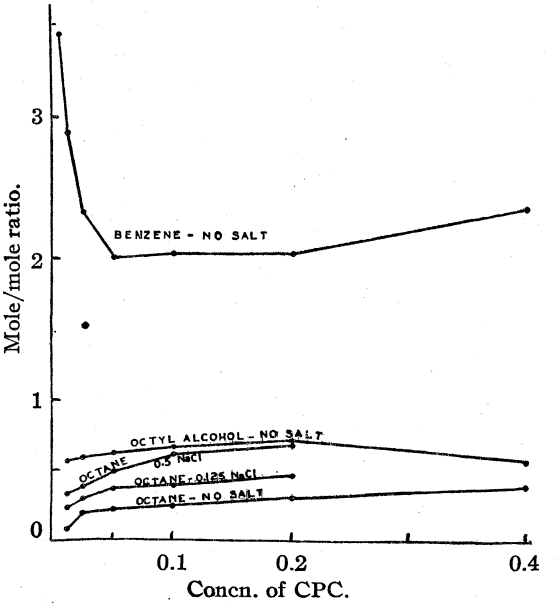

Fig. 3.—Effect of varying concentration of sodium chloride and of cetylpyridinium chloride on the solubilization of octane. Two curves from Fig. 2 are repeated for comparison.

bons, benzene and octane, but of lowering that of octyl alcohol, are noted in all cases, as appears in Figs. 2 and 3.

Discussion

In a dilute solution of detergent one can readily understand favorable effects of added salt because the salt increases the amount of colloid present, as is also shown by the decrease of the osmotic coefficient of the detergent.[10] However, even in dilute solution of detergent the reduction of solubilization of octyl alcohol by added salt is in the opposite direction. It is a requirement of the mass law that in more concentrated solution practically all of the detergent (apart from Gegenions) is already in colloidal form, and the osmotic coefficient is rather increased than decreased. Hence it is clear that the added salt has changed the micelles.

One of us (J. W. M.) has long maintained that many kinds, shapes and sizes of colloidal micelles must occur simultaneously in a soap solution, the relative amounts being determined by such factors as concentration, temperature and presence of added salts or solubilized or other matter. Any manner in which ions, ion pairs or molecules of detergents can associate with a diminution of free energy (including such factors as surface energy, hydrogen bonding or cybotaxis of the solvent), will produce a micelle in competition with all other conceivable micelles of greater and less free energy. Hence, in any given solution all types and sizes of micelles must be present, their relative amounts being determined by the conditions just indicated. Hess and collaborators and McBain have elsewhere given diagrammatic sketches of numerous kinds of small micelles, including the McBain ionic micelle, which may, and probably do, occur.

In most cases of solubilization, the amount solubilized per unit amount of detergent increases from zero at zero concentration of detergent, quite appreciably before the so-called critical concentration is reached; and it rapidly grows to an approximately constant value, but finally increases rapidly again in more concentrated solution where the detergent micelles are evidently more effective solubilizers. In all examples hitherto published, salt has increased the solubilization, first in dilute solutions by producing colloid with which to solubilize, and in more concentrated solutions by promoting or stabilizing those sizes and kinds of micelles which are most effective. Wherever tested, the well known X-ray evidence has indicated that the solubilized material expands the micelles, and in the case of lamellar X-ray micelles much of the solubilized material lies between the hydrocarbon layers, completely shut away from the solvent. This is the only way in which the observed increase in long spacing has been explained.

Now, however, we have a clear case in octyl alcohol where the salts, in all concentrations of detergent and of salt, *lower* the solubilization. We therefore suggest that with this polar compound, the solubilization occurs on or between the *polar* ends of the micelles that are exposed to the water. Hence the salt is now in competition with the solubilized material at the polar ends of the detergent molecules and interferes with its solubilization. Salt itself is sorbed by the micelles.[11]

Benzaldehyde gives results similar to octyl alcohol. With 0.1 *N* cetylpyridinium chloride alone, the mole:mole ratio is 1.94, but in the presence of 0.5 *N* sodium chloride the solubilization is lowered to a mole:mole ratio of only 0.61.

Some Solubilization Data for Detergents without Salt.—The results set forth in Tables III and IV supplement (and in a few instances repeat) those previously reported.[7] In the former investigation thirty-five organic liquids were solubilized by dodecylamine hydrochloride, sodium

TABLE III

SOLUBILIZATION BY 0.1 *N* CETYLPYRIDINIUM CHLORIDE AT 25°

Material	Total in 100 cc. solution	G. solubilized	Mole/mole ratio

oleate and potassium laurate, and seven of the thirty-five were solubilized by Emulsol 607L and cetylpyridinium chloride. Tables III and IV of the present paper also include solubilization of 8 additional organic liquids by a non-ionic detergent, Triton X-100. Not shown in the tables are the results of solubilization of amyl valerate and of 1-chloronitropropane by decinormal Emulsol 607L at 25°, namely: 0.44 and 1.14 cc. total in 100 cc. solution, or 0.39 and 1.40 g. solubilized, or 0.25 and 1.14 mole ratio, respectively.

The order of solubilization by the six detergents of this and the previous study is maintained for most of the forty-three organic liquids tested, with comparatively minor exceptions or specificities. The non-ionic detergent Triton X-100 is the poorest solubilizer. Next comes potassium laurate. Then come, near together, sodium oleate and Emulsol 607L (one anionic and the other cationic). Much the best are the cationic dodecylamine hydrochloride and cetylpyridinium chloride.

It may have been over-emphasized in the previous publication[7] that high molecular weight of compounds undergoing solubilization hinders their solubilization. This is very true within any one homologous series, and it is emphasized when the volume or percentage solubilized is calculated in mole ratios. However, high molecular weight may be offset for such compounds as oleic acid by their belonging to an homologous series that is especially readily solubilized. Thus, although the mole ratio may be very small the actual volume or weight percentage solubilized may be quite comparable with that of such substances as *n*-decane.

Warren W. Woods and Dr. J. V. Robinson (Stanford Laboratories, unpublished) have found that castor oil is appreciably solubilized in lubricating oil by Aerosol OT, and similarly, sulfonated castor oil was solubilized in lubricating oil by Lead Aerosol OT.

Summary

1. Solubilization of organic liquids in solutions of the cationic detergents cetylpyridinium chloride and Emulsol 607L, and the non-ionizing Triton X-100 have been determined. The results, in general, follow the same order for different liquids as was previously described for three other detergents, dodecylamine hydrochloride, sodium oleate and potassium laurate. The non-ionic detergent Triton X-100 was the poorest solubilizer, and the best were the cationic cetylpyridinium chloride and dodecylamine hydrochloride.

2. Whereas all previous studies have shown that added salts greatly enhance solubility, and this is confirmed for the solubilization of benzene and octane by cetylpyridinium chloride, it is found that the solubilization of the polar compounds octyl alcohol and benzaldehyde is greatly depressed by the addition of sodium or potassium chloride. It is suggested that whereas with hydrocarbons and many other organic liquids solubilization occurs in the hydrocarbon portion of the micelles, with these polar compounds the solubilization occurs at the polar ends of the detergent molecules in the micelles.

The Polarographic Reduction of Gadolinium

BY SHERMAN W. RABIDEAU AND GEORGE GLOCKLER

On the basis of a dual wave obtained in the polarographic reduction of 0.01 *M* solutions of scandium, yttrium, and the rare earth sulfates without supporting electrolyte, Noddack and Brukl[1] concluded that the reduction proceeded first to the bivalent state and then to the metal. Leach and Terrey[2] observed a single wave in solutions of scandium chloride with 0.1 *N* potassium chloride as the supporting electrolyte. With additions of 1/6 *N* hydrochloric acid, the single wave gradually separated into two waves. The first wave was found to be due to the reduction of hydrogen ions while the second was attributed to the deposition of scandium.

Kolthoff and Lingane[3] expressed doubt that the double wave observed by Noddack and Brukl[1] corresponded in each case to the bivalent state, and suggested that it may have been caused by the discharge of hydrogen from the hydrolyzed solutions. This study was undertaken in an attempt to establish the half-wave potentials of gadolinium and to investigate polarographically the possibility of the existence of a bivalent state for this rare earth.

Experimental Procedure

The Sargent Model XX visible recording polarograph, the characteristics of which have been previously described by Lingane,[4] was used to record the current–voltage curves. The initial and span potentials were determined potentiometrically since the voltmeters supplied with the instrument are not of the requisite accuracy. All polarograms were recorded for uniformity with the damping control in position 5. An Erlenmeyer type flask served as the electrolysis vessel when the mercury pool anode was used. An H-cell of the design described by

(4) Lingane, *Ind. Eng. Chem., Anal. Ed.*, **18**, 734 (1946).

Lingane and Laitinen[5] was used in all other cases. The temperature was maintained at 25.0 ± 0.1°. Oxygen was removed from the solutions with nitrogen or hydrogen. With the exception of the waves recorded using the mercury pool anode, all diffusion currents have been corrected for the residual currents, and the half-wave potentials were corrected for the *iR* drop in the cell. Because of the lag of the recorder, and the difficulty of measuring the diffusion currents, the reported half-wave potentials are believed to be reliable within ±0.01 volt.

A spectrographic analysis of the rare earth confirmed the presence of traces of europium. Small amounts of terbium in the sample are suspected because of the disappearance of the brown color of the oxide in a reducing atmosphere. Because of the limited sample of rare earth it was necessary to recover the gadolinium for subsequent analyses. The gadolinium was precipitated as the oxalate in dilute hydrochloric acid solution, and ignited to the oxide. Before use in preparing a solution for polarographic analysis, the sample was carried through the oxalate–oxide conversion twice to remove salts of the supporting electrolyte and gelatin. The oxide was chosen as the weighing form, and precautions were taken to avoid the interference of carbon dioxide and moisture. The sulfate solutions were prepared from the dry oxide by adding an excess of sulfuric acid, evaporating to dryness, and finally heating to complete removal of fumes of sulfur trioxide. The desired molarities were obtained by dilution with conductivity water.

Experimental Results

The procedure of Noddack and Brukl[1] was followed in an attempt to repeat their work with regard to the polarographic reduction of gadolinium. A 0.01 *M* solution of gadolinium sulfate was electrolyzed using a mercury pool anode. A polarogram of the type illustrated in Fig. 1 was obtained. It is of interest to note that the step height of the wave is much less than would be predicted on the basis of results obtained with supporting electrolyte present. Though Noddack and Brukl[1] reported values of −1.810 and −1.955 volts *vs.* the N.C.E. for the *Knickpunkt* of the two waves, the results of Fig. 1 indicate that the second wave is not sufficiently well enough defined to establish the existence of a second reduction step.

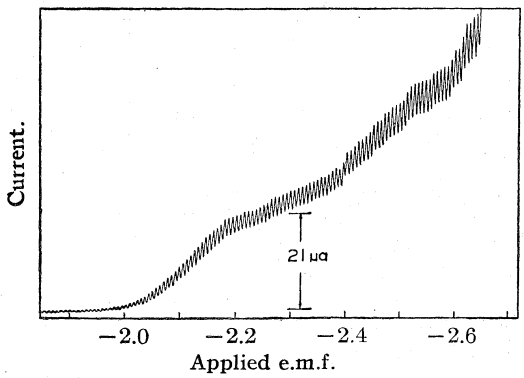

Fig. 1.—0.01 *M* gadolinium sulfate without supporting electrolyte: mercury pool anode.

The polarographic behavior of gadolinium sulfate was studied with a supporting electrolyte of 0.1 *N* lithium chloride plus 0.01% gelatin using the H-cell. A single well-defined wave was obtained with a linear relationship observed between the concentration and the diffusion current (Table I).

(5) Lingane and Laitinen, *Ind. Eng. Chem., Anal. Ed.*, **11**, 504 (1939).

TABLE I

GADOLINIUM SULFATE IN 0.1 *N* LITHIUM CHLORIDE PLUS 0.01% GELATIN

Millimoles of Gd^{+3} per liter	$E_{1/2}$ *vs.* S. C. E. volts	$m^{2/3}t^{1/6}$	i_d microamp.	i_d/c	I_d
0.80	−1.74	1.693	5.1	6.4	3.8
1.60	−1.74	1.758	10.1	6.3	3.6
4.00	−1.77	1.716	26.2	6.6	3.8

To note the effect of additions of acid on the current-voltage curves, increasing quantities of 0.05 *N* hydrochloric acid were added to 14 ml. of 4.00 millimolar Gd^{+3}. As the solution became more acidic, the hydrogen wave increased proportionately with the half-wave at −1.5 volts *vs.* the S.C.E., but the wave height due to the reduction of gadolinium was not appreciably affected. The half-wave potential of gadolinium was shifted to more negative values with increasing acid concentration as shown in Table II.

TABLE II

EFFECT OF ACID ON THE HALF-WAVE POTENTIAL OF GADOLINIUM IN 0.1 *N* LITHIUM CHLORIDE PLUS 0.01% GELATIN

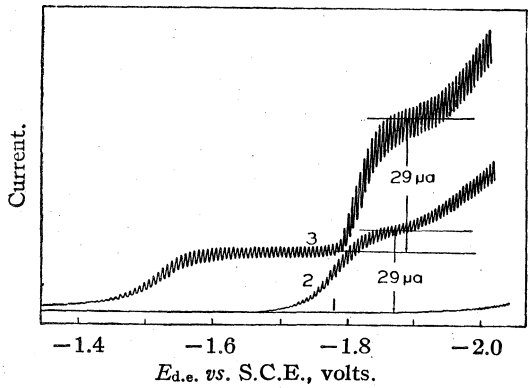

Fig. 2.—Gd^{+3} in 0.1 *N* tetramethylammonium iodide plus 0.01% gelatin: (1) residual current; (2) 4.0 millimolar; (3) 0.30 ml. of 0.05 *N* HCl added to 14 ml. of 4.0 millimolar.

The wave definition in a supporting electrolyte of 0.1 *N* potassium chloride was about the same

as that observed with lithium chloride. The results of the polarographic reduction of gadolinium sulfate in potassium chloride are given in Table III.

TABLE III

GADOLINIUM SULFATE IN 0.1 *N* POTASSIUM CHLORIDE PLUS 0.01% GELATIN

Millimoles Gd^{+3} per liter	$E_{1/2}$ S. C. E. volts	$m^{2/3}t^{1/6}$	i microamp.	i_d/c	I_d
0.80	−1.75	1.780	5.2	6.5	3.9
1.60	−1.75	1.788	10.3	6.4	3.6
4.00	−1.77	1.728	26.9	6.7	3.7

Discussion

The values of the quantity $m^{2/3}t^{1/6}$ were determined at the potential at which the diffusion current was measured. The average value of the diffusion current constant, I_d, for Gd^{+3} was found to be 3.7. Using equivalent conductance data given by Pascal,[6] and extrapolating to infinite dilution, a value of 125 ohm^{-1} $cm.^2$ was obtained for gadolinium sulfate. If the value 80 is used for the sulfate ion, the equivalent ionic conductance of gadolinium is then 45 ohm^{-1} sq. cm. By substituting the value of the ionic conductance of gadolinium into the Nernst relation

$$D_i^0 = 2.67 \times 10^{-7} (\lambda^0/Z)$$

the diffusion coefficient is found to be 4.0×10^{-6} sq. cm. sec^{-1}. With the above quantities substituted into the Ilkovic equation, the number of electrons involved in the electrode reaction is found to be three. Thus the results indicate that the reduction of gadolinium at the dropping electrode takes place according to the reaction

$$Gd^{+3} + 3e \longrightarrow Gd^0$$

An analysis of the polarographic waves was made by noting the slope of the line produced in plotting values of log $i/i_d - i$ *vs.* $E_{d.e.}$ The irreversibility of the electrode reaction is indicated by the fact that the slope is not as steep as would be expected on the basis of a three electron reduction.

(6) Pascal, "Traité de Chimie Minérale," Masson et Cie., Éditeurs, Paris, 1933.

Summary

1. The results of Noddack and Brukl were not confirmed with regard to the polarographic reduction of gadolinium sulfate.

2. An increasing acid concentration shifts the half-wave potential of gadolinium to more negative potentials.

3. A value of 4.0×10^{-6} sq. cm. $sec.^{-1}$ was calculated for the diffusion coefficient of Gd^{+3} at 25°.

4. The results indicate that the reduction of gadolinium at the dropping mercury electrode involves three electrons.

5. The average value of the diffusion current constant for Gd^{+3} was found to be 3.7 at 25° in a supporting electrolyte of 0.1 *N* lithium chloride or 0.1 *N* potassium chloride.

6. The half-wave potential for 4.0 millimolar Gd^{+3} was found to be −1.77 volts *vs.* the S.C.E. with 0.1 *N* lithium chloride, and with 0.1 *N* potassium chloride as the supporting electrolytes.

Reduction of Neodymium at the Dropping Mercury Electrode

BY C. R. ESTEE AND GEORGE GLOCKLER

The polarographic behavior of neodymium in the presence of supporting electrolyte has not previously been described. The present study was undertaken to allow the application of the Ilkovic equation[1] to obtain the *n*-value for the reduction of the trivalent neodymium ion, and to establish under proper polarographic conditions the half-wave potential for the reduction. No evidence of the previously reported[2] two-step reduction from water solutions was obtained.

Experimental

The polarograms were recorded with a Sargent Model XX Visible Recording Polarograph of the Heyrovsky type, the design and operating characteristics of which have recently been discussed by Lingane.[3] A conventional dropping mercury cathode assembly was used, the stand tube being provided with an adjustable mercury reservoir. The usual H-type electrolysis vessel[4] with a sintered glass plug and agar bridge was employed. Measurements were made with respect to a mercury anode. Solution temperatures were maintained at 25.0 ± 0.1° by means of a thermostat. The drop time was varied between two and five seconds. Hydrogen or nitrogen was bubbled through the solution to remove dissolved oxygen.

The neodymium salt was obtained as the nitrate and an examination of the absorption curve found with a Bell and Coleman spectrophotometer showed no detectable impurities. Neodymium oxide was prepared by ignition of the oxalate precipitated from a warm acid solution of the nitrate. The oxide was treated with an excess of sulfuric acid and heated for eight hours at 440° to give the octahydrate of neodymium sulfate. Solutions of supporting electrolytes prepared from analytical grade reagents showed no detectable impurities.

Diffusion coefficients of 6.03×10^{-6} sq. cm./sec. for the neodymium ion and 8.15×10^{-6} sq. cm./sec. for

(4) Lingane and Laitinen, *ibid.*, **11**, 504 (1930).

neodymium sulfate were calculated by means of conductance data[5] and the Nernst equation.[6]

Half-wave potentials were measured in the usual manner, with all values being calculated with respect to the saturated calomel anode and corrected for the iR drop in the cell to an accuracy of ± 0.01 volt.

Data and Discussion

No Supporting Electrolyte.—No indication of the double waves (Inset, Fig. 1) reported by Noddack and Brukl[2] was found; a single wave (Fig. 1) resulted when water solutions of neodymium sulfate were reduced at the dropping mercury electrode. The suggestion[7] has been made that the first wave reported by Noddack and Brukl[2] might be due to the discharge of hydrogen ion from the hydrolyzed solutions. However, although fresh solutions of both neodymium and praseodymium sulfate were slightly acidic, no indication of such a wave could be found. Recent work by Thomas and Kurbatov[8] with yttrium likewise makes doubtful the existence of the two-step waves reported by Noddack and Brukl.[2]

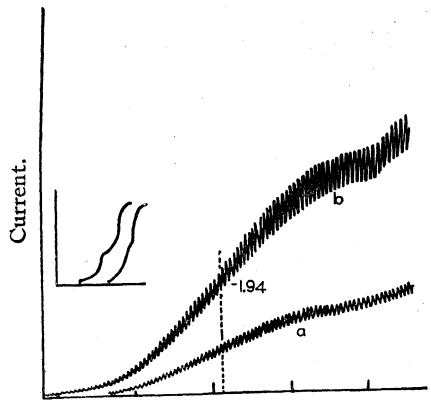

Fig. 1.—Neodymium sulfate, 4.0 molar, no supporting electrolyte. Inset shows curves of Noddack and Brukl.[2]

Lithium Chloride as Supporting Electrolyte.—The half-wave potential was found to vary with the concentration when lithium chloride (0.01% gel added) was used as the supporting electrolyte; no consistent linear relationship between step height and concentration was observed (Table I). The variation in the step heights is probably caused by the simultaneous deposition of hydrogen and neodymium. To separate the two waves sulfuric acid was added to the solutions; as the concentration of acid increased, the hydrogen preceded and was well separated from the neodymium wave (Fig. 2). With the use of

electrolyte; the apparent second wave in the range −1.94 to −2.04 being characteristic of the supporting electrolyte used. In the absence of

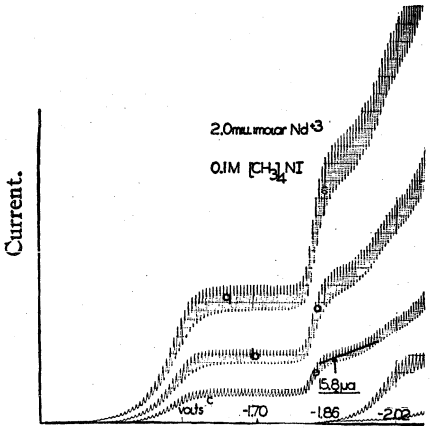

Fig. 4.—Acid solution with tetramethylammonium iodide: recorder sensitivity, (a) 3–75; (b) 3–50; (c) 3–25.

acid, variations in half-wave potentials and diffusion currents occur (Table III) which are not evident when a 2.0 millimolar acid solution is used (Table IV). These data serve to indicate that in neutral media the measured diffusion currents are the result of the simultaneous deposition of neodymium and hydrogen since the measured currents are larger than those expected by the application of the Ilkovic equation. When acid is added to cause a definite prewave due to hydrogen the measured diffusion currents are less than those predicted on the basis of the Ilkovic equation; this is to be expected. The diffusion current constant (I_d) obtained in 2.0 millimolar sulfuric acid solution agrees closely with the theoretical value of 4.46 obtained if the reaction at the electrode is assumed to be $Nd^{+3} \rightarrow Nd^0$.

TABLE III

NEUTRAL SOLUTION OF 0.1 M TETRAMETHYLAMMONIUM IODIDE AS SUPPORTING ELECTROLYTE (0.1% GEL ADDED)

2.0	15.6	16.0	4.32	−1.83
2.0	15.9	16.0	4.41	−1.83
0.8	6.4	6.4	4.48	−1.83
.8	6.4	6.4	4.46	−1.83
.4	3.1	3.2	4.26	−1.83
.4	3.2	3.2	4.45	−1.83

Other Supporting Electrolytes.—A single step curve (Fig. 5) was obtained from potassium chloride solutions; half-wave potential was −1.83 from a 2.0 millimolar sulfuric acid solution of 0.1 M potassium chloride. Again the single step indicates the reduction $Nd^{+3} \rightarrow Nd^0$. Ammonium chloride was not satisfactory as a supporting electrolyte, the curves being poorly defined.

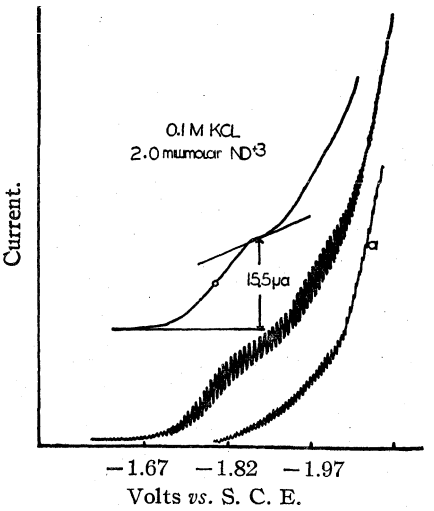

Fig. 5.—Neutral potassium chloride solution: (a) residual current.

Summary

A single wave is obtained from water solutions of neodymium sulfate; this is in contradiction to the results of earlier investigators. Similar single waves are obtained when lithium chloride, tetramethylammonium iodide or potassium chloride is used as supporting electrolyte.

By means of the Ilkovic equation it is shown that the reduction corresponds in all cases to $Nd^{+3} \rightarrow Nd^0$.

The half-wave potentials are found to be dependent upon the concentration and acidity of the solution. From solutions of the above-mentioned electrolytes containing 2 millimoles of sulfuric acid per liter (with 0.01% gel added) diffusion currents

proportional to the concentration of neodymium ion were obtained. The half-wave potentials remained constant in the range studied (0.01 *M* and below) at -1.83 ± 0.01 volt *versus* the saturated calomel electrode in all cases.

IOWA CITY, IOWA RECEIVED JUNE 9, 1947

[CONTRIBUTION FROM THE DEPARTMENT OF CHEMISTRY AND CHEMICAL ENGINEERING, STATE UNIVERSITY OF IOWA]

The Half-Wave Potential of Samarium

BY ANDREW TIMNICK AND GEORGE GLOCKLER

Noddack and Brukl[1] who studied the electrolytic decomposition of 0.01 molar rare earth sulfate solutions, containing no supporting electrolyte, report that samarium undergoes a two-step reduction at the dropping mercury electrode. In an earlier report[2] outlining the progress of the work, Brukl announced their intentions of publishing the inflection points, (Knickpunkte) of the *c–v* curves representing the stepwise reduction of the rare earth ions. In the discussion following the report, Hohn[2] suggested that if the half-wave potentials[3] of the steps were reported, the results would be expressed as a reproducible constant which is independent of concentration. It was also suggested that if an indifferent electrolyte were added to the solutions the diffusion current[4] or step height would be directly proportional to the concentration. The advice evidently was disregarded for only the inflection points were reported.[1]

Holleck[5] electrolyzed 0.02 molar samarium chloride solutions, without supporting electrolyte, at the dropping mercury electrode but his interest was the detection of the conversion of the samarium ion from one isoelectronic form to another. He obtained single and double waves, the form varying with methods of preparation of the salt, the temperature of the solution being electrolyzed and with the addition of zinc chloride. Neither half-wave potentials, nor diffusion currents were reported. Divalent samarium compounds have been prepared.[6,7] It is known that samarous ions are stable in aqueous solutions under limited conditions. A two-step reduction can logically be predicted.

The present study was undertaken to evaluate the diffusion current and half-wave potentials of samarium ion from its chloride and sulfate solutions. The influence of concentration, *p*H and supporting electrolyte was also observed.

Experimental Procedure

A 0.02 molar samarium chloride stock solution was prepared with C. P. $SmCl_3 \cdot 6H_2O$. Spectrographic examination indicated only traces of gadolinium and europium. Samarium sulfate was prepared by converting the chloride to the oxide followed by the conversion to the sulfate. This was done by adding excess sulfuric acid to the oxide, heating the resulting mixture to 450° on a hot-plate until the excess acid was decomposed, and followed by heating in a regulated furnace at 600° for two hours to ensure complete acid decomposition and dehydration. The product was recrystallized from water solutions with subsequent acid and heating treatments. Excellent yellow translucent crystals (octahydrate) were obtained, some 5 mm. long, after the third treatment. These were washed, broken up, mixed with sulfuric acid and heated to the anhydrous form. A 0.01 molar samarium sulfate stock solution was made with this material. The salts employed as supporting electrolyte were of C. P. grade. An H-cell with a saturated calomel anode[8] was used. The salt bridges consisted of saturated potassium chloride solution containing 4% agar. The resistance of the cell and calomel electrode was 230 ohms. This value was used to correct the half-wave potentials for *iR* drop when the magnitude of the diffusion current warranted this procedure.

All measurements were made at $25.0 \pm 0.1°$. Nitrogen was used to remove dissolved air from the solutions. The *m* and *t* values of the Ilkovic equation[4] were found for twenty-five drops of mercury at the applied potential at which the diffusion current was measured. Polarograms were recorded with a Sargent Model XX Polarograph. The operating characteristics of this instrument have been described by Lingane.[9] Accurate checks of applied potential were made with a K-type potentiometer. The polarographic waves for measurement purposes were obtained by connecting the midpoints of the galvanometer oscillations recorded by the instrument. The *p*H of solutions was measured with a glass electrode Type 200 Coleman *p*H Electrometer. This instrument was tested with buffer solutions and found to be accurate to 0.1 unit. The concentration *c* in all cases is expressed in millimoles of samarium ion per liter.

Results and Discussion

Samarium Chloride

No Supporting Electrolyte, No Gelatin.—The preliminary determinations were made with samarium chloride solutions ranging in concentration from 0.5 millimolar samarium ion to 20 millimolar. Some potassium chloride would be expected to diffuse from the agar plug into the solution being electrolyzed, but poorly defined waves were nevertheless obtained.

Supporting Electrolyte, No Gelatin.—Supporting electrolyte media of 1.0 molar potassium chloride, 0.1 molar potassium chloride, 0.1 molar tetramethylammonium iodide, or 0.1 molar lithium chloride, containing 5 millimolar

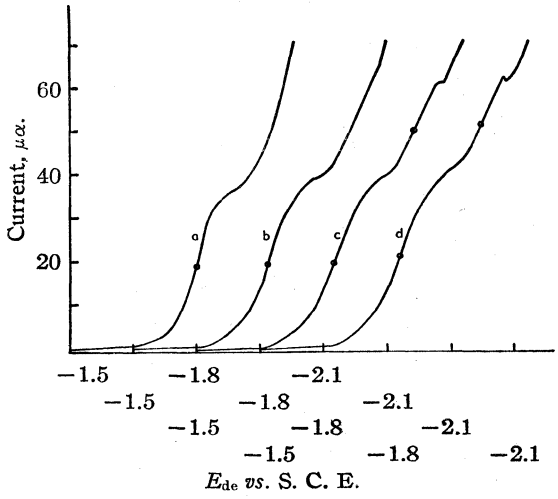

Fig. 1.—Samarium chloride, 5 millimolar, in various media: curves a-d, 1.0 *M* KCl, 0.1 *M* KCl, 0.1 *M* $(CH_3)_4NI$, 0.1 *M* LiCl, respectively.

samaric ion gave rise to well defined first steps as shown by Fig. 1, curves a–d respectively. In the 0.1 molar lithium chloride and 0.1 molar tetramethylammonium medium a second step seems to begin but is apparently terminated by the discharge of the supporting electrolyte. Figure 2 is a representative example of the variation of the ratio i_d/C observed in the polarograms recorded with the samarium chloride solutions shown in Fig. 1. It is evident that the expected proportionality of step height between the first and second step is not attained. Curves a and b are reproductions of the midpoint tracing of polarograms recorded with 0.1 molar tetramethylammonium iodide solutions containing 5 and 2.5 millimoles of samarium chloride, respectively. The residual current is shown by curve c.

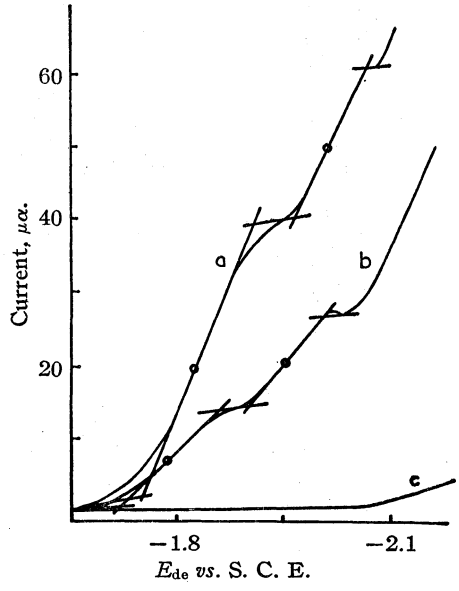

Fig. 2.—Relationship between concentration of samarium chloride and step height in 0.1 *M* tetramethylammonium iodide medium. Curves a and b are recorded with 5 and 2.5 millimolar solutions, respectively; c is the residual current.

Because of this variation in the current–concentration ratio, sulfate solutions of samarium were investigated.

Samarium Sulfate

No Supporting Electrolyte.—Several attempts to reproduce results reported[1] were made employing a mercury pool anode. Stock solutions of samarium sulfate which had stood a month or two yielded no waves, but a three step wave was recorded with a one day old 20 millimolar solution containing no gelatin. Discharge of hydrogen, observed from a wave with a half-wave potential at −1.64 volts against the mercury pool anode, occurred.

Supporting Electrolyte, 0.01% Gelatin.—Polarograms were recorded with various concentrations of samarium in 0.1 molar lithium chloride medium. With concentrations from 5 to 20 millimolar the polarograms consisted of two steps. At lower concentrations the second step terminated in a maximum. The results listed in Table I are corrected for iR drop.

Since the reduction of samarium ion proceeds at a potential more negative than the reduction of hydrogen ion, small amounts of dilute sulfuric acid were added to samarium solutions and polarograms recorded.[10] Two waves, one due to hydrogen and the other due to samarium discharge, were observed. In 0.1 molar lithium chloride solution (0.001 normal in sulfuric acid) containing varying concentrations of samarium, the half-wave potential of the hydrogen wave was −1.5 volts against the saturated calomel electrode. As shown in Table II the addition of acid reduced the

(10) R. H. Leach and H. Terrey, *Trans. Faraday Soc.*, **33**, 480 (1937).

half-wave potential shift by 0.03 volt in the samarium ion concentration range of 2 to 8 millimoles as compared to a 0.07 volt shift observed in an approximately similar concentration range without acid addition. The diffusion current varied directly with concentration in the acid series. Stabilization of *p*H could possibly explain the improved regularity.

From equivalent conductivity data[11] and application of Kohlrausch's law and the Nernst[12] equation, D was calculated to be 6.07×10^{-6} sq. cm. sec.$^{-1}$. Calculated I_d values for samarium ion would be 1.49 when n is 1 or 4.47 when n is 3. Experimentally the average I_d for the first step of the lithium chloride, sulfuric acid medium series of runs was found to be 3.57 which lies between the two theoretical values cited above. As shown by Fig. 3, a polarogram of the 4 millimolar solution of this series, the second step is terminated before its complete development and therefore no selection of the proper n value can be made. The two polarograms were recorded with the same solution but with different galvanometer sensitivities. The residual current is shown by curve a'.

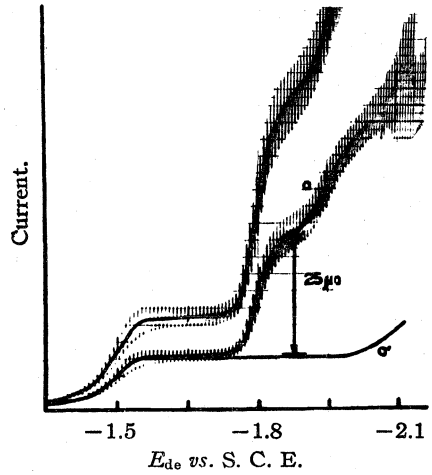

Fig. 3.—Sm^{+++} ion, 4 millimolar, in 0.001 N H_2SO_4, 0.1 M LiCl, 0.01% gelatin medium. Curve a' is the residual current.

Figure 4 is a polarogram recorded with 4 millimolar samarium ion concentration in a 0.1 molar tetramethylammonium iodide and 0.001 N sulfuric acid medium. A well defined two step wave was obtained with an I_d of 3.56 for the first step and 6.49 for the second. As can be seen the two steps are approximately of equal height. This is not the case for a 1 millimolar solution in a similar medium as shown by Fig. 5. I_d for the first step was 3.85 and for the second 12.1 which would indicate a one electron reduction for the first step and a two electron reduction for the second. The multiple polarogram was recorded with various galvanometer sensitivities. The residual current is shown by curve a' in Fig. 5.

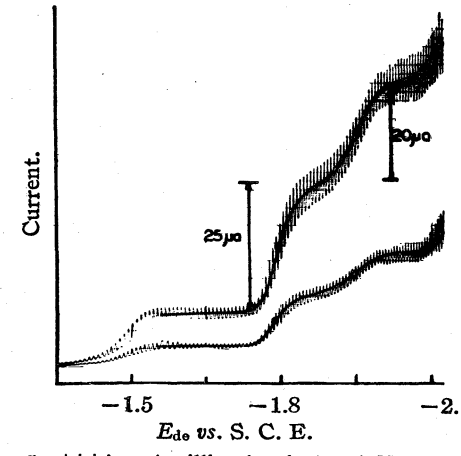

Fig. 4.—Sm^{+++} ion, 4 millimolar, in 0.001 N H_2SO_4, 0.1 M $(CH_3)_4NI$, 0.01% gelatin medium.

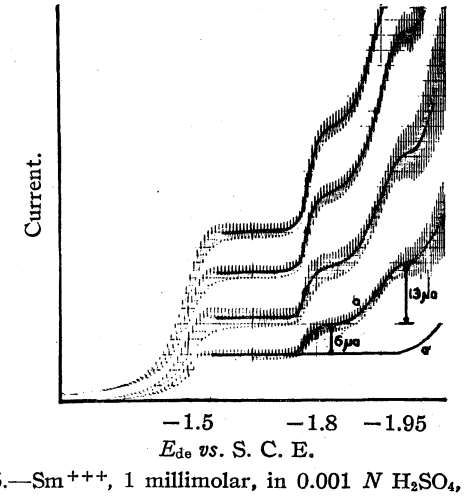

Fig. 5.—Sm^{+++}, 1 millimolar, in 0.001 N H_2SO_4, 0.1 M $(CH_3)_4NI$, 0.01% gelatin medium.

From the preceding observations it is obvious that the discharge of samarium ions at the dropping mercury electrode in aqueous solutions is a complex process. There is evidence of a two-step reduction but in most cases the second step is terminated by discharge of the supporting electrolyte.

It has been noted[6,7] that samarous ion is not very stable in aqueous solutions. It reverts to the samaric state with the evolution of hydrogen. This fact could possibly explain the anomalous results observed, in a manner similar to the case of ytterbium, mentioned by Laitinen and Taebel.[13]

Samarous ion is more unstable[14] than ytterbous ion and therefore hydrogen should be evolved more easily than in the ytterbous case, with greater discrepancy between the expected and ex-

perimentally obtained diffusion currents and thus offer an explanation for the anomalous diffusion current constant in the case of samarium.

Acknowledgment.—This work was undertaken while one of us (A. T.) held a graduate college research assistantship at the State University of Iowa.

Summary

Solutions of samarium chloride and sulfate were studied polarographically without supporting electrolyte and in the presence of lithium chloride, potassium chloride and tetramethylammonium iodide. Addition of sulfuric acid to the sulfate solutions stabilized the half-wave potential. With one millimolar samarium ion, in 0.001 normal sulfuric acid, 0.1 molar tetramethylammonium iodide and 0.01% gelatin medium a two step polarogram was obtained. The half-wave potentials were −1.80 and −1.96 volts against the saturated calomel electrode. The diffusion currents were, respectively, 6.0 and 13.0 microamp., corresponding to $Sm^{+++} \rightarrow Sm^{++}$, and $Sm^{++} \rightarrow Sm^{0}$. However, in 4 millimolar solution the behavior is anomalous.

Heat Capacities at Low Temperatures and Entropies of $3CaO \cdot B_2O_3$, $2CaO \cdot B_2O_3$, $CaO \cdot B_2O_3$, and $CaO \cdot 2B_2O_3$[1]

BY K. K. KELLEY,[2] S. S. TODD[3] AND C. H. SHOMATE[4]

In a recent paper, Torgeson and Shomate[5] presented data for the heats of formation of the crystalline calcium borates, $3CaO \cdot B_2O_3$, $2CaO \cdot B_2O_3$, $CaO \cdot B_2O_3$, and $CaO \cdot 2B_2O_3$. These are all the compounds in the CaO–B_2O_3 system, according to the work of Carlson.[6] The present paper reports low temperature heat capacity and entropy determinations of these same substances, thus enabling the calculation of their free energies of formation. There are no previous similar data for any of these compounds.

Materials.—The samples of calcium borates used in the present measurements were virtually the same as those employed in the heat of formation studies of Torgeson and Shomate.[5] Their paper included the method of preparation of the samples, their densities, and X-ray diffractions, and repetition here appears unnecessary. About one mole of each compound was used in the present measurements and all weighings were corrected to vacuum. The chemical purity of the samples is indicated by the following analyses:

Substance	Actual analysis CaO, %	Actual analysis B_2O_3, %	Theoretical analyses CaO, %	Theoretical analyses B_2O_3, %
$3CaO \cdot B_2O_3$	70.75	29.31	70.72	29.28
$2CaO \cdot B_2O_3$	61.71	38.41	61.69	38.31
$CaO \cdot B_2O_3$	44.59	55.26	44.61	55.39
$CaO \cdot 2B_2O_3$	28.57	71.02	28.71	71.29

Only the calcium diborate contained any appreciable impurity. As mentioned by Torgeson and Shomate,[5] this material contained 0.42% of insoluble impurity from superficial reaction with the nickel crucible in which it was prepared. No correction for this impurity was made in the present results.

Heat Capacities.—The heat capacities were measured by means of previously described[7] apparatus and methods. The results, expressed in defined calories,[8] are listed in Table I and shown graphically in Fig. 1. The molecular mass figures in the headings of Table I accord with the 1947 International Atomic Weights.[9] The precision error in the results is under 0.1% and it is believed they are accurate on the average to within ±0.3% in the absolute sense.

The heat capacities of all four calcium borates are higher at the lower temperatures, and lower at the higher temperatures, than the sum of the heat capacities of the component oxides. The greatest average deviation from additivity is shown by $CaO \cdot 2B_2O_3$, the heat capacity of which averages over 2 cal. per deg. per mole lower than the sum of the heat capacities of the component oxides in the temperature range 100 to 298.16°K. In this connection it is of interest to note that this substance also has the highest atomic density (lowest mean atomic volume). Other things being equal, high atomic density generally parallels low heat capacity at low temperatures.

Entropies at 298.16°K.—In each instance, the entropy increment between 52.00 and 298.16°K. (measured portion, Table II) was obtained, as usual, by numerical integration of a large-scale plot of C_p against log T. To obtain the entropy

increments between 0 and 52.00°K., the measured heat capacities were fitted with the following combinations of Debye and Einstein functions, the maximum deviation between measurements and function sums being shown in parentheses

$$3CaO \cdot B_2O_3 \quad 4D\left(\frac{332}{T}\right) + 4E\left(\frac{534}{T}\right) + 3E\left(\frac{1362}{T}\right) \quad (0.5\%)$$

$$2CaO \cdot B_2O_3 \quad 3D\left(\frac{316}{T}\right) + 3E\left(\frac{511}{T}\right) + 3E\left(\frac{1330}{T}\right) \quad (0.5\%)$$

$$CaO \cdot B_2O_3 \quad 2D\left(\frac{280}{T}\right) + 2E\left(\frac{503}{T}\right) + 3E\left(\frac{1328}{T}\right) \quad (1.0\%)$$

$$CaO \cdot 2B_2O_3 \quad 3D\left(\frac{334}{T}\right) + 4E\left(\frac{700}{T}\right) + 3E\left(\frac{1217}{T}\right) \quad (1.0\%)$$

These function sums were employed in obtaining the extrapolated portions of the entropies in Table II. The extrapolated portion constitutes

TABLE II

ENTROPIES AT 298.16°K., CAL./DEG./MOLE

	$3CaO \cdot B_2O_3$	$2CaO \cdot B_2O_3$	$CaO \cdot B_2O_3$	$CaO \cdot 2B_2O_3$
0°–52.00°K., (extrapolation)	2.16	1.84	1.65	1.59
52.00°–298.16°K., (measured)	41.73	32.84	23.41	30.61
$S^0_{298.16}$	43.9 ± 0.3	34.7 ± 0.2	25.1 ± 0.2	32.2 ± 0.3

only 6.6% of the total entropy for $CaO \cdot B_2O_3$ and is lower for the other substances.

The entropies of $3CaO \cdot B_2O_3$, $2CaO \cdot B_2O_3$, and $CaO \cdot B_2O_3$ differ, in order, by 9.2 and 9.6 units, corresponding to successive decreases of one mole of calcium oxide. These figures are to be compared with the measured value for free calcium oxide,[10] $S^0_{298.16} = 9.5 \pm 0.2$. This type of approximate additivity of entropies of some interoxidic compounds has been noted previously in work of this Laboratory and is the result of compensation of plus and minus deviations from additivity of heat capacities. In the case of $CaO \cdot 2B_2O_3$ such compensation is quite incomplete and the entropy difference between $CaO \cdot 2B_2O_3$ and $CaO \cdot B_2O_3$ is only 7.1 units, whereas the entropy of crystalline boric oxide[11] is $S^0_{298.16} = 13.0 \pm 0.1$.

Related Thermal Data.—Free energies of formation at 298.16°K. of the four calcium borates from the oxides and from the elements are given in Table III, being obtained from the relationship $\Delta F^0 = \Delta H - T\Delta S$. The heats of formation, $\Delta H_{298.16}$, are from the paper of Torgeson and Shomate.[5] The entropies employed in calculation of the $\Delta S_{298.16}$ values are from publications of Kelley.[10,11]

Precision uncertainties have been assigned to the free energies of formation from the oxides. It is not possible to do this for the values from the elements because the probable error in the heat of formation of crystalline boric oxide, on which the free energies depend, is not known.

TABLE III

FREE ENERGIES OF FORMATION AT 298.16°K., CAL./MOLE

Substance	$\Delta H_{298.16}$	$\Delta S_{298.16}$	$\Delta F^0_{298.16}$
	From oxides		
$3CaO \cdot B_2O_3$	−60,000 ± 40	2.4 ± 0.7	−60,720 ± 210
$2CaO \cdot B_2O_3$	−45,760 ± 30	2.7 ± 0.5	−46,570 ± 150
$CaO \cdot B_2O_3$	−29,420 ± 20	2.6 ± 0.3	−30,200 ± 90
$CaO \cdot 2B_2O_3$	−42,930 ± 20	−3.3 ± 0.5	−41,950 ± 150
	From elements		
$3CaO \cdot B_2O_3$	−858,200	−136.4 ± 0.6	−817,500
$2CaO \cdot B_2O_3$	−692,100	−111.2 ± 0.5	−659,000
$CaO \cdot B_2O_3$	−524,000	− 86.3 ± 0.5	−498,300
$CaO \cdot 2B_2O_3$	−880,200	−156.2 ± 0.9	−833,700

The free energy of formation values from the oxides follow a normal pattern. The formation of $CaO \cdot B_2O_3$ from the oxides gives a decrease in free energy of 30,200 cal. Smaller decreases in free energy accompany each successive step of adding one mole of oxide to $CaO \cdot B_2O_3$ to form the other calcium borates.

Summary

Low temperature heat capacity measurements of $3CaO \cdot B_2O_3$, $2CaO \cdot B_2O_3$, $CaO \cdot B_2O_3$, and $CaO \cdot 2B_2O_3$ were made throughout the temperature range 52° to 298.16°K.

The entropies of the four calcium borates were determined as 43.9 ± 0.3, 34.7 ± 0.2, 25.1 ± 0.2, and 32.2 ± 0.3 cal./deg./mole, respectively.

Free energy of formation values from the oxides and from the elements are included.

The Reactions of Antiserum Homologous to the *p*-Azosuccinanilate Ion Group[1a]

BY DAVID PRESSMAN,[1b] JOHN H. BRYDEN AND LINUS PAULING

It was discovered by Landsteiner and van der Scheer[2] that the precipitation of azoprotein containing the *p*-azosuccinanilate ion haptenic group by hapten-homologous antiserum (anti-S_p serum) is inhibited just as well by maleate ion as by succinate ion, whereas fumarate ion is practically ineffective, and from this observation the cautious conclusion was drawn[3,4] that "Accordingly, one could suppose that the succinic acid molecule can exist in a form corresponding to the *cis* configuration, or that the antibodies adjust themselves to this." Because of our interest in the use of immunochemical techniques for the determination of the configuration of molecules and haptenic groups,[5] we have extended our quantitative studies of hapten inhibition of serological precipitation to include the S_p system, and have investigated the effect of over fifty haptens on the precipitation of S_p-ovalbumin and anti-S_p serum. The analysis of the data has shown that the normal configuration of the *p*-azosuccinanilate ion group in aqueous solution is a *cis* configuration, presumably stabilized by a hydrogen bond, and has provided information about the configuration of other ions.

Experimental Methods

Haptens.—The following substances used in this work have been described previously[6]: succinanilic acid, *p*-aminosuccinanilic acid, *p*-nitrosuccinanilic acid, and *d*-

and *l*-N-(α-methylbenzyl)-succinamic acids. The substances prepared in this investigation are described in the following section. All other substances used were commercial preparations purified to the correct melting point and acidic equivalent weight.

Antiserum and Protein Antigens.—The preparation of antiserum and antigens used in this work has been described previously.[6] Only one pool of anti-S_p serum and one preparation of S_p-ovalbumin were used in these experiments.

Reaction of Antiserum with Antigen and Hapten.—One-milliliter portions of S_p-ovalbumin, anti-S_p serum, and hapten solution were mixed and permitted to stand about one hour at 37° and over two nights at 5°. The amount of antigen used, 320 μg. (by Nessler analysis), was that which gave optimum precipitation in the absence of hapten. The hapten solution was made with 0.9% sodium chloride solution and the antigen solution was made with borate buffer of *p*H 8.0.[7] The precipitates were centrifuged, washed three times with 10-ml. portions of 0.9% sodium chloride solution, and analyzed by our standard method.[8]

Preparation of Substances

Malonanilic acid was prepared by the method of Rügheimer,[9] by heating a mixture of 0.24 mole of malonic acid and 0.24 mole of aniline at 105° for one hour. The resultant mass was dissolved in 2 *N* sodium hydroxide solution and filtered, and the filtrate was acidified with hydrochloric acid. Malonanilic acid separated on partial evaporation and cooling. The product was recrystallized from water; m. p. 132.0–132.5°, reported 132°. *Acidic equivalent weight:* calcd. for $C_9H_9O_3N$, 179.1; found 185.6, 186.4.

Glutaranilic acid was prepared by heating a mixture of 0.06 mole of glutaric acid, 0.06 mole of aniline, and 2 g. of fused zinc chloride in an oil-bath at 160 to 170° for forty-five minutes. After cooling, the mixture was extracted with potassium hydroxide solution and was filtered, and the filtrate was acidified with hydrochloric acid. The crystals which separated were recrystallized from water; m. p. 127.0–128.0°, reported 126–127°.[10] *Acidic equivalent weight:* calcd. for $C_{11}H_{13}O_3N$, 207.1; found 208.8, 209.0.

Adipanilic acid was prepared by the method of Dieckmann,[11] by heating a mixture of 0.1 mole of adipic acid, 0.1 mole of aniline, and 2 g. of fused zinc chloride on an oil-bath at 150–160° for one and one-half hours. Upon cooling, the material was dissolved in sodium hydroxide solution and was filtered, and the adipanilic acid was precipitated with hydrochloric acid. The product was recrystallized from water: m. p. 152.0–153.0°, reported 152–153°. *Acidic equivalent weight:* calcd. for $C_{12}H_{15}O_3N$, 221.1; found, 216.9, 218.7.

Maleanilic acid was prepared by the method of Anschütz,[12] by adding 0.3 mole of aniline dissolved in 75 ml. of anhydrous ether to 0.26 mole of maleic anhydride dissolved in 250 ml. of anhydrous ether. The product precipitated as it was formed, and was purified by dissolving it with sodium hydroxide solution and reprecipitating with hydrochloric acid; m. p. 197–198°, reported 198°. *Acidic equivalent weight:* calcd. for $C_{10}H_9O_3N$, 191.1; found, 185.3, 190.5.

Fumaranilic acid was prepared by slowly adding 0.12 mole of aniline in 100 ml. of chloroform to 0.12 mole of fumaryl chloride in 100 ml. of chloroform. The chloroform was evaporated from the emulsion formed by the addition of 350 ml. of 1 *N* sodium hydroxide solution. The solution was filtered and the filtrate was acidified with hydrochloric acid. The precipitate was dissolved with sodium hydroxide solution and reprecipitated with hydrochloric acid; m. p., 238–238.5°, reported, 233–234.0°. *Acidic equivalent weight:* calcd. for $C_{10}H_9O_3N$, 191.1; found, 195.9, 196.9.

d-**Tartranilic acid** was prepared by slowly adding 0.4 mole of aniline to 0.4 mole of *d*-α,β-diacetoxysuccinic anhydride in 400 ml. of chloroform at the refluxing temperature. The cooled solution was extracted with about 400 ml. of 1 *N* sodium hydroxide solution. The aqueous phase was treated with 200 ml. of concentrated hydrochloric acid. A colorless oil separated which dissolved on heating. Subsequent cooling produced crystals; m. p. 181.9–182.4°, reported 180°[13] $[\alpha]^{23}D$ in water, +106.2° (α, +2.13°, 1 dm., 20 g./l.); reported[14] $[\alpha]^{15}D$ +105.6°. *Acidic equivalent weight:* calcd. for $C_{10}H_{11}O_5N$, 225.1; found 224.8, 225.3.

α,β-Diacetylsuccinic anhydride was prepared by the method of Lucas and Pressman.[15]

o-**Bromosuccinanilic acid**, *m*-**bromosuccinanilic acid**, *p*-**bromosuccinanilic acid**, **N-α-naphthylsuccinamic acid**, **and N-β-naphthylsuccinamic acid** were prepared by adding 0.06–0.2 mole of the appropriate amine to a boiling chloroform solution of an equimolar amount of succinic anhydride. The products precipitated as formed and were purified by dissolving in sodium hydroxide solution, extracting with ether, precipitating from the aqueous phase with hydrochloric acid, and finally crystallizing from water or alcohol. The melting points and acidic equivalent weights are as follows:

Substance, acid	Formula	M. p., °C.	Acidic equivalent weight Calcd.	Obs.
o-Bromosuccinanilic	$C_{10}H_{10}O_3NBr$	154.1–156.1	272.2	270.1, 270.1
m-Bromosuccinanilic	$C_{10}H_{10}O_3NBr$	150.9–151.9	272.1	266.7, 266.7
p-Bromosuccinanilic	$C_{10}H_{10}O_3NBr$	187.2–188.2 reported[16] 186–187°	272.1	272.7, 270.8

(8) D. Pressman, *Ind. Eng. Chem., Anal. Ed.*, **51**, 357 (1943). It has been suggested by E. A. Kabat (*Ann. Rev. Biochem.*, **15**, 511 (1946)) that our experimental results are unreliable because the mixtures are allowed to stand only two days, instead of five, before the precipitates are removed and analyzed. We have continued to use the two-day period, for convenience, and we feel that no significant error is introduced thereby. If the tubes containing antiserum and antigen and those also containing hapten were allowed to stand three days longer the amounts of precipitate would increase somewhat, and their ratios might change slightly (by perhaps 5%), leading to correspondingly small changes in the derived values of K_0'. But the values of K_0' obtained with different pools of antiserum differ by as much as two-fold (although usually without changing the order of various haptens), so that the small expected effects of increasing the time of standing are unimportant.

If a true equilibrium were achieved in five days it might be worth while to adopt this longer period. However, on still longer standing the amount of precipitate decreases, presumably as the result of slow degradation of the materials; this suggests that the use of the shorter rather than the longer period may give the more reliable results.

The suggestion has also been made by W. C. Boyd and J. Behnke (*Science*, **100**, 13 (1944)), and repeated by Kabat, that some of the conclusions drawn from our experimental results may be invalidated by the polymerization (aggregation) of some of the haptens or simple precipitating antigens in solution. A detailed discussion of this question will be published shortly; it may be pointed out here that the hapten-inhibition studies reported in the present paper were made with an azoprotein, rather than a polyhaptenic simple substance, as precipitating antigen, and the haptens themselves are so simple as to have little tendency to aggregate, and that for these reasons (as well as others, to be discussed in the later paper) it is unlikely that the arguments presented are to any extent invalidated by the possibility of aggregation of the hapten molecules.

Substance, acid	Formula	M. p., °C.	Acidic equivalent weight Calcd.	Obs.
N-α-Naphthylsuccinamic	$C_{14}H_{13}O_3N$	171.1–171.6	243.1	241.4, 241.2
N-β-Naphthylsuccinamic	$C_{14}H_{13}O_3N$	189.4–190.0 reported[17] 184–185°	243.1	240.5, 240.6

p-(p-Hydroxyphenylazo)-succinanilic acid was made by diazotizing 0.01 mole of p-aminosuccinanilic acid, making the solution neutral, and adding it to 0.10 mole of phenol in the presence of sodium hydroxide solution. Coupling was complete within fifteen minutes. The solution was neutralized and was extracted twice with ether, and the free acid was precipitated with hydrochloric acid from the aqueous phase. The product was crystallized twice from dilute alcohol; m. p. 231.5 dec. *Acidic equivalent weight:* calcd. for $C_{16}H_{15}O_4N_3$, 313.2; found, 312.7.

Succinamic acid was prepared by adding an equimolar amount of 15 *N* ammonium hydroxide to solid succinic anhydride. The solid product was recrystallized from acetone; m. p., 156.3–157.8°; reported, 157°.[18] *Acidic equivalent weight:* calcd. for $C_4H_7O_3N$, 117.1; found, 116.9, 116.7.

N-Methylsuccinamic acid was synthesized by adding slowly 0.56 mole of anhydrous methylamine to a mixture of 0.54 mole of succinic anhydride and 200 ml. of anhydrous ether under a "Dry Ice" reflux condenser. The waxy lumps which resulted were broken up several times during the addition. After two days the ether was decanted and the solid residue was recrystallized from absolute alcohol; m. p. 107.7–108.2°. *Acidic equivalent weight:* calcd. for $C_5H_9O_3N$, 131.1; found, 132.1, 132.3.

N,N-Dimethylsuccinamic acid was prepared similarly from dimethylamine; m. p. 81.6–82.6°. *Acidic equivalent weight:* calcd. for $C_6H_{11}O_3N$, 145.1; found, 145.7, 145.1.

N-Isopropylsuccinamic acid was prepared similarly from isopropylamine but at the boiling point of ether; m. p. 97.9–98.9°. Acidic equivalent weight: calcd. for $C_7H_{13}O_3N$, 159.1; found, 162.0, 163.1.

N,N-Diethylsuccinamic acid was prepared similarly from dimethylamine at the refluxing temperature. The product was recrystallized from isopropyl ether; m. p. 82.1–84.1°. *Acidic equivalent weight:* calcd. for $C_8H_{15}O_3N$, 173.1; found 173.2, 173.8.

N-Methylsuccinanilic acid was prepared by the method of Auwers[11] from 0.20 mole of methylaniline and 0.20 mole of succinic anhydride in chloroform solution. The chloroform solution was extracted with sodium hydroxide solution. The aqueous phase was extracted with ether and then treated with hydrochloric acid to precipitate the product, which was then recrystallized from water; m. p. 89.3–89.8°, reported, 91–92.5°. *Acidic equivalent weight:* calcd. for $C_{11}H_{13}O_3N$, 207.1; found, 205.8, 207.8.

N-Benzylsuccinamic acid was prepared similarly from benzylamine; m. p. 137.7–138.2°; reported, 139°.[19] *Acidic equivalent weight:* calcd. for $C_{11}H_{13}O_3N$, 207.1; found, 207.2, 207.4.

N-Cyclohexylsuccinamic acid was prepared similarly from cyclohexylamine; m. p. 166.5–167.0°. *Acidic equivalent weight:* calcd. for $C_{10}H_{17}O_3N$, 199.1; found, 199.1, 200.0.

N,N-Pentamethylenesuccinamic acid was prepared by adding 0.32 mole of piperidine to 0.32 mole of succinic anhydride in 200 mole of anhydrous ether and refluxing. The ether was decanted from the heavier liquid phase, which crystallized upon the removal of residual ether under vacuum. The solid was recrystallized from ethyl acetate; m. p. 93.8–94.8°. *Acidic equivalent weight:* calcd. for $C_9H_{15}O_3N$, 185.1; found, 186.1, 186.1.

γ-Anilinobutyric acid hydrochloride was prepared by the method of Anschütz and Beavis,[20] by hydrolyzing 1 g. of N-phenyl-α-pyrrolidone with barium hydroxide octahydrate in 10 moles of water in a sealed tube for twenty hours. The solution was diluted and carbon dioxide was added to precipitate excess barium hydroxide. The silver salt of the acid was precipitated from the filtrate by adding silver nitrate solution. The dried silver salt was suspended in absolute ether and saturated with hydrogen sulfide. The silver sulfide was removed by filtration and the γ-anilinobutyric acid hydrochloride was precipitated by saturating the ether solution with dry hydrogen chloride; m. p. 135.5–136.5°, reported 135.5–136.5°.

The N-phenyl-α-pyrrolidone was prepared by the method of Anschütz and Beavis,[20,21] by heating 0.21 mole of succinanil with 0.86 mole of phosphorus pentachloride at about 130–140° until all the solid was dissolved to form dichloromaleanil chloride, which was purified by distilling at reduced pressure; b. p. 218–219° at 35 mm. The dichloromaleanil chloride was reduced by slowly adding a solution of 0.05 mole of the compound in 50 ml. of acetic acid and 100 ml. of anhydrous ether to 800 g. of 3% sodium amalgam with agitation and cooling in an ice-bath. The mixture was allowed to stand two weeks. The ether phase was fractionally distilled and the N-phenyl-α-pyrrolidone was collected at 193–195° at 24 mm. The N-phenyl-α-pyrrolidone was recrystallized from petroleum ether containing a few drops of alcohol; m. p. 59.0–61.0°, reported, 68–69°.

Phenylhydantoic acid was prepared by the method of Paal,[22] by stirring 0.21 mole of phenylisocyanate with a solution of 0.21 mole of glycine in sodium hydroxide. After thirty minutes of stirring the odor of the isocyanate had disappeared. The solution was filtered, the phenylhydantoic acid was precipitated with hydrochloric acid, and the solid was recrystallized from water; m. p. 196.5–197.0°, reported, 195°. *Acidic equivalent weight:* calcd. for $C_9H_{10}O_3N_2$, 194.1; found, 195.0, 196.6.

γ-Benzoylbutyric acid was prepared by the method of Somerville and Allen[23] and was recrystallized from water; m. p. 127.5–128.5°, reported, 125–126°. *Acidic equivalent weight:* calcd. for $C_{11}H_{12}O_3$, 192.1; found, 193.7, 194.9.

δ-Phenyl-n-valeric acid was prepared by heating γ-phenyl-n-propylmalonic acid and a few drops of hydrochloric acid on a water-bath for eight hours. The product was crystallized from water; m. p. 54.4–55.5°, reported, 57°[24]. *Acidic equivalent weight:* calcd. for $C_{11}H_{14}O_2$, 178.1; found, 181.2, 181.4.

The γ-phenyl-n-propylmalonic acid used above was prepared as an oil by reducing 0.05 mole of cinnamalmalonic acid in 100 ml. of ethanol with hydrogen in the presence of platinum oxide, removing the catalyst by filtration, and evaporating the alcohol. The cinnamalmalonic acid was prepared by the method of Stuart,[25] by refluxing 0.20 mole of malonic acid, 0.20 mole of cinnamaldehyde, and 25 g. of glacial acetic acid for nine hours. The solid product was filtered off, washed with chloroform, and recrystallized from absolute alcohol.

Citraconic acid was prepared by the method of Shriner, Ford, and Roll[26]; m. p. 92.8–93.8°, reported 92–93°. *Acidic equivalent weight:* calcd. for $C_5H_6O_4$, 65.1; found, 65.3, 65.4.

Mesaconic acid was prepared by the method of Shriner, Ford, Roll[27]; m. p. 204.6–205.6°; reported, 203–205°. *Acidic equivalent weight:* calcd. for $C_5H_6O_4$, 65.1; found, 65.2, 65.2.

gen-ion concentration on the precipitation of anti-S_p serum with S_p-ovalbumin is shown in Table I. Optimum precipitation takes place between *p*H values of 7.4 and 8.1, as has been found previously for other azo-protein antigens with negatively charged haptenic groups.[28,29] The antigen concentration for optimum precipitation was found to be between 240 and 480 μg. of antigen added. In the experiments reported in Table II 320 μg. of antigen was used.

TABLE I

THE EFFECT OF HYDROGEN-ION CONCENTRATION ON THE PRECIPITATION OF ANTI-S_p SERUM WITH S_p-OVALBUMIN

Antigen solution, antiserum, and buffer, 1 ml. each.

[a] The amounts of precipitate are in parts per mille of the amounts in the absence of hapten: 665, 664, 699, and 649 μg. for series A, B, C, and D, respectively. Blanks of serum and buffer 27, 27, 27, and 17, respectively. Values are averages of triplicate analyses, with mean deviation ±2%, except for duplicate analyses in parentheses.

Inhibition of Precipitation by Haptens.—Data on hapten inhibition are given in Table II. Values of the hapten inhibition constant K_0' and the heterogeneity index σ obtained on application of the theory of heterogeneous antisera[30] are also listed.

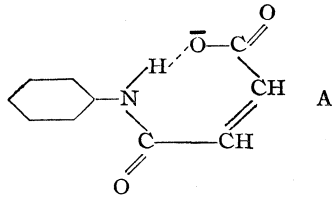
The Structure of the *p*-Azosuccinanilate Haptenic Group.—Through the consideration of the relative inhibiting powers of haptens of known molecular configuration knowledge can be obtained about the configuration of the combining regions of the antibodies, and hence about the normal configuration of the haptenic groups of the immunizing antigen, if we accept the postulate that these regions are complementary to this antigen. In addition, the data for haptens with uncertain configuration may be interpreted to provide information about either the normal configurations of these haptens in aqueous solution or about configurations which do not differ greatly in energy from the normal ones.

(28) D. Pressman, S. M. Swingle, A. L. Grossberg, and L. Pauling, THIS JOURNAL, **66**, 1731 (1944).

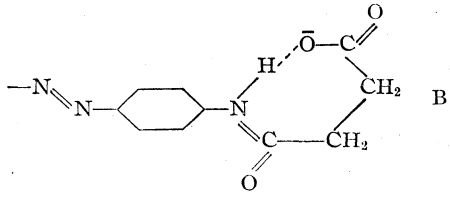
(29) Our work showing the same effect of hydrogen-ion concentration on the precipitation with protein antigen of antiserum specific to the *p*-azophenylarsonate ion and the *p*-(*p*-azophenylazo)-phenyl arsonate ion has not been published.

(30) L. Pauling, D. Pressman, and A. Grossberg, THIS JOURNAL, **66**, 784 (1944).

It was found by Landsteiner and van der Scheer that the maleate ion combines much more strongly with anti-S_p serum than does the fumarate ion, and that the citraconate (methylmaleate) ion combines much more strongly than does the mesaconate (methylfumarate) ion. We have verified these observations (Table II), and have also found that the hapten inhibition constant for the maleanilate ion (0.25) is much greater than that for the fumaranilate ion (0.01). It may accordingly be concluded that the antibody is complementary to a *cis* configuration similar to that of the maleanilate ion, A; and, since there is no reason to believe that the normal configuration of the *p*-azosuccinanilate group is inferior to any other accessible configuration in acting as a template during antibody formation, a corresponding *cis* configuration, presumably B, is indicated for this group.



A



B

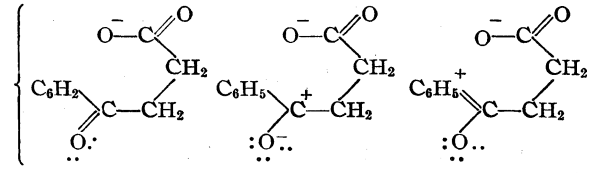
It seems to us likely that the *cis* configuration indicated for this haptenic group is that represented by B, with a hydrogen bond between the amide nitrogen atom and one of the oxygen atoms of the carboxyl group, and that it is largely the energy of this hydrogen bond which stabilizes the *cis* configuration. (The ring closed by the hydrogen bond is probably not coplanar; the two methylene groups may well have nearly the staggered rather than the eclipsed relative orientation.)

The Structure of the Succinanilate Ion, the Succinate Ion, and Related Ions.—The large value of K_0' for the succinanilate ion (1.00, four times the value for the maleanilate ion) indicates strongly that the *cis* configuration is for this ion, too, the normal configuration, and not just an easily accessible one. On the other hand, the value of K_0' for the succinate ion, 0.01, is considerably smaller than that for the maleate ion, 0.03, and it hence seems likely that the *cis* configuration with the two carboxylate groups nearly coplanar with the rest of the ring is not the normal or preferred one for the succinate ion in aqueous solution, but is instead only one of several readily accessible configurations, being itself represented by about 8% of the dissolved ions (the percentage being indicated by the product of ratios of the above K_0' values). The lack of preference for the *cis* configuration presumably is due in part to the inability of the ion to form a hydrogen bond and in part to the electrostatic repulsion of the two carboxylate groups.

The succinamate ion, however, can form a hydrogen bond stabilizing the *cis* configuration, and it contains only one charged group. It is accordingly not surprising that the value of K_0' for this ion (0.035) is considerably greater than that for the succinate ion, and this fact may be taken as verifying that the normal configuration of the succinamate ion, and also of its various monosubstituted derivatives, is the hydrogen-bonded *cis* configuration described above for the succinanilate ion.

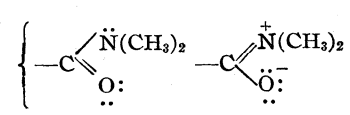
***cis* Configuration without Hydrogen-bond Stabilization.**—It is interesting that there is evidence for predominance of the *cis* configuration, also for some molecules in which this configuration is not stabilized by a hydrogen bond. Thus the large value, 0.59, of K_0' for the β-benzoylpropionate ion requires that the *cis* configuration predominate for this ion in solution, this being essentially the value that would be expected for the *cis* configuration. (The decrease of 41% from the succinanilate ion would be expected to result from the somewhat different orientation of the phenyl group than that for the immunizing haptenic group.)

A reasonable explanation of this observation is that the *cis* configuration for this molecule is stabilized by the electrostatic attraction of the negative charge of the carboxyl ion for a positive charge on the benzene ring and carbonyl carbon atom. The resonance structure places a significant



amount of positive charge in this region, the corresponding negative charge being on the carbonyl oxygen atom, and it is obvious that the electrostatic interactions would stabilize the *cis* configuration, less effectively, however, than would a hydrogen bond.

The sequence of values 0.035, 0.053, 0.134 for K_0' for succinamate ion, N-methylsuccinamate ion, and N,N-dimethylsuccinamate ion strongly indicates that the third of these substances has, like the other two, predominantly the *cis* configuration. For it the positive charge attracting the carboxyl ion is placed on the nitrogen atom by amide resonance



The *cis* configuration indicated for benzylsuccinate ion, $C_6H_5CH_2OCO(CH_2)_2COO^-$, by its rather large value of K_0' (0.134, as compared with 0.255 for N-benzylsuccinamate ion) has a similar explanation, the positive charge being on the oxygen atom to which the benzyl group is attached and on the adjacent carboxyl carbon atom.

The Structural Features Affecting Interaction with Antibody.—The electrically charged carboxyl group is without doubt the structural feature which is of greatest importance in the interaction of haptens and anti-S_p antibody; this feature was, however, not varied in the present investigation.[31] The other structural features which might be important are the imino group, the carbonyl group, the benzene ring, and the framework determining the relative positions of these groups and the carboxyl group.

The data given in Table II indicate that the imino group is not involved directly in attraction of the antibody (hydrogen-bond formation), but exerts only an indirect effect through stabilizing the *cis* configuration for some haptens.

The carbonyl group, on the other hand, makes an important contribution to the attractive forces between hapten and antibody, without doubt by serving as the proton receptor in a hydrogen bond with the antibody. This is strikingly shown by the relative values of K_0' for succinanilate ion (1.00) and γ-anilinobutyrate ion (0.01), and for β-benzoylpropionate ion (0.59) and γ-phenylbutyrate ion (0.01), and is indicated also by other comparisons among the data in Table II (levulinate ion, $CH_3COCH_2CH_2COO^-$ (0.066) and valerate ion (0.01)).

The data also show clearly that the antibody is not pliable, but is rigid: it cannot adjust itself to a change by as much as 1 Å. in the relative position of the carbonyl group and the carboxyl group, but requires for strong combination with a hapten that these groups be the same distance apart as in the haptenic group of the immunizing antigen. This is shown by the comparison of succinanilate ion ($K_0' = 1.00$) with malonanilate ion (0.03) and glutaranilate ion (0.03), and of β-benzoylpropionate ion (0.59) with γ-benzoylbutyrate ion (0.053).

The considerable effect of the van der Waals attraction of the antibody for the benzene ring of the haptenic group is indicated by the 30-fold increase in value of K_0' caused by introduction of a benzene ring in succinamate ion. The effect of the azo group and an additional benzene ring is, however, very small—*p*-(*p*-hydroxyphenylazo) succinanilate ion shows an increase in K_0' of only 38% over the succinanilate ion. We may accordingly conclude that the combining group of the antibody is complementary in structure to the succinamate group and also to the benzene ring, but that it does not extend much farther along the haptenic group.

The value of K_0' for N-cyclohexylsuccinamate ion (0.150), corresponding to decrease to one-seventh on replacing phenyl by cyclohexyl, is probably due to the smaller van der Waals attraction of cyclohexyl, resulting from its smaller polarizability and greater thickness[32] than for the phenyl group.

The value $K_0' = 0.00$ found for the tartranilate ion requires explanation. The great effect of the two hydroxyl groups can hardly be attributed to steric hindrance, since citraconate ion was found to be nearly as effective as maleate ion, and the methyl group is as large as the hydroxyl group. It seems probable that the small effectiveness of the tartranilate ion as an inhibiting hapten results from the fact that hydroxyl groups of the ion in solution are holding water molecules by hydrogen bonds, and that these molecules must be removed in order for the ion to fit into the antibody. This would reduce the free energy of combination with antibody by an amount equal to the free energy of hydration of the hydroxyl groups. This explanation is the same as that previously suggested[33] for the low values of K_0' for *p*-amino and *m*-amino substituted haptens. The same phenomenon explains the low value (0.102, only one-tenth that for the succinanilate ion) of K_0' for the phenylhydantoate ion, $C_6H_5NHCONHCH_2COO^-$. A steric explanation could hardly be invoked here, because the NH group is essentially equal in size to the methylene group which it replaces.

The Effect of Substituents in the Benzene Ring of the Succinanilate Ion.—The effect of various groups in the para position of the benzene ring of the succinanilate ion on the value of K_0' is in the order

$$NO_2 > HOC_6H_4NN > Br > NH_2 > H$$

The action of the nitro group to cause even greater combination than the homologous azo-group was observed previously with anti-R_p serum (antiserum specific for the *p*-azophenylarsonate ion group).[30]

The effect on K_0' of the position of the substituent is in the order $p > m > o$, in agreement with earlier observations,[5,28,30] on *p*-azohaptenic systems.

The magnitude of the effect of substituents in this system is less, however, than for other systems, the spread for the above groups in the para position being by a factor of less than 2 in K_0', as compared with 5 for these groups with anti-R_p serum, 15 with anti-R_p' serum (antiserum specific for the *p*-(*p*-azophenylazo)-phenylarsonate ion group), and 20 with anti-X_p serum (specific to the *p*-azobenzoate ion group). Also in changing a substituent from the *para* to the *ortho* position there is a factor of only 2.6 involved, which is a little larger than the value 2 for anti-R_p' serum but is much smaller than those for anti-R serum (5 to 90) and anti-X_p serum (20 to 1000). The small effect of the substituents in the present system

(31) See ref. 1 and earlier papers.

(32) The effect has been found also in the benzoic acid system, D. Pressman, S. M. Swingle, A. L. Grossberg, and L. Pauling, THIS JOURNAL, **66**, 1731 (1944).

(33) L. Pauling and D. Pressman, *ibid.*, **67**, 1003 (1945).

must be due to a rather poor fit of the antibody to the benzene ring, which probably results from the greater distance from the part of the haptenic group which carries the electric charge.

The values of K_0' for N-α- and N-β-naphthylsuccinamate ions, 0.45 and 1.09, are reasonable when compared with the observed effects of substituents in the *o*-, *m*-, and *p*-positions.

Discussion of Other Haptens.—The order of effectiveness of various groups replacing one hydrogen atom on the nitrogen atom of the succinamate ion in increasing the value of K_0' is $C_6H_5 > C_6H_5CH_2 > C_6H_5(CH_3)CH > cyc\text{-}C_6H_{11} > (CH_3)_2CH > CH_3 > H$. The range of values of K_0' from the benzyl group to hydrogen is through a factor of 8. Replacement of a hydrogen atom by a methyl group presumably increases the value of K_0' from 0.035 to 0.053 through the action of the increased van der Waals attraction, corresponding to the increase in polarizability of the group. Further increasing the size of the alkyl group causes additional increase in K_0'.

The larger value (0.165) of K_0' for N,N-pentamethylenesuccinamate ion than for N,N-diethylsuccinamate ion (0.122) is probably in the main due to the more compact structure of the pentamethylene group than of the two ethyl groups.

In the homologous series of ions of dibasic acids, succinic, glutaric, adipic, and sebacic, the last combines the most strongly with anti-S_p serum, as was reported also by Landsteiner and van der Scheer.[7] We checked this effect for larger amounts of haptens, up to 10^{-4} mole, in both the system S_p-ovalbumin:anti-S serum and the system ovalbumin:antiovalbumin, and found the effect to be specific to the anti-S_p serum. In general an increase in the hapten inhibiting effect would be expected for such a series with increase in the number of methylene groups, because of the increasing van der Waals attraction. In the S_p system, however, it might be expected that the succinate ion would have the maximum effect, because of its close relation to the immunizing para-azosuccinanilate ion haptenic group. It is very probable that the failure of the succinate ion to be active is, as discussed above, due to the predominance of the *trans* configuration for this ion, which does not bring an oxygen atom of the second carboxyl group into the position corresponding to the carbonyl group of the original immunizing antigen.

Asparagine, the aspartate ion, and the glutamate ion were all found to be ineffective as haptens. It is likely that this ineffectiveness is to be ascribed to the effect of the positively charged ammonium ion group in these haptens.

Conclusion.—In general, it has been found that the inhibiting power of haptens in the *para*-azosuccinanilate system depends upon the structural features found previously for other systems, principally the shape of the hapten, the polarizability of groups, and the distribution of charge. The previously recognized phenomenon of decrease in inhibiting power for haptens that are hydrated in solution and must have water removed for combination with antibody has been substantiated by several examples in this system. An interesting result of the studies has been the discovery that the *para*-azosuccinanilate group has the *cis* configuration in the azoprotein used as the immunizing antigen, and that a similar *cis* configuration is shown by the succinanilate ion, the succinamate ion, and many related substances in which this configuration can be stabilized by hydrogen bond formation. The *cis* configuration has also been found to predominate for some other substances in solution, the stabilizing influence presumably being the attraction of the negative charge of the carboxyl group for a positive charge produced elsewhere in the molecule by resonance.

It may be pointed out that the results presented in this paper, like those reported in the preceding papers of this series, strongly support the concept that the forces of attraction between antibody and antigen are interatomic forces operating through distances of a few ångströms, and that the specificity of the resultant integrated attraction depends upon a detailed complementariness in structure of antibody and antigen.

Acknowledgment.—This investigation was carried out with the aid of a grant from The Rockefeller Foundation. We wish to thank Mr. Dan Rice for assisting in the analytical work.

Summary

A quantitative study has been made of the precipitation reaction of S_p-ovalbumin and anti-S_p serum, prepared by injecting rabbits with an azoprotein made by coupling sheep serum with diazotized *p*-aminosuccinanilic acid, and of the inhibiting effect of fifty haptens on this precipitation. The data have been interpreted to show that the normal configuration of the *p*-azosuccinanilate ion haptenic group is a *cis* configuration, which is presumably stabilized by a hydrogen bond between the nitrogen atom of the amide group and an oxygen atom of the carboxyl group. They further indicate that a similar *cis* configuration is the predominant configuration for the succinamate ion and related ions, including some which are not stabilized by hydrogen-bond formation.

The results support the concept that complementariness in structure of antibody and antigen is responsible for their specific combination, and that the forces involved require approximation of the attracting molecules to within one or two ångströms. The values of the hapten inhibition constant show that the principal forces of attraction between the antibody and the hapten are the attraction for the negative charge of the carboxyl group, attraction for the carbonyl group (presumably by formation of a hydrogen bond), and van der Waals attraction for the benzene ring and other parts of the hapten.

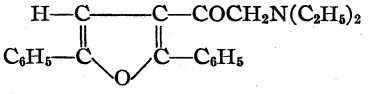
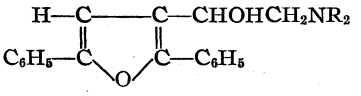
Antimalarials. 2,5-Diphenyl-3-furyl Amino Ketones and Alcohols[1]

BY ROBERT E. LUTZ AND RUSSELL J. ROWLETT, JR.[2]

This research was a part of an exploratory program on quinine-type synthetic antimalarials.[3] The objective was the preparation of some novel α-aryl-β-dialkylamino ketones and alcohols of the type I, II, XI (and its alcohol), and XVI, involving the furyl group as the central aromatic nuclear system. Early leads had indicated slight activity

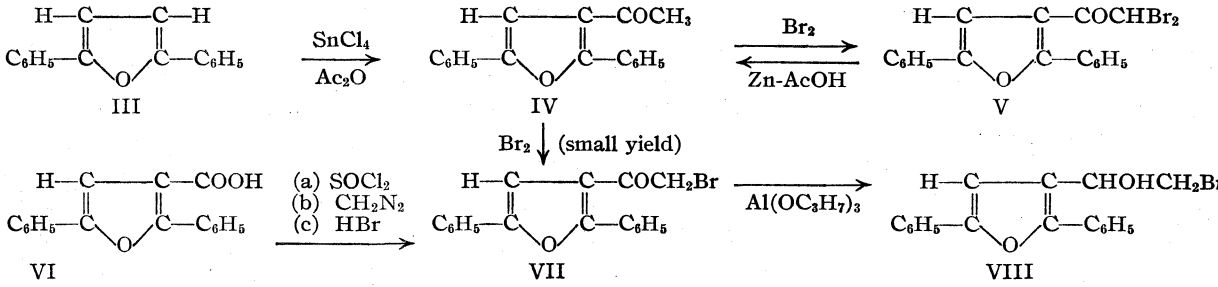


I



II

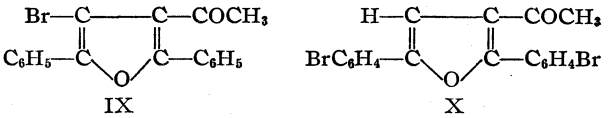
against avian malaria of certain 2,5-diphenylfuran types which contained basic groups,[3c,d] although by present standards of testing[4] few of the compounds so far obtained in this field are to be regarded as active at all, and then only very slightly so. Because of this, although the objectives were only partially achieved, the work was discontinued.



III IV V VI VII VIII

The first attempt to synthesize the key intermediate, 3-bromoacetyl-2,5-diphenylfuran (VII), was through the Friedel–Crafts acylation of 2,5-diphenylfuran followed by bromination. The Friedel–Crafts reaction, although it was unsuccessful using aluminum chloride,[5] proceeds in excellent yields using the combination stannic chloride and acetic anhydride. Bromination of the resulting 3-acetylfuran (IV), however, proved to be difficult to control. Under the various conditions employed only a small amount of the desired bromo ketone (VII) was isolated; the chief product evidently was a mixture which included unchanged material and the dibromo compound (V). This was shown by the reaction of a second molecule of bromine which produced the dibromoacetyl derivative (V) in good yield. It was somewhat surprising to us that the substitution of the second bromine proceeded so rapidly and involved the acetyl group rather than the vulnerable 4-furyl or *para*-phenyl positions, but there is analogy for this in the bromination of 2-acetylfuran.[6]

The nature of the dibromoacetyl compound (V) was demonstrated by the facile reductive dehalogenation back to the acetylfuran (IV), a reaction which showed that the two bromines were aliphatic. The non-reactivity of the 4-nuclear and *para*-phenyl bromines was demonstrated by the stability under the reducing conditions of two compounds, one, the 3-acetyl-4-bromo-2,5-diphenylfuran (IX) which was made from 3-bromo-2,5-diphenylfuran by the Friedel–Crafts reaction, and the other, the isomeric 3-acetyl-2,5-di-(4-bromophenyl)-furan (X), which was made by the Friedel–Crafts reaction with 2,5-di-(4-bromophenyl)-furan.



IX X

The use of chloro and bromoacetyl chlorides in Friedel–Crafts reactions with 2,5-diarylfurans was unsuccessful except in one case. Bromoacetyl chloride and aluminum chloride reacted with 2,5-di-(4-bromophenyl)-furan to give an intractable mixture which on bromination gave a small yield of the dibromoacetyl compound. The latter compound was obtainable in better yields by the bromination of 3-acetyl-2,5-di-(4-bromophenyl)-furan. These experiments showed that the bromoacylation must have produced some of the desired 3-bromoacetyl derivative, even though it was not isolated as such.

The 3-bromoacetyl-2,5-diphenylfuran (VII) was best obtained from the 3-carboxylic acid (VI) by

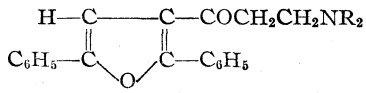
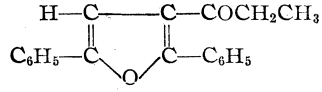
the well known steps, conversion into the acid chloride, diazomethylation, and subsequent treatment with hydrobromic acid.[7]

Condensation of the 3-bromoacetylfuran (VII) with diethylamine gave a typical amino ketone. Condensation of the bromohydrin (VIII) with diethylamine gave a product which resisted crystallization either as the base or the salt. However, a crystalline morpholino alcohol was obtained by this method. Further work in this direction was abandoned because of lack of material.

Six β-dialkylamino ketones of the type XI were made by the Mannich reaction with 3-acetyl-2,5-diphenylfuran, utilizing the following amines: morpholine, piperidine, dimethylamine, diethylamine, dibutylamine and benzylmethylamine. Only two of these compounds were active, and very slightly so, against avian malaria.[4]



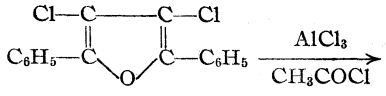
XI



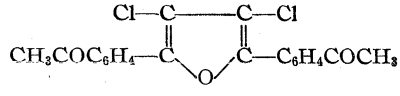
XII

Attempts to reduce these compounds to the amino alcohols by catalytic hydrogen or by aluminum isopropoxide, failed, and only the fission product, the secondary amine, and non-crystalline materials were obtained. From the products of catalytic hydrogenation in one case there was isolated in considerable yields a crystalline deamination product, the ketone XII, which was synthesized independently by the Friedel–Crafts reaction between propionic anhydride and 2,5-diphenylfuran.

In a start toward making an amino alcohol through the *para* position of a phenyl group, a Friedel–Crafts reaction was carried out with 3,4-dichloro-2,5-diphenylfuran (XIII) where the 3,4-furan positions were blocked by chlorine atoms which could be removed later by catalytic hydrogenation. The acylation by means of acetyl chloride and aluminum chloride proceeded twice, however, instead of once as desired, and the di-*para*-acetyl derivative (XIV) was isolated as the chief product. Its structure was demonstrated by oxidation to terephthalic acid.

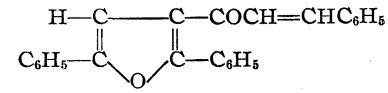


XIII

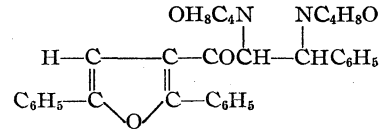


XIV

In connection with the α,β-dimorpholinylbenzylacetophenones,[8] benzaldehyde was condensed with 3-acetyl-2,5-diphenylfuran (IV). The benzal derivative (XV) was brominated and the dibromide reacted with morpholine to give the dimorpholino ketone XVI. This compound showed no activity against avian malaria.



XV



XVI

Acknowledgment.—The synthesis of XII was carried out by Mr. C. R. Bauer.

Experimental[9]

The Preparation of 2,5-Diphenylfuran (III).—Two hundred and fifty grams of *trans*-dibenzoylethylene was added portionwise to a vigorously stirred and refluxing mixture of 250 g. of stannous chloride and 500 ml. each of concd. hydrochloric and concd. acetic acid. The mixture was refluxed for fifteen minutes, and allowed to cool to 50°, and poured into cold water. The solidified product was crystallized slowly from ethanol; yield 154 g. of m. p. 89.5–90° and 36 g. of m. p. 86–87° (86%).

2,5-Di-(4-bromophenyl)-furan.[10]—Twenty-five grams of di-(4-bromobenzoyl)-ethylene was added to a stirred mixture of 50 ml. of concd. hydrochloric and 200 ml. of concd. acetic acids. The addition was rapid enough to keep the mixture boiling gently under the heat of reaction. After refluxing for forty minutes and cooling, the product was isolated by pouring into water. Crystallization from benzene gave 17 g. (73%); melting point 206.5–208°.

Catalytic reduction of 2,5-di-(4-bromophenyl)-furan using palladium on barium sulfate in 95% ethanol at atmospheric pressure and room temperature for eight hours gave 2,5-diphenylfuran.

3-Bromo-2,5-diphenylfuran[11] was made on a large scale by adding 10 ml. of concd. sulfuric acid to a stirred mixture of 120 g. of dibenzoylbromoethane in 500 g. of acetic anhydride. The temperature rose to 54°. Hydrolysis and crystallization of the product gave 94 g. (83%); m. p. 84–86°.

The Preparation of 3-Acetyl-2,5-diphenylfuran (IV).[5]—The Friedel–Crafts acylation of 2,5-diphenylfuran was carried out by means of acetic anhydride and stannic chloride under a variety of conditions in which the solvents tetrachloroethane, carbon disulfide and benzene were used, and in which the mole ratio of stannic chloride was varied between one and two. Acetic anhydride was always used in about 10% excess. The temperature ranges were from 20–50° and the time one-half to eighteen hours. The yields ranged from 64 to 80%. The best procedure is as follows:

Acetic anhydride [28.6 g. (0.28 mole)] was added slowly to a stirred mixture of 55 g. (0.25 mole) of 2,5-

(7) This reaction scheme has been applied at least twice in the furan series starting from furoic acid [Reichstein and Morsman, *Helv. Chim. Acta*, **17**, 1219 (1934); Burger and Harnest, THIS JOURNAL, **65**, 2382 (1943)].

(8) A paper to be published shortly from this Laboratory, dealing with a study of this class of compounds with respect to antimalarial activity.

(9) All melting points are corrected.

(11) Lutz and Smith, THIS JOURNAL, **63**, 1148 (1941).

diphenylfuran and 250 ml. of dry thiophene-free benzene. A solution of 65 g. (0.25 mole) of anhydrous stannic chloride in 50 ml. of dry benzene was added slowly over thirty minutes with the mixture temperature starting at 13° and not allowed to exceed 20°. Stirring was continued for thirty minutes (15–20°) and the mixture was poured into ice and concd. hydrochloric acid. The product, recovered from the benzene layer, was crystallized from ethanol (with Darco treatment); yield 52 g. (80%) of m. p. 62–64°.

2,5-Diphenyl-3-propionylfuran (XII) was made exactly as was the 3-acetyl analog, but using propionic anhydride. The yield of the product melting at 92.5–95.5° was 72%. A mixture melting point with the sample prepared by reduction of the 3-(β-dialkylamino) ketones showed no depression; melting point 95.5–96°.

Anal. Calcd. for $C_{19}H_{16}O_2$: C, 82.53; H, 5.84. Found: C, 82.04; H, 6.19.

2,5-Diphenyl-3-furoic acid[5,11] (VI) was made by passing dry carbon dioxide into a cold ether solution of 2,5-diphenyl-3-furylmagnesium bromide which had been made from carefully purified and dried 3-bromo-2,5-diphenylfuran in the usual way in carefully dried apparatus.

2,5-Diphenyl-3-furoyl chloride.—Five hundred milliliters of thionyl chloride was added cautiously to 49 g. of 2,5-diphenyl-3-furoic acid and the mixture was refluxed for thirty minutes. Unused thionyl chloride was distilled under reduced pressure, and the last traces were eliminated by boiling out with added benzene. Crystallization from ligroin with Norit treatment and cooling to −20° for forty-five minutes gave 44 g. of yellow crystals of m. p. 95–97° (83%).

Anal. Calcd. for $C_{17}H_{11}ClO_2$: Cl, 12.54. Found: Cl, 12.54. (This analysis was carried out by solution of the sample in warm alcohol, addition of alcoholic sodium hydroxide and boiling for ten minutes. After acidification with dilute nitric acid the solution was titrated by Mohr's method with standard silver nitrate and 4% potassium dichromate as indicator.[12])

2,5-Diphenyl-3-furyl Diazomethyl Ketone.—A solution of diazomethane in 1300 ml. of methylene chloride[3a] (0.4675 *N* as determined by titration) was cooled to 0°; and 40 g. of 2,5-diphenyl-3-furoyl chloride was added with gentle stirring. Effervescence continued for thirty minutes. After two hours in the ice-bath and standing overnight, the solvent was evaporated under reduced pressure. A small sample was recrystallized from ethyl acetate and melted at 136.5–138°.

Anal. Calcd. for $C_{18}H_{12}N_2O_2$: N, 9.71. Found: N, 9.79.

The bulk of the product was used directly in the preparation of the bromoketone.

3-Bromoacetyl-2,5-diphenylfuran (VII).—Attempts to brominate 3-acetyl-2,5-diphenylfuran (IV) with one equivalent of bromine under a variety of conditions gave mixtures of products. When the bromine in carbon disulfide was added slowly to a carbon disulfide solution of IV at room temperature (over one hour), an oil was obtained which, when treated with a small volume of ethanol, gave a low-melting crude solid. Laborious purification from ethanol gave a small amount of moderately pure VII which was identified. The bulk of the residue on further manipulation gave some dibromo compound (V). That the original crude mixture was largely VII was shown by treatment with diethylamine and isolation of the diethylamino ketone (as the hydrochloride) in 54% yield.

The unsuccessful attempts at Friedel–Crafts reactions between bromoacetyl and chloroacetyl chlorides involved the use of aluminum, ferric and stannic chlorides, with carbon disulfide, benzene or tetrachloroethane as solvent, and temperatures ranging from −5 to 60°.

The best preparation of the 3-bromoacetyl compound is as follows: The ether suspension of the diazoketone (prepared as described above from 40 g. of the acid chloride of VI) in 1 liter of dry ether, was cooled to 0° and treated slowly over three hours under stirring with 23 ml. of 48% hydrobromic acid in 23 ml. of dry ether. Stirring was continued for three hours. After washing and evaporating the solvent, the resulting oil slowly crystallized. Crystallizations from ethanol containing a little ethyl acetate, and from 85% ethanol, gave diamond-shaped light yellow plate-like crystals of melting point 62–64°.

Anal. Calcd. for $C_{18}H_{13}BrO_2$: C, 63.37; H, 3.84. Found: C, 63.17; H, 4.17.

3-(2-Bromo-1-hydroxyethyl)-2,5-diphenylfuran (VIII).—A mixture of 375 ml. of 0.6 *N* aluminum isoproxoxide and 25.6 g. of the bromoacetylfuran (VII) was refluxed for one and one-half hours at which time the evolution of acetone had ceased. Hydrolysis in dilute hydrochloric acid and crystallization of the precipitate from 80% ethanol (with Darco treatment), cooling to −20°, gave 17.4 g. (68%). After crystallization it melted at 124–126°.

Anal. Calcd. for $C_{18}H_{15}BrO_2$: Br, 23.29. Found: Br, 23.26. (The analysis was carried out by warming the sample in alcoholic sodium hydroxide for ten minutes, acidifying with dilute nitric acid, and titrating with standard silver nitrate.[12])

Condensation of the small sample of VIII available, with diethylamine, gave an oil which we were not able to crystallize, either as the base or as the hydrochloride.

3-Acetyl-4-bromo-2,5-diphenylfuran (IX).—Two equivalents of stannic chloride was added dropwise to a stirred and ice-cooled mixture of 3-bromo-2,5-diphenylfuran and a 10% excess of the calculated amount of acetic anhydride in carbon disulfide. Hydrolysis in ice and concd. hydrochloric acid, separation, and evaporation of the solvent gave a crude product which was crystallized from concd. acetic acid to which a small amount of water had been added. Crystallization from 60% ethanol gave pale yellow needles of melting point 81°.

Anal. Calcd. for $C_{18}H_{13}BrO_2$: C, 63.37; H, 3.84. Found: C, 63.18; H, 3.80.

The compound was not affected by zinc dust and concd. acetic acid at boiling-water-bath temperature for thirty minutes.

3-Acetyl-2,5-di-(4-bromophenyl)-furan (X).—To a suspension of 18.9 g. (0.05 mole) of 2,5-di-(4-bromophenyl)-furan in 200 ml. of tetrachloroethane and 26.1 g. (0.1 mole) of stannic chloride, was added over five minutes 5.1 g. (0.05 mole) of acetic anhydride in 20 ml. of tetrachloroethane. After stirring for thirty minutes at room temperature and 1.6 hours at 68–69° (yellow crystals had appeared), and working up the product as above, 22.9 g. (98%) of fairly pure product was obtained.

A reaction using two equivalents of aluminum chloride in the same solvent and adding one equivalent of acetyl chloride (stirring for three hours) gave the same product but in only 77% yield.

After recrystallizations from ethanol containing a small amount of ethyl acetate, the compound melted at 129–130°.

Anal. Calcd. for $C_{18}H_{12}Br_2O_2$: C, 51.46; H, 2.88. Found: C, 52.10; H, 3.21.

3-Dibromoacetyl-2,5-di-(4-bromophenyl)-furan was made in nearly quantitative yield by bromination of X in carbon tetrachloride at room temperature over thirty minutes. It was crystallized from an ethyl acetate–ethanol mixture and melted at 168.5°.

Anal. Calcd. for $C_{18}H_{10}Br_4O_2$: C, 37.41; H, 1.74. Found: C, 37.28; H, 2.41.

In an attempt to obtain the 3-bromoacetyl analog by the Friedel–Crafts acylation of 2,5-di-(4-bromophenyl)-furan with aluminum chloride and bromoacetyl chloride in tetrachloroethane (three hours at room temperature), a difficultly separable mixture was obtained which was evidently largely the desired **3-bromoacetyl-2,5-di-(4-bromophenyl)-furan** (m. p. 128–132°). Bromination of

(12) See Willard and Furman, "Elementary Quantitative Analysis," 2nd ed., D. Van Nostrand Co., New York, N. Y., 1935.

this in carbon tetrachloride gave the 3-dibromoacetyl compound in 83% yield.

The 3-(β-Dialkylaminopropionyl)-2,5-diphenylfurans (XI).—Mixtures in the ratio of approximately 0.1 mole each of the furan (IV) and the secondary amine hydrochloride or hydrobromide, and 0.11 mole of paraformaldehyde in 100 ml. of 99.5% ethanol and 2 ml. of concd. hydrochloric or hydrobromic acid, were refluxed. The products were precipitated as the salts upon cooling (in some cases after first concentrating the solution under reduced pressure). When the hydrobromide of the amine was used in the reaction, usually with concd. hydrobromic acid instead of hydrochloric, the base was liberated by means of alkali, extracted into ether and converted into the hydrochloride. The crystallizations of the salts, and of the one crystalline base which was handled in that form, were from ethanol, except in the last case where the solvent was ethanol containing a small proportion of ethyl acetate.

[a] The SN number identifies the drug in the Survey Tables.[4] [b] Quinine equivalent determined against Gallinaceum in the chick (see ref. 4). [c] Every twenty-four hours an additional 0.05 mole of paraformaldehyde was added. [d] In these reactions the secondary amine hydrobromide was used instead of the hydrochloride. [e] Hydrobromic rather than hydrochloric acid was used. [f] This compound was formulated erroneously as the monoamylamino ketone under this number in the Survey Table.[4] [g] Fully purified material (the other yields listed above were for partially purified material). [h] Unsharp melting point; softens at 182°.

Attempted reduction of the diethylamino ketone (XI) by aluminum isopropoxide (refluxing for three hours) gave only unchanged material. Reduction of the dibutylamino analog (XI) under refluxing involved only very slow evolution of acetone as shown by test with 2,4-dinitrophenylhydrazine. After eight hours the product was worked up and the only compound isolated (and that in large quantity) was dibutylamine (as the hydrochloride).

Catalytic hydrogenation at atmospheric pressure and room temperature of 21.1 g. (0.055 mole) of the β-diethylamino ketone (XI) with 0.5 g. of platinum oxide in 300 ml. of 99.5% ethanol, was stopped after ten hours and absorption of one equivalent of hydrogen (although the rate of absorption had not dropped). Concentration of the solution gave 5.5 g. of a product which, after crystallization from 60% ethanol, melted at 93° and was identified as 2,5-diphenyl-3-propionylfuran (XII) by mixture melting point.

The same compound was obtained by a similar reduction of the dibutylamino analog (XI). Here the hydrogenation had been allowed to go further (1.3 equivalents).

3-Diethylaminoacetyl-2,5-diphenylfuran Hydrochloride (I).—An absolute ether solution (75 ml.) of 3.4 g. of the bromoketone (VII) and 2.9 g. of diethylamine quickly gave a precipitate. After standing for five hours the diethylamine hydrobromide was filtered (81%), and the solution was washed, treated with Norite, and dried over sodium sulfate. Acetone was added and the solution acidified with ethereal hydrogen chloride and cooled to −20° for two hours; yield 1.84 g. Recrystallization from anhydrous ethyl acetate and absolute ethanol mixture, gave long needles of melting point 202–204°.

Anal. Calcd. for $C_{22}H_{23}NO_2 \cdot HCl$: N, 3.79; Cl, 9.59. Found: N, 3.53; Cl, 9.54 (by titration).

2,5-Diphenyl-3-[2-(N-morpholinyl)-1-hydroxyethyl]-furan Hydrochloride (II).—Condensation of morpholine with the bromohydrin (VIII), with no added solvent, and standing for twenty-eight hours, and diluting with ether, gave 88% of the calculated amount of morpholine hydrobromide. Evaporation under reduced pressure and conversion to the hydrochloride in ether gave 2.1 g. (55%). It was recrystallized from ethyl acetate by addition of absolute ethanol; melting point 202–203°.

Anal. Calcd. for $C_{22}H_{23}NO_3 \cdot HCl$: C, 68.47; H, 6.27; Cl, 9.18. Found: C, 68.49; H, 6.27; Cl, 9.21 (by titration).

2,5-Di-(4-acetylphenyl)-3,4-dichlorofuran (XIV).—A mixture of 13.4 g. (0.1 mole) of aluminum chloride, 14.5 g. (0.05 mole) of 3,4-dichloro-2,5-diphenylfuran (XIII) and 100 ml. of tetrachloroethane, was treated with 5.9 g. (0.025 mole) of acetyl chloride in 25 ml. of tetrachloroethane (30°, for two hours). Hydrolysis, washing and steam distillation of the solvent gave a residual oil which partly solidified. Crystallization from ethanol gave 11.2 g. of nearly pure product. It was recrystallized from ethanol; yellow needles of melting point 130.5°.

Anal. Calcd. for $C_{20}H_{14}Cl_2O_3$: C, 64.37; H, 3.78. Found: C, 64.42; H, 4.11.

A higher reaction temperature (68°) gave tars, and no reaction occurred at a lower temperature (0–2°).

Oxidation.—A cooled suspension of the furan (XIV) in ten parts of concd. acetic acid and one of concd. nitric acid, was warmed. Reaction began with evolution of oxides of nitrogen at 40–45° and the solid dissolved. The mixture was heated at 80–85° for fifty minutes and poured into water. The product, which we were unable to crystallize, was then oxidized by potassium permanganate in 10% sodium carbonate, and gave almost two equivalents of terephthalic acid (identified by m. p. 301° and mixture melting point with an authentic sample).

3-Benzalaceto-2,5-diphenylfuran[5] (XV).—Eighty milliliters of 10% sodium hydroxide was added dropwise to a well-stirred mixture of 38 g. of the acetylfuran (IV), 500 ml. of ethanol and 21.2 g. of benzaldehyde. An oil separated. Stirring was continued for two hours. The product solidified, and was filtered and crystallized from ethanol; yield 47 g. (93%). Crystallization from ethanol containing a small amount of ethyl acetate gave pale yellow needles; melting point 123°.

Anal. Calcd. for $C_{25}H_{18}O_2$: C, 85.69; H, 5.18. Found: C, 85.83; H, 5.77.

The dibromide[5] was made by bromination of XV in ether. The yield of material after crystallization from ethanol–ethyl acetate mixture, was 77%; melting point 180°.

Anal. Calcd. for $C_{25}H_{18}Br_2O_2$: C, 58.84; H, 3.56. Found: C, 58.82; H, 3.94.

3-(2,3-Dimorpholinyl-3-phenylpropionyl)-2,5-diphenylfuran (XVI).—A mixture of 30.8 g. of the dibromide of XV, 26.1 g. of morpholine and 200 ml. of absolute ethanol was refluxed for thirty minutes and allowed to stand overnight. The solid product was filtered, washed with water and recrystallized from an ethanol–ethyl acetate mixture; yield 15 g. (48%); melting point 192°.

Anal. Calcd. for $C_{33}H_{34}N_2O_4$: C, 75.83; H, 6.56. Found: C, 75.59; H, 6.89.

Summary

Six β-dialkylamino ketones, one α-dialkylamino ketone and one α-dialkylamino alcohol, were made, based on the 2,5-diphenyl-3-furyl system.

The synthetic work involved a study of (a) the Friedel–Crafts acylation of 2,5-diarylfurans and bromination of the 3-acetyl group, and (b) conversion of the 3-carboxylic acid through the acid chloride and diazomethyl ketone into the bromoketone and bromohydrin.

The α,β-dimorpholino ketone was made from the benzal derivative of the 3-acetylfuran.

Very little or no antimalarial activity was observed in the limited studies in this field.

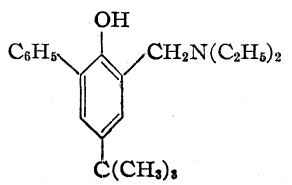
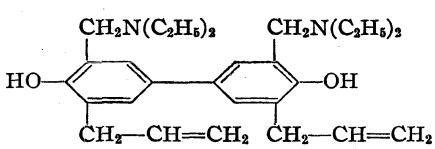
Aminoalkylphenols as Antimalarials. II.[1] (Heterocyclic-amino)-α-amino-o-cresols. The Synthesis of Camoquin[2]

BY J. H. BURCKHALTER,[3] F. H. TENDICK, ELDON M. JONES, PATRICIA A. JONES, W. F. HOLCOMB AND A. L. RAWLINS

In an earlier publication[1] we described a new class of antimalarial compounds represented by 4-*t*-butyl-α-diethylamino-6-phenyl-*o*-cresol (SN 7,744) and 6,6′-diallyl-α,α′-bis-(diethylamino)-4,4′-bi-*o*-cresol (SN 6,771). The high activity of

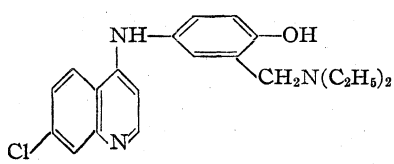


SN 7744



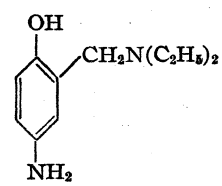
SN 6771

SN 6,771, SN 7,744 and simple analogs led, in 1943, to the synthesis of analogs containing substituent heterocyclic nuclei. This paper describes the work on quinolines, acridines and other heterocyclic compounds which has resulted in the preparation of a new antimalarial, SN 10,751.[2,4]

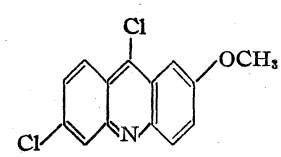


SN 10,751

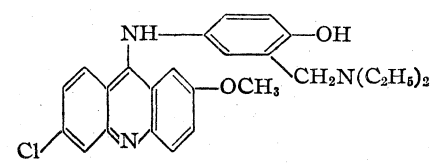
Early attempts to prepare the first member of the new heterocyclic series were unsuccessful. Treatment of 6-chloro-9-(4-hydroxyanilino)-2-methoxyacridine with formaldehyde and diethylamine in the manner of the Mannich reaction failed to yield a product.[5] A method was developed, however, through the preparation of 4-amino-α-diethylamino-*o*-cresol (SN 12,458) and its condensation with 6,9-dichloro-2-methoxyacridine (I) in phenolic solution[6] to give 4-(6-chloro-2-methoxy-9-acridylamino)-α-diethylamino-*o*-cresol (SN 8,617).



SN 12,458



I



SN 8,617

The intermediate 4-amino-α-diethylamino-*o*-cresol (SN 12,458) is new and has been prepared both by acid deacetylation of 4-acetamido-α-diethylamino-*o*-cresol (SN 7,767) and by reduction of 4-nitro-α-diethylamino-*o*-cresol (SN 7,292). The last two compounds were obtained from 4-

(1) For paper I see Burckhalter, Tendick, Jones, Holcomb and Rawlins, THIS JOURNAL, **68**, 1894 (1946).

(2) (a) Camoquin is the Parke, Davis name for 4-(7-chloro-4-quinolylamino)-α-diethylamino-*o*-cresol, SN 10,751. (b) The designation SN identifies a compound in the monograph *A Survey of Antimalarial Drugs*, 1941–1945, F. Y. Wiselogle, Editor, J. W. Edwards, Ann Arbor, Mich., 1946.

(3) Present address: University of Kansas, Lawrence, Kansas.

(4) This drug has been receiving extensive clinical trial in many parts of the world with promising results. Chemical data are summarized in Table VI, compound 9.

(5) F. F. Blicke, "Organic Reactions," Vol. I, John Wiley and Sons, Inc., New York, N. Y., 1942, Chapter 10. Subsequently, incomplete studies have shown that the reaction can be effected with certain substituted aminophenols, *e. g.*, see compound 3, Table XII (VI).

(6) Because of the objection to the handling of phenol, this and similar condensations were later carried out in dilute mineral acid according to a procedure used by Banks, THIS JOURNAL, **66**, 1127 (1944).

TABLE I

ACETAMIDOPHENOLS[a]

No.	Compound	Yield, %	M. p., °C.	Formula	Analyses, % Carbon Calcd.	Carbon Found	Hydrogen Calcd.	Hydrogen Found	Nitrogen Calcd.	Nitrogen Found
1	4-Acetamidophenol	56[b]	168

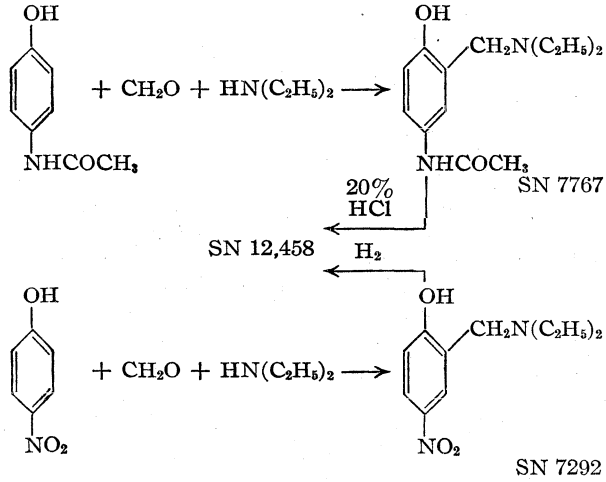
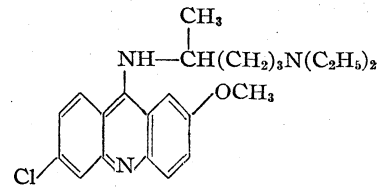
acetamidophenol and 4-nitrophenol, respectively, by the Mannich reaction.[5]



SN 8,617 proved to be as active as quinacrine (SN 390) in screening tests and thus provided the impetus for the work which followed. The structural relationship of SN 8,617 to both SN 6,771 and SN 7,744, as well as to SN 390, suggested that a practical antimalarial might be found among its analogs.



SN 390

Many analogs of intermediates SN 7,767 and SN 7,292 were prepared (Tables II and III). Although several others could not be readily crystallized, we found that deacetylation of the crude materials yielded the desired intermediates which, without isolation, could be successfully condensed with reactive chloroheterocycles. Certain analogs of SN 7,292, *e. g.*, α-monoisobutylamino-4-nitro-*o*-cresol (II), were best obtained by conden-

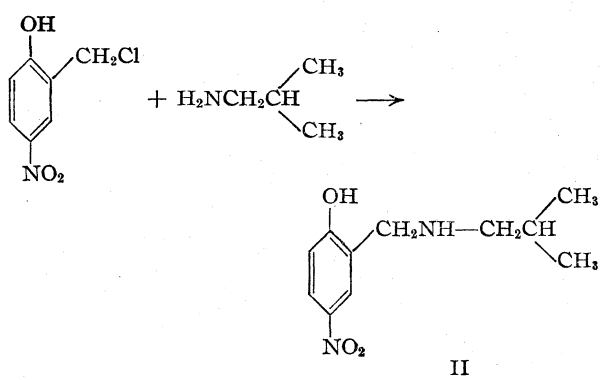
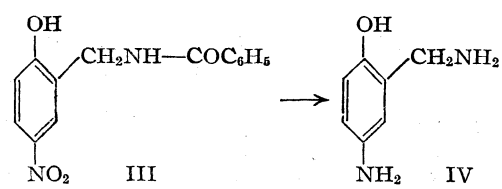
[a] Prepared by the general procedure of this table; b. p. 145–148° (6 mm.); picrate, m. p. 161°. Noelting and Kragczy, *Bull. soc. chim.*, [4], **19**, 336 (1916), prepared the same compound in a pressure bottle; b. p. 206–208° (42 mm.); picrate, m. p. 161°. [b] From acetone–ethanol. [c] From acetone–ligroin. [d] From ethanol–isopropanol. [e] From isopropanol. [f] Intermediate 2-methoxy-5-nitrobenzyl chloride prepared by the method of U. S. Patent 2,278,996. [g] From ligroin–isopropanol. [h] The separation of the hydrochloride of this compound from *n*-amylamine hydrochloride was very difficult. Analytical data indicated the presence of this impurity to a considerable extent. However, compound 8, Table XIII, was readily prepared from the crude product.

sation of α-chloro-4-nitro-*o*-cresol[7] with the proper mono- and dialkylamines.



II

α,4-Diamino-*o*-cresol[8] (IV) was prepared by catalytic reduction of α-benzamido-4-nitro-*o*-cresol (III) followed by acid hydrolysis of the derived 4-amino-α-benzamido-*o*-cresol.



As a part of our studies, certain non-phenolic and O-methylated analogs of SN-8,617 and Camoquin were synthesized. These compounds listed in Table XIII were prepared prior to the appearance of another publication[9] describing 6-chloro-9-(2-diethylaminomethylanilino) - 2 - methoxyacridine, which is a position isomer of compounds 10 and 11. The two necessary types of non-phenolic inter-

mediates related to 4-amino-α-diethylamino-*o*-cresol (SN 12,458) were prepared by condensation of nitrobenzyl chlorides and alkoxy nitrobenzyl chlorides with aliphatic amines (Table IV). During the course of this work 2-chloromethyl-4-nitrophenetole was obtained in 75% yield by the chloromethylation of 4-nitrophenetole.

In the preparation of a group of acetamido-α-dialkylamino-*o*-cresols, several new alkyl, phenyl, and chloro acetamidophenols were obtained from the corresponding nitrophenols by catalytic reduction in the presence of acetic anhydride (Table I).

Although several of the intermediate 4-chloroquinolines were first prepared by rearrangement of the corresponding quinoline-N-oxides,[10] the ethoxymethylene malonic ester method of Price

and Roberts,[11] made available to us prior to its publication, was adopted for the preparation of all the 4-chloroquinolines originating in this Laboratory. Since the completion of these studies, many identical data have been reported by others, especially in the January, March and July, 1946, numbers of THIS JOURNAL. Table V therefore lists only a group of 4-chloroquinolines which have not yet appeared in the literature.

The preparation of various intermediates analogous to both SN 12,458 and I made possible the synthesis of many new antimalarial compounds related to SN 8,617. Tables VI to XIII present chemical data, show the development of the SN 8,617 lead, and afford a study of the relationship between chemical structure and pharmacological activity. Some of the most effective compounds appear in Table XII.[12]

4-(7-Chloro-4-quinolylamino)-α-monoethylamino-*o*-cresol, Table XII, compound 3, (VI) could not be prepared by the usual procedures. It was finally obtained in very low yield by means of the Mannich reaction using 7-chloro-4-(4-hydroxyanilino)-quinoline (V), paraformaldehyde and monoethylamine. This application of the Mannich reaction employing heterocyclic and aromatic ami-

(11) Price and Roberts, THIS JOURNAL, **68**, 1204 (1946).

(12) Compound 25 (Camoquin) was found to be 25 times as active as quinine against *gallinaceum* malaria in chicks, while its monoisobutyl analog (compound 8) is 75 times as active—a considerable improvement over the simpler α-amino-*o*-cresols,[1] as well as over other 4-aminoquinolines heretofore reported [*cf.* tables of 4-aminoquinolines, ref. (2b), pp. 154–163].

[a] Intermediate 4-chloroquinoline was identical with that prepared by Riegel, *et al.*, THIS JOURNAL, 68, 1264 (1946). [b] Yellow crystals. [c] From ethanol. [d] See Experimental part. [e] From methanol–acetone. [f] Same reference as footnote (*m*), Table VI, for preparation of 4-chloro-6-methoxyquinoline. [g] From water–alcohol. [h] 7-Methoxy-4-chloroquinoline melts at 83–85°; Lauer, *et al.*, THIS JOURNAL, 68, 1268 (1946), found 82–83°. [i] From methanol–ethanol. [j] 8-Methoxy-4-chloroquinoline melts at 83°; Lauer, *et al.*, *ibid.*, found 79–80°. [k] Light greenish tan color. [l] Intermediate 4-chloro-6,7-dimethoxyquinoline, independently prepared, was found to be identical with that of Riegel, *et al.*, *ibid.* [m] From ethanol–ethyl acetate. [n] The structure of this compound has not been definitely established. However, a formula has been assigned based on the fact that 4-chloroquinoline was found to condense much more readily than 2-chloroquinoline with aromatic amines. Intermediate, 4,7-dichloroquinoline prepared by the method of Brooker and Smith, THIS JOURNAL, 64, 1357 (1942). [o] For chemical data, see compound 9, Table VI. [p] Intermediate dichloroquinoline was independently prepared by the same procedure of Tarbell, THIS JOURNAL, 68, 1278 (1946). [q] From chloroform–ether. [r] From acetone. [s] From ethanol–acetone. [t] Greenish yellow crystals. [u] Intermediate 4,5,7-trichloroquinoline prepared by the general method of Price[11]; m. p. 108°. *Anal.* Calcd. for $C_9H_4Cl_3N$: C, 46.50; H, 1.73. Found: C, 46.90; H, 1.80. Surrey and Hammer, THIS JOURNAL, 68, 1244 (1946), employed a different procedure. [v] Surrey and Hammer, *ibid.*, also prepared the intermediate trichloroquinoline by a different procedure. [w] From acetone. [z] Intermediate 4-chloro-6-methylquinoline, b. p. 139–140 (10 mm.). *Anal.* Calcd. for $C_{10}H_8ClN$: C, 67.61; H, 4.54. Found: C, 67.23; H, 4.55. Breslow, *et al.*, THIS JOURNAL, 68, 1236 (1946), reported b. p. 140–142 (9 mm.). [y] Pale tan crystals. [z] From methanol. [aa] Independent preparation of intermediate 4-chloro-6,7-dimethylquinoline gave identical results of Price and Roberts.[11] [ab] From methanol–ether; analysis corresponds to the presence of a half

mole of methanol: Calcd. volatile loss, 3.53. Found: 3.30. [ac] Intermediate 4-chloroquinoline obtained through Dr. R. C. Elderfield. [ad] Bright orange crystals. [ae] From ligroin. [af] From water; calcd. volatile loss 5.93. Found: 5.71. [ag] From 20% ethanol. [ah] Intermediate 4-chloro-6-dimethylaminoquinoline hydrochloride obtained as a bright orange powder; m. p. 249° d. *Anal.* Calcd. for $C_{11}H_{11}ClN_2 \cdot HCl$: C, 54.37; H, 4.97. Found: C, 54.12; H, 4.75. Riegel, *et al., ibid.*, p. 1265, reported m. p. 225–230°. [ai] Intermediate 6-nitro-4-chloroquinoline prepared in low yield by the general method of Price and Roberts,[11] but see a better method for this compound by Baker, *et al.*, THIS JOURNAL, 68, 1267 (1946). Orange-red crystals. Calcd. volatile loss, 6.01. Found: 5.79. From methanol–ether.

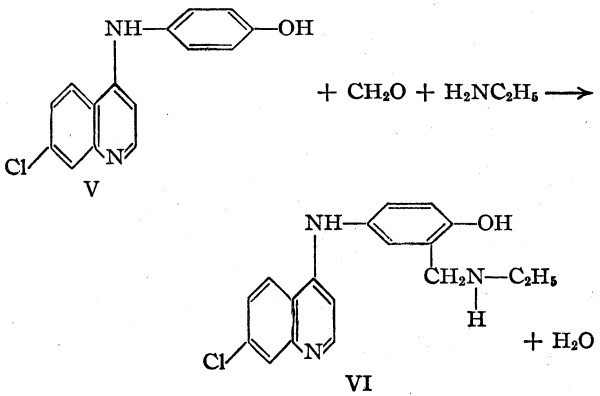
nophenols is being continued with the prospect of obtaining better yields.



V

VI

4-(6-Hydroxy-4-quinolylamino)-α-diethylamino-*o*-cresol (Table IX, compound 2) was prepared from the corresponding 6-methoxy analog (compound 3) by demethylation with hydrobromic acid.

Acknowledgments.—The authors are greatly indebted to Drs. R. J. Porter of the University of Michigan, A. L. Tatum of the University of Wisconsin and E. K. Marshall of the Johns Hopkins University for their pharmacological study of the compounds presented in this publication.[13] For the sake of simplicity, only the quinine equivalents of Dr. Porter have been reproduced. Dr. Robert C. Elderfield, who represented the O.S.R.D., kindly supplied several 4-chloroquinolines, 9-chloroacridines and dialkylamines of high molecular weight. We are grateful to Dr. C. K. Banks, Messrs. H. J. Nicholas, D. F. Walker, L. M. Montibeller, M. H. Darwish, M. L. Black and H. A. DeWald, of this Laboratory, who contributed several of the compounds reported, and to Dr. L. A. Sweet, Director of Chemical Research, for his keen interest during the course of the studies. Mr. A. W. Spang and Miss Patricia Keller supplied the microanalytical data.

(13) The facilities for testing the compounds described were provided by the Office of Scientific Research and Development through the Committee on Medical Research and by Dr. A. L. Tatum of the Department of Pharmacology in the University of Wisconsin.

Experimental

Acetamidophenols (Table I).—One-tenth of a mole each of the nitrophenol and acetic anhydride were dissolved in 50 cc. of acetic acid. After the addition of 0.2 g. of platinum oxide catalyst, the mixture was shaken in the customary manner under a pressure of about three atmospheres of hydrogen gas until three molecular equivalents had been absorbed. The catalyst was removed by filtration and the acetic acid removed by distillation under reduced pressure. Usually the crude acetamidophenol separated as a white or light gray crystalline solid pure enough for further syntheses.

2-Allyl-4-acetamidophenol.[14]—A solution of 96 g. (1.1 moles) of the allyl ether of 4-acetamidophenol in 70 g. of diethylaniline was heated at boiling temperature for forty minutes. The solution was cooled and diluted with chloroform prior to thorough extraction with 10% sodium hydroxide solution. Enough ether was added to form a distinct upper layer. The combined alkaline extracts were washed twice with ether, and then treated with a slight excess of acetic acid. Extraction of the product with ether, drying and evaporation of the extracts left an oil which was crystallized from a benzene and petroleum ether mixture; m. p. 91–93°. Recrystallization from the same mixture with charcoal treatment yielded 80 g. (83%) of pure product; m. p. 93–94°.

Acetamido-α-alkylamino-*o*-cresols[15] (Table II).—A mixture of equivalent amounts of the acetamidophenol, formaldehyde and aliphatic amine, suspended in about 250 cc. of alcohol per mole of the phenol, was heated in a steam-bath for one to three hours. Upon cooling a crystalline mass usually formed readily, and the product was washed with acetone, alcohol or dilute alcohol. After drying, the product was ordinarily white and of high enough purity to be used in further syntheses.

In certain cases when a crystalline product could not

(14) Claisen, *Ann.*, **418**, 97 (1919).

(15) German Patent 92,309; *Frdl.*, **4**, 103 (1897).

be readily obtained by the foregoing procedure, the volatile materials were removed under reduced pressure and the residue taken into ether and treated with excess alcoholic hydrogen chloride. The monohydrochloride of the desired acetamido-α-alkylamino-*o*-cresol precipitated as an oil, but after treatment with acetone or ether, it crystallized as a white solid.

4-Amino-α-diethylamino-*o*-cresol Dihydrochloride (SN 12,458).—A mixture of 500 g. (2.12 mole) of 4-acetamido-α-diethylamino-*o*-cresol and one liter of 20% hydrochloric acid was heated at refluxing temperature for an hour. The solution was evaporated under reduced pressure to a thick sirup. A liter of benzene was stirred well into the sirup, and the evaporation repeated. Once again the process was repeated using a liter of denatured absolute alcohol. Finally, the sirup was dissolved in two liters of alcohol. The desired salt was then precipitated by the addition of a liter and a half of ether. A total of 541 g. (96% yield) of off-white product was obtained; m. p. 218–220° (dec.).

For analysis a sample was recrystallized from a mixture of alcohol and ethyl acetate; the melting point of the white product did not change.

Anal. Calcd. for $C_{11}H_{18}N_2O\cdot 2HCl$: C, 49.44; H, 7.54. Found: C, 49.70; H, 7.60.

4-Amino-α-1-piperidyl-*o*-cresol Dihydrochloride.—In the same manner, this analog was obtained in a yield of 91% from 4-acetamido-α-1-piperidyl-*o*-cresol[15]; m. p. 153–155° (dec.). Recrystallized from alcohol for analysis, there was no change in the melting point.

Anal. Calcd. for $C_{12}H_{18}N_2O\cdot 2HCl\cdot H_2O$: C, 48.49; H, 7.46; N, 9.43. Found: C, 48.63; H, 7.43; N, 9.10.

4-Amino-α-4-morpholinyl-*o*-cresol Dihydrochloride.—Similarly this compound was obtained in a yield of 45% from 4-acetamido-α-4-morpholinyl-*o*-cresol; m. p. 259–260° (dec.).

Anal. Calcd. for $C_{11}H_{16}N_2O_2\cdot 2HCl$: N, 9.97. Found: N, 9.93.

α-Alkylamino-4-nitro-*o*-cresols (Table III).—The two synthetic methods used in obtaining these compounds are described in the following procedures.

Procedure A.—One-tenth of a molecular equivalent each of the nitrophenol, paraformaldehyde and aliphatic amine were dissolved in 25 cc. of alcohol. The solution was heated in a steam-bath for at least two hours or until the alcohol had evaporated. The residue was treated with an excess of dilute hydrochloric acid to precipitate an insoluble white hydrochloride.

The yellow crystalline free base could be obtained by trituration of the hydrochloride with ammonia.

Procedure B.—A mixture of one-tenth of a mole of α-chloro-4-nitro-*o*-cresol[7] and two-tenths of a mole of aliphatic amine in 150 cc. of absolute ethanol was heated at refluxing temperature for three hours. The volatile materials were removed by distillation under reduced pressure, and the residue was washed with water for the removal of recovered aliphatic amine hydrochloride. The washed residue was dissolved in acetone and the solution dried over potassium carbonate. An equal volume of ether was added, and an excess of alcoholic hydrogen chloride precipitated the desired product as a white crystalline hydrochloride.

2-Ethoxy-5-nitrobenzyl Chloride.—A mixture of 33.4 g. (0.2 mole) of 4-nitrophenetole, 19.8 cc. (0.26 mole) of 37% formalin, and 16.5 g. of zinc chloride was stirred well at 95 to 100° while a rapid stream of hydrogen chloride gas was allowed to pass through it. After five hours, the mixture was allowed to cool overnight. The temperature was raised to 90°, and 35 cc. of water was added. The mixture was cooled, while stirring in an ice-bath, to precipitate the product in small lumps. The solid was collected on a filter and washed with water. A yield of 32.4 g. (75%) of white material was obtained; m. p. 72–75°. A sample was recrystallized from methanol for analysis, with no change in melting point.

Anal. Calcd. for $C_9H_{10}ClNO_3$: C, 50.13; H, 4.67. Found: C, 50.54; H, 4.84.

Nitrobenzylamines (Table IV).—The synthetic method is essentially the same as that of Procedure B, Table III. However, benzene was found more desirable here than alcohol as a solvent since the nitrobenzyl chlorides and the 2-alkoxy-5-nitrobenzyl chlorides, in contrast with α-chloro-4-nitro-*o*-cresol, dissolved quite readily in it. Furthermore, the excess alkylamine hydrochlorides were removed almost quantitatively by their insolubility in benzene, giving an indication of the expected yield of crude product.

In practice, the reaction mixture was cooled and the separated alkylamine salt collected. The filtrate was evaporated under reduced pressure, and the residue was dissolved in ether. After thorough washing of the ether solution with water and finally with saturated salt solution, drying was effected over potassium carbonate. The desired product could be obtained as the hydrochloride by the addition of alcoholic hydrogen chloride to the filtered solution.

4-Chloroquinolines (Table V).—The method of Price and Roberts[11] was employed. Ethoxymethylene malonic ester was condensed with the appropriate aromatic amine by heating them in diphenyl oxide. Ring closure to the 3-carbethoxy-4-hydroxyquinoline was effected in the same medium. The corresponding acid was obtained by alkaline hydrolysis and decarboxylated by heating in diphenyl oxide. The final step was accomplished by treatment of the 4-hydroxyquinoline with phosphorus oxychloride.

Heterocyclic-amino-α-amino-*o*-cresols (Tables VI to XIII, inclusive).—The preparative methods for these compounds, together with the heterocyclic-amino-benzylamines, are described in the following procedures.

Procedure C.—For each mole of acetamido-α-alkylamino-*o*-cresol (Table II), 500 cc. of 20% hydrochloric acid was added, and the mixture was heated at refluxing temperature for an hour. The solution was cooled and treated with concd. sodium hydroxide solution until just acid to congo red. An equivalent amount of chloroheterocyclic was added, and the resulting mixture was then heated in a steam-bath for about two hours. In many cases, a crystalline hydrochloride formed after cooling, and the product was purified by recrystallization. At other times, the reaction mixture was made basic with ammonia or alkali solution and the free base either crystallized or it was extracted with chloroform. In the latter case, the extract was washed with water and dried over potassium carbonate. The filtered solution was then treated with excess alcoholic hydrogen chloride and diluted with ether or acetone for the precipitation of the desired salt. The product was then recrystallized from the solvent indicated in the table.

Procedure D.—The α-alkylamino-4-nitro-*o*-cresol, base or hydrochloride, (Table III) or the nitrobenzylamine (Table IV) was suspended in absolute alcohol and reduced catalytically using platinum oxide catalyst. The solution was treated with a slight excess of alcoholic hydrogen chloride and filtered to remove the catalyst. An equivalent amount of chloroheterocyclic was added to the filtrate, and the directions in Procedure C were followed thereafter.

Procedure E.—In a manner similar to Procedure D, the crystalline 4-amino-α-substituted-amino-*o*-cresol dihydrochloride was simply heated with the desired chloroheterocycle in water or alcohol.

Procedure F.—This method is the same as Procedure C, except that the intermediate acetamido-α-alkylamino-*o*-cresol was not isolated as a pure compound. After the Mannich reaction had been carried out, the volatile materials were removed under reduced pressure. The crude residue was treated thenceforth as the crystalline intermediate in Procedure C. Yields are based on the amount of acetamidophenol used. A by-product of this reaction is the usually relatively insoluble 4-hydroxyanilinoheterocycle; when 4,7-dichloroquinoline is employed, the by-product has been shown to be 7-chloro-4-(4-hydroxyanilino)-quinoline.

7-Chloro-4-(4-hydroxyanilino)-quinoline Monohydrochloride.—To a solution of 72.8 g. (0.5 mole) of 4-amino-

phenol hydrochloride in 500 cc. of water, 99 g. (0.5 mole) of 4,7-dichloroquinoline[16] was added. The mixture was heated in a steam-bath for two hours. After standing for two days, the yellow product was collected on a filter, washed with water and dried at 110°; yield 145 g. (94%); m. p. over 320°. A small sample was recrystallized from methanol for analysis.[17]

Anal. Calcd. for $C_{15}H_{11}ClN_2O \cdot HCl$: C, 58.64; H, 3.94. Found: C, 59.17; H, 4.11.

6-Chloro-9-(4-hydroxyanilino)-2-methoxyacridine.—This compound was obtained as the orange monohydrochloride by the foregoing procedure in 98% yield; m. p. over 300°. Trituration of a small sample with excess ammonia gave the free base. Recrystallized from dioxane, it melted at 266° (dec.).

Anal. Calcd. for $C_{20}H_{15}ClN_2O_2 \cdot H_2O$: C, 65.13; H, 4.65. Found: C, 65.54; H, 4.62.

4-(7-Chloro-4-quinolylamino)-α-monoethylamino-*o*-cresol Dihydrochloride (Table XII, Compound 3).—A mixture of 30.7 g. (0.1 mole) of 7-chloro-4-(4-hydroxyanilino)-quinoline monohydrochloride, 6.3 g. (0.2 mole) of 95% paraformaldehyde, 27.2 cc. (0.2 mole) of alcoholic ethylamine, and 125 cc. of alcohol was heated at refluxing temperature for sixteen hours. Upon cooling, 9 g. of starting material was recovered unchanged. The filtrate was evaporated to dryness and the residue triturated with acetone to yield a solid which was collected on a filter. Treatment of this solid with 100 cc. of warm water left a total of 23.2 g. of unchanged starting material. The aqueous filtrate was made basic with ammonia, and the precipitated free base was extracted with chloroform. After being washed with water, the extract was dried over potassium carbonate. The filtered solution was evaporated to dryness, and the residue taken up in acetone. The addition of excess alcoholic hydrogen chloride precipitated a crude yellow salt. Recrystallized first from alcohol and then from alcohol–methanol, only 1.5 g. (4% yield) of the desired product was obtained; m. p. 280° (dec.).

4-(6-Hydroxy-4-quinolylamino)-α-diethylamino-*o*-cresol Dihydrochloride (Table IX, Compound 2).—A mixture of 10 g. of 4-(6-methoxy-4-quinolylamino)-α-diethylamino-*o*-cresol dihydrochloride (Table IX, compound 3) and 100 cc. of 48% hydrobromic acid was heated at boiling temperature for two hours. The mixture was made basic with ammonia, precipitating a yellow solid base. This was collected on a filter, washed with water, converted to the dihydrochloride by treatment with alcoholic hydrogen chloride.

(17) Microanalysis by Arlington Laboratories.

Summary

A group of 122 heterocyclic-amino α-amino-*o*-cresols and a related group of 12 heterocyclic-amino benzylamines have been synthesized with the object of finding the most effective antimalarial compounds in the general class. All these compounds are new. For the purpose of studying the relationship of chemical structure to antimalarial effectiveness, they have been classified in seven tables. Preparation of the intermediate acetamidophenols, acetamido-α-alkylamino-*o*-cresols, α-alkylamino-4-nitro-*o*-cresols, nitrobenzylamines, and 4-chloroquinolines is also described.

This general class includes the most active 4-aminoquinolines heretofore reported in trophozoite-induced *P. gallinaceum* infection in the chick. Recent clinical reports on one member of the series (Camoquin) are promising.

A New Synthesis of Cinnoline Derivatives: Heterocyclic Steroid Analogs

BY EDMUND C. KORNFELD

In connection with another synthetic problem in progress in these laboratories *m*-hydroxyphenylacetic acid (I) was coupled in alkaline solution with diazotized *p*-nitroaniline (II) to form the azo dye (III) in the normal fashion. It was planned to carry out reactions on the carboxyl group of this product, and in order to effect these changes it was necessary to protect the free hydroxyl function. The azo compound was, therefore, subjected to the action of acetic anhydride in the presence of a trace of sulfuric acid as catalyst, and from the resulting reaction mixture was isolated in good yield a non-acidic, yellow, crystalline product. The analyses indicated that one acetyl group had been introduced, but they showed also that one molecule of water had been eliminated under the acetylating conditions. From the properties and reactions of the product it was evident that cyclization to a cinnoline derivative (V) had taken place. The steps in the process involved first a cyclization of the azo compound in its tautomeric form (IIIa) to 2-*p*-nitrophenyl-3,6-diketo-2,3,4,6-tetrahydrocinnoline (IV) and then acetylation of the enol form of IV to yield 2-*p*-nitrophenyl-3-acetoxy-6-keto-2,6-dihydrocinnoline (V).

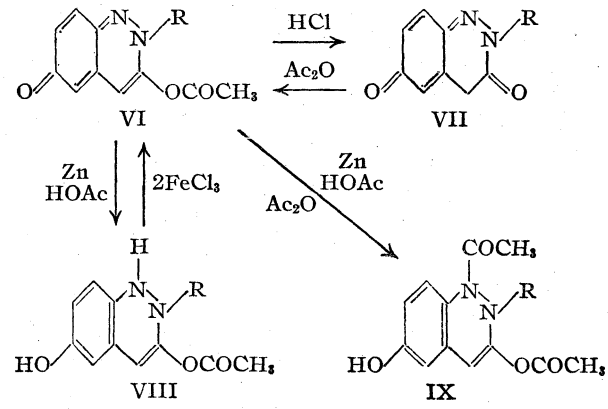
Tautomerism of the type III ⇄ IIIa is well known and has been thoroughly studied by previous investigators.[1]

Further investigation proved the above reaction to be quite a general one. A number of diazotized aromatic amines were coupled with *m*-hydroxyphenylacetic acid, and the resulting azo compounds were cyclized with great facility to cinnoline derivatives similar to V. Table I lists the properties of these products. In most cases the azo compounds were used for the cyclization reaction without purification.

Evidence supporting the above proposed formulations was obtained from several of the reactions of the cinnoline derivatives. Hydrolysis of the monoacetyl compound (VI) (R = 3-acetylphenyl) with concentrated hydrochloric acid produced the 2 - *m* - acetylphenyl - 3,6 - diketo - 2,3,4,6 - tetrahydrocinnoline (VII). Reacetylation of VII regenerated the starting material (VI). Reduction of VI (R = 3-acetylphenyl, 2-naphthyl, or 4-acetoxyphenyl) with zinc dust and acetic acid



gave the corresponding colorless, phenolic, dihydro derivatives (VIII), which could be oxidized by means of ferric chloride at room temperature to the original quinonoid compound (VI). When the reduction was conducted in the presence of acetic anhydride, two hydrogen atoms and one acetyl group were introduced. The structure of the product is probably IX (R = 2-naphthyl in this case) since amines are more readily acetylated than phenols under these conditions.[2]

The ultraviolet absorption spectra of the first three cinnoline derivatives in Table I were determined in ethanol, and that of 2-phenyl-3-acetoxy-6-keto-2,6-dihydrocinnoline is shown in Fig. 1. This compound shows maxima at 235, 330 and 413 mμ, while the 4-bromophenyl derivative has peaks at 235, 338 and 415 mμ. The corresponding maxima for the 4-nitrophenyl-3-acetoxy-6-keto-2,6-dihydrocinnoline lie at 239, 311 and 415 mμ. For clarity and because of the close similarity of these spectra only one is shown in Fig. 1.

The gross structural resemblance of these 2-phenyl-cinnoline derivatives to the basic ring system of the steroid hormones prompted the prepa-

(1) Fierz-David, *et al.*, *Helv. Chim. Acta*, **29**, 1718, 1765 (1946).

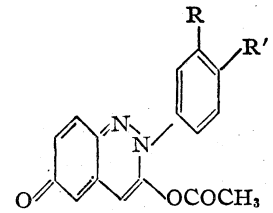
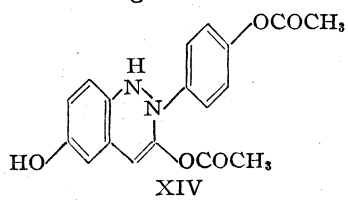
ration of several new heterocyclic steroid analogs by the method outlined above. 2-*p*-Acetoxyphenyl-3-acetoxy-6-keto-2,6-dihydrocinnoline (X)



X R = H, R′ = $OCOCH_3$
XI R = H, R′ = $COCH_3$
XII R = $COCH_3$, R′ = H
XIII R = H, R′ = $COCH_2OCOCH_3$

resembles the testosterone esters, while 2-*p*-acetylphenyl - 3 - acetoxy - 2,6 - dihydrocinnoline (XI), and its isomer (XII) are related to progesterone. Finally, 2-*p*-acetoxyacetylphenyl-3-acetoxy-6-keto-2,6-dihydrocinnoline (XIII) was prepared as an analog of desoxycorticosterone acetate. In the partially reduced series 2-*p*-acetoxyphenyl-3-acetoxy-6-keto-2,6-dihydrocinnoline (X) on reduction with zinc and acetic acid gives the corresponding phenolic derivative (XIV) which is a model for the estrogenic hormones.



XIV

The aromatic amine intermediates requisite for the preparation of these analogs were available by published procedures.

Pharmacology.—The various steroid analogs were tested for hormone activity by Drs. K. K. Chen, R. C. Anderson and E. D. Campbell of these laboratories. Compounds X, XIV, and XII showed one mouse unit of estrogenic activity at levels of 1800, 500 and 100γ, respectively. Analogs X and XII, however, had no testosterone or progesterone activity. Compound XIII, the analog of desoxycorticosterone, was found to be ineffective in maintaining adrenalectomized rats.

Acknowledgment.—The author is indebted to Dr. R. G. Jones for helpful suggestions throughout the course of this work.

Experimental[3]

***m*-Hydroxyphenylacetic Acid.**—*m*-Methoxyphenylacetothiomorpholide was prepared by the method of Schwenk and Bloch[4] from *m*-methoxyacetophenone, morpholine and sulfur. The thioamide (600 g.) was dissolved in a mixture of 1.5 l. of glacial acetic acid and 2.5 l. of concentrated hydrochloric acid, and the solution was refluxed for seventeen hours. The solvents were removed *in vacuo*, and water was added to the residue. The crude *m*-methoxyphenylacetic acid was filtered and washed with water and then dissolved in dilute sodium hydroxide. The solution was filtered, and the product was reprecipitated with hydrochloric acid. It was filtered, washed with water, and dried; yield, 60%. The methoxy compound (1.4 moles) was then dissolved in 750 ml. of hydriodic acid (sp. gr., 1.7), and the solution was refluxed for one and one-half hours while continuously separating the methyl iodide which was formed. The solvent was removed by distillation *in vacuo*, and the *m*-hydroxyphenylacetic acid was filtered and washed with a small portion of cold water. The crude, dry product weighed 153 g. (72%), and was easily purified by recrystallization from ethyl acetate–petroleum ether, m. p. 133–134°.

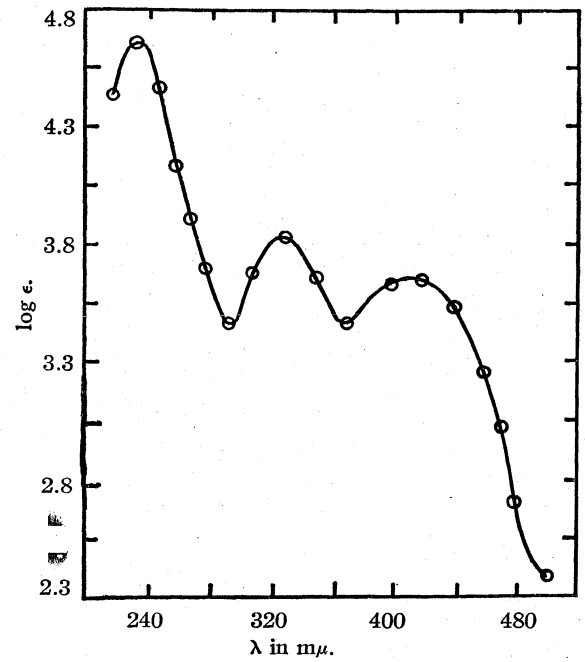


Fig. 1.—Ultraviolet absorption spectrum of 2-phenyl-3-acetoxy-6-keto-2,6-dihydrocinnoline.

Coupling of Diazotized Aromatic Amines with *m*-Hydroxyphenylacetic Acid.—The amines used in this study were commercial products except for *p*-acetoxyaniline[5] and *p*-acetoxyacetylaniline.[6] The procedure employed in the preparation of the azo compounds was as follows: The amine was dissolved or suspended in ice and water containing 2.2 equivalents of hydrochloric acid, and the solution was diazotized with a slight excess of sodium nitrite below 0°. The diazo solution was then poured with stirring into a prepared solution of one equivalent of *m*-hydroxyphenylacetic acid and 4.2 equivalents of sodium hydroxide in ice water. Excess ice kept the temperature below 0° throughout. The bright orange solution was then filtered and acidified with acetic acid or hydrochloric acid. The azo compound was filtered, washed with water and dried. The yields averaged 84%. Analytic data for several of these coupling products are given in Table II. The other azo compounds

were not purified but were used directly for the cyclization reaction.

Cyclization of Azo Compounds to Cinnoline Derivatives.—For the cyclization reaction the azo compounds were dissolved in about 10 parts of acetic anhydride containing 0.02 part of concentrated sulfuric acid, and the solutions were refluxed for thirty to sixty minutes. (The sulfuric acid was omitted in the case of the pyridine derivative derived from 3-aminopyridine.) The solutions were then concentrated *in vacuo* to a small volume, and ether was added. The products were filtered and washed thoroughly with ether. The other pertinent details are given in Table I.

Hydrolysis of 2-*m*-Acetylphenyl-3-acetoxy-6-keto-2,6-dihydrocinnoline (VI).—This acetyl compound (0.5 g.) was dissolved in 50 ml. of concentrated hydrochloric acid, and the solution was refluxed for fifteen minutes. The yellow product began to separate from the reaction mixture toward the end of the reflux period. The solvent was then distilled *in vacuo*, and water was added to the residue. The product was filtered and washed with water and dried. The yield was practically quantitative. Pure 2-*m*-acetylphenyl-3,6-diketo-2,3,4,6-tetrahydrocinnoline (VII) was obtained by precipitation from pyridine solution with ether, m. p. 290–300°, dec.

Anal. Calcd. for $C_{16}H_{12}N_2O_3$: C, 68.56; H, 4.32. Found: C, 68.53; H, 4.45.

Acetylation of 2-*m*-Acetylphenyl-3,6-diketo-2,3,4,6-tetrahydrocinnoline (VII).—The diketo compound (VII), when treated with acetic anhydride in the manner described above for the azo compounds, gave a 70% yield of VI.

Reduction of 2-β-Naphthyl-3-acetoxy-6-keto-2,6-dihydrocinnoline.—The quinonoid compound (1.8 g.) was dissolved in 100 ml. of boiling glacial acetic acid, and 3.6 g. of zinc dust was added gradually. After a few minutes the mixture was filtered through sintered glass and the filtrate was concentrated *in vacuo* to a small volume. Addition of water precipitated the product, which was obtained in the theoretical yield. The 2-β-naphthyl-3-acetoxy-6-hydroxy-1,2-dihydrocinnoline was purified by recrystallization from dilute methanol, and was obtained as colorless plates, m. p. 131–133°.

Anal. Calcd. for $C_{20}H_{16}N_2O_3$: C, 72.27; H, 4.85. Found: C, 72.60; H, 4.98.

Two other dihydro derivatives were similarly prepared: 2-*m*-acetylphenyl-3-acetoxy-6-hydroxy-1,2-dihydrocinnoline, m. p. 164–166°, 70%.

Anal. Calcd. for $C_{18}H_{16}N_2O_4$: C, 66.65; H, 4.97. Found: C, 66.15; H, 4.86. 2-*p*-Acetoxyphenyl-3-acetoxy-6-hydroxy-1,2-dihydrocinnoline (XIV), m. p. 164–165°, 83%. *Anal.* Calcd. for $C_{18}H_{16}N_2O_5$: C, 63.52; H, 4.74. Found: C, 63.32; H, 4.87.

Reductive Acetylation of 2-β-Naphthyl-3-acetoxy-6-keto-2,6-dihydrocinnoline.—This compound (2.0 g.) was dissolved in a mixture of 40 ml. of acetic anhydride and 20 ml. of glacial acetic acid, and 3 g. of zinc dust was added. The mixture was then refluxed for one-half hour, after which it was filtered and the filtrate concentrated *in vacuo* to a straw-colored oil. The oil was taken up in ether, washed with water, and the ether solution was dried over calcium chloride (acetone was added to prevent precipitation of the product at this point). Concentration of the ether solution *in vacuo* gave the product; yield, 32%. The 1-acetyl-2-β-naphthyl-3-acetoxy-6-hydroxy-1,2-dihydrocinnoline (IX) was recrystallized several times from benzene–petroleum ether for analysis, m. p. 141–143°.

Anal. Calcd. for $C_{22}H_{18}N_2O_4$: C, 70.58; H, 4.85; N, 7.48. Found: C, 70.57; H, 5.01; N, 7.66, 7.37.

Oxidation of 2-*m*-Acetylphenyl-3-acetoxy-6-hydroxy-1,2-dihydrocinnoline.—This colorless dihydro derivative (2.3 g.) was dissolved in 50 ml. of acetic acid at room temperature, and to it was added a solution of 4.0 g. of ferric chloride crystals in 5 ml. of water and 1.0 ml. of concentrated hydrochloric acid. Upon dilution of the solution with two volumes of water the yellow 2-*m*-acetylphenyl-3-acetoxy-6-keto-2-6-dihydrocinnoline separated. It was filtered and washed with water; yield, 84%; m. p. 236–238°, dec.

Summary

1. Azo dyes formed by coupling diazotized aromatic amines with *m*-hydroxyphenylacetic acid have been found to cyclize to 2-aryl-substituted cinnolines under acetylating conditions.

2. This new synthesis of cinnoline derivatives has been used to prepare heterocyclic analogs of the steroid hormones.

3. Several of the compounds show a slight estrogenic activity.

The Synthesis of Palmitic Acid and Tripalmitin Labeled with Carbon Fourteen

BY WILLIAM G. DAUBEN

Isotopic high molecular weight fatty acids, such as palmitic and stearic, have been prepared containing deuterium and radioactive bromine. In order to study the fate of the carbon chain itself, palmitic acid containing radioactive carbon was prepared.

The synthesis of palmitic acid labeled in the carboxyl group with C^{14} was readily accomplished, in a yield of 72%, by the carbonation of *n*-pentadecylmagnesium bromide with radioactive carbon dioxide.[1] Carboxyl-labeled tripalmitin was prepared from this acid in a yield of 75% by employing the acid chloride method of Stephenson.[2] The tripalmitin has a specific activity of 760 cts./min./mg. ester.

The preparation of *n*-hexadecanoic acid (palmitic acid) labeled at carbon atom six with C^{14} was carried out as shown in the scheme.

$$\underset{\text{I}}{C_{10}H_{21}MgBr} \xrightarrow{C^*O_2} \underset{\text{II}}{C_{10}H_{21}C^*OOH} \xrightarrow{CH_2N_2}$$

$$\underset{\text{III}}{C_{10}H_{21}C^*OOCH_3} \xrightarrow{CuCr_2O_4} \underset{\text{IV}}{C_{10}H_{12}C^*H_2OH} \xrightarrow{HBr}$$

$$C_{10}H_{21}C^*H_2Br \xrightarrow[2.\ CdCl_2]{1.\ Mg.}$$

(1) Dauben, Reid and Yankwich, *Anal. Chem.*, **19**, 828 (1947).

(2) Stephenson, *Biochem. J.*, **7**, 429 (1913).

$$(C_{10}H_{21}C^*H_2)_2Cd \xrightarrow[2.\ KOH]{1.\ CH_3OOC(CH_2)_3COCl} \underset{VI}{}$$

$$C_{10}H_{21}C^*H_2CO(CH_2)_3COOH \xrightarrow[NH_2NH_2]{NaOH} \underset{VII}{}$$

$$C_{10}H_{21}C^*H_2(CH_2)_4COOH \quad \underset{VIII}{}$$

Yields: $C^*O_2 \longrightarrow$ III, 83%; III $\longrightarrow$ V, 79%; V $\longrightarrow$ VIII, 54%

It was found necessary to use three times the normal amount of copper chromite catalyst in the hydrogenolysis of ester III to obtain high yields consistently.[3] This was probably due to the fact that the methanol produced in the reaction is a strong enough acid to destroy the activity of the catalyst. The over-all yield of palmitic acid, based on barium carbonate, was 30% and the palmitic acid has a specific activity of 40,000 cts./min./mg. acid.

After this work had been completed, Houston[4] reported the synthesis 4-keto-*n*-hexadecanoic acid by the same general procedure employing *n*-dodecyl bromide and β-carbomethoxypropionyl chloride. However, the yield of the keto-acid isolated, based on the bromide, was only 7.4%. In view of the great discrepancy in this yield and the yield obtained in the above synthesis, the reaction was investigated. It was found when the procedure outlined in this paper for the preparation of the 5-keto-acid was followed, the 4-keto-acid was obtained in 69% yield. The failure of Houston to obtain a high yield may have been due to the fact that insufficient time was allowed for the conversion of the Grignard reagent to the dialkylcadmium compound.

Acknowledgment.—The author wishes to express his appreciation to the Bio-Organic Group of the Radiation Laboratory for their kind assistance.

Experimental[5]

1-Pentadecanol. (a) From Paraformaldehyde.[6]—*n*-Tetradecylmagnesium bromide was prepared in an all-glass apparatus under nitrogen from 1.54 g. (0.0623 mole) of magnesium turnings and 15.5 g. (0.057 mole) of redistilled *n*-tetradecyl bromide in 60 cc. of anhydrous di-*n*-butyl ether. The bromide solution was added to the magnesium during one hour, and the temperature was kept at 35° or below. The temperature was raised to 105° and 2.84 g. (0.094 mole) of paraformaldehyde (dried in a vacuum desiccator) was added in small portions over a period of thirty minutes. After the addition was complete, the clear solution was heated for an additional period of forty-five minutes at 105° during which time the solution became cloudy. The heating was then continued for one hour at 110°, the reaction mixture was cooled, decomposed in the usual manner with dilute sulfuric acid, and the ether was removed by steam distillation. The cooled residue from the distillation was extracted with ether, the solvent was removed and the product was distilled. A small amount of 1-pentadecanol (2.2 g., 17.2%, b. p. 118° (0.3 mm.)) was obtained. The pot residue was heated for six hours on a steam-bath with 15 cc. of absolute ethanol and 3 cc. of concentrated hydrochloric acid but only *n*-octacosane was isolated.

When the Grignard reagent was prepared at a temperature above 35°, the yield was only slightly less, 15.7%.

(b) From the Ester.—Ethyl *n*-pentadecanoate (14.6 g., 0.054 mole) was hydrogenated over copper chromite catalyst (2.5 g.). The initial pressure was 3000 p. s. i. at room temperature and hydrogenolysis took place readily at 250° and was complete in five to six hours. The 1-pentadecanol distils at 112–114° (0.2 mm.), yield 10.5 g. (85.4%).

***n*-Pentadecyl Bromide.**—The bromide was prepared in the usual manner[7] employing anhydrous hydrogen bromide and 1-pentadecanol (27.3 g., 0.12 mole) except that the reaction mixture was diluted with 50 cc. of *n*-hexane before processing. *n*-Pentadecyl bromide boils at 127–128° (0.5 mm.), yield 28.4 g. (82.7%).

Carboxyl-Labeled Hexadecanoic Acid.—*n*-Pentadecylmagnesium bromide was prepared in an all-glass apparatus in a nitrogen atmosphere from 1.6 g. (0.066 mole) of magnesium turnings and 15.9 g. (0.0547 mole) of *n*-pentadecyl bromide in 110 cc. of anhydrous ether. An aliquot of the solution was titrated and the concentration was found to be 0.00044 mole of Grignard reagent per cc. of solution.

A volume of 110 cc. (0.0484 mole) of Grignard solution was carbonated with radioactive carbon dioxide generated from 9.1 g. (0.046 mole) of radioactive barium carbonate with a specific activity of 1060 cts./min./mg.[8] following the procedure described in detail in previous publications. The acid was isolated in the usual manner and converted directly to the methyl ester. The ester distils at 132–133° (0.3 mm.), yield 10.0 g. (80.4%), $n^{25}D$ 1.4386.

The ester (10.0 g., 0.037 mole) was saponified with a solution of 2.3 g. of potassium hydroxide, 35 cc. of methanol, and 2 cc. of water by heating on a steam-bath overnight. The crude acid was recrystallized from 40 cc. of ten per cent. aqueous acetone. The pure acid melts at 60–61°, yield 8.55 g. (90.1%). The over-all yield based on barium carbonate was 72.4%, specific activity × 16: 1050 cts./min./mg. barium carbonate,[9] activity of compound: 810 cts./min./mg. acid.

Carboxyl-labeled Tripalmitin.—Palmityl chloride was prepared as described by earlier workers[10] from 8.3 g. (0.0324 mole) of the carboxyl-labeled palmitic acid prepared above and 10 cc. of purified thionyl chloride.

Tripalmitin was prepared by slow addition, with stirring, of a chloroform solution of palmityl chloride to a cooled mixture of 0.975 g. (0.0106 mole) of redistilled glycerol, 8 cc. of dry pyridine, and 25 cc. of dry chloroform.[2] The light-yellow solution was allowed to stand three days at room temperature during which time it gradually darkened. The mixture was processed in the usual manner, and the residual light-tan solid was recrystallized twice from acetone (Norit) to give white tripalmitin, m. p. 61–62°, sinters 59°, yield 6.15 g. (75.5%). The over-all yield from barium carbonate was 54.7%, specific activity

(8) All measurements of radioactivity were carried out with a thin mica-window Geiger–Müller tube on a scale of 64 circuit with a geometry of 17.6 ± 2.5 disintegrations per count. The activity was determined with thin uniform layers of barium carbonate according to the procedure described in earlier publications. The over-all counting error was ±2%.

(9) This value was obtained by the oxidation of a microsample with Van Slyke's oxidizing solution and precipitation of the carbon dioxide as barium carbonate, which was counted. To correct for the dilution of activity in the compound, the observed specific activity was multiplied by sixteen.

(10) (a) Hann and Jamieson, THIS JOURNAL, **50**, 1442 (1928); (b) Rose, *ibid.*, **69**, 1284 (1947).

× 17: 1040 cts./min./mg. barium carbonate, activity of compounds: 760 cts./min./mg. tripalmitin.

Carboxyl-labeled Methyl *n*-Hendecanoate (III).—*n*-Decylmagnesium bromide was prepared as described for the other Grignard reagents from 1.8 g. (0.074 mole) of magnesium turnings and 15 g. (0.068 mole) of *n*-decyl bromide dissolved in 80 cc. of anhydrous ether. An aliquot of the solution was titrated and the concentration was found to be 0.00075 mole of Grignard reagent per cc.

A volume of 15.7 cc. (0.0117 mole) of Grignard solution was carbonated with radioactive carbon dioxide generated from 1.860 g. (0.00942 mole) of radioactive barium carbonate with a specific activity of 54,400 cts./min./mg. following the procedure described previously.[1] The acid was isolated in the usual manner and was then methylated with an ethereal solution of diazomethane. The ester was distilled in a small sublimation-type still, block temperature 54–58°, pressure 0.3 mm., yield 1.560 g. (82.9%), n^{23}D 1.4275, specific activity × 12: 53,500 cts./min./mg. barium carbonate, activity of compound: 52,800 cts./min./mg. ester.

Anal. Calcd. for $C_{12}H_{24}O_2$: C, 71.95; H, 12.07. Found: C, 71.97; H, 11.95.

***n*-Hendecyl Bromide Labeled at Carbon Atom One (V).**—Carboxyl-labeled methyl *n*-hendecanoate (1.538 g., 0.00767 mole) was hydrogenated over copper chromite catalyst (1.0 g.) at an initial pressure of hydrogen of 3000 p. s. i. at room temperature. The hydrogenolysis took place at 250° and was complete in six hours. The crude alcohol was converted directly to the bromide by passage of anhydrous hydrogen bromide through the alcohol at steam-bath temperature.[7] The *n*-hendecyl bromide was distilled in a small sublimation-type still, block temperature 70–75°, pressure 0.5 mm., yield 1.432 g. (79.3%), n^{25}D 1.4548, specific activity × 11: 53,100 cts./min./mg. barium carbonate; activity of compound: 44,800 cts./min./mg. bromide.

Anal. Calcd. for $C_{11}H_{23}Br$: C, 56.17; H, 9.86. Found: C, 56.61; H, 10.28.

***n*-Hendecanoic Acid Labeled at Carbon Atom Six (VIII).**—Methyl 5-keto-*n*-hexadecanoate was prepared following the procedure outlined by Cason and Prout except for one modification.[11] The Grignard reagent was prepared from 0.15 g. (0.0062 mole) of magnesium turnings and 1.412 g. (0.006 mole) of *n*-hendecyl bromide labeled at carbon atom one in 50 cc. of anhydrous ether. The resulting Grignard reagent was converted to the dialkylcadmium compound with 0.71 g. (0.00389 mole) of anhydrous cadmium chloride. After the addition of the cadmium chloride, the mixture was heated under reflux until a negative Gilman test for a Grignard reagent was obtained. This required about two hours. The ether was replaced with benzene, and the resulting suspension was treated with 1.00 g. (0.0061 mole) of γ-carbomethoxybutyryl chloride.[12] The reaction mixture, after heating under reflux for one hour, had set to a solid mass and then was decomposed as usual. The crude reaction mixture was directly saponified with a solution of 0.4 g. of potassium hydroxide in 10 cc. of methanol. After dilution to 50 cc. with water, the mixture was extracted with ether to remove the neutral compounds. *n*-Docosane (100 mg.) marked at carbon atoms eleven and twelve was isolated. The alkaline layer was acidified and then extracted with ether.

The crude keto acid was reduced by the modified Wolff–Kishner method[13] using 6.4 cc. of diethylene glycol, 0.8 g. of sodium hydroxide, and 0.77 cc. of one-hundred per cent. hydrazine hydrate. The crude acid was distilled onto a cold-finger type condenser at a bath temperature of 110° and pressure of 1 mm. The distillate was recrystallized from 15 cc. of ten per cent. aqueous acetone (Norit), m. p. 61–62°, yield 700 mg. (45.7%), specific activity × 16: 52,700 cts./min./mg. barium carbonate, activity of compound: 40,500 cts./min./mg. acid.

Anal. Calcd. for $C_{16}H_{32}O_2$: C, 74.94; H, 12.58. Found: C, 74.55; H, 12.47.

In a practice experiment with non-radioactive *n*-hendecyl bromide (6.71 g., 0.00286 mole) and γ-carbomethoxybutyryl chloride (3.76 g., 0.0228 mole), the keto acid was isolated, and recrystallized from methanol, m. p. 84.5–85°, yield, 4.87 g. (64% based on bromide, 79% based on acid chloride). This acid, when subjected to the Wolff–Kishner reaction, was reduced to palmitic acid in a yield of 82%.

Summary

1. Palmitic acid and tripalmitin, labeled in the carboxyl carbon with carbon fourteen, have been prepared.

2. Palmitic acid, labeled at carbon atom six with carbon fourteen, has been synthesized.

3. A re-examination of the work of Houston on the synthesis of 4-ketohexadecanoic acid by the cadmium procedure, has shown that it is critical to allow sufficient time for the conversion of a Grignard reagent to a dialkylcadmium compound.

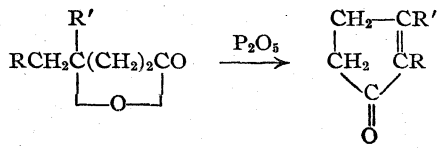
The Preparation of Cyclopentenones from Lactones

BY ROBERT L. FRANK, ROSE ARMSTRONG, JACK KWIATEK AND HAROLD A. PRICE

The reaction of lactones with phosphorus pentoxide to form cyclopentenones, by which syntheses of dihydrojasmone (VII)[1] and dihydrocinerone (VI)[2] have been recently accomplished, has now been further investigated to determine its scope and usefulness as an alternative method to those developed by Hunsdiecker[3] and by Johnson and Petersen.[4]

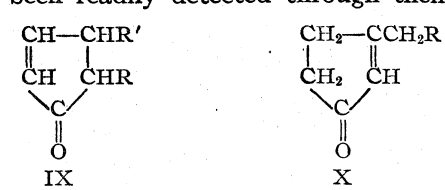


I, R = R′ = H
II, R = H, R′ = CH_3
III, R = n-C_6H_{13}, R′ = H
IV, R = R′ = CH_3
V, R = n-C_3H_7, R′ = CH_3
VI, R = n-C_4H_9, R′ = CH_3
VII, R = n-C_5H_{11}, R′ = CH_3
VIII, R = n-C_6H_{13}, R′ = H

The lactones were prepared in yields of 15–64% by the addition of the appropriate Grignard reagents to esters of levulinic acid, using the low-temperature technique of Cason, Adams, Bennett and Register.[5] Both ethyl and cyclohexyl levulinates were used, the choice depending on the ease of separation by fractional distillation of the lactones from the starting materials.

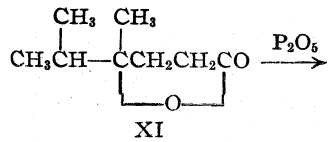
The reaction of the simplest lactones (I and II) with phosphorus pentoxide was found to yield only black tarry products rather than the desired cyclopentenones, probably because of insufficient steric hindrance around the α,β-unsaturation of the products to prevent polymerization in the strongly acidic reaction mixture.

Better results are obtained with increased substitution, the respective yields being 30, 32, 30[2] and 50%[1] of the cyclopentenones represented by Structures IV, V, VI and VII. In these instances, in which R′ = methyl, the transformation gives only 2-cyclopentenones. 2,3-Disubstituted 4-cyclopentenones (IX) were not found; nor were β-substituted products (X), which might have been expected by ring closure involving the γ-methyl group. If formed these latter compounds would have been readily detected through their ultraviolet absorption spectra, as described below. Thus, a methylene group adjacent to the γ-position of the lactone appears to react in preference to a similarly-attached methyl group in the formation of the five-membered ring.

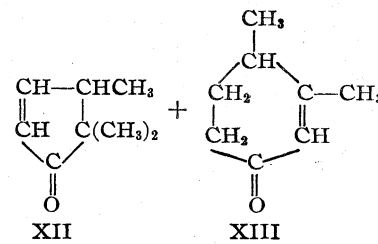


IX X

γ,δ-Dimethyl-γ-caprolactone (XI), however, a *gamma* lactone having a methyl and a methinyl group attached to the *gamma* carbon atom, gives on treatment with phosphorus pentoxide a complex mixture containing at least two α,β-unsaturated ketones. A 6% yield of 2,2,3-trimethyl-4-cyclopentenone (XII), characterized by ozonolysis to trimethylsuccinic acid and reduction to 2,2,3-trimethylcyclopentanone, was isolated by fractional distillation.



XI



XII XIII

The other ketone (6%) has not been positively identified, but its C-methyl determination (1.5)[6,7] and ultraviolet absorption maximum of 231 mμ[8] indicate its structure to be 3,4-dimethyl-2-cyclohexenone (XIII), the reaction product which would result by ring closure involving the δ-methyl group of the lactone (XI).

One additional lactone, γ-undecanolactone (III), gave results similar to those of Plattner and St. Pfau[9] in their study of the action of sulfuric acid on ω-undecylenic acid. The main product was 2-n-hexyl-2-cyclopentenone (VIII), but the yield was low (17%) and high purity of product difficult to attain due to the occurrence of smaller amounts of an isomer, 2-n-hexyl-4-cyclopentenone.

It is significant that when the lactone contains both a methyl and a methylene group, a single product is formed, while a complex mixture results if the methyl group is absent.

The ultraviolet absorption spectra of substituted cyclopentenones have been studied by Gil-

lam and West,[10] who have shown for several 2,3-disubstituted 2-cyclopentenones an approximate deviation of −11 mμ from Woodward's average value of 247 ± 5 mμ for open-chain α,β-unsaturated carbonyl compounds triply substituted around the double bond with non-absorbing groups. Gillam and West have suggested that this can be extended as a general amendment to Woodward's rule.[8] The absorption maxima for 2-cyclopentenones unsubstituted, singly substituted, and doubly substituted at the double bond should, therefore, appear at 214 ± 5 mμ, 224 ± 5 mμ and 236 ± 5 mμ, respectively.

Absorption spectra of our cyclopentenones, with one exception (XII), fall within the range of these predictions, with maxima as follows: 2,3-dimethyl-2-cyclopentenone (IV), 235 mμ; 2-*n*-propyl-3-methyl-2-cyclopentenone (V), 235 mμ; 2-*n*-hexyl-2-cyclopentenone (VIII), 229 mμ; 2,2,3-trimethyl-4-cyclopentenone (XII), 221 mμ; 2-*n*-hexyl-4-cyclopentenone, 212 mμ.

Experimental

Cyclohexyl Levulinate.—This was prepared by a procedure analogous to that for ethyl levulinate[1] from 581 g. (5.00 moles) of levulinic acid, 990 g. (9.88 moles) of cyclohexanol and 1 ml. of concentrated sulfuric acid in 500 ml. of benzene. The yield was 803 g. (81.5%) of cyclohexyl levulinate, b. p. 116–118° (2 mm.); $n^{20}D$ 1.4559; sp. gr. $^{20}_{20}$ 1.023; *MR* calcd., 52.35; *MR* found, 52.66.

Anal.[11] Calcd. for $C_{11}H_{18}O_3$: C, 66.54; H, 9.15. Found: C, 66.60; H, 9.35.

Preparation of Lactones.—Procedures similar to that of Cason, Adams, Bennett and Register[5] for γ-methyl-γ-*n*-propylbutyrolactone were used. γ-Methyl-γ-valerolactone was prepared from 200 g. (1.41 moles) of methyl iodide and 34.0 g. (1.40 gram atoms) of magnesium turnings in 500 ml. of dry ether and 318 g. (1.60 moles) of cyclohexyl levulinate in 1 liter of dry ether. The crude product, after shaking with zinc dust, was fractionally distilled through a twelve-inch helix-packed column to give a fore-run of cyclohexanol and 78.8 g. of the lactone, b. p. 85–90° (18 mm.). Redistillation gave 67.4 g. (42%) of colorless product, b. p. 89–91° (17 mm.); $n^{20}D$ 1.4352; sp. gr. $^{20}_{20}$ 1.020; *MR* calcd.: 29.24; *MR* found, 29.22.

γ-Methyl-γ-caprolactone was prepared similarly from 230 g. (2.11 moles) of ethyl bromide and 48.6 g. (2.00 gram atoms) of magnesium turnings in 500 ml. of dry ether and 396.5 g. (2.00 moles) of cyclohexyl levulinate in 2 liters of dry benzene and 500 ml. of dry ether. Fractional distillation of the crude product gave 146.5 g. (65% based on unrecovered cyclohexyl levulinate) of lactone, b. p. 102–103.5° (15 mm.); $n^{20}D$ 1.4412; sp. gr. $^{20}_{20}$ 1.004; *MR* calcd., 33.86; *MR* found, 33.71. There were also obtained 86.5 g. of cyclohexanol and 46.6 g. of cyclohexyl levulinate, b. p. 115° (3 mm.).

γ-Methyl-γ-octanolactone was synthesized from 430 g. (3.14 moles) of *n*-butyl bromide and 73.0 g. (3.00 gram atoms) of magnesium turnings in 800 ml. of dry ether, and 500 g. (3.52 moles) of ethyl levulinate in 3 liters of benzene. The crude product, after shaking with zinc dust, gave on fractional distillation 279.8 g. (60%) of the colorless lactone, b. p. 85–87° (2 mm.) (reported,[12] 120–123° (15 mm.)); $n^{20}D$ 1.4452; sp. gr. $^{20}_{20}$ 0.964; *MR* calcd.: 43.10; *MR* found: 43.11.

Anal. Calcd. for $C_9H_{16}O_2$: C, 69.19; H, 10.32. Found: C, 69.40; H, 10.53.

γ,δ-Dimethyl-γ-caprolactone (XI) was prepared from 1275 ml. (1684 g., 13.70 moles) of isopropyl bromide and 314 g. (12.9 gram atoms) of magnesium turnings in 3900 ml. of absolute ether and 1885 g. (13.08 moles) of ethyl levulinate in 6.5 liters of dry benzene. Fractional distillation of the crude product gave 274.9 g. (15.1%) of the lactone, b. p. 116° (16 mm.); $n^{20}D$ 1.4460; sp. gr. $^{20}_{20}$ 0.991; *MR* calcd., 38.49; *MR* found, 38.26.[13]

The Reaction of Lactones with Phosphorus Pentoxide.—The transformations were carried out similarly with all the lactones. One-fifth mole of phosphorus pentoxide was placed in a distilling flask equipped with a ground-glass joint. The lactone (0.27 mole) was then poured into the flask, which was immediately attached to a distilling column partially filled with glass helices. The mixture was heated gently with a flame to initiate reaction, the pressure was gradually reduced to 2–28 mm., and the products finally distilled directly from the dark reaction mixture by the use of a free flame. They were then redistilled.

2,3-Dimethyl-2-cyclopentenone (IV).—γ-Methyl-γ-caprolactone (in three runs totaling 101.6 g., 0.78 mole) gave 53.0 g. of distillate, b. p. 102–115° (28 mm.). Redistillation yielded 29.6 g. of starting material, b. p. 101–110° (25 mm.), and 18.8 g. (30.4% based on unrecovered lactone) of 2,3-dimethyl-2-cyclopentenone, b. p. 90–92° (25 mm.); $n^{20}D$ 1.4830; sp. gr. $^{20}_{20}$ 0.969; *MR* calcd., 31.89; *MR* found, 32.47; ultraviolet absorption maximum 235 mμ (log ε = 3.04). The semicarbazone of the product melted at 247–250° (dec.) (reported,[3] 247° (dec.)).

3-Methyl-2-*n*-propyl-2-cyclopentenone (V).—γ-Methyl-γ-octanolactone (in five runs totaling 210 g., 1.35 moles) gave 136.4 g. of distillate. Redistillation yielded 39.6 g. (32% based on unrecovered lactone) of 3-methyl-2-*n*-propyl-2-cyclopentenone of mint-like odor, b. p. 55–58° (2 mm.); $n^{20}D$ 1.4778; ultraviolet absorption maximum, 235 mμ (log ε = 3.04); and 71.2 g. of starting material, b. p. 82–88° (2 mm.). The semicarbazone of the product melted at 209–210.5° (reported,[3] 212°).

2,2,3-Trimethyl-4-cyclopentenone (XII) and 3,4-Dimethyl-2-cyclohexenone (XIII).—γ,δ-Dimethyl-γ-caprolactone (XI) was treated with phosphorus pentoxide in ten runs of 32 g. (0.23 mole) each to give 18.8 to 23.7 g. of slightly yellow distillate per run, $n^{20}D$ 1.4563–1.4621. All were combined to total 212.2 g., $n^{20}D$ 1.4601. Careful distillation through a thirty-six inch helix-packed column with a total reflux-partial takeoff head and reflux ratio 20:1 yielded 11.8 g. (6%, based on unrecovered lactone) of 2,2,3-trimethyl-4-cyclopentenone (XII) of camphor-like odor, b. p. 66–66.5° (19 mm.), 169.5–170° (740 mm.); $n^{20}D$ 1.4599; sp. gr. $^{20}_{4}$ 0.911; *MR* calcd., 36.50; *MR* found, 37.06; C-methyl[14] calcd. (2 methyls), 24.2%; found, 19.5, 19.7%; ultraviolet absorption maximum 221 mμ (log ε = 2.77). *Anal.* Calcd. for $C_8H_{12}O$: C, 77.37; H, 9.74. Found: C, 77.18; H, 9.80. The semicarbazone of this fraction, recrystallized from ethanol as shiny colorless needles, melted at 189–190°.

Anal. Calcd. for $C_9H_{15}N_3O$: C, 59.64; H, 8.34. Found: C, 59.38; H, 8.60.

Attempts to prepare a crystalline oxime were unsuccessful.

A second fraction, probably 3,4-dimethyl-2-cyclohexenone (XIII), weighed 11.0 g. (6%, based on unrecovered lactone), b. p. 100–101° (18 mm.); $n^{20}D$ 1.4779; C-methyl calcd. (2 methyls): 24.2%; found: 18.0, 17.4%; ultraviolet absorption maximum 231 mμ (log ε = 3.02). *Anal.* Calcd. for $C_8H_{12}O$: C, 77.37; H, 9.74. Found: C, 75.14, 74.91; H, 9.79, 9.78.

The semicarbazone, recrystallized from 40% ethanol as colorless platelets, melted at 183–184°.

Anal. Calcd. for $C_9H_{15}N_3O$: C, 59.64; H, 8.34. Found: C, 59.77; H, 8.48.

(11) Microanalyses were carried out by Miss Theta Spoor, Miss Lillian Hruda and Miss Betty Alice Snyder.

(12) Wilson, THIS JOURNAL, **67**, 2161 (1945).

(13) Blaise, *Compt. rend.*, **130**, 1033 (1900).

(14) C-Methyl determinations were carried out by Mr. Howard Clark of the Illinois State Geological Survey.

This semicarbazone was shown to be different from that of 2,2,3-trimethyl-4-cyclopentenone (XII) by a depressed mixed m. p., 168–170°.

Attempts to prepare a solid oxime were unsuccessful. As a higher-boiling fraction, 99.3 g. of the starting lactone was recovered.

2-*n*-Hexyl-2-cyclopentenone (VIII) and 2-*n*-Hexyl-4-cyclopentenone.—γ-Undecanolactone (commercial product of Givaudan-Delawanna, Inc., New York) (in two runs totaling 100.0 g., 0.54 mole) gave 25.3 g. of a mixture of ketones, b. p. 74–94° (2 mm.); $n^{20}D$ 1.4728. Redistillation yielded 15.7 g. (17.5%) of 2-*n*-hexyl-2-cyclopentenone, b. p. 97–100° (5 mm.); $n^{20}D$ 1.4675; sp. gr. $^{20}_{20}$ 0.910, *MR* calcd., 50.32; *MR* found, 50.72; ultraviolet absorption maximum 229 mμ (log ε = 2.70). The semicarbazone, recrystallized as a colorless powder from 40% ethanol, melted at 194.5–196° (reported,[9] 196°). A 4-g. lower-boiling fraction, b. p. 60–70° (5 mm.); $n^{20}D$ 1.4854; ultraviolet absorption maximum 212 mμ (log ε = 2.40), yielded a semicarbazone corresponding in melting point (192–193.5°) to that of Plattner and St. Pfau[9] (m. p. 189–190°) for 2-*n*-hexyl-4-cyclopentenone. A mixture with the semicarbazone of 2-*n*-hexyl-2-cyclopentenone melted at 186–187°.

Ozonolysis of 2,2,3-Trimethyl-4-cyclopentenone (XII).—Ozone was bubbled for twelve hours through a solution of 3.3 g. (0.027 mole) of 2,2,3-trimethyl-4-cyclopentenone in 35 ml. of glacial acetic acid. The solution was then added dropwise to 25 ml. of 11% aqueous hydrogen peroxide, the mixture being agitated by a stream of air bubbles, and refluxed for two hours. The acetic acid was removed by steam distillation and the residue evaporated to a volume of approximately 5 ml. To this was added 5 ml. of concentrated nitric acid, followed by reevaporation to 5 ml., the process being repeated three times. On standing the solution then deposited platelets of trimethylsuccinic acid, weighing 0.75 g. (18%) after recrystallization from concentrated nitric acid, m. p. 147.5–149° (reported,[15] 148–149°); neutral equivalent calcd., 80.1; found, 84.6.

Anal. Calcd. for $C_7H_{12}O_4$: C, 52.49; H, 7.55. Found: C, 52.22; H, 7.81.

Distillation of 0.25 g. of the acid gave a colorless solid melting *ca.* 30° (anhydride). On standing with an equimolar amount of *p*-toluidine in benzene this deposited crystals of the mono-*p*-toluidide of trimethylsuccinic acid. Recrystallization from 95% ethanol gave colorless needles melting at 125–126° (reported,[16] 127°).

(15) Auwers, *Ann.*, **292**, 142 (1896).

(16) Auwers and Umgemach, *Ber.*, **68**, 349 (1935).

Hydrogenation of 2,2,3-Trimethyl-4-cyclopentenone (XII).—Two grams of the ketone dissolved in 8 ml. of ethanol was hydrogenated over Raney nickel at room temperature and a pressure of 1900 lb. per square inch. The reaction was stopped after five minutes when one molar equivalent of hydrogen had been absorbed (estimated by pressure drop). The catalyst was removed by filtration and the semicarbazone and oxime prepared from the alcoholic solution. The semicarbazone, recrystallized from 40% ethanol, took the form of shiny plates, m. p. 197–198° (reported,[17] 210–212°).

Anal. Calcd. for $C_9H_{17}N_3O$: C, 58.99; H, 9.35. Found: C, 58.76; H, 9.15.

A mixed m. p. with the semicarbazone of 2,2,3-trimethyl-4-cyclopentenone (XII) was depressed, 184–185°.

The oxime, recrystallized from water or aqueous ethanol as colorless needles, melted at 103–104° (reported,[18] 104°).

Anal. Calcd. for $C_8H_{15}NO$: C, 68.05; H, 10.71. Found: C, 67.45; H, 10.56.

Ultraviolet Absorption Spectra.—Miss Ruth Johnston carried out the determinations using a Beckmann Model D Spectrophotometer. The ketones were dissolved in 95% ethanol, concentration 0.006 g. per liter of solution; $\log \epsilon = \log (1/cl) \cdot \log (I_0/I)$, in which c = g./100 ml. of solution, l = 1 cm.

Summary

γ-Methyl-γ-lactones having a methylene group adjacent to the *gamma* carbon atom are converted smoothly by action of phosphorus pentoxide to 2,3-disubstituted 2-cyclopentenones. This method is not applicable, however, for the preparation of 2-cyclopentenone and 3-methyl-2-cyclopentenone.

γ,δ-Dimethyl-γ-caprolactone, when treated with phosphorus pentoxide, is converted in low yield to 2,2,3-trimethyl-4-cyclopentenone and other products.

The ultraviolet absorption spectra of substituted 2-cyclopentenones are briefly discussed.

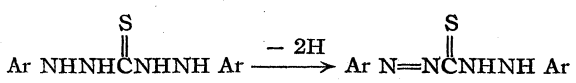
The Synthesis of Some Substituted Thiocarbazones[1]

BY D. S. TARBELL, C. W. TODD,[2a] M. C. PAULSON,[2b] E. G. LINDSTROM[2c] AND V. P. WYSTRACH[2d]

The observation[3] that thiocarbazones, especially di-(*p*-biphenyl)-thiocarbazone, were sensitive reagents for the detection of small amounts of arsenicals, led to the preparation and testing of a number of substituted thiocarbazones. The synthesis of these compounds, and their properties as arsenical detectors, are described in the present paper.

Thiocarbazones (I) are prepared by oxidation of the corresponding thiocarbazides (II) by air in alkaline solution or by hydrogen peroxide



Several methods were used for the preparation of the necessary thiocarbazides in our work.

(1) The work described in this paper was done under Contract OEM-sr-319, recommended by the National Defense Research Committee, between the Office of Scientific Research and Development, and the University of Rochester.

(2) Present address: (a) Experimental Station, E. I. du Pont de Nemours, Inc., Wilmington, Del.; (b) Research Laboratory, Grasselli Chemical Company, Cleveland, Ohio; (c) California Research Corporation, Richmond, Calif.; (d) Research Laboratory, American Cyanamid Company, Stamford, Conn.

(3) By Professor Weldon G. Brown of the University of Chicago.

(1) **The Fischer Method.**—This involves formation of the hydrazine salt of a dithiocarbazinic acid (III), which, on heating, evolves hydrogen sulfide and yields the thiocarbazide II.

$$2ArNHNH_2 + CS_2 \longrightarrow ArNHNHCS_2H\cdot H_2NHNAr \xrightarrow{-H_2S} II$$
III

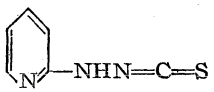
A number of hydrazines were prepared by the usual procedure of reduction of the diazonium compound with sodium sulfite[4] or stannous chloride.[5] Diazonium compounds having electron-donating groups in the ortho- or para-positions were cleaved by reduction, with the formation of the original amine or the corresponding nitrogen-free aromatic compound instead of the hydrazine. This behavior was shown by the diazonium salts from *p*-aminodimethylaniline, 2,6-dimethoxyaniline, 4-dimethylamino-1-naphthylamine, N-(*p*-aminophenyl)-morpholine, and 2-aminodiphenyl sulfide. In order to test the feasibility of a projected synthesis of *p*-dimethylaminophenylhydrazine, a model experiment was tried by treating N-magnesiobromoaniline with monochloroamine; the only product isolated was *p*-bromoaniline, identified through the mixed melting point as the acetyl derivative. Apparently the following reactions took place, instead of the desired formation of phenylhydrazine.

$$C_6H_5NHMgBr + ClNH_2 \longrightarrow C_6H_5NHMgCl + BrNH_2$$
$$\downarrow$$
$$p\text{-}BrC_6H_4NHMgCl + NH_3$$

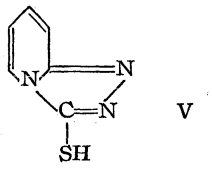
Much variation was noted in the ability of the various arylhydrazines to react with carbon disulfide. *p*-Nitrophenylhydrazine did not react unless a base was present; in the presence of pyridine, a product was obtained which was probably $p\text{-}NO_2C_6H_4NHNHCS_2H\cdot C_6H_5N$, but no thiocarbazide could be obtained from it. *p*-Phenoxyphenylhydrazine did not react normally; the thiocarbazide; if formed, apparently was unstable.[6]

The reaction of thiophosgene with arylhydrazines to form thiocarbazides was also used in a few cases, but it did not offer any advantage over carbon disulfide.[7]

2-Pyridylhydrazine and carbon disulfide gave a compound at first believed to have the structure IV, but it was later found to be V, which had been previously prepared from 2-pyridylhydrazine and potassium trithiocarbonate.[8]



IV



V

In the second stage of the reaction between carbon disulfide and the hydrazine (III → II), long-continued heating after the evolution of hydrogen sulfide has stopped may lead to formation of a thiosemicarbazide from the thiocarbazide III by disproportionation. Thus, when 2-methylthiolphenylhydrazine VI was treated with carbon disulfide and heated overnight on the steam-bath, the thiosemicarbazide VII was the only product isolated. When the heating was limited to about an hour, the thiocarbazide was obtained as usual.

$o\text{-}CH_3SC_6H_4NHNH_2$ VI $o\text{-}CH_3SC_6H_4NHNHCSNH_2$ VII

(2) **The Bamberger Nitroformazyl Method.**[9]—This method avoids the preparation of the hydrazines, and although it requires careful attention to detail and some practice, is usually better than the Fischer method. It involves the coupling of two moles of diazonium compound with sodionitromethane, followed by reduction of the resulting nitroformazyl VIII with ethanolic ammonium sulfide:

$$2ArN_2Cl + CH_3NO_2 \longrightarrow ArN{=}NCHN{=}NAr$$
VIII
$$\downarrow NO_2$$
$$\downarrow EtOH(NH_4)_2S$$
II

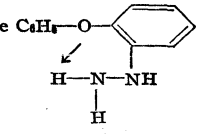
A modified procedure, due to Professor N. L. Drake,[9a] in which the *p*H of the diazonium solution is brought to 6 before adding the sodionitromethane, has been found very useful.

A number of trials runs showed that the procedure could be modified further with advantage by carrying out the coupling reaction in an acetate buffer containing 40% acetic acid at a *p*H of about 4.5; nitromethane itself was found to couple just as well as the sodio derivative under these conditions,[10] since the sodio derivative would obviously revert to nitromethane at this *p*H in an acetate buffer. The mechanism of the coupling reaction can be represented as[11]

(4) "Organic Syntheses," Coll. Vol. I, 2nd ed., p. 442.

(5) Graebe and Rateanu, *Ann.*, **279**, 267 (1894).

(6) It may be noted that *o*-phenoxyphenylhydrazine is stable indefinitely, while the *p*-compound is stable for only a few hours; this may be due to chelation of the type



(7) Thiophosgene is much more readily prepared by the method given in Sartori, "The War Gases," D. Van Nostrand Co., New York, N. Y., 1939, p. 213, than by the "Organic Syntheses" method Coll. Vol. 1, 2nd ed., p. 506).

(9a) Private communication from Professor N. L. Drake, University of Maryland.

(10) This procedure is based in part on Bamberger's work (ref. 9); a somewhat similar procedure has been published by Hubbard and Scott, THIS JOURNAL, **65**, 2390 (1943).

(11) Coupling of diazonium compounds with phenols and aromatic amines involves the diazonium ion, and the phenoxide ion or the free amine, respectively (Bartlett and Wistar, THIS JOURNAL, **63**, 413 (1941)).

$$ArN_2^+ + CH_2NO_2^- \longrightarrow ArN{=}NCH_2NO_2 \rightleftharpoons ArNHN{=}CHNO_2$$

$$ArN_2^+ + ArN{=}NCHNO_2^- \longrightarrow ArN{=}NCH(NO_2)N{=}NAr$$

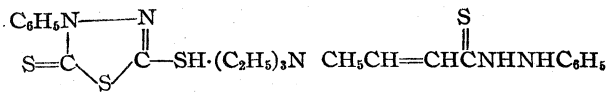
2-Aminodiphenyl sulfide yielded a nitroformazyl by this procedure, but it was unsuccessful with 2-aminofluorene and 4-aminostilbene. The suggestion that the reaction involves the anion in each step is supported by our observation that the phenylmethylhydrazone of nitroformaldehyde, $C_6H_5N(CH_3)N{=}CHNO_2$, which is insoluble in alkali, does not couple with benzenediazonium chloride in an acetate buffer or in glacial acetic acid.

The compound $C_6H_5NHN{=}CHNO_2$, in contrast, is readily soluble in dilute alkali, and couples so rapidly with a diazonium compound to form the nitroformazyl, as above, that it can be isolated from the reaction mixture only with difficulty.

The thiocarbazones obtained in fairly pure form are indicated in Table I; compounds whose preparation in pure form failed are listed in Table II. The *p*-acetyl and *p*-benzoyl derivatives listed in Table II apparently are unstable because they oxidize very readily to the carbodiazone type, $ArN{=}NC(=S){-}N{=}NAr$, in which there is a more extended conjugated system. In order to prevent this oxidation to the diazone type, which seemed to be one cause of the instability of the thiocarbazones when used as detecting agents, much time was spent in attempts to make a methyl substituted thiocarbazone (XX), which should be stable to oxidation of this type. Compound XX should

$C_6H_5N(CH_3)(NHCSN{=}NC_6H_5$ (XX) $\qquad C_6H_5NHN{=}C{=}S$ (XXI)

be obtained, after oxidation, from α-methylphenylhydrazine and compound XXI, but the latter does not seem to have been reported, and an attempt to prepare it from phenylhydrazine, carbon disulfide and triethylamine yielded instead the triethylamine salt of phenyldithiadiazolonmercaptan XXII; the structure of this product is proved by



XXII XXIII

its formation from potassium phenyldithiadiazolonmercaptide and triethylamine. The interaction of $C_6H_5NHNHCSSH$ and $C_6H_5N(CH_3)NH_2$, which should yield XX, after oxidation, was also unsuccessful.

The preparation of cinnamic thiophenylhydrazide[12] XXIII was undertaken because of its simi-

TABLE II

THIOCARBAZONES WHOSE PREPARATION WAS ATTEMPTED

Parent amine	Method	Remarks
p-Aminoacetophenone	2a	Thiocarbazide unstable
p-Aminobenzophenone	2a	Thiocarbazide unstable
2,6-Dimethoxyaniline	1, 2a	Thiocarbazone unstable, thiosemicarbazide isolated
2-Aminofluorene	1, 2a, 2b	
2-Aminodibenzofuran	1	Oxidation to thiocarbazone failed
o-Fluoroaniline	2a	Not obtained analytically pure
2-Amino-5-methylbenzenesulfonic acid	2a	Thiocarbazone apparently obtained, but could not be isolated from aqueous solution
4-Aminostilbene	1, 2a, 2b	
2-Aminothiazole	2a	Diazonium solution unstable
2-Aminopyridine	1	Ring closure occurred
2-(*p*-Aminophenyl)-naphthalene	2b	Not obtained pure

(12) Suggested by Dr. Donald E. Pearson.

larity to the thiocarbazone structure. It could not be obtained by the action of phosphorus pentasulfide on cinnamic phenylhydrazide, and the imido chloride of the phenylhydrazide could not be obtained. Another approach, through styrylnitromethane and the nitroformazyl $C_6H_5CH=CHCH(NO_2)N=NC_6H_5$ was not successful, although styrylnitromethane was apparently obtained from cinnamyl bromide and silver nitrite in acetonitrile solution, and a red product, presumably the nitroformazyl, was obtained by treatment of this with benzenediazonium chloride.

The thiocarbazones listed in Table I were tested as arsenical detectors and the *o*-phenoxy derivative (IX) was found the most promising, considering stability, sensitivity, sharpness of color change and ease of synthesis.

Experimental Part[13]

2-Aminodiphenyl Ether.—Reduction of 78 g. of 2-nitrodiphenyl ether (in three batches) with hydrogen and Raney nickel in alcohol yielded 51.0 g. (78%) of the amine, m. p. 45.5–47°, and a second crop of 9.5 g., m. p. 43–47° (total 94%). Zinc dust and calcium chloride in ethanol gave a 68% yield of the amine from the nitro compound.[14]

2-Phenoxyphenylhydrazine.—Twenty-five grams of the above amine was diazotized, the excess nitrous acid destroyed with sulfamic acid, and 107 g. of stannous chloride in 107 cc. of concentrated hydrochloric acid added. After stirring one hour, the complex tin salt was removed and treated with 77 g. of sodium hydroxide dissolved in 650 cc. of water. The precipitate was treated with 500 cc. of water and 20 cc. of concentrated hydrochloric acid, warmed until solution was effected and cooled to obtain the hydrazine hydrochloride, which melted with decomposition at 171°. The hydrochloride was dissolved in warm water, treated with hydrogen sulfide and filtered; the hydrazine was obtained as a white precipitate, which after recrystallization from alcohol, had the m. p. 152–154°, yield, 12 g. (45%).

Anal. Calcd. for $C_{12}H_{12}N_2O$: C, 72.00; H, 6.00. Found: C, 72.33; H, 6.10. The benzal derivative melts at 129–130.5°.

The m. p. of the hydrazine is surprisingly high, compared to the *para* isomer, which melts at 52°, and is very unstable.

2-Nitro-4′-methoxydiphenyl Ether.[15]—The potassium salt of hydroquinone monomethyl ether (6.2 g.) was prepared in ethanol, the solvent removed and 7.9 g. of *o*-nitrochlorobenzene added: the temperature was brought to 160° for one hour, the mixture cooled and poured into dilute alkali. The product (8.6 g., 70%) melted, after crystallization from ethanol, at 74–74.5°.

2-Nitrodiphenyl Sulfide.—The procedure of Cullinane and Davis[16] was improved as follows: To a mixture of thiophenol (33 g.), 39 g. of sodium carbonate and 120 cc. of water was added a solution of 47.1 g. of *o*-chloronitrobenzene in 150 cc. of hot ethanol. The mixture was stirred and warmed on the steam-bath for four hours, then poured in 500 cc. of cold water, filtered and washed with water. Recrystallization from 200 cc. of ethanol yielded 61 g. (87%) of bright yellow crystals, m. p. 78–80°. The reported value[16] is 82°.

2-Aminodiphenyl Sulfide.—This compound was obtained by reduction of the nitro compound, and also by the following procedure. 2-Chloroacetanilide (20 g.) and a few tenths of a gram of copper powder were added to a solution prepared by dissolving 13.2 g. of potassium hydroxide and 26 g. of thiophenol in 40 cc. of *n*-butanol with heating. The solvent was removed, the residue heated rapidly and held at 280–300° (inside temperature) for fifteen minutes. The cooled melt, which had darkened considerably, was taken up in hot benzene and 10% sodium hydroxide solution; the two layers were filtered with suction and separated. The benzene layer was evaporated, and the crude acetyl compound hydrolyzed with hydrochloric acid and ethanol. The amine was distilled at 154–160° (3 mm.), and 11 g. (46%) of material, m. p. 33°, obtained. The reported[16] m. p. is 35°.

4-Amino-3-phenoxybiphenyl.—3-Bromo-4-acetaminobiphenyl[17] (3 g.) and 0.1 g. of copper powder were added to the potassium salt from 10 g. of phenol, and the melt heated for thirty minutes at 180°. When worked up as above, 2.9 g. of crude 2-acetamino-5-phenyldiphenyl ether was obtained, which after six recrystallizations from dilute alcohol melted at 166–167°. The free amine obtained by hydrolysis melted at 100.5–101.5° after three recrystallizations from alcohol.

Anal. Calcd. for $C_{18}H_{15}NO$: C, 82.74; H, 5.79. Found: C, 83.12; H, 5.79.

In a second preparation, the crude acetaminodiphenyl ether was hydrolyzed to the free amine directly, which was obtained in 50% yield by vacuum distillation, m. p. 94–99°. After one crystallization from alcohol, it melted at 99–101°.

4-Amino-3-thiophenoxybiphenyl.—3-Chloro-4-acetaminobiphenyl (20 g.), 20 cc. of thiophenol, 9 g. of potassium hydroxide, 30 cc. of *n*-butanol and a small amount of copper powder were heated at 260–280° for one hour. The reaction mixture was worked up as usual, yielding 13 g. (59%) of the free amine, m. p. 68–70°.

Anal. Calcd. for $C_{18}H_{15}NS$: C, 77.94; H, 5.45. Found: C, 77.87; H, 5.41.

The acetyl derivative melted at 132–134.5°. When the bromoacetaminobiphenyl was used instead of the chloro compound, a 66% yield was obtained.

2-Pyridylhydrazine.—This was prepared more conveniently from 2-bromopyridine than from the chloro compound,[18] and was obtained in 57% yield by heating the halogen derivative with 85% hydrazine hydrate at 125° for twenty-four hours.

3-Mercaptopyrido(2,1-c)-*s*-triazole.[19]—2-Pyridylhydrazine (5 g.) was added to 12 cc. of carbon disulfide in 40 cc. of chloroform. A precipitate was formed, and the mixture refluxed on the steam-bath for twenty hours, with the evolution of hydrogen sulfide. The crystals present were isolated, weighed 6.10 g. (88%), and melted at 209–210°. The product is insoluble in benzene and dioxane, but is soluble in methanol and dilute sodium hydroxide.[20]

Anal. Calcd. for $C_6H_6N_2S$: C, 47.7; H, 3.3; mol. wt., 151. Found: C, 48.1; H, 3.4; mol. wt. (Rast), 165.

This compound was also obtained by action of thiophosgene on 2-pyridylhydrazine.

(13) Analyses by Robert Bauman.

(19) Ring Index numbering.

(20) Mills and Schindler report this compound as melting at 205–206°, and their other properties agree with those of our material.

Thiocarbazone Preparations by the Fischer Method.—The preparation of *di-(2-methoxyphenyl)-thiocarbazone* (*X*) is typical of the procedures followed. 2-Methoxyphenylhydrazine (10 g.), 50 cc. of alcohol and 5 g. of carbon disulfide were refluxed on the steam-bath until hydrogen sulfide ceased to be liberated. The thiocarbazide was not isolated, but was treated directly in solution after cooling with enough 10% ethanolic potassium hydroxide to give a clear red color; the solution was allowed to stand with air bubbling through for about five minutes, and was acidified with 1 *N* sulfuric acid. The thiocarbazone was obtained as a black powder, and was isolated by filtration with thorough washing. In the alternate procedure, the alcoholic solution of the thiocarbazide was cooled and treated with 5 cc. of 30% hydrogen peroxide, allowed to stand five minutes, with stirring, and the product was washed with water and cold methanol.

Recrystallization of the thiocarbazone proved difficult. The best method found was to dissolve the substance in the minimum volume of chloroform, filter and precipitate by adding half the volume of methanol. The product formed a finely crystalline material, copper bronze in color. The m. p. and analysis are given in Table I.

Thiocarbazones by the Modified Nitroformazyl Procedure; Di-(2-phenoxyphenyl)-thiocarbazone.—2-Aminodiphenyl ether (b. p. 187–188° (30 mm.)) was dissolved in 160 cc. of concentrated hydrochloric acid and 270 cc. of water. The cold solution was diazotized by adding 23 g. of sodium nitrite in 135 cc. of water. After one hour the excess nitrous acid was removed with sulfamic acid, the solution was filtered through a sintered glass funnel and washed with 50 cc. of water. The solution was poured into 1430 g. of sodium acetate trihydrate in 725 cc. of glacial acetic acid, and stirred at room temperature for fifteen minutes, at which point most of the sodium acetate had dissolved; 25 cc. of nitromethane was added in one portion and the mixture stirred for five hours. The nitroformazyl precipitated rapidly, and the mixture was an almost solid mass after two hours; the product was collected, washed thoroughly with water and twice with alcohol. The nitroformazyl had not dried completely after standing several days on paper towels, and was reduced directly.

Reduction to the Thiocarbazide.—The nitroformazyl was added in one portion to 750 cc. of alcohol saturated with ammonium hydrosulfide. The color of the mixture changed from red to cream in thirty minutes; after stirring one hour, the slurry was poured into 2 liters of cold water, filtered, washed thoroughly with water and air dried on paper towels. It was not completely dry after two days.

Oxidation to the Thiocarbazone.—The thiocarbazide was dissolved in 2 liters of warm alcohol containing 35 g. of potassium hydroxide, and the calculated amount of 3% hydrogen peroxide (175 cc.) added. The mixture was heated almost to boiling on a hot plate, allowed to stand for fifteen minutes, then cooled in an ice-bath. When the temperature had reached 5°, the solution was filtered, and acidified with 100 cc. of concentrated hydrochloric acid. The precipitated thiocarbazone was filtered, and washed thoroughly with water and twice with methanol. The product was bronze colored and microcrystalline, m. p. 162–163.5° with dec., wt. 48 g. after air drying. For purification, it was dissolved in 500 cc. of hot chloroform, filtered and 800 cc. of hot methanol was added to the hot solution. Beautiful bronze crystals were obtained, m. p. 167–167.5° with decomposition (very slow heating), yield 39.5 g. (thoroughly air dried, or 58% based on amine).

Preparation of Diphenylthiocarbazone (Dithizone).—Dithizone was prepared by essentially the same method; 30 g. of clean nitroformazyl, m. p. 146–147°, was obtained from 37 g. of aniline. The sodium acetate and then the acetic acid were added directly to the diazonium solution. The coupling with the nitromethane proceeded quite slowly in the resulting 25% acetic acid solution with acetate–acetic acid ratio of 0.24.

A second preparation was run in the same manner but with an acetate–acetic acid ratio of 0.65. The reaction proceeded more rapidly; after two hours 200 cc. of water was added (changing the acetic acid concentration from 24 to 19%) because the reaction mixture had become too thick to stir. The thiocarbazone obtained from the usual oxidation step was quite pure without the final crystallization, as it melted sharply at 165–166°.

Interaction of Phenylhydrazine, Carbon Disulfide and Triethylamine.—To 15 g. of triethylamine and 25 g. of carbon disulfide in 50 cc. of chloroform was added dropwise 10.8 g. of phenylhydrazine. The mixture was heated on the steam-bath for five hours, causing evolution of hydrogen sulfide. After cooling, the mixture was subjected to steam distillation, and the residue crystallized, giving 18.6 g., m. p. 87–89°. Two crystallizations from benzene raised the m. p. to 91.5–92.5°. This product was shown to be the triethylamine salt of phenyldithiadiazolonmercaptan **XXII** by analysis, and by preparation from potassium phenyldithiadiazolonmercaptide[21] and triethylamine.

Anal. Calcd. for $C_{14}H_{21}N_3S_3$: C, 51.5; H, 6.4. Found: C, 51.9; H, 6.4.

2-Methylthiolphenylthiosemicarbazide (VII).—A mixture of 2-methylthiolphenylhydrazine and carbon disulfide in ethanol was refluxed overnight on the steam-bath. After the solvent was removed, the residue was treated with benzene and a white crystalline product was obtained, which, after two recrystallizations from xylene, melted at 172–173° with decomposition. Two recrystallizations from acetic acid did not change the m. p. or the percentage composition.

Anal. Calcd. for $C_8H_{11}N_3S_2$: C, 45.1; H, 5.2. Found: C, 45.3; H, 5.2.

When the heating with carbon disulfide was limited to an hour, the disproportionation did not occur, and the thiocarbazide and the thiocarbazone (XVII) were obtained.

Summary

A number of new substituted diarylthiocarbazones have been prepared, and several compounds obtained incidental to the work have been described. A modification of the Bamberger nitroformazyl procedure, consisting of coupling the diazonium compound with nitromethane in dilute acetic acid containing acetate ion, has been found useful.

Physiologically Active Indanamines. II. Compounds Substituted in the Aromatic Ring[1]

BY R. V. HEINZELMANN, H. G. KOLLOFF AND JAMES H. HUNTER

Previous work in this Laboratory[1] has shown that certain aminoindanes, aminoindanones and aminoindanols unsubstituted in the nucleus possess valuable properties as bronchodilators. For this reason it was considered desirable to prepare some derivatives of these compounds containing one or more hydroxyl or methoxyl groups in the aromatic ring. The present paper deals with indanamines substituted in this manner (I, II, III, IV).

Much work has been done and considerable success achieved in efforts to correlate the pressor activity with the structure of phenethylamine derivatives.[2] However, when other physiological phenomena are considered, it is found that in general they do not parallel that of pressor activity. For instance, in the case of bronchodilator activity it is even found in some cases that structural changes which affect the pressor potency adversely tend to produce an increase in the bronchodilator effect.[1,3,4,5] In other cases,[5] no clear-cut relationship appears to exist between the two phenomena. In general, it may be stated that introduction of alkyl or aralkyl groups into the amino group reduces or even reverses the pressor effect, and at the same time favors bronchodilator activity[2,3,5]; large substituents of this type seem to be most effective.[5,6] This variation might thus be expected to result in the formation of an ideal bronchodilator. Extension of the side chain to three carbon atoms results in increased duration of action[7] and, as with the pressor property, confers oral activity due to increased resistance to deamination in the body.[8]

The adverse circulatory effect of alkoxyl substitution, as compared with hydroxyl substitution[2,9] in the benzene ring, has been shown recently not to apply with respect to bronchodilation.[5] Indeed, in twenty-four of thirty-one pairs studied the methoxyl derivative was equal to, or more active than, the corresponding hydroxyl derivative. These facts lend considerable interest to the compounds reported here.

The intermediate hydroxy-, methoxy- and methylenedioxyindanones were prepared from the corresponding substituted phenylpropionic acids by cyclization with anhydrous hydrogen fluoride or phosphorus pentoxide, and in one instance through their acid chlorides *via* the Friedel–Crafts reaction. Cyclization of *o*-hydroxy (methoxy) phenylpropionic acid has not been reported and difficulty in effecting ring closure in these acids having an *ortho*-directing group present was correctly anticipated.[10] Under the usual conditions,[11] attempts to cyclize with anhydrous hydrogen fluoride led to the formation of an amorphous product, insoluble in ordinary solvents,[12] together with a trace of starting material. When phosphorus pentoxide was employed under optimum conditions for this type of reaction,[13] no ring closure occurred. There was isolated a 70% yield of a compound, (m. p. 67–69.5°) whose analysis was in good agreement with the value calculated for the anhydride; on hydrolysis, the starting acid was recovered. Cyclization of *o*-nitrophenylpropionic acid,[14] as well as nitration of indanone with subsequent isolation of the 4-nitro isomer,[15] were not promising procedures because of inaccessibility of starting materials or difficulty in

isolating the desired isomer. When the excellent cyclization procedure for *p*-methoxyphenylpropionic acid, using the Friedel–Crafts reaction,[10] was reported by Johnson, these conditions were applied to the *ortho*-isomer. There was obtained 46% of starting material, 45% of amorphous material (m. p. about 220–30°), soluble in pyridine, but not in the usual organic solvents, 6% of an alkali insoluble product (m. p. 103–110°), and a trace of alkali-insoluble material (m. p. about 140°) whose analysis was inconclusive but approached that of the desired indanone.

Of the other three monosubstituted indanones, the 5-hydroxy-(methoxy-) and 7-hydroxy-(methoxy-)indanones were prepared by cyclization of *m*-hydroxyphenylpropionic acid with anhydrous hydrogen fluoride,[16] followed by methylation; the 7-isomer can be prepared in only insignificant yields by this method. 6-Methoxyindanone was made by Johnson's Friedel–Crafts procedure[10]; however, using Ohio-Apex grade aluminum chloride the best yield obtained in a 10-g. batch was 39%.

Cyclodehydration of 2,4-dimethoxyphenylpropionic acid could not be achieved by the methods used; anhydrous hydrogen fluoride yielded a tar, and from an attempted cyclization using phosphorus pentoxide there was recovered 43% of starting material and 35% of an oil which appeared to be the acid anhydride. It is interesting that while 2,3-dimethoxy- and 3-methoxy-4-hydroxy-phenylpropionic acid could be cyclized in excellent yield using liquid hydrogen fluoride, this method was not applicable to 3,4-methylenedioxyphenylpropionic acid.

The substituted indanones were converted, through the 2-isonitroso derivatives, to the amino ketones and amino alcohols essentially as described[1] for the unsubstituted analogs. The tendency for solutions of the aminoketone hydrochlorides to become slightly red was prevented to a considerable extent by the addition of a trace of alcoholic hydrogen chloride during any recrystallization.

Reaction of the aminoindanols with benzaldehyde produced, instead of the Schiff bases, a mixture of bases which could be separated by fractional crystallization and converted to their respective hydrochlorides. In the monosubstituted series one of these proved to be the starting material, and the other, the oxazolidine (III), which is isomeric with the Schiff base.[17] Hydrogenation with active palladium charcoal gave the desired benzylaminoindanol hydrochlorides. In the disubstituted series, reaction of the aminoindanols with benzaldehyde produced, instead of the Schiff bases, racemic mixtures of diastereoisomeric oxazolidines which were separated and purified by fractional crystallization. The isomers on hydrogenation with palladium charcoal gave different benzylaminoalcohols. These benzylaminoalcohols could also be obtained as isomeric mixtures by reductive alkylation with benzaldehyde.

Reductive alkylation of 6-methoxy-2-aminoindanol and 5,6-dimethoxy-2-aminoindanol using acetone yielded the corresponding isopropylaminoindanols; when one mole of formaldehyde was used instead of acetone only the dimethylaminoindanols were formed.

The pharmacology of the aminoketones, aminoalcohols, oxazolidines and substituted aminoalcohols will be reported elsewhere.

The authors wish to acknowledge the technical assistance of Mr. Brooke D. Aspergren in a portion of this work.

Experimental[18]

Substituted Phenylpropionic Acids

The requisite cinnamic acids were prepared from the appropriately substituted benzaldehydes and malonic acid by the Doebner reaction.[19,20]

The cinnamic acids were converted to the corresponding phenylpropionic acids by electrolytic reduction or catalytic hydrogenation using Adams platinum catalyst.[21] The former procedure frequently resulted in products difficult to purify and almost invariably in lower yields.

In view of the difficulty in preparing *m*-hydroxybenzaldehyde,[23] the Schwenk–Papa Raney nickel reduction procedure[24] for preparing *m*-hydroxyphenylpropionic acid from the readily available piperonylacrylic acid was investigated. After numerous attempts and variations of this procedure had been made the maximum yield obtained was only 35%.

(16) Johnson, Anderson and Shelberg, THIS JOURNAL, **66**, 218 (1944).

(17) Indeed it appears that the compounds referred to by Levin, Graham and Kolloff[1] as Schiff bases are also oxazolidines. For instance, a sample (m. p. 163–165°) identical with their compound XX and prepared by their procedure was ether-soluble and formed a hydrochloride, m. p. 178–180° (dec.); the oxazolidine free base (m. p. 163–164°) could be regenerated from the hydrochloride. Our oxazolidine hydrochlorides showed a tendency to hydrolyze, even during recrystallization from alcohol and ether.

(18) Melting points are uncorrected. Microanalyses by Mr. C. H. Emerson and the staff of the microanalytical laboratory.

(19) "Organic Reactions," Vol. I, 1942, pp. 226–227.

(20) When condensation was carried out with crude *m*-hydroxybenzaldehyde (m. p. 98.5–100.5°) for four hours on the steam-bath, or for twelve days at room temperature, the yield of *m*-hydroxycinnamic acid after two crystallizations was 68 and 69.5%, respectively; however, when once-crystallized aldehyde (m. p. 102°) was employed under the latter conditions the yield was 93% and the product without purification melted higher than the twice purified acid above and could be hydrogenated directly. In the case of 3-methoxy-4-hydroxybenzaldehyde, the prolonged low-temperature modification (ref. 19, pp. 235 and 250) increased the yield from 50% to 94%.

(21) It was necessary to stop the hydrogenation of *p*-methoxycinnamic acid when one mole of hydrogen had been absorbed since hydrogen uptake continued rapidly until four moles had been consumed; even slight over-reduction caused purification difficulties. Catalytic hydrogenation (PtO_2) of piperonylacrylic acid in ethanol was too slow to be practicable due to its insolubility; hydrogenation was also too slow in glacial acetic acid even at an elevated temperature. The sodium salt of the acid could not be hydrogenated in aqueous alcohol or in distilled water. Toward the end of this work hydrogenation of the acid in warm dioxane was reported.[22] This method proved satisfactory; after having been filtered from the catalyst and concentrated to half the volume, the dioxane solution was mixed with chipped ice and shaken, whereupon the product was deposited as fine, glistening crystals.

Indanones, Aminoindanones and Aminoindanols

Cyclization of the substituted phenylpropionic acids was carried out as indicated in Table I.

5-Methoxy-6-hydroxyindanone.—Fifty grams of crude hydroferulic acid (m. p. 85–88°), prepared by catalytic hydrogenation of ferulic acid and evaporation of the alcoholic solution to dryness, was placed in a pint copper retort. Four hundred grams of chilled anhydrous hydrogen fluoride was added, the top quickly clamped in place, the retort swirled gently once and left overnight with the side arm projecting into the vent of a good hood. The amber liquid was then evaporated gently on the steam-bath in a copper beaker to a purple paste and then to a gray-purple powder. This was suspended in 8 to 10 liters of boiling water, treated with charcoal, filtered quickly while hot, and allowed to cool; yield, 38.2 g. (85%) of beautiful, long, golden needles, m. p. 192–192.5°. Concentration of the filtrate to 3 liters gave 2.0 g. more, and re-extraction of the residue from the first extraction with 750 cc. of boiling water gave an additional 0.8 g.; total yield, 41 g. or 91%.

All cyclizations of this type attempted in open or partially covered copper beakers gave poor to negative results, probably due to condensation of moisture from the air on the cold walls of the beaker.

As indicated in Table I, the isonitrosoindanones were prepared by three methods: using methyl nitrite and anhydrous ethereal hydrogen chloride, butyl nitrite and concentrated hydrochloric acid in methanol, or butyl nitrite and dry hydrogen chloride gas in ether. In general they had to be recrystallized at least twice to attain sufficient purity to undergo subsequent hydrogenation. Conversion (two atmospheres pressure of hydrogen and active palladium Norite) to the aminoketone hydrochlorides was carried out in absolute alcoholic hydrogen chloride, and these were then hydrogenated to the amino-alcohol hydrochlorides in distilled water (Table II); yields were practically quantitative. Occasionally an elevated temperature and two or three additions of catalyst were necessary to effect complete reduction. The aminoindanone hydrochlorides are considerably less soluble in alcohol than the aminoindanol hydrochlorides. With both classes of compounds water was occasionally added in small amounts to dissolve the product away from the catalyst, and during recrystallization to keep the volume down. Raney nickel and also PtO_2 (elevated temperature) were used in the reduction of one of the aminoketone hydrochlorides and were found to be satisfactory catalysts. The hydroxymethoxyamine hydrochlorides seemed to be somewhat more unstable than the corresponding dimethoxy compounds.

Oxazolidines and Benzylaminoindanols (Table III)

Preparation of the monosubstituted oxazolidines may be illustrated by the formation of III from 5-methoxy-aminoindanol hydrochloride.

Two and sixteen-hundredths grams (0.01 mole) of the amino alcohol hydrochloride was heated under reflux for six hours in 50 cc. of 95% alcohol with 1.20 cc. (0.012 mole) of benzaldehyde and 0.84 g. (0.01 mole) of sodium bicarbonate. The solution was filtered from the sodium chloride, concentrated to about one-third, excess water added and the oily suspension chilled, giving 2.52 g. (94%) of buff-colored solid. After recrystallization (Norite) from about 15 cc. of 3A alcohol a product was obtained which proved to be the free base of the starting material.

The filtrate from the alcohol recrystallization of the free base was treated with water and chilled, giving about one gram of white solid, m. p. 85°. Without purification it was converted into the oxazolidine hydrochloride which, after recrystallization from alcohol–ether, melted at 154.5° (dec.).

Anal. Calcd. for $C_{17}H_{18}O_2NCl$: C, 67.21; H, 5.97; N, 4.61. Found: C, 67.16; H, 5.69; N, 4.60.

Similarly in the disubstituted series attempts to prepare the Schiff bases by treating the amino alcohol hydrochlorides with an equivalent amount of benzaldehyde and sodium bicarbonate in 3A alcohol resulted in the formation of oxazolidines in all cases; here, however, conditions were such that two racemic mixtures of the latter could often be isolated. For example, with 5,6-dimethoxy-indanol hydrochloride two racemic mixtures of the oxazolidine were formed by this procedure, and also when a dry fusion of the amine hydrochloride, benzaldehyde and sodium acetate was made *in vacuo* at 100 to 150°; a dry fusion at room temperature for several days gave smaller yields of the desired products as well as some starting material as the free base and some which analyzed as the acetate of the starting base. The formation of isomeric mixtures made estimation of yields as well as melting points difficult.

In the case of 5,6-dimethoxyaminoindanol hydrochloride the solid product, obtained by precipitation from the reaction mixture with water, was recrystallized from acetone–ether; fractionation resulted in separation of the isomers. In the remainder of the disubstituted series the oxazolidines were ether-soluble; the precipitate was either recrystallized from dilute alcohol to separate the isomers or converted to the hydrochloride prior to fractionation from alcohol–ether.

[a] Approximate; free base melts about 80–82°. [b] Compound hydrolyses progressively on recrystallization, even from absolute alcohol–ether, giving a progressively higher decomposition point; *anal.* after 2 recrystallizations: C, 63.15; H, 6.33; N, 5.12. [c] Free base, m. p. 150.5–152°. [d] Obtained also a second crop, m. p. 180° (dec.) (isomeric?). [e] Without recrystallization; recrystallization, even from absolute alcohol, causes conversion into a product, darkening, but not melting, below 200°, and giving a m. p. depression with the unrecrystallized material; may result from hydrolysis to the original aminoalcohol–HCl. [f] Mixed m. p. with B_1, 130°; compound too highly charged to permit good combustions, or any nitrogen analysis. [g] Hydrochloride darkens about 191°. [h] Mixed m. p. with B_1, 136°.

During the work-up of several of the oxazolidines there were indications that these compounds were gradually hydrolyzing to yield benzaldehyde and the amino alcohol. This was most apparent in the case of the 6-methoxy compound. Here the odor of benzaldehyde persisted throughout the fractionation from dilute alcohol, even though the alcohol solutions were diluted with water at room temperature. During the purification of the oxazolidine hydrochloride considerable amounts of the starting amino alcohol hydrochloride (identified by analysis and mixed melting point) were isolated. The oxazolidine hydrochloride (m. p. about 137° (dec.)) analyzed poorly, and further recrystallization from absolute alcohol–ether caused the melting point to broaden and rise toward that of the amino alcohol; the filtrate from this yielded considerable benzaldehyde, identified as the dinitrophenylhydrazone. Conversion of the oxazolidine to the benzylamino alcohol was considered as sufficient evidence of structure.

Hydrogenation of the bases (platinum oxide or active palladium charcoal) gave the desired benzylamines which were converted into the hydrochlorides. In some cases, however, it was found advantageous to hydrogenate the oxazolidine hydrochlorides to the benzylamine hydrochlorides, using active palladium charcoal; reaction was usually complete in about three quarters of an hour.

Reductive Alkylations

6-Methoxy-2-isopropylaminoindanol-1 Hydrochloride.—Four and thirty-one hundredths grams (0.02 mole) of 6-methoxy-2-aminoindanol-1 hydrochloride, 1.6 cc. (0.022 mole) of acetone and 2.12 g. (0.02 mole) of sodium carbonate were shaken in a Parr hydrogenation apparatus in the presence of 0.5 g. of pre-reduced Adams platinum catalyst in absolute ethanol under a hydrogen pressure of two atmospheres. Hydrogenation was complete in an hour and the filtrate from the catalyst was poured into cold ethereal hydrogen chloride and chilled. After recrystallization from absolute alcohol the white crystals melted at 214° (dec.).

Anal. Calcd. for $C_{13}H_{20}O_2NCl$: C, 60.57; H, 7.82; N, 5.44. Found: C, 60.54; H, 7.66; N, 5.29.

6-Methoxy-2-dimethylaminoindanol-1 Hydrochloride.—This compound was prepared similarly to that above except that slightly more than two molecular equivalents of formaldehyde (as a 37% solution) were used. The filtrate from the catalyst was concentrated to about a third before conversion to the hydrochloride. After recrystallization the product melted at 215–215.5° (dec.).

Anal. Calcd. for $C_{12}H_{18}O_2NCl$: C, 59.13; H, 7.44; N, 5.75. Found: C, 59.07; H, 7.23; N, 5.84.

5,6-Dimethoxy-2-benzylaminoindanol-1 Hydrochloride.—Four and ninety-one hundredths grams (0.02 mole) of the primary aminoalcohol hydrochloride, 2.12 g. (0.02 mole) of freshly distilled benzaldehyde and 2.12 g. (0.02 mole) of sodium carbonate were added to a suspension of freshly reduced Adams platinum catalyst in absolute ethanol and the mixture subjected to hydrogenation at three atmospheres pressure. The calculated uptake of hydrogen occurred in thirty minutes after which the suspension was warmed, filtered from the catalyst and the filtrate poured into chilled ethereal hydrogen chloride. After chilling, the white precipitate was collected and recrystallized several times from absolute alcohol. The pure white, crystalline product melted at 181.5° (dec.).

Anal. Calcd. for $C_{18}H_{22}O_3NCl$: C, 64.37; H, 6.60; N, 4.17. Found: C, 64.36; H, 6.58; N, 4.41.

In some cases starting material was isolated by the addition of ether to the alcohol filtrate from the main product.

5,6-Dimethoxy-2-isopropylaminoindanol-1 Hydrochloride.—By a procedure similar to that described above but using acetone, there was obtained a product which, after several recrystallizations from absolute alcohol, amounted to 2.3 g. and melted at 190° (dec.).

Anal. Calcd. for $C_{14}H_{22}O_3NCl$: C, 58.43; H, 7.71; N, 4.87. Found: C, 58.54; H, 7.66; N, 5.05.

5,6-Dimethoxy-2-dimethylaminoindanol-1 Hydrochloride.—By a procedure analogous to that described above but using one mole of formaldehyde there was obtained no monomethylamine, but only the dimethylaminoindanol hydrochloride, melting at 172° (dec.).

Anal. Calcd. for $C_{13}H_{20}O_3NCl$: C, 57.03; H, 7.36; N, 5.12. Found: C, 56.87; H, 7.46; N, 5.58.

Summary

A series of thirty-six aminoindanones, aminoindanols and N-substituted aminoindanols containing one or more hydroxyl, methoxyl or methylenedioxy groups in the aromatic ring, have been synthesized. The nitrogen substituents were hydrogen, dimethyl, isopropyl and benzyl; the benzylaminoindanols were prepared through the intermediate oxazolidines and were in some cases isolated in two racemic forms.

The Structures of Some Isopropylidene-*aldehydo*-L-arabinose Derivatives

BY JAMES ENGLISH, JR., AND PAUL H. GRISWOLD, JR.[1]

In a previous paper[2] the positions of the isopropylidene groups in di-isopropylidene-*aldehydo*-L-arabinose and the products of its reaction with Grignard reagents were left indeterminate. An extension of our work on C-substituted pentitols has disclosed evidence leading to the establishment of the structures of these arabinose derivatives in both the D- and L- series.

The triacetone mannitol of Fischer[3] has been shown by Wiggins[4] to be 1,2:3,4:5,6-triacetone mannitol. A graded hydrolysis of this substance[4,5] has been found to yield a diacetone mannitol which Wiggins has converted to an *aldehydo*-diacetone-D-arabinose by lead tetraacetate oxidation. In view of the earlier work of Brigl and Grüner[6] and of Baer and H. O. L. Fischer[7] the structure of this arabinose derivative may be considered established beyond reasonable doubt as 2,3:4,5-diacetone-*aldehydo*-D-arabinose.

2,3:4,5-Di-isopropylidene-*aldehydo*-D-arabinose prepared by the method of Wiggins, or better by periodate oxidation of the same starting material, was treated with cyclohexylmagnesium chloride to form a crystalline di-isopropylidene-1-C-cyclohexylpentitol. This substance was found to be the enantiomorph of the di-isopropylidene-1-C-cyclohexylpentitol previously prepared in this Laboratory[2] from di-isopropylidene-*aldehydo*-L-arabinose. On recrystallizing an equimolar mixture of the two enantiomorphs there resulted a di-isopropylidene-D,L-1-C-cyclohexylpentitol which gave a depression in mixed melting points with both isomers.

In the preparation of di-isopropylidene-L-arabinose diethyl mercaptal the intermediate monoisopropylidene derivative was obtained in a manner analogous to that reported by Gätzi and Reichstein[8] for the D-isomer. Since this substance can be converted into the di-isopropylidene derivative[8] by excess acetone it is evident that the isopropylidene group in this case must be on either the 2,3 or the 4,5 carbon atoms. A lead tetraacetate oxidation of monoisopropylidene-L-arabinose diethyl mercaptal followed by removal of the mercaptal and isopropylidene groups, led to a mixture from which glyoxal was identified as its nitrophenylhydrazone and dinitrophenylhydrazone. This established the structure of this substance as 4,5-isopropylidene-L-arabinose diethyl mercaptal, since no other monoisopropylidene derivative would be expected to yield glyoxal.

Hence it may be concluded that the positions of the isopropylidene groups in this series are as shown in the reaction scheme below.

It is worthy of note that in both the D- and L-series the ratio of the two stereoisomeric pentitols obtained in the reaction of *aldehydo*-di-isopropylidene arabinose with cyclohexylmagnesium chloride is far from unity. In one case as much as

80% of the total 1-C-cyclohexylpentitol was obtained as a pure isomer, crystallized to constant rotation, and it has not yet been possible to isolate any of the other anomer in pure form.

Experimental[9]

2,3:4,5-Di-isopropylidene-*aldehydo*-D-arabinose.—This substance was prepared by oxidation of 3,4:5,6-di-isopropylidene-D-mannitol by the method of Wiggins[4] with a yield of 19%. Improved yields were obtained as follows.

In a well-stirred and cooled flask was placed a solution of 31.4 g. of 3,4:5,6-di-isopropylidene-D-mannitol dissolved in 100 cc. of water. A solution of 28.8 g. of sodium periodate in 450 cc. of water was added, maintaining the temperature at 0–5°. The reaction mixture was allowed to remain at this temperature for thirty minutes, then saturated with salt and extracted with ten 100-cc. portions of chloroform. After drying over sodium sulfate, removing the solvent at room temperature and distillation, there was obtained 24.6 g. (89%) of colorless sirupy 2,3:4,5-di-isopropylidene-*aldehydo*-D-arabinose, b. p. 60–65° (0.08 mm.). This compound was found to be unstable as shown by a change in rotation with time from an initial $[\alpha]^{22}D$ −18.2° in chloroform (*c*, 13.5) to $[\alpha]^{25}D$ +16 after standing for two months. Accordingly the fresh preparations were used immediately for subsequent operations.

1-C-Cyclohexyl-2,3:4,5-di-isopropylidene-D-arabitol.[10]—To a solution of cyclohexylmagnesium chloride prepared from 33.4 g. of chlorocyclohexane and 7.69 g. dry magnesium in 100 cc. dry ether was added 22.5 g. of 2,3:4,5-di-isopropylidene-*aldehydo*-D-arabinose in 100 cc. of ether. The reaction mixture was refluxed for fifteen minutes, cooled in ice, and decomposed with saturated ammonium chloride solution. After ether extraction, drying over sodium sulfate and removal of solvent at low temperatures there remained a solid that was recrystallized from petroleum ether (30–60° b. p.). The yield was 18 g. of 1-C-cyclohexyl-2,3:4,5-di-isopropylidene-D-arabitol after recrystallization to a constant melting point 75–76° and constant rotation $[\alpha]^{25}D$ +27.2 in pyridine (*c*, 2.8). *Anal.* Calcd. for $C_{17}H_{30}O_5$: C, 64.94; H, 9.62. Found: C, 64.96; H, 9.60.

1-C-Cyclohexyl-2,3:4,5-di-isopropylidene-D,L-arabitol.—This substance was prepared by mixing saturated hot petroleum ether solutions of the two enantiomorphs. On cooling the D,L-form separated as large prisms with a melting point 90° which could not be altered by further recrystallization. Mixed melting points with both the D- and L-forms were depressed. *Anal.* Calcd. for $C_{17}H_{30}O$: C, 64.94; H, 9.62. Found: C, 65.05; H, 9.83.

1-C-Cyclohexyl-D-arabitol was prepared by the hydrolysis of its di-isopropylidene derivative as already described for its enantiomorph.[2] After recrystallization from ethanol to constant properties a crystalline product, m. p. 148°, $[\alpha]^{24}D$ −12.6° in pyridine (*c*, 5.2), was obtained. On drying at 60° prior to analysis it was observed that the rotation had changed to $[\alpha]^{24}D$ −15.0° in pyridine (*c*, 4.4). This same phenomenon was then observed with the previously reported L-isomer which was found to change to $[\alpha]^{25}D$ + 15.0°. The loss of weight corresponded to the loss of one molecule of ethanol of crystallization in each case. Since the solvent is reasily lost even in the melting point tube without much change in crystal structure the melting points of both the alcoholate and the free pentitol are apparently the same.

Anal. Calcd. for $C_{11}H_{22}O_5 \cdot C_2H_5OH$: C, 55.68; H, 10.06. Found: C, 55.75; H, 10.37. Calcd. for $C_{11}H_{22}O_5$: C, 56.34; H, 9.47. Found: C, 56.24; H, 9.33. 7.616 g. alcoholate lost 0.848 g. at 60°. Calcd. for $C_{11}H_{22}O_5.C_2H_5OH$: 0.8478 g.

4,5-Monoisopropylidene-L-arabinose Diethyl Mercaptal.—Thirty grams of L-arabinose diethyl mercaptal was shaken with 600 cc. of dry acetone and 150 g. of anhydrous copper sulfate for three days. Some sodium carbonate was added to insure freedom from acidity, the solution filtered and evaporated at room temperature. There was obtained 29 g. of crude product (m. p. 72°) which was recrystallized from ether–petroleum ether to yield pure 4,5-minoisopropylidene-L-arabinose, m. p. 75.6° and $[\alpha]^{23}D$ +7.6° in methanol (*c*, 8.5). Gätzi and Reichstein[3] reported the same melting point and $[\alpha]^{19}D$ −7.4° in methanol for the D-form.

Anal. Calcd. for $C_{12}H_{24}O_4S_2$: C, 48.7; H, 8.2; Found: C, 49.0; H, 8.3.

Lead Tetraacetate Oxidation of 4,5-Isopropylidene-L-arabinose Diethyl Mercaptal.—A fine suspension of 15 g. of lead tetraacetate in 400 cc. of benzene was stirred vigorously at room temperature with 10 g. of 4,5-di-isopropylidene-L-arabinose diethyl mercaptal. In ten minutes all the oxidizing agent had been consumed. The mixture was filtered and the benzene removed through a fractionating column. The residue distilled at 48–52° (14 mm.). After heating with 4 *N* sulfuric acid for ten minutes the distillate yielded a crystalline *p*-nitrophenylhydrazone. After recrystallization from nitrobenzene, pure glyoxal *p*-nitrophenylhydrazone m. p. 306° (dec.) was obtained. *Anal.* Calcd. for $C_{14}H_{12}O_4N_6$: N, 26.5. Found: N, 25.9. The dinitrophenylhydrazone m. p. 321° (dec.) was also prepared. *Anal.* Calcd. for $C_{14}H_{10}O_8N$: N, 26.8. Found: N, 27.0.

1-C-Cyclohexyl-1,2,3,4-tetraacetyl-5-trityl-D-arabitol was prepared in the same manner as already reported for the enantiomorphous pentitol. There was obtained an 82% yield of pure material, m. p. 134°, $[\alpha]^{25}D$ +15° pyridine (*c*, 27.2). *Anal.* Calcd. for $C_{38}H_{44}O_9$: C, 70.79; H, 6.88. Found: C, 70.80; H, 6.97.

Summary

The position of the isopropylidene groups in 2,3:4,5-di-isopropylidene-D- and L-arabinose diethyl mercaptal and related compounds has been

(9) All melting points are corrected.

(10) These pentitols are referred to as arabitols to distinguish them from the corresponding derivatives prepared from other aldehydo sugars. It is recognized that proper nomenclature must await the establishment of the configuration of the new asymmetric carbon atoms in this series.

established by conversion through D- and L-di-isopropylidene-*aldehydo*-arabinose to enantiomorphous, crystalline, 1-C-cyclohexylarabitols. These substances have all been related to 3,4:5,6-di-isopropylidene-D-mannitol of known structure.

The position of the isopropylidene group in 4,5-isopropylidene-L-arabinose diethyl mercaptal has been established by lead tetraacetate oxidation.

1-C-Cyclohexyl-1,2,3,4-tetraacetyl-5-trityl-D-arabitol has been prepared.

1-Thiosorbitol

BY M. W. FARLOW, MADISON HUNT,[1] C. M. LANGKAMMERER, WILBUR A. LAZIER,[2] W. J. PEPPEL[3] AND F. K. SIGNAIGO[4]

The deactivation or poisoning of hydrogenation catalysts by even small amounts of sulfur, hydrogen sulfide, or sulfur-containing organic compounds is a familiar phenomenon of hydrogenation chemistry. Accordingly, the discovery in this laboratory[5] that catalysts, such as cobalt polysulfide, function effectively in the conversion of aldehydes, ketones, and nitriles to thiols by hydrogenation in the presence of sulfur or hydrogen sulfide represents an important advance in this field.

Among the aldehydes and ketones to which this reaction can be applied, sugars are of especial interest since their hydrogenation in the presence of hydrogen sulfide has made available for study a variety of new polyhydroxyalkane monothiols. This paper describes the preparation, properties, and more interesting chemical reactions of 1-thiosorbitol[6] which is derived from D-glucose.

The preparation of thiosorbitol from D-glucose by hydrogenation in the presence of sulfur can be represented by the equations

$$H_2 + S \xrightarrow{\text{catalyst}} H_2S$$

$$CH_2OH\overset{\overset{\text{O}}{\frown}}{CH}(CHOH)_3CHOH + H_2S \longrightarrow \left[CH_2OH\overset{\overset{\text{O}}{\frown}}{CH}(CHOH)_3CHSH\right] + H_2O$$

$$\left[CH_2OH\overset{\overset{\text{O}}{\frown}}{CH}(CHOH)_3CHSH\right] + H_2 \xrightarrow{\text{catalyst}} CH_2OH(CHOH)_4CH_2SH$$

This mechanism is supported by the following facts: (1) thioketones and thioaldehydes readily hydrogenate to thiols under the conditions used here; (2) aldehydes and ketones have not undergone hydrogenation to alcohols under the conditions and with the catalysts used here; and (3) alcohols and hydrogen sulfide have not yielded thiols under these conditions. The reactions indicated have been carried out conveniently in pressure equipment using an aqueous reaction medium, free sulfur, and commercial dextrose. At 125–150° and a hydrogen pressure of 1000–1500 lb./sq. in. the reaction is complete in three to four hours. There is obtained a good yield of crude thiosorbitol sirup from which highly purified thiosorbitol can be isolated by several procedures. The preferred method for the isolation of thiosorbitol involves preparation and separation of the cuprous salt which is suspended in ethanol and treated with hydrogen sulfide to regenerate the free thiol. The aqueous solution is evaporated to dryness, and white crystalline 1-thiosorbitol, m. p. 92–93°, is recovered in 25–30% over-all yields by crystallization at low temperatures from alcohol. Nearly pure varieties of thiosorbitol can be obtained by direct crystallization of concentrated crude sirup from ethanol or by oxidation to the corresponding disulfide, which is recrystallized and subsequently cleaved by catalytic reduction in the presence of sulfactive catalysts. Crude thiosorbitol sirup contains organic sulfur compounds which are not thiols. Some of these products are thought to be the result of side reactions involving thioacetal formation or dehydration of thiosorbitol to cyclic sulfides. Low molecular weight cleavage products are also present in crude sirup. Removal of these prior to the above purification procedure is best accomplished by steam distillation or by extracting the aqueous reaction medium with an immiscible organic solvent.

1-Thiosorbitol is a white, crystalline, water-soluble compound showing the reactions characteristic of aliphatic mercaptans and of polyhydric alcohols. For example, oxidation with iodine in hot absolute alcohol gives the corresponding disulfide in excellent yields. The hexaacetate can be prepared by treatment of thiosorbitol with fused sodium acetate and acetic anhydride at 100°. The corresponding benzoate was obtained as a sirup.

Reaction of 1-thiosorbitol in alkaline dioxane with *n*-dodecyl bromide yields *n*-dodecyl 2,3,4,5,6-pentahydroxyhexyl sulfide.

Perhaps the most unusual property of 1-thiosorbitol is its ability to form water soluble salts with a

(6) Lazier and Signaigo, U. S. 2,402,640, June 25, 1946.

variety of heavy metals.[7] For example, aqueous 1-thiosorbitol solutions dissolve silver chloride readily with the liberation of hydrochloric acid. Similarly, 1-thiosorbitol forms soluble salts with Cu^+, Cu^{++}, Fe^{++}, Pb^{++}, Hg^{++}, Sn^{++}, Ni^{++}, and Zn^{++} ions. The ability of thiosorbitol to retain these heavy metals in solution in the presence of the usual precipitating negative ions indicates a very low degree of ionization of the thiosorbitol heavy metal derivative. Hydrogen sulfide, however, generally precipitates the metals from thiosorbitol solutions. The preparation of the cuprous salt is described in connection with the purification of 1-thiosorbitol.

The general process described in the experimental part for the conversion of D-glucose to 1-thiosorbitol has been applied successfully to other sugars such as sucrose, maltose, D-fructose and soluble starches. In these cases, the products were sirups from which pure crystalline polyhydroxyalkane thiols have not been isolated.

Experimental

Preparation of Cobalt Sulfide Catalysts.—To 1500 ml. of water in a vessel of 2-liter capacity provided with a stirrer was added 240 g. of $Na_2S \cdot 9H_2O$ and 64 g. of sulfur and the whole was stirred until the sulfur was dissolved. The filtered solution was added over a ten to fifteen-minute period to a solution of 242 g. of $CoCl_2 \cdot 6H_2O$ in 1700 ml. of water contained in a vessel of 4–5 liter capacity equipped with a large paddle stirrer. After the addition, stirring was continued for another half hour. The catalyst was collected by suction filtration and washed with water on the funnel until the filtrate was colorless. The 750–1000 g. of hard paste obtained contains approximately 150 g. of cobalt polysulfide (CoS_3) and is 15–20% solids. If it is not to be used at once, it should be stored out of contact with air.

Preparation of 1-Thiosorbitol.—A 3-gallon, stainless steel, horizontal autoclave equipped with stirrer was charged with 1500 g. of D-glucose, 800 g. of sulfur, 2500 g. of water and 1000 g. of 15% cobalt polysulfide catalyst paste prepared as described above. The autoclave was then sealed and hydrogen introduced from high-pressure storage tanks until the total pressure was 1000 lb./sq. in. The autoclave and contents were heated to a temperature of 125° and maintained at this temperature. The pressure dropped as a result of the reaction of hydrogen with sulfur and additional hydrogen was forced into the autoclave to maintain a pressure of 1000 lb./sq. in. The temperature was then raised to 150° and the pressure was raised to 1500 lb./sq. in. These conditions were maintained for a period of three hours at the end of which time absorption of hydrogen had practically ceased. Excess hydrogen and hydrogen sulfide were vented from the cooled autoclave and then the product was rinsed out with 700 ml. of water. The reaction mixture was filtered to remove catalyst and then evaporated to one-half its original volume at 60° and at 40 mm. pressure. If all the water is removed, 1430 g. of a sirup containing about 13% thiol sulfur and 15% total sulfur is obtained. The viscous liquid remaining from the evaporation was diluted with 2000 g. of water and converted into a solution of the cuprous salt by adding 563 g. of powdered cuprous oxide with stirring at a temperature of 55°. The reaction mixture was kept under an atmosphere of nitrogen during this and subsequent operations. The solution of the cuprous salt was added slowly with vigorous stirring to 13 liters of methanol to precipitate the cuprous salt, which was then separated by filtration and washed twice on the filter with 1500-ml. portions of methanol. The copper salt was suspended in 2400 g. of 90% ethanol in a 3-gallon stainless steel autoclave and treated with hydrogen sulfide under 500 lb./sq. in. pressure until no further pressure drop was observed. The contents of the autoclave were rinsed out with 400 g. of absolute alcohol. The cuprous sulfide was removed by filtration, and the filtrate was treated with 20 g. of carbon black and refiltered. The alcohol solution was evaporated to dryness at 50° and 28 mm. pressure. Seven hundred milliliters of absolute alcohol was added and the evaporation procedure repeated to complete removal of water. The thiosorbitol residue was dissolved in 700 ml. of warm absolute alcohol and filtered. The solution was cooled first to room temperature and finally was kept at 5° overnight. The crystalline 1-thiosorbitol which separated was filtered and washed with cold absolute alcohol and finally with ethyl ether. After drying *in vacuo*, the resulting white crystalline non-hygroscopic material, m. p. 92–93°, weighed 427 g. (27% yield based on *d*-glucose). By titration with standard iodine solution it was found to contain thiol groups corresponding to a purity of 96.2% 1-thiosorbitol.

Anal. Calcd. for $C_6H_{14}O_5S$: C, 36.3; H, 7.12. Found: C, 36.7, 36.7; H, 7.2, 7.2.

1-Thiosorbitol is readily soluble in water, pyridine, ethylene glycol, and formamide. It is insoluble in benzene, petroleum ether, carbon tetrachloride and carbon disulfide. At 20°, 100 ml. of absolute ethanol, dioxane, ethyl ether, trichloroethylene and acetone, respectively, dissolve 1.7 g., 1.2 g., 0.016 g., 0.016 g. and 0.010 g. of 1-thiosorbitol. 1-Thiosorbitol has a specific rotation in water of $[\alpha]^{27}D$ −1.9 at 2% concentration and 27° in a tube 40 cm. in length.

1-Thiosorbitol Disulfide.—Ten grams of 1-thiosorbitol dissolved in 50 ml. of hot absolute alcohol was treated with alcoholic iodine until the iodine color persisted. The solution was then filtered and cooled overnight to allow the product to separate. Recrystallized from alcohol, eight grams of disulfide (80% yield), m. p. 128–130°, was obtained.

Anal. Calcd. for $C_{12}H_{26}O_5S_2$: C, 36.6; H, 6.7. Found: C, 36.7; H, 6.9.

The decaacetate of thiosorbitol disulfide was prepared by treatment with fused sodium acetate and acetic anhydride, m. p. 125–130°.

Anal. Calcd. for $C_{32}H_{46}O_{20}S_2$: S, 7.87. Found: S, 7.82.

1-Thiosorbitol Hexaacetate.—Two grams of thiosorbitol and 1 g. of fused sodium acetate were treated with 10 ml. of acetic anhydride and heated at 90–100° for three hours. The product was poured into water and washed by decantation several times. The solid product purified by recrystallization from aqueous alcohol melted at 87–89°.

Anal. Calcd. for $C_{18}H_{26}O_{11}S$: C, 48.0; H, 5.8. Found: C, 48.4; H, 6.0.

The corresponding benzoate obtained by the reaction of benzoyl chloride with 1-thiosorbitol in pyridine could not be induced to crystallize.

S-Dodecyl-1-thiosorbitol.—Twenty grams of 1-thiosorbitol was dissolved in 50 ml. of water and 4 g. of sodium hydroxide added. To this was added 25 g. of dodecyl bromide in 50 ml. of dioxane and the mixture heated under reflux for two hours. The solid which separated on cooling was washed with water, dioxane and ether. Thirty-one grams (84%) was obtained, m. p. 107°.

Anal. Calcd. for $C_{18}H_{38}O_5S$: C, 58.95; H, 10.48; S, 8.73. Found: C, 58.12; H, 10.37; S, 8.45.

Summary

1-Thiosorbitol has been prepared by the hydrogenation of D-glucose in the presence of sulfur. Methods for the isolation and purification of this new polyhydroxyalkane thiol have been described.

(7) Peppel and Signaigo, U. S. 2,410,844, November 12, 1946.

1-Thiosorbitol has been found to undergo normal mercaptan reactions such as oxidation to the disulfide, acylation, and etherification with alkyl halides. In addition, it has been observed to form water-soluble salts with a variety of heavy metals.

L-α-Glycerylphosphorylcholine

BY ERICH BAER AND MORRIS KATES[1]

Studies with labelled choline (N^{15}) and radioactive phosphorus (P^{32}) have shown that a rapid metabolic turnover of phospholipids, particularly of the small intestine, liver and kidney, takes place. These observations evoke considerable interest in the role of glycerylphosphorylcholine (G.P.C.) as an intermediary metabolite, since it is highly probable that this diester plays an essential part in the biosynthesis and the turnover of lecithins. Until quite recently (1945) an investigation of the metabolic fate of the diester was difficult because it was not obtainable in sufficient quantity or purity.

Attempts to isolate G.P.C. from biological material have been made frequently. In 1935 Contardi and Ercoli[2] incubated lysolecithin with purified rice bran extracts and observed the formation of a water-soluble organic phosphate. Although this substance was not isolated in pure state, its behavior indicated that it was a glycerylphosphorylcholine. Kahane and Lévy[3] on hydrolysis of egg yolk lecithin with lecithinase B (rat intestine) obtained a choline derivative of glycerophosphoric acid which was soluble in water, methanol, ethanol and insoluble in acetone. Further experimental work strongly suggesting the presence of G.P.C. in commercial preparations of dried beef pancreas,[4] and in tissue of fresh heart muscle of frogs and rabbits[5] has been reported.

Schmidt, Hershman and Thannhauser[6] succeeded in isolating from beef pancreas autolysates *levo*-rotatory G.P.C. in fairly pure form and were able to establish its constitution as that of the choline ester of α-glycerophosphoric acid. Utilization of a biological source, however, does not lend itself readily to the preparation of G.P.C. on a laboratory scale in amounts exceeding a few grams.

During the past ten years much of the work in this Laboratory has been directed toward the synthesis of optically pure enantiomers of asymmetrically substituted glycerol derivatives. In the desire to extend our synthetic endeavours to the field of the phospholipids and in the hope of being able to supply the biochemist with a much needed material, the synthesis of L-α-G.P.C., a substance closely related to the lecithins, was attempted.

In a previous communication[7] it was shown that the optically active α-glycerophosphoric acid isolated from lecithins belongs to the L-series and can be synthesized by phosphorylation of D(+)-acetone glycerol. The use of the latter substance insured simultaneously the position of attachment of the phosphate group and the desired L-configuration of the α-glycerophosphoric acid.[8] It was to be expected that the α-G.P.C. obtained from lecithin would have the same configuration and should be obtainable in a similar manner by esterification of phosphoric acid with D(+)acetone glycerol and choline. The synthesis, especially the phosphorylation step offered, however, a number of technical difficulties which had to be overcome before a procedure could be found which would give consistently satisfactory yields of glycerylphosphorylcholine. The method of synthesis of L-α-G.P.C. which was finally adopted and the steric relationships of the various intermediate compounds are illustrated in the accompanying reaction scheme. After trying numerous phosphorylation procedures it was found that the intermediary acetone glycerylphenylphosphorylcholine chloride (C-Cl) is obtainable in adequate amounts by phosphorylation of D(+)acetone glycerol with phenylphosphoryl dichloride in the presence of quinoline, followed by esterification of the reaction product with choline in the presence of pyridine. The isolation of the choline ester from the reaction mixture was greatly facilitated by the observation that its reineckate, in contrast to the reineckates of pyridine and quinoline, precipitates from an alkaline–aqueous solution and can be separated from the similarly alkali-insoluble reineckates of choline and other choline-containing reaction products by means of its solubility in ethyl acetate. The reineckate of (C) was converted to the corresponding sulfate ($C\text{-}SO_4/2$) before removing the protective phenyl and acetone groups in order to avoid complications introduced

(1) This paper forms part of a thesis which will be submitted by M. Kates to the Department of Chemistry, University of Toronto, in partial fulfillment of the requirements for the degree of Doctor of Philosophy. An account of this work was presented before the Canadian Physiological Society, at the London (Ontario) meeting, October 24–25, 1947.

(8) An optically active α-monoglyceride is considered as being related to the glyceraldehyde which would be obtained by oxidation of the γ-carbon atom.

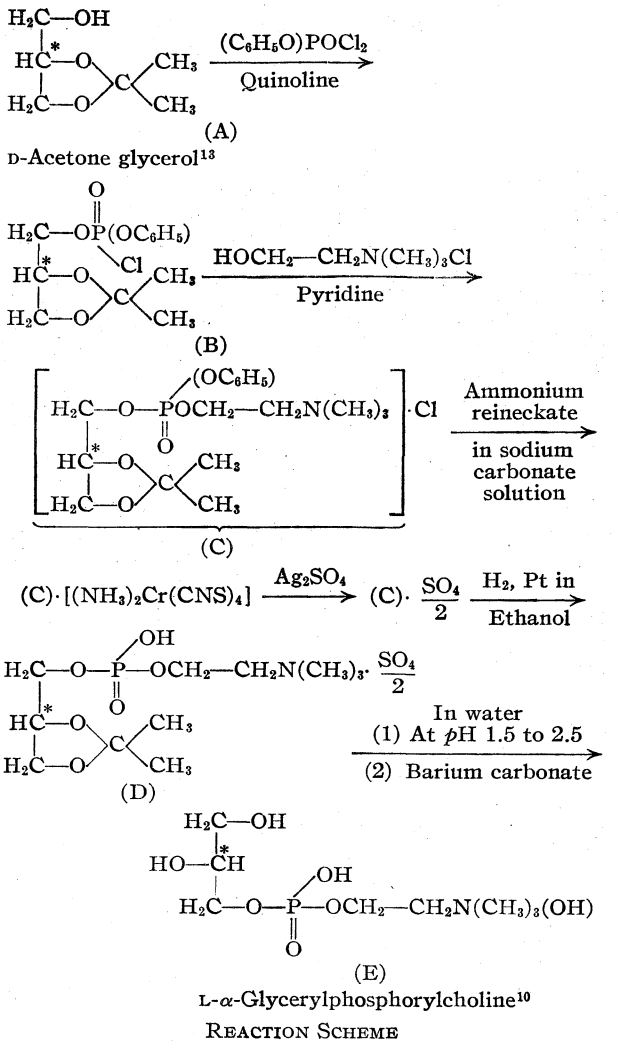
by the reineckate ion. It was found that the order of removal of these groups was a decisive factor in obtaining L-α-glycerylphosphorylcholine. All attempts to prepare the diester by removing first the acetone group of (C-SO_4/2) failed because, at the *p*H required for its removal, liberation of choline and $\alpha \leftrightarrows \beta$ migration of phosphoric acid took place. In contrast, when the phenyl group of (C-SO_4/2) was removed first, the resulting acetone glycerylphosphorylcholine (D-SO_4/2) was found to be stable enough to permit its deacetonation within the *p*H-range of 1.5–2.5 without simultaneous liberation of choline or phosphoric acid migration to give a good yield of the diester (E).

The synthetic L-α-G.P.C. was obtained as a colorless, hygroscopic and viscous liquid in an over-all yield varying from 35–40%; $[\alpha]^{23}D$ −2.85° (±0.1°) in water (average of 15 preparations). The diester is fairly stable in aqueous solution at room temperature within the *p*H-range of 1.5 to 7; in alkaline solution or in strongly acid solution, however, it is rapidly hydrolyzed. The cleavage of its choline-phosphoric acid linkage is also effected by the recently described enzyme preparation from carrots.[9] The diester is precipitated from alcoholic solution by ammonium reineckate or cadmium chloride.

The synthetic L-α-G.P.C. was shown to contain neither inorganic phosphate nor free choline. It analyzed correctly for $C_8H_{22}O_7NP$ and its molecular ratio of *choline : phosphoric acid : α-glycerol ester* corresponded very closely to the theoretical value of 1:1:1. The diester was further characterized by means of an amorphous cadmium chloride compound ($[\alpha]D$ −1.2°) and a crystalline cadmium chloride compound (m. p. 100–102°; $[\alpha]D$ −1.4°), both of which were obtained in excellent yields. On the basis of the analytical data formula $[C_8H_{22}O_7NP]_2 \cdot [CdCl_2]_3$ had to be assigned to the amorphous compound and formula $[C_8H_{22}O_7NP][CdCl_2] \cdot 2H_2O$ to the crystalline compound. On decomposition of the two cadmium chloride addition compounds with silver carbonate the L-α-G.P.C. was recovered unchanged ($[\alpha]D$ −2.9°).

The properties of the synthetic L-α-G.P.C. were similar to those described by Schmidt, Hershman and Thannhauser for the natural G.P.C. except that the rotation of the synthetic diester was considerably lower than that reported for the biological diester ($[\alpha]D$ − 4.87°). This discrepancy could be accounted for either by a partial inactivation of the synthetic α-diester during the later stages of the synthesis or by contamination of the biological diester with compounds of high optical activity.

First of all attempts were made to establish the optical purity of the synthetic diester by degradation to the well known L-α-glycerophosphoric acid.[7] The glycerophosphoric acid obtained by



REACTION SCHEME

acid or alkaline hydrolysis had, however, a much lower rotation than that reported for the synthetic compound and, depending on the method of hydrolysis, containing varying proportions of L-α-, D,L-α- and β-glycerophosphoric acid. The formation of β-glycerophosphoric acid from pure α-G.P.C. must have been caused by acyl-migration during hydrolysis. In order to prevent this migration attempts were made to block both alcoholic hydroxy groups by methylation. The low solubility of the G.P.C. in all solvents commonly used in etherification procedures made the complete methylation of the glycerol-moiety impossible. After several other unsuccessful attempts to establish the optical purity of the synthetic L-α-G.P.C. by relating it to L-α-glycerophosphoric acid, work in this direction was abandoned.

It was then decided to repeat the isolation of G.P.C. from autolyzed beef pancreas as described

(9) D. J. Hanahan and I. L. Chaikoff, *J. Biol. Chem.*, **168**, 233 (1947); **169**, 699 (1947).

(10) The guiding principles in establishing the steric classification of the enantiomeric glycerides and related compounds are outlined by H. O. L. Fischer and E. Baer in *J. Biol. Chem.*, **128**, 475 (1939), and in *Chem. Rev.*, **29**, 287 (1941).

by Schmidt, Hershman and Thannhauser. In view of the complex nature of the autolysate, it was considered possible that small amounts of impurities of high optical activity might still be associated with the product obtainable by this procedure. The rotation of the G.P.C. obtained by us was even higher than that reported by Schmidt, *et al.* However, several repetitions of the Amberlite treatment gradually removed the basic impurities and lowered the rotation to a point where it became not only constant ($[\alpha]_D$ $-2.8°$) but was in complete agreement with that of the synthetic diester. Furthermore, the crystalline cadmium chloride addition compound obtained from the highly purified natural diester was identical with the corresponding compound of the synthetic glycerylphosphorylcholine. The identity of the natural levorotatory G.P.C. and the synthetic L-α-G.P.C. was thus established beyond doubt. The L-configuration, as anticipated, must therefore be assigned to the natural diester. The fact that the optical activities of both compounds, each obtained by a different procedure, and those of their derivatives are in complete agreement suggests with high probability that the synthetic L-α-G.P.C. is optically pure, the possibility that both compounds have been inactivated to the same extent being remote.

By means of the same series of reactions as described for the synthesis of L-α-G.P.C., but starting with L(−)acetone glycerol or racemic acetone glycerol, D-α- or D,L-α-G.P.C. are obtainable. In the course of the present investigation the racemic α-G.P.C. has been prepared. Since, however, its synthesis is identical with that of the optical isomer only the physical and analytical data of the diester and its intermediary compounds are reported.

A kinetic study of the acid and alkaline hydrolysis of the L-α-G.P.C. has shown that the liberation of choline is accompanied by a reversible phosphoric acid migration resulting in the formation of a mixture of L-α-, D,L-α- and β-glycerophosphoric acid. The close relationship of α-G.P.C. to lecithins permits the prediction of similar chemical changes on subjecting lecithins to acid or alkaline hydrolysis. A detailed account of this work which seems to invalidate the methods commonly used in the elucidation of the structure of lecithins, will be published elsewhere. In the light of these findings a critical re-examination of the data in the literature has raised serious doubts as to the natural existence of β-lecithins.

The synthesis of the enantiomeric forms (as well as the racemic form) of α-lysolecithins[11] and α-lecithins of known constitution and configuration *via* the corresponding enantiomers of α-G.P.C. has now become possible. Work along these lines is in progress in this Laboratory.[12] The synthetic α-glycerylphosphorylcholines and the synthetic α-lecithins should be ideal substrates in studies concerning the specificity of the enzymes responsible for the cleavage of the various phosphatide linkages.

Finally it should be mentioned that the synthesis described in this paper should make possible the preparation of α-G.P.C. or of α-lecithins with all or some of their groups labelled by the use of (1) acetone glycerol containing deuterium,[13] (2) choline with heavy nitrogen, (3) phenylphosphoryl dichloride with radioactive phosphorus and (4) fatty acids containing deuterium or preferably heavy carbon.

(11) The α indicates the position of the phosphoric acid.

(12) Attempts to prepare optically active lecithins via the enantiomeric forms of α,β diglycerides by means of the double phosphorylation procedure are also being made.

Experimental Part

I. Synthesis of L-α-Glycerylphosphorylcholine

Monophenylphosphoryl Dichloride.[14]—The chloride was prepared according to Jacobsen,[15] using, however, the slightly modified procedure reported by Brigl and Müller,[14] which yields in approximately equal amounts monophenylphosphoryl dichloride and diphenylphosphoryl monochloride. The acid chlorides were separated and carefully purified by fractional distillation *in vacuo*. Boiling point of the pure phenylphosphoryl dichloride 107–109° (9 mm.)).

D(+)Acetone Glycerol.—The glycerol derivative was prepared according to the simplified procedure reported by Fischer and Baer.[16] The reduction, however, was carried out at atmospheric pressure, using Raney nickel catalyst.[17] It should be noted that the yields of L-α-glycerylphosphorylcholine reported in this communication are obtainable only by using preparations of D(+)acetone glycerol with specific rotations ranging from +13.5° to +14.0°. Preparations of lower optical activity contain moisture; their use reduces greatly the yield of the diester.

Acetone Compound of L-α-Glycerylphenylphosphorylcholine: Phosphorylation, Step 1.—In a 500-ml. round-bottomed, two-necked and thick-walled flask equipped with a mercury-sealed, motor-driven stirrer and dropping funnel were placed 18.2 ml. (0.123 mole) of monophenylphosphoryl dichloride, 16.2 ml.[18] (0.138 mole) of dry quino-

(13) H. Erlenmeyer, H. O. L. Fischer and E. Baer, *Helv. Chim. Acta*, **20**, 1012 (1937).

(14) Phosphorus oxychloride, widely used as a phosphorylating agent, has the disadvantage of giving rise to the formation of phosphorus-containing by-products which are not only difficult to remove but also reduce the yield considerably. Most of the undesired effects associated with the use of this agent may be avoided by utilizing its phenyl esters. The successful use of the diphenylphosphoryl-chloride as a phosphorylating agent has been reported frequently during recent years but the first successful application of phenylphosphoryl dichloride for the preparation of *mixed* diesters of phosphoric acid will be described in this communication. *Cf.* P. Brigl and H. Müller, *Ber.*, **72**, 2121 (1939). This reagent should prove useful in the synthesis of other compounds of biological interest.

(15) G. Jacobsen, *Ber.*, **8**, 1519 (1875).

(16) E. Baer and H. O. L. Fischer, *J. Biol. Chem.*, **128**, 463 (1939).

(17) A detailed description of the most recent procedure for the preparation of D(+)acetone glycerol will appear in "Biochemical Preparations" as a part of the preparation of L-α-glycerophosphoric acid.

(18) Quinoline of a good commercial grade was dried over potassium hydroxide and fractionated within narrow limits of boiling point. By substituting pyridine for quinoline in Step 1, only very small amounts of the acetone compound of glycerylphenylphosphorylcholine are formed in Step 2, presumably because of the increased formation of di-(acetone-glyceryl)-phenylphosphate in Step 1. This assumption is supported by the observation of E. Fischer and E. Pfähler, *Ber.*, **53**, 1606 (1920), that the tendency of phosphorus oxychloride to react simultaneously with more than one of its chloride groups is greater in pyridine than in quinoline.

line[18] and 50 to 60 ml. of glass beads (6–7 mm. diameter).[19] The flask was immersed in a cold bath (−10°) and 16.15 g. (0.123 mole) of freshly prepared D(+)acetone glycerol was added dropwise in the course of four to five minutes to the vigorously stirred phosphorylating mixture. After five minutes the cold-bath was removed and the mixture allowed to come to room temperature. The reaction product, acetone-L-α-glycerylphenylphosphoryl chloride, was not isolated.

Phosphorylation, Step 2.—The reaction mixture was immediately broken up as quickly as possible, covered with 100 ml. of dry pyridine[20] and vigorously stirred until a fine suspension was formed. To this suspension were added 15.8 g. (0.115 moles) of dry choline chloride[21] and 90 to 100 ml. of glass beads. The stirring was continued for a period of at least forty hours.[22]

Isolation of the Phosphorylation Product as Reinecke Salt.—The reaction flask was attached to a receiver and the mixture concentrated *in vacuo* (bath 40°) to a sirup. The residue was poured with stirring into 450 ml. of an ice-cold sodium carbonate solution (60 g. of anhydrous sodium carbonate in 600 ml. of water). The remainder of the carbonate solution was used to rinse the flask and glass beads. The combined aqueous solutions were freed from suspended quinoline by centrifugation and the aqueous layer poured through a wet filter into a freshly prepared solution of 53–55 g. of ammonium reineckate[23] in 1800 ml. of distilled water containing 10 g. of sodium carbonate.[24] After the addition of a small amount of filter-aid (Hyflo-Super-Cel) the mixture was filtered with suction. The precipitate was washed thoroughly with water and dried *in vacuo* over solid sodium hydroxide and phosphorus pentoxide to constant weight. The dry reineckate was powdered, extracted by stirring with 700 ml. of dry ethyl acetate[25] and the suspension was sharply centrifuged. The extraction of the reineckate was repeated with successively smaller amounts of ethyl acetate until the extracts were only faintly colored. Seven to eight extractions, using a total of 2200 ml. of ethyl acetate, were required. The combined extracts, if necessary, were cleared by centrifugation. The supernatant liquid was concentrated *in vacuo* to a volume of approximately 100 ml. and the concentrate diluted gradually with 500 ml. of dry and ethanol-free ether. The precipitate was filtered off with suction, washed thoroughly on the filter with ether and dried *in vacuo*. The yield of already fairly pure reinecke salt of acetone-L-α-glycerylphenylphosphorylcholine varied from 38 to 47 g. (45 to 55%); m. p. 136.5–137.5°. The reineckate is readily soluble in acetone or ethyl acetate, less soluble in ethanol and insoluble in water, ether or benzene. For analytical purposes only, the reineckate was crystallized from 95% ethanol; prisms, m. p. 137.0–137.5°.

(19) By the use of glass beads the choline chloride is brought into a finely dispersed state and the formation of a sticky gum, which would enclose unreacted material, is minimized. The efficiency of the phosphorylating procedure is thus greatly increased.

(20) This base rather than quinoline was used in the second step of the phosphorylation because of the greater activity of the phosphorus oxychlorides in pyridine. Pyridine of a good commercial grade was refluxed over barium oxide and distilled with exclusion of moisture.

(21) The choline chloride was thoroughly dried *in vacuo* over phosphorus pentoxide at 56°.

(22) The reaction vessel was partially immersed in a large water-bath (20–25°) to prevent a rise in temperature due to the friction of the glass beads. Otherwise a marked darkening of the reaction mixture occurs.

(23) The commercial ammonium reineckate is often not sufficiently pure. It was found more economical to prepare the ammonium salt as described in "Organic Syntheses," Coll. Vol. II, p. 555.

(24) The alkalinity of the dilute sodium carbonate solution suffices to prevent the precipitation of pyridine reineckate and quinoline reineckate.

(25) Ethyl acetate, if moist, also dissolves some of the impurities. It suffices to dry the commercial ethyl acetate with anhydrous potassium carbonate.

Anal. Calcd. for $C_{21}H_{35}O_6N_7S_4PCr$ (692.6): C, 36.4; H, 5.52; N, 14.15; P, 4.47. Found: C, 36.5; H, 5.32; N, 14.08; P, 4.41.[26]

Conversion of the Reineckate to the Sulfate.—Ten grams of the reineckate[27] was dissolved in 40 ml. of acetone and the solution was diluted with 60 ml. of 95% ethanol. To this solution was added gradually and with cooling a lukewarm 1% aqueous silver sulfate solution (approximately 225 ml.) until the precipitation of the silver reineckate was complete. The precipitate was removed by centrifugation, washed with 95% ethanol and the combined supernatants were concentrated *in vacuo* as rapidly as possible to a volume of approximately 50–60 ml. at a bath temperature not exceeding 40°.[28] Remaining traces of the original reineckate were decomposed by the dropwise addition of a dilute silver sulfate solution. The silver reineckate was removed, the solution taken to dryness under reduced pressure (bath 35 to 40°) and the residue dried in a vacuum of 0.5 mm. The crude sulfate (5.1 g.) was dissolved in 25–30 ml. of 99% ethanol, freed from insoluble material (100–300 mg.) and the solution taken to dryness *in vacuo*. At this stage the sulfate (4.8 g., 79%) is a glass-like mass which is pure enough for further processing. The sulfate can be obtained in crystalline state by taking it up with warm, dry acetone (7 ml./g.) and keeping the mixture overnight in the ice-box (+5°); recovery approximately 85%.

For analytical purposes the crystalline sulfate was purified further by dissolving it in 99% ethanol, centrifuging the suspension, evaporating the supernatant liquid *in vacuo* to a small volume and adding gradually dry acetone to the concentrate until crystallization set in. After five minutes another portion of dry acetone equal to the first was added and the mixture kept in an ice-box for twenty-four hours. The hygroscopic crystals were filtered rapidly with suction, washed with a small portion of anhydrous acetone and dried *in vacuo* over fresh calcium chloride. Recovery of sulfate approximately 50%; m. p. 108–109.5° (sint. 101°); $[\alpha]^{27}D$ −8.3° in water (*c*, 7.8); $[\alpha]^{28}D$ −3.0° in dry ethanol (*c*, 6.1).[29]

The strongly hygroscopic sulfate is readily soluble in water or ethanol, sparingly soluble in cold acetone or dioxane and insoluble in ether. *Anal.* Calcd. for $C_{24}H_{58}O_{16}N_2P_2S$ (844.5): C, 48.25; H, 6.91; N, 3.31; P, 7.34; SO_4 11.37; acetone, 13.70; choline, 28.8. Found: C, 48.95; H, 7.06; N, 3.29; P, 7.17; SO_4 11.18; acetone, 13.35; choline,[30] 28.8.

L-α-Glycerylphosphorylcholine: Removal of the Phenyl Group by Reductive Cleavage.—Sixteen grams of the L-α-glycerylphenylphosphorylcholine reineckate[27] was converted into the crude sulfate as described above. The sulfate (8.5 g.) was dissolved in 80 ml. of 99% ethanol and freed by centrifugation from insoluble material. The clear solution together with 2 g. of platinic oxide (Adams catalyst) was shaken vigorously in an atmosphere of pure hydrogen at room temperature and a pressure of 40 to 50 cm. of water in excess of atmospheric

(26) The P-determination on the reineckate was carried out according to King (*Biochem. J.*, **26**, 292 (1932)). The determination, however, was somewhat complicated by the presence of chromic acid anhydride, one of the digestion products. At the completion of the digestion the cooled solution was filtered through a sintered glass filter and the chromic anhydride crystals washed with small amounts of 60% perchloric acid. The filtrate and washings were made up to volume and used for the colorimetric determination of phosphorus.

(27) The reineckate obtained directly from the ethyl acetate extraction may be used here.

(28) The aqueous solution of the sulfate is acid. To avoid hydrolysis resulting in the liberation of acetone and choline all operations should be carried to completion as rapidly as possible and at the lowest possible temperature.

(29) The readings were taken immediately after preparing the solutions.

(30) The substance was hydrolyzed in 1.5 *N* hydrochloric acid at 100° (two hours) and the choline determined gravimetrically in form of its reineckate as described by Schmidt, Hershman and Thannhauser.

pressure until the absorption of hydrogen ceased. In about seventy-five minutes 2010 ml. (N. T. P.) or 93% of the theoretical amount of hydrogen were taken up. The catalyst was filtered off, washed with ethanol and the combined filtrate and washings evaporated to dryness *in vacuo* (bath 40°). The residue, a colorless glass weighing 6.0 g., contained in general 20% less acetone than calculated for the acetone compound of L-α-glycerylphosphorylcholine sulfate. No attempt was made to isolate a pure compound.

Deacetonation.—The crude acetone compound (6.0 g.) was dissolved in 150 ml. of distilled water and the solution, which had a *p*H of 1.5, was allowed to stand at room temperature (20 to 25°) for a period of fifteen hours.[31]

To remove traces of nitrogenous impurities, a dilute solution of ammonium reineckate was then added dropwise until the precipitation was complete and after centrifugation, the excess of ammonium reineckate was removed with dilute silver sulfate solution. The supernatant was triturated with barium carbonate until free from sulfate ions and the silver ions were removed with hydrogen sulfide in the presence of the barium salts. The mixture was centrifuged and the aqueous solution concentrated under reduced pressure (bath 35–40°) to a small volume. The deposit of insoluble material (mostly barium carbonate) was removed and the concentration *in vacuo* continued. The drying was completed in a vacuum of 0.1 mm. at a bath temperature not exceeding 40°; yield 4.0 to 4.6 g. of L-α-glycerylphosphorylcholine (65 to 75% of the theoretical from reineckate or 35 to 40% over-all yield). The synthetic diester is a viscous liquid which is readily soluble in water, ethanol or methanol and insoluble in acetone, ether or benzene; $[\alpha]^{23}D$ $-2.85 \pm 0.1°$ in water (*c*, 2.2 determined from P-content; *p*H 6–7). The optical activity of α-G. P. C. seems to decrease slightly with increasing acidity.

Anal. Calcd. for $C_8H_{22}O_7NP$ (275.2): choline, 44.0; P, 11.27. Found: choline, 42.4; P, 10.95.

Vicinal Glycol Titration with Periodic Acid.—0.1157 gram of the diester was dissolved in water and the volume made up to 100 ml. The titration was carried out according to Voris, Ellis and Maynard[32] on 10.0-ml. aliquots. After one hour 0.0422 mM. of the diester had consumed on the average 0.0414 mM. of periodic acid or 98.2% of the theoretical amount calculated for the α-glycerylphosphorylcholine. Ratio of choline:P:α-glycerol ester[33]: calcd. 1:1:1. Found: 0.99:1.00:1.01.

Amorphous Cadmium Chloride Addition Compound of L-α-Glycerylphosphorylcholine.—A solution of 5.8 g. of cadmium chloride (2.5-H_2O) in 4 ml. of water, diluted with 65 ml. of 99% ethanol, was added slowly and with stirring to a solution of 4.0 g. of L-α-glycerylphosphorylcholine in 75 ml. of 99% ethanol. After standing in the ice-box for one hour the dense, white precipitate was filtered with suction, washed with ethanol and ether, and dried *in vacuo;* yield of the amorphous cadmium chloride addition compound 7.3 g. (92%). This compound is quite stable and can be used advantageously for the storage of L-α-glycerylphosphorylcholine. If need arises it can be quickly converted into the free diester; $[\alpha]^{25}D$ $-1.2°$ in water (*c*, 5.0). *Anal.* Calcd. for $(C_8H_{22}O_7NP)_2 \cdot (CdCl_2)_3$ (1100): C, 17.44; H, 4.03; N, 2.54; P, 5.62; Cl, 19.35; Cd, 30.60; choline, 21.9; ratio of $CdCl_2:C_8H_{22}O_7NP = 3:2$. Found: C, 17.6; H, 4.24; N, 2.58; P, 5.58; Cl, 19.90; Cd, 30.15; choline, 21.1; ratio of $CdCl_2:C_8H_{22}O_7NP = 3.01:2.00$. Calcd. for the cadmium chloride-free moiety, $C_8H_{22}O_7NP$ (275): C, 34.9; H, 8.05; N, 5.08; P, 11.27; choline, 44.0. Found by calculation from the analytical values above: C, 35.2; H, 8.48; N, 5.17; P, 11.17; choline, 42.2.

Vicinal-Glycol Titration with Periodic Acid.—The sample of the cadmium chloride derivative in aqueous solution was freed from cadmium by the addition of potassium carbonate. The filtrate was made up to a known volume and the content of diester ascertained by a phosphorus determination. Several aliquots each containing 0.0218 mM. of the diester consumed in two hours on the average 0.0201 mM. (96.3%) of periodic acid.

Crystalline Cadmium Chloride Compound of L-α-Glycerylphosphorylcholine: (a) Prepared from the Amorphous Cadmium Chloride Compound.—A solution of 3.1 g. of the *amorphous* cadmium chloride compound in 38 ml. of water was diluted gradually with 150 ml. of 99% ethanol and a small amorphous precipitate removed immediately by centrifugation. The clear supernatant liquid was first kept at room temperature for twenty-four hours, during which time crystals (prisms) began to form and was then kept in an ice-box (+5°) for two days. The crystals were filtered with suction, washed with a small volume of cold 80% ethanol and *dried in air* to constant weight. The crystalline cadmium chloride compound of L-α-glycerylphosphorylcholine was obtained in a yield of 1.85 g. (66.4%); m. p. 100–102° with sintering from 97° (rise in temperature 3°/min. starting with a bath temperature of 80°); $[\alpha]^{24}D$ $-1.4°$ in water (*c*, 5.5). *Anal.* Calcd. for $(C_8H_{22}O_7NP)(CdCl_2) \cdot 2H_2O$ (494.7): C, 19.46; H, 5.30; N, 2.83; P, 6.27; Cl, 14.33; Cd, 22.7; choline, 24.5. Found: C, 19.31; H, 5.21; N, 2.84; P, 6.28; Cl, 14.50; Cd, 22.8; choline, 24.6. Ratio of $C_8H_{22}O_7NP:CdCl_2$. Calcd. 1.0:1.0. Found. 1.00:1.01. The air-dried cadmium chloride compound lost on drying over phosphorus pentoxide in a vacuum of 0.1 mm. at 56° 10.62% of its weight. Calcd. for a loss of three moles of water 10.92%.[34]

Vicinal-Glycol Titration with Periodic Acid.—Carried out as described for the amorphous cadmium chloride compound. At the end of two hours 0.0235 mM. of the diester had consumed on the average 0.0233 mM. (99.2%) of periodic acid.

(b) **Prepared directly from the diester.** To the combined solutions of 2.0 g. of the diester in 13 ml. of water and of 2.6 g. of cadmium chloride (2.5 H_2O) in 15 ml. of water were added gradually and with swirling 100 ml. of 99% ethanol. The solution was immediately cleared of a small amount of amorphous material by centrifugation. The supernatant liquid was diluted with an additional portion of 10 ml. of 99% ethanol and crystallization induced mechanically. After the mixture had stood for six hours at room temperature and twenty-four hours in the ice-box the crystals (prisms) were filtered with suction, washed with 80% ethanol and dried in air to constant weight; yield of crystalline cadmium chloride compound 80% (2.8 g.); m. p. 97–101° (sintered 94°); $[\alpha]^{27}D$ $-1.4°$ in water (*c*, 5.8). *Anal.* Found: C, 19.14; H, 5.25; N, 2.85; P, 6.22.

Recovery of L-α-Glycerylphosphorylcholine from its Cadmium Chloride Compound.—To a solution of 1.0 g. of the *amorphous* cadmium chloride compound in 35 ml. of water was added 1.6 g. of silver carbonate and the mixture was stirred vigorously until free from chloride ions. After removal of the solids the solution was freed from cations with hydrogen sulfide and the sulfides removed by filtration over Hyflo-Super-Cel. The filtrate was concentrated to a sirup under reduced pressure (bath 35–40°) and the residue was dried to constant weight in a vacuum of 0.1 mm. at a temperature not exceeding 40°. In the event that the residue was still slightly colored by colloidal material it was taken up in ethanol, centrifuged, concentrated and dried *in vacuo* as described above. The recovery of L-α-glycerylphosphorylcholine was 98% (0.49 g.); $[\alpha]D$ $-2.9°$ in water (c, 2.6).

(31) According to our experience a complete hydrolysis of acetone without liberation of choline or migration of phosphoric acid is achieved within the *p*H-range of 1.5 to 2.5 at the stated time interval and temperatures. Hydrolysis at greater acidity liberates choline and at lower acidity is incomplete with regard to acetone.

(32) L. Voris, G. Ellis and L. A. Maynard, *J. Biol. Chem.*, **133**, 491 (1940).

(33) Determined by the periodic acid titration.

(34) The loss of the third mole of water during the process of drying may be explained by the formation of an inner salt of the glycerylphosphorylcholine.

II. Synthesis of D,L-α-Glycerylphosphorylcholine

The synthesis of D,L-α-glycerylphosphorylcholine is identical with that described for the L-form, except that D,L-acetone glycerol[35] is used as starting material. Only the analytical and physical data of the various compounds will be reported here.

Acetone Compound of D,L-α-Glycerylphenylphosphorylcholine: (a) **Reineckate.**—Yield 56%; m. p. 136–137°. *Anal.* Calcd. for $C_{21}H_{35}O_6N_7PCr$ (692.6): C, 36.4; H, 5.52; N, 14.15; P, 4.47. Found: C, 36.6; H, 5.49; N, 14.13; P, 4.40.

(b) **Sulfate.**—Obtained by the decomposition of the reineckate in yields of 70–80% (oil) or 60–68% (crystals). *Anal.* Calcd. for $C_{34}H_{58}O_{16}N_2P_2S$ (844.5); P, 7.34; SO_4, 11.37; acetone, 13.70; choline, 28.8. Found: P, 7.25; SO_4, 11.00; acetone, 13.76; choline, 28.2.

D,L-α-Glycerylphosphorylcholine.—Over-all yield 35–40%; viscous liquid, soluble in water, ethanol, methanol; insoluble in acetone, ether or benzene. **Amorphous cadmium chloride compound.**—Yield 90%. *Anal.* Calcd. for $(C_8H_{22}O_7NP)_2(CdCl_2)_3$: C, 17.44; H, 4.03; N, 2.54; P, 5.62; Cl, 19.35; Cd, 30.60; choline, 21.9. Found: C, 17.68; H, 4.16; N, 2.64; P, 5.72; Cl, 19.45; Cd, 30.05; choline, 21.8. Theoretical values for the cadmium chloride-free moiety $C_8H_{22}O_7NP$: C, 34.9; H, 8.05; N, 5.27; P, 11.27; choline, 44.0. Found by calculation from the analytical values above: C, 35.0; H, 8.23; N, 5.23; P, 11.32; choline, 43.4.

Vicinal-Glycol Titration with Periodic Acid.—Carried out as described for the corresponding cadmium chloride compound of the synthetic L-α-glycerylphosphorylcholine. Aliquots containing 0.0226 mM. of D,L-α-glycerylphosphorylcholine consumed in 15, 45, 90 minutes 0.0204 mM. (90.4%), 0.0215 mM. (95.2%) and 0.0217 mM. (95.9%) of periodic acid, respectively.

III. Isolation of α-Glycerylphosphorylcholine from Beef Pancreas According to Schmidt, Hershman and Thannhauser[6]

Five pounds of beef pancreas treated as outlined by Schmidt, Hershman and Thannhauser yielded 2.9 g. of crude α-glycerylphosphorylcholine with a rotation of $[\alpha]^{25}D$ −7.8° in water (*c*, 2.7). This rotation, much higher than that reported by Schmidt, Hershman and Thannhauser ($[\alpha]^{20}D$ −4.87°), indicated that our biological product still contained extraneous material of high optical activity and needed further purification. The diester was dissolved in 40 ml. of water and a dilute aqueous ammonium reineckate solution added until no further precipitation took place. The excess of ammonium reineckate was removed with dilute silver sulfate solution; the filtrate was triturated with barium carbonate and the silver ions removed with hydrogen sulfide in the presence of the barium salts. The aerated aqueous solution of the diester (approx. volume 60 ml.) was stirred for one hour with 20 g. of Amberlite (I. R.-100), filtered and the filtrate concentrated *in vacuo* at a bath temperature not exceeding 40°. The colorless oil, which weighed 1.15 g. and now had an optical activity of $[\alpha]^{25}D$ −4.2° in water, (*c*, 2.3) was again treated in aqueous solution (60 ml.) with 20 g. of Amberlite for a period of thirty minutes. The filtrate was concentrated *in vacuo* to a volume of 5 ml. and the diester precipitated by the addition of 50 ml. of dry acetone. The precipitate, freed *in vacuo* from solvent, weighed 0.7 g. and had an optical activity of $[\alpha]^{25}D$ −2.7° in water (*c*, 2.5, *p*H 2.8). This rotation, although considerably lower than that reported by Schmidt, Hershman and Thannhauser, is, however, identical with that of our synthetic product $[\alpha]^{23}D$ −2.85° (±0.1°). To ensure that the progressive decrease in optical activity was due to the removal of impurities and not to inactivation of the glycerylphosphorylcholine by the Amberlite, the oil (0.7 g.) was treated once more with the ion-exchanger. The optical activity of the recovered diester (0.6 g.) remained unchanged, $[\alpha]^{25}D$ −2.7° in water (*c*, 2.7, *p*H 2.5) or $[\alpha]^{25}D$ −2.8° (*c*, 2.6; *p*H 5.8). The fact that the optical activity of the synthetic L-α-glycerylphosphorylcholine also remained unchanged after a treatment with Amberlite is further evidence of the harmlessness of this treatment.

Crystalline Cadmium Chloride Compound of the Natural α-Glycerylphosphorylcholine.—For the purposes of analysis and further comparison of the natural L-α-glycerylphosphorylcholine with the synthetic L-α-glycerylphosphorylcholine the natural diester (0.5 g.) was converted via the amorphous cadmium chloride compound (0.88 g.) to the crystalline cadmium chloride addition compound (prisms, 0.56 g.) as described for the synthetic product; m.p. of the crystalline cadmium chloride compound 99–100° (sintered at 90°; rise in temperature 3°/minute, starting with a bath of 80°); $[\alpha]^{24}D$ −1.4° in water (*c*, 5.5). *Anal.* Calcd. for the crystalline cadmium chloride compound $(C_8H_{22}O_7NP)(CdCl_2)\cdot 2H_2O$ (494.7): C, 19.46; H, 5.30; N, 2.83; P, 6.27; choline, 24.5. Found: C, 19.20; H, 5.35; N, 2.83; P, 6.34; choline, 24.9. The air-dried cadmium chloride compound lost on drying *in vacuo* (0.1 mm.) over phosphorus pentoxide at 56°, 11.05% of its weight. Calcd. for the loss of three moles of water 10.92%.

Periodic Acid Titration.—The titration was carried out as described for the amorphous cadmium chloride compound of the synthetic diester: 0.0236 mM. of diester consumed 0.0229 mM. or 97% of periodate.

Acknowledgment.—This work is an extension of studies of enantiomeric derivatives of glycerol conducted during the past ten years by one of us (E. B.) in association with Professor Hermann O. L. Fischer whose continued interest and friendly criticism are gratefully acknowledged.

The authors wish to express their gratitude to the Banting Research Foundation for grants to one of them (M. K.) during part of the investigation.

Summary

1. A synthetic procedure is described by means of which the L- and D,L-α- glycerylphosphorylcholine have been prepared.

2. The synthetic L-α-glycerylphosphorylcholine was found to be identical with a product obtained from autolyzed beef pancreas by a slight modification of the purification procedure described by Schmidt, Hershman and Thannhauser.

3. The first successful application of monophenylphosphoryl dichloride as a phosphorylating agent is described. This reagent may prove useful in the synthesis of other phosphate-containing compounds of biological interest.

Chlorides and Other Derivatives of Tetramethylsilane

BY JOHN L. SPEIER AND B. F. DAUBERT

Chloromethyltrimethylsilane has been prepared[1,2] and some compounds derived from it have been studied.[3,4]

In this paper the study of compounds derived from chloromethyltrimethylsilane is continued and broadened to include two new chlorides of tetramethylsilane with some of their reactions and derivatives. The new chlorides are dichloromethyltrimethylsilane and bis-(chloromethyl)-dimethylsilane.

Trimethylsilylmethylmagnesium chloride[1,4] was found to react vigorously with phenyl isocyanate in absolute ether, but hydrolysis of the addition compound resulted in the formation of acetanilide rather than of α-trimethylsilylacetanilide, thus showing again that a carbonyl group in a position *beta* to silicon decidedly facilitates cleavage of the group.[4] This result perhaps may explain the findings of Kipping[5] who attempted unsuccessfully to prepare benzylethylpropylsilylacetic acid from the appropriate chlorosilane and sodioacetoacetic ester. No silicon-containing acid derivative could be isolated from the hydrolyzed products of the reaction. The reaction products of Gilman and Clark[6] obtained by a similar procedure might be another example of this phenomenon as pointed out by Whitmore, *et al.*,[4] who reported the hydrolytic instability of other *beta* oxygenated organosilicon compounds.

Dichloromethyltrimethylsilane in absolute alcoholic sodium ethoxide rapidly formed methylene chloride and ethoxytrimethylsilane with the liberation of a large amount of heat. Cleavage of the dichloromethyl group from silicon was also brought about by potassium acetate in glacial acetic acid at elevated temperatures. These findings extend those of Krieble and Elliott,[7] who showed that alkaline reagents caused cleavage of chlorinated methyl groups from siloxane structures and that the ease of cleavage increased with the degree of substitution upon the methyl group.

Potassium acetate in glacial acetic acid was found to convert bis-(chloromethyl)-dimethylsilane into the corresponding diacetate ester in good yield. The diacetate yielded the dialcohol, dimethylsilylenedimethanol, [bis-(hydroxymethyl)-dimethylsilane] when subjected to methanolysis in the presence of hydrochloric acid. Chloromethyltrimethylsilane treated in essentially the same manner yielded trimethylsilylmethanol.[3]

Experimental Part

Preparation of Dichloromethyltrimethylsilane and bis-(Chloromethyl)-dimethylsilane.—Chloro-(dichloromethyl)-dimethylsilane[7] and (chloro)-bis-(chloromethyl)-methylsilane[7] were each found to react smoothly with a slight excess of methylmagnesium bromide in ether to yield the expected dichloromethyltrimethylsilane (70% yield) and bis-(chloromethyl)-dimethylsilane (63% yield), respectively. These compounds were found to possess the following properties: dichloromethyltrimethylsilane, b. p. 133° at 730 mm., $n^{25}D$ 1.4430, d^{25}_4 1.0395. Molar Refraction: Calcd.[8] for $Cl_2CHSiMe_3$: 39.96. Found: 40.04. *Anal.* Calcd. for $C_4H_{10}SiCl_2$: Cl, 45.2. Found: Cl, 44.9, 45.1. bis-(Chloromethyl)-dimethylsilane, b. p. 160° at 724 mm., $n^{25}D$ 1.4579, d^{25}_4 1.075. Molar refraction: Calcd.[8] for $(ClCH_2)_2SiMe_2$: 39.96. Found: 39.87. *Anal.* Calcd. for $C_4H_{10}SiCl_2$: Cl, 45.2. Found: Cl, 45.0, 44.8.

The synthesis of chloromethyltrimethylsilane by the above method has been described.[2]

Formation of Acetanilide from Trimethylsilylmethylmagnesium Chloride.—To an ethereal solution of about 0.014 mole of trimethylsilylmethylmagnesium chloride[1,4] was added an excess of phenyl isocyanate. A vigorous reaction occurred and the mixture set to a gelatinous mass. After twenty-four hours the mass was stirred with water and filtered with suction. The solids collected were stirred with 95% ethanol and filtered. To the ethanolic solution thus obtained, dilute aqueous sodium carbonate was added and the mixture was heated to boiling and quickly filtered free of the precipitate that formed. The filtrate on becoming cool yielded carbanilide, m. p. 225–235°. After the removal of this compound, most of the alcohol was driven from the solution by evaporation. When the essentially aqueous solution thus obtained was cooled, acetanilide precipitated, m. p. 110–111°. Further evaporation of the mother liquor yielded a second crop of acetanilide, m. p. 111–112°. These crops were combined and recrystallized from water to yield a product, m. p. 111–112°, (approx. 80%) which showed no change of melting point when mixed with an authentic sample of acetanilide, m. p. 112°, and which contained only a trace of silicon.

Cleavage Reactions of Dichloromethyltrimethylsilane.—Dichloromethyltrimethylsilane (154 g., 0.98 mole) was added to absolute ethanol (350 ml.) at room temperature into which sodium (25 g.) had been dissolved. A vigorous boiling ensued immediately. Before the apparatus could be assembled for distillation through a one-foot Vigreux column, a certain amount of material was lost. Distillate boiling over a range from 40 to 78° was collected. This distillate was washed with dilute hydrochloric acid to remove the ethanol and to hydrolyze any ethoxytrimethylsilane that might be present. The washed product was distilled and found to consist only of methylene chloride (60 g., 71%) b. p. 40–41°, $n^{25}D$ 1.4217, d^{25}_4 1.310, and of hexamethyldisiloxane (57 g., 73%), b. p. 99°, $n^{25}D$ 1.3749.

Dichloromethyltrimethylsilane (14 g.) was sealed into a glass tube with anhydrous potassium acetate (22 g.) and glacial acetic acid (11 ml.) and heated at 200° for three hours. A large amount of potassium chloride formed. The tube was opened and its contents washed with water. A dark liquid was thus obtained which smelled strongly of formaldehyde. A portion of this liquid was treated with 2,4-dinitrophenylhydrazine in acidified ethanol solution and yielded the 2,4-dinitrophenylhydrazone of formaldehyde, m. p. 159°, which

(8) Warrick, *ibid.*, **68**, 2455 (1946).

showed no depression of melting point when mixed with an authentic sample of the derivative of formaldehyde, m. p. 165°. The derivative contained only a trace of silicon. At 150° a similar mixture after nineteen hours showed no signs of having reacted in any way.

Preparation of bis-(Acetoxymethyl)-dimethylsilane (Dimethylsilylenedimethanol Diacetate).—bis-(Chloromethyl)-dimethylsilane (292 g., 1.85 moles), potassium acetate (412 g., 4.2 moles) and glacial acetic acid (300 ml.) were heated together and shaken in a stainless steel autoclave at 118–130° for four hours and at 148–160° for sixteen hours. The contents of the autoclave were then washed once with water to remove the salts and most of the acid present. The water insoluble liquid was distilled. The only compound found, other than acetic acid, was bis-(acetoxymethyl)-dimethylsilane (339 g., 90%), b. p. 124° at 27 mm., 223° at 739 mm., $n^{25}D$ 1.4309–1.4310, d^{25}_4 1.0135. Molar refraction: Calcd.[8] for $(AcOCH_2)_2SiMe_2$: 52.34. Found: 52.17. *Anal.* Sap. equiv. Calcd. for $(AcOCH_2)_2SiMe_2$: 102.2. Found: 102.6, 102.1.

bis-(Acetoxymethyl)-dimethylsilane (110 g.) was dissolved in a ten-fold excess of dry methanol and acidified with three drops of concentrated hydrochloric acid. Periodically during three weeks methyl acetate was removed by distillation. Each time methanol was added to restore the solution to its original volume and the solution was permitted to stand at room temperature for several days before more methyl acetate was removed. The solution was distilled, after no further amount of methyl acetate appeared to form. bis-(Hydroxymethyl)-dimethylsilane (dimethylsilylenedimethanol) was obtained as a colorless, odorless, viscous liquid, completely soluble in water; b. p. 130° at 27 mm., $n^{25}D$ 1.4611, d^{11}_4 0.993. Molar refraction: Calcd.[8] for $(HOCH_2)_2SiMe_2$: 33.38. Found: 33.20. Saponification number, 12.7. *Anal.* Calcd. for $C_4H_{12}O_2Si$: Si, 23.3. Found: Si, 23.2, 23.3.

Summary

Some of the reactions of the chlorides of tetramethylsilane have been studied. These compounds showed a tendency, under certain conditions, toward cleavage of the substituted methyl group from the silicon atom. The dichloromethyl group was found to be more easily cleaved than the chloromethyl group. Hydrolysis of the addition product of trimethylsilylmethylmagnesium chloride and phenyl isocyanate was shown to result in the formation of acetanilide, thus revealing the ease of cleavage of *beta* carbonyl silicon compounds.

The new compounds, bis-(chloromethyl)-dimethylsilane, dimethylsilylenedimethanol diacetate, dimethylsilylenedimethanol, and dichloromethyltrimethylsilane were prepared and characterized during the investigation.

The Basic Strengths of Amines as Measured by the Stabilities of Their Complexes with Silver Ions

BY RICHARD J. BRUEHLMAN[1] AND FRANK H. VERHOEK

The relationship of the basic strengths of amines as determined by the stability of their ammonium ions to their strengths as measured by the stability of their complexes with silver ion has been discussed repeatedly. It has been stated that a parallelism between the two measures exists[2] and that a parallelism does not exist.[3,4] Except for the last paper cited,[4] the conclusions have commonly been based on a consideration of the instability or association constants for the over-all reaction

$$Ag^+ + 2A \rightleftharpoons AgA_2^+ \qquad (1)$$

where A represents the amine. It was pointed out,[5] however, that each such constant contains an equilibrium constant for the reaction

$$AgA^+ + A \rightleftharpoons AgA_2^+ \qquad (2)$$

in which the ion reacting with the amine is different for each amine considered, and that a more just comparison is that between the two reactions

$$Ag^+ + A \rightleftharpoons AgA^+ \qquad (3)$$

$$H^+ + A \rightleftharpoons AH^+ \qquad (4)$$

Accordingly the equilibrium constants of reactions (3) have been measured for several amines and compared with those for reactions (4) measured in similar systems. The equilibrium constants of reactions (2) were also measured.

The equilibrium constants were determined by means of *p*H measurements on solutions of amine, silver ion, acid and neutral salt according to the method of Bjerrum,[6] on selected groups of primary, secondary, and tertiary amines of varied basic strength. The selection was severely limited by the requirements that the amine be reasonably soluble in water, that it form complexes in such a *p*H range that silver oxide would not precipitate out, that it have a basic strength different from other members of the group, and that the complex formed be sufficiently soluble that a solid phase did not form. This paper reports equilibrium constants for the formation of ammines of silver ion with five primary amines, three secondary amines, and four pyridines. In order to estimate the validity of the comparison of equilibrium constants for equations (3) and (4) at a single temperature, temperature coefficients over a ten-degree temperature interval were determined in most cases.

In addition, equilibrium constants were deter-

mined for the formation of copper ammines with two of the pyridines.

Experimental

The *p*H measurements were made with a glass electrode and a Coleman Style 200 *p*H Electrometer. The glass and calomel electrodes were mounted in a specially designed glass apparatus that was thermostated at 25 or 35°; the two compartments were connected through ungreased stop-cocks by a saturated potassium nitrate bridge. The electrometer was adjusted for asymmetry and temperature by using buffer solutions prepared from samples of potassium acid phthalate, potassium dihydrogen phosphate and disodium hydrogen phosphate and sodium tetraborate decahydrate furnished by the National Bureau of Standards.

Each *p*H measurement was made on a separate sample prepared by adding a known amount of amine from a weight buret to a 100-ml. sample of a standard solution of metal ion, acid, and neutral salt, precautions being taken to prevent absorption of carbon dioxide. Fifty milliliters of the solution thus prepared was used to rinse the glass electrode chamber and the remaining 50 ml. was used for the measurement.

All of the amines were research grade materials obtained from Eastman Kodak Co. General treatment involved refluxing for eight to twelve hours over barium oxide or potassium hydroxide, followed by distillation through a packed column, taking the middle fraction boiling within 0.2–0.3°. Boiling points in all cases agreed well with those in the literature. As a further precaution, the amines of high basic strength were titrated with standard acid to determine the neutral equivalents; these agreed with the theoretical values. All amines except ethylamine and β-methoxyethylamine, which were used as standardized solutions, were used as the pure amine.

Results

Dissociation Constants of the Amines.—Since it is necessary to know the acid dissociation constants of the amines for the calculation of the formation curves, these were determined in solutions of the same ionic strength as the solutions containing the complex-forming metal ion. Varying amounts of amines were added to standard solutions 0.525 *M* in potassium nitrate and 0.100 *M* in nitric acid. The results are given in Table I. Each value reported here represents an average of 10–12 determinations at different ratios of amine concentration to amine salt concentration.

Metal Ammine Formation.—The over-all and successive association constants for the systems studied were calculated from accurately-drawn large-scale plots of the formation curves ($\bar{n}$, the average number of moles of amine combined with one mole of silver ion, *vs.* $p[A]$, the negative logarithm of the concentration of free amine) by the method of Bjerrum.[5,6] Each formation curve was plotted from 15–25 separate points, each point representing a *p*H measurement on an individually prepared sample of known concentrations of amine, acid, metal ion and neutral salt. The standard solutions to which known amounts of the amines were added were 0.500 *M* in potassium nitrate, 0.1000 *M* in nitric acid and 0.0250 *M* in silver nitrate. Table II gives a summary of the values obtained for the silver ammines at 25° and 35°; k_1 is the equilibrium constant for equation

Ammonia[a]	3.99	3.34	2.73	1.97	12.03

[a] Measured by Bjerrum in 0.5 M ammonium nitrate solutions.

Discussion

Since silver ion is a Lewis acid, the equilibrium constants for equations (3) and (4) for a series of amines measure the strengths of the amines relative to two different reference acids. If the relative strengths of the amines are independent of the reference acid, a plot of the logarithm of k_1 against the negative logarithm of the dissociation constant of the substituted ammonium ion would be expected to give a straight line of unit slope. Such a plot for the data at 25° from Tables I and II is given in Fig. 1.

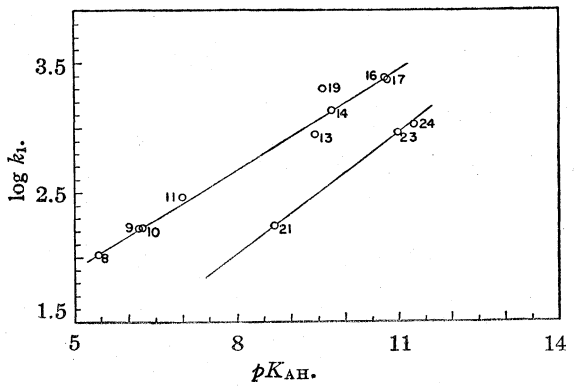

Fig. 1.—Variation of the first association constant of silver ammines with the strength of the amine relative to hydrogen ion at 25°. Amines are numbered as in Fig. 2.

It is evident that a straight line relationship is obtained, but that the data fall into two groups. The pyridines and primary amines lie on one curve, and the secondary amines on another. Thus a secondary amine and a primary amine which have the same strength relative to hydrogen ion will differ in strength by a factor of about 3.5 when measured relative to silver ion.

It is also evident that the lines obtained are not of unit slope; the slopes are about one-fourth. Although the curves are drawn with different slopes for the two groups, it cannot be definitely stated that the slopes should be different, since the number of points is small. The slopes will be changed somewhat by a change in temperature, but the data in the tables show that the temperature coefficients are sufficiently alike that this change will not be great. The slope of approximately one-fourth may then be taken as real, and indicates a very great compression of the range of basicities when silver ion is used as a standard acid to measure the basic strength. Thus two amines which differ in strength by a factor of ten thousand when measured relative to hydrogen ion will differ only by a factor of ten when measured relative to silver ion.

It is seen from Table II that the ratio of k_1/k_2, although larger for the pyridines than for the other amines, is in all cases of the order of unity, and that log K_2 is about twice log k_1. This modifies the statements made in the introduction because it means that log K_2 will vary in a similar fashion to log k_1, so that except for a factor of two, comparisons of log K_2 with pK_{AH} will be valid. This is convenient, because it permits the use of the large number of values of K_2 available in the literature, obtained on systems to which the present technique is not applicable, for comparison. Figure 2 shows a plot of these data as log K_2 *vs.* pK_{AH}; in drawing conclusions from the figure one must remember that the ordinate of each point, and consequently the slopes of the curves

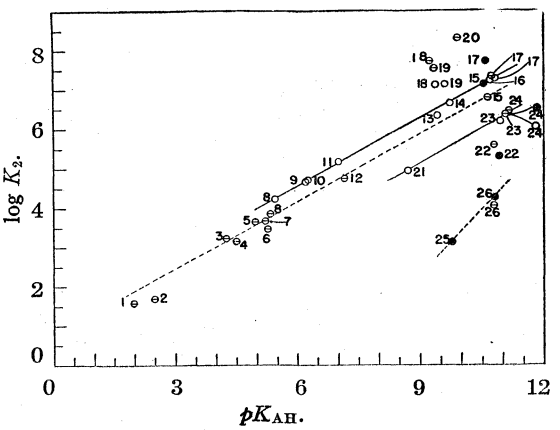

Fig. 2.—Variation of the over-all association constant of silver ammines with the strength of the amine relative to hydrogen ion: ⊖, Larsson; ●, Britton and Williams; O, this paper; 1, *p*-nitroaniline; 2, *m*-nitroaniline; 3, α-naphthylamine and β-naphthylamine; 4, aniline; 5, quinoline; 6, *p*-toluidine; 7, pseudo-cumidine; 8, pyridine; 9, α-picoline; 10, γ-picoline; 11, 2,4-lutidine; 12, *s*-collidine; 13, β-methoxyethylamine; 14, ethanolamine; 15, methylamine; 16, isobutylamine; 17, ethylamine; 18, ammonia; 19, benzylamine; 20, ethylenediamine; 21, morpholine; 22, dimethylamine; 23, diethylamine; 24, piperidine; 25, trimethylamine; 26, triethylamine.

would be decreased by one-half if log k_1 was plotted. The full lines are drawn through the values obtained in this investigation; they are represented by the equations

$$\log K_2 = 0.577\ pK_{AH} + 1.08$$
$$\log K_2 = 0.577\ pK_{AH} - 0.02$$

for the upper and lower curves, respectively. The dotted lines are drawn through the points of Larsson[2] for the primary amines and through the tertiary amine points of Britton and Williams.[3] The curve for Larsson's data lies below that for this investigation because his values are for a 50–50 alcohol water mixture; if, as he reports, the values in water are 0.3 to 0.6 logarithmic units higher than in the alcohol solution, the dotted line will coincide with the full line for the primary amines.

The figure confirms the smaller range of basic strengths relative to silver ion and shows that the aliphatic tertiary amines comprise a third group, although the slope of the curve for the latter is uncertain since only two points are available. It is this difference between primary, secondary, and tertiary amines which has led to the belief that there is no relationship between the basic strengths of the amines measured relative to the two standard acids; actually within the three groups there is a parallelism between the two measures, although the ratios of strengths of two bases is not the same in the two systems.

The explanation for the smaller range of base strengths referred to silver ion as compared to hydrogen ion is not immediately obvious. Evidently a change in the groups attached to the nitrogen atom which makes a great change in its tendency to coördinate with a proton makes little change in its tendency to coördinate with a silver ion. This is probably connected with the larger size of the silver ion as compared to the hydrogen ion, but the exact mechanism is obscure. That the effect is not peculiar to the silver ion is shown by the correspondence of the data on the copper complexes to those for the silver complexes.

Nor is it clear why the silver ion separates the aliphatic amines into three groups. It is tempting to attribute this to the increasing importance of steric effects with increasing substitution on the nitrogen, yet this can hardly be the explanation. The silver ion is not large enough to interfere with any of the groups on the amines investigated.

A further problem appears in the position of the pyridines, which do not lie with the tertiary aliphatic amines. It may be noted, however, that resonance structures are possible in a compound of silver ion with pyridine which are not possible with tertiary aliphatic amines, nor for compounds of hydrogen ion with pyridine. These would tend to cause the pyridine complexes to be more stable as compared to those of the aliphatic amines, raising them above the position of tertiary aliphatic amines of the same strengths relative to hydrogen ion. From this point of view, the fact that the points for the pyridine complexes lie on the same curve as those for the primary aliphatic amines is fortuitous.

Summary

1. The association constants for the reactions of silver ion with groups of primary aliphatic amines, secondary amines and pyridines have been measured, together with similar constants for cupric ion and two pyridines, and temperature coefficients.

2. When the logarithm of the first association constant is plotted against the pK value for the corresponding substituted ammonium ion, two straight lines are obtained: one for the pyridines and primary aliphatic amines, and one for the secondary amines. Data from the literature indicate that tertiary aliphatic amines lie on a third curve.

3. The slope of the curve obtained is approximately one-fourth, indicating a much smaller range of basic strengths when measured against silver ion as a reference acid than when measured against hydrogen ion.

The Determination of Pore Size Distribution from Gas Adsorption Data

BY C. G. SHULL*

Introduction

There has been widespread application in the past of gas adsorption data in determining quantitatively the physical structure of finely divided and porous materials. Most notable among the theories of adsorption which have been advanced are those of Brunauer, Emmett and Teller[1] and Harkins and Jura,[2] both of which have proved very successful in evaluating the specific surface of such materials. There are, however, frequent isotherm phenomena which cannot be treated by these theories and, in order to explain some of these, the presence of capillary condensation in the porous structure has been suggested. Excellent summaries of some of the early quantitative or semi-quantitative attempts in this direction have been given by Brunauer[3] and by Cohan.[4] These attempts have all been recognized as merely approximations for one reason or another.

Recently, Wheeler[5] has introduced a composite theory which combines the BET multilayer adsorption and capillary condensation viewpoints. Upon suitable application of this theory to the experimental isotherm, the pore size distribution which would account for the experimental data may be evaluated. It is the purpose of the present paper to point out a simple method by which the Wheeler theory can be applied to isotherm data thereby obtaining the pore size distribution.

The Wheeler theory can be summarized in one simplified equation

$$V_s - V = \pi \int_R^\infty (r - t)^2 L(r) \mathrm{d}r \qquad (1)$$

In this equation, V_s is the volume of gas adsorbed at saturation pressure, V is the volume of gas adsorbed at intermediate pressure p, $L(r)\mathrm{d}r$ is the total length of pores whose radii fall between r and $r + \mathrm{d}r$, R is the corrected Kelvin radius which is obtained as a function of the pressure, and t is the multilayer thickness which is normally built up at pressure p. This equation merely states that the volume of gas $V_s - V$ not yet adsorbed at a pressure p is equal to the total volume of pores which have not been filled.

The left hand side of Equation (1) is known from experimental data and it is desired to determine the pore size distribution function $L(r)$ which when integrated will show agreement with these experimental data. Before this can be done, it is necessary to evaluate R and t as functions of the pressure.

Evaluation of Critical Kelvin Radius and Multilayer Thickness.—Wheeler has introduced a modified Kelvin equation in evaluating the corrected Kelvin radius R. In this equation, the corrected or critical pore radius (critical in the sense that all pores having smaller radii than R have already been filled by multilayer adsorption and capillary condensation) is placed equal to the sum of the multilayer thickness and the radius normally calculated from the simple Kelvin equation. In other words

$$R = t - \frac{2\sigma v}{R_g T \ln p/p_0} \qquad (2)$$

σ being the surface tension, v the molar volume of the condensed liquid, and R_g the gas constant per mole, and T the temperature. This equation states, very reasonably, that the radius determining the presence or absence of capillary condensation is that of the open section (the part not occupied due to multilayer adsorption) in the pore and not that of the entire pore.

An approximate expression from the BET theory of multilayer adsorption has been used by Wheeler for calculating multilayer thickness values. It is known, however, that the BET thicknesses become much larger than experimental thicknesses *for flat surfaces* in the high pressure region. Figure 1 shows a comparison of these thickness values. In the upper part of this figure are shown experimental data taken from nine published isotherms[6] (nitrogen gas) for crystalline materials of large crystal size (1100 to 16,000 ångströms). These data are plotted on a V/V_m basis where V_m is the adsorbed volume corresponding to monomolecular coverage of the surface. Deviations of the experimental points from the average isotherm are seen, but the general trend of the data is well established. The average isotherm is next transferred to a multilayer thickness curve (t values) by assuming the monomolecular thickness to be 4.3 ångströms for nitrogen. This is shown in the lower part of Fig. 1 with the curve corresponding to the BET theory. Pronounced differences between the BET and experimental curves are to be noted in the higher pressure region.

Figure 2 shows curves for the corrected Kelvin radius R as a function of pressure, calculated from Equation (2) by use of the above experi-

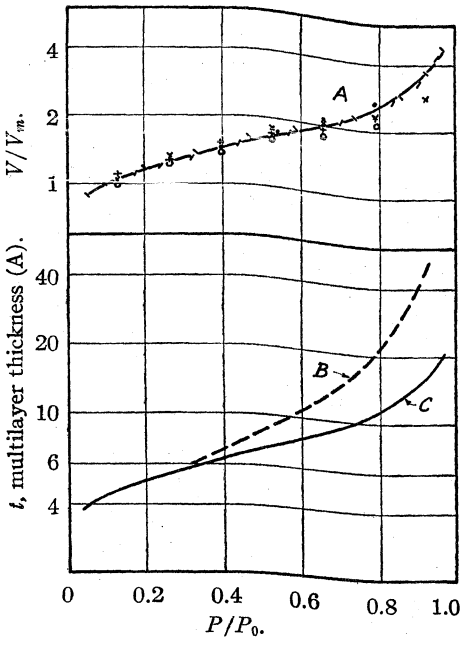

Fig. 1.—Multilayer thickness as obtained for large crystals and as calculated from the BET theory: Curve A, experimental values of the number of adsorbed layers (V/V_m) for crystalline materials of large crystal size; curve B, multilayer thickness for N_2 calculated from BET theory; curve C, multilayer thickness curve derived from curve A.

mental and BET values for multilayer thickness. As expected, the differences between the two curves show up in the high pressure region. Obviously it is necessary to make a decision as to which curve should be used in interpreting experimental isotherms.

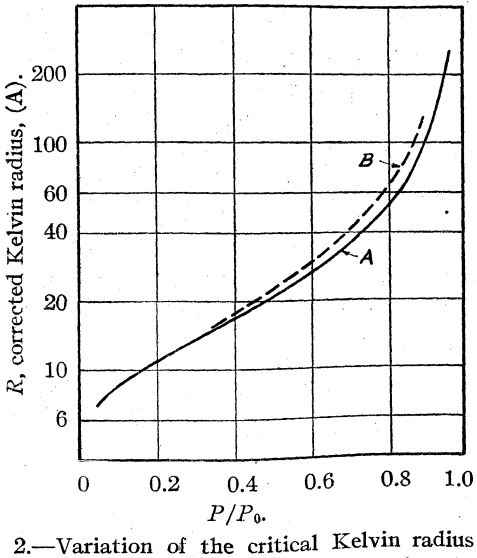

Fig. 2.—Variation of the critical Kelvin radius as a function of the adsorption pressure: curve A, calculated using experimental multilayer thickness values; curve B, calculated using BET thickness values (Wheeler).

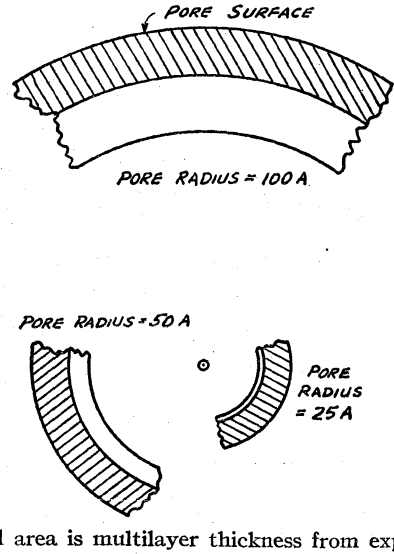
Wheeler has argued that since adsorption occurs on the curved surface of a pore, larger thicknesses would be expected than on a flat surface, and hence the use of the BET theory is justified. Notwithstanding this, there are arguments which seem to indicate that the use of BET values is an over-correction for the effect and that it is probably better to use the flat surface experimental data.

Some insight into this can be gained by considering the adsorption process on systems having hypothetical pore structure. Consider first a system where all of the pores are 100 ångströms in radius. According to the curve derived from experimental data, which is shown in Fig. 2, capillary condensation should occur at a partial pressure of 0.895 after a multilayer thickness of 14.8 ångströms had been reached. On the other hand, the BET curve predicts capillary condensation as occurring at a partial pressure of 0.865 with a multilayer thickness of 31 ångströms. Wheeler's argument that the pore curvature would increase the adsorption to BET values seems to be an overcorrection for the effect. It appears very unlikely that the curvature in a pore of radius 100 ångströms would place in effect additional adsorptive forces sufficient to more than double the adsorbed film thickness.

A simple scale drawing with the pertinent relative dimensions indicates a much smaller effect than that given by the BET theory. Figure 3 illustrates the predicted multilayer thicknesses at the time of capillary condensation for pores of radii 100, 50 and 25 ångströms. For a radius of 100 ångströms the BET thickness seems much too large, for a 50 ångström radius it is still larger than would be expected but perhaps not unreason-



Shaded area is multilayer thickness from experimental data for large crystals. Unshaded area is extra thickness predicted by BET theory.

Fig. 3.—Diagram showing multilayer thickness at pressure of capillary condensation for pores of various sizes.

ably so, and for a 25 ångström radius the two multilayer thicknesses are close together. Since the curvature effect becomes more pronounced as the radius is reduced and has little or no effect with large radii pores, it is seen that the BET values are inherently incorrect in their dependence upon the pore radius. If anything, the true curvature values of the thickness should differ from flat surface values most drastically in the small pore region, and this is just the opposite of the result obtained by use of the BET multilayer thickness values. Until a more satisfactory theory accounting for curvature effects is available, the use of flat surface data would appear to be preferable. Accordingly, the curves on Figs. 1 and 2 corresponding to experimental data will be used in the isotherm analysis given below. It should be mentioned that the procedure of isotherm analysis to be discussed in the following section is a general one applicable to whatever multilayer thickness values are selected.

Evaluation of Pore Size Integral.—There does not appear to be a simple method of inversion applicable to the pore size integral, Equation (1), by which the pore size distribution $L(r)$ can be obtained from numerical values of $V_s - V$. Indirect methods are available, however, which permit an easy and convenient solution of the equation. The present method is one of comparison of the experimental isotherm with standard or calculated isotherms.

Wheeler has suggested that pore size distributions may be represented by simple analytical forms of Maxwellian or Gaussian type. Thus for a Maxwellian distribution of pore sizes

$$L(r) = Are^{-r/r_0} \qquad (3)$$

with A and r_0 constants, and when this is substituted into Equation (1) and the integration performed we obtain

$$V_s - V = Ar_0^4 M(R, r_0) \qquad (4)$$

where

$$M(R,r_0) = \frac{\pi}{r_0^3} e^{-R/r_0}\{R(R-t)^2 + 6r_0^3 + 2r_0^2(3R-2t) + r_0(3R-t)(R-t)\} \qquad (5)$$

The function $M(R, r_0)$ has been evaluated for various values of R and r_0, and a family of such curves is shown in Fig. 4. These curves will be referred to as standard inverted isotherms.[7]

Likewise for a Gaussian distribution of pore sizes

$$L(r) = Ae^{-[\beta/r_0(r-r_0)]^2} \qquad (6)$$

with A, β, and r_0 constants, and this integrates into

$$V_s - V = 2A(r_0^3/\beta)G_\beta(R, r_0) \qquad (7)$$

where

$$G_\beta(R, r_0) = \frac{\pi}{4r_0^3}\left\{\frac{r_0}{\beta} e^{-\rho^2}(R - 2t + r_0) + \sqrt{\pi}[1 - H(\rho)][(r_0 - t)]^2 + \frac{1}{2}\left(\frac{r_0}{\beta}\right)^2\right\} \qquad (8)$$

(7) Numerical values for the standard inverted isotherms of Figs. 4 to 6 have been tabulated and are available from the author.

$$\rho = \frac{\beta}{r_0}(R - r_0), \text{ and } H(x) = \frac{2}{\sqrt{\pi}}\int_0^x e^{-y^2}dy$$

$G_\beta(R, r_0)$ has been evaluated for $\beta = 2$, 5 and 10 and various values of R and r_0, and some of these standard isotherms are shown on Figs. 5 and 6. It may be mentioned that the parameter β determines the width of the pore size distribution while r_0 controls the average pore size.

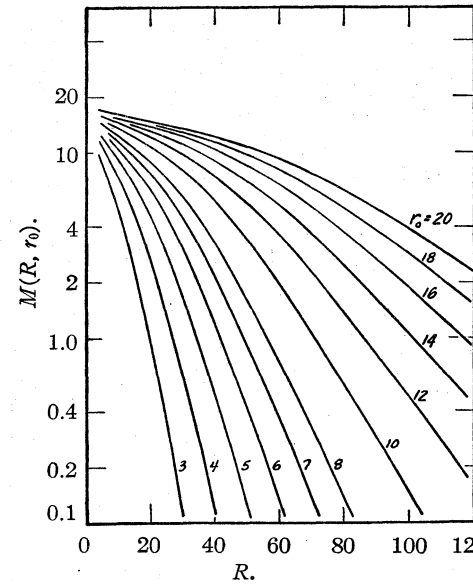


Fig. 4.—Standard inverted isotherms: calculated for a Maxwellian distribution of pore sizes.

The procedure in interpreting experimental data is then the following. The experimental isotherm is replotted as $V_s - V$ (log scale) *versus* the Kelvin radius R. This is conveniently known as an *inverted isotherm*. This inverted isotherm is next matched with one of the standard isotherms of Figs. 4–6. If a satisfactory match is obtained, the pore size distribution is known immediately from the parameters of the standard isotherm.

Sometimes the experimental inverted isotherm cannot be fitted to one of the standard isotherms and it is necessary then to resolve the experimental isotherm into two or more standard isotherms. For instance if an experimental isotherm can be resolved into the sum of a Maxwellian and a Gaussian standard isotherm, then

$$V_s - V = A_0 r_0^4 M(R, r_0) + 2A_1 \frac{r_1^3}{\beta_1} G_{\beta_1}(R, r_1) \qquad (9)$$

and hence

$$L(r) = A_0 re^{-r/r_0} + A_1 e^{-\left[\frac{\beta_1}{r_1}(r-r_1)\right]^2} \qquad (10)$$

In all cases, the coefficients A_n can be evaluated from the relative amplitudes of the component isotherms. Needless to say, as many component isotherms can be used as is necessary to fit the data to the desired accuracy. For all practical cases to date, two terms have been found suf-

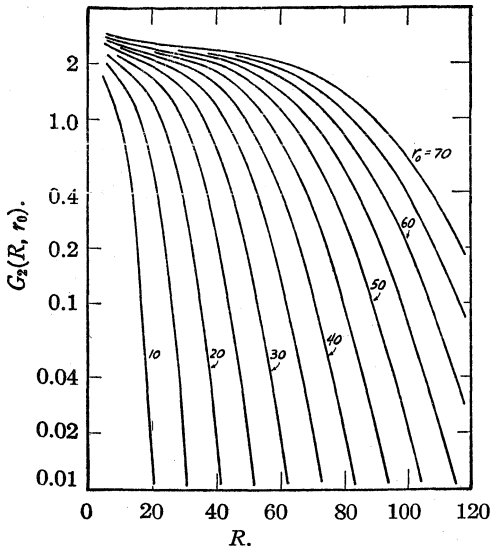

Fig. 5.—Standard inverted isotherms calculated for a Gaussian distribution ($\beta = 2$) of pore sizes.

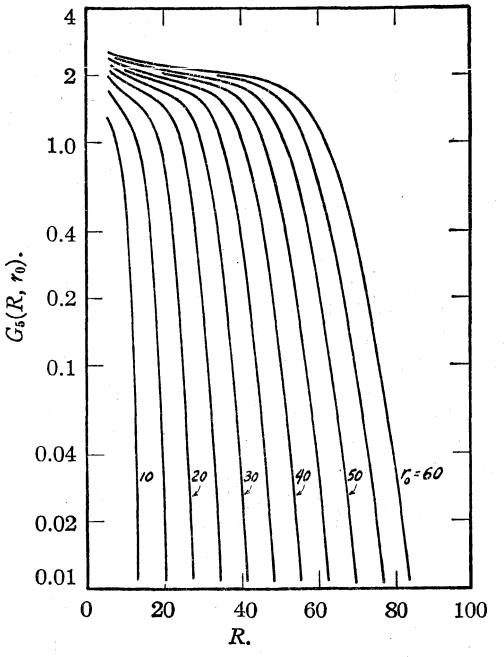

Fig. 6.—Standard inverted isotherms calculated for a Gaussian distribution ($\beta = 5$) of pore sizes.

ficient. The whole procedure can be carried out in fifteen or twenty minutes.

It is obvious that the specific surface may be calculated from the distribution $L(r)$, using the equation

$$S = 2\pi \int_0^\infty rL(r)\, dr \qquad (11)$$

This method of calculation is, of course, independent of the usual BET method[8] of determining the specific surface from adsorption isotherm data, but is more laborious and time-consuming. In particular instances, in which a variety of adsorbates have been adsorbed on the same adsorbent, more consistent values of specific surface have been obtained by this calculation than by the BET method. It should also be pointed out that the Wheeler procedure[5] of isotherm analysis does not permit a wholly independent calculation of the specific surface since the BET surface has entered directly in the pore size evaluation.

The above procedure of matching the experimental data to a calculated curve is, of course, an indirect one in that the mathematical inversion required in Equation (1) is not accomplished in a straightforward fashion. This raises the question of uniqueness in the derived pore size distribution. It has been found that the selection of the matched standard curve is, in general, a well-defined one showing that one type of distribution is in considerably better agreement with the data than any other. In cases where ambiguity in the choice of matching exists (for instance where the matching is equally good with a single curve or with the sum of two other curves), experience has shown that it makes little difference in the final distribution. It would seem that uncertainties in the basic assumptions necessary to the application of the inversion procedure are much more troublesome than the problem of uniqueness in the inversion.

Examples of Isotherm Interpretation.—As examples of the above procedure of analysis, the two isotherms given in Fig. 7 will be considered. These were obtained[9] with samples of silica gel possessing widely different physical properties. Both adsorption and desorption data are presented, there being no hysteresis loop in the case of gel I. The solid line for gel II represents the adsorption data while the broken line corresponds to desorption data. Selected isotherm points from the desorption curves have been replotted as inverted isotherm points (open and shaded circles) in Fig. 8. The isotherm points for gel I are seen to agree closely with the standard isotherm $M(R, 3)$, which has been drawn in from Fig. 4. Therefore the pore size distribution $L(r)$ for this gel can be represented by a Maxwellian distribution with the parameter r_0 having the value 3Å. On the other hand, the isotherm points for gel II cannot be matched to one of the standard curves but they can be matched to the sum of two standard isotherms, $G_5(R, 43)$ and $M(R, 18)$.

(8) It will be recognized that this independence is not strictly true since the BET theory has been used to obtain values of V_m used in the determination of the multilayer thickness t as shown in Fig. 1. However, this procedure has drawn on the validity of the BET determination of specific surface only in the case of materials of large crystal size and this has been shown by many studies to be quite correct. No assumptions regarding the validity of the BET theory for the material being studied have been made. It follows that the specific surface calculated from the pore size distribution is not necessarily the same as that generally calculated from the BET theory since the presence of the pore size distribution may have made questionable the application of the simple BET theory.

(9) I am indebted to Dr. P. B. Elkin for supplying the isotherm data on these materials.

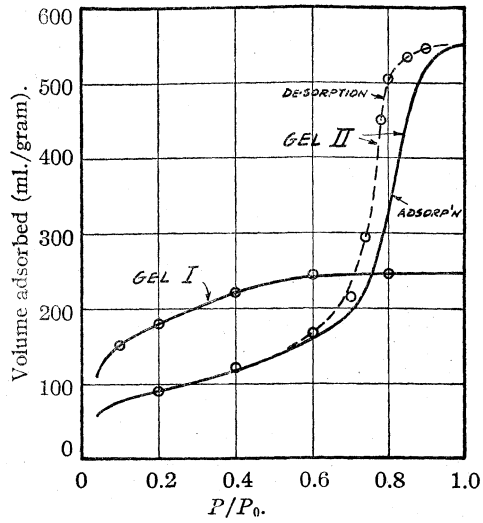

Fig. 7.—Nitrogen isotherms for two samples of silica gel. The solid and broken lines are the experimental isotherms. The circled points are taken from the matched standard isotherms of Figure 8.

The triangular points on Fig. 8 are matched with the standard isotherm $G_5(R, 43)$ and have been obtained by subtracting the standard isotherm $M(R, 18)$ from the experimental data (the open circles) for gel II. Thus the pore size distribution for gel II can be represented by an expression of the type given by Equation (10) with $r_0 = 18$, $r_1 = 43$, $\beta_1 = 5$ and relative values of A_1 and A_0 obtained ($A_1/A_0 = 222$) from the amplitudes of the two standard isotherms.

The differences between the experimental points and the standard isotherms in Fig. 8 have been transferred to the original isotherms given in Fig. 7, since here the fluctuations can be more easily visualized in terms of experimental error. The circled points on the isotherms of Fig. 7 are taken directly from the standard inverted isotherms of Fig. 8. The agreement shown by the matching process is within the experimental error of the adsorption measurements.

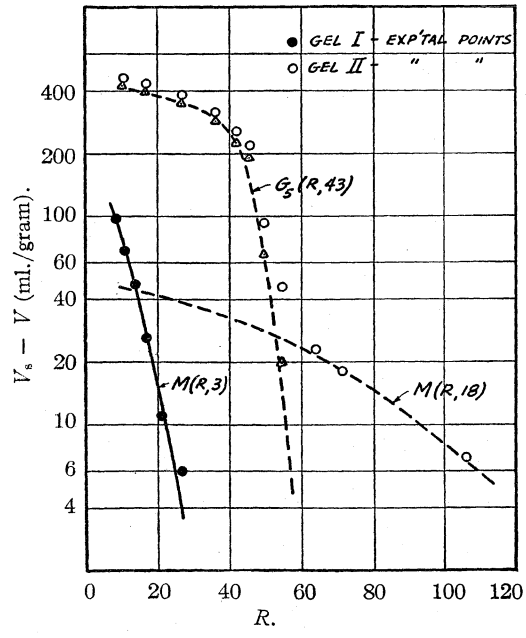

Fig. 8.—Comparison of silica gel isotherm data with selected standard inverted isotherms.

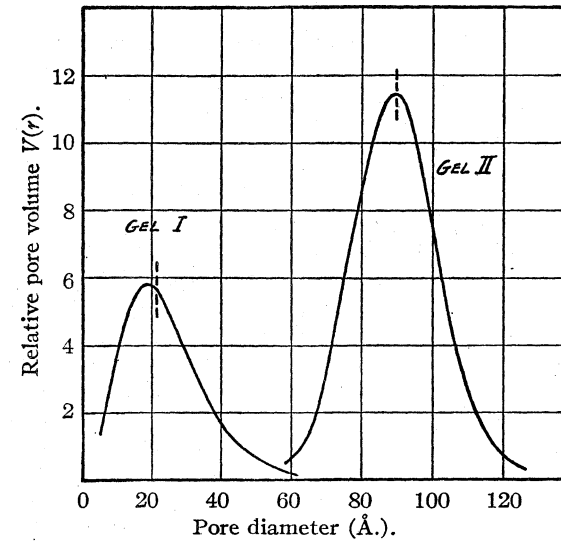

Fig. 9.—Pore volume distributions calculated for silica gel samples.

Pore size distributions for these two gels have been calculated and are shown in Fig. 9. These have been plotted as volume distributions $V(r)$, rather than length distributions, since the former seem to have greater physical significance. This transformation is easily performed since

$$V(r) = \pi r^2 L(r) \qquad (12)$$

Values of the average pore diameter (defined as that size which divides the pore volume distribution into two equal parts) have been marked on the distribution curves. These values are 21 and 90 Å. for gels I and II, respectively. It is interesting to compare these with values of the mean pore diameter calculated from the expression[10] $4V_s/S$ where S is the specific surface determined by the standard BET method. Calculation shows the latter to be 23 and 107 Å., respectively. Comparisons of the pore size distributions obtained by the above procedure with other independent data have been made for a variety of materials and these will be the subject of an accompanying publication.[11]

Summary

The theory of the interpretation of gas adsorp-

(10) If all pore volume is contained in one long cylindrical pore L units long, the diameter of this pore can be written

$$D = 4\,\frac{\frac{\pi D^2}{4}L}{\pi DL} = \frac{4V_s}{S}$$

(11) C. G. Shull, P. B. Elkin and L. C. Roess, THIS JOURNAL, **70**, 1410 (1948).

tion data in terms of capillary condensation as advanced by Wheeler is discussed. It is suggested that the empirical use of experimental adsorption data for materials of large crystal size is preferable to the employment of the BET theory at the higher relative pressures (0.35 to 0.99) in evaluating the multilayer thickness of the adsorbed layers. A simplified procedure for applying the theory of capillary condensation to experimental data, thereby obtaining the pore size distribution, is presented. Examples of this procedure are given in the treatment of data for two silica gels.

Physical Studies of Gel Microstructure

BY C. G. SHULL,[1] P. B. ELKIN[2] AND L. C. ROESS

Introduction

During the past few years a number of new techniques have become available for studying the physical microstructure of porous and finely divided materials. Low temperature gas adsorption has found widespread application in the determination of the specific surface available to gases.[3] More recently, attempts have been made to interpret the adsorption isotherm in terms of pore dimensions in addition to specific surface.[4] X-Ray scattering at small angles has been used in obtaining information on the solid discontinuities present in colloidal materials, and these data have been correlated to a certain extent with crystal size data from the broadening of X-ray diffraction lines and with specific surface results.[5,6]

In the application of either of these techniques certain simplifying assumptions must be made with consequent uncertainty or ambiguity in the results of the analysis. One procedure for testing the validity of these assumptions for any particular material presents itself in the correlation of independent data to form a consistent over-all picture of the physical microstructure. Thus, as will be shown later in this paper, the specific surface should show a dependence on the particle size distribution; and the pore size and the particle size distributions should be related through the porosity factor. If the various physical data can be shown to be consistent, then confidence in the validity of the analysis is gained. It is to be emphasized that conclusions of this sort drawn for one material are not sufficient to justify the validity of the assumptions for all cases.

The present paper is concerned with a series of observations of the type outlined above obtained for a series of ten silica and silica–alumina gels. These particular gels were selected because they possessed a wide range of physical properties and hence should serve as good illustrative examples of the correlative procedure.

Experimental Techniques

Nitrogen adsorption–desorption isotherms were obtained in a conventional volumetric apparatus at liquid nitrogen temperature and over a pressure range from a few millimeters of mercury up to near saturation pressure. Measurements in the high pressure region were continued to high enough pressures to determine the plateau of adsorbed volume characteristic of complete filling of the micropore volume. The saturation pressure p_0 was measured continuously throughout the runs by means of a tube containing condensed nitrogen and connected to a manometer. From the data specific surface values were calculated by the Brunauer–Emmett–Teller equation.[3] The data fit the linear plot of this method over the usual range of pressure values.

The micropore size distributions were obtained by analyzing the adsorption and desorption isotherms in terms of a composite multilayer adsorption and capillary condensation theory introduced by Wheeler.[4] A modification in the procedure of applying the Wheeler theory to the experimental data was used in the present study and details of this are given in an accompanying paper.[7] Essentially, the method consists in matching the experimental isotherm with one of a series of standard isotherms which have been calculated for various pore size distributions. Values of median and mean pore diameters (defined in the following section) have been calculated from the size distribution.

Values for the solid density ρ were obtained by displacement in helium gas in an apparatus similar to the one described by Schumb and Rittner.[8] The apparent density ρ_a was determined in a mercury pycnometer. From these values the percentage porosity was calculated by the equation

$$\% \text{ porosity} = 100(\rho - \rho_a)/\rho \qquad (1)$$

The small angle X-ray scattering technique has been described[6] previously.

The gels were obtained from several sources and the methods of preparation for some gels were not reported. The emphasis here, however, is placed on physical properties rather than on methods of preparation. It may be mentioned that the gels were heated in a furnace at about 540° prior to all physical measurements so that the residual water content must have been quite small. No correction for this was made.

Experimental Results

A list of the silica–alumina gels which have been studied is given in Table I. The alumina content of these gels is seen to vary between 0 and 28 weight per cent. with most of the samples at the ends of this range. The variety of physical properties obtained are believed for the most part to reflect the various physical and chemical conditions of preparation rather than the alumina content.

TABLE I

SUMMARIZED GAS ADSORPTION AND DENSITY DATA

Gel	Weight per cent. Al_2O_3	Specific surface, sq. m./g.	V_p micropore volume (cc./g.)	Density (g./cc.) by displacement of Helium ρ	Mercury ρ_a	Percentage porosity	Total pore volume, cc./g.
I	25	453	0.563	2.53	1.031	59	0.575
II	23	425	.733	2.45	0.854	65	.774
III	24	475	.681	2.46	.750	69	.927
IV	26	321	.855	2.49	.787	68	.868
V	28	267	.994	2.31	.719	69	.958
VI	13	568	.863	2.30	.755	67	.890
VII	..	344	.870	2.32	.786	66	.840
VIII	0	657	.384	2.39	1.168	51	.436
IX	0	248	.612	2.32	0.911	61	.667
X	0	478	.575	2.19	0.982	55	.562

The nitrogen adsorption–desorption isotherms are shown in Fig. 1. The desorption curves are the upper ones in each case. All except that for sample VIII have similar shapes, but differ in the magnitude and position of the steepest part of the curves. The isotherm for sample VIII, in which the adsorption and desorption data fell on the same curve, is the Langmuir type.

From the adsorption data, the values shown in Table I for the specific surface S and the specific micropore volume V_p (expressed as cc. of void per gram of gel) have been calculated. The solid density ρ obtained by helium displacement, the apparent density ρ_a obtained by mercury displacement and the percentage porosity and total pore volume calculated from the density values are also listed. The specific micropore volume has been obtained from the volume of gas adsorbed at saturation pressure and presumably is indicative of the pore volume in pores of diameter less than about 1000 Å. On the other hand, the percentage porosity and total pore volume given in the last two columns include all pores up to the size which is penetrated by mercury at atmospheric pressure, namely, about 50,000 Å. It is seen that practically all of the pore volume (with the exception of that for gel III) exists in the micropore region. The total pore volume is listed as being slightly smaller than the micropore volume (obviously an impossibility) for three of the gels and this must be due to the presence of small errors in one or more of the measurements.

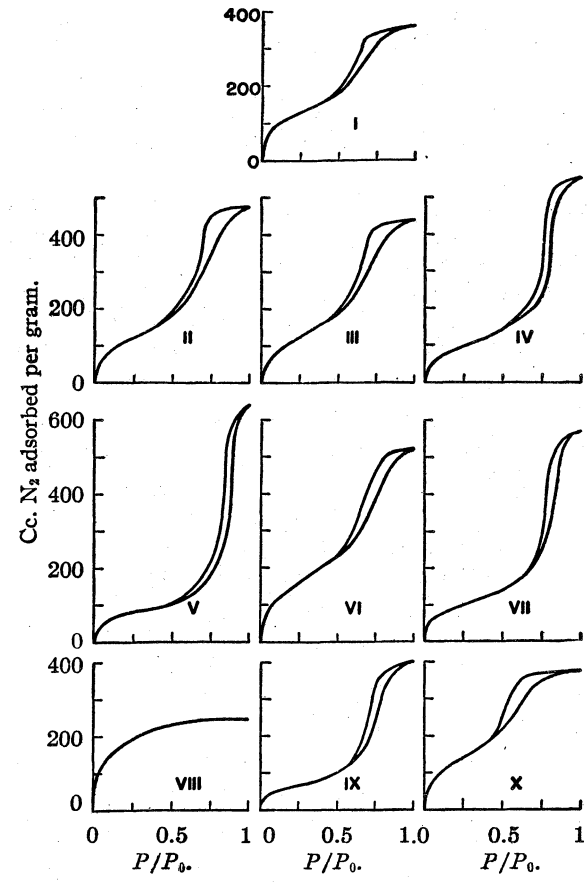

Fig. 1.—Nitrogen adsorption–desorption isotherms (−195°) for gels I to X.

Both the specific surface and the micropore volume are seen to vary over a wide range of values. As is expected, the solid density shows little variation from gel to gel with some indication that the gels with higher alumina content possess somewhat higher solid density values.

Table II summarizes the results of pore size analysis as obtained from both adsorption and desorption isotherms on the assumption that the pores are cylindrical. In this table the mean pore diameter D_0 is defined by

$$D_0 = 4V_p/S \qquad (2)$$

the median pore diameter $\overline{D}$ is defined by

$$\frac{V_p}{2} = \int_0^{\overline{D}} V(D)\, dD \qquad (3)$$

where $V(D)$ is the pore volume distribution function. $\overline{D}$ is thus defined as the pore diameter such that one half of the pore volume is contained in

pores smaller than $\overline{D}$. The mean pore diameter $\overline{D}_0$ is defined as

$$\overline{D}_0 = \frac{\int_0^\infty V(D)\,dD}{\int_0^\infty \frac{V(D)}{D}\,dD} \qquad (4)$$

Since in equation (4) the numerator is the pore volume per gram and the denominator is one-fourth the specific surface, it follows that D_0 and $\overline{D}_0$ represent equivalent mean values. They are designated differently to emphasize that they have been calculated in an independent manner. It is not expected that the median and mean values should agree in magnitude since they represent differently weighted quantities. Also given in Table II is the ratio of the two mean values for the pore diameter.

TABLE II

PORE DIAMETER VALUES CALCULATED FROM ADSORPTION AND DESORPTION DATA (ALL VALUES EXPRESSED IN ÅNGSTRÖMS)

D_0 is mean pore diameter calculated from $4Vp/S$. $\overline{D}$ is median pore diameter calculated from pore size distribution. $\overline{D}_0$ is mean pore diameter calculated from pore size distribution.

		From desorption data			From adsorption data		
Gel	D_0	$\overline{D}$	$\overline{D}_0$	$D_0/\overline{D}_0$	$\overline{D}$	$\overline{D}_0$	$D_0/\overline{D}_0$
I	50	52	48	1.04	59	48	1.04
II	69	65	60	1.15	73	60	1.15
III	57	57	53	1.08	70	57	1.00
IV	107	90	89	1.20	114	105	1.02
V	149	136	126	1.18	170	157	0.95
VI	61	61	56	1.09	74	58	1.05
VII	101	95	94	1.07	131	121	0.84
VIII	23	21	18	1.31	21	18	1.31
IX	99	73	72	1.37	92	85	1.17
X	48	41	41	1.17	46	37	1.30
			Average	1.17			1.08

Figure 2 illustrates the agreement found between values for D_0 and $\overline{D}_0$ using both adsorption and desorption data. The general sequence of the points indicates that D_0 is about 10% larger than $\overline{D}_0$ and, considering the assumptions which are necessary in evaluating the pore size distributions, this can be considered quite satisfactory. Although it is seen that slightly better agreement is obtained when adsorption data are used, it is not felt that this is conclusive of a general criterion on the basis of the present data.

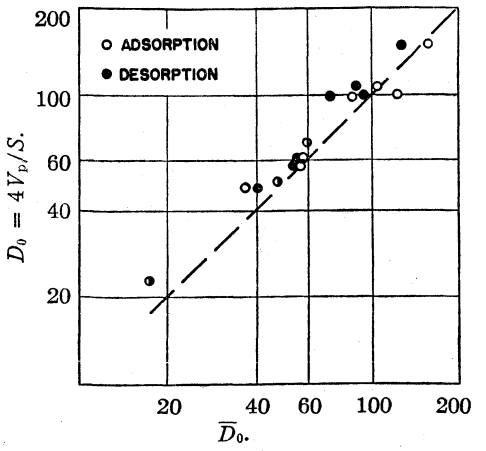

Fig. 2.—Comparison of mean pore diameters (ångströms) calculated from $V_p(D_0)$ and from pore size distribution curves ($\overline{D}_0$).

The results of the small angle X-ray scattering analysis and their correlation with adsorption data for these gels are given in Table III. The scattering analysis has been carried through in terms of a particle size distribution for spherical particles and from this the median particle diameter $\overline{L}$ is evaluated as defined by

$$\int_0^\infty M(L)\,dL = 2\int_0^{\overline{L}} M(L)\,dL \qquad (5)$$

where $M(L)$ is the mass distribution function in terms of the particle diameter L. Values of $\overline{L}$ ranging from 29 to 88 Å. are to be noted in the second column of Table III.

TABLE III

COMPARISON OF PARTICLE SIZE VALUES WITH PORE SIZE AND POROSITY RESULTS

Values of L and D are in ångströms and $S\rho$ in 10^4 cm.$^{-1}$

Gel	$\overline{L}$	$S\rho$	$\overline{D}/\overline{L}$	$V_{p\rho}$
I	48	1147	1.08	1.42
II	47	1041	1.38	1.80
III	45	1170	1.27	1.68
IV	65	799	1.38	2.13
V	88	617	1.55	2.30
VI	48	1308	1.27	1.99
VII	75	798	1.27	2.02
VIII	29	1570	0.72	0.92
IX	81	576	0.90	1.42
X	48	1048	0.85	1.26

In view of the dependence of the X-ray intensity scattered at small angles on differences in electron density, independent evidence is required to establish whether the scattering is characteristic of the particles or of the pores. With crystalline materials, good agreement[6] is found between the crystal size and the average particle size calculated on the assumption that the scattering is characteristic of the particles, and this can be considered as good evidence that the small angle scattering is indeed characterized by the particles. With amorphous materials such evidence is not available, and hence it is particularly interesting to compare the particle size data and the pore size data for the ten amorphous gels being discussed.

It can be shown that the specific surface of an assemblage of particles is given by an expression of the type

$$S = \frac{K}{\rho}\frac{\int_0^\infty \frac{M(L)}{L}\,dL}{\int_0^\infty M(L)\,dL} = K_0/\rho\bar{L} \qquad (6)$$

where K_0 is a constant whose value depends insensitively on the geometrical shape of the particle and the shape of the particle size distribution curve. Values for the product $S\rho$ are given in the third column of Table III and these are plotted versus $\bar{L}$ in the log-log graph of Fig. 3. The inverse relationship between these variables is clearly indicated by the sequence of the points. The line drawn on the figure is the theoretical line to be expected for spherical particles and appears to be shifted from the median correlation line by about 10%. In view of the uncertainties in the interpretation of small angle scattering analysis, this discrepancy of the particle size values by 10% on an absolute basis is certainly not outside of possible error. It should be mentioned that correlation of the type given in Fig. 3 is by no means restricted to one class of materials (*viz.*, silica–alumina gels) but can be obtained with a whole variety of substances whose solid density, specific surface and particle size cover much wider ranges than are indicated in the present data.

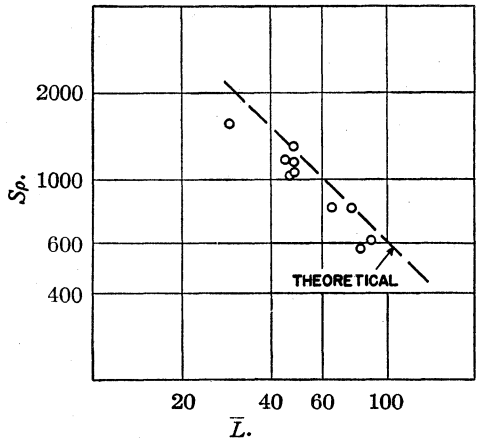

Fig. 3.—Correlation between specific surface times density $S\rho$ and median particle diameter $\bar{L}$. The dashed line is that calculated for spheres. $S\rho$ is given in units of 10^4 cm.$^{-1}$ and $\bar{L}$ in ångströms.

Of particular interest is the comparison of pore and particle size. The ratio of these variables is given in the fourth column of Table III. This ratio is seen to include values between 0.72 and 1.55. Since the surface area of the pores must equal that of the particles, it follows from Equations (2) and (6) that

$$\bar{D}/\bar{L} = k(V_p\rho) \qquad (7)$$

since $\bar{D}$ is proportional to D_0 for a given distribution. The product $(V_p\rho)$ is called the *porosity factor* and is merely the ratio of total micropore volume to total solid volume in the gel. The constant k depends insensitively on the pore and particle size distributions. Figure 4 illustrates the agreement of the experimental data with the correlation predicted by Equation (7). Values for the pore diameter are those obtained from the desorption analysis and the line is the theoretical correlation using a value of 2/3 for the constant k which is the average for the size distributions encountered experimentally. A consistent trend in the values of the pore to particle size ratio with the porosity factor is to be noted and this can be considered evidence that the small angle X-ray scattering is characteristic of the particle size rather than the pore size. If the X-ray scattering were indicative of the pore size, values of $\bar{D}/\bar{L}$ should have remained constant independent of the porosity factor.

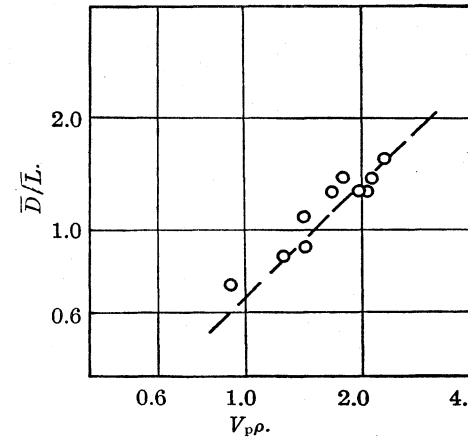

Fig. 4.—Correlation between pore to particle size ratio $\bar{D}/\bar{L}$ and porosity factor $V_p\rho$. The line is the theoretical correlation according to Equation (7).

The over-all agreement of the independently determined variables above appears very satisfactory and is even somewhat surprising in view of the several assumptions which are necessary in interpreting the data. It is recognized immediately that the assignment of a spherical shape to the particles and a cylindrical shape to the pores is inconsistent in a strict sense. The pores and particles are very probably irregular in both shape and size, but it would appear from the data that as far as the determination of average dimensions is concerned, they can be represented by these simple geometrical shapes. Once these discontinuity shapes are decided upon, further assumptions specific to the technique are required. Principal among these are the assumption of incoherence in the X-ray scattering from adjacent particles and the assumption that vapor condensation in a capillary of colloidal size is exactly similar to that in macroscopic capillaries. Neither of these has been the subject of direct experimental test, but as the evidence presented above would indicate indirectly, they appear not far from being correct.

Acknowledgments.—Several of the gel preparations were kindly supplied by the Shell Development Company and the Standard Oil Development Corporation and the remaining ones were prepared by M. M. Stewart of these laboratories. Grateful acknowledgment is also accorded to Dorothy Diener, Bernice Good and Sybil Cumming for assistance in the accumulation of experimental data.

Summary

Physical data on the microstructure of a series of ten amorphous silica and silica–alumina gels have been obtained from studies of low temperature gas adsorption, porosity and small angle X-ray scattering. Good correlations are obtained between (1) the mean pore diameter calculated from the specific micropore volume and the specific surface and the mean pore diameter calculated according to a capillary condensation theory of isotherm analysis, (2) the average particle size and the specific surface and (3) the pore to particle size ratio and the porosity factor. It is concluded that the over-all correlations which are found indicate the validity of the assumptions necessary in the data interpretation at least for the materials which have been studied.

The Preparation of Nitrite Salts of Alkyl Amines[1]

BY JOHN K. WOLFE[2] AND KENNETH L. TEMPLE[3]

Alkyl ammonium nitrite salts have been prepared by the reaction of the amine hydrochloride with sodium nitrite[4] or silver nitrite,[5] the amine sulfate with barium nitrite, or the amine with nitrogen sesquioxide,[6] all of these reactions being carried out in aqueous solution. The present study outlines a new method of preparation, employing the amine, sodium nitrite, solid carbon dioxide, methanol and a small amount of water. Sodium carbonate precipitates as the reaction proceeds, leaving a methanol solution of the nitrite. The general reaction, using a primary amine as the example, can be represented by the equation

$$2RNH_2 + CO_2 + H_2O + 2NaNO_2 \longrightarrow 2RNH_2{\cdot}HNO_2 + Na_2CO_3$$

The reaction between the amine and carbon dioxide in methanol in the absence of water formed a white powder which precipitated at about −20° and corresponded to the formula $(RNH_2)_2{\cdot}CO_2$. These substances could be filtered and isolated at room temperature but they sublimed readily. Compounds of this type have been previously observed and identified.[7]

This white powder reacted with sodium nitrite and water in the presence of methanol to produce the ammonium nitrite.

This method has been applied successfully to isopropylamine, diisopropylamine, diisobutylamine and triethylamine, with a yield of about 75% of the nitrite in each case.

The use of methanol instead of water as the solvent permits the use of a lower temperature, thus decreasing the formation of nitrosamines and the decomposition of unstable nitrites. The evolution of carbon dioxide gas during the preparation excludes oxygen and thus tends to prevent the formation of nitrates.

Table I summarizes the various reaction conditions studied. Sodium nitrite is superior to potassium nitrite since potassium carbonate separates in a flocculent condition and is much harder to filter. Absolute ethanol, acetone and isopropanol are inferior to methanol as a solvent, undoubtedly due to the higher solubility of sodium nitrite in methanol. The yield of sodium carbonate is fairly constant in all of the cases in which methanol was used. The yield of sodium carbonate is probably a better measure of the extent of the nitrite reaction than is the yield of the nitrite, since in many cases the nitrites are difficult to isolate.

This new method of synthesis was tried for higher molecular weight amines, whose nitrite salts are not water soluble, and quite low yields were obtained. It was found that some of these nitrites had been described in the literature and were prepared in aqueous solution but the yields reported were often quite low and the methods were poorly described. Dicyclohexylammonium nitrite, a compound not previously described, was prepared in this study in 98% yield and the experimental method used in its preparation is described as an example. Dicyclohexylaminenitrite is easily converted to the N-nitrosamine by warming in dilute acid solution. A comparison of these two materials shows the expected chemical behavior.

A study of the alkyl ammonium nitrite salts which have been investigated indicates that, in general, the salts of primary amines of low molecular weight and the salts of tertiary amines are

[a] Contained unreacted inorganic nitrite.

hygroscopic while the salts of primary amines of high molecular weight and the salts of secondary amines are not hygroscopic. The salts of highly branched secondary amines appear to be the most stable.

Experimental[8,9]

The following method was used in the preparation of the nitrite salts: A mixture of 200 mesh C. P. sodium nitrite, water and methanol was placed in a three-necked two-liter round-bottom flask fitted with dropping funnel and Hershberg stirrer. The stirred mixture was cooled to 0° by the addition of solid carbon dioxide and the amine was then added over a period of one and one-half to two hours, a temperature of 0–5° being maintained by the addition of solid carbon dioxide. Stirring was continued for about two hours, sufficient methanol being added to wash the foam from the sides of the flask. The precipitated sodium carbonate was filtered at room temperature and washed well with methanol.[10] The solvent was removed from the filtrate under reduced pressure and the solid product recrystallized from a suitable solvent.

The molecular weight of each of the nitrites was determined by boiling a weighed sample of the nitrite with an excess of 0.5 *N* sodium hydroxide solution until the free amine was volatilized and then titrating the residual alkali with standard acid.

Diisopropylammonium Nitrite.—One mole of diisopropylamine (boiling at 81–85°), one mole of sodium nitrite, 0.5 mole of water and 300 ml. of methanol gave 80 g. of sodium carbonate. The solution of the solid nitrite in 500 ml. of anhydrous isopropanol, filtered to remove sodium nitrite, gave 112 g. of nitrite when cooled to −40°. The melting point of 136–7° was unchanged by recrystallization from acetone and ethyl acetate.[11]

Anal. Calcd. for $C_6H_{16}O_2N_2$: C, 48.6; H, 11.0; N, 18.9; mol. wt., 148. Found: C, 48.7; H, 11.5; N, 18.6; mol. wt., 147.

Diisobutylammonium Nitrite.—The salt obtained from 0.5 mole of diisobutylamine (boiling at 136–140°), 0.5 mole of sodium nitrite, 0.25 mole of water and 300 ml. of methanol was dissolved in 250 ml. of isopropanol. By cooling the solution to −40°, 58.6 g. of colorless plates melting at 145–146° was obtained.

Anal. Calcd. for $C_8H_{20}O_2N_2$: C, 54.5; H, 11.5; N, 15.9; mol. wt., 176. Found: C, 54.7; H, 11.2; N, 15.6; mol. wt., 174.5.

Triethylammonium Nitrite.—One mole of triethylamine (boiling at 88–90°), one mole of sodium nitrite, 0.5 mole of water and 500 ml. of methanol gave 81 g. of sodium carbonate. Removal of the methanol in an atmosphere of dry carbon dioxide at a temperature not exceeding 25° gave one hundred grams of light tan crystals melting at 94–97° with decomposition. The product turned brown on standing at room temperature for a few hours but was stable when stored at −40° over calcium chloride in a vacuum desiccator. A solution of 2 g. of the salt in 400 ml. of absolute ether gave white silky needles when cooled to −60°. These needles melted at 96.5–98° in a sealed tube.[12]

Anal. Calcd. for $C_6H_{16}O_2N_2$: mol. wt., 148. Found: mol. wt., 146, 147.

Isopropylammonium Nitrite.—The reaction of one mole of isopropylamine (boiling at 31–35°), one mole of sodium nitrite, 0.5 mole of water and 470 ml. of methanol gave a methanol solution which was evaporated under reduced pressure in an atmosphere of carbon dioxide, the temperature being maintained below 25°. The white crystalline product weighed 79 g. and melted at 47–49°. This substance is very hygroscopic and turns brown when stored in a vacuum desiccator at room temperature, but is stable in a dry atmosphere at −40°. Recrystallization of the product from a solution of four parts of ethyl acetate and one part of isopropanol, by cooling the solution to −60°, gave white crystals which melted at 49–50° in a sealed tube.

Anal. Calcd. for $C_3H_{10}O_2N_2$: mol. wt., 106. Found: mol. wt., 107.

Di-cyclohexylammonium Nitrite $[(C_6H_{11})_2NH\cdot HNO_2]$.—Ten milliliters (9.1 g., 0.045 mole) of di-cyclohexylamine (Monsanto) were mixed with 400 ml. of water, an excess of concentrated hydrochloric acid was added and the mixture was heated almost to boiling to dissolve the salt formed. The solution was adjusted to *p*H 8 with ammonium hydroxide. Solid C. P. sodium nitrite (150 g.) was added, the mixture was stirred at 0° for one hour and the precipitate was filtered and dried. The yield was 11.2 g. (98%) of light tan crystals melting at 176–178° with decomposition. Recrystallization from methanol yielded colorless plates melting at 178–180° with decomposition. Acidification of this product produced the characteristic nitric oxide odor.

Anal. Calcd. for $C_{12}H_{24}N_2O_2$: C, 58.8; H, 11.8; N, 13.7. Found: C, 58.6; H, 11.7; N, 14.0.

N-Nitroso-Di-cyclohexylamine $[(C_6H_{11})_2NNO]$.—A sample of dicyclohexylamine acetate (m. p. 115–116°) was warmed with an aqueous solution of acetic acid and sodium nitrite. The insoluble precipitate was filtered and recrystallized from acetone, yielding colorless crystals of nitrosamine melting at 104–105°.

Anal. Calcd. for $C_{12}H_{22}N_2O$: C, 68.5; H, 10.5. Found: C, 68.6, 68.8; H, 10.3, 10.5.

(8) The authors wish to acknowledge the help of Miss Nyla Mack of the Chemistry Division, NRL, for some of the analyses.

(9) All melting points are corrected.

(10) The identity of the precipitate was established by X-ray diffraction examination, performed by Ens. Birks of the Physical Optics Division of NRL, and by comparison with an authentic sample of anhydrous sodium carbonate.

(11) Van der Zande[4] reported a melting point of 140°. The authors find that the melting point depends on the rate of heating, approaching 140° in a rapidly heated bath.

(12) Neogi [*J. Chem. Soc.*, **99**, 1252 (1911)] and Ray [*ibid.*, **101**, 216 (1912)] reported that this compound forms yellow prisms decomposing at 75°.

A mixed melting point of the nitrosamine with dicyclohexylammonium nitrite showed the normal depression and wide range. N-Nitroso di-cyclohexylamine failed to give nitric oxide fumes on treatment with cold hydrochloric acid.

Summary

1. A new method is described for the preparation of alkyl ammonium nitrites from amines, employing sodium nitrite, carbon dioxide and methanol. The nitrites of isopropylamine, diisopropylamine, diisobutylamine and triethylamine have been prepared.

2. Alkyl ammonium nitrite salts of primary amines of low molecular weight and the salts of tertiary amines are in general hygroscopic while the salts of secondary amines are not hygroscopic.

The Selective Degradation of Certain Pyrryl Polycarboxylic Esters[1,2]

BY ALSOPH H. CORWIN AND J. LLOYD STRAUGHN[3]

Publication of a method for the conversion of Knorr's pyrrole (2,4-dimethyl-3,5-dicarbethoxypyrrole) into 2-carboxyl-3,5-dicarbethoxy-4-methylpyrrole[4] opened the way for the preparation of many new pyrrole derivatives from this substance, providing that methods for selective degradations of the new acid could be found. The present paper describes these selective degradations. Knorr's pyrrole is already one of the most readily available substitution products of pyrrole. The numerous additional substances that can be prepared from it by transformations recorded below make it the most versatile of all pyrrole derivatives in the number and variety of chemical individuals which can be prepared from it.

Mechanism of Formation of 2-Carboxyl-3,5-dicarbethoxy-4-methylpyrrole.—When Knorr's pyrrole is chlorinated with sulfuryl chloride in glacial acetic acid, best yields of the desired acid are obtained if the reaction is performed at as low a temperature as possible. The use of 5% acetic anhydride lowers both the freezing point of the solution and its water content and increases the yield of acid by 5–10%. Increasing the temperature of the reaction, on the other hand, lowers the yield of acid and increases the yield of aldehyde. This observation suggests that the aldehyde represents a by-product of the reaction and not an intermediate in the formation of the acid. This conclusion was confirmed by attempting to halogenate the aldehyde under the conditions of the reaction. No acid could be obtained and the aldehyde was recovered unchanged. When the same reaction was tried using 2-dichloromethyl-3,5-dicarbethoxy-4-methylpyrrole, however, 45% of acid and 36% of aldehyde could be obtained. These results show that the dichloromethylpyrrole can be an intermediate in the reaction and that any of it which is converted to aldehyde in the course of the reaction will not yield acid.

It is possible to convert benzal chloride and acetic acid to benzaldehyde and acetyl chloride.[5] The analogous reaction in the pyrrole series can be represented schematically as

$$RCHCl_2 + CH_3COOH \longrightarrow RCHO + CH_3COCl + HCl$$

It is easily demonstrated that this reaction proceeds at 50° but not rapidly at 17°. At the higher temperature hydrogen chloride is given off and the distillate contains acetyl chloride, as shown by its reaction with aniline to form acetanilide. The dichloromethylpyrrole is best prepared by chlorination in chloroform, to avoid the possibility of aldehyde formation.

It follows from the observations recorded above that the aldehyde is not an intermediate in the formation of the acid, that the dichloro- and trichloro-pyrroles are intermediates and that reaction conditions should be directed toward the stabilization of the dichloromethylpyrrole.

The Stability of Pyrryl-carboxylic Acids.—By methods outlined below several pyrryl-carboxylic acids were prepared which had one methyl group and various combinations of three electron attracting groups, either carboxyl or carboxylic ester groups. None of these acids could be decarboxylated smoothly by the usual methods. When combinations were tried which contained only two electron attracting groups, however, decarboxylation took place smoothly. This behavior is analogous to that found in the benzene series in which electron releasing groups, such as phenolic hydroxyl groups, facilitate decarboxylation and the addition of electron attracting groups, such as carboxyl, to phenolic compounds hinders decarboxylation.[6] Because of this situation, further reactions were directed toward preparation and degradation of derivatives of methyl-dicarboxyl pyrroles.

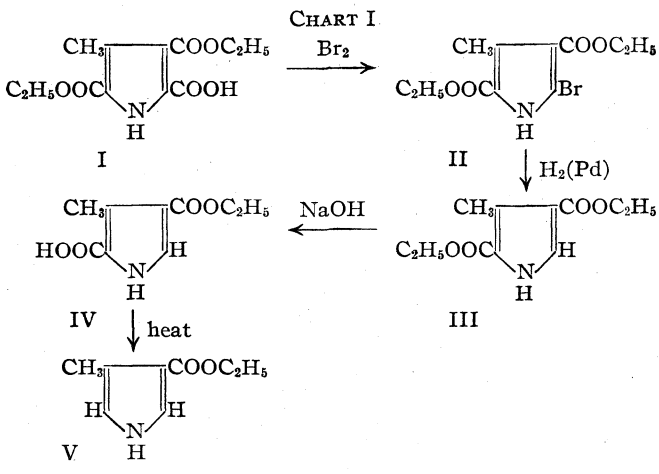
(6) A close analogy is afforded in the resorcylic acids. 2,6-Dihydroxybenzoic acid decomposes in the range of 150–170° while the addition of a carboxyl group in the 3 position increases the stability so that the material melts at 312° without marked decomposition. See Senhofer and Brunner, *Wien. Akad. Ber.*, **80**, 504 (1879), and Brunner, *Ann.*, **351**, 320 (1907).

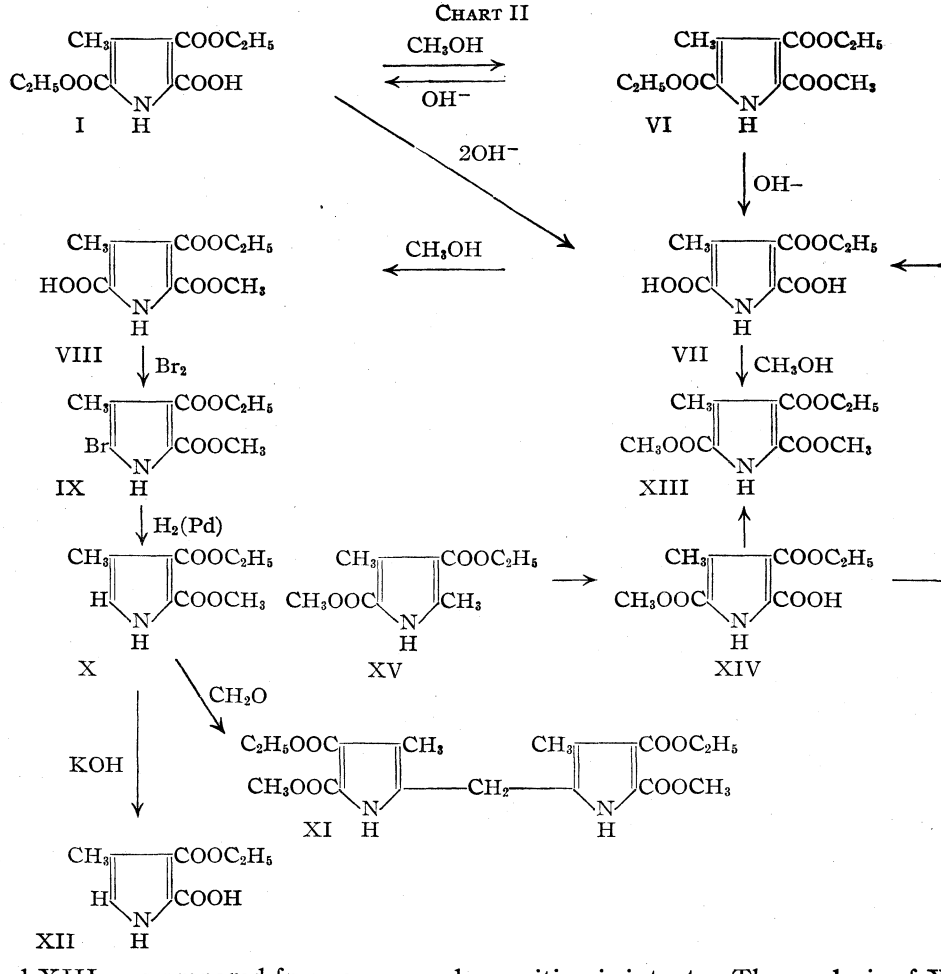
The flow sheet for the reactions to free the 2 and 5 positions is given in Chart I.[4,7]

CHART I



The flow sheet for the reactions to free the 5 position is given in Chart II.

CHART II



Compound XIII was prepared from compound XV by reactions analogous to those discussed in the first section of this paper. These reactions prove that compound XIII has a methyl ester group in the 5 position. Compound X had been prepared previously by Fischer and Wiedemann by esterification of XII.[8] This esterification proves the structure of compound X.

The flow sheet for the freeing of the 3 position is given in Chart III.

Compounds XXI and XIX were prepared by Kordo, Ono and Sato[9] by a method which establishes the structure of XIX.

In addition to the reactions outlined above, certain other derivatives of compound I were made as sketched in Chart IV. Interrelationships with substances with previously tagged ester groups are also shown.

The lack of identity of XXV and XXVII makes possible the location of the free carboxyl group in XXV, since it is known from XXXI that the carbomethoxy group in the 3 position is intact. The analysis of XXXI makes

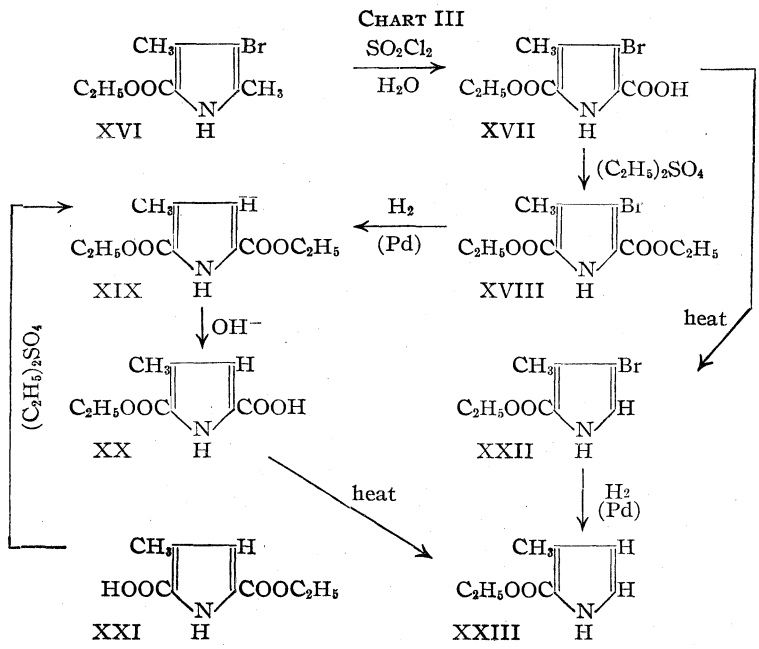
CHART III



it possible to deduce the position of the group in compound XXX which has been hydrolyzed by alkali.

Compounds XXXIII, XXXIV and XXXV were all prepared from compound I. The ester interchange observed in preparing compound XXXIV is not unusual when α-esters are treated with strong base.[10a] A corresponding change when esterification takes place under the influence of an acid catalyst is rare. The melting point of the triethyl ester, XXXV, is so low, 45–46°, as to render the substance undesirable for preparational purposes. This is the reason for choosing to make derivatives from the monomethyl ester, VIII, which melts at 75°.

The experiments summarized above add five new cases, compounds I, III, VI, X and XXX to the generalization that attack by an alkaline catalyst upon an ester group is oriented α in preference to β whenever there is a choice.

One of us, J. L. S., wishes to acknowledge a grant-in-aid from the Hynson, Westcott and Dunning Research Fund.

Experimental Section

2-Carboxy-3,5-dicarbethoxy-4-methylpyrrole (I).—The directions given by Corwin, Bailey and Viohl[4] were modified in an effort to find optimum conditions for the reaction. The use of 10% of anhydrous formic acid in glacial acetic acid gave a slight increase in yield, due to the lower freezing point. A 5% solution of acetic anhydride in glacial acetic acid gave a lower freezing point and a consistently higher yield. At 50°, no acid was obtained but a good yield of aldehyde was formed.

2-Formyl-3,5-dicarbethoxy-4-methylpyrrole was treated with bromine and sulfuryl chloride in acetic acid under the conditions used for the halogenation of 2,4-dimethyl-3,5-dicarbethoxypyrrole. The acetic acid was removed by distillation under reduced pressure and the residue extracted with ether and then with toluene. The ether solution was concentrated by evaporation and the red oil remaining was allowed to crystallize. These crystals give a positive Beilstein test but on treating with alcohol and water the precipitate formed was the starting aldehyde. After partial evaporation of the toluene solution crystals of the aldehyde were also obtained. In still another experiment the halogenation was completed and the hydrolysis with water carried out in a manner identical to that used for the preparation of the acid. No acid was obtained.

When the same reaction was repeated on 2-dichloromethyl-3,5-dicarbethoxy-4-methylpyrrole (see below) a yield of 45% of the acid and 36% of the aldehyde was obtained.

2-Dichloromethyl-3,5-dicarbethoxy-4-methylpyrrole.—Fifty grams of 2,4-dimethyl-3,5-dicarbethoxypyrrole was dissolved in 200 cc. of dry, freshly redistilled C. P. chloroform (U. S. P. chloroform is unsuitable because it contains alcohol); 34 cc. of sulfuryl chloride was added at about 40°. The solution was boiled to remove hydrogen chloride and the chloroform was then removed under vacuum. The crystals which formed were washed with hexane and crystallized from toluene. The use of alcohol for the crystallization, as suggested by Fischer, Sturm and Friedrich,[11] causes decomposition of the substance and is probably responsible for the failure of these investigators to obtain the compound; m. p. 124–125°.

Anal. Calcd. for $C_{12}H_{15}O_4NCl_2$: C, 46.77; H, 4.91. Found: C, 46.83; H, 4.88.

Reaction with Glacial Acetic Acid. (a) Cold.—A solution of 3 g. of the dichloromethylpyrrole in 25 ml. of glacial acetic acid at 17° in a flask was closed with a rubber stopper and placed in an ice-box for eight hours with occasional shaking. The semi-solid mass was then filtered with suction. The filtrate gave no test for acetyl chloride with aniline; 2.3 g. of the starting material was recovered. We conclude that these substances do not react appreciably under the conditions of the trichlorination reaction.

(b) Warm.—A solution of 4 g. of the dichloromethylpyrrole and 25 ml. of glacial acetic acid was placed in a 50-ml. round flask fitted with a small fractionating column with a condenser attached to the side arm. The solution was heated on a water-bath for one hour at 50°, then distilled. The fraction below 60° gave a crystalline precipitate with aniline, identified as acetanilide by its melting point. The solid remaining in the flask was crystallized from dry toluene. A mixed m. p. with 2-formyl-3,5-dicarbethoxy-4-methylpyrrole gave no depression.

2-Carbomethoxy-3,5-dicarbethoxy-4-methylpyrrole (VI). First method.—Five grams of (I) was dissolved in a cold solution of 1.1 g. of potassium hydroxide in 25 ml. of methanol and 2.3 ml. of dimethyl sulfate added dropwise while stirring. After standing half an hour, it was poured into aqueous sodium bicarbonate, filtered and the precipitate crystallized from methanol-water. The methyl ester can be purified by distillation at 235–240° at 20 mm. or by crystallization from hexane, in which it is slightly soluble; m. p. 75°.

Second Method.—This is the method of choice. To a mixture of 25 g. of (I) in 125 ml. of anhydrous methanol in a 250 ml. standard taper Erlenmeyer flask 1.5 g. of dry hydrogen chloride was added and the solution then refluxed for an hour. The solution was stirred into five times its volume of ice water containing 6 g. of sodium

(10) Corwin and Ellingson, THIS JOURNAL, **66**, (a) 1146, (b) 1150, (c) 1149 (1944).

bicarbonate to dissolve any starting material. The ester separated as an oil which hardened after two hours of standing and was purified by distillation under reduced pressure and by crystallization from purified hexane; yields, 85–95%; m. p. 75°. This ester is insoluble in bicarbonate but is soluble in sodium hydroxide solutions, due to the acidity of the NH group under the influence of the three electron-attracting groups present.

Anal. Calcd. for $C_{13}H_{17}O_6N$: C, 55.09; H, 6.05. Found: C, 55.17; H, 5.92.

2,5-Dicarboxy-3-carbethoxy-4-methylpyrrole (VII).—This substance is best prepared from (I). Fifteen grams of (I), 4.5 g. of sodium hydroxide and 150 ml. of water were refluxed two and one-half hours in a 500-ml. Erlenmeyer flask. The solution was poured into an equal volume of water and acidified to the congo red endpoint with hydrochloric acid. The precipitate was filtered off, washed well with distilled water and pressed dry. The pyrrole acid was then resuspended in water to remove the hydrochloric acid. After filtering and washing, it was dried to constant weight at 70°. A small amount of the di-acid was obtained from the filtrates by allowing them to stand. The material was crystallized from ethanol and from 60% acetone in water; yield (crude), 85–95%; m. p. 236–237° (dec.).

Anal. Calcd. for $C_{10}H_{11}O_6N$: C, 49.79; H, 4.60. Found: C, 49.71; H, 4.56.

The crude material is sufficiently pure for subsequent reactions if prepared from starting material which has been recrystallized several times from ethanol.

The same substance is obtained by the alkaline hydrolysis of (VI) and of (XXXV). The acidity of the pyrryl nitrogen is sufficient in each case to dissolve the pyrryl esters in aqueous alkali.

2-Carbomethoxy-3-carbethoxy-4-methyl-5-carboxypyrrole (VIII).—Seven and three-tenths grams of (VII) previously crystallized from acetone-water, and 75 ml. of methanol containing 0.5 g. of dry hydrogen chloride were refluxed in a 250-ml. Erlenmeyer flask for one hour, the solution cooled to room temperature and then poured into 300 ml. of ice water containing sufficient sodium bicarbonate to dissolve the half esterified pyrrole. After standing in the ice-box for one hour, the by-product (XIII) was filtered off (dry yield 0.7 g.) and the 5-carboxypyrrole was isolated by acidification of the filtrate. It was washed with water and dried in the oven at 70°; yield, 6.2 g. or 88%. The pyrrole was crystallized from acetone–water or alternatively from acetone–hexane; m. p. 204–205°.

2-Carbomethoxy-3-carbethoxy-4-methyl-5-bromopyrrole (IX).—To a solution of 2.7 g. of (VIII) in 30 ml. of glacial acetic acid at 45°, 1.8 g. of bromine in 8 ml. of glacial acetic acid was added in ten minutes. The solution became clear. After ten minutes of standing 20 ml. of water was added in twenty minutes. After standing for forty-five minutes it was poured into 200 ml. of ice water and placed in the ice-box for one hour. The precipitate was filtered off, washed with water, dissolved in 50 ml. of methanol and sodium bicarbonate added until no more carbon dioxide was evolved. The bromopyrrole was reprecipitated by pouring the methanol solution into 200 ml. of ice water. After standing for one hour, the precipitate was filtered, washed with water and dried at 50°. It can be recrystallized from methanol-water. A small amount (0.2 g.) of the starting acid was recovered on acidification of the filtrate obtained after the bicarbonate treatment; yield, 1.8 g. or 60%; m. p. 116–117°.

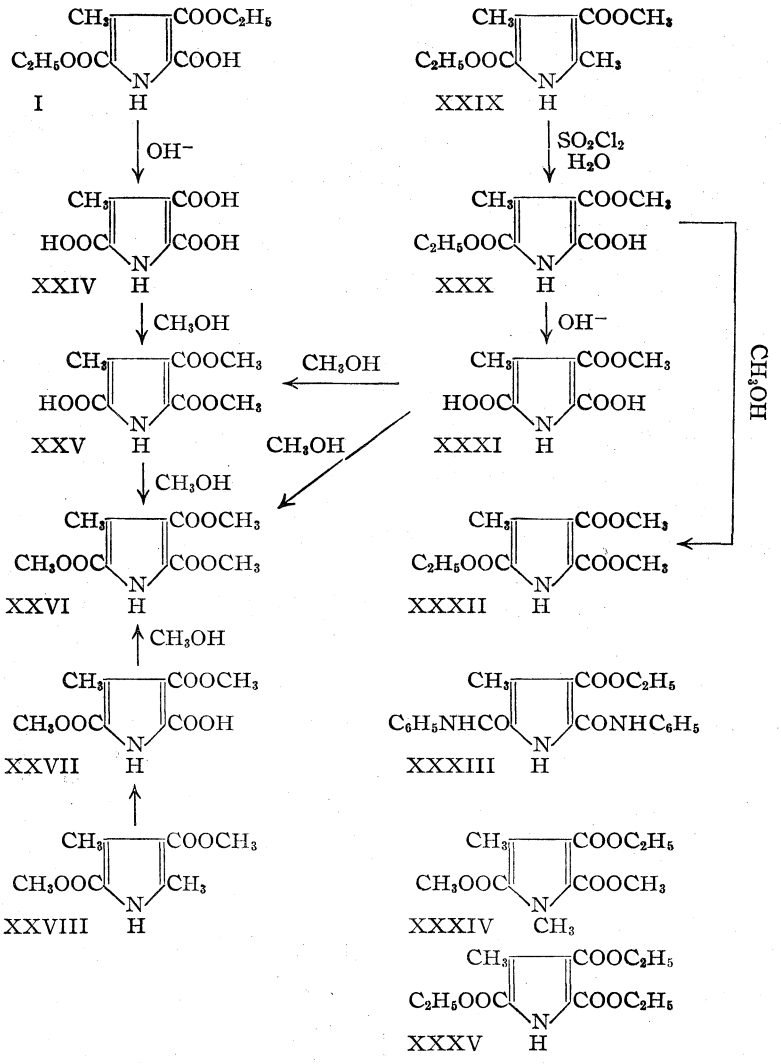
Anal. Calcd. for $C_{10}H_{12}O_4NBr$: C, 41.40; H, 4.17. Found: C, 41.32; H, 4.24. This substance was also obtained by the bromination of compound X (see below).

2-Carbomethoxy-3-carbethoxy-4-methylpyrrole (X).—For the dehalogenation of 2 g. of (IX), it was dissolved in 50 ml. of methanol and 500 mg. of magnesium oxide, 500 mg. of Norite and ten drops of 10% palladium chloride solution were added. The reduction required two hours under a pressure of two atmospheres of hydrogen. The catalyst was filtered off and washed with a few milliliters of hot methanol. The filtrate and washings were combined and dried under reduced pressure below 45°. The solid was dissolved in ether, transferred to a small beaker and the ether evaporated. It was then dissolved in the minimum quantity of ethanol at room temperature and cooled in an ice-bath. Ice water was added, drop by drop, while scratching the sides of the beaker, until the pyrrole crystallized; yield, 1.2 g. or 83%; m. p. 62°.

This pyrrole has also been prepared by the esterification of (XII) with diazomethane[8]; m. p. reported, 59°.

For further identification the pyrrole was brominated in glacial acetic acid. Fine needles of (IX) were obtained, m. p. 116°, mixed m. p., no depression.

CHART IV



2-Carboxy-3-carbethoxy-4-methylpyrrole (XII).[12]—Two hundred milligrams of (X) was hydrolyzed with 70 mg. of potassium hydroxide and 10 ml. of 80% ethanol. After precipitation and separation from unchanged ester the pyrrole was filtered off, washed, and crystallized from ethanol–water; colorless crystals, m. p. 197–197.5° with loss of carbon dioxide. Piloty and Hirsch[12] report 196°.

3,3′-Dimethyl-4,4′-dicarbethoxy-5,5′-dicarbomethoxydipyrrylmethane (XI).—Two hundred milligrams of (X), 3 ml. of 70% acetic acid and 0.3 ml. of 40% formaldehyde were refluxed for five minutes and 0.1 ml. more of formaldehyde was added through the condenser. After refluxing for ten minutes longer, 2 ml. of water was added and the solution was placed in an ice box until crystallization was complete. The product was recrystallized from methanol–water; m. p. 158–159°.

Anal. Calcd. for $C_{21}H_{26}O_8N_2$: C, 58.06; H, 6.03. Found: C, 57.79; H, 6.01.

2-Carboxy-3-carbethoxy-4-methyl-5-carbomethoxypyrrole (XIV).—Twenty-five grams of (XV)[10b] was treated with sulfuryl chloride and bromine by the procedure given for compound I; yields: aldehyde, 36%; acid 38%; m. p. 187°.

Anal. Calcd. for $C_{11}H_{13}O_6N$: C, 51.76; H, 5.13. Found: C, 51.69; H, 5.17.

2,5-Dicarbomethoxy-3-carbethoxy-4-methylpyrrole (XIII).—This was prepared from (XIV) by esterification with dimethyl sulfate and with methanol and acid, in each case following the procedure used for compound VI. The latter method gave better yields. The product crystallizes from methanol in colorless crystals; m. p. 131–132°.

Anal. Calcd. for $C_{12}H_{15}O_6N$: C, 53.52; H, 5.62. Found: C, 53.61; H, 5.59.

2-Carboxy-3-bromo-4-methyl-5-carbethoxypyrrole (XVII).—This was prepared from (XVI)[13] by a procedure essentially the same as for (I), given above; m. p. 254° with decomposition.

Anal. Calcd. for $C_9H_{10}O_4NBr$: C, 39.13; H, 3.65. Found: C, 39.12, 38.98; H, 4.31, 4.29.

2-Formyl-3-bromo-4-methyl-5-carbethoxypyrrole.—This was obtained as a by-product in the preceding preparation. If desired in quantity it can be prepared in a manner exactly analogous to that used for 2-formyl-3,5-dicarbethoxy-4-methylpyrrole.[4b] It was prepared by Fischer, Berg and Schormüller[14a] using ether as a solvent. The use of glacial acetic acid is preferable.

2,5-Dicarbethoxy-3-bromo-4-methylpyrrole (XVIII).[15]—This pyrrole was prepared by the esterification of (XVII) with diethyl sulfate in alcoholic potassium hydroxide by the first procedure under compound VI. The product crystallizes from ethanol–water in colorless needles melting at 85°.

Anal. Calcd. for $C_{11}H_{14}O_4NBr$: C, 43.44; H, 4.64. Found: C, 43.43; H, 4.73.

2,5-Dicarbethoxy-4-methylpyrrole (XIX).—The procedure for the dehalogenation of (XVIII) was the same as that used in the preparation of (X), given above; yield, 62%. Recrystallized from hexane or alcohol–water; m. p. 62°. This pyrrole has also been prepared from (XXI) which in turn was prepared by the condensation of the ethyl ester of glycine hydrochloride with acetylacetoacetic ester in alkaline solution.[9] Kordo, Ono and Sato report m. p. 61°.

2-Carboxy-4-methyl-5-carbethoxypyrrole (XX).—One and five-tenths grams of (XIX) was placed in a solution of 0.25 g. of sodium hydroxide in 25 ml. of 80% ethanol and the mixture refluxed for two hours. An equal volume of water was then added, the solution filtered and the filtrate acidified with hydrochloric acid. The acid was filtered off, washed with water and crystallized from ethanol-water; m. p. 210–215° with decomposition.

Anal. Calcd. for $C_9H_{11}O_4N$: C, 54.82; H, 5.62. Found: C, 54.88; H, 5.58.

2-Carbethoxy-3-methyl-4-bromopyrrole (XXII).—The decarboxylation of (XVII) was carried out by the method of Fischer, Berg and Schormüller.[14b] This method could be used only with quantities less than 2.5 g. The decarboxylation must be performed within five to ten seconds, for the bromopyrrole reacts with hot glycerol to form acrolein; m. p. 179–183°; yield, 40%.

Anal. Calcd. for $C_8H_{10}O_2NBr$: C, 41.38; H, 4.31. Found: C, 41.34; H, 4.38.

2-Carbethoxy-3-methylpyrrole (XXIII).—One and a half grams of (XX) was heated with 6 g. of anhydrous glycerol and the distillate collected in a distilling flask cooled with running water. The new pyrrole distilled between 270 and 290°. Five cc. of ethanol was added to it cautiously and the solution was poured into 25 cc. of ice water. After scratching, the pyrrole precipitated as fine crystals which were filtered off and air-dried; m. p. 56°. Fischer and Wiedemann report 56°.[8]

This substance was also prepared by the dehalogenation by (XXII) by the method used in the preparation of (X) above; m. p. 56°; mixed m. p. with material from the decarboxylation of compound XX, 56°.

2,3,4-Tricarboxyl-4-methylpyrrole (XXIV).—A solution of 25 g. of (I) and 12 g. of sodium hydroxide in 100 ml. of water was placed in a 200-ml. round flask connected to a fractionating column filled with glass helices and fitted with a reflux finger. The side arm of the column was connected to a condenser with a graduated cylinder as the receiver. The flask was heated on a water-bath for two hours. During this time 5 ml. of alcohol was collected below 80°. The flask was then heated with a free flame for four hours longer until the calculated amount, 12 ml., was obtained. The mixture was transferred to a 250-ml. beaker, cooled in an ice-bath and hydrochloric acid added to the congo red end-point. A thick white precipitate was formed which was filtered off with suction and the filtrate used to wash out the beaker. The product was crystallized from boiling water using Norite. It contained some sodium chloride which could be removed by several recrystallizations. The pyrrole is too soluble in cold water to permit washing to remove the salt. The product is insoluble in most organic solvents. It chars slightly when heated to 360°; yield, 15 g. or 76%.

Anal. Calcd. for $C_8H_7O_6N$: C, 45.08; H, 3.31. Found: C, 44.97; H, 3.37.

2,3-Dicarbomethoxy-4-methyl-5-carboxypyrrole (XXV). First Method.—A solution of 400 mg. of (XXIV) in 7 ml. of methanol previously saturated with dry hydrogen chloride was refluxed for five hours and then poured into 40 ml. of ice-cold sodium bicarbonate solution. After standing overnight in the ice box, the precipitate (XXVI) was removed by filtration and the filtrate acidified with hydrochloric acid. It was necessary to add a small amount of salt and to cool the solution before the product (XXV) precipitated. It was filtered off and crystallized from acetone–water; m. p. 211–211.5° with slight decomposition.

Anal. Calcd. for $C_{10}H_{11}O_6N$: C, 49.79; H, 4.60. Found: C, 49.92; H, 4.71.

Second Method.—Five hundred milligrams of (XXXI) and 10 ml. of methanol containing dry hydrogen chloride were allowed to react in the manner described for the preparation of (VIII) above. The pyrrole obtained crystallized from acetone–water and melted at 211–212°; mixed m. p. with XXV prepared from the tricarboxylpyrrole, no depression.

2,3,5-Tricarbomethoxy-4-methylpyrrole (XXVI).—This was prepared from (XXVII) with dimethyl sulfate and with methanol and hydrochloric acid by the procedures described above for (VI). The triester crystallizes from methanol; m. p. 142–143°.

(14) Fischer, Berg and Schormüller, *ibid.*, **480**, (a) 155, (b) 114 (1930).

(15) Performed by S. R. Buc.

The same substance was also obtained in small amounts in the esterification of XXIV (see XXV above) and of (XXXI). It was also prepared by the esterification of (XXV). Melting points and mixed melting points of all these preparations are identical.

Anal. Calcd. for $C_{11}H_{13}O_6N$: C, 51.76; H, 5.13. Found: C, 51.67; H, 5.10.

2 - Carboxy - 3,5 - dicarbomethoxy - 4 - methylpyrrole (XXVII).—Seven grams of (XXVIII)[16] was treated with sulfuryl chloride and bromine by the method given for (I); yield of acid, 4.5 g. or 59%; colorless needles from methanol; m. p. 205–206°.

Anal. Calcd. for $C_{10}H_{11}O_6N$: C, 49.79; H, 4.60. Found: C, 49.69; H, 4.58.

2-Carboxy-3-carbomethoxy-4-methyl-5-carbethoxypyrrole (XXX).—Twenty-one grams of (XXIX)[10e] was treated with sulfuryl chloride and bromine in the manner described for the preparation of (I); yield of acid, 17.3 g., or 73%. This pyrrole crystallizes from ethanol in fine needles; m. p. 157–158°.

Anal. Calcd. for $C_{11}H_{12}O_6N$: C, 51.76; H, 5.13. Found: C, 51.87; H, 5.16.

2,5-Dicarboxy-3-carbomethoxy-4-methylpyrrole (XXXI).—One gram of (XXX) was dissolved in 15 ml. of water containing 0.55 g. of potassium hydroxide and the same procedure followed as for the preparation of (VII). The product obtained was crystallized twice from acetone–water, the first time using Norite; m. p. 243° with decomposition.

Anal. Calcd. for $C_9H_9O_6N$: C, 47.58; H, 3.99. Found: C, 47.59; H, 4.02.

2,3-Dicarbomethoxy-4-methyl-5-carbethoxypyrrole (XXXII).—The same procedure was followed as for the preparation of (VI) using potassium hydroxide and dimethyl sulfate. The product crystallizes from methanol in colorless needles melting at 111°.

Anal. Calcd. for $C_{12}H_{15}O_6N$: C, 53.52; H, 5.62. Found: C, 53.45; H, 5.57.

2,5-Dicarbanilido-3-carbethoxy-4-methylpyrrole (XXXIII).—A solution of 10 g. of (I) and 20 cc. of aniline was refluxed for three and a half hours and poured into a mixture of 100 ml. of hydrochloric acid and 500 ml. of water. The precipitate was filtered off, dissolved in hot alcohol and reprecipitated in an ice–hydrochloric acid mixture. The precipitate was then crystallized from methanol; m. p. 196° after sintering at 192°.

Anal. Calcd. for $C_{22}H_{21}O_4N_3$: C, 67.48; H, 5.41. Found: C, 67.34; H, 5.86.

The position of the second anilide group has not been established. It seems probable that it is in the *alpha* position because of the numerous analogies in the pyrrole series.

1,4-Dimethyl-2,5-dicarbomethoxy-3-carbethoxypyrrole (XXXIV).—A solution of 25 g. of (VI) in 250 ml. of dry toluene was treated with 3 g. of metallic sodium, added in small portions between 95 and 100°. When all of the sodium had reacted, 11 ml. of dimethyl sulfate was added slowly to the solution. The solution was refluxed for one hour, filtered while hot and the toluene distilled off with steam. The residue was dissolved in cold methanol and the pyrrole precipitated by pouring into five times its volume of water. After standing for two hours the pyrrole was filtered off and crystallized from methanol–water; m. p. 60°.

Anal. Calcd. for $C_{14}H_{19}O_6N$: C, 57.33; H, 6.33. For $C_{13}H_{17}O_6N$: C, 55.05; H, 6.04. Found: C, 55.19, 55.18; H, 6.11, 6.02.

1,4-Dimethyl-2-carboxyl-3-carbethoxy-5-carbomethoxypyrrole.—A solution of 1 g. of potassium hydroxide in 25 ml. of methanol was added to 5 g. of (XXXIV). A precipitate formed immediately and dissolved on the addition of water. The solution was filtered and the filtrate acidified with hydrochloric acid to precipitate the pyrrole acid. The procedure used for the purification of (VII) was then followed. The product was crystallized from methanol–water; m. p. 88°.

Anal. Calcd. for $C_{12}H_{15}O_6N$: N, 5.21. Found: N, 5.19.

2,3,5-Tricarbethoxy-4-methylpyrrole (XXXV).[17]—This must be prepared from acid (I) which has been recrystallized several times. The preparation is the same as for (VI) except that anhydrous ethanol is used. The alcoholic solution was poured into water containing an excess of sodium bicarbonate. An oil separated and was extracted with ether. The extract was evaporated on a steam-bath. Portions of the residue were purified by distilling three times at 195° and 1 mm. pressure in the Craig microdistillation apparatus.[18] A yellowish oil is obtained that solidifies slowly to give a white, waxy solid; m. p. 45–46°.

Anal.[19] Calcd. for $C_{14}H_{19}O_6N$: C, 56.56; H, 6.44. Found: C, 56.33, 56.15; H, 6.54, 6.63.

Summary

1. It is shown that 2-dichloromethyl-3,5-dicarbethoxy-4-methylpyrrole reacts with glacial acetic acid to form the pyrryl aldehyde and acetyl chloride.

2. This pyrryl aldehyde is not an intermediate in the formation of 2-carboxyl-3,5-dicarbethoxy-4-methylpyrrole.

3. Carboxylic ester groups hinder decarboxylation in the pyrrole series.

4. Selective freeing of ring positions on tricarboxylpyrrole derivatives may be secured by replacing the first carboxyl group with bromine followed by selective degradations of the resulting dicarboxyl derivatives.

5. Flow sheets are given for the freeing of the 2,3 and 5 positions in derivatives of 2,3,5-tricarboxyl-4-methylpyrrole.

6. Five new cases have been added to the generalization that attack by an alkaline catalyst upon pyrryl-carboxylic ester groups is oriented α instead of β whenever there is a choice.

The Leuckart Reaction: A Study of the Mechanism

BY VINCENT J. WEBERS[1] WITH WILLIAM F. BRUCE

The preparation of N-benzhydryl formamide from benzophenone by the Leuckart reaction has been reported by Leuckart and Bach[2] using ammonium formate. The compound has been prepared in this laboratory by the general procedure of Ingersoll[3] with good results. Since Ingersoll[4] stated that somewhat higher yields might be expected in the Leuckart reaction if formamide itself were used rather than ammonium formate, benzophenone was refluxed with 99% formamide; after refluxing for four hours or more, much lower yields of the order of 40% N-benzhydryl formamide were obtained, accompanied by recovery of the benzophenone. This unexpected result led the authors to a study of some factors that influence the Leuckart reaction, in order to determine the conditions under which formamide can be used effectively in the reaction, and to elucidate the mechanism. Catalysis by a selected group of salts was found to be important in securing a good yield in this reaction.

Benzophenone is a good choice for a study of the reaction, as there are apparently no significant side reactions except the decomposition of formamide and the product is readily identified and purified. The reaction of benzophenone with formamide was carried out under a variety of conditions. Since the Leuckart reaction is concerned essentially with the formation of a formyl derivative, and not *per se* with the hydrolysis of the formyl compound to the amine, this formyl intermediate itself was isolated. It was found that one mole of benzophenone gave a homogeneous reaction mixture with six moles of formamide at 180–190°, but not with four moles; hence all the experiments were run using six moles of the reagent. The results of these experiments are summarized in Table I. For convenience, the amounts of reagents are referred to on the basis of one mole of benzophenone, although 0.467 mole was used in each case.

The procedure given in "Organic Syntheses" was followed, and a 92% yield of N-benzhydryl formamide was obtained (Table I, run 1). Schiedt,[5] using a very large excess of formamide, reported excellent yields. In order to test this with the 99% formamide, benzophenone was treated with 18 moles of this reagent for four hours. The amide was obtained in 87% yield, based on the benzophenone used (Table I, run 2). In contrast with this, the use of six moles of formamide gave less than 50% conversion (Runs 3-A and 4-A).

In testing the effect of the addition of various substances to the reaction mixture, all the runs numbered 3 were made in the same oil-bath at the same time and likewise for the runs numbered 4 in order to secure reaction conditions as comparable as possible. Runs 3-A and 4-A, with the same reagents, served as controls so that a comparison might be made between the two sets. The runs were made for four hours in each case. The results given in Table I show that the addition of a base, dimethyl aniline, or the "Zwitterion," pyridine-3-sulfonic acid to the reaction mixture had little effect on the amount of conversion (Runs 3-B and 4-C). The addition of the ammonium salts of sulfuric and formic acids, and of anhydrous magnesium chloride, an acid in the Lewis sense, increased the conversion by significant amounts (Runs 3-C, 4-B, and 4-C).

Mechanism.—The mechanism generally proposed for the reaction was advanced by Wallach[6] and reiterated by Crossley and Moore[7]

$$\underset{\text{I}}{H_2NCHO} \xrightarrow{H_2O} NH_4OCHO \xrightarrow{185^\circ} NH_3 + HCOOH$$

$$\underset{\text{II}}{R_1R_2CO} + NH_3 \longrightarrow \underset{\text{III}}{R_1R_2C(NH_2)OH} \xrightarrow{HCOOH} R_1R_2CHNH_2 + CO_2 + H_2O$$

$$R_1R_2CHNH_2 + HCOOH \longrightarrow R_1R_2CHNH_3OOCH \longrightarrow R_1R_2CHNHCHO + H_2O$$

Doevre and Courtois[8] and Davies and Rogers[9] suggest that in the reaction between ketones and formamide, the first reaction is the addition of formamide to the carbonyl group

$$\underset{\text{II}}{R_1R_2CO} + \underset{\text{I}}{H_2NCHO} \rightleftharpoons \underset{\text{IV}}{R_1R_2C(OH)NHCHO}$$

A compound of the same type as IV is reported by Shive and Shive[10]; they isolated α-hydroxy-α-formaminopropionic acid on mixing pyruvic acid with formamide at 40°. These investigators agree that the first step is the formation of a car-

TABLE I

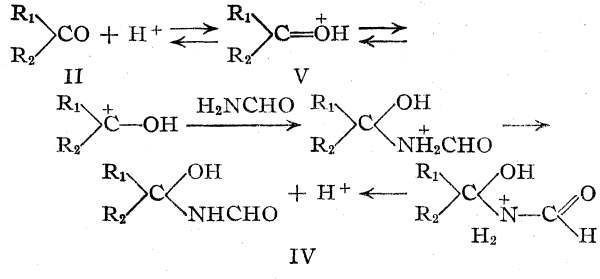
LEUCKART REACTIONS UNDER VARIOUS CONDITIONS WITH BENZOPHENONE (1 MOLE)

Run	Reagent	Temp. of reaction, °C.	Ketone[a] recovered, %	Amide obt., %	M. p. of distilled amide (cor.), °C.
1	("Org. Syn.") 6 moles HCO_2NH_4	180–190	2[b]	92	131–132
2	18 moles 99% $HCONH_2$	180–190	1	87	130–132
3-A	6 moles 99% $HCONH_2$	180–190	46	48	125–129
3-B	Same, plus 2.1 g. $Me_2NC_6H_5$	180–190	40	51	126–129
3-C	Same, plus 6.4 g. $(NH_4)_2SO_4$	180–190	12	80	123–126
4-A	Same as 3-A[c]	180–190	61.5	37.5	123–129
4-B	1 mole NH_4OOCH plus 5 moles 99% $HCONH_2$	170–176[d]	2	95.5	131–133
4-C	4-A plus 6.3 g. pyridine-3-sulfonic acid	180–190	67.5	30.5	124–130
4-D	4-A plus 6.3 g. $MgCl_2$	180–190	2	95.6	129.5–133

[a] These figures for benzophenone recovered on distillation are 1–2% too high; see experimental. [b] This ketone distilled over during the reaction. [c] To compare series 3 with series 4, run on different days. [d] The temperature is lower because of the lower boiling point of this mixture.

bon–nitrogen bond between the carbon atom of the carbonyl group, and the nitrogen atom of ammonia or formamide. This is then followed by the reduction of the alcohol thus formed by means of formic acid or formamide, respectively.

It is probable that the catalytic effects observed by us are due to an initial polarization of the carbonyl group of the ketone. The magnesium chloride, or its reaction product with formamide, $Mg(HNCHO)_2$, or magnesium ion could coordinate with the oxygen atom of the carbonyl group. The function of an ammonium salt as a catalyst for the reaction is probably to furnish a proton from a complex in equilibrium[11] with its dehydration product, the amide. It can be assumed that the formation of an amide from an ammonium salt involves stepwise loss of an hydroxyl ion and a proton from the intermediate, $R\text{-}C(OH)_2NH_2$, proposed by Noyes and Goebel[12]; Krieble and Holst[13] suggest that that the ion $RC(OH)=NH_2^+$ is also intermediate in this reaction; this ion can give up a proton to form the amide. A proton can also coördinate with the carbonyl group, increasing the effective positive charge on the carbon atom (making it more acidic), and facilitating the condensation with the relatively basic nitrogen atom of formamide



II V IV

The reaction sequence in the case of magnesium chloride is similar; and if the reaction proceeds as suggested by Wallach, by the addition of ammonia, the catalysis could be explained on the same basis. The report of Crossley and Moore,[7] that the yield in the Leuckart reaction is lower at higher temperatures, may be due to lower concentrations of ammonium formate at these temperatures.

The Leuckart reaction using monoalkyl formamides[14,15] or dialkyl formamides[6,16,17] has not been investigated by the authors, but it is probable that they show the same catalysis. Wallach[6] found that when formic or acetic acid is added to a mixture of benzaldehyde and ammonium formate, only tribenzylamine was found in the product, whereas Leuckart[17] showed that the reaction without the addition of acid gave a mixture of N-benzyl formamide, N,N-dibenzyl formamide, and tribenzylamine. Nabenhauer[16] found that the addition of formic acid is essential when tertiary amines are prepared by the Leuckart reaction with dialkyl formamides. The mechanism of the reduction of the alcohol, III or IV, with formic acid or formamide is not known, but it may be related to the mechanism of the pyrolysis of alkyl formates to form the corresponding hydrocarbon derivative.[18]

The authors wish to acknowledge the benefit of discussions with Dr. R. T. Arnold in which possible mechanisms were critically examined.

Experimental

Decomposition of Formamide.—Refluxing formamide alone gave slow decomposition to ammonia and carbon monoxide: about one liter of carbon monoxide collected in an hour from 30 cc. of formamide. The formamide, meanwhile, turned black, both in the flask and in the reflux condenser. Replacing the air in the system with nitrogen prevented most of the tar formation. Novelli and Somaglino[19] conducted a current of carbon dioxide through the system, perhaps for the same reason. During the Leuckart reaction, the evolution of carbon dioxide

and ammonia protects the formamide from the air, and no trouble is encountered unless the heating is interrupted, or unless the heating is continued after the evolution of gases has ceased.

Standard Method of Carrying Out the Reaction.—Eighty-five grams of benzophenone (0.467 mole) and 110 cc. of 99% formamide (6 × 0.467 mole) (obtained from the Eastman Kodak Co.) together with any substances to be tested for catalytic effect, and a chip of porous plate were placed in a 200-cc. balloon flask equipped with an air-reflux-condenser. The air was displaced with nitrogen, and the flask immersed in an oil-bath kept at 190–200°. After boiling had started, the temperature in the flask was at 180–190°. A small quantity of ammonium carbonate sublimed into the reflux condenser, and ammonia and carbon dioxide were evolved. At exactly four hours after boiling started, the flask was removed from the oil-bath, allowed to cool to about 140°, and cautiously poured into about 200 cc. of cold water. (If it was cooled much below 130°, the formyl derivative crystallized, and removal from the flask was difficult.) The flask was washed out with a little water, and the mixture of benzophenone, N-benzhydryl formamide, and water soluble substances was cooled, seeded with a crystal of benzophenone, and the mixture of solids collected on a Buchner funnel, washed with a little water, and dried. The amount of benzophenone and of N-benzhydryl formamide in the mixture of solids was determined by distillation *in vacuo* without a column. Benzophenone boils at 114° at 1.2 mm., but was collected at 120–130° in order to speed up the distillation. When the benzophenone was all gone, the boiling point rose rapidly; at 160° the receiver was changed, and the remaining formyl derivative was distilled with strong enough heating to prevent crystallization in the side arm of the flask. The amide boils at 173° at 1.2 mm., but as before, it saved time to collect it at 185–190°. A small amount of tar (about a gram) remained in the Claisen flask. The amount of benzophenone determined by this method may be too great by one to two grams (estimated), as a small amount of formamide remains with the solids, and distills over with the first few drops of benzophenone.

All of the reaction mixtures were homogeneous, with the exception of 3-C; the ammonium sulfate added is not completely soluble in the reaction mixture. The results are shown in Table I. The melting point determined by Fischer block method was higher when the reaction was more complete. The value for the pure substance in the literature and in our hands is 132°.[2] In order to judge the purity of the amide, a solution of 2% benzophenone in molten N-benzhydryl formamide was made up and allowed to cool. This material melted at 126.5–130.5°, from which it is concluded that the maximum impurity in the amide samples in Table I is about 2 or 3%.

Summary

1. The Leuckart reaction with benzophenone and formamide has been run under various conditions; with pure formamide (99%) the yield is low unless a large amount of the reagent is used.

2. Ammonium formate, ammonium sulfate, and magnesium chloride have been shown to be effective catalysts for the reaction.

3. A partial mechanism is advanced for the reaction.

Gelsemine

BY BERNHARD WITKOP[1]

Several recent papers[1a,2,3] deal with the structure of gelsemine, $C_{20}H_{22}O_2N_2$, the principal crystalline alkaloid of *Gelsemium sempervirens*, the American "yellow jasmine." Marion[2] isolated an indole derivative as the product of soda-lime or selenium treatment of gelsemine. This is the first major degradation product reported, and relates gelsemine to the indole alkaloids. Indole itself occurs in the oils from the enfleurage of jasmine flowers, where it is present in the form of an unknown complex.[4] Marion and other investigators,[1a,2] studying the degradation of gelsemine, report the presence of bases that were difficult to purify and obtainable only in very small yield.

By the use of a modified mild zinc dust distillation three degradation products have been obtained from gelsemine. Two of basic nature were separated by the difference in basicities. The stronger base is an oil with quinoline or isoquinoline odor, and yields a well-crystallized picrate. Analysis of the latter corresponds to an ethyl- or dimethyl- quinoline or -isoquinoline. It is clear from the data of Table I that gelsemine is such a strong tertiary base that the basic nitrogen atom can neither be attached to a benzene nucleus nor form part of an unreduced pyridine ring, as has been suggested already by Forsyth, Marrian and Stevens.[1a] A more weakly basic product, probably $C_{14}H_{11}N$, was obtained in the form of a picrate. According to the analytical data it might be a methylbenzquinoline (or -isoquinoline). Skatole was isolated as the main non-basic product of indolic nature in the form of the picrate.

TABLE I

*p*Ka (negative logarithms of acidity constants of the hydrochlorides)

Quinoline	4.89[5]
Isoquinoline	5.36
Py-tetrahydroquinoline	5.03
Py-tetrahydroisoquinoline	9.41
Gelsemine	9.37[1a]

The dimethylindole reported by Marion[2] has not been observed in the present investigation. It should be pointed out, however, that the identification of alkyl indoles is often rendered difficult

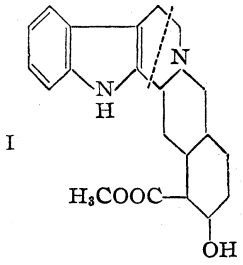
by the tendency of these substances to form mixed crystals. Soda-lime fusion, zinc dust distillation and dry distillation of yohimbine invariably lead to an isomorphous mixture of 3-ethylindole and skatole,[6] which has been looked upon as an unknown dimethylindole.[7] The same conditions are encountered in the case of C-dihydrotoxiferine-I, an alkaloid of calebash curare. Here, too, an isomorphous mixture of the two β-indole homologs simulates the properties of a new compound.[8] However, in the case of gelsemine purification of skatole could be effected with no great difficulties, which suggests the absence of other homologs.

The isolation from gelsemine of cleavage products containing nine and eleven carbon atoms intimates that the decomposition has taken the simple course

$$C_{20}H_{22}O_2N_2 \longrightarrow C_9H_9N + C_{11}H_{11}N$$

and that the alkaloid may be built up by a combination of the indole and the quinoline or isoquinoline nucleus. The latter possibility further suggests a relationship to the yohimbé alkaloids (*cf.* yohimbine (I)). It must be pointed out however that gelsemine contains an N-methyl group,



and that, if the above hypothesis be accepted, it is necessary to assume a migration of the methyl group from nitrogen to carbon. Since this change is somewhat unlikely,[9] the possibility must be considered that the reactions occurring during the degradation may be much more involved than is indicated by the above argument.

TABLE II

MELTING POINTS OF THE PICRATES

1-Ethylisoquinoline	209–210[10]
1,4-Dimethylisoquinoline	221–222[10,11]
1,3-Dimethylisoquinoline	180–181[12,a]

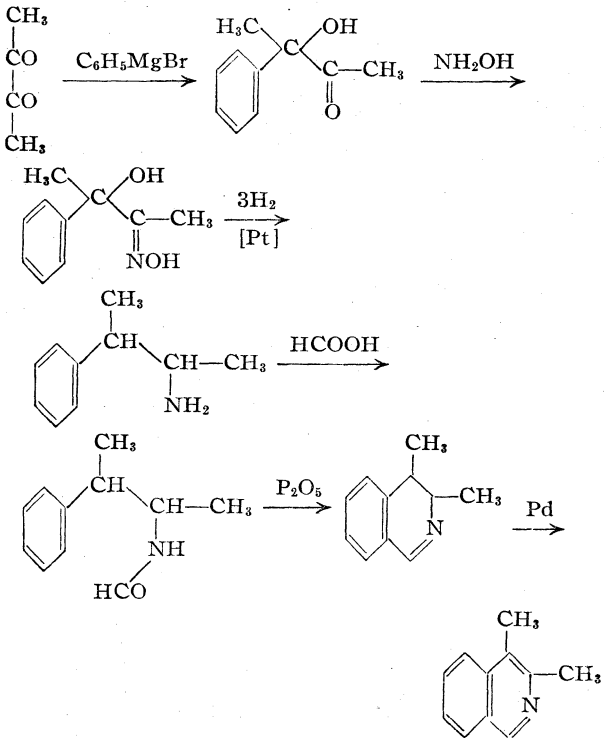
Comparison of the properties of the base $C_{11}H_{11}N$ with those of the previously known dimethyl- and ethylisoquinolines, and further with two new substances, *viz.*, 1,3- and 3,4-dimethylisoquinolines, which have been synthesized in the course of this investigation, has shown that the new base is not identical with any of those substances (Table II).

3,4-Dimethylisoquinoline was prepared by a modification of the method of Pictet and Gams.[13,14] The oxime of dimethylphenylketol,



on catalytic hydrogenation, lost its hydroxyl group and yielded 2-phenyl-3-aminobutane. Formylation, ring closure and dehydrogenation gave the final isoquinoline.

Attempts have been made to prove the presence of an indole ring by ozonolysis[6] or by the very characteristic reaction that is given by indole compounds with perbenzoic acid.[15] Only the reactive double bond present in gelsemine[3] will react with ozone to yield an ozonide explosive in a dry state. Perbenzoic acid gives products that are no longer precipitated on addition of alkali. These findings together with the spectroscopic evidence[16] and the positive "Otto reaction"[17] speak for a hydrogenated indole ring present in gelsemine.

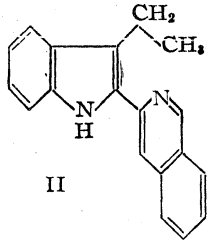
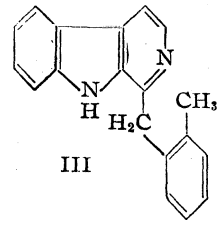
Sempervirine.—The concomitant alkaloid sempervirine, $C_{19}H_{16}N_2$, is a very interesting substance. It is isomeric with isoyobyrine (II)[18] and yobyrine (III).[19] In its strong fluorescence and lack of optical activity also it resembles yobyrine.



II



III

On the other hand, the spectra of the three compounds[20,21] are entirely dissimilar. This difference is emphasized by the behavior of sempervirine toward perbenzoic acid. Derivatives of harmine form amine oxides and lose their fluorescence; the reaction is very prompt and characteristic.[15] Sempervirine is very stable to perbenzoic acid; a non-fluorescent amine oxide could not be isolated.[21a]

Experimental[22]

Gelsemine.—*Anal.* Calcd. for $C_{20}H_{22}O_2N_2 \cdot CH_3COCH_3$: C, 72.63; H, 7.42; NCH_3, 9.0. Found: C, 72.90; H, 7.64; NCH_3, 11.4.

Gelsemine Hydrochloride.—*Anal.* Calcd. for $C_{20}H_{22}O_2N_2 \cdot HCl$: C, 67.04; H, 6.42; NCH_3, 8.1. Found: C, 67.21; H, 6.61; NCH_3, 9.49 (no methoxyl; calcd. for NC_2H_5: 12.01).[23]

Zinc Dust Distillation of Gelsemine.—For every distillation 50 mg. of gelsemine is mixed with 5 g. of zinc dust (reagent). The reaction is carried out in an apparatus described previously.[24] The mixture is separated from the constriction by a 2 g.-layer of zinc dust. The temperature inside the oven is regulated to 370°. Nitrogen is passed through a tube at such a velocity that one distillation does not take longer than ten minutes. Eighty such distillations were carried out.

Phenolic Fraction.—The combined ethereal solutions of the volatile degradation products are concentrated to 50 cc. and extracted twice with 5 cc. of dilute alkali. The alkaline solution is acidified and extracted with ether. The solvent is removed and leaves a very small amount of an oil possessing a distinct phenolic odor. It does not give the reaction of Gerngross, Voss and Herfeld[25] and, therefore, cannot be a phenol with a substituent in the *para* position.

Bases.—A.—The ether solution which contains a mixture of bases is extracted first with 10 cc. of 2 *N* acetic acid which removes preponderantly the stronger base. This base is liberated by alkali, taken up in ether, and, after evaporation of the solvent, obtained in the form of an oil with a characteristic quinoline or isoquinoline odor. The crude base is purified by steam distillation in a micro-apparatus similar to that described by Gettler and Siegel.[26] The resulting colorless oil is dissolved in little 0.1 *N* hydrochloric acid and precipitated as the picrate by the addition of the necessary amount of an aqueous solution of picric acid. The flocculent picrate is collected, washed with water and dried. Recrystallized twice from acetone, it forms bright yellow needles, m. p. 185–187°.

Anal. Calcd. for $C_{11}H_{11}N \cdot C_6H_3O_7N_3$: C, 52.85; H, 3.64. Found: C, 52.95; H, 3.59.

B.—A weaker base is obtained by extracting the ethereal solution from (A) with 2 *N* hydrochloric acid. It is liberated with alkali and taken up in ether. The ether is boiled off, and the oily residue subjected to steam distillation. Here, too, the resulting colorless oil has a characteristic odor reminiscent of isoquinoline. The picrate of this base is prepared in the same way as described for the stronger base. Twice recrystallized from acetone, it forms beautiful needles, m. p. 218–220°.

Anal. Calcd. for $C_{14}H_{11}N \cdot C_6H_3O_7N_3$: C, 56.87; H, 3.36. Found: C, 56.47; H, 3.36.

Non-basic Fraction.—The ethereal solution, which is now free of bases, is evaporated. The residue is separated by steam distillation into a steam volatile and a non-volatile part. The dry volatile part, which has a strong indolic odor, is distilled in high vacuum. The colorless oil which distills at 80–90° is dissolved in 4 drops of benzene. On addition of 4 drops of a cold benzenic solution of picric acid and not too much petroleum ether one obtains a red picrate (m. p. 153°). The addition of eight further drops of picric acid solution to the mother liquor yields a second purer crop of the red picrate. Recrystallized twice from benzene it forms dark red, glossy needles, m. p. 165°.

Anal. Calcd. for $C_9H_9N \cdot C_6H_3O_7N_3$: C, 50.00; H, 3.33. Found: C, 49.99; H, 3.49.

When mixed with a very pure sample of skatole picrate (m. p. 174°) it melted at 172°. Careful study of the picrate from gelsemine on a micro hot stage proves the identity in all respects with skatole picrate. It shows the two transformation points at 138° and 155° characteristic of skatole picrate.[12]

Admixture of 2,3-dimethylindole picrate with the picrate obtained from gelsemine does not lower the melting point below 156°. Equal parts of pure samples of skatole picrate and 2,3-dimethylindole picrate show a mixed melting point of 165°. In the same way, 2,3-dimethylindole (m. p. 106°) and skatole (m. p. 95°) fail to show a characteristic depression on admixture: the mixed melting point is 96°.

The residue from the steam distillation can be purified by high vacuum distillation. At 130° one obtains an oil which partially crystallizes on cooling. Recrystallization from low boiling petroleum ether yields a very small amount of needles, m. p. 195°, which do not give the reaction of Hopkins–Cole. With dimethylaminobenzaldehyde in alcoholic solution and concentrated hydrochloric acid a purple coloration is obtained at room temperature, slightly intensified on heating.

1,3-Dimethylisoquinoline Picrate.—1,3-Dimethyl-3,4-dihydroisoquinoline[27] is easily dehydrogenated by treatment with palladium black at 200° for thirty minutes. The base is dissolved in *N* hydrochloric acid and precipitated as the picrate. Recrystallized from acetone it forms short needles, m. p. 180–181°.

Anal. Calcd. for $C_{11}H_{11}N \cdot C_6H_3O_7N_3$: C, 52.85; H, 3.64. Found: C, 53.15; H, 3.66.

On admixture with the isomeric picrate from gelsemine (m. p. 185–187°) the melting point is lowered to 145°.

Dimethylphenylketoloxime Hydrochloride.—Dimethylphenylketol[28] (10 g., prepared by the Grignard method)

(21) Private communication and reference (16); the author wishes to express his gratefulness to Prof. Janot, Paris, for his friendly donation of a sample of sempervirine.

(21a) Addendum in proof: very recently Goutarel, Janot and Prelog were able to obtain yobyrine as well as tetrahydroisoyobyrine by dehydrogenation of sempervirine, *Experientia*, **4**, 24 (1948).

(22) All melting points corrected.

(23) Many indole derivatives split off some volatile iodide under the conditions of the N-methyl determination: yohimbol, 3.04%; quinamine [Henry, Kirby and Shaw, *J. Chem. Soc.*, 524 (1945)], 1.63% "NCH_3."

(24) Witkop, *Ann.*, **554**, 123 (1943).

(25) Gerngross, Voss and Herfeld, *Ber.*, **66**, 435 (1933).

(26) Gettler and Siegel, *Arch. of Pathol.*, **19**, 208 (1935).

(27) Hey, *J. Chem. Soc.*, 18 (1930).

(28) Wegmann and Dahn, *Helv. Chim. Acta*, **26**, 101 (1946).

is heated with hydroxylamine hydrochloride (4.1 g.) and anhydrous sodium acetate (4.1 g.) in 200 cc. of absolute ethanol under reflux for four hours. After removal of the sodium chloride the ethanol is evaporated in vacuum. The residue is taken up in 200 cc. of absolute ether. On passing dry hydrogen chloride through the solution the oxime hydrochloride is deposited in form of a sticky oil, which completely crystallizes after twenty hours in the ice box, m. p. 99°.

2-Phenyl-3-aminobutane.—The oxime hydrochloride (4.7 g., 0.2 mole) of 50 cc. of glacial acetic acid with 0.5 g. of platinum oxide takes up somewhat less than three moles of hydrogen. The solvent is removed in vacuum. The residue is taken up in ether, the base extracted with dilute hydrochloric acid, liberated with alkali, and taken up in ether. The amine was obtained as an oil (1.8 g., 60%).

3,4-Dimethyldihydroisoquinoline.—The amine (1.8 g.) is heated with 20 cc. of 87% formic acid on the steam-bath for two hours. The formic acid is evaporated in vacuum and the procedure repeated. The resulting crude formylamino compound still contains some amine which is extracted with dilute acetic acid. The ethereal solution is evaporated to dryness. The carefully dried crude formylamino compound (1.1 g.) is dissolved in 30 cc. of freshly distilled tetralin and treated with 3.5 g. of phosphorus pentoxide. The mixture is refluxed for thirty minutes and another 3.5 g. of pentoxide is added in the middle of this time. The resulting base is isolated in the usual manner and distilled at 120° (10 mm.). It is converted into the picrate and recrystallized from acetone as needles, m. p. 208°.

Anal. Calcd. for $C_{11}H_{13}N \cdot C_6H_3O_7N_3$: C, 52.57; H, 4.12. Found: C, 52.80; H, 4.12.

The hydrochloride is prepared from the picrate by trituration with dilute alkali and extraction with ether. When hydrogen chloride is passed through the dry ethereal solution the hydrochloride crystallizes and forms beautiful needles from ethanol, m. p. 208° (sublimes).

3,4-Dimethylisoquinoline Picrate.—As in the case of the 1,3-dimethyl compound palladium (220°, thirty minutes) easily dehydrogenates the dihydro base in almost quantitative yield. The picrate crystallized immediately from the aqueous solution in short needles, m. p. 224–226°.

Anal. Calcd. for $C_{11}H_{11}N \cdot C_6H_3O_7N_3 \cdot H_2O$: C, 50.37; H, 3.95. Found: C, 50.37; H, 3.69.

Acknowledgment.—The author is indebted for support of this work to Prof. L. F. Fieser in whose laboratory part of this work was performed.

Summary

Gelsemine can be degraded to skatole and a base $C_{11}H_{11}N$ which is considered to be a dimethylisoquinoline. None of the three possible dimethylisoquinolines bearing the methyl groups in the pyridine part of the molecule is identical with the base from gelsemine.

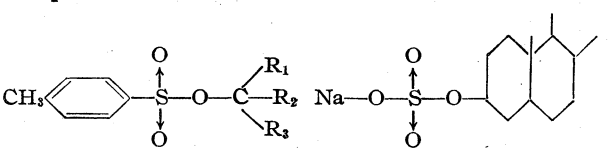
Studies in Steroid Metabolism. V. The Problem of Walden Inversion in the Reactions of Steroid Hydrogen Sulfates and Steroid Sulfites[1,2]

BY SEYMOUR LIEBERMAN, LUCIE B. HARITON AND DAVID K. FUKUSHIMA

This paper deals with the problem of Walden inversion in the reactions of steroid hydrogen sulfates and with the point of cleavage of the S-O-R linkage in these compounds. Since urinary steroids are excreted, at least in part, as water-soluble sulfates,[3] this problem is of biological interest as well as chemical. The isolation of these conjugates is difficult, their quantitative estimation impractical, and therefore it is the general practice to hydrolyze these conjugates with boiling acid in order to estimate or identify the free steroids. Although it has been recognized that various artefacts result from this hydrolytic procedure, the possibility that another type of transformation product might be formed has been overlooked. This type of artefact would result from a Walden inversion accompanying the hydrolysis of those urinary steroids conjugated with sulfuric acid. The supposition is based on the results obtained on the cleavage of analogous sulfonoxy compounds.



I II

Kenyon and Phillips[4] have shown that displacement reactions of *p*-toluenesulfonates of optically active alcohols (I) are accompanied by inversion of configuration, and there are at least three reports[5] demonstrating that steroid toluenesulfonates undergo displacement reactions accompanied by Walden inversion. Esters of sulfonic acids, therefore, unlike esters of carboxylic acids react by a rupture of the alkyl oxygen (SO-R) linkage.

(1) This paper was presented before the Division of Organic Chemistry at the 112th Meeting of the American Chemical Society, New York City, September, 1947.

(2) A portion of this paper was taken from the Master's Thesis of Lucie B. Hariton, June, 1947, Department of Chemistry, New York University.

(3) The following steroids have been isolated from urine as their sulfuric acid esters: (a) Estrone [Schachter and Marrian, *J. Biol. Chem.*, **126**, 663 (1938)]; (b) androsterone [Venning, Hoffman and Browne, *J. Biol. Chem.*, **146**, 369 (1942)]; (c) dehydroisoandrosterone [Munson, Gallagher and Koch, *ibid.*, **152**, 67 (1944)]; (d) Δ^{16}-allopregnenol-3β-one-20 [Klyne and Marrian, *Biochem. J.*, **39**, Proc. xlv (1945)]; (e) uranediol [Klyne, *ibid.*, **40**, Proc. lv (1946)].

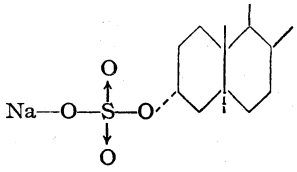
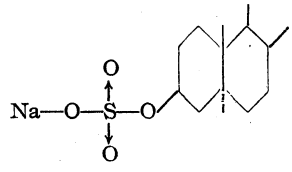
It has been generally assumed[6] that esters of sulfuric acid likewise are cleaved at the SO-R linkage. The 6-sulfates of various hexoses when treated with barium hydroxide for long periods at 100° gave 3,6-anhydro sugars,[7] a result which may be interpreted to indicate that the SO-R linkage had been ruptured. If the urinary steroid sulfates (II) are similarly cleaved at the SO-R linkage by acid hydrolysis, it would be expected that Walden inversion would occur and as a consequence, a steroid which had been excreted as the 3β-sulfate would be isolated and identified after acid hydrolysis as a 3α-hydroxy compound. The direction of cleavage of these steroid sulfates is therefore of considerable biological importance and in addition affords information on the general problem of cleavage of esters.

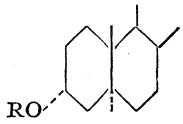
We have studied the fission of the S-O-R linkage by examining the products obtained from the acid hydrolysis and displacement reactions of sulfuric acid esters of several steroid alcohols. The acid hydrolysis has been accomplished by continuous ether extraction of a suspension of the steroid sulfate in aqueous acid. Under these conditions the free steroid accumulates in the ether extract and it is therefore unnecessary to resort to the prolonged heating usually employed for the acid hydrolysis of urinary steroid conjugates. The ether soluble reaction products were separated and were identified by melting point, melting point of mixtures and by their characteristic infrared spectra. Mother liquors and all non-crystalline residues were also submitted to infrared spectral analysis in order that every precaution be made to detect small amounts of an isomer resulting from a reaction involving Walden inversion. Under these conditions, cholestanol-3α sulfate (III) and cholestanol-3β sulfate (IV) yielded the corresponding alcohols (Va and VIIa) without any inversion of configuration. Hydrolysis of the sulfates of cholesterol and dehydroisoandrosterone was similarly accomplished without inversion of configuration.



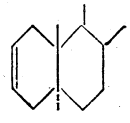
III



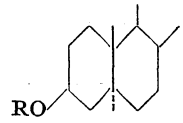
IV



Va, R = H
Vb, R = CH_3CO

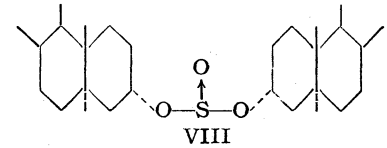


VI

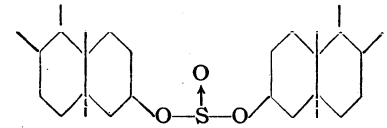


VIIa, R = H
VIIb, R = CH_3CO

In view of these results, a series of reactions were investigated under conditions favorable for a displacement reaction with inversion of configuration. Sodium cholestanol-3α sulfate (III) was heated with silver acetate in acetic acid, and from the reaction mixture, cholestanol-3α (Va) and its acetate (Vb), together with a small amount of neocholestene (VI) were obtained as the reaction products. The isomeric sodium cholestanol-3β sulfate (IV) when treated with silver acetate in acetic acid also yielded products (VIIa and VIIb) without inversion. The results indicated that these reactions were also accomplished with retention of configuration about C_3. Sodium cholestanol-3α sulfate (III) and sodium cholestanol-3β sulfate (IV) when treated at room temperature with dry hydrogen chloride in absolute methanol solution, were converted in high yield to the corresponding alcohols (Va and VIIa) without any evidence of inversion about the asymmetric carbon atom.



VIII



IX

In order to determine whether cleavage of the S-OR linkage was a general phenomenon, we have investigated the cleavage of alkyl sulfites. The sulfites of cholestanol-3α (VIII) and cholestanol-3β (IX) were treated with silver acetate in acetic acid and with dry hydrogen chloride in methanol precisely as were the sulfates, and the products were isolated as in the previous experiments. Here, also, the products retained their configuration about the asymmetric carbon atom and no evidence of Walden inversion was observed.

Discussion

The complete retention of configuration in all of the foregoing replacement reactions of the sulfates and the sulfites indicates that the principal course of the reaction was cleavage of the S–OR bond. Double inversion cannot account for retention of configuration because both the sulfates and sulfites were prepared by methods which do not involve the O–R bond. The reagents appear always to have attacked the sulfur rather than the asymmetric carbon atom. In the acid-catalyzed reaction, it may be postulated that a proton adds to the oxygen between the sulfur and carbon atoms. This positive charge weakens the S–OR bond since there already exists a positive formal charge of two on the sulfur; the sulfur–oxygen linkage is then cleaved by an attack of a solvent molecule (water or methanol) on the sulfur atom yielding the alcohol with the original configuration.

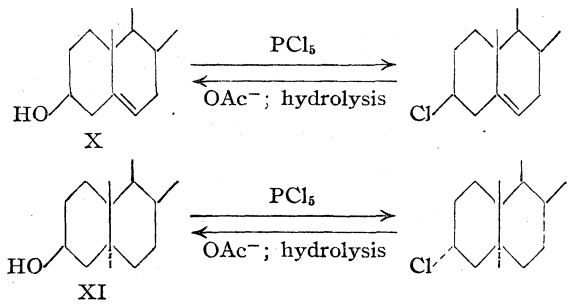
That a carbonium ion was formed as an intermediate is possible, but unlikely, from the experimental results. The possibility exists that a carbonium ion is so oriented by virtue of the many asymmetric centers in the steroid nucleus that the entering group could attack the carbonium carbon from one side preferentially. If this were the case, both the isomeric α- and β-sulfates would yield a common carbonium ion and would consequently yield the same isomer or mixture of isomeric alcohols. Since each sulfate was hydrolyzed with complete retention of configuration, this mechanism is unlikely and this view is strengthened by the results of the experiments in methanol with dry hydrogen chloride. Had these reactions taken place by a carbonium ion mechanism, the products would have been the methyl ethers which were in no case isolated. These results eliminate not only the carbonium ion as a possible intermediate but also exclude the displacement reaction involving a cleavage of the SO-R linkage.

In view of some recent work of Shoppee, who has pointed out that derivatives of the unsaturated series[8] (X) react differently from those of the saturated series[9] (XI), the hydrolysis of the sulfates of the two unsaturated steroids, cholesterol and dehydroisoandrosterone cannot be unobjectionably interpreted with respect to the direction of cleavage of the S–O–R linkage.



Replacement of chlorine by acetoxyl and replacement of hydroxyl by chlorine in derivatives of the unsaturated series (X) was accomplished with retention of configuration, whereas these replacement reactions were accompanied by inversion with the saturated compounds (XI) cholestane and androstane. Since the presence of the β,γ-double bond influences the steric course of reactions at the asymmetric C_3, most of the reactions reported here were carried out with derivatives of the saturated steroids in order to facilitate the interpretation of the experimental results.

It is important to note that in the reactions with silver acetate in acetic acid the uninverted **alcohol** was isolated. The cholestanol acetates found among the reaction products were probably not produced by the displacement of the sulfate ion by the acetate ion. Such a displacement must lead to inversion, and since this was not observed in any experiment, the ester must result from the secondary acetylation of the alcohol produced by fission of the sulfate. In agreement with this interpretation we have found that cholestanol-3α acetate is formed from cholestanol-3α under the same experimental conditions employed for the cleavage, whereas cholestanol-3α acetate was recovered unchanged when subjected to this treatment. The formation of the uninverted **alcohols** from the reactions with silver acetate can only be explained by the direct cleavage of the S–OR linkage. In addition to this, it is apparent that under the somewhat more drastic conditions utilized in these reactions, some cleavage of the SO-R bond has occurred as evidenced by the formation of small amounts of neocholestene.

While the formation of unsaturated substances is without significance for the problem of Walden inversion in the displacement reaction, it has considerable interest because similar unsaturated derivatives of steroids have been frequently isolated from urine. Among these are the compounds: $\Delta^{2(\text{or } 3)}$-androstenone-17,[10] $\Delta^{3,5}$-androstadienone-17,[11] Δ^{9}-etiocholenol-3α-one-17[12] and Δ^{9}-androstenol-3α-one-17.[13] The first two of these substances very probably arise from androsterone and dehydroisoandrosterone which have been shown to be, in part at least, excreted as sulfates in human urine. In our experiments, neocholestene was found in only those reactions conducted at elevated temperature and it is likely that it is produced from the steroid sulfate by an elimination reaction. The unsaturated steroid derivatives which are isolated from urine after hydrolysis at reflux temperature are also probably formed by such an elimination reaction and need not necessarily be produced by the prolonged action of the hot acid on the free steroid alcohols resulting from the cleavage of the conjugates. This contention is supported by the results of Talbot, Ryan and Wolfe[14] who, working with the sulfate of dehydroisoandrosterone reported that "acid hydrolysis damages the conjugated dehydroisoandrosterone sterone before hydrolysis to the unconjugated form." Since it appears that temperature is the factor which favors the elimination reaction of these steroid sulfates, the hydrolytic procedure employed in this investigation involving only a room temperature extraction offers marked advantage for the circumvention of this undesirable reaction.

Experimental[15,16]

Sodium Cholesterol Sulfate.—This compound was prepared with pyridine sulfur trioxide according to the method of Sobel[17] and crystallized from methanol–ether as shiny plates, m. p. 182–183°. It was dried for analysis at 100° *in vacuo* for twenty-four hours.

Anal. Calcd. for $C_{27}H_{45}O_4SNa\cdot 3H_2O$: Na, 4.23. Found: Na, 4.14.

Potassium Dehydroisoandrosterone Sulfate.—This substance was prepared according to the method of Sobel.[17] After several recrystallizations from ethanol–ether, potassium dehydroisoandrosterone sulfate melted at 221–223°.

Anal. Calcd. for $C_{19}H_{27}O_5SK$: K, 9.6; S, 7.88. Calcd. for $C_{19}H_{27}O_5SK\cdot H_2O$: K, 9.2; S, 7.55. Found: K, 9.23; S, 7.70.

Sodium Cholestanol-3β Sulfate.—To a cold solution of 1 g. of cholestanol-3β in 30 cc. of dry ether, 0.4 cc. of chlorosulfonic acid was added dropwise with swirling. After the mixture stood for one hour at room temperature, the ether was removed by distillation under reduced pressure. To the residue 4 cc. of 2 *N* sodium hydroxide solution was added slowly while the mixture was cooled in an ice-bath. The crystalline precipitate which formed was collected on a Büchner funnel, washed several times with ether and dried (1.15 g., 91%). Several recrystallizations from methanol yielded pure sodium cholestanol-3β sulfate, m. p. 174–175.5°; $[\alpha]^{29}D$ +16.6 ± 4° (ethanol).

Anal. Calcd. for $C_{27}H_{47}O_4SNa$: C, 66.08; H, 9.65; S, 6.53; Na, 4.69. Found: C, 66.04; H, 9.72; S, 6.61; Na, 4.52.

Sodium Cholestanol-3α Sulfate.—This sulfate was prepared in 76% yield according to the method of Sobel.[17] After three recrystallizations from methanol, sodium cholestanol-3α sulfate melted at 136–137°; $[\alpha]^{29}D$ +15.0 ± 5° (ethanol).

Anal. Calcd. for $C_{27}H_{47}O_4SNa$: C, 66.08; H, 9.65; S, 6.53; Na, 4.69. Found: C, 65.91; H, 9.54; S, 6.39; Na, 4.55.

It was also prepared in 95% yield using chlorosulfonic acid as described for cholestanol-3β sulfate. In general the preparation of the steroid sulfates by the chlorosulfonic acid method was more convenient and gave higher yields than the pyridine sulfur trioxide method.

Cholestanol-3β Sulfite.—To a solution of 1.5 g. of cholestanol-3β in 25 cc. of dry ether and 1 cc. of pyridine was added slowly 5 cc. of dry ether containing 0.2 cc. of thionyl chloride. After standing overnight at room temperature, an equal volume of ether was added to the mixture. The ether solution was washed with dilute hydrochloric acid solution, water, sodium bicarbonate solution and water and dried over sodium sulfate. The ether was then evaporated and the residue digested with 50 cc. of ethanol. The hot suspension was filtered to separate the insoluble starting material (650 mg.), m. p. 135–139°. The filtrate was evaporated to dryness and the residue (720 mg.) was digested in 100 cc. of hot acetone. On cooling, 690 mg. of platelets, m. p. 196–197°, was obtained. Cholestanol-3β sulfite was recrystallized for analysis from ethyl acetate and dried overnight in vacuo at 100°; m. p. 196–197.5°; reported[9] 194°; $[\alpha]^{31}D$ +5.2 ± 2.5° (chloroform).

Anal. Calcd. for $C_{54}H_{94}O_3S$: C, 78.77; H, 11.51; S, 3.89. Found: C, 78.71; H, 10.91; S, 3.97.

Cholestanol-3α Sulfite.—This compound was prepared in the same manner as the 3β isomer. When the reaction product was digested with ethanol, the cholestanol-3α sulfite was separated as the insoluble fraction. Recrystallization from ethyl acetate gave tiny rods, m. p. 210.5–211.5°. After drying *in vacuo* at 100° overnight the m. p. was lowered to 204–205°; $[\alpha]^{31.5}D$ +39.0 ± 2° (chloroform).

Anal. Calcd. for $C_{54}H_{94}O_3S$: C, 78.77; H, 11.51; S, 3.89. Found: C, 79.00; H, 11.28; S, 4.08.

Acid Hydrolysis of Sodium Cholestanol-3α Sulfate.—A suspension of 150 mg. of sodium cholestanol-3α sulfate in 50 cc. of 0.2 *N* hydrochloric acid solution (*p*H 0.9) was extracted with ether in a continuous extractor for forty-eight hours at room temperature. The ether extract was washed with sodium carbonate solution and water, dried over sodium sulfate, and then evaporated to dryness yielding a crystalline residue weighing 116 mg. (97% of the theoretical yield).

The crystalline residue was dissolved in 8 cc. of absolute ethanol and a solution of 100 mg. of digitonin in 2 cc. of 50% ethanol was added. The mixture was allowed to stand overnight at room temperature during which time the digitonide precipitated. About 100 cc. of anhydrous ether was added, the suspension was centrifuged and the supernatant ether was carefully decanted. This process was repeated several times with fresh portions of ether. The ether extracts were combined, washed with small portions of water and dried. Evaporation of the ether left 96 mg. (81%) of cholestanol-3α, m. p. 183–187°. Recrystallization from acetone gave a sample melting at 185–187°; $[\alpha]^{23}D$ +30.0 ± 2° (ethanol); reported[18] $(\alpha)D$ +33.9°, and which did not depress the m. p. of an authentic sample of cholestanol-3α, m. p. 186–187°. Cholestanol-3α acetate was prepared in the usual way, m. p. 94–95.5° (methanol); reported[19] m. p. 95–96°.

The ether insoluble digitonide was dissolved in 5 cc. of pyridine and heated on a steam-bath for one hour. After cooling to room temperature, 100 cc. of anhydrous ether was added to precipitate the digitonin. The suspension was centrifuged, the supernatant carefully decanted, and the process repeated with fresh portions of ether. The ether fractions were combined, washed with 10% sulfuric acid solution and water, and dried over sodium sulfate. Upon evaporation of the ether, 19 mg. (16%) of a crystalline residue, m. p. 175–182° with softening at 150°, was obtained. Recrystallization from acetone gave 12 mg. of cholestanol-3α identified by its infrared spectrum and m. p. 185–186°. The presence of cholestanol-3α in the β-hydroxy steroid fraction was not unexpected since Noller[20] has shown that α-hydroxy as well as β-hydroxy steroids may form insoluble digitonides.

The oily material (7 mg.) remaining in the mother liquor from the above recrystallization was submitted to infrared spectroscopy. The spectrum obtained showed absorption characteristic of cholestanol-3α in the region 1185–875 cm.$^{-1}$. In Figure 1 are shown the infrared absorptions of cholestanol-3α and cholestanol-3β in the region of 1185–875 cm.$^{-1}$. These curves are the tracings obtained directly from the automatic recording instrument. They illustrate the relative characteristic absorption of these compounds in this region of the infrared and they demonstrate how these tracings can be used for the rapid detection and identification of compounds with-

(15) The melting points were determined in a Hershberg melting point apparatus and are correct to about ±1°. The analyses were done by Dr. A. Elek, Rockefeller Institute for Medical Research, and Mr. J. Alicino, Metuchen, N. J.

(16) We wish to express our gratitude to Dr. K. Dobriner and Mrs. P. Humphries for their help in determining and interpreting the infrared spectra reported herein.

out the necessity of establishing the per cent. transmission curves.[21]

In this experiment 91% (100 mg.) of crystalline cholestanol-3α was obtained from its sulfate by hydrolysis. If any isomeric cholestanol-3β was present in the residue from the mother liquor of the β-hydroxy fraction, it was in too small an amount to be detected by infrared analysis.

Acid Hydrolysis of Sodium Cholestanol-3β Sulfate.—A suspension of 200 mg. of sodium cholestanol-3β sulfate in 50 cc. of 0.2 *N* hydrochloric acid solution (*p*H 0.9) was extracted in a continuous extractor for nineteen hours at room temperature. The ether extract was washed with sodium carbonate solution and water and dried over sodium sulfate. Evaporation of the solvent yielded 156 mg. (98% of the theoretical). This material was recrystallized from acetone (113 mg.), m. p. 143–143.5°, reported[22] 141–142°; $[\alpha]^{29}D$ +33.2 ± 5°; reported[18] $[\alpha]D$ +28.8°; admixture with pure cholestanol-3β did not depress the melting point. Cholestanol-3β acetate was prepared in the usual way. After recrystallization from methanol, it melted at 108–110°; reported[22] m. p. 110–111°; the admixture with an authentic sample did not depress the melting point.

The mother liquor from the recrystallization of the cholestanol-3β was concentrated to dryness and the residue (43 mg.) was separated by digitonin as described above. The crystalline β-hydroxy steroid fraction weighed 26 mg. Recrystallization from acetone gave cholestanol-3β, m. p. 140.5–141°. Infrared analysis of the material remaining in the mother liquor demonstrated the presence of cholestanol-3β; no α-isomer was indicated. The non-crystalline α-hydroxysteroid fraction weighed 11 mg. and showed no characteristic absorption between 1185 and 875 cm.$^{-1}$. The presence of cholestanol-3α in quantities greater than 1 mg. would have been detected in this fraction by this method.

Eighty-eight per cent of crystalline cholestanol-3β was obtained by acid hydrolysis of its sulfate.

Acid Hydrolysis of Sodium Cholesterol Sulfate.—A suspension of 150 mg. of sodium cholesterol sulfate in 50 cc. of 0.2 *N* hydrochloric acid was extracted with ether in a continuous extractor for forty-eight hours at room temperature. The ether extract was worked up in the same manner as that used for sodium cholestanol-3α sulfate. The residue from the ether extract weighed 106 mg. (98% based on hydrated sulfate). After digitonin separation the crystalline β-hydroxy fraction weighed 93 mg. (86%). Recrystallization from acetone gave a sample, m. p. 147–148.5°; $[\alpha]^{22}D$ −30.0 ± 2° (ethanol); which did not depress the melting point of an authentic sample of cholesterol; reported[23] $[\alpha]D$ −29.9° (ethanol). The acetate melted at 114.5–115.5° and did not depress the m. p. of an authentic sample.

The α-hydroxy fraction (10 mg.) was a brown oil which did not crystallize. Infrared analysis indicated no characteristic absorption in the region 1185–875 cm.$^{-1}$.

Acid Hydrolysis of Potassium Dehydroisoandrosterone Sulfate.—By the foregoing procedure 150 mg. of potassium dehydroisoandrosterone sulfate was hydrolyzed. The hydrolysate weighed 96 mg. (94% based on hydrated sulfate) and was separated by digitonin. The β-hydroxysteroid fraction weighed 87 mg. (85%) and after recrystallization from acetone, the product melted at 146–148°; $[\alpha]^{23}D$ +12.5 ± 2° (ethanol); reported[24] 148–149°; $[\alpha]D$ +10.9° (ethanol)[25]; the admixture with dehydroisoandrosterone melted at 145–147°. The acetate melted at 168–170°; reported[26] 170–171°.

The α-hydroxysteroid fraction weighed 8 mg. and was not crystalline. It showed no characteristic absorption in the 1185–875 cm.$^{-1}$ region of the infrared spectrum.

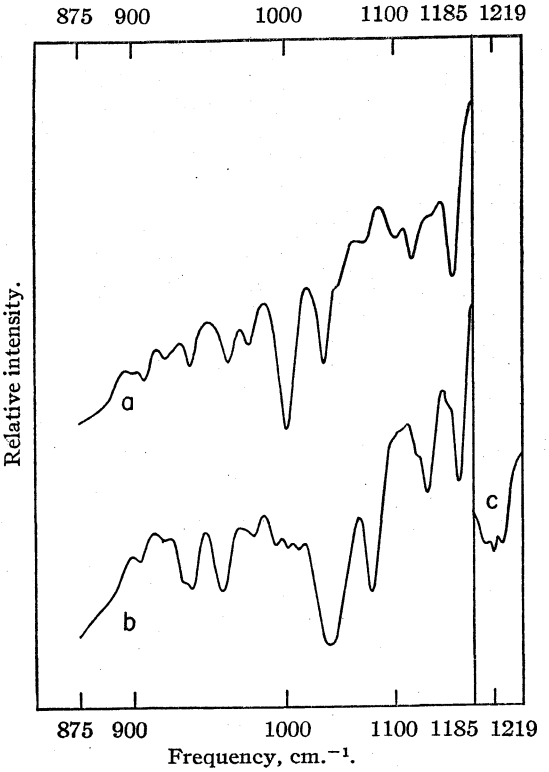

Fig. 1.—Infrared tracings of approximately 1% carbon disulfide solutions of (a) cholestanol-3α and (b) cholestanol-3β taken in a 1-mm. cell. Curve C shows some characteristic absorption bands of acetone vapor which is used as an external standard.

Reaction of Sodium Cholestanol-3α Sulfate with Silver Acetate.—About 20 cc. of anhydrous acetic acid (distilled over triacetyl borate)[27] was distilled into a flask containing 100 mg. of sodium cholestanol-3α sulfate and 200 mg. of silver acetate and the mixture was refluxed for four hours. The acetic acid was distilled *in vacuo* and the residue was extracted several times with ether. The ether extract was washed with sodium carbonate solution, water and dried over sodium sulfate. The oily residue (75 mg.) was dissolved in 7 cc. of ligroin and chromatographed on 2 g. of alumina.[28] Three fractions were obtained: (1) 2 mg. of oil eluted by ligroin and identified by infrared analysis as neocholestene. (2) 51 mg. of crystalline cholestanol-3α acetate, eluted with ligroin. Recrystallization from methanol–acetone gave needles melting at 95.5–96°, which did not depress the melting point of an authentic sample. Infrared analysis of the mother liquor showed the presence of cholestanol-3α acetate, but did not indicate any cholestanol-3β acetate. (3) 22 mg. of crystalline cholestanol-3α after recrystallization from methanol–acetone melting at 186–187°.

(26) Ruzicka and Wettstein, *Helv. Chim. Acta*, **18**, 986 (1935).

(27) Eichelberger and LaMer, THIS JOURNAL, **55**, 3633 (1933). This experiment was repeated with acetic acid which was dried simply by freezing and decantation and the results were essentially the same except that more neocholestene was formed. The neocholestene was identified by m. p. (70–71°) and infrared analysis.

(28) This alumina was specially prepared and kindly made available to us by Dr. T. F. Gallagher [Hollander and Gallagher, *J. Biol. Chem.*, **162**, 549 (1946)]. It has been observed that 3-acetoxysteroids are not appreciably hydrolyzed when chromatographed on this acetic acid-washed alumina.

Infrared analysis of the residue from the mother liquor did not indicate any cholestanol-3β.

The total amount of cholestanol-3α corresponds to 68 mg. (46 mg., as the acetate and 22 mg. as the free alcohol) or 86%.

When cholestanol-3α acetate was heated in acetic acid in the presence of silver acetate, cholestanol-3α acetate was recovered unchanged; cholestanol-3α under the same conditions yielded 62% cholestanol-3α acetate and 38% cholestanol-3α.

Reaction of Sodium Cholestanol-3β Sulfate with Silver Acetate.—A suspension of 100 mg. of sodium cholestanol-3β sulfate, 200 mg. of silver acetate and 20 cc. of acetic acid (distilled over triacetyl borate) was refluxed for four hours. The reaction mixture was worked up as above and yielded on chromatographic analysis: (1) 39 mg. of crystalline cholestanol-3β acetate. After recrystallization from methanol–acetone, 29 mg., m. p. 109–110°, was obtained. The residue in the mother liquor was shown by infrared analysis to be cholestanol-3β acetate. (2) 28 mg. of crystalline cholestanol-3β. After recrystallization from methanol–acetone, it weighed 18 mg., m. p. 140–142°. Infrared analysis of the mother liquor again indicated the presence of only the β isomer. The amount of cholestanol-3β recovered was 63 mg. (35 mg. as the acetate and 28 mg. as the alcohol) or 80%.

Reaction of Sodium Cholestanol-3α Sulfate in Methanolic Hydrogen Chloride.—Dry hydrogen chloride gas was bubbled through a suspension of 185 mg. of sodium cholestanol-3α sulfate in 20 cc. of absolute methanol for five minutes. The sulfate dissolved immediately but after the solution remained overnight at room temperature, a precipitate had formed. The product (101 mg., 69%) melted at 186–186.5°, and when mixed with an authentic sample of cholestanol-3α, the melting point was not depressed.

The filtrate was concentrated to dryness and extracted with ether. The ether extract was washed with sodium carbonate solution and water, dried and the solvent removed by distillation under reduced pressure. The residue (31 mg.), m. p. 175–183°, was separated by digitonin. The α-hydroxy fraction (16 mg., 11%) was crystalline cholestanol-3α, m. p. 185–187°. The digitonide was dissociated and yielded 11 mg., m. p. 165–178°. Crystallization from acetone gave cholestanol-3α, m. p. 185–186°. The residue (2 mg.) from the mother liquor had an infrared spectrum characteristic of cholestanol-3α and there was no absorption characteristic of cholestanol-3β. In this experiment 126 mg. (86%) of crystalline cholestanol-3α was obtained.

Reaction of Sodium Cholestanol-3β Sulfate with Methanolic Hydrogen Chloride.—Sodium cholestanol-3β sulfate (200 mg.) was suspended in 20 cc. of absolute methanol into which dry hydrogen chloride gas had been bubbled for five minutes. The mixture was allowed to stand overnight at room temperature and the solvent removed by distillation under reduced pressure. The residue was extracted with ether, the ether solution was washed with sodium carbonate solution and water, and dried. Evaporation of the solvent yielded 144 mg. which was recrystallized from acetone. Sixty-six mg. (42%), m. p. 142–142.5° was obtained which upon mixing with cholestanol-3β did not depress the melting point. The residue (78 mg.) from the crystalline product was separated by digitonin. The β-hydroxy fraction (69 mg., 44%) was crystalline and upon crystallization from acetone gave cholestanol-3β, m. p. 140–142°. The residue (4 mg.) showed absorption bands in the infrared characteristic of cholestanol-3β. The non-crystalline α-hydroxysteroid fraction weighed 7 mg. and exhibited no characteristic absorption in the 1185–875 cm.$^{-1}$ region. The total yield of crystalline cholestanol-3β was 86%.

Reaction of Cholestanol-3α Sulfite with Silver Acetate.—A mixture of 150 mg. of cholestanol-3α sulfite with 200 mg. of silver acetate was refluxed seven hours in 45 cc. of acetic acid (dried by freezing and decantation). After working up in the usual way, 151 mg. of an ether soluble oil, was obtained. It was separated by chromatographic analysis on 4.6 g. of alumina and yielded 14 mg. of neocholestene, 70 mg. of crystalline cholestanol-3α acetate (recrystallized from acetone, 55 mg., m. p. 87–91°), 12 mg. of unreacted sulfite (eluted with benzene–ligroin (1:1)), and 42 mg. crystalline cholestanol-3α (recrystallized from methanol–acetone, 26 mg., m. p. 186.5–187°). The cholestanol-3α recovered amounted to 106 mg. (64 mg. as the acetate and 42 mg. as the alcohol) or 84% based on the sulfite which had reacted.

The compounds were identified by melting point and infrared spectral analysis. The infrared analysis of the residues showed that only cholestanol-3α and its acetate were present. Neither cholestanol-3β nor its acetate was detected.

Reaction of Cholestanol-3β Sulfite with Silver Acetate.—A mixture of 150 mg. of cholestanol-3β sulfite, 200 mg. of silver acetate and 45 cc. of anhydrous acetic acid was refluxed for four hours. The reaction mixture was worked up in the usual way and yielded on chromatographic analysis: (1) 2 mg. of neocholestene; (2) 11 mg. of unreacted sulfite; (3) 58 mg. of crystalline cholestanol-3β acetate which melted at 107–109.5° after a recrystallization from methanol–acetone. The infrared analysis of the mother liquor indicated the presence of only cholestanol-3β acetate; (4) 58 mg. of crystalline cholestanol-3β. After recrystallization from methanol, 43 mg., m. p. 140–142° was obtained. The residue in the mother liquor was shown by infrared analysis to be cholestanol-3β.

Reaction of Cholestanol-3α Sulfite with Methanolic Hydrogen Chloride.—Dry hydrogen chloride was bubbled through 20 cc. of absolute methanol for five minutes. After the solution had cooled to room temperature, 100 mg. of cholestanol-3α sulfite was added and the suspension allowed to stand at room temperature for twenty-four hours. The reaction product was worked up in the usual way and chromatographed on alumina. The fractions obtained were: 4 mg. of an oil eluted with ligroin whose spectra could not be identified, 15 mg. of unreacted sulfite, and 64 mg. (80% based on reacted sulfite) of crystalline cholestanol-3α, m. p. 181–185°.

Reaction of Cholestanol-3β Sulfite with Methanolic Hydrogen Chloride.—Cholestanol-3β sulfite (100 mg.) was treated with methanolic hydrogen chloride as above. The reaction product was worked up in the usual way and chromatographed on alumina. Twenty-four milligrams of cholestanol-3β sulfite, and 69 mg. (95% based on reacted sulfite) of cholestanol-3β were obtained. Recrystallization from methanol–acetone gave 60 mg. of m. p. 141–142°. The infrared analysis of the mother liquor from the recrystallization of cholestanol-3β showed the presence of only the β-isomer.

Summary

The acid sulfates and the sulfites of several steroids have been prepared and their cleavage has been studied. The reaction of these compounds with aqueous acid solution, dry hydrogen chloride in methanol, or silver acetate in acetic acid proceeds with retention of configuration indicating that these compounds react by a rupture of the S-OR linkage. These results are of biological importance because they demonstrate that the steroid acid sulfates excreted in the urine are hydrolyzed without Walden inversion.

Cyclic Polyolefins. I. Synthesis of Cycloöctatetraene from Pseudopelletierine[1]

BY ARTHUR C. COPE AND C. G. OVERBERGER[2]

This paper presents data amplifying our recent communication[3] which reported duplication of the Willstätter synthesis of cycloöctatetraene from pseudopelletierine.[4,5] Indirect evidence of three kinds had been interpreted as indicating that the Willstätter product might not have been 1,3,5,7-cycloöctatetraene[6]: Similarity of the product to styrene; the fact that catalytic dehydrogenation of cycloöctene at 425–455° yielded styrene; proof that application of the Hofmann exhaustive methylation procedure to diaminobutanes (investigated as open chain models of intermediates in the Willstätter synthesis) yielded ethylacetylene and methylallene in addition to the conjugated 1,3-butadiene. Development of a catalytic synthesis of cycloöctatetraene from acetylene[7] has renewed interest in the hydrocarbon. A correspondence in properties[7] made it appear likely that the catalytic and Willstätter products were identical. This has now been fully established by repetition of the Willstätter synthesis and direct comparison of the product with cycloöctatetraene prepared catalytically from acetylene.

Our synthesis began with the preparation of pseudopelletierine (I) from glutaraldehyde, methylamine and acetonedicarboxylic acid.[8] Subsequent steps are shown in the equations, which include yields and a comparison of the melting points of solid intermediates with those recorded previously. The following evidence was obtained for the structures of intermediates. N-Methylgranatenine (III) was hydrogenated quantitatively in the presence of Adams platinum catalyst to the corresponding saturated compound, N-methylgranatanine, m. p. 47–48.5° (lit. 49–50°).[9] The diene resulting from the first Hofmann exhaustive methylation step (α-des-dimethyl-granatenine, V) also was hydrogenated quantitatively and yielded dimethylaminocycloöctane, which was identified by its physical properties and also converted to the methiodide, m. p. 274–275° (dec.) (lit. 270–271°).[4] The ultraviolet absorption curve of V (Fig. 1) showed a maximum at approximately 2200 Å. (log ε 3.9) indicating conjugation of the two double bonds; compare $\lambda_{max.}$ 2170 Å. (log ε 4.32) for 1,3-butadiene.[10] 1,3,5-Cycloöctatriene (VII), the product of the second exhaustive methylation step in the synthesis, absorbed three molar equivalents of hydrogen in a quantitative hydrogenation and yielded cycloöctane. The ultraviolet absorption spectrum of VII (Fig. 2) showed a maximum at 2650 Å. (log ε 3.57) indicating conjugation of the three double bonds. The absorption maximum for an open-chain conjugated triene, 2,4,6-octatriene, is cited as 2600 Å. (log ε 3.90).[11]

The dibromide prepared by adding bromine to VII was not isolated, but was treated directly with dimethylamine to form a bis-(dimethylamino)-cycloöctadiene which was formulated by Willstätter and Waser[4] as VIII. Our data support but do not rigorously prove this structure, in the absence of information definitely establishing the relative positions of the two dimethylamino groups. Quantitative hydrogenation of VIII yielded a bis-(dimethylamino)-cycloöctane believed to be the 1,4-isomer, which was converted to a dimethiodide, m. p. 258–259° (dec.). The purification of VIII included treatment with warm, dilute hydrochloric acid, which would eliminate easily hydrolyzed vinylamine type isomers. The ultraviolet absorption spectrum of VIII (Fig. 1) approached a maximum below but near 2200 Å., indicating conjugation of the two double bonds. These data appear to eliminate all possible isomeric structures derivable from VII except VIII and 1,2-bis-(dimethylamino)-3,5-cycloöctadiene. It should be noted that both bromines would be allylic in type in the product of 1,6-, 1,4 or 3,4-addition of bromine to 1,3,5-cycloöctatriene, and that the displacement reaction with dimethylamine could proceed with rearrangement, so that the diamine does not necessarily have the same arrangement of groups as the dibromide. Through a combination of displacement with and without rearrangement any of the four possible dibromides (products of 1,2-, 1,4-, 1,6- or 3,4-addition) could lead to either structure VIII or to 1,2-bis-(dimethylamino)-3,5-cycloöctadiene, and accordingly the dibromide could have any of these structures or be a mixture. The diamine (VIII) reacted with methyl iodide to give an excellent yield of a pure, crystalline dimethiodide (IX), and accordingly is homogeneous rather than a mixture of isomers.

The final exhaustive methylation gave a low yield of cycloöctatetraene (X), and a high proportion of polymer. After purification by distillation through a Craig micro-fractionating column[12] the cycloöctatetraene was obtained in 6.5–8.6% yield as a light yellow liquid, $n^{25}D$ 1.5342. The melting point of the product was −5.8 to −5.4°, and was not depressed on mixture with a sample prepared catalytically from acetylene.[13] The maleic anhydride adducts obtained from cycloöctatetraene from the two sources also were identical (m. p. and mixed m. p.). Both samples of cycloöctatetraene had practically identical ultraviolet (Fig. 3) and infrared absorption spectra.[14] The synthetic

(13) By the German procedure described by Copeland and Youker in Fiat Final Report No. 720, 1946, p. 26 (distributed by the Office of the Publication Board, U. S. Department of Commerce).

(14) We are indebted to Dr. R. C. Lord, Jr., and Mr. R. S. McDonald for the infrared data, which will be published separately. Infrared spectra also were determined for intermediates I, II, III, V, VII and VIII. The spectra contain nothing inconsistent with the structures assigned to these compounds, and have no features which would indicate the presence of allene or acetylene structures.

sample absorbed four molar equivalents of hydrogen in the presence of Adams platinum catalyst and yielded cycloöctane.

The melting point observed for the synthetic cycloöctatetraene is of interest, because Willstätter and Heidelberger[5] had reported a freezing point of about −27° for their product, which was purified by vacuum distillation without fractionation. The molal freezing point depression constant of cycloöctatetraene was determined to be approximately 5.5. Using this value and assuming a m. p. of −5° for pure cycloöctatetraene, a m. p. of −27° would correspond to the presence of approximately 30% of an isomeric impurity. Infrared spectra[14] indicated the presence of small amounts of styrene (in the neighborhood of 3%) in our samples of cycloöctatetraene prepared by the Willstätter synthesis and in most samples prepared from acetylene. This impurity may have been responsible for the low freezing point originally reported for cycloöctatetraene, and may have been removed from our product during the fractional distillation, possibly by polymerization.

Experimental[15]

N-Methylgranatoline (II).[9]—A solution of 78.9 g. of pseudopelletierine (b. p. 101° (7 mm.), m. p. 45–46°)[8] in 1550 ml. of commercial absolute ethanol was placed in a 3-liter three-necked flask equipped with an efficient reflux condenser. The solution was heated to the boiling point and 120 g. of sodium was added in small pieces during two to three hours, as rapidly as possible without flooding the condenser. After all of the sodium had reacted, the mixture was cooled, diluted with 600 ml. of water and concentrated under reduced pressure until the residue contained an aqueous phase of approximately 100 ml. After cooling, 300 ml. of water and 500 ml. of ether were added to the residue and the ether solution was separated. The aqueous solution was extracted with 500 and 200 ml. portions of ether, and the combined ether extracts were dried over magnesium sulfate. The solvent was removed under reduced pressure and the brown solid residue recrystallized from commercial hexane, b. p. 60–66°. II was obtained as brown plates in two crops; yield 66.6 g. (83.5%), m. p. 86–95°. The average yield in four preparations was 82%. The crude product was sufficiently pure for use in preparing III. Several recrystallizations from ligroin (b. p. 74–93°) gave II as small, white plates, m. p. 98–99.1°.

Anal. Calcd. for $C_9H_{17}NO$: C, 69.60; H, 11.04; N, 9.02. Found: C, 69.88; H, 11.06; N, 9.31.

Willstätter and Waser[4] stated that II was obtained from natural pseudopelletierine in a yield corresponding to 80%.

N-Methylgranatenine (III).—Glacial acetic acid (34 g.) was added with cooling to 66.6 g. of N-methylgranatoline (II). Concentrated sulfuric acid (122 g.) was added slowly with cooling to the resulting sirup. The solution was placed in a flask attached to a reflux condenser and heated in a bath at 165° for six and one-half hours. The mixture was cooled, 400 ml. of water was added and the solution was made basic by adding a 20% sodium hydroxide solution with good cooling. The dark oil which separated was taken up in 200 ml. of ether and the aqueous layer was extracted with four 300-ml. portions of ether. In some cases emulsions were formed during the extraction. Water was added if necessary to keep inorganic salts in solution. The extracts were dried over magnesium sulfate and the product was distilled through a column with a 20 × 1.2 cm. section packed with glass helices. The yield of III was 50.3 g. (85.5%), b. p. 71–72° (17 mm.). The average yield in four preparations was 85.5%. A sample purified by redistillation had the following physical constants: b. p. 56° (10 mm.); m. p. 16.5–17°; $n^{25}D$ 1.4945; d^{25}_4 0.9549.

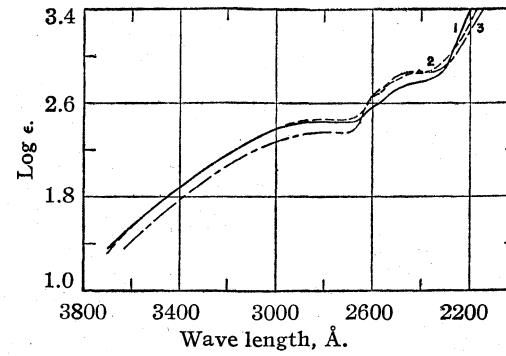

Fig. 3.—Absorption spectrum of cycloöctatetraene. Curve 1, sample prepared from acetylene, freshly distilled; curve 2, sample prepared from pseudopelletierine; curve 3, sample prepared from acetylene, four days after distillation.

Anal. Calcd. for $C_9H_{15}N$: C, 78.77; H, 11.01; N, 10.20. Found: C, 78.77; H, 11.09; N, 10.55.

This procedure is based upon the preparation of tropidine from tropine described by Ladenburg[16] and Willstätter.[17] Willstätter and Waser[4] reported b. p. 62–62.2° (9 mm.) and m. p. 17.2–17.4° for III prepared in a similar manner in unspecified yield.

Hydrogenation of 1 g. of III in 16 ml. of absolute ethanol in the presence of 0.3 g. of pre-reduced Adams platinum catalyst was complete in two hours and required 103.6% of one molar equivalent of hydrogen. The product, N-methylgranatanine, was isolated by distillation under reduced pressure. It crystallized as a hygroscopic solid and was purified by sublimation at 40° and 3 mm.; m. p. 47–48.5°.

Anal. Calcd. for $C_9H_{17}N$: C, 77.39; H, 12.30; N, 10.06. Found: C, 77.34; H, 12.35; N, 10.00.

Ciamician and Silber[9] reported the m. p. of N-methylgranatanine obtained by the phosphorus and hydroiodic acid reduction of III as 49–50°. Willstätter and Veraguth[18] reported m. p. 55–58° for the compound, prepared by electrolytic reduction of pseudopelletierine. Their product was not analyzed and may have contained some N-methylgranatoline, which also was obtained from the electrolytic reduction.

N-Methylgranatanine was converted to the methiodide by heating to reflux with an excess of methyl iodide in cyclohexane solution. The salt which separated on cooling was recrystallized from 80% ethanol as a white powder, m. p. 353–359° (dec.).

Anal. Calcd. for $C_{10}H_{20}NI$: I, 45.13. Found: I, 45.06.

N-Methylgranatenine Methiodide (IV).—N-Methylgranatenine (III) (50.3 g.), methyl iodide (78 g.) and 500 ml. of cyclohexane were placed in a 1-liter flask attached to a reflux condenser and heated to 40° for three hours. After addition of 5 g. of methyl iodide the mixture was heated at 40° for an additional two hours. Filtration separated 96.5 g. of IV, a white crystalline salt. The filtrate was warmed with 10 g. of methyl iodide for three hours at 40°. An additional 2 g. of IV was obtained, making the yield 98.5 g. (96%). The average yield in

(15) Melting points are corrected and boiling points are uncorrected. We are indebted to Mr. S. M. Nagy, Mr. Philip H. Towle and Mrs. Louise W. Spencer for analyses.

(16) Ladenburg, *Ann.*, **217**, 118 (1882).

(17) Willstätter, *ibid.*, **326**, 28 (1902).

(18) Willstätter and Veraguth, *Ber.*, **39**, 1984 (1905).

four preparations was 96.5%. An analytical sample was recrystallized from 95% ethanol; m. p. 352–357° (dec.) after partial sublimation at 280°.

Anal. Calcd. for $C_{10}H_{18}NI$: C, 43.02; H, 6.49; N, 5.01; I, 45.46. Found: C, 42.79; H, 6.59; N, 4.88; I, 45.15.

α-Des-dimethylgranatenine (V).—Silver hydroxide was prepared by adding a solution of 28.3 g. of sodium hydroxide in 150 ml. of water to 120 g. (0.706 mole) of silver nitrate in 400 ml. of water. The precipitate was washed until free from alkali and added to 98.5 g. (0.353 mole) of the methiodide (IV) and 400 ml. of water in a 1-l. flask. After mechanical stirring and heating at 60° for one hour, the mixture was filtered. The silver iodide–silver hydroxide mixture was washed with water on the filter and then heated with 100 ml. of water at 60–70° with intermittent shaking for fifteen minutes. After again filtering, the combined filtrates were concentrated under reduced pressure. The concentrate was transferred to a 250-ml. Claisen flask attached to a well-cooled receiver and the quaternary base was decomposed (with some foaming) by heating in a bath at 100–110° at 15–20-mm. pressure. The upper parts of the flask were rinsed with 10 ml. of water to dissolve any remaining quaternary base, and the solution was again distilled to dryness in the same manner.

The colorless oil was separated from the water in the distillate by extraction with 50 and 100 ml. portions of ether. The ether extracts were dried over magnesium sulfate and distilled through a column with a 20 × 1.2 cm. section packed with glass helices. Foaming interfered with the distillation, which yielded 44.3 g. (83%) of V, b. p. 80° (12 mm.). The average yield in four preparations was 81.5%. An analytical sample had the following properties: $n^{25}D$ 1.4988; d^{25}_4 0.9038; M_D calcd. 49.18, found 49.12.

Anal. Calcd. for $C_{10}H_{17}N$: C, 79.40; H, 11.33; N, 9.26. Found: C, 79.46; H, 11.20; N, 9.25.

Willstätter and Waser[4] reported a 90% yield of V, b. p. 71–71.5° (8 mm.); d^{20}_4 0.910.

Hydrogenation of 1.5 g. of V in the presence of 0.2 g. of pre-reduced Adams platinum catalyst in 16 ml. of absolute ethanol was complete in four hours and required 101% of two molar equivalents of hydrogen. After separation of the catalyst, distillation yielded 1.3 g. (85%) of dimethylaminocycloöctane. After redistillation, its properties were b. p. 110° (40 mm.); $n^{25}D$ 1.4707; d^{25}_4 0.877; M_D calcd. 50.14, found 49.76.

Anal. Calcd. for $C_{10}H_{21}N$: C, 77.34; H, 13.63; N, 9.02. Found: C, 77.41; H, 13.45; N, 9.04.

The methiodide of dimethylaminocycloöctane obtained in this manner, prepared in cyclohexane solution and purified by recrystallization from a mixture of acetone and commercial hexane (b. p. 60–66°), had m. p. 274–275° (dec., slight darkening at 270°).

Anal. Calcd. for $C_{11}H_{24}NI$: C, 44.44; H, 8.13; N, 4.71; I, 42.70. Found: C, 44.39; H, 8.13; N, 4.49; I, 42.82.

Willstätter and Waser[4] reported b. p. 86–86.5° (11 mm.), $n^{20}D$ 1.4790, d^{20}_4 0.883 and M_D 49.78 for dimethylaminocycloöctane and m. p. 270–271° for its methiodide.

α-Des-dimethylgranatenine Methiodide (VI).—VI was prepared from 44.3 g. of V and 80 g. of methyl iodide in 500 ml. of cyclohexane. The conditions of reaction were similar to those described for the preparation of IV, and the product was obtained in two crops as slightly pink, chloroform soluble crystals; yield 81 g. (94.5%). The average yield in three preparations was 92.3%. An analytical sample was recrystallized from a mixture of acetone and commercial hexane; m. p. 183–183.5° (dec.).

Anal. Calcd. for $C_{11}H_{20}NI$: C, 45.05; H, 6.88; N, 4.77; I, 43.28. Found: C, 44.96; H, 7.05; N, 4.69; I, 42.90.

1,3,5-Cycloöctatriene (VII).—The freshly prepared, alkali-free silver hydroxide obtained from 77.6 g. of silver nitrate and 18.3 g. of sodium hydroxide was added to a solution of 67 g. of VI in 100 ml. of water. The reaction conditions were similar to those described under V. Foaming occurred during concentration and also during the decomposition of the quaternary base, which was conducted in a 500-ml. Claisen flask at a bath temperature of 90–110° and 20–30 mm. pressure. The organic layer which separated in the receiver, which was cooled with Dry Ice, was extracted with ether, dried over magnesium sulfate and distilled through a column with a 20 × 1.2 cm. section packed with glass helices. A trace of picric acid was added as a polymerization inhibitor before distillation. The yield of VII was 16.8 g. (70%), b. p. 65–66° (60 mm.). After redistillation its properties were: b. p. 45° (18 mm.); $n^{25}D$ 1.5248; d^{25}_4 0.9042; M_D calcd. 35.65, found 35.94.

Anal. Calcd. for C_8H_{10}: C, 90.50; H, 9.50. Found: C, 90.49; H, 9.51.

VII proved to be somewhat unstable and accordingly was used at once.

Willstätter and Waser[4] reported a 72% yield of VII.

Hydrogenation of 1 g. of VII in the presence of 0.2 g. of Adams platinum catalyst in 25 ml. of absolute ethanol was complete in one hour and required 99.5% of three molar equivalents of hydrogen. The cycloöctane formed could not be separated from ethanol by distillation. The alcohol solution was diluted with water and extracted with ether. The extracts were dried over magnesium sulfate, distilled and redistilled through a Craig micro fractionation column[12]; $n^{25}D$ 1.4562; m. p. 11.7°.

Anal. Calcd. for C_8H_{16}: C, 85.62; H, 14.37. Found: C, 85.57; H, 14.18.

1,6-*bis*-(Dimethylamino)-2,4-cycloöctadiene (VIII).—A solution of 28 g. (0.175 mole) of dry bromine in 130 ml. of dry, alcohol-free chloroform was added dropwise during five hours to 18.5 g. (0.175 mole) of VII in 250 ml. of dry chloroform at −20° with mechanical stirring in a flask protected from atmospheric moisture. The solution remained colorless throughout the addition and no hydrogen bromide was evolved. The chloroform was removed under reduced pressure at room temperature and 500 ml. of a benzene solution containing 1.48 moles of dry dimethylamine was added to the residue with cooling. Dimethylamine hydrobromide began to separate after a few minutes. After standing for eleven hours, the mixture was cooled and extracted with an excess of 15% hydrochloric acid. The acid extracts were made basic by adding an excess of 20% sodium hydroxide solution with cooling and extracted with four 200-ml. portions of ether. The ether was removed under reduced pressure, and approximately 300 ml. of 2 *N* hydrochloric acid was added to the residue. The acid solution was heated at 55–70° for three to five minutes to hydrolyze any substituted vinyl amine types present in the crude product. After cooling, the solution was extracted with 100 ml. of ether, made basic with 20% sodium hydroxide solution with cooling, and extracted with three 125-ml. portions of ether. The ether extracts of the basic solution were dried over magnesium sulfate for one hour and distilled under nitrogen through a column with a 20 × 1.2 cm. section packed with glass helices. VIII was obtained as a light straw-yellow liquid which was kept under nitrogen and cooled to prevent rapid darkening which occurred otherwise; yield 15.9 g. (47%); b. p. 116° (8 mm.), $n^{25}D$ 1.4990; d^{25}_4 0.9317.

Anal. Calcd. for $C_{12}H_{22}N_2$: C, 74.16; H, 11.41; N, 14.41. Found: C, 74.38; H, 11.13; N, 14.53.

The above procedure is similar to the one used by Willstätter and Waser.[4] These investigators purified their product by acid hydrolysis to remove vinyl amine types after distillation of VIII, before conversion to quaternary salts, and do not report physical constants for VIII after purification.

A sample of VIII was treated with picric acid in alcohol solution and converted into the dipicrate, which was recrystallized from a large volume of absolute alcohol containing 5–10% acetone; m. p. 194.6–195.2° (dec.).

Anal. Calcd. for $C_{24}H_{28}N_8O_{14}$: C, 44.17; H, 4.33; N, 17.17. Found: C, 44.41; H, 4.51; N, 16.97.

Hydrogenation of 0.879 g. of VIII in the presence of 0.3 g. of prereduced Adams catalyst was complete in seventeen hours and required 108% of two molar equivalents of hydrogen. Distillation followed by redistillation through the Craig micro column gave 1,4-bis-(dimethylamino)-cycloöctane, b. p. 105° (6 mm.), $n^{25}D$ 1.4823; d^{25}_4 0.9166.[19]

Anal. Calcd. for $C_{12}H_{26}N_2$: C, 72.65; H, 13.21; N, 14.13. Found: C, 72.53; H, 13.12; N, 14.08.

The product of a similar quantitative hydrogenation, in which 1.5 g. of VIII absorbed 103% of two molar equivalents of hydrogen in twenty-two hours, was distilled through the Craig micro column. Methyl iodide (4 g.) in 25 ml. of absolute ethanol was added to several fractions from this distillation (0.85 g.), and the mixture was boiled under reflux for three minutes. The yield of 1,4-bis-(dimethylamino)-cycloöctane dimethiodide was 1.98 g. (96%), m. p. after recrystallization from absolute ethanol 258–259° (dec.).

Anal. Calcd. for $C_{14}H_{32}N_2I_2$: C, 34.86; H, 6.69; N, 5.81; I, 52.64. Found: C, 35.07; H, 6.67; N, 5.60; I, 52.99.

Another sample of 1,4-bis-(dimethylamino)-cycloöctane obtained by hydrogenation of VIII was converted to the dipicrate, which was recrystallized from absolute ethanol; m. p. 171.5–172.2° (dec.).

Anal. Calcd. for $C_{24}H_{32}N_8O_{14}$: C, 43.90; H, 4.90; N, 17.07. Found: C, 43.96; H, 5.07; N, 16.88.

1,6-bis-(Dimethylamino)-2,4-cycloöctadiene Dimethiodide (IX).—Methyl iodide (35 g.) was added to 10.1 g. of VIII in 300 ml. of absolute ethanol. The reaction mixture was boiled under reflux for five minutes, 2 g. of methyl iodide was added, and the mixture was allowed to cool slowly. IX separated as colorless to light yellow crystals in three crops in a total yield of 24.2 g. (97.5%), m. p. after recrystallization from absolute ethanol 173.4–174.1° (dec.).

Anal. Calcd. for $C_{14}H_{28}N_2I_2$: C, 35.16; H, 5.90; N, 5.86; I, 53.08. Found: C, 35.27; H, 6.14; N, 5.87; I, 52.76.

Cycloöctatetraene (X).—The freshly prepared silver hydroxide obtained from 25.5 g. of silver nitrate and 6 g. of sodium hydroxide was added to 23 g. of the dimethiodide (IX) in 100 ml. of water. The suspension was stirred and heated at 30–40° for twenty-five minutes, cooled and filtered. The mixture of silver iodide and silver hydroxide was warmed with 75 ml. of water and shaken intermittently for ten minutes. The mixture was filtered and the combined filtrates were concentrated to a volume of 75 ml. by warming in a bath at 30–35° under reduced pressure. The residue was transferred to a 500-ml. Claisen flask and distilled at 0.5 mm. into a receiver cooled with a Dry Ice–solvent mixture. The decomposition of the quaternary base occurred with foaming at a bath temperature of 40–65° and 0.5 mm. pressure. The light yellow liquid which separated when the distillate was allowed to come to room temperature in a nitrogen atmosphere was extracted with a small volume of ether and dried over magnesium sulfate. The ether solution was concentrated and the product distilled through a Craig micro distillation column under nitrogen at 50 mm. The yellow product was separated from a polymeric distillation residue as six fractions; yield 0.43 g. (8.6%), $n^{25}D$ 1.5342; m. p. −5.8 to −5.4°; mixed m. p. with a sample of cycloöctatetraene prepared from acetylene (melting at −5.9 to −5.3°) −6.0 to −5.3°.

Anal. Calcd. for C_8H_8: C, 92.26; H, 7.74. Found: C, 92.47; H, 7.91.

A repetition of this preparation gave a 6.5% yield of X with the same physical properties.

A maleic anhydride adduct was prepared by heating 30 mg. of the sample of cycloöctatetraene described above and 20 mg. of maleic anhydride under nitrogen until refluxing occurred for two minutes. On cooling the mixture solidified, and was recrystallized from chlorobenzene. The adduct melted at 166.2–167.8° (m. p. determined by the hot-stage microscope technique) and showed no depression in mixed m. p. (165.4–167°, hot stage) with a sample of the adduct prepared from X obtained from acetylene (described below).

Hydrogenation of 0.165 g. of this sample of cycloöctatetraene in the presence of 0.2 g. of pre-reduced Adams catalyst in 20 ml. of glacial acetic acid was complete in seventy-five minutes and required 101.5% of four molar equivalents of hydrogen. After separation of the catalyst, the solution was made alkaline by adding 10% sodium carbonate solution and extracted with ether. The ether solution was dried and distilled through a Craig micro column. The last of three fractions of the cycloöctane obtained melted at 8.8°, presumably depressed by slight contamination with solvent.

Cycloöctatetraene–Maleic Anhydride Adduct.—Cycloöctatetraene (0.5 g.) prepared from acetylene[13] and maleic anhydride (0.48 g.) were heated under nitrogen at a temperature which caused refluxing for five minutes. The solid which separated on cooling was crystallized from 8 ml. of chlorobenzene. The crystalline adduct (0.4 g.) was recrystallized from 6 ml. of chlorobenzene; m. p. 166.5–167.6° (lit. 166°).[20]

Anal. Calcd. for $C_{12}H_{10}O_3$: C, 71.27; H, 4.95. Found: C, 71.10; H, 5.03.

Ultraviolet Absorption Spectra.—Ultraviolet absorption spectra of compounds V, VII, VIII and X were determined with a Beckmann quartz ultraviolet spectrophotometer. Purified cyclohexane[21] was used as the solvent in each case. The spectra are shown in Figs. 1–3, in which logarithms of the molar extinction coefficients are plotted against the wave lengths in ångström units.

Summary

The Willstätter synthesis of cycloöctatetraene from pseudopelletierine has been duplicated, and the product has been shown to be identical to cycloöctatetraene prepared catalytically from acetylene. Evidence supporting the structures of intermediates in the synthesis has been obtained.

Structure of Alkali Amylose

BY F. R. SENTI AND L. P. WITNAUER

X-Ray diffraction studies of the structure of amylose and amylose complexes have been limited for the most part to preparations which give powder patterns. Less ambiguous interpretations of structure can be given fiber patterns, but oriented preparations are required, which are difficult to prepare by conventional methods owing to the low wet strength and hydrophilic character of amylose films.

These difficulties can be circumvented by orienting a non-hydrophilic derivative of amylose and then converting this derivative to amylose under such conditions that orientation is retained. Amylose triacetate serves this purpose well, for it is easily oriented by stretching in glycerol at 170°. Oriented alkali amylose is produced directly on deacetylation of clamped filaments in alcoholic alkali solution. Alkali amylose can be converted to the A, B[2] and V structural modifications by methods previously described.[3]

All structural modifications give well-defined fiber patterns. The alkali amyloses give patterns especially rich in reflections and, because they constitute an isomorphous series, their patterns can be more readily interpreted than those of the other modifications.

Experimental

Amylose was prepared by twice fractionating autoclaved potato starch with nitrobenzene.[4] Acetylation was carried out by the method of Whistler, Jeanes and Hilbert,[5] and films about 0.25 mm. thick were cast from chloroform solution. Strips 2 to 4 mm. wide were oriented by stretching in glycerol[6] at 170°. Films stretched 500% are highly oriented, as evidenced by their diffraction pattern, and are suitable for deacetylation.

In the deacetylation experiments, 3- to 10-centimeter filaments of oriented amylose triacetate were held taut in stainless steel clamps and suspended in the various deacetylating solutions. Unless clamped, the filaments retract considerably, especially at higher alkali concentrations, and give disoriented diffraction diagrams. The characteristic diffraction pattern of potassium hydroxide amylose is given by filaments deacetylated at 25° in 0.01 to 0.30 *N* potassium hydroxide (carbonate-free) in 75% ethanol. Completion of deacetylation has been checked by analysis of the filaments and is also evidenced by the disappearance of the amylose triacetate reflections from the diffraction pattern.

That ethanol is not an integral part of the structure is demonstrated by the identical patterns produced by filaments deacetylated in 0.25 *N* potassium hydroxide in 75% ethanol, 75% methanol, saturated butanol or in water. Deesterification proceeds slowly in the last two media and is accompanied by breakage of many filaments in the aqueous alkali solutions.

Filaments from which the alkali has been removed by extraction with absolute methanol give amorphous diffraction diagrams. Extraction with 75% methanol or ethanol results in fiber patterns characteristic of the "V structure. Reconstitution, by soaking in 0.2 *N* potassium hydroxide in 75% ethanol, restores the original diffraction pattern.

Amylose triacetate filaments deacetylated in 75% ethanol, 0.01 to 0.30 *N* in lithium or cesium hydroxide, give the characteristic diffraction patterns of lithium hydroxide amylose and cesium hydroxide amylose. At the higher concentration of alkali (above 0.3 *N* potassium hydroxide, for example) the characteristic fiber pattern diminishes in intensity and is gradually replaced by a diffuse pattern of the V-type.

Sodium hydroxide and guanidine in 75% ethanol likewise deacetylate amylose triacetate and produce the corresponding alkali amyloses with characteristic X-ray diagrams. No systematic study of the composition of these filaments or those of ammonium hydroxide amylose, prepared as described below, has been made. The similarity of their diffraction patterns to those of lithium, potassium, and cesium hydroxide amylose, however, indicates that they have the same structure and composition as the latter.

Preparation of an alkali amylose is not limited to the deacetylation of amylose triacetate by the corresponding hydroxide, but is also accomplished by the exchange of one alkali for another. For example, cesium hydroxide amylose results when potassium hydroxide amylose is immersed in alcoholic cesium hydroxide. Thallium hydroxide amylose has been obtained in similar manner. Barium hydroxide can be exchanged for potassium hydroxide, but the resulting fiber gives a poorly defined diffraction pattern. Attempts to prepare ammonium hydroxide amylose by deacetylation have failed, whereas exchange with alcoholic ammonia solutions has been successful.

(6) Method of N. C. Schieltz, private communication.

Many salts in aqueous alcohol solution can be exchanged for the alkali in alkali amylose. By this method we have obtained compounds of amylose with the iodide, bromide, acetate, formate and propionate of potassium. All give excellent fiber diffraction patterns, which will be described in another publication.

Alkali and Water Content.—On removal from the deacetylating solution, the clamped filaments were wiped dry with absorbent tissue to remove adhering alkali solution. Adsorbed alcohol, which is difficult to remove by vacuum drying, was removed by humidification of the filaments over water in a vacuum desiccator for sixteen to twenty-four hours. The vacuum-dried filaments were weighed, excess acid added, and titrated with sodium hydroxide. Figure 1 presents data on the alkali content of the filaments as a function of the normality of the deacetylation solution.

It is to be noted that the alkali content of the filaments increases rapidly with concentration of base in the deacetylation solution up to a normality of 0.02. Above 0.02 *N*, the alkali content of the fibers increases at a much lower rate, and the composition curve is nearly horizontal over a range of normalities, particularly in the case of cesium and potassium hydroxide. At higher normalities, the slope of the composition curve again increases. These observations suggest stoichiometric compound formation between amylose and alkali at a composition corresponding to the horizontal portion of the curve. For cesium hydroxide amylose, this composition corresponds to an alkali content of 26%, whereas for potassium and lithium hydroxide amyloses, the alkali contents are 11 and 5%, respectively. The observed values are in satisfactory agreement with those calculated from the formula $1MOH \cdot 3C_6H_{10}O_5$, which requires 23.7% cesium hydroxide, 10.3% potassium hydroxide and 4.7% lithium hydroxide.

At both extremes of the composition curve, however, the alkali content of the filaments deviates considerably from that corresponding to the stoichiometric ratio $1MOH:3C_6H_{10}O_5$, and the problem of the distribution of the alkali arises. One possibility is that the alkali is distributed at random among a number of crystallographically related sites, which are progressively filled as the alkali content increases. On this hypothesis we should expect the relative intensities of the diffraction maxima to vary with the alkali content. Since the lithium, potassium and cesium amyloses appear to be isomorphous, the magnitude of the shift in relative intensities is indicated by a comparison of the patterns of cesium and potassium amylose having the same mole per cent. alkali. On the cesium amylose ($1CsOH:3C_6H_{10}O_5$) pattern, $I_{(101)} \ll I_{(200)}$, whereas for potassium amylose ($1\ KOH:3C_6H_{10}O_5$), $I_{(101)} \gg I_{(200)}$. If the amount of potassium is increased and the cesium is decreased until the two isomorphous structures contain equivalent alkali on the basis of scattering power, the ratio $I_{(101)}/I_{(200)}$ should be the same for the two patterns. Since the scattering factor of cesium is three times that for potassium, patterns of cesium amylose of composition approximately $0.5CsOH:3C_5H_{10}O_5$ were compared with those of potassium amylose of composition approximately $1.5KOH:3C_6H_{10}O_5$. For each pattern, the ratio $I_{(101)}/I_{(200)}$ was unchanged within the error of visual estimation, and it is certain that the inequalities indicated above were not reversed. Random substitution in a set of sites related by symmetry is thus not consistent with our observations.

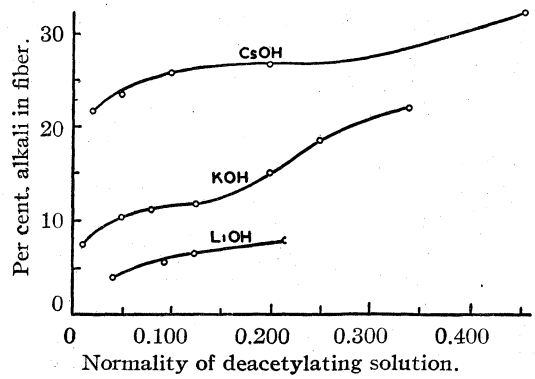

Fig. 1.—Alkali content of lithium, potassium and cesium hydroxide amylose as a function of the normality of alkali in the deacetylating solution.

It appears more likely that the crystalline portions of the fibers are essentially constant in composition with respect to the symmetry-related alkali. Alkali present in other sites would not affect the relative intensities of the discrete diffraction maxima but would contribute to the amorphous background. Any large excess would be expected to distort the structure, causing a change in lattice constants and resulting ultimately in a new or amorphous structure. The possibility that the amorphous regions of the filaments increase in extent and contain an excess or deficiency of alkali at the extremes of composition is not excluded. Experimentally, it is observed that the background scattering increases and the discrete maxima diminish in intensity when the filaments have either a low or high alkali content.

The water content of lithium, potassium and cesium hydroxide amyloses was determined at several humidities after preliminary humidification at 85% R.H. to remove adsorbed ethanol. Humidities were maintained by saturated salt solutions in vacuum desiccators. Water contents on desorption are given in Table I. Diffraction patterns were taken of filaments enclosed in glass capillaries after equilibration at the humidities listed in Table I. Below 30% R.H., corresponding to a water content of about 10%, the patterns diminished in intensity, and there was a slight decrease in lattice dimensions. Precise values of the lattice dimensions of the dry fibers were not determined because accurate measurement of the

weak patterns was impossible. A water content of 10% corresponds to one molecule of water per glucose residue, and this is concluded to be the normal content in the crystalline regions of the filaments.

TABLE I

MOISTURE CONTENT OF ALKALI AMYLOSE AT 25° IN PER CENT. OF DRY WEIGHT ON DESORPTION

Relative humidity, %	Water, %, in LiOH–Amylose	KOH–Amylose	CsOH–Amylose
50	12.6	12.9	11.4
30	9.7	9.9	9.0
12.5	6.3	6.3	6.0

It should be noted that lithium hydroxide amylose also occurs in a more highly solvated structure. Filaments deacetylated in 0.2 *N* lithium hydroxide in 75% ethanol and X-rayed while moist with deacetylating solution give an X-ray pattern showing the same fiber repeat period (22.6 kX), but at least one lateral identity period larger than that of the normal hydrate to which the structure reverts upon drying in air. Under the conditions of deacetylation we have employed, neither cesium nor potassium hydroxide amylose has given any indication of a more highly solvated structure.

X-Ray Diffraction Patterns.—Patterns for indexing were taken in a cylindrical cassette of 5-cm. radius with filtered CuK_α radiation. Filaments mounted with the fiber axis along the cylinder axis show only the second-order reflection of the fiber repeat period. To observe the higher orders, filaments were oscillated with the fiber axis perpendicular to the cylinder axis. Superposition of reflections from planes not perpendicular to the fiber axis on the desired orders of the fiber repeat period was prevented by restriction of the oscillation range. By maintaining a common reflection on succeeding photographs, it was possible to compare the relative intensities of the various orders. Relative intensities of the meridian (orders of the fiber identity period) reflections of lithium, potassium and cesium amyloses were placed on a common basis by the comparison of timed photographs of filaments of known thickness and alkali content. Intensities were estimated visually by comparison with a scale of known relative intensities.

Unit Cell.—The fiber identity period of the alkali amyloses is readily determined from the layer line separation on cylindrical cassette patterns or from the *d*-values of the various orders of the fiber identity period obtained from the oscillation photographs. Determination of the lateral identity periods is ambiguous. The assumption was made that a reflection corresponding to a primitive lateral translation would appear on at least one of the eight layer lines observed. Thus, the first and second nearest reflections to the meridian were indexed as $0kl$ and $lk0$, respectively, where k is the layer line index. On the further assumption that the lattice is orthorhombic, sin θ values were computed and compared with the observed values. The results for potassium hydroxide amylose, based on the orthorhombic unit having $a_0 = 12.7$ kX, $b_0 = 22.6$ kX, and $c_0 = 9.0$ kX, are presented in Table II. A comparison of the dimensions of the orthorhombic unit cells found for the alkali amyloses is given in Table III. All reflections were indexed on the patterns of lithium and cesium hydroxide, whereas the unit cell dimensions of sodium, ammonium and guanidinium hydroxide amylose were derived from measurement of equatorial reflections and layer line separations alone. The lateral dimensions increase regularly with increasing size of the cation except for cesium hydroxide amylose, which has a smaller a_0 than expected. Since the fiber repeat period remains the same, the decrease in a_0 is probably due to a small rotation of the glucose residues about the *b*-axis, and it is unlikely that this will affect the validity of the isomorphous relations which we apply.

Potassium hydroxide amylose containing 10% potassium hydroxide and 13% water has a density (determined by flotation in carbon tetrachloride–petroleum ether mixtures) of 1.53. If it is assumed that the water and alkali are uniformly distributed throughout the filaments, then the number of glucose residues (mol. wt. 162) in the unit cell is

$$N = \frac{12.7 \times 9.0 \times 22.6 \times 1.53 \times 0.77}{162 \times 1.65} = 11.4$$

A similar computation for cesium hydroxide amylose (28.1% cesium hydroxide, 9.0% water, $d = 1.86$) gives a value of 11.3 for N. Consequently, there are twelve glucose residues in the orthorhombic unit cell.

Space Group.—If the alkali amylose structures are based on an orthorhombic lattice, as appears likely from the agreement of observed and calculated sin θ values, the space group must be isomorphous with the point group D_2. All other point groups of the orthorhombic system contain planes of symmetry which are not permitted by the optically active amylose molecules.

Of the reflections $(0k0)$, only those with k even were observed out to $k = 16$ in lithium, potassium and cesium hydroxide amyloses. It is therefore probable that the structures possess a twofold screw axis parallel to the fiber axis. Observed reflections of the form $(h00)$ and $(00l)$ are consistent in all cases with twofold screw axis in the directions *a* and *c*, although not sufficient orders were observed to establish this beyond a possibility of doubt. The observed reflections thus allow space groups $P_{2_12_12_1}$, $P_{2_22_12_1}$, $P_{2_12_12}$, and $P_{2_22_12}$.

Intensity considerations, however, permit only space group $P_{2_12_12_1}$. This follows from the Patterson projections $P_v(uw)$ of the lithium (Fig. 2) and potassium hydroxide (Fig. 3) amyloses. Since the amylose chains lie along *b* (fiber axis), the projection $P_v(uw)$ should give lateral vector distances *u*,

series required by the observed reflections results in low inherent resolution. We interpret the maxima in Figs. 2 and 3 at (0, 0) and ($^1/_2$, $^1/_2$) to indicate two amylose chains in the unit cell separated by the vector distance ($^1/_2$, $^1/_2$). Such an

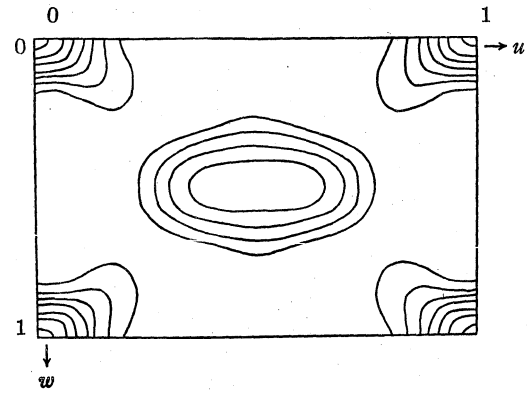

Fig. 2.—Patterson function $P_v(uw)$ for lithium hydroxide amylose.

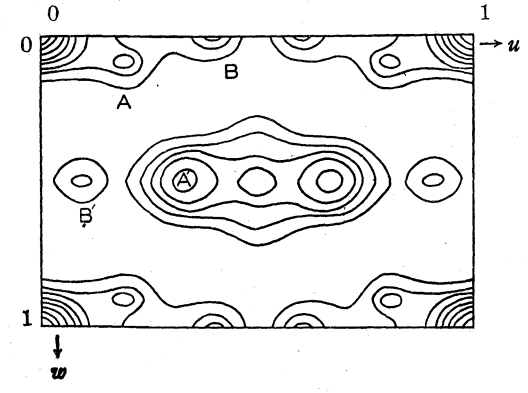

Fig. 3.—Patterson function $P_v(uw)$ for potassium hydroxide amylose.

arrangement is consistent with space group $P_{2_12_12_1}$ as indicated in Fig. 4, where the chains lie on the screw axis along b. Since the amylose molecule does not possess twofold symmetry, it cannot lie on a twofold axis, and a structure based on P_{22_12} would have four chains in the orthorhombic cell. Disposition of the four chains in the unit cell according to symmetry requirements and packing considerations demands a Patterson projection having maxima at approximately ($^1/_2$, 0) and (0, $^1/_2$) in addition to the observed maximum at ($^1/_2$, $^1/_2$). Likewise, structures based on $P_{2_12_12}$ or $P_{22_12_1}$ can be eliminated by comparison of their projected intermolecular vectors with the observed Patterson projection.

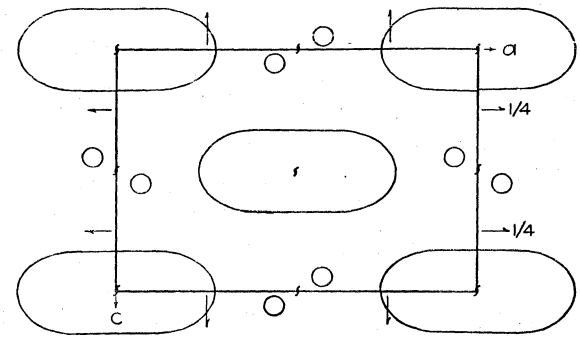

Fig. 4.—Projection of the alkali amylose structure on (010), showing position of amylose chains and alkali ions.

Isomorphism of the Alkali Amyloses.—The near identity of the unit cell dimensions and the fact that all diffraction patterns are consistent with space group $P_{2_12_12_1}$, indicate that the alkali amyloses are isomorphous. Further evidence is provided by a comparison of the $|F|$-values (Table IV) of the ($0k0$) reflections of lithium, potassium and cesium hydroxide amyloses. Filaments having the same content of alkali on a mole basis (1 mole alkali/3 glucose units) were used for this purpose. Appropriate corrections were made for the time of exposure, sample thickness, absorption, Lorentz and polarization factors. The assumption was made that all filaments are equally crystalline. This appears reasonable, since all filaments were prepared from amylose triacetate stretched and deacetylated under identical conditions except for the variation of the alkali. If the structures are isomorphous then

$$\frac{|F|_{0k0}\ (\text{KOH-Amylose}) - |F|_{0k0}\ (\text{LiOH-Amylose}}{|F|_{0k0}\ (\text{CsOH-Amylose}) - |F|_{0k0}\ (\text{KOH-Amylose})} = \frac{f_{K^+} - f_{Li^+}}{f_{Cs^+} - f_{K^+}}$$

where the f's represent the ionic scattering factors. At low angles the value of the ratio is $^1/_2$ and decreases with increasing angles. Thus $|F|_{(0k0}$KOH-Amylose) $-$ $|F|_{0k0}$(LiOH-Amylose) $=$ $^1/_2$ to $^1/_3[|F|_{0k0}$(CsOH-Amylose) $-$ $|F|_{0k0}$(KOH-Amylose)] for the orders considered. These differ-

0·16·0	(−) 10	5	17	5	22	+ 7.8

ences are listed in Table IV,[7] in columns 4 and 5, respectively. The agreement is satisfactory, considering the difficulty of making accurate intensity measurements.

Structure of the Alkali Amyloses.—The lateral arrangement of the amylose chains and alkali ions in the isomorphous structures is evident from the Patterson projections of Figs. 2 and 3. Owing to its low scattering, lithium ion contributes little to the Patterson projection, and the maxima in Fig. 2 result from glucose–glucose interactions. Elongation of the maxima in Fig. 2 indicates that the planes of the glucose residues are nearly parallel to the *ab* plane, as represented in Fig. 4. Since there are twelve glucose residues in the unit cell, each of the positions indicated in Fig. 4 must correspond to the projection of six glucose residues. Alkali ion parameters are determined by comparison of Figs. 2 and 3; the additional maxima in the latter result from potassium-potassium and potassium-amylose interactions. Assigning maxima A and A' to the former and maxima B and B' to the latter, the structure represented in Fig. 4 is derived with alkali ions at approximately $x = \frac{24}{60} a_0$, $z = \frac{3}{60} c_0$ and positions derived by symmetry.

Patterson projections of the structure perpendicular to b (the fiber axis) should give the y parameter of the glucose residues and the alkali ions. Unfortunately, the superposition of reflections of different forms having nearly identical $\sin\theta$ values does not permit the assignment of F^2-values to the forms which contribute to the functions $P_w(uv)$ and $P_u(vw)$. The Patterson projections $P_{uw}(v)$ on the fiber axis can be evaluated, however, since only forms $(0k0)$ contribute, and the corresponding F^2-values were determined from oscillation photographs. $P_{uw}(v)$ for cesium hydroxide amylose is given in Fig. 5. Because of the high scattering factor of cesium, the dominant peaks in this function should correspond to Cs^+–Cs^+ distances along b. According to Fig. 5, these distances are $^1/_6\ b_0$.

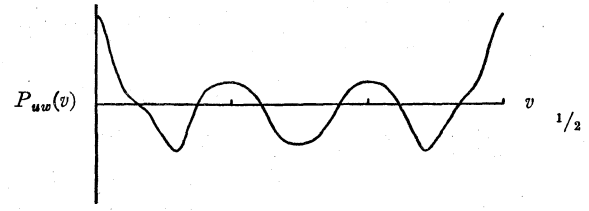

Fig. 5.—Patterson function $P_{uw}(v)$ for cesium hydroxide amylose.

The data of Table IV should also determine the y parameter of the alkali ions, for $|F|_{0k0}$ (Cesium hydroxide–Amylose) $-|F|_{0k0}$ (KOH-Amylose) represents the contribution of an alkali ion of scattering factor $f_{Cs^+} - f_{K^+}$ to the amplitude of the reflection $(0k0)$. Column 6 of Table IV gives the calculated F-values for an alkali ion at $y = 63°$ using a scale factor to give agreement with the observed value for (060). The agreement with the observed values of column 5 are satisfactory except for (0·14·0) and (0·16·0). Part of this discrepancy may be due to error in intensity measurements of the high orders which appeared as weak reflections on the photographs. From the sign of the contribution of the alkali ions to the structure amplitudes of the $(0k0)$ reflections, we can determine the sign of the F-values of lithium hydroxide amylose (as given in column 2 of Table IV). A Fourier series using these values gives the projection of the amylose chain on [010]. This projection appears in Fig. 6 and has maxima at $y = 2/60$, $y = 7.5/60$, $y = 13/60$ and positions related by the center of symmetry of the projection. If it is assumed that these peaks correspond to the centers of the glucose residues of the two amylose chains which have been projected on [010], then we can consider that one chain is displaced with respect to the other by $5.5/60\ b_0$ or by about one half the projected length $(10/60\ b_0)$ of a glucose residue on the fiber axis. This interpretation, however, is somewhat doubtful, because models of extended amylose chains show that there are concentrations of atoms roughly $5/60\ b_0$ along its axis. The Fourier projection would then be explained by placing the two chains in the unit cell with their centers at the same level along b.

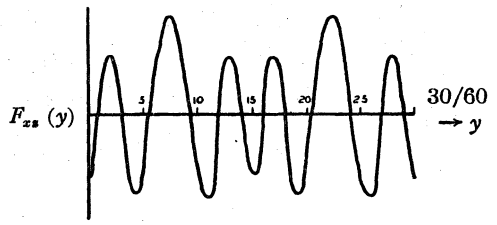

Fig. 6.—Fourier projection of lithium hydroxide amylose on [010].

The exact configuration of the glucose residues in alkali amylose can be determined only by a complete structural analysis, which involves the location of thirty-three atoms of the three independent residues. Fourier series methods have limited application in this case, and the analysis would have to be carried out by trial-and-error methods which we have not attempted. A frequently used but less satisfactory procedure is the comparison of the observed fiber repeat period with that calculated on the basis of various chain configurations.

If it is assumed that all glucose residues have the symmetrical chair configuration[8] with the

(7) The signs of the F_{0k0}'s for lithium hydroxide–amylose which appear in parentheses were determined by the procedure described in the following section.

(8) Pierce, *Trans. Faraday Soc.*, **42**, 545 (1946), has shown that the unit cell dimensions and the intensities of the meridian reflections of cellulose are consistent with the symmetrical chair configuration of the glucose residues. We have used Pierce's bond distances and angles with the exception of the C–C distance, which we take as 1.54 kX instead of 1.52 kX.

bond distances C—C = 1.54 kX, C—O = 1.43 kX and all angles tetrahedral except the ring angle C—O—C, which was taken as 90°, the projection of six maximally extended residues is computed to be 22.4 kX. A chain of maximally extended residues in this configuration does not possess the required twofold screw symmetry, and rotation of the residues to give the required symmetry decreases the fiber repeat period. Bond angles or lengths must be changed, therefore, to obtain agreement with the observed fiber repeat period of 22.6 kX. If the symmetrical chair configuration of minimum steric repulsion is retained, the most reasonable change is to increase the oxygen angle in the ring. Increasing this angle to 109° and using the same values as above for all other angles and distances, the projection of six maximally extended residues is computed to be 26.1 kX. It is evident that models can be constructed having the symmetrical chair configuration and satisfying the requirements of twofold screw symmetry and the observed fiber repeat period by selecting a value for the ring oxygen angle between 90 and 109°. Such agreement, of course, does not eliminate from consideration models of the amylose chain based on other configurations of the glucose ring.

In the structure proposed, the effective thickness of the glucose residue is 4.5 Å., which is consistent with the value found in cellulose and alkali cellulose.[9] The width of the glucose residues plus the contribution of alkali and water (position undetermined) is 12.7 Å., again consistent with the corresponding value found in sodium cellulose III.[8]

Summary

Amylose forms crystalline addition compounds with lithium, sodium, potassium, ammonium, cesium and guanidinium hydroxide. Diffraction patterns indicate these compounds constitute an isomorphous series based on the orthorhombic space group $P_{2_12_12_1}$. Analyses of lithium, potassium and cesium hydroxide amylose shows their composition to be $3C_6H_{10}O_5 \cdot MOH \cdot 3H_2O$, and it is probable that this formula represents the composition of the entire series.

All compounds have the same fiber repeat period, 22.6 kX, corresponding to the extension of six glucose residues. Positions of the alkali ions and the lateral packing of the amylose chains have been determined with the aid of Patterson projections.

Surfaces of Solids. XVIII. The Heats of Emersion and Desorption of Water from Graphite at 25°

BY PAUL R. BASFORD, GEORGE JURA AND WILLIAM D. HARKINS

I. Introduction

A recent paper,[1] gives the adsorption isotherms of water and *n*-heptane on a sample of graphite with a content of less than 0.004% ash and presumably free from oxygen. In that paper some of the problems associated with the graphite–water system were indicated, but their discussion was deferred until after the completion of the calorimetric study of the system as presented here.

II. Experimental

The graphite, furnished through the courtesy of Dr. Lester L. Winter of the National Carbon Company, is described elsewhere. The calorimeter and technique of the measurements was that of Harkins and Jura.[2] Because of the low area of the sample, 4.22 sq. m. g.$^{-1}$, the limited supply of the powder and the small amount of water adsorbed per gram, the technique of Harkins and Jura[2] for determining the amount of water adsorbed could not be used. Instead, the equilibrium pressure of the adsorbed vapor was determined. The amount of adsorbed water was then obtained from the data of the isotherm. For high values of p/p_0 this leads to a considerable uncertainty in the exact amount adsorbed. However the actual results in this region are such that this error is insignificant.

(2) W. D. Harkins and G. Jura, *ibid.*, **66**, 919 (1944).

III. Experimental Results

The heat of emersion of graphite as a function of the amount of water adsorbed (molecules per sq. cm.) is exhibited in Fig. 1. Each value listed in Table I is the average of either two or three determinations, usually three. The table gives also the number of determinations and the average deviation of each determination. From this table it is possible to calculate all the heat values given.

Unfortunately, the results are not very precise, due to (1) low area coupled with small heat effects per unit area, and (2) difficulty of dispersion. The absolute error in a single determination is about twice that of Harkins and Jura[2] in their cor-

responding determinations with titanium dioxide of area 13.8 sq. m. g.$^{-1}$. In order to obtain much more precise values, a calorimeter with an increased sensitivity by a factor of 10 would be essential. The present results, however, are the best that can be obtained with our present equipment. Fortunately, many of the changes in energy are so large that certain conclusions can be drawn.

Figure 1 exhibits two points of interest: (1) the heats of emersion are negative when the amount of water adsorbed per gram is between 0.5 × 10^{14} and 7.0 × 10^{14} molecules per sq. cm. and also for all values above 13.5 × 10^{14} molecules per sq. cm.; and (2) there are two discontinuities in the values of the heat of emersion, the first between 1.8 × 10^{14} and 2.5 ×^{14} and the second between 12.6 × 10^{14} and 13.6 × 10^{14} molecules per sq. cm. The first of these is important, since, insofar as is known to the writers, this is the first case in which heat has been found to be absorbed in the process of immersion of a solid. In other later work it was found also that when a sample of clean silver sulfide is immersed in *n*-heptane at 25° heat is absorbed. The detailed set of data for this and other systems will be presented in a later paper.

The general position of the two discontinuities in the heat of emersion corresponds to those in the derivative of the volume with respect to the pressure in the adsorption isotherm. Jura, Loeser, Basford and Harkins[3] have shown that if a second order phase transition occurs there is finite discontinuity in $(\partial v/\partial p)_{T,\Sigma}$. If there is a finite discontinuity in this derivative, it can be shown that there should also be a finite discontinuity in the heat of emersion. Similarly, for a first-order change, the heat of emersion is independent of the amount adsorbed for those values of the amount adsorbed over which the transition occurs. For a third order change there is a finite discontinuity in the derivative of the heat of emersion with respect to the amount adsorbed. Thus, the behavior of the heat of emersion can be used as a criterion for a phase change of the second or third order. The effect of temperature on isotherms in the region of a first order change is so striking that there can be no reasonable doubt of the phenomenon. In the vicinity of second order changes the experimental problem is more exacting, since it is necessary to prove the existence of a discontinuity in the derivative.

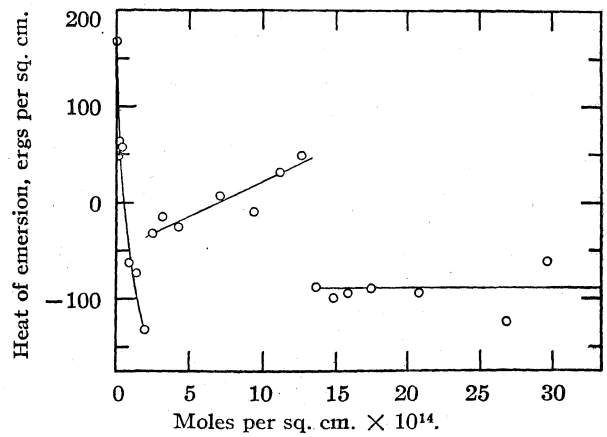

Fig. 1.—The heat of emersion of graphite, with various amounts of water adsorbed in its surface from water at 25°.

However, for the water–graphite system discussed in this paper, the discontinuities in the derivative are supported by a directly measured discontinuity in the heat functions. For the adsorption of water on graphite the discontinuities in the adsorption isotherm are so small that their existence was not entirely certain until the discontinuities in the heats were found. The isotherm is shown in Fig. 2. In this respect the discontinuities found here differ from those previously reported by the writers. Those discontinuities reported earlier were so large that the isotherm was sufficient to establish their existence without doubt.

One of these discontinuities occurs in the monomolecular film at *ca.* 56 Å.^{2} per molecule, but the second does not appear until the film becomes polymolecular at *ca.* 7.5 Å.^{2} per molecule. (The area occupied by a water molecule at 25° is at least 10.6 Å.^{2} in a monolayer.) The regions of the discontinuities in this isotherm are shown on an expanded scale in Fig. 3. The chord-area method

against the number of molecules per sq. cm. in Fig. 5. Both quantities show discontinuities at substantially the same points.

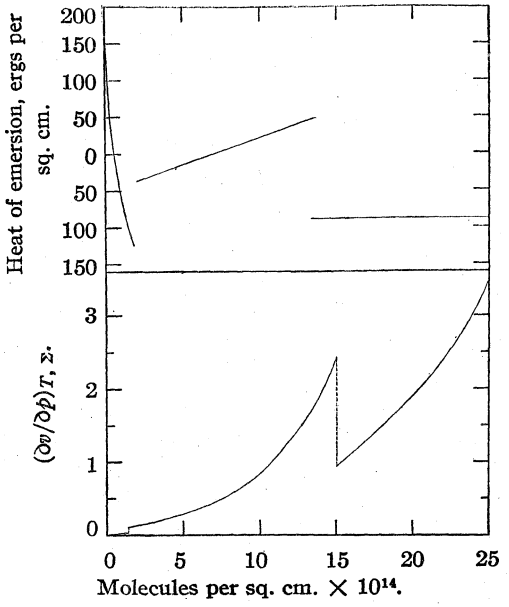

Fig. 5.—The discontinuities in the heat of emersion and in $(\partial v/\partial p)_{T,\Sigma}$.

In addition to the work on water, the heats of emersion from benzene and *n*-heptane of the graphites of 0.004 and 0.46% of ash were determined. These values and those of Harkins and Boyd[4] for a sample of graphite containing 10% ash are listed in Table II.

TABLE II

THE HEATS OF EMERSION OF GRAPHITE FROM LIQUIDS (ERGS CM.$^{-2}$ AT 25°)

Graphite	Water	Benzene	*n*-Heptane
10% ash	265	225	.....
0.46% ash	225 ± 8	147 ± 10	167 ± 10
Less than 0.004% ash	167 ± 3	163 ± 2	146 ± 10

The values indicate that the heat of emersion is highly dependent on the ash content of the graphite. These differences do not seem to be explained by the assumption that a certain fraction of the surface is ash and the remainder is graphite.

In the case of the graphite with 0.46% ash the heat of emersion was determined also in undried benzene. The value found was 219 ± 16 ergs cm.$^{-2}$, while with thoroughly dried benzene it was 147 ± 10 ergs cm.$^{-2}$ (*cf.* 225 ± 8 for water). This indicates that when working with non-polar solids, it is essential to dry even hydrocarbons if correct results are to be obtained.

The absolute method for the determination of area[5] was applied to the graphite of less than 0.004% ash by saturating the powder with *n*-hep-

(5) W. D. Harkins and G. Jura, *ibid.*, **66**, 1362 (1944).

tane. The area of the particles covered with the film was found to be 4.6 ± 0.6 sq. m. g.$^{-1}$. For graphite the geometry of the individual particles is not well enough known to correct this figure exactly for the additional area due to the film. If the graphite particles were cubes, the area of the sample would be 4.1 sq. m. g.$^{-1}$, while if they were rectangular parallelopipeds whose dimensions are in the ratio of 10–10–1 the area would be 4.4 sq. m. per gram, and if these dimensions are 100–100–1 the correction is negligibly small. Actually, the particles are thin flakes, so a ratio of 10-10-1 (*i. e.*, $\Sigma = 4.4 \pm 0.6$ sq. m. g.$^{-1}$) is the best that can be estimated. The areas determined by the adsorption of nitrogen, *n*-heptane, and *n*-hexane vary from 4.06 to 4.42 sq. m. g.$^{-1}$, depending on the gas and on whether the relative method of Harkins and Jura[6] or the theory of Brunauer, Emmett and Teller[7] is used. From the available data it is not possible to decide which of the areas determined by adsorption is the correct one, so the weighted average, 4.22 sq. m. g.$^{-1}$ was used. The good agreement between the area as determined by the absolute method and those obtained by adsorption indicates that the sample is non-porous and that capillary condensation need not be considered. If an appreciable fraction of the area were in small pores, the area determined by the absolute method would be less than those by adsorption. Since this is not the case, the solid may be considered to be non-porous.

Figure 6 exhibits the integral heat of desorption of water vapor at 25° from the low ash content graphite. The values were calculated from the data for the heat of emersion by the relationship

$$h_{D(VS)} = h_{E(SL)} - h_{E(SfL)} + n\lambda \qquad (1)$$

where $h_{E(SL)}$ is the heat of emersion of the clean solid from water, $h_{E(SfL)}$, is equal to $-h_{I(SfL)}$ when n moles is adsorbed per sq. cm., and λ is the heat of condensation, 10,480 cal. mole^{-1}. Table I includes the values of $h_{D(VS)}$ so calculated. The two discontinuities correspond to those in the heat of emersion. The data on adsorption available to the writers indicate that these discontinuities are quite common when a sufficiently detailed investigation is made of the heat of adsorption.

The differential heat of adsorption in calories per mole of water is equal to 1.463×10^{16} times the slope of the curve in Fig. 6. It decreases from approximately 100,000 cal. mole^{-1} when 4.65×10^{12} molecules are adsorbed per sq. cm. to 30,000 cal. mole^{-1} at 1.80×10^{14} molecules per sq. cm. When the amount of water adsorbed is between 2.47 and 12.60×10^{14} molecules per sq. cm., the heat is constant, within the limits of the large experimental error, at 9,100 cal. mole^{-1}. Above 13.59×10^{14} molecules adsorbed per sq. cm. the heat is again constant and equal to 10,500 cal. mole^{-1}, which is equal to the heat of condensation. Of these results the high values exhibited by the differential heat of adsorption below 1.80×10^{14} molecules per sq. cm. are not understood at the present time.

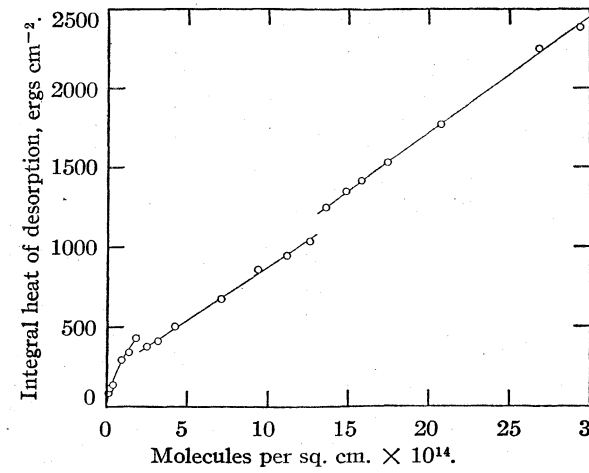

Fig. 6.—The integral heat of desorption of water from graphite in ergs per sq. cm.

There is no precedent in the literature for such high values for the heat of adsorption when physical adsorption is involved. However, to the knowledge of the writers, no data are available in the literature when so few molecules are present on the surface. Analogous results in the very low pressure region have been obtained with water and titanium dioxide. Until more data are available, it is not possible to give any explanation of the seemingly unreasonably high values. The amount of ash is too small to be responsible. The remainder of the values are in complete accord with results which have been obtained when water is adsorbed on charcoal.

Figure 7 shows the change in total surface energy, free surface energy, and the product of the temperature and entropy as a function of the amount of water adsorbed. In this system, in that of water–titanium dioxide, as well as in previously reported systems, the greatest contribution to the heat evolved arises from the entropy rather than from the free energy. The discontinuities in the derivative of the free energy do not show on the scale of Fig. 7.

IV. Discussion

The film of water on graphite exhibits certain relations which are difficult to understand. The results of the calorimetric and adsorption determinations in this and the preceding paper are not sufficient for this purpose. It is probable, before a more complete understanding is possible, that (1) other graphites and other solids which exhibit a similar behavior must be investigated, (2) the precision of the measurements, especially those of the heat involved, must be increased, and (3) experimental procedures other than those used thus far must be used.

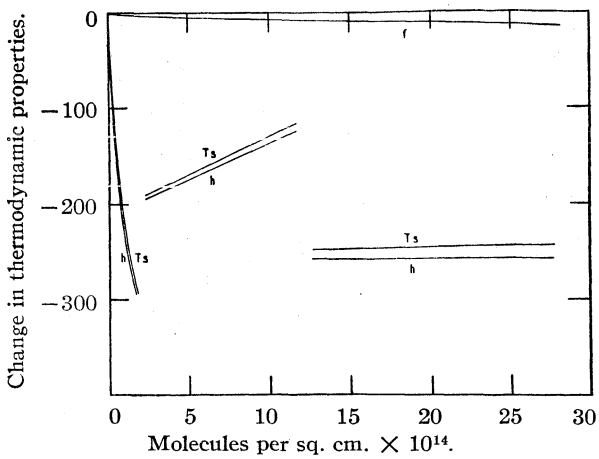

Fig. 7.—The decrease of free surface energy (f), of total surface energy (h), and of the product, temperature times surface entropy (Ts), as a function of the amount of water adsorbed. The uppermost curve is the decrease of free surface energy; this accounts for relatively little of the total surface energy. The two curves to the left below (h below Ts above) very nearly coincide. In the remaining two sets of curves, h is in both cases below and Ts above. All curves are drawn to the same scale.

The two experimental facts which lead to the greatest difficulty are (1) the film is polymolecular at high vapor pressures, and (2) the contact angle is not zero. Unfortunately, the thickness of the film cannot be determined with any certainty. This difficulty arises on account of the fact that there is no reliable estimate of the number of molecules required to form a monomolecular layer. The only method for obtaining this quantity lies in the theory of Brunauer, Emmett and Teller,[7] which, as indicated below, does not seem to be applicable to this case.

Although the simple two-constant equation of this theory apparently reproduces well the experimental data from $p/p_0 = 0.1$ to $p/p_0 = 0.35$, the value of v_m (0.3 cc. g.$^{-1}$) is such that the effective area of the water molecule obtained is 52 Å.^{2} per molecule, or five times that which would be expected for a closely packed monolayer. Though a loosely packed film would not be unexpected, the actual number of molecules required to form a monolayer would seem to be greater than corresponds to this value. Thus, the BET theory does not seem to be applicable. Second, the value of c is less than unity, which means that $E_1 - E_L < 0$. Actually, as is shown later, $E_1 - E_L > 0$, and is over 2300 cal. mole^{-1}. Thus, it appears that *in this particular case* the theory fails. The failure is probably due to the fact that the agreement between theory and experiment in the region $p/p_0 =$ 0.1 to 0.35 is fortuitous, since, at relative pressures above 0.4, $p/v(p_0 - p)$ actually decreases with an increase in p/p_0. This behavior is unusual.

If it is assumed that the water molecules form a tightly packed film, v_m must equal 1.49 cc. g.$^{-1}$ and the average thickness of the film at a relative pressure of 0.985 would be 3 v_m, or about 10 Å. The extrapolation of the observed isotherm to $p/p_0 =$ 1 gives as the thickness about 5 v_m, or 17 Å. Thus, the minimum estimated thickness of the film is 10 Å., but it is more probable that it is 16 Å. On the basis of the theory of Brunauer, Emmett and Teller (v_m = 0.3 cc.) the calculated minimum thickness of the film would be about 50 Å., and probably 83 Å. The value of the contact angle for water–graphite is discussed in an earlier paper.[1]

The fact that the contact angle is not zero indicates that the film is non-duplex, which in turn signifies that in the outermost layer of the film the water molecules do not assume the packing and orientation that exists in the surface of liquid water. If the film were only monomolecular, this state would be understandable and expected. It is difficult to conceive, however, how the effect of the surface can be sufficiently marked at a distance of at least three molecular diameters, and probably more, to affect seriously the packing and orientation of the water molecules.

The available evidence indicates the existence of a polymolecular non-duplex film, a type of film postulated by Harkins.[8] If future work should show that this class of film exists, then this film of water on graphite is the first member of this class to be found.

Thermodynamically, there is no question as to the self-consistency of the available data. This can be shown in the following manner. For the formation of a duplex film it is necessary that

$$\gamma_S - \gamma_{SL} \geqq \gamma_L \qquad (2)$$

while the condition that a duplex film cannot be stable is[9]

$$\gamma_S - \gamma_{SL} < \gamma_L \qquad (3)$$

If the inequalities are combined with the relation

$$\gamma_{Se} = \gamma_{SL} + \gamma_L \cos\vartheta \qquad (4)$$

it is found, if inequality (2) holds for the system under discussion, that

$$\pi_e \geqq \gamma_L (1 - \cos\vartheta) \qquad (5)$$

while if a duplex film cannot be formed

$$\pi_e < \gamma_L (1 - \cos\vartheta) \qquad (6)$$

It is inequality (6) which is of interest. The question is, can π_e have a value less than a pre-assigned positive value for a film of a given thickness. It is possible for the following reasons. π_e is given by the integration of the Gibbs adsorption equation, as suggested by Bangham.[10,11,12] The equation is

$$\pi_e = \frac{RT}{V_M \Sigma} \int_0^{p_0} \frac{v}{p}\, dp \qquad (7)$$

$$\pi_e = \frac{RTp_0}{V_M \Sigma} \left(\frac{v}{p}\right)_{\text{Average}} \qquad (8)$$

(12) D. H. Bangham and R. I. Razouk, *Proc. Roy. Soc.* (*London*), **A166**, 572 (1938).

From eq. (8) it is apparent that, even if the values of π_e and the volume of gas adsorbed at saturation are fixed, then, mathematically it is possible to construct an infinite number of isotherms so that eq. (8) is satisfied. The only general statement is that for a given π_e, the larger the value of the volume adsorbed at saturation, the smaller must be the volume adsorbed at low pressures. Whether or not any of these mathematically possible isotherms exist physically can be determined only by experiment. The results of the adsorption of water on graphite indicate that such a case actually occurs.

The preceding paragraphs show also that, from the thermodynamic standpoint, the thickness of the adsorbed film does not determine whether or not the contact angle is zero or greater than zero. The physical evidence also indicates that the film thickness of itself does not determine the contact angle.

The only point upon which there might be a reasonable doubt is the value of the contact angle of water against graphite, but even here all the evidence is that the angle is not zero. The actual determinations of this quantity are discussed in the earlier paper.[1] The present calorimetric data also indicate a contact angle greater than zero. If the contact angle were zero over a small temperature region within which the measurements are made, the heat of emersion at $p/p_0 = 1.0$ would be 119 ergs cm.$^{-2}$. At $p/p_0 = 0.985$ this quantity is -86 ergs cm.$^{-2}$ and is apparently not increasing with p/p_0. To judge from the behavior of the heat of emersion up to a relative pressure of 0.985, another phase transition would be essential if the heat of emersion is to become that characteristic of a zero contact angle. Experimental difficulties encountered in this region preclude any definite statement as to this possibility.

It would be of interest to estimate the decrease of the energy of interaction of the solid as the film thickness increases, but the observed data are not sufficiently accurate to do this quantitatively. The uncertainty in the amount of gas adsorbed in a single layer is even more serious. If it is assumed, as a rough approximation, that the water molecules have an effective cross-sectional area of 10.6 Å.^{2}, *i. e.*, that the film is tightly packed, the energy of interaction between the solid and the first V_m adsorbed is a maximum. If it is also assumed that the second and third layers have the same packing, then the average energy in excess of condensation for the adsorption of the first v_m is 2300 cal. mole^{-1}; for the second, 1500 cal. mole^{-1}; and for the third, zero cal. mole^{-1}. These figures are obtained from Fig. 6 by dividing the appropriate value of $h_{D(VS)}$ by the number of molecules per sq. cm., multiplying by 1.423×10^{16} and subtracting λ (*i. e.*, 10,480 cal. mole^{-1}). Since none of these is very large compared with RT (RT = 600 cal. per mole) it is evident that even the first layer is not nearly complete before an appreciable number of molecules are adsorbed in the second and higher layers. Under these conditions, the 2300 cal. per mole calculated for the first layer must be too low, since many of the molecules included are in the second and higher layers, with lower interaction energies. The figures for the second and third layers must be similarly revised.

Neither the data nor the assumptions about the number of molecules in a monolayer are good enough to attempt to determine $E_1 - E_L$ to any degree of accuracy. The values of 2700, 1300 and -150 cal. mole^{-1} for $E_1 - E_L$, $E_2 - E_L$ and $E_3 - E_L$ approximate the observed values moderately well if the usual assumption is made of a Boltzmann distribution between the layers. Another difficulty with this simple treatment is that the heat must be a continuous function of the amount adsorbed. This is contrary to the experimental results. Even in this respect any simple approach is precluded. It is evident that no analysis based on the simplified theories now available is capable of explaining the observed facts.

Summary

1. The heat of emersion (h_e) from water of a graphite of specific area = 4.22 sq. m. g.$^{-1}$ and of ash content less than 0.004%, presumably free from any oxygen complex, was determined as a function of the amount of water adsorbed on the surface. For the clean graphite (h_e) is 167 ergs cm.$^{-2}$, decreasing to -132 ergs cm.$^{-2}$ when 1.80×10^{14} molecules of water are adsorbed per sq. cm. From 2.47×10^{14} to 12.60×10^{14} molecules per sq. cm. the heat of emersion increases from -32 to $+49$ ergs cm.$^{-2}$. From 13.59 to 29.63×10^{14} molecules adsorbed per sq. cm. the value, within a large experimental error, is constant at -84 erg cm.$^{-2}$.

2. There are two finite discontinuities in the heat of emersion. These discontinuities coincide with two discontinuities in the derivative of the volume with respect to the pressure in the isotherm. Either of the above is sufficient to show that a second order phase change occurs in the film formed by adsorption. The actual determination of both discontinuities is the best evidence which can be obtained for this type of phase change.

3. For the first time negative heats of emersion have been obtained.

4. The area of the solid was determined by the use of the *absolute* method of Harkins and Jura, using *n*-heptane at 25°. The area obtained was 4.4 ± 0.6 sq. m. g.$^{-1}$. This agrees with the area determined by adsorption (4.06 to 4.42 sq. m. g.$^{-1}$). Since the absolute method gives the value at saturation, and adsorption at low relative pressures, it is evident that capillary condensation is negligibly small.

5. From the amount of water adsorbed as determined from the isotherm, the area of the solid,

and the fact that capillary condensation is negligible, it is shown that the film of water on graphite attains a minimum thickness of 10 Å. at a relative pressure very close to saturation. The extrapolation of the isotherm to unit relative pressure indicates a minimum thickness of 16 Å. These figures are obtained on the postulate that the density of the adsorbed material is that of the liquid at the same temperature. The physical relations indicate that the packing must be looser than in the liquid. Consequently, the figures quoted are to be considered minima and not a reliable estimate of the true thickness.

6. It is shown thermodynamically that the film can be polymolecular with a contact angle not equal to zero. It is also pointed out that this situation leads to a difficult problem in the construction of a model compatible with both conditions.

7. It is shown that $E_1 - E_L > 0$, $E_2 - E_L > 0$ and $E_3 - E_L < 0$.

8. The integral and differential heats of adsorption of water on graphite are determined from the heats of emersion.

9. The heats of emersion are used to determine the change in total surface energy caused by the adsorption of water. These values combined with the free surface energy changes as determined from the adsorption isotherm permit the calculation of the change in surface entropy.

Synthesis of DL-Methionine

BY EARL PIERSON, MARIO GIELLA[1] AND MAX TISHLER

Consideration of the various syntheses of methionine indicates that the first recorded synthesis, that of Barger and Coyne,[2] using β-methylmercaptopropionaldehyde, is the most direct in approach. The over-all yield of about six per cent. by the modified Strecker reaction and the difficulty in obtaining the required aldehyde discouraged the use and the further development of this synthesis.

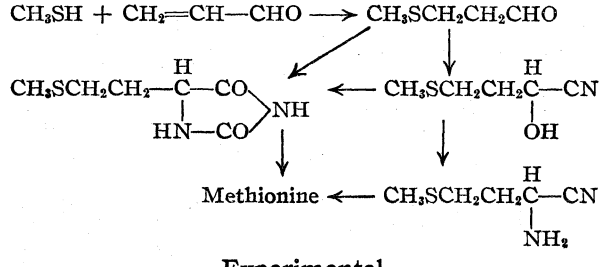
With the recent availability of commercial acrolein, and the reports that β-methylmercaptopropionaldehyde has been prepared from acrolein and methylmercaptan,[3] the development of a practical synthesis of methionine became of interest.

Catch and his collaborators[4] recently prepared methionine from acrolein and methyl mercaptan in 29% yield by a modified Strecker reaction employing liquid hydrogen cyanide. We have also prepared methionine in about the same over-all yield (25%) by the Strecker reaction without resorting to the use of liquid hydrogen cyanide. Further improvement was observed using the well-known Bücherer hydantoin synthesis, whereby an over-all yield of 50% was obtained.

It was found that methyl mercaptan adds smoothly to acrolein at atmospheric pressure when the reaction is catalyzed by a small amount of copper methyl mercaptide.[5]

The conversion of β-methylmercaptopropionaldehyde into 5-(β-methylmercaptoethyl)-hydantoin was accomplished by the usual Bücherer procedure and also by transformation into the cyanohydrin followed by treatment with ammonium carbonate.

The hydrolysis of the hydantoin to methionine was effected by concentrated hydrochloric acid at 135°, by ammonium sulfide solution at 135°, and by aqueous sodium hydroxide at 100°. The routes investigated are indicated.



Experimental

1. **β-Methylmercaptopropionaldehyde.**—Gaseous methyl mercaptan, 48 g., 1.0 mole, was bubbled during the course of thirty minutes under the surface of a cooled, stirred mixture of 56 g. (1.0 mole) of acrolein and 0.5 g. of cupric acetate, while the internal temperature was maintained at 35–40°. The mixture was agitated for an hour and distilled under reduced pressure giving β-methylmercaptopropionaldehyde, 87 g., 84%; boiling 52–54° (11 mm.), $n^{20}D$ 1.4850, d_{20} 1.036; MR_D (calcd.) 28.4, found 28.7. The undistilled aldehyde is sufficiently pure for use in the reactions described below.

The 2,4-dinitrophenylhydrazone was prepared in the conventional manner, m. p. 116–119°.

Anal. Calcd. for $C_{10}H_{12}O_4N_4S$: C, 42.45; H, 4.26; N, 19.70. Found: C, 42.23; H, 4.20; N, 19.61.

2. **α-Hydroxy-β-methylmercaptobutyronitrile.**—β-Methylmercaptopropionaldehyde, 10.4 g., 0.10 mole, was shaken for ten minutes with a solution of 10.4 g., 0.10 mole, of sodium bisulfite in 35 ml. of water. A substantial amount of the adduct crystallized upon cooling to room temperature. A solution of 4.9 g., 0.10 mole, of sodium cyanide in 15 ml. of water was added in three portions, without permitting the temperature to exceed 35°. The oil that separated immediately was extracted

(5) The English investigators[4] used a tertiary amine as a catalyst.

three times with benzene; the combined benzene extracts were extracted with sodium bisulfite solution and then the solvent was removed under reduced pressure. The crude cyanohydrin was thus obtained as a colorless oil weighing 11.8 g. (90%). For analyses, a small sample of this product was distilled at 100° under a pressure of three microns.

Anal. Calcd. for C_5H_9NOS: C, 45.8; H, 6.87; N, 10.68. Found: C, 46.0; H, 6.88; N, 10.49.

3. 5(β-Methylmercaptoethyl)-hydantoin. A. From β-Methylmercaptopropionaldehyde.—A mixture of 26 g. (0.25 mole) of β-methylmercaptopropionaldehyde, 113 g. (1.17 moles) of finely divided ammonium carbonate, 24.5 g. (0.5 mole) of sodium cyanide, 335 ml. of ethanol and 335 ml. of water was agitated and heated for four hours at 50–55°. The light yellow reaction mixture was filtered, and the filtrate was concentrated at 60° to a volume of 300 ml., acidified with 50 ml. of concentrated hydrochloric acid and heated for five minutes at 90° to cyclize the hydantoic acid, which was found to be present in small amounts. After crystallization, separation and drying, the hydantoin weighed 34 g. (79% yield) and melted at 103–105°. The melting point remained unchanged after recrystallization from ethanol.

Anal. Calcd. for $C_6H_{10}O_2N_2S$: C, 41.38; H, 5.74. Found: C, 41.36; H, 5.81.

B. From α-Hydroxy-γ-methylmercaptobutyronitrile.—The cyanohydrin was prepared by the method given previously from 2.0 moles of the aldehyde. Removal of the benzene solvent left 255 g. of crude cyanohydrin, which was converted into the hydantoin, 174 g. (50% yield based on β-methylmercaptopropionaldehyde), by reaction with 420 g. of ammonium carbonate in 1000 ml. of 50 volume per cent. methanol for two and one-half hours at 50–55°. The product was isolated by the procedure described above.

4. DL-Methionine. A. From the Hydantoin.—5-(β-Methylmercaptoethyl)-hydantoin, 17.4 g. (0.10 mole) was refluxed for six hours with a solution of 8.8 g. of sodium hydroxide in 75 ml. of water contained in a stainless steel flask; an additional 4.4 g. of sodium hydroxide was added, and refluxing was continued for a total of twenty-four hours. The reaction mixture was decolorized with Norit, neutralized to litmus with concentrated hydrochloric acid, and allowed to crystallize at 5°. The product weighed 10.8 g. (73.5%); m. p. 269° with decomposition. An additional 1.7 g. (11%) of material could be isolated by a procedure involving acidification (hydrochloric acid), concentration to dryness, extraction with ethanol, and neutralization of the filtered ethanol extract to Congo with pyridine. After recrystallization of the combined fractions from aqueous ethanol, 10.6 g. of analytically pure methionine was obtained.

By omitting the isolation of both the β-methylmercaptopropionaldehyde and 5-(β-methylmercapto)-hydantoin, pure methionine was obtained in 50% yield based on the charge of acrolein and methyl mercaptan.

B. From the Cyanohydrin.—Gaseous ammonia was passed into 123 g. (0.94 mole) of the stirred cyanohydrin, maintained at 60° for thirty minutes. The reaction mixture was dissolved in benzene, heated to expel excess ammonia, and extracted with dilute hydrochloric acid. The aqueous layer was made alkaline with ammonia water and extracted with benzene; evaporation of the solvent left 49 g. (40%) of crude methionine nitrile. Several futile attempts were made to purify this intermediate and to obtain a crystalline derivative. The crude aminonitrile (10 g.) was hydrolyzed by heating on the steam-bath for five and one-half hours with 20 ml. of concentrated hydrochloric acid. The reaction mixture was diluted with 50 ml. of water, decolorized with Darco, and the solution concentrated to dryness under vacuum. The resulting solid was extracted with hot ethanol, and the ethanolic solution was filtered and neutralized to Congo with pyridine. Methionine in 75% yield (8.5 g.) was obtained.

Summary

A three-step synthesis of methionine has been devised based on the catalyzed addition of methyl mercaptan to acrolein, followed by the Bücherer hydantoin reaction, and then by hydrolysis.

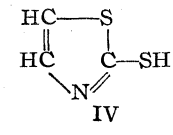
A Synthesis of 2-Thiazolethiol and its Disulfide

BY ROGER A. MATHES AND ADOLPH J. BEBER

2-Thiazolethiols, particularly 2-mercaptobenzothiazole, have been used extensively for many years as accelerators for the vulcanization of rubber. The preparation of 2-thiazolethiol (IV), the parent compound of this series, recently has been reported[1] in the patent literature. This synthesis which was effected by treating α-chloroacetaldehyde (I) with ammonium dithiocarbamate (II), has been investigated by us in some detail and under varied conditions. The intermediate, formylmethyl dithiocarbamate (III), was isolated and characterized. The yield of IV was 50% based on I. The synthesis of IV is attended by troublesome side reactions, giving rise to gummy by-products, which apparently result from intermolecular reactions of aldehydes I and III with amino groupings in II and III. Acetaldehyde is known to react with II,[2] and I likewise reacts as a typical aldehyde.[3] Substituted 2-thiazolethiols,[4] on the other hand, can be prepared, usually in high yields,[4c] by the conventional reaction of α-halogen ketones with II. 1,2-Dichloroethyl ether which is known to replace I in thiazole syntheses[5] reacts with II to give a liquid of uncertain composition.[6]

$$\underset{\text{I}}{ClCH_2CHO} + \underset{\text{II}}{NH_2CSSNH_4} \longrightarrow \underset{\text{III}}{NH_2CSSCH_2CHO} \longrightarrow$$



IV

(6) Mathes, U. S. Patent 2,411,219.

The preparation of the previously undisclosed disulfide, 2,2′-dithio-bis-thiazole (V), was effected using a number of oxidizing agents; the best of these, ammonium persulfate, gave a 93% yield.

Experimental

Formylmethyl Dithiocarbamate (III).—Fifty-eight grams (0.53 mole) of II was dissolved in a solution of 50 cc. of water and 20 cc. ethanol. While stirring this solution and maintaining the temperature at 20°, 43.8 g. (0.5 mole) of I was added in thirty minutes. An oily layer separated but quickly solidified as agitation was continued. After cooling to −3°, the product was recovered by filtration, and upon drying at room temperature, 47 g. (69% yield), melting at 101–103°, was obtained. As a considerable amount of gum precipitated in the filtrate, the recovery of more product was not attempted. After recrystallizing from water, III was obtained as colorless crystals melting at 110°.

Anal. Calcd. for $C_3H_5NOS_2$: C, 26.65; H, 3.73; N, 10.36; S, 47.43; mol. wt., 135. Found: C, 26.74; H, 3.78; N, 10.31; S, 47.51; mol. wt., 138.5.

2-Thiazolethiol (IV).—One hundred and twenty grams (1.1 moles) of II[7] was dissolved in 250 cc. of water and while stirring vigorously 87.5 g. (1 mole) of I dissolved in 150 cc. of ethanol was added rapidly. The temperature rose from 25 to 82° during this reaction. The water solution of the reaction mixture was decanted from a small amount of sticky, yellow gum and was transferred to an evaporating dish. The solution was evaporated at 50° almost to dryness and was then extracted with 200 cc. of chloroform. The chloroform solution, after evaporating to dryness, gave 95 g. of crude product which upon recrystallizing from water yielded 58 g. (50%) as colorless plates, melting at 79–80°.

Anal. Calcd. for $C_3H_3NS_2$: C, 30.75; H, 2.58; N, 11.95; S, 54.72; mol. wt., 117. Found: C, 30.82; H, 2.64; N, 11.88; S, 54.58; mol. wt., 115.5.

A sample of the gum formed in the reaction, after repeated extractions with hot water, gave positive qualitative tests for nitrogen and sulfur. The composition of the gum was not determined because its physical condition made purification difficult.

It was concluded from further experimental work that no improvement in yield is obtained when the following variations in reaction conditions are employed: reversal of the order of addition, length of time of addition, reaction temperatures of 0 to 50°, concentration of reactants, the absence of air and light, the control of *p*H and the use of organic solvents as reaction diluents.[8]

In an attempt to promote ring closure by the addition of sulfuric acid to the solution resulting from the initial interaction of I and II, a colorless, apparently amorphous product melting at 96–98° was precipitated. The composition of this compound was not determined but it slowly undergoes spontaneous decomposition to form IV in rather low yield (38%).

2,2′-Dithio-bis-thiazole (V).—One hundred and fifty-two grams (1.3 moles) of IV was dissolved in a solution of 500 cc. of water and 54.6 g. (1.35 moles) of sodium hydroxide. While vigorously stirring this solution, 163 g. (0.72 mole) of ammonium persulfate, dissolved in 500 cc. of water, was added in one hour at 8°. During the addition of ammonium persulfate, a crystalline solid precipitated. After stirring for thirty minutes, the product was recovered by filtration, washed with water and dried at room temperature to give 141 g. (93% yield), melting at 79–80°. After recrystallizing from *n*-hexane, the disulfide was obtained as fine, light yellow needles melting at 83°.

Anal. Calcd. for $C_6H_4N_2S_4$: C, 31.01; H, 1.74; N, 12.06; S, 55.19; mol. wt., 232. Found: C, 31.13; H, 1.79; N, 12.13; S, 55.27; mol. wt., 236.

The disulfide decomposed slowly on storage. A similar effect has previously been reported for 2,2′-dithio-bis-(4,5-dimethylthiazole).[9]

Summary

The synthesis of 2-thiazolethiol and its intermediate, formylmethyl dithiocarbamate, from the interaction of chloroacetaldehyde and ammonium dithiocarbamate has been described. The oxidation of 2-thiazolethiol, under mild conditions, is shown to proceed normally to give the disulfide, 2,2′-dithio-bis-thiazole.

(7) Mathes, U. S. Patent 2,117,619. Ammonium dithiocarbamate was prepared according to Example 2.

(8) In these experiments, chloroacetaldehyde was used both as the hemihydrate and as the anhydrous compound which was prepared by passing hot vapors of the hemihydrate over calcium chloride.

A Synthesis of 2-Pyrimidinethiols

BY ROGER A. MATHES, FLOYD D. STEWART AND FRANK SWEDISH, JR.[1]

In view of the usefulness of heterocyclic thiols as vulcanization accelerators, the authors had occasion to investigate 2-pyrimidinethiols. A new synthesis has been developed which simplifies the preparation, results in improved yields and extends the scope of former methods.

Methods previously employed to prepare 2-pyrimidinethiols include, among others, the interaction of 2-amino-2-methyl-4-pentanone (diacetonamine) and isothiocyanates[2] and the reaction of aliphatic ketones with ammonium thiocyanate.[3]

When mesityl oxide reacts with ammonium thiocyanate in the presence of a strong mineral acid, 2-methyl-2-thiocyano-4-pentanone[4] is formed. When this compound reacts with a primary amine or ammonia and an acid catalyst, a condensation takes place resulting in the formation of a 2-pyrimidinethiol. In the absence of an acid catalyst, ring closure is less readily effected and the intermediate thiourea is formed along with the 2-pyrimidimethiol.

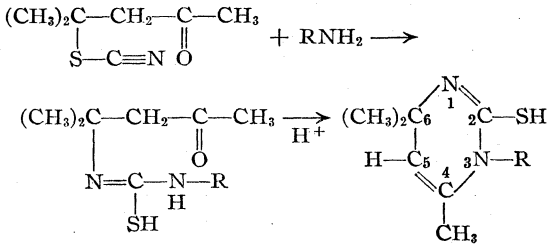
[a] Melting points given are for analytical samples. [b] Yields are based on crude products. [c] Compounds 2, 3, 4, 7 were recrystallized from ethanol; 5, 6, 8 from chloroform; 1 from benzene. [d] During the preparation of this compound, the intermediate, 1-ethanol-3-[2-(2-methyl-4-pentanonyl)]-2-thiourea, was isolated. It melted at 144°. [e] In addition to this compound, 1-isopropyl-2-thiourea (m. p. 168–169°) was recovered from the reaction mixture. [f] This compound was recovered from the reaction mixture in low yield. The principal product of the reaction was 1-cyclohexyl-2-thiourea (m. p. 162°). [g] 1,3-Phenylene-bis-3,3′-(2-mercapto-4,6,6-trimethylpyrimidine).



This method of preparing 2-pyrimidinethiols from 2-methyl-2-thiocyano-4-pentanone and a primary amine or ammonia, in the presence of an acid catalyst, is of quite general application. It can be used successfully to prepare 2-pyrimidinethiols from mono and poly aromatic amines, alicyclic amines, aliphatic amines and hydroxy aliphatic amines. The reactions take place more readily and result in higher yields when aromatic amines are employed.

A second method was developed whereby the reaction can be carried out in one step, thus eliminating the initial preparation of 2-methyl-2-thiocyano-4-pentanone. In this modified procedure, acid is added to an agitated aqueous mixture of ammonium thiocyanate, mesityl oxide and a primary amine. Under the experimental conditions employed, this method was found to be applicable only to aromatic amines. Cyclohexylamine, isopropylamine, *n*-amylamine and ethanolamine were tried but in no case was a reaction product isolated. Apparently amines having dissociation constants greater than about 10^{-9} do not form 2-pyrimidinethiols in the modified procedure.

Experimental[5]

2-Methyl-2-thiocyano-4-pentanone.—Forty-nine grams (0.5 mole) of sulfuric acid dissolved in 50 ml. of water was added over a period of fifteen minutes to 98 g. (1 mole) of mesityl oxide at 15°. Seventy-six grams (1 mole) of ammonium thiocyanate dissolved in 100 ml. of water was added quite rapidly to this mixture at 20°. After stirring for fifteen minutes, the upper, red, oily layer was separated and was washed with water until free from acid. The crude product weighed 145 g., a yield of 92%. An analytical sample boiled at 97° (10 mm.), $n^{20}D$ 1.5030, d^{20}_{20} 1.0363.

Anal. Calcd. for $C_7H_{11}ONS$: C, 53.50; H, 7.00; N, 8.91; S, 20.38; mol. wt., 157. Found: C, 53.47; H, 7.06; N, 8.88; S, 20.30; mol. wt., 161.

The 2,4-dinitrophenylhydrazone derivative was prepared and when purified melted at 204°.

Anal. Calcd. for $C_{13}H_{15}O_4N_5S$: N, 20.77; S, 9.49. Found: N, 20.75; S, 9.45.

2-Mercapto-3-phenyl-4,6,6-trimethylpyrimidine—General Procedure.—A mixture of 78.5 g. (0.5 mole) of 2-methyl-2-thiocyano-4-pentanone, 46.5 g. (0.5 mole) of aniline, 2 g. (0.02 mole) of sulfuric acid and 150 ml. of water was agitated and warmed to refluxing temperature. The buff-colored crystalline product precipitated almost immediately. After cooling to room temperature, filtering, washing with water and drying, 96 g. (82.8% yield) of crude product melting at 188–190° resulted. On recrystallizing twice from alcohol, the melting point was 192–193°.

Anal. Calcd. for $C_{13}H_{16}N_2S$: C, 67.25; H, 6.90; N, 12.05; S, 13.80; mol. wt., 232. Found: C, 67.11; H, 6.98; N, 11.97; S, 13.84; mol. wt., 232.

3-*o*-Tolyl-2-mercapto-4,6,6-trimethylpyrimidine—Modified Procedure.—A mixture of 49 g. (0.5 mole) of mesityl oxide, 38 g. (0.5 mole) of ammonium thiocyanate, 53.5 g. (0.5 mole) of *o*-toluidine and 100 ml. of water was agitated in the reaction flask. Fifty-five grams (0.55 mole) of hydrochloric acid was added in ten minutes at a temperature of 20°. When heated to reflux, the buff-colored, crystalline product precipitated. After cooling to room temperature, filtering, washing with water and drying, 104.6 g. (85% yield) of crude product melting at 199–201° resulted. On recrystallizing twice from alcohol, the melting point was 202°.

Anal. Calcd. for $C_{14}H_{18}N_2S$: C, 68.29; H, 7.31; N, 11.40; S, 13.00; mol. wt., 246. Found: C, 68.08; H, 7.30; N, 11.41; S, 13.08; mol. wt., 253.

Summary

1. A new synthesis for 2-pyrimidinethiols, which consists of the reaction of 2-methyl-2-thiocyano-4-pentanone with primary amines, has been developed.

2. In a modified method it is shown that 3-aryl-2-pyrimidinethiols can be prepared in one step, with no evidence of the intermediate formation of 2-methyl-2-thiocyano-4-pentanone.

3. The preparation by these methods of ten representative compounds is described.

A New Method for the Preparation of 17(α)-Hydroxy-20-ketopregnanes

BY LEWIS H. SARETT

Two methods[1,2] have been described for the fabrication of 17(α),21-dihydroxy-20-ketopregnanes.[3] Both of these methods suffer from the circumambience involved in total degradation of the sterol or bile acid side chain to a 17-ketone, followed by reassembly of the two carbon side chain. One of these processes comprises five steps, the other seven, with respective yields of about 3.5 and 5%. The present reaction series, however, employs 20-ketopregnanes as starting material and gives yields of 15 to 50%, depending on the nature of the other substituents in the molecule.

Pregnane-3(α)-ol-11,20-dione acetate (I) reacted with hydrogen cyanide in alcohol solution to give 60–80% of a crystalline cyanhydrin (V). The mother liquors consisted of somewhat lower melting crystals, which presumably contained the epimeric cyanhydrin. Some very interesting properties of the pure cyanhydrin and of the lower melting mixture were observed. While both were stable to hot alcohol, to alcohol–pyridine mixtures and to silver acetate in alcohol, they decomposed when eluted from chromatographic alumina. However, the nature of the products depended on how the alumina had been prepared. With acid-washed alumina, dehydration was the principal reaction. A small yield of a mixture of unsaturated nitriles was obtained. With alumina which had not been treated with acid and which therefore was, as is almost invariably the case, alkaline to phenolphthalein, loss of hydrogen cyanide occurred. About 90% of the parent ketone was recovered from the eluate.

The presence of the acetate group at C_3 was found to affect greatly the stability of the C_{20} cyanhydrin group. When pregnane-3(α)-ol-11,20-dione (II) was converted to the corresponding cyanhydrin (VI), the latter rapidly decomposed to the parent ketone in warm alcohol solution, with or without the addition of pyridine. It was, however, perfectly stable to dilute acetic acid and could be smoothly oxidized with chromic acid to the 3-keto derivative (IX). In this compound also the tendency to lose hydrogen cyanide in alcohol or alkaline alumina was marked. Even acid-washed alumina gave 40% of the 20-ketone, together with oily fractions representing dehydration or rearrangement products.

(1) Reichstein and von Euw, *Helv. Chim. Acta*, **23**, 1258 (1940); von Euw and Reichstein, *ibid.*, **24**, 1140 (1941).

(2) Sarett, *J. Biol. Chem.*, **162**, 601 (1946).

(3) The stereochemical conventions used in this paper are based upon the recent findings of Gallagher and Long [*J. Biol. Chem.*, **162**, 495 (1946)], of Sorkin and Reichstein [*Helv. Chim. Acta*, **29**, 1218 (1946)] and of von Euw and Reichstein, *ibid.*, **30**, 205 (1947)]. The data presented in the last-mentioned contribution show that the configuration of the two carbon side chains in those naturally-occurring pregnane derivatives which bear a hydroxyl group at the 17 position is probably β.

The reactions of the cyanhydrins of 17-keto-steroids have been investigated by Butenandt and Schmidt–Thomé[4] who showed that they can be dehydrated with phosphorus oxychloride in pyridine at 150°. Upon testing the action of this agent with the 20-cyanhydrin of pregnane-3(α)-ol-11,20-dione acetate (V), it was found that the α,β unsaturated nitrile (XI) was produced very smoothly at room temperature. When the C_3 substituent was a keto group, however, the more facile loss of hydrogen cyanide from the cyanhydrin group reflected an increased difficulty in the dehydration reaction. Thus, the 20-cyanhydrin of pregnane-3,11,20-trione (IX) gave only 20% of the unsaturated nitrile (XII). Accompanying, XII, however, there was a considerable quantity of a lower melting mixture, consisting apparently of isomeric nitriles or rearrangement products. When the dehydration of the cyanhydrins was effected by boron trifluoride or acid-washed alumina, similar mixtures, from which no pure compound was isolable, were obtained.

The reaction of the unsaturated XI and XII with osmium tetroxide in benzene was extremely slow, as would be predicted from the presence of the negative cyano group attached to the ethylene linkage. However, a small amount of pyridine[5] accelerated the addition so that formation of the osmate was complete in a few hours. Hydrolysis of the osmate ester proceeded smoothly with sodium sulfite at room temperature but the corresponding 17,20-dihydroxy-20-cyano-pregnane (XVII) could not be isolated. The 17(α)-hydroxy-20-ketopregnane derived from it by loss of hydrogen cyanide was indeed the only product. This result is in accord with the previously mentioned instability of 3-hydroxy- and 3-keto-20-cyanhydrins, but it is mildly surprising that the 17(α)-hydroxy-20-ketones are stable in the decidedly alkaline (*p*H 10) hydrolysis medium.

From Δ^{17}-20-cyanopregnene-3,11-dione (XII), pregnane-17(α)ol-3,11,20-trione (XX) was obtained. The latter was identical with the previously described oltrione obtained by oxidation of a pregnane-17,20-diol-3,11-dione.[6] Hence this dioldione also belongs in the 17(α)-hydroxy series. Δ^{17}-20-Cyanopregnene-3(α)-ol-11-one acetate (XI) gave upon hydroxylation a mixture of pregnane-3(α),17(α)-diol-11,20-dione (XVIII) and its 3-acetate (XIX). That the 17-hydroxyl in XVIII and XIX is α was demonstrated by oxidation of XVIII to XX.

The addition of a 21-acetoxy group to the 20-

ketopregnane structures did not materially alter the course of the synthesis. Pregnane-3(α),21-diol-11,20-dione diacetate (III) and the corresponding 21-monoacetate (IV) gave the respective cyanhydrins (VII and VIII). Dehydration of the diacetate cyanhydrin afforded a good yield of the unsaturated nitrile, (XVI), but the 20-cyanhydrin of pregnane-21-ol-3,11,20-trione acetate (X) gave only 20% of the unsaturated compound (XIV). The adverse influence of the 3-keto group on the dehydration is again evident. The hydroxylation of XIV and XV proceeded normally to yield 70–80% of pregnane-3(α),17(α),21-triol-11,20-dione (XXI) and pregnane-17(α),21-diol-3,11,20-trione (XXIII). Treatment with acetic anhydride–pyridine replaced the 21-acetate groups which were removed during the sodium sulfite hydrolysis.

The surprising durability of the side chain permitted conversion of the 3-keto derivatives (XX and XXIV) to the corresponding unsaturated ketones, Δ^4-pregnene-17-ol-3,11,20-trione (XXV) and Δ^4-pregnene-17,21-diol-3,11,20-trione acetate (XXVI, Kendall's compound E acetate).

The assignment of the α or "natural" configuration to the C 17 hydroxyl group in the dioltrione XXIII follows from its conversion into Compound E. Evidence indicates that the other 17-hydroxy-20-ketones described (XVIII, XX and XXII) also belong in the 17(α)-hydroxy series. First, the method of preparation is identical in each case and only one compound is obtained. Second, the rotations fall in the range predicted for 17(α)-hydroxy compounds,[3] the rotations for the 17(β)-hydroxypregnanes being of the order of 100° more toward the *levo* side.

The conversion of Δ^5-pregnene-3(β)-ol-20-one into 17-hydroxyprogesterone was also attempted but the drastic conditions required for hydroxylation of the 17,20 double bond, when conjugated with the 20-cyano group, led to an extensive attack on the $\Delta^{5,6}$ linkage. Oppenauer oxidation of $\Delta^{5,17}$-20-cyanopregnadiene-3(β)-ol gave $\Delta^{4,17}$-20-cyanopregnadiene-3-one but osmium tetroxide in the presence of pyridine appeared to attack both double bonds here also.

Experimental

Rotations were taken in acetone, $c \sim 1.0$. Melting points are corrected.

20-Cyanhydrin of Pregnane-3(α)-ol-11,20-dione Acetate (V).—A solution of 1.70 g. of pregnane-3(α)-ol-11,20-dione acetate (I) in a mixture of 17 cc. of alcohol and 6.4 cc. of acetic acid was cooled to 0° and treated with 6.0 g. of potassium cyanide. The mixture was stirred for one-half hour, then permitted to warm to room temperature. After two hours the solution was diluted with water and the crystalline precipitate was filtered and washed. The wet cake was dissolved in ethyl acetate, excess water removed and the solution concentrated *in vacuo* to a small volume. The addition of petroleum ether gave 1.64 g. of crystals which melted with decomposition at 205–220°. Recrystallization from ethyl acetate gave 1.3 g. of product; m. p. about 221–223° (dec.). A second recrystallization afforded a sample of melting point 217–232° (dec.). Recrystallization from alcohol lowered the melting point to 205–210°.

Anal. Calcd. for $C_{24}H_{35}NO_4$: C, 71.78; H, 8.80. Found: C, 71.50; H, 8.67.

A sample (35 mg.) dissolved in a minimum volume of benzene was put on a column of 1 g. of untreated chromatographic alumina. Elution with 20 cc. of ether gave 29 mg. of pregnane-3(α)-ol-11,20-dione acetate (I); m. p.

and mixed m. p. 135–136°. The experiment was repeated using acid-washed[7] alumina. A crystalline mixture, which melted at 149–170°, was obtained. Repeated recrystallization from methanol yielded a small amount of product of melting point 152–160°.

20-Cyanhydrin of Pregnane-3(α)-ol-11,20-dione (VI).—This cyanhydrin was prepared from II by the procedure given above. From 1.8 g. of ketone, 1.5 g. of recrystallized cyanhydrin, dec. 160–170°, was obtained.

Anal. Calcd. for $C_{22}H_{33}NO_3$: C, 73.49; H, 9.26. Found: C, 73.60; H, 9.51.

20-Cyanhydrin of Pregnane-3(α),21-diol-11,20-dione 21-Acetate (VIII).—This cyanhydrin failed to crystallize readily upon dilution of the alcohol–hydrogen cyanide reaction mixture. The diluted solution was consequently extracted with ethyl acetate, the latter solution washed with water and concentrated *in vacuo* to a small volume. From 2.0 g. of ketone (IV) 1.3 g. of recrystallized cyanhydrin was obtained. It decomposed at 175–185° and lost hydrogen cyanide in alcohol or dilute pyridine solution. A trace of acetic acid appeared to stabilize the compound completely, however.

Anal. Calcd. for $C_{24}H_{35}NO_5$: C, 69.03; H, 8.45; N, 3.35. Found: C, 68.91; H, 8.37; N, 3.60.

Pregnane-3(α),21-diol-11,20-dione Diacetate (III) and its 20-Cyanhydrin (VII).—A sample of pregnane-3(α),21-diol-11,20-dione 21-acetate (IV) was warmed on the steam-bath with pyridine–acetic anhydride for ten minutes. The solution was diluted with water and extracted with ether. The ethereal solution was washed with dilute hydrochloric acid, dilute sodium carbonate, finally with water and concentrated to a small volume. The addition of petroleum ether gave crystals of the diacetate, dec. 100–110°, which contained 10% of solvent of crystallization. From benzene–petroleum ether a sample of dec. p. 82–90° was obtained. Conversion of 3.0 g. of this ketone (solvated) to the cyanhydrin gave 2.2 g. of crystals; dec. 148–160°.

Cyanhydrin of Δ⁵-Pregnene-3(β)-ol-20-one Acetate.—The usual procedure afforded 88% of a product of melting point 194–198° with decomposition.

Anal. Calcd. for $C_{24}H_{35}NO_3$: C, 74.96; H, 8.92; N, 3.64. Found: C, 74.70; H, 9.05; N, 3.71.

20-Cyanhydrin of Pregnane-3,11,20-trione (IX).—A solution of 1.4 g. of the 20-cyanhydrin of pregnane-3(α)-ol-11,20-dione (VI) in 70 cc. of glacial acetic acid was cooled to 16° and treated over a period of twenty minutes with a solution of 0.9 g. of chromic acid in 7 cc. of acetic acid and 7 cc. of water. After one hour the solution was diluted with water, the precipitate filtered and dissolved in ethyl acetate. Excess water was removed and the solvent was taken off *in vacuo*. The crystalline residue weighed 1.1 g. Recrystallization from ethyl acetate gave 930 mg. of cyanhydrin; dec. 170–180°. For analysis the compound was dried *in vacuo* at room temperature, as with the other cyanhydrins, but, presumably because of solvation, no agreement with theory could be obtained.

20-Cyanhydrin of Pregnane-21-ol-3,11,20-trione Acetate (X).—A solution of 1.2 g. of the 20-cyanhydrin of pregnane-3(α),21-diol-11,20-dione acetate (VIII) in 20 cc. of acetic acid and 2 cc. of water was treated over a period of five minutes with a solution of 600 mg. of chromic acid in 1.2 cc. of water and 11 cc. of acetic acid. After the mixture had stood at room temperature for an hour, water was added and the product worked up as in the preceding oxidation. After purification, 1.0 g. of cyanhydrin, dec. 214–217°, was obtained.

Anal. Calcd. for $C_{24}H_{33}NO_5$: C, 69.36; H, 8.01; N, 3.37. Found: C, 69.31; H, 8.30; N, 3.36.

Samples of this cyanhydrin and of the cyanhydrin IX were treated with alkaline alumina in the manner described above. In both cases the parent ketone was obtained in high yield. Even acid-washed alumina gave 30–40% of the ketone, the remainder of the product being non-crystalline.

Δ¹⁷-20-Cyanopregnene-3(α)-ol-11-one Acetate (XI).—A solution of 2.5 g. of the 20-cyanhydrin of pregnane-3(α)-ol-11,20-dione acetate (V) in 8 cc. of pyridine was treated with 1.2 cc. of phosphorus oxychloride. After standing at room temperature overnight, the solution was diluted, the crystalline precipitate filtered and recrystallized from dilute alcohol. The product weighed 1.9 g. and melted at 199–201°. A sample was recrystallized from methanol for analysis and melted at 201.0–201.5°; $[\alpha]^{25}D$ +40°.

Anal. Calcd. for $C_{24}H_{33}NO_3$: C, 75.15; H, 8.67; N, 4.05. Found: C, 75.10; H, 8.62; N, 4.07.

With crude cyanhydrin the yield of the desired unsaturated nitrile was decreased out of all proportion to the amount of impurities initially present. A sample of cyanhydrin (V) which had been crystallized once from ethyl acetate–petroleum ether (90% of theory, dec. 200–210°) was dehydrated as above. Chromatography of the product gave only 20% of the unsaturated nitrile XI. The remaining crystalline fractions consisted of a mixture, m. p. 172–182°, the properties of which could not be greatly altered by recrystallization and for which the analytical data corresponded most closely to the same empirical formula as the nitrile XI.

Anal. Calcd. for $C_{24}H_{33}NO_3$: C, 75.15; H, 8.67; N, 4.05. Found: C, 75.57; H, 8.33; N, 3.55.

Δ¹⁷-20-Cyanopregnene-3,11-dione (XII).—The dehydration of the cyanhydrin IX was carried out in the manner described above. After chromatography of the crude product, 20% of XII was obtained; m. p. 229–237°; $[\alpha]^{25}D$ +38°.

Anal. Calcd. for $C_{22}H_{29}NO_2$: C, 77.84; H, 8.62. Found: C, 78.05; H, 8.67.

Δ¹⁷-20-Cyanopregnene-3(α),21-diol-11-one (XVI).—The dehydration of 2.2 g. of the cyanhydrin VII was carried out in the usual manner. The product was an oil (2.0 g.) which was chromatographed and the portions eluted with petroleum ether–ether mixtures combined. This material, which was presumably XIII, weighed 1.84 g. and failed to show signs of crystallizing. Hence it was saponified by dissolving in a mixture of 10 cc. of benzene and 10 cc. of 1.1 *N* methanolic potassium hydroxide. After ten minutes the solution was acidified with acetic acid, the benzene removed *in vacuo* and the residue crystallized from dilute methanol. The free diol melted at 242–254° and weighed 1.45 g. After recrystallization from acetone and from dilute alcohol it melted at 256–257°; $[\alpha]^{25}D$ +19.5°.

Anal. Calcd. for $C_{22}H_{33}NO_3$: C, 73.92; H, 8.73; N, 3.92. Found: C, 73.68; H, 8.48; N, 4.22.

Δ¹⁷-20-Cyanopregnene-21-ol-3,11-dione Acetate (XIV).—Dehydration of 6.2 g. of the cyanhydrin X according to the usual procedure gave a mixture which was diluted with water and extracted with benzene. The benzene solution was concentrated to dryness and the residue (4.7 g.) was chromatographed. The unsaturated nitrile (XIV) was isolated in 28% yield. Some samples melted at 181–182° with resolidification and remelting at 195–196°, while others only showed the higher melting point; $[\alpha]^{25}D$ +50°.

Anal. Calcd. for $C_{24}H_{31}NO_4$: C, 72.52; H, 7.85; N, 3.53. Found: C, 72.68; H, 7.85; N, 3.57.

Δ¹⁷-20-Cyanopregnene-21-ol-3,11-dione (XV).—Hydrolysis of the acetate (150 mg.) was accomplished by dissolving it in 5 cc. of methanol and adding 2 cc. of water containing 200 mg. of potassium carbonate. The solution was kept at 50° for fifteen minutes, the methanol was then removed *in vacuo* and the crystalline precipitate filtered. Recrystallization from ethyl acetate gave a product of melting point 263–265° (sample introduced at 250°); $[\alpha]^{25}D$ +36°.

(7) Chromatographic alumina was suspended in water and sufficient dilute sulfuric acid added to bring the *p*H to 3.0. The alumina was then washed repeatedly with sufficient distilled water to bring the *p*H to 5.5–6.0, then dried at 150°.

Anal. Calcd. for $C_{22}H_{29}NO_3$: C, 74.34; H, 8.22; N, 3.94. Found: C, 74.23; H, 8.00; N, 4.22.

$\Delta^{5,17}$-20-Cyanopregnadiene-3(β)-ol Acetate.—The dehydration of the cyanhydrin of Δ^5-pregnene-3(β)-ol-20-one acetate (900 mg.) in the usual manner gave 60% of a product of melting point 170–172°. This was chromatographed and recrystallized, but this treatment failed to produce an analytically pure sample. Hence, it was converted to the free alcohol.

$\Delta^{5,17}$-20-Cyanopregnadiene-3(β)-ol.—The benzene–methanolic potassium hydroxide method described above was used to hydrolyze $\Delta^{5,17}$-20-cyanopregnadiene-3(β)-ol acetate. Recrystallization of the crude product from dilute methanol gave 85% of the free alcohol; m. p. 176–177°; $[\alpha]^{25}D$ −86°.

Anal. Calcd. for $C_{22}H_{31}NO$: C, 81.18; H, 9.60. Found: C, 81.22; H, 9.16.

Attempted hydroxylation of this compound or of the corresponding Δ^5-3-acetoxy derivative by the osmium tetroxide–pyridine procedure described below gave oily products. Milder treatment gave only starting material.

Pregnane-3(α),17(α)-diol-11,20-dione (XVIII) and Its 3-Monoacetate (XIX).—To a solution of 1.65 g. of Δ^{17}-20-cyanopregnene-3(α)-ol-11-one acetate (XI) in 16 cc. of dry benzene was added 1.7 g. of osmium tetroxide and 0.75 cc. of pyridine. After standing at room temperature overnight, the mixture was treated with 50 cc. of water containing 3.0 g. of sodium sulfite. The benzene was then concentrated *in vacuo* to about 5 cc., and the whole was diluted with 50 cc. of alcohol. The mixture was stirred at room temperature for twenty hours, filtered, acidified with a few drops of acetic acid and concentrated *in vacuo* to a small volume. The aqueous mixture was extracted with chloroform, the chloroform solution concentrated to dryness *in vacuo* and the residue crystallized from acetone–ether. The 800 mg. so obtained was recrystallized from dilute alcohol, giving pregnane-3(α),17(α)-diol-11,20-dione; m. p. 207–208°; $[\alpha]^{25}D$ +68.5°.

Anal. Calcd. for $C_{21}H_{32}O_4$: C, 72.39; H, 9.25. Found: C, 72.54; H, 9.19.

The mother liquors (850 mg.) consisted of a crystalline mixture of the dioldione and its 3-acetate. It was converted entirely to the latter by dissolving it in 3 cc. of pyridine and 3 cc. of acetic anhydride. The addition of water after three hours gave 850 mg. of crystals; m. p. 206–208°. Recrystallization from dilute alcohol gave the pure 3-acetate (XIX); m. p. 208–209°; $[\alpha]^{25}D$ +84°. A mixed melting point with XVIII showed a depression of 30°.

Anal. Calcd. for $C_{23}H_{34}O_5$: C, 70.73; H, 8.79. Found: C, 70.83; H, 8.96.

Pregane-17(α)-ol-3,11,20-trione (XX) from Δ^{17}-20-Cyanopregnene-3,11-dione (XII).—The hydroxylation of XII was carried out according to the procedure described above. A yield of 83% of the oltrione, m. p. 205–206°, was obtained. A mixed melting point with the pregnane-17(α)-ol-3,11,20-trione prepared by oxidation of pregnane-3(α),17(α),20-triol-11-one showed no depression.

Anal. Calcd. for $C_{21}H_{30}O_4$: C, 72.78; H, 8.81. Found: C, 72.81; H, 8.70.

Pregnane-17(α)-ol-3,11,20-trione (XX) from Pregnane-3(α),17(α)-diol-11,20-dione (XVIII).—A solution of 75 mg. of XVIII in a mixture of 0.8 cc. of acetic acid and 0.2 cc. of water was treated with a solution of 60 mg. of chromic acid in 0.06 cc. of water and 1.14 cc. of acetic acid. After standing at room temperature for ten minutes the solution was diluted with water and extracted twice with chloroform. The washed chloroform solution was concentrated to dryness *in vacuo* and the residue crystallized from ether. Recrystallization from dilute acetone gave the pure oltrione; m. p. and mixed m. p. 205–206°.

Pregnane-3(α),17(α),21-triol-11,20-dione Diacetate (XXII).—The osmium tetroxide–sodium sulfite procedure described above was applied to 1.1 g. of Δ^{17}-20-cyanopregnene-3(α),21-diol-11-one diacetate (amorphous, prepared by acetylation of the pure Δ^{17}-20-cyanopregnene-3(α),21-diol-11-one (XVI) in the usual manner). The crude product was amorphous and presumably consisted of equal amounts of pregnane-3(α),17(α),21-triol-11,20-dione and its 3-monoacetate. In addition, the product was contaminated with some green osmium salts. These were partially removed by dissolving the product in a small volume of acetone and diluting with 100 cc. of absolute ether. The flocculent precipitate was separated, the supernatant yellowish solution was concentrated to dryness and dissolved in a mixture of 5 cc. of pyridine and 5 cc. of acetic anhydride. After standing at room temperature for several hours, the solution was diluted with water and the crystalline precipitate was filtered. Recrystallization from dilute acetone and from alcohol gave 504 mg. of the diacetate; m. p. 233–236°. Additional recrystallization from benzene and from acetone–ether failed to raise the melting point or to remove a trace of greenish discoloration; $[\alpha]^{25}D$ +93°.

Anal. Calcd. for $C_{25}H_{36}O_7$: C, 66.94; H, 8.08. Found: C, 66.41; H, 8.08.

Pregnane-17(α),21-diol-3,11,20-trione (XXIII).—One gram of Δ^{17}-20-cyanopregnane-21-ol-3,11-dione acetate (XIV) was treated with osmium tetroxide–pyridine and then hydrolyzed with sodium sulfite in the fashion described above. After concentration of the aqueous-alcoholic solution to a small volume *in vacuo*, it was extracted with four 150-cc. portions of chloroform which were then combined and washed with successive small portions of sodium bicarbonate, dilute hydrochloric acid and water, the washes being back extracted each time. The chloroform solution was then concentrated to dryness *in vacuo* and the residue (861 mg.) crystallized from acetone. A yield of 60% of dioltrione, m. p. 233–235°, was obtained. The pure material was sparingly soluble in chloroform, ethyl acetate and acetone.

Anal. Calcd. for $C_{21}H_{30}O_5$: C, 69.59; H, 8.33. Found: C, 69.45; H, 8.13.

The 21-monoacetate was prepared by treatment of the dioltrione with pyridine–acetic anhydride at room temperature. The initially insoluble starting material dissolved after five to ten minutes of stirring. After an additional five minutes the acetate was precipitated by addition of water. It melted at 228–230°; $[\alpha]^{25}D$ +82°.

Anal. Calcd. for $C_{23}H_{32}O_6$: C, 68.29; H, 7.98. Found: C, 68.14; H, 7.91.

Δ^4-Pregnene-17(α)-ol-3,11,20-trione (XXV).—To a solution of 86 mg. of pregnane-17(α)-ol-3,11,20-trione (XX) in 1.0 cc. of acetic acid was added a solution of 41 mg. of bromine in 0.41 cc. of acetic acid. After two minutes the bromine color suddenly disappeared, the solution was poured into water and extracted with chloroform. The chloroform solution was washed with dilute potassium carbonate and water, then concentrated to dryness *in vacuo*. The residue was crystallized from ether to give 71 mg. of crude crystalline 4-bromopregnane-17(α)-ol-3,11,20-trione; dec. *ca.* 185°. This substance was refluxed for five hours in pyridine, the latter removed *in vacuo* and the residue dissolved in ether and dilute hydrochloric acid. The washed ether layer was concentrated to a small volume and the crystalline precipitate (19 mg.) recrystallized twice from methanol. It then melted at 236–239°.

Anal. Calcd. for $C_{21}H_{28}O_4$: C, 73.23; H, 8.18. Found: C, 73.43; H, 7.49.

Δ^4-Pregnene-17(α),21-diol-3,11,20-trione Acetate (XXVI) (Kendall's Compound E Acetate).—A solution of 333 mg. of pregnane-17(α),21-diol-3,11,20-trione 21-acetate (XXIV) in 5.0 cc. of acetic acid was treated with a solution of 132 mg. of bromine in 1.0 cc. of acetic acid. After decolorization had ensued, the solution was worked up as above. Crystallization of the chloroform residue gave 300 mg. of the 4-bromo derivative; dec. 190°. This material was then refluxed with 12 cc. of pyridine for five hours and the mixture then concen-

trated *in vacuo*, dissolved in chloroform, washed with dilute hydrochloric acid and with water, and concentrated to dryness *in vacuo*. The residue (170 mg.) was crystallized from benzene by the addition of ether, giving 118 mg. of crude crystalline XXVI. This product was dissolved in 2.5 cc. of hot alcohol and the solution permitted to cool slowly to room temperature. It was then kept at −5° for two days at the end of which time the initial precipitate of long dense needles had become contaminated by a small superficial layer of fluffy crystalline balls, apparently containing the saturated dioltrione (XXIV). The needles were easily separated mechanically and after two further recrystallizations from alcohol melted at 236–238°. A total of 83 mg. was obtained; $[\alpha]^{25}D$ +170°. A mixed melting point with an authentic sample of Compound E acetate gave no depression.

Anal. Calcd. for $C_{23}H_{30}O_6$: C, 68.61; H, 7.52. Found: C, 68.85; H, 7.34.

The author is indebted to Miss Jean Andrews for assistance. Acknowledgment for microanalyses is made to Messrs. R. Boos, W. H. Humphrey, E. Thornton, J. McGregor and R. Funk.

Summary

A new method for the preparation of 17(α)-hydroxy-20-ketopregnanes is described. A 20-ketopregnane is converted to its cyanhydrin which is then dehydrated to give a Δ^{17}-20-cyanopregnene. With osmium tetroxide followed by aqueous sodium sulfite, the unsaturate nitrile is converted to the 17(α)-hydroxy-20-ketopregnane, hydrogen cyanide being spontaneously eliminated from the hypothetical intermediate, 17,20-dihydroxy-20-cyanopregnane. The method is also feasible for introducing a 17(α)-hydroxy group into a 20-keto-21-acetoxypregnane. This permits the synthesis of Kendall's Compound E.

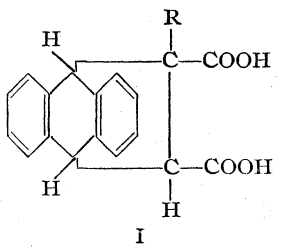
The Reaction of Anthracene with Maleic and Fumaric Acid and their Derivatives and with Citraconic Anhydride and Mesaconic Acid

BY W. E. BACHMANN AND L. B. SCOTT[1,2]

In the present work the addition of seven dienophiles to anthracene is described, the relative rates of reaction are compared, and the effects of changes in some of the reaction variables are noted. By the addition of both the *cis* and *trans* forms of a dienophile, information on the application of the rule of *cis* addition in the Diels–Alder reaction was obtained.

The reaction of maleic anhydride and anthracene to give *cis*-9,10-dihydroanthracene-9,10-endo-α,β-succinic anhydride[3] is well known. We obtained the same anhydride (and not the acid) in high yield from the reaction of maleic acid with anthracene in boiling dioxane. It is not known whether the molecule of water is lost before or after addition, but the latter seems probable in view of the ease with which the *cis*-diacid (I, R = H) is converted to the anhydride (*e.g.*, on recrystallization or on standing in a vacuum desiccator). Diels, Alder and Beckmann[4] prepared the *cis*-dimethyl ester from the anhydride. We have obtained this ester by the addition of dimethyl maleate to anthracene.



I

In spite of the impression that fumaric acid does not engage in the Diels–Alder reaction,[5] we tried its reaction with anthracene and obtained the addition product, the *trans*-acid (I, R = H) in 95% yield. Fumaric acid[6] reacts more slowly (see Table I) than maleic anhydride, requiring days of refluxing in a given solvent to hours for the anhydride. The reaction of anthracene with maleic acid (or maleic anhydride) to give the *cis* adduct and with fumaric acid to give the *trans* acid offers a simple classroom illustration of the

(1) From the Ph.D. dissertation of L. B. Scott, 1944.

(2) Present address: Shell Development Company, Emeryville, California.

(3) In this paper the prefixes *cis* and *trans* refer solely to the configuration at the two carbon atoms attached to the carboxyl groups and not to the configuration at the 9,10 positions.

(4) Diels, Alder and Beckmann, *Ann.*, **486**, 191 (1931).

(5) Alder and Stein, *Ann.*, **514**, 203 (1934) mention that fumaric acid does not add to cyclopentadiene. On page 309 of Richter's "Textbook of Organic Chemistry," 2nd ed., John Wiley and Sons, Inc., New York, N. Y. 1943, the following statement appears in the section on the Diels–Alder reaction: "This type of reaction does not occur with the *trans* isomer, fumaric acid."

Dilthey and Henkels, *J. prakt. Chem.*, **149**, 85 (1937), stated that the product obtained from acecyclone and fumaric acid was identical with that obtained with maleic acid (or anhydride) and attributed this result to the addition of maleic acid formed by rearrangement of the fumaric acid. After our work had been completed (1942; publication delayed by the war), Bergmann, Eschinazi and Neenam, *J. Org. Chem.*, **8**, 179 (1943), reported the formation of an amorphous acid adduct from 1,1′-bicyclohexenyl and fumaric acid at 190–200°. The nature of the adduct, which was characterized as a dianilide, was not clearly indicated.

(6) In the paper which follows a Diels–Alder reaction is reported in which fumaric acid was superior to maleic anhydride in that it gave a higher yield of adduct and a lower yield of copolymer.

principle of *cis* addition of the diene to the double bond of the dieneophile. We have also prepared the *trans*-dimethyl ester in high yield by the direct addition to anthracene of dimethyl fumarate. Unlike the *cis*-diacid, the *trans*-diacid showed no tendency to lose water and form an anhydride and could be recrystallized unchanged from a mixture of acetic anhydride and acetic acid.

cis-9,10-Dihydroanthracene-9,10-endo-α-methyl-α,β-succinic anhydride (anhydride of I, R = CH_3) had been prepared previously in unspecified yield, by melting together anthracene and citraconic anhydride.[4] We have prepared it in 96% yield by refluxing the same reactants in either toluene or xylene solution. The *trans*-diacid was obtained directly through the reaction of anthracene and mesaconic acid. Here, too, the *cis*-diacid lost water readily to form the corresponding anhydride whereas the *trans*-diacid did not; in fact, the latter could be sublimed unchanged at 200°. The *cis*-dimethyl ester and the *trans*-dimethyl ester were prepared by treating the corresponding diacids with diazomethane. The *cis*-diester was isomerized to the *trans*-diester by prolonged treatment with methanolic potassium methoxide. The rearrangement of this *cis*-ester with an α-methyl group to the *trans* configuration proceeded much more slowly than the rearrangement of the *cis*-ester without the α-methyl group.

The reaction of bromomaleic anhydride and anthracene yielded *cis*-9,10-dihydroanthracene-9,10-endo-α-bromo-α,β-succinic anhydride. When this anhydride was warmed gently with potassium hydroxide, the bromine group was replaced and the corresponding α-hydroxy diacid was isolated. No attempt was made to determine whether the hydroxy diacid was *cis* or *trans*, but its method of preparation and its stability toward anhydride formation during recrystallization favor the *trans* configuration. These compounds should prove useful for a study of the Walden inversion.

The relative rates of most of the above Diels–Alder reactions were compared in a series of experiments in which homogeneous dioxane solutions of equimolar quantities of the two reactants were refluxed for measured periods of time. The yields of the product are recorded in Table I; the relative accuracy of the results is considered to be ±2–3%.

TABLE I

RELATIVE RATE OF ADDITION OF DIENOPHILES TO ANTHRACENE

Anthracene, 0.0112 mole; dienophile, 0.0112 mole; dioxane, 50 cc.; reaction temperature, *ca.* 102°

Dienophile	Reaction time, hr.	Anthracene isolated, %	Yield[a] of product, %
Maleic anhydride	2	31	67
Bromomaleic anhydride	2	62	36
Maleic acid	2	92	6.5
Maleic acid	24	52	47
Dimethyl fumarate	24	58	41[b]
Fumaric acid	24	70	28
Citraconic anhydride	24	70;73	28;26
Mesaconic acid	24	92	7.5

[a] High yields of the adducts were obtained by increasing the reaction time, the concentration or the temperature (by means of a higher boiling solvent) (see Experimental). [b] Product isolated as the *trans*-diacid.

Slower rates resulted when the maleic anhydride was replaced by a *cis*-diacid, a *trans*-diacid or a *trans*-diester, or when a hydrogen on one of the double-bond carbons was replaced by a bromine or a methyl group. It is of interest that bromomaleic anhydride reacts very much more rapidly than does citraconic anhydride although the bromine atom and the methyl group are thought to be similar in size.[7] The substitution of a hydrogen by a bromine would increase the electron affinity of the dienophile while replacement by a methyl group would not. The rate of addition of chloromaleic and fluoromaleic anhydride would be of interest in this connection as the steric factor should have a lesser magnitude and the electronic factor a greater one.

In another series of runs (Table II) the rate of reaction of citraconic anhydride with anthracene in equal volumes (sufficient for complete solution) of different solvents was determined. As expected, the rate of reaction increased as the reaction temperature was increased. The rate of reaction was greater than expected from the increase in temperature when a mildly polar solvent such as acetic or propionic acid was used instead of low polarity solvents such as toluene and xylene.[8] An experiment was conducted in 2-nitropropane because of this solvent's somewhat polar nature, but no enhancement of the rate was observed.

TABLE II

EFFECT OF REACTION TEMPERATURE AND SOLVENT ON THE RATE OF REACTION OF ANTHRACENE AND CITRACONIC ANHYDRIDE

Anthracene, 0.0112 mole; citraconic anhydride, 0.0112 mole; solvent, 25 cc. except as noted; reaction time, 24 hours

Solvent	Approx. reaction temperature, °C.	Anthracene isolated, %	Yield of product, %
Benzene	78	91	8
Dioxane	102	59;58	40;41
Toluene	111	52;49	47;49
2-Nitropropane	122	38	62
Xylene	142	21;21;18	78;78;80
Acetic acid (50 cc.)	119	40	59
Acetic acid (30 cc.)	119	15	83
Propionic acid	144	13	86

The effect of the concentration of the reactants on the rate of addition of anthracene to citraconic anhydride was studied in still another group of experiments (Table III). Different volumes of dioxane were used for equimolar quantities of the

reactants, and the homogeneous solutions were refluxed for twenty-four hours. The values calculated for a bimolecular reaction rate constant were in fairly close agreement.

TABLE III

EFFECT OF CONCENTRATION OF REACTANTS ON THE RATE OF REACTION OF ANTHRACENE AND CITRACONIC ANHYDRIDE

Anthracene, 0.0112 mole; citraconic anhydride, 0.0112 mole; reaction time, 24 hours; reaction temperature, *ca.* 102°

Volume of dioxane, cc.	Anthracene isolated, %	Yield of product, %	k^a
12.5	43	57	69
25	58; 59	41; 40	69
50	70; 73	28; 26	71
100	85	14.5	67

[a] Bimolecular reaction rate constant (cc./hr. moles) calculated using the higher value for "% anthracene isolated" where there was a choice. The volume of the solution was taken as the volume of the solvent + 1.5 cc.

Experimental

Reactions of Anthracene

With Maleic Acid.—A solution of 2 g. (0.0112 mole) of anthracene and 3.9 g. (0.0336 mole) of maleic acid in 17 cc. of dioxane was refluxed for thirty hours. The dioxane was removed in a current of air on a steam-bath and the residue was shaken for two hours at room temperature with excess, dilute sodium bicarbonate (this treatment had been shown to have no effect on the anhydride). The mixture was filtered and the filtrate was added to an excess of hydrochloric acid; yield of *cis*-9,10-dihydroanthracene-9,10-endo-α,β-succinic acid, 0.035 g. (1%). The bicarbonate-insoluble residue (the anhydride) was warmed gently with 45% potassium hydroxide, water and benzene (in that order) and the clear layers were separated. The benzene layer contained 0.065 g. (3%) of anthracene while the aqueous layer, upon addition to excess hydrochloric acid, yielded 3.10 g. (94%) of *cis*-diacid (I, R = H). As has been reported,[9] the *cis*-diacid crystallized from ethyl acetate as colorless prisms of the corresponding *cis*-anhydride; m. p. 264–264.5° cor. (reported,[4] 262–263° for the product prepared directly by the addition of maleic anhydride to anthracene). When a small sample of the diacid in a melting point tube was plunged into a bath at 255° cor., it melted with gassing, solidified after 20–30 seconds and remelted (presumably as the *cis*-anhydride) at 261–263° cor.

With Fumaric Acid.—A solution of 6 g. (0.0336 mole) of anthracene and 1.3 g. (0.0112 mole) of fumaric acid in 50 cc. of dioxane was refluxed for three days, the solvent was removed, and the residue was shaken several hours with dilute sodium bicarbonate and then worked up in the same manner as was the maleic acid mixture; the benzene layer contained 4.08 g. of anthracene. The bicarbonate solution was slowly added with stirring to warm, dilute hydrochloric acid and the mixture was filtered while warm (to keep fumaric acid in solution); yield of *trans*-9,10-dihydroanthracene-9,10-endo-α,β-succinic acid, 3.13 g. (95%); m. p. 240–242° dec. with previous softening at 238° (reported,[4] 241–242° dec.). A portion of the diacid treated with ethereal diazomethane gave the *trans*-dimethyl ester which crystallized from methanol in colorless, rhombic plates; m. p. 108.4–108.9° cor. (reported,[4] 106–107° for the product obtained by isomerization of the *cis*-diester by sodium methylate). The *trans*-diacid showed no tendency to form either a *cis* or a *trans*-anhydride when recrystallized from acetic anhydride–glacial acetic acid or when stored for several days in a vacuum desiccator.

(9) Bachmann and Kloetzel, THIS JOURNAL, **60**, 481 (1938).

With Dimethyl Maleate.—Two grams (0.0112 mole) of anthracene, 2.43 g. (0.0168 mole) of dimethyl maleate[10] and 10 cc. of dioxane were refluxed for eight days. The clear solution was transferred to a sublimation tube, the solvent was removed and the residue was evaporatively distilled at about 0.05 mm. The light-yellow material distilling between 140 and 175° (*cis*-dimethyl ester contaminated with a small amount of anthracene) weighed 3.56 g. and melted at 139–146° with previous softening; estimated yield of diester, 90–95%. After three recrystallizations from methanol, the square, colorless plates of the dimethyl ester of *cis*-9,10-dihydroanthracene-9,10-endo-α,β-succinic acid melted at 150–150.5° cor. This ester (m. p. 150–151°) has been prepared previously by the action of methanolic hydrogen chloride on the *cis*-acid.[4]

In a second experiment a solution of 2 g. (0.0112 mole) of anthracene, 8.1 g. (0.056 mole) of dimethyl maleate and 65 cc. of xylene was refluxed for three days. The xylene was removed and the residue was refluxed for seventeen hours with 50 cc. of methanol and 25 cc. of 45% potassium hydroxide. The methanol was removed, water and benzene were added and the clear layers were separated. The benzene layer contained 0.24 g. (12%) of anthracene and the aqueous layer 2.89 g. (87%) of *trans*-diacid; m. p. 239.5–241° dec. The product was converted to the *trans*-dimethyl ester with diazomethane and was crystallized from methanol; m. p. 108–108.5° cor. alone and when mixed with an authentic sample of the *trans*-diester.

With Dimethyl Fumarate.—A solution of 2 g. (0.0112 mole) of anthracene and 2.43 g. (0.168 mole) of dimethyl fumarate (prepared by the action of methanolic hydrogen chloride on maleic anhydride; m. p. 101–100.5° after recrystallization from methanol) in 12 cc. of dioxane was refluxed for three days. The solvent was removed and the residue was evaporatively distilled at about 0.05 mm. A total of 3.63 g. of light-yellow *trans*-dimethyl ester contaminated with a small amount of anthracene distilled at 140–175°; estimated yield of diester, 90–95%. Three recrystallizations from methanol raised the melting point of the product from 90–96° to 107–108° cor.

In another experiment a solution of 2 g. (0.0112 mole) of anthracene and 16.2 g. (0.11 mole) of dimethyl fumarate in 150 cc. of xylene was refluxed for three days, and the reaction product was hydrolyzed with methanolic potassium hydroxide and worked up in the manner described in the corresponding dimethyl maleate experiment; anthracene, 0.20 g. (10%); *trans*-diacid, 2.87 g. (87%).

With Citraconic Anhydride.—A solution of 2 g. (0.0112 mole) of anthracene and 2.52 g. (0.0224 mole) of citraconic anhydride[11] in 25 cc. of xylene (or toluene) was refluxed for eighty-four hours. Most of the solvent was removed in a current of air, the residue was treated with 45% potassium hydroxide, water and benzene, and the clear layers were worked up in the usual manner; anthracene, 0.06 g. (3%); *cis*-9,10-dihydroanthracene-9,10-endo-α-methyl-α,β-succinic acid (I, R = CH_3), 3.33 g. (96%). When a small sample of the diacid in a melting point tube was plunged into a bath at 173°, it melted with gassing, solidified after 15–20 seconds and remelted (presumably as the *cis*-anhydride) at 181–182°.

The *cis*-diacid was readily converted into the *cis*-anhydride by prolonged drying in a vacuum desiccator or recrystallization from ethyl acetate. The anhydride product evaporatively distilled at 160–190° and *ca.* 0.05 mm. without appreciable decomposition and crystallized from ethyl acetate in fine, colorless prisms; m. p. 185.1–185.5° cor. (reported,[4] 182° after repeated recrystallizations). The *cis*-anhydride was formed in about 60% yield by heating 1.8 g. of anthracene with 1.3 g. of citraconic anhydride at 155–165° for two hours according to the procedure of Diels, Alder and Beckmann.[4]

(10) Wolf and Straete, *Bull. classe sci., Acad. roy. Belg.*, **21**, 216 (1935).

(11) Shriner, Ford and Roll, "Organic Syntheses," **11**, 28, 70 (1931).

Three grams of recrystallized *cis*-anhydride was hydrolyzed by warm dilute sodium hydroxide, and the clear solution was added to an excess of hydrochloric acid. The damp *cis*-diacid was treated with ethereal diazomethane and the product was triturated with dilute sodium bicarbonate; yield, 3.40 g.; m. p. 133–134.5°. After recrystallization from methanol and evaporative distillation at 135–145° and *ca.* 0.05 mm., the **dimethyl ester of *cis*-9,10-dihydroanthracene-9,10-endo-α-methyl-α,β-succinic acid** crystallized from methanol in colorless plates; m. p. 140.9–141.2° cor.

Anal. Calcd. for $C_{21}H_{20}O_4$: C, 74.97; H, 5.99. Found: C, 75.00; H, 6.01.

The same compound was prepared in only slightly lower yield by refluxing for eight hours a solution of 5 g. of the anhydride in 250 cc. of methanol which had been saturated with dry hydrogen chloride at 0° and which was treated with hydrogen chloride during the refluxing period.

With Mesaconic Acid.—Two grams (0.0112 mole) of anthracene, 7.3 g. (0.056 mole) of mesaconic acid[12] (m. p. 204–205° cor.) and 40 cc. of propionic acid were refluxed for ninety-six hours at about 144°. The temperature was then held at 90–95° for seventy-two hours more, a total reaction time of seven days. The light-yellow solution gradually darkened but remained clear. The reaction mixture was worked up as before; anthracene, 0.35 g. (17.5%); *trans*-diacid, 2.79 g. (80%). The ***trans*-9,10-dihydroanthracene-9,10-endo-α-methyl-α,β-succinic acid** (I, R = CH_3), after a treatment with Norit in acetone, crystallized from acetone–ethyl acetate as a colorless powder; m. p. 232.1–232.4° dec. cor.

Anal. Calcd. for $C_{19}H_{16}O_4$: C, 74.02; H, 5.23; neut. equiv., 154. Found: C, 74.04; H, 5.29; neut. equiv., 154.

The *trans*-diacid showed no tendency to form an anhydride. When an unpurified sample (m. p. 214–219° dec.) was heated in a sublimation tube at 200–220° and *ca.* 0.05 mm., some decomposition occurred; but most of the material sublimed as colorless, bicarbonate-soluble, *trans*-diacid.

The ***trans*-dimethyl ester,** prepared from recrystallized acid and diazomethane, crystallized from methanol in colorless, rhombic prisms; m. p. 119.2–119.7° cor.

Anal. Calcd. for $C_{21}H_{20}O_4$: C, 74.97; H, 5.99. Found: C, 75.17; H, 6.05.

The *trans*-diester was also prepared from the *cis*-isomer. A solution of 1 g. of the *cis*-dimethyl ester, 60 cc. of methanol and 30 cc. of 45% potassium hydroxide was refluxed for thirty-two hours. From it 0.78 g. of diacid was isolated, which on treatment with diazomethane and recrystallization of the product from methanol yielded 0.6 g. (60%) of *trans*-dimethyl ester; m. p. 117–118.5°. In another experiment, 1 g. of the *cis*-dimethyl ester and 0.03 g. of potassium metal were dissolved in 75 cc. of anhydrous methanol, and the solution was refluxed for forty-five hours. The recovered product was shown to be a mixture of about 75% *trans*- and 25% *cis*-diester by fractional crystallization. When a solution of 1.91 g. of the ester in 60 cc. of anhydrous methanol in which 20 mg. of sodium had been dissolved was refluxed for thirty minutes, no change occurred. Under the same conditions the corresponding maleic ester addition product was isomerized to the *trans*-ester.

With Bromomaleic Anhydride.—A mixture of 2 g. (0.0112 mole) of anthracene, 3 g. (0.0169 mole) of bromomaleic anhydride (prepared from dibromosuccinic acid by the method of Walden[13]; b. p. 72–75° at 2–3 mm.) and 15 cc. of toluene was heated on a steam cone for forty-eight hours. The reaction mixture was cooled, a few dark-brown particles were removed by filtration, and the filtrate was concentrated to about one-half of its original volume in a vacuum desiccator. The crystals of ***cis*-9,10-dihydroanthracene-9,10-endo-α-bromo-α,β-succinic anhydride** which precipitated were filtered and washed with ether; yield, 2.59 g.; m. p. 169–170° cor. A single recrystallization from acetone raised the melting point to 171.5–172.9° cor.

Anal. Calcd. for $C_{18}H_{11}BrO_3$: C, 60.87; H, 3.12. Found: C, 60.81; H, 3.13.

The solvent was removed from the filtrate and the residue was warmed gently with 45% potassium hydroxide, water and benzene. The benzene layer contained 0.06 g. (3%) of anthracene and the acidified and concentrated aqueous layer yielded 1.02 g. (31%) of **9,10-dihydroanthracene-9,10-endo-α-hydroxy-α,β-succinic acid**; m. p. 224–230° dec. cor. with previous softening. The hydroxy diacid crystallized from ethyl acetate in colorless prisms; m. p. 232.5–233.2° dec. cor.

Anal.[14] Calcd. for $C_{18}H_{14}O_5$: C, 69.66; H, 4.55; neut. equiv., 155. Found: C, 69.63; H, 4.69; neut. equiv., 155.

Summary

The reaction of anthracene with seven dienophiles is described. The order of reactivity with anthracene was found to be: maleic anhydride > bromomaleic anhydride > maleic acid > dimethyl fumarate > fumaric acid, citraconic anhydride > mesaconic acid.

The addition of the *trans*-dienophiles fumaric acid and mesaconic acid yielded *trans*-acids in agreement with the rule of *cis*-addition.

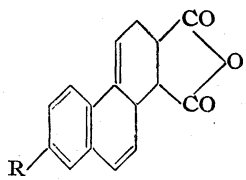
The Reaction of 1-Vinylnaphthalene and 6-Methoxy-1-vinylnaphthalene with Citraconic Anhydride, Fumaric Acid and Mesaconic Acid[1]

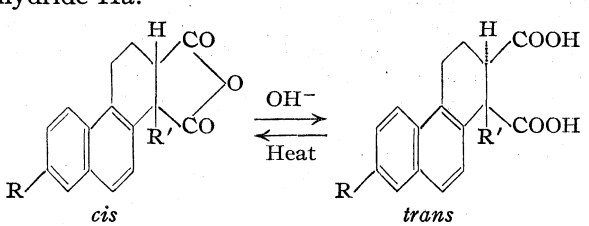
BY W. E. BACHMANN AND L. B. SCOTT[2]

Cohen[3] made the interesting discovery that 1-vinylnaphthalene can function as a diene in the Diels–Alder reaction. From the reaction of this hydrocarbon with maleic anhydride in xylene, *cis*-1,2,3,10a-tetrahydrophenanthrene-1,2-dicarboxylic anhydride (Ia) was obtained.[4] The product was isomerized to the naphthalenic compound 1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic anhydride (IIa) by treatment with glacial acetic acid saturated with dry hydrogen chloride.



Ia, R = H
Ib, R = OCH_3

We have investigated this reaction and similar ones and have examined the by-products. It was found that when 1-vinylnaphthalene and maleic anhydride reacted in toluene at 90–100° a mixture of monomeric and copolymeric addition products was formed.[5] The monomeric portion which was essentially the non-naphthalenic anhydride (Ia) could be isolated from the mixture in 16% yield by recrystallization. When the crude mixture was subjected to evaporative distillation at low pressure, the distillate was the *cis*-naphthalenic anhydride IIa.

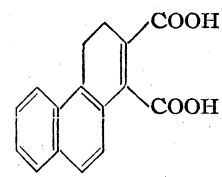


cis *trans*

IIa, R = R′ = H
IIb, R = OCH_3, R′ = H
IIc, R = H, R′ = CH_3
IId, R = OCH_3, R′ = CH_3

IIIa, R = R′ = H
IIIb, R = OCH_3, R′ = H
IIIc, R = H, R′ = CH_3
IIId, R = OCH_3, R′ = CH_3

Various procedures were tried to separate the maximum amount of monomeric product from the mixture. The best procedure consisted in hydrolysis of the crude mixture, esterification of the resulting diacid with diazomethane, and evaporative distillation. In this manner the dimethyl ester of *cis*-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid (acid corresponding to IIa) was obtained in 60% yield. Recently, Cohen's structure for this ester was confirmed by Fujimoto[6] in this Laboratory, who obtained the same ester by esterifying the acid prepared by sodium amalgam reduction of the acid IV derived from the 3,4-dihydrophenanthrene-1,2-dicarboxylic anhydride of Fieser and Hershberg.[7] The formation of the *cis* acid showed that *cis* addition of hydrogen to the double bond had taken place.



IV

When vinylnaphthalene and maleic anhydride were refluxed in acetic or propionic acid, the monomeric addition product was entirely naphthalenic and consisted of a mixture of anhydride and diacid that contained some of the *trans*-isomer. It is considered that the primary product Ia is isomerized under the conditions of the experiment.

Of considerable interest is the result with the *trans*-dienophile, fumaric acid. Although fumaric acid reacts more slowly than maleic anhydride (110 hours required compared with 3 hours for maleic anhydride), it was found to be superior: the yield of monomeric adduct was higher and that of copolymer was lower. The addition product from fumaric acid and vinylnaphthalene in boiling propionic acid was entirely naphthalenic. After esterification with diazomethane and evaporative distillation of the product, an 89% over-all yield of *trans*-diester (ester of IIIa) containing some *cis*-diester was obtained. The presence of the *cis*-isomer may have been the result of a conversion of some of the fumaric acid to maleic anhydride during the long reflux period at elevated temperatures.

Pure *trans*-diacid (IIIa) can be prepared by treating either the *cis*-diacid or diester (or *cis*–*trans*-mixtures) with methanolic potassium hydroxide, while pure *cis*-diacid can be obtained by gentle alkaline hydrolysis of distilled and recrystallized *cis*-anhydride (IIa). Both the *cis*- and

trans-diacids can be recrystallized unchanged but each is converted to the *cis*-anhydride by evaporative distillation at 160–200° under reduced pressure. The pure diesters were prepared by treating the corresponding diacids with diazomethane; *cis*-dimethyl ester was also obtained by refluxing pure *cis*-anhydride with methanol and treating the resultant acid-ester with diazomethane. Both esters can be evaporatively distilled unchanged. The above results indicate that the best preparative procedure for this group of compounds involves the addition of fumaric acid to vinylnaphthalene in acetic or propionic acid followed by conversion of the *cis–trans*-mixture so obtained to either a pure *cis*- or a pure *trans*-addition product by the methods outlined above.

The results from 6-methoxy-1-vinylnaphthalene and maleic anhydride to give IIb and with fumaric acid to yield IIIb were entirely analogous. Here, too, the *cis–trans* and *trans–cis* interconversions could be carried out. The only previous work with these compounds was that of Cohen and Warren,[4] who obtained the methoxy derivative Ib from the reaction of 6 methoxy-1-vinylnaphthalene and maleic anhydride in xylene.

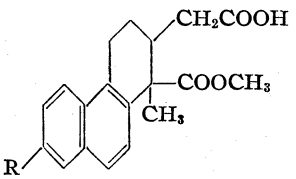
It has been reported[8] that citraconic anhydride does not react with 1-vinylnaphthalene. We found that reaction did occur in benzene, toluene, xylene, and dioxane but only alkali-soluble copolymers were formed. However, when the reaction was carried out in boiling acetic or propionic acid, the product was a mixture of copolymeric material and *cis*-naphthalenic monomer (44–49%). The Diels–Alder reaction followed by isomerization could give rise to two *cis*-naphthalenic anhydrides, one with the methyl group in the 1-position (IIc) and the isomer with the methyl group in the 2-position. Only a single isomer was isolated and all the evidence indicates that it is the product with the methyl group in the 1-position, namely, *cis*-1 methyl-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic anhydride (IIc).[9] The *trans*-diacid (IIIc) was prepared directly in yields as high as 57% from mesaconic acid and 1-vinylnaphthalene in propionic acid.

The *cis*- and the *trans*-diacids were both converted to the *cis*-anhydride by evaporative distillation. When the *cis*-diester was refluxed with methanolic potassium hydroxide for twenty-four hours, a *cis–trans*-diacid mixture was obtained.

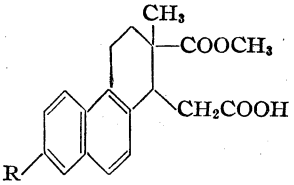
The evidence for the location of the methyl group in the 1-position is three-fold. A methyl group was introduced into the alicyclic ring of the dimethyl ester of *trans*-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid (ester of IIIa) by forming a sodio derivative with triphenylmethylsodium and adding methyl iodide. It was expected that the α-H adjacent to the naphthalene ring would be the one to be replaced by the methyl group in this reaction. The complex mixture of *cis*- and *trans*-compounds that resulted was converted to a totally *cis*-mixture and was fractionally crystallized. The only product isolated in pure form was the dimethyl ester of *cis*-1-methyl-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid (ester of acid of IIc).

The calcium salt of the *cis*-diacid (derived from IIc) was dry-distilled and the distillate was dehydrogenated. The product was a mixture but it gave a single, pure picrate: the picrate of 1-methylphenanthrene.

The *trans*-diester of IIIc was half-hydrolyzed in 99% yield by refluxing its methanolic solution with one equivalent of sodium hydroxide. Since esters of secondary carboxyl groups are saponified much more rapidly than esters of tertiary carboxyl groups, the half-ester probably has the free carboxyl group in the 2-position. When a sample of *cis*-diester was similarly half-hydrolyzed a *cis–trans*-acid ester mixture resulted. An Arndt–Eistert synthesis was carried out on the *trans*-acid ester. The product, which is considered to be IV (R = H) depressed the melting point of both the *cis*- and *trans*-forms of V[10] (R = H) one of which was expected if the original adduct had the methyl group in the 2-position.



IV



V

The addition of 1-vinyl-6-methoxynaphthalene in boiling acetic or propionic acid to citraconic anhydride gave IId (60% yield isolated as the ester) and to mesaconic acid yielded IIId (72% yield isolated as the ester). The properties of the products were similar to those of the desmethoxy compounds. The *cis* and *trans* forms of the dimethyl ester of 7-methoxy-1-methyl-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid were obtained by C-methylation of the ester of IIIb. The product (probably IV, R = OCH_3) obtained by an Arndt–Eistert reaction on the half-ester differed from the *cis* and *trans* forms of V (R = OCH_3). Further confirmation of the structures is being sought by synthesis by other methods.

Experimental

Reactions of 1-Vinylnaphthalene

With Maleic Anhydride. (a) In Toluene.—A solution of 4.45 g. (0.0289 mole) of freshly prepared and distilled 1-vinylnaphthalene[4] (b. p. 93–99° at 9–10 mm.), 3.36 g. (0.0342 mole) of freshly sublimed maleic anhydride and 10 cc. of dry toluene was warmed on a steam-cone for three hours. Light-yellow solid began to precipitate almost immediately. The mixture was cooled and the precipitate was filtered and washed with 10 cc. of toluene; yield, 6.63 g. of a mixture of monomeric and copolymeric

(8) Bergmann and Bergmann, THIS JOURNAL, **59**, 1443 (1937).

(9) The preparation of the isomer with the methyl group in the 2-position is described in the paper by Bachmann and Chemerda which follows.

(10) Bachmann and Wilds, THIS JOURNAL, **62**, 2084 (1940).

addition products, which sintered at 125°, softened at 170° and melted at 177–191° dec. It was soluble in warm, dilute sodium hydroxide but not in dilute sodium bicarbonate, and it reacted with neutral permanganate and 5% bromine in carbon tetrachloride, in agreement with results previously reported. The solvent was removed from the filtrate in a current of air on a steam cone and the residue was treated with 45% potassium hydroxide, water and benzene (in that order). A minimum of gentle warming was used to effect solution, the clear layers were separated, and an additional 0.34 g. of almost completely copolymeric product and 0.15 g. (3% of the charged diene) of viscous, brown oil were isolated from the aqueous and benzene phases, respectively. The hydrocarbon fraction, which reacted instantly with permanganate, was presumably 1-vinylnaphthalene and its homopolymers.

A portion of the initial 6.63 g. of product was dissolved in dilute sodium hydroxide with a minimum of gentle warming and was added to excess hydrochloric acid. The resultant diacid mixture was treated with diazomethane and was evaporatively distilled at 160–200° and *ca.* 0.05 mm. A light-yellow distillate of the dimethyl ester of *cis*-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid (ester of IIa) was obtained in what corresponded to a 60% yield based on 1-vinylnaphthalene; a residue, presumably polymeric, remained undistilled after two hours at 200°. The diester distillate which was inactive toward neutral permanganate and 5% bromine in carbon tetrachloride crystallized from methanol in stout colorless prisms, m. p. 105.5–106.5° cor. Cohen[3,4] prepared this compound by the action of methanolic hydrogen chloride on the naphthalenic anhydride and by the action of dilute sodium hydroxide and dimethyl sulfate on the non-naphthalenic anhydride (Ia).

A second portion of the initial product was dissolved in glacial acetic acid saturated with dry hydrogen chloride and was refluxed for ninety minutes with the constant addition of a slow stream of hydrogen chloride.[4] It was then converted to the diacid, esterified with diazomethane, and evaporatively distilled as above. Approximately the same over-all yield of monomeric product was obtained as above, but it proved to be a mixture of the *cis*- and *trans*-naphthalenic dimethyl esters; m. p. 92–96.5° with previous softening at 90° after one crystallization from methanol. Fractional recrystallization using seeds of pure *cis*- and *trans*-diesters (m. p. 106° and 68°, respectively) resulted in the isolation of pure, colorless samples of each of these compounds.

A third portion was treated with acetic acid–hydrogen chloride as above and was evaporatively distilled without further treatment at 180–200° and *ca.* 0.05 mm. Yellow *cis*-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic anhydride (IIa) distilled in what corresponded to a 36% over-all yield based on 1-vinylnaphthalene. The *cis*-anhydride showed no activity toward neutral permanganate or 5% bromine in carbon tetrachloride and crystallized from ethyl acetate in light-yellow prisms melting at 168.5–170° cor. After treatment with Norit in acetone and recrystallization from acetone-ethyl acetate, the pale-yellow prisms melted at 170.3–170.8° cor. (reported,[3,4] 167–168° for a sample of adduct treated with acetic acid-hydrogen chloride; 169–170°[8] for a solid treated with hot glacial acetic acid and recrystallized from acetic acid–acetic anhydride and from toluene). A portion of the recrystallized *cis*-anhydride was converted to the *cis*-diacid which crystallized from glacial acetic acid in colorless, powdery crystals melting at 228–229° dec. (reported,[4] 220° dec.). Another portion of the anhydride was refluxed in methanol for twenty hours. After about one and one-half hours the pale-yellow crystals had completely dissolved to form a faintly yellow solution, which became colorless during the next few hours. The solution was cooled and treated with diazomethane without the isolation of the intermediate acid-ester. The *cis*-dimethyl ester melted at 108.5–109° cor.

When a portion of the initial addition product was evaporatively distilled without prior treatment of any kind, much decomposition occurred and some maleic anhydride was collected; over-all yield of *cis*-anhydride (IIa), *ca.* 10%.

With the rest of the initial product it was shown that the polymeric material was more soluble than the monomeric in toluene, in ethyl acetate, in glacial acetic acid and in acetone. Accordingly, the above Diels–Alder reaction was duplicated on a 0.13-mole scale and the initially precipitated addition product was recrystallized once from toluene and twice from acetone. The colorless crystals of *cis*-1,2,3,10a-tetrahydrophenanthrene-1,2-dicarboxylic acid anhydride (Ia) weighed 5.3 g. (16%); m. p. 187.5–190° dec. with previous softening at 186° (reported,[4] 186–189° for a product obtained in a similar manner).

(b) **In Acetic or Propionic Acid.**—A solution of 4.2 g. (0.027 mole) of 1-vinylnaphthalene and 3.35 g. (0.034 mole) of maleic anhydride in 10 cc. of acetic acid was warmed on a steam cone for three hours. The clear, yellow solution was cooled and the colorless precipitate was filtered and washed, yield 2.91 g. (39%). The solvent was removed from the filtrate and the residue was warmed with 45% potassium hydroxide, water and benzene as before. The aqueous layer gave 3.38 g. (45%) of product; the hydrocarbon fraction weighed 0.61 g. (14%). Experiments similar to those conducted above established the following facts: (a) the product was a mixture of monomeric and copolymeric solids that reacted sluggishly and to only a slight extent with neutral permanganate and 5% bromine in carbon tetrachloride; (b) the monomeric product, a mixture of anhydride and diacid, was essentially *cis* but contained some *trans;* (c) by esterification of the total addition product, followed by evaporative distillation, the naphthalenic diester (ester of IIa) could be obtained in 45% over-all yield.

With Fumaric Acid.—A solution of 5.2 g. (0.034 mole) of 1-vinylnaphthalene and 15 g. (0.129 mole) of recrystallized fumaric acid in 250 cc. of propionic acid and 2.5 cc. of propionic anhydride was refluxed for 110 hours. The solvent was removed and the residue was treated with 45% potassium hydroxide, water and benzene as before. The aqueous layer was added with stirring to an excess of hot, dilute hydrochloric acid and the mixture was filtered hot (to keep fumaric acid in solution). The product was esterified with diazomethane and was fractionally and evaporatively distilled at *ca.* 0.05 mm., a small dimethyl fumarate fraction being discarded. The main fraction, which came over at 180–220°, was the dimethyl ester of *trans*-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid mixed with 20–30% of the *cis*-diester, yield, 8.95 g. (89% yield based on 1-vinylnaphthalene). The diester mixture crystallized from methanol in large, stout prisms, m. p. 88–93.5° cor.

***cis*- to *trans*-Inversion.**—A mixture of 2 g. of the *cis*–*trans*-diester product from the fumaric acid experiment and 1.56 g. of *cis*-diacid from distilled *cis*-anhydride when refluxed with 20 cc. of 45% potassium hydroxide and 40 cc. of methanol for twenty-four hours gave 3.2 g. (95%) of ***trans*-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid** (IIIa), m. p. 222–223° dec. cor. with previous softening at 221°. The acid crystallized from glacial acetic acid in powdery, colorless crystals, m. p. 225–227° dec. cor.

Anal. Calcd. for $C_{16}H_{14}O_4$: C, 71.09; H, 5.22; neut. equiv., 135. Found: C, 70.97; H, 5.39; neut. equiv., 136.

A portion of the above recrystallized *trans*-diacid was esterified with diazomethane and the ***trans*-dimethyl ester** was recrystallized from methanol. The colorless mixture of glistening prisms and clusters of needles melted at 67.8–68.6° cor.

Anal. Calcd. for $C_{18}H_{18}O_4$: C, 72.47; H, 6.08. Found: C, 72.32; H, 6.13.

***trans*- to *cis*-Inversion.**—One gram of recrystallized *trans*-diacid (XVII) was evaporatively distilled at *ca.* 0.05 mm. and 160–200° (residue, 0.02 g.). The light-yellow distillate was triturated with dilute sodium bicarbonate and with water and dried, yield, 0.895 g. (96%) of the *cis*-anhydride (IIa). Its identity was established

by mixed melting points of the anhydride and the derived *cis*-dimethyl ester.

Reduction of 3,4-Dihydrophenanthrene-1,2-dicarboxylic Acid by Sodium Amalgam.[6]—A solution of the disodium salt of the acid, prepared by warming 0.78 g. of the anhydride[7] with 0.28 g. of sodium hydroxide and 2.8 cc. of water, was swirled with 28 g. of 2% sodium amalgam for twenty-five minutes while the mixture was warmed on a steam-bath. Acidification yielded 0.69 g. of acid which crystallized from acetic acid in colorless prisms, m. p. 219–221°. The dimethyl ester, prepared by means of diazomethane, crystallized from methanol in colorless prisms, m. p. 102–104°, and, after evaporative distillation, 104–105.5° alone and when mixed with the dimethyl ester of *cis*-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid.

With Citraconic Anhydride.—In twenty-one different experiments in which 1 g. of freshly prepared 1-vinylnaphthalene and various weights of citraconic anhydride[11] were brought into reactive relationship with or without a solvent of low dipole moment, no monomeric product was isolated. These experiments involved reaction temperatures of 25° to 215°, reaction periods of one hour and twenty minutes to fourteen days, solvents such as benzene, toluene and xylene, and the use of sulfur, an atmosphere of nitrogen, hydroquinone and a commercial rubber-polymerization inhibitor. The copolymeric addition products that were obtained reacted sluggishly or not at all with neutral permanganate, gave indefinite neutral equivalents ranging from 165–220 (calculated for the monomer, 142), had molecular weights of more than 400 (calculated for the monomer, 284) as determined in camphor by the Rast method, and did not evaporatively distil at 240° and 0.05 mm.

A subsequent series of ten experiments conducted in acetic, propionic and valeric acids gave addition mixtures of monomeric and copolymeric addition products from which a single *cis*-naphthalenic monomer was isolated by means of evaporative distillation or fractional crystallization in yields up to 49%. In a typical run a clear solution of 8 g. (0.052 mole) of 1-vinylnaphthalene and 17.5 g. (0.156 mole) of citraconic anhydride in 50 cc. of propionic acid was refluxed for seventeen hours. The solvent was removed on a steam cone in a current of air, excess citraconic anhydride was distilled at 0.3–0.4 mm., and the residue was warmed gently with 45% potassium hydroxide, water and benzene (in that order). The benzene layer contained 1.75 g. (22%) of viscous, brown oil which reacted instantly with neutral permanganate. The dark-brown, gummy diacid addition product isolated from the aqueous layer was evaporatively distilled at 0.05 mm. and 160–200°. The light-yellow distillate of **cis-1-methyl-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic anhydride** (IIc) weighed 6.1 g. A sample after decolorization in acetone, crystallized from acetone–ethyl acetate in fine, colorless prisms, m. p. 140.8–141.1° cor.

Anal. Calcd. for $C_{17}H_{14}O_3$: C, 76.67; H, 5.30. Found: C, 76.64; H, 5.42.

Distilled anhydride was dissolved in a moderate excess of warm sodium hydroxide and the solution was added to an excess of hydrochloric acid. The precipitated *cis*-diacid was isolated and 1 g. was esterified with diazomethane, yield, 1.08 g. (98%), m. p. 100–101°. The **dimethyl ester of *cis*-1-methyl-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid** crystallized from methanol in fine, colorless needles, m. p. 101–101.5 cor.

Anal. Calcd. for $C_{19}H_{20}O_4$: C, 73.06; H, 6.45. Found: C, 72.97; H, 6.26.

With Mesaconic Acid.—A solution of 9.6 g. (0.062 mole) of 1-vinylnaphthalene and 20 g. (0.154 mole) of mesaconic acid[12] in 60 cc. of propionic acid was refluxed for one hundred and six hours. The solvent was removed on a steam cone in a current of air and the residue was treated with warm potassium hydroxide, water and benzene. Undissolved copolymeric material (3.35 g.) was filtered off and the clear layers were worked up as before; neutral oil in benzene layer, 1.85 g. (19%); unpurified diacid addition product, 10.35 (59%). An aliquot of the product was esterified with diazomethane and the ester was evaporatively distilled at 0.01 mm. and 160–190°; yield 57% based on 1-vinylnaphthalene. The **dimethyl ester of *trans*-1-methyl-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid,** after decolorization in acetone, crystallized from acetone–methanol in large, colorless prisms, m. p. 118.8–119.5° cor.

Anal. Calcd. for $C_{19}H_{20}O_4$: C, 73.06; H, 6.45. Found: C, 73.18; H, 6.35.

The rest of the addition product was treated with Norit in acetic acid solution and was recrystallized from acetic acid. The ***trans*-diacid (IIIc)** crystallized in small, colorless prisms; m. p. 251–252° dec. cor.

Anal. Calcd. for $C_{17}H_{16}O_4$: C, 71.81; H, 5.67. Found: C, 72.07; H, 5.69.

***cis*- to *trans*-Inversion.**—A solution of 0.5 g. of *cis*-dimethyl ester in 25 cc. of 45% potassium hydroxide and 50 cc. of methanol was refluxed for twenty-four hours, and the resulting mixture of *cis*- and *trans*-diacids was esterified with diazomethane. A 30% yield of *trans*-diester melting at 112–114° was isolated from the mixture.

***trans*- to *cis*-Inversion.**—Evaporative distillation of 2 g. of unpurified *trans*-diacid at 190–200° and 0.01 mm. gave 1.78 g. (95%) of the *cis*-anhydride (IIc), m. p. 136.5–138.5°. The distillate was insoluble in dilute sodium bicarbonate; its identity was established by mixed melting points of the anhydride and the derived *cis*-dimethyl ester.

Introduction of a Methyl Group into the Alicyclic Ring.—A solution of triphenylmethylsodium (prepared from 1.1 g. of triphenylchloromethane in 40 cc. of ether–benzene) was added dropwise to an ether–benzene solution of 0.75 g. of the dimethyl ester of *trans*-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid in a nitrogen atmosphere. The blood-red solution reacted immediately with the ester and a yellow-green solid precipitated. The addition was continued until a blood-red color persisted for fifteen minutes. The mixture was then shaken with 15 g. of methyl iodide for twenty-four hours. A slight excess of dilute acid was added, the solvent was removed and the residual oil was refluxed with methanolic potassium hydroxide for six hours. Preliminary crystallizations indicated that the resulting diacids were a complex mixture of *cis*- and *trans*-compounds. In order to reduce this complexity, the *cis*- and *trans*-diacids were converted to the *cis*-anhydride by evaporative distillation at 0.01 mm. and 160–200°. The light-yellow distillate was refluxed in methanol and the solution was treated with diazomethane. Fractional crystallization yielded 0.47 g. (60% yield based on starting diester) of the dimethyl ester of *cis*-1-methyl-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid; m. p. 96–99°. Recrystallization of this fraction from methanol gave colorless prisms; m. p. 99.5–100.5° alone and when mixed with an authentic sample. The m. p. was depressed by the original diester.

Degradation to 1-Methylphenanthrene.—The calcium salt of IIc prepared from 1 g. of recrystallized *cis*-anhydride was intimately mixed with 1.5 g. of calcium oxide and a little water, and the mixture was distilled. The gummy distillate was triturated with warm, dilute sodium hydroxide and was evaporatively distilled at 110–135° and *ca.* 0.05 mm. The light-yellow oil (0.35 g.) proved to be a mixture, at least a part of which contained active double bonds. Accordingly, 90 mg. of the oil was treated with 10 mg. of 30% palladium-charcoal catalyst[13] at 310° for thirty minutes in an atmosphere of nitrogen, and the aromatized product was redistilled. From the colorless distillate (m. p. 98–105°) and picric acid in absolute ethanol was obtained the picrate of 1-methylphenanthrene in fine, yellow needles; m. p. 135.7–136.2°; mixed melting point with the picrate of authentic 1-methylphe-

(11) Shriner, Ford and Roll, *Org. Syntheses*, **11**, 28, 70 (1931).

(12) Shriner, Ford and Roll, *ibid.*, **11**, 74 (1931).

(13) Zelinsky and Turowa-Pollak, *Ber.*, **58**, 1295 (1925).

nanthrene (136–136.5°), 136–136.5°. The hydrocarbon, regenerated from the picrate by treatment with ammonium hydroxide, crystallized from ethanol in thin, colorless plates, m. p. 116–118°; mixed melting point with 1-methylphenanthrene (120–121°), 118.5–120.5° with previous softening at 117°. A portion of the regenerated hydrocarbon was converted to the trinitrobenzene complex, which crystallized from ethanol in fine, yellow needles melting at 157.5–158.5° alone and when mixed with an authentic sample (m. p. 157.5–158.5°). 2-Methylphenanthrene melts at 55–56°; its picrate at 118–119°.

Hydrolysis to the Acid Ester.—A solution of 1.5 g. of recrystallized *trans*-dimethyl ester, 9.7 cc. of 0.5 *N* sodium hydroxide (1.01 equivalents) and 35 cc. of methanol was refluxed for twenty-four hours. From the solution was isolated 1.425 g. (99.5%) of the acid ester, presumably *trans*-**1-methyl-1-carbomethoxy-1,2,3,4-tetrahydrophenanthrene-2-carboxylic acid,** melting at 186–189.5°. The acid ester crystallized from methanol in colorless prisms, m. p. 193–195° cor.; after another recrystallization from acetone, 194.2–195° cor.

Anal. Calcd. for $C_{18}H_{18}O_4$: C, 72.47; H, 6.08; neut. equiv., 298. Found: C, 72.47; H, 6.11; neut. equiv., 301.

When the above hydrolysis was carried out on the *cis*-dimethyl ester, the product was a mixture of *cis*- and *trans*-acid esters, m. p. 169.5–181° with previous softening at 162°. Esterification of this acid ester mixture with diazomethane and fractional crystallization of the product gave crystals of pure *cis*-diester and of pure *trans*-diester.

Arndt–Eistert Reaction on the Acid Ester.—A mixture of 4.54 g. of unpurified *trans*-acid ester, 5 cc. of dry ether, 5 cc. of dry benzene and 4 cc. of oxalyl chloride (a large excess) was allowed to react for six hours. A solution was obtained in three hours and gassing ceased after about five and one-half hours. Volatile compounds were removed completely *in vacuo*, the acid chloride was dissolved in dry ether–benzene, and the solution was added dropwise with swirling to a 3-mole excess of ice-cold, ethereal diazomethane. After two hours at room temperature, the solvents were removed and the crystalline yellow diazoketone was refluxed with silver oxide in absolute methanol for six hours. A total of seven 0.05-g. portions of silver oxide was added during this period; no evolution of nitrogen was noted after the first three hours. The diester isolated from the filtered mixture was evaporatively distilled at 175–195° and *ca.* 0.05 mm. Since the viscous, yellow oil (4.28 g.) did not crystallize readily, it was dissolved in methanol and refluxed for two and one-half hours with 1.01 equivalents of *N* methanolic sodium hydroxide.[10] The acid ester (4.05 g.), presumably **1-methyl-1-carbomethoxy-1,2,3,4-tetrahydrophenanthrene-2-acetic acid** (IV, R = H), after decolorization in acetone, crystallized from acetone-methanol in colorless prisms; yield, 2.48 g. (52%), m. p. 148–149.5° cor. After a second recrystallization, a sample melted at 150.9–151.7° cor.

Anal. Calcd. for $C_{19}H_{20}O_4$: C, 73.06; H, 6.45. Found: C, 73.27; H, 6.43.

This compound depressed the melting points of samples of α- (m. p. 133–134°) and β- (m. p. 158–160°) 2-methyl-2-carbomethoxy-1,2,3,4-tetrahydrophenanthrene-1-acetic acid.[10]

Reactions of 1-Vinyl-6-methoxynaphthalene

With Maleic Anhydride.—Two grams (0.011 mole) of freshly prepared and recrystallized 1-vinyl-6-methoxynaphthalene (obtained in 68–79% yield[4]) and 2.2 g. (0.022 mole) of sublimed maleic anhydride were refluxed in 8 cc. of glacial acetic acid for two and one-half hours. The yellow color that appeared at the instant of mixing gradually deepened to a red-orange. The solvent was removed from the clear solution and the reaction mixture was treated with 45% potassium hydroxide, water and benzene. The mixture was filtered and the clear layers were separated and worked up as in the case of desmethoxy experiments. From the benzene layer was isolated 0.98 g. (49%) of a brown oil (presumably the starting vinyl compound and/or its homopolymers) that reacted instantly with neutral permanganate and from the aqueous phase there was obtained 1.27 g. of red-orange diacid that showed little double bond activity, m. p. indefinite. A portion of the diacid evaporatively distilled at 185–225° and *ca.* 0.03 mm. gave yellow *cis*-anhydride (26% over-all yield). After treatment with Norit in acetone solution, the ***cis*-7-methoxy-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic anhydride** (IIb) crystallized from ethyl acetate in glistening yellow prisms, m. p. 160.5–161° cor. A recrystallization from acetone did not change the color or the melting point.

Anal. Calcd. for $C_{17}H_{14}O_4$: C, 72.33; H, 5.00. Found: C, 72.37; H, 4.95.

Cohen and Warren reported 171–175° for the non-naphthalenic adduct (Ib). The rest of the diacid was esterified with diazomethane and the *cis*-dimethyl ester (30% over-all yield) was evaporatively distilled, m. p. 117.5–118° after recrystallization from methanol. There was some indication that a small impurity of *trans*-diester was present.

When distilled *cis*-anhydride was refluxed with methanol for five hours, the yellow crystals dissolved to give a solution which gradually became colorless. Upon cooling, thin, colorless flakes of *cis*-acid ester precipitated, m. p. 208.5–210.5° cor. The mixture was treated with diazomethane; the **dimethyl ester of *cis*-7-methoxy-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid** crystallized from methanol in large, colorless prisms, m. p. 119.5–120° cor.

Anal. Calcd. for $C_{19}H_{20}O_5$: C, 69.50; H, 6.14. Found: C, 69.50; H, 6.24.

Several other similar runs were made with quantities of reactants identical to the above but varying one or more of the reaction conditions. In an experiment in which only half as much acetic acid (4 cc.) and a reaction temperature of only 90–95° was used, solid began to precipitate after six minutes of the two and one-half hour reaction period. The addition product (2.38 g.) was mainly copolymeric and only a 9% over-all yield of *cis*-diester distilled. When 4 cc. of toluene was used as a solvent only 7% yield of *cis*-diester was obtained. When additional maleic anhydride was used as the solvent in a two and one-half hour run at 90–95°, the addition product was one-half monomeric (15% yield).

With Fumaric Acid.—A solution of 2 g. (0.011 mole) of 1-vinyl-6-methoxynaphthalene and 1.5 g. (0.013 mole) of recrystallized fumaric acid in 10 cc. of glacial acetic acid was refluxed for eighteen hours, and the reaction mixture was worked up as above; 0.42 g. (21%) of brown oil with active double bonds was isolated from the benzene layer. The aqueous suspension of the nearly colorless diacid addition product was filtered while hot; yield 2.44 g. A portion of the diacid was esterified with diazomethane and was fractionally and evaporatively distilled at *ca.* 0.05 mm. After traces of dimethyl fumarate had distilled at 100–140°, the *trans*-dimethyl ester came over at 170–225° in what corresponded to a 71% over-all yield, m. p. 117–118° after recrystallization from methanol. Fractional crystallization of the diester indicated that it contained about 5–12% of the *cis*-isomer.

In a second experiment identical with the preceding one except that a fifty-six hour reflux period was used, a 72% over-all yield of distilled diester (80–90% *trans*- and 10–20% *cis*-) was obtained. Addition had taken place to the extent of 90%, but more copolymeric material was produced.

Part of the diacid addition product from the first experiment was dissolved in methanol and was refluxed for ten hours with 45% potassium hydroxide to isomerize the *cis*-impurity. The resultant ***trans*-7-methoxy-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid,** after decolorization with Norit and recrystallization from glacial acetic acid, crystallized from acetone in colorless prisms; m. p. 220.5–221.5° dec. cor.

Anal. Calcd. for $C_{17}H_{16}O_5$: C, 67.99; H, 5.37; neut.

equiv., 150. Found: C, 68.16; H, 5.45; neut. equiv., 152.5.

The *trans*-**dimethyl ester** prepared by means of diazomethane crystallized from methanol in fine, colorless crystals; m. p. 118.5–119° cor.; after another recrystallization from methanol–acetone, 119.4–119.8° cor.

Anal. Calcd. for $C_{19}H_{20}O_5$: C, 69.50; H, 6.14. Found: C, 69.50; H, 6.15.

The mixed melting point of the *cis*- (m. p. 119.5–120° cor.) and *trans*- (m. p. 118.8–119.3° cor.) dimethyl esters was 100–115° with previous softening at 98°.

***cis*- to *trans*-Inversion.**—A solution of 1 g. of the *cis*-diester in 10 cc. of 45% potassium hydroxide and 20 cc. of methanol was refluxed for twenty-three hours. The diacid was treated with diazomethane and the resultant *trans*-diester was crystallized from methanol; yield, 95%; m. p. 118.8–119.5° cor. alone or when mixed with an authentic sample.

***trans*- to *cis*-Inversion.**—Evaporative distillation of the unpurified *trans*-diacid at 100–225° and *ca.* 0.03 mm. yielded the *cis*-anhydride as shown by mixed melting points of the recrystallized anhydride and of the derived *cis*-dimethyl ester.

With Citraconic Anhydride.—A solution of 4.75 g. (0.026 mole) of 1-vinyl-6-methoxynaphthalene and 6.2 g. (0.055 mole) of citraconic anhydride in 50 cc. of propionic acid was refluxed for twenty-one hours. The diacid (5.84 g.), which showed no olefinic activity, was divided into two portions. One part on evaporative distillation at 200–225° and *ca.* 0.02 mm. gave ***cis*-1-methyl-7-methoxy-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic anhydride (IId)** (56% yield), which crystallized from ethyl acetate in fine, colorless prisms; m. p. 127.5–128.5°, and after two more recrystallizations, 129–129.7° cor.

Anal. Calcd. for $C_{18}H_{16}O_4$: C, 72.96; H, 5.44. Found: C, 72.74; H, 5.28.

The rest of the diacid was treated with excess diazomethane, and the *cis*-**dimethyl ester** was evaporatively distilled (60% yield) and crystallized from methanol in fine, colorless needles; m. p. 165–166°, and after another recrystallization from acetone, 168.3–168.8° cor.

Anal. Calcd. for $C_{20}H_{22}O_5$: C, 70.16; H, 6.48. Found: C, 70.32; H, 6.55.

With Mesaconic Acid.—A solution of 4.75 g. (0.026 mole) of 1-vinyl-6-methoxynaphthalene and 7.07 g. (0.055 mole) of mesaconic acid in 40 cc. of propionic acid was refluxed for four days. Considerable copolymeric material insoluble in both warm benzene and warm base was filtered off during the isolation procedure. Grayish-white *trans*-diacid (5.43 g.) was esterified with diazomethane and the ester was evaporatively distilled under reduced pressure, 64% yield. The **dimethyl ester** of the *trans*-acid after two recrystallizations from methanol and two from acetone–methanol formed colorless platelets; m. p. 134.4–135° cor.

Anal. Calcd. for $C_{20}H_{22}O_5$: C, 70.16; H, 6.48. Found: C, 70.47; H, 6.54.

The ***trans*-1-Methyl-7-methoxy-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid (IIId)**, obtained by methanolic alkaline hydrolysis of the distilled ester, after decolorization with Norit in glacial acetic acid, crystallized in fine, colorless crystals; m. p. 227–232° dec. with previous softening; after further recrystallization from acetic acid and then from acetone, 243–244° dec. cor.

Anal. Calcd. for $C_{18}H_{18}O_5$: C, 68.78; H, 5.77; neut. equiv., 157. Found: C, 68.96; H, 5.81; neut. equiv., 158.

***cis*- to *trans*-Inversion.**—When 0.5 g. of the *cis*-diester 30 cc. of 45% potassium hydroxide and 60 cc. of methanol were refluxed for thirty-six hours, the diacid (0.44 g., m. p. 195–199.5° dec.) was mainly *trans* as judged by fractional crystallization of the *cis*-*trans*-diester mixture obtained by esterification. About a 40% yield of *trans*-dimethyl ester melting at 130–132.5° was isolated.

***trans*- to *cis*-Inversion.**—Evaporative distillation of a sample of crude *trans*-diacid at 180–225° and *ca.* 0.01 mm. gave the *cis*-anhydride in about 90% yield.

Introduction of a Methyl Group into the Alicyclic Ring.—The reaction between 1 g. of the dimethyl ester of *trans*-7-methoxy-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid and a solution of triphenylmethylsodium was carried out as described for the desmethoxy analog; much dark-green solid precipitated. The mixture was then shaken with 20 g. of methyl iodide for fourteen hours and was worked up as before. The diacid mixture (from which 0.2 g. of the *cis*- and a few mg. of the *trans*-diester can be isolated if it is esterified) was evaporatively distilled at *ca.* 0.01 mm. and the resultant *cis* anhydride was refluxed with methanol for ten hours. The *cis*-acid ester was treated with diazomethane and the product was recrystallized from methanol; yield, 0.79 g. (76% over-all yield) of the dimethyl ester of *cis*-1-methyl-7-methoxy-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid; m. p. 163.5–165°, and after another recrystallization 164.5–165.5° alone or when mixed with an authentic sample.

Hydrolysis of the *trans*-Dimethyl Ester to the Acid Ester.—Two grams of *trans*-dimethyl ester, 5.46 cc. of 1.07 *N* sodium hydroxide and 75 cc. of methanol were refluxed for twenty-four hours. An aqueous suspension of the sparingly soluble sodium salt of the acid ester was added slowly with stirring to an excess of hydrochloric acid, stirring was continued for three hours, and the mixture was left overnight before filtering; yield 1.81 g. (95%), m. p. 186.5–188.5° with previous softening. The acid ester, presumably ***trans*-1-methyl-1-carbomethoxy-7-methoxy-1,2,3,4-tetrahydrophenanthrene-2-carboxylic acid**, was decolorized with Norit and recrystallized from acetone; m. p. 194.5–195.5° cor.

Anal. Calcd. for $C_{19}H_{20}O_5$: C, 69.50; H, 6.14; neut. equiv., 328. Found: C, 69.52; H, 5.98; neut. equiv., 328.

Arndt–Eistert Reaction on the Acid Ester.—By the method described for the desmethoxy analog, the acid ester (2.5 g.) gave yellowish crystals of the diazoketone; m. p. 151–153° dec. This was refluxed for five hours with absolute methanol and several portions of silver oxide, and the resulting dimethyl ester was evaporatively distilled at 170–190° and *ca.* 0.03 mm.; yield of light-yellow, glassy solid, 2.39 g. This was refluxed in methanolic solution with one equivalent (+1.5% excess) of *N* sodium hydroxide for two and one-half hours; yield, 2.11 g. The acid ester, presumably ***trans*-1-methyl-1-carbomethoxy-7-methoxy-1,2,3,4-tetrahydrophenanthrene-2-acetic acid (IV**, R = OCH_3), after decolorization in acetone, crystallized from methanol in colorless prisms; yield, 1.16 g. with m. p. 171–172° and 0.52 g. with m. p. 169–170.5°; total, 64% over-all yield. After a recrystallization from ethyl acetate, the acid ester crystallized from acetone–methanol in stout, colorless plates; m. p. 173.4–173.8° cor.

Anal. Calcd. for $C_{20}H_{22}O_5$: C, 70.16; H, 6.48. Found: C, 70.47; H, 6.51.

This compound markedly depressed the melting points of samples of α- (m. p. 137–138°) and β- (m. p. 211–212°) 2-methyl-2-carbomethoxy-7-methoxy-1,2,3,4-tetrahydrophenanthrene-1-acetic acid.[14]

The **dimethyl ester** prepared by means of diazomethane, after one crystallization from ligroin–benzene and two recrystallizations from acetone–methanol, formed colorless prisms; m. p. 85.2–86.3° cor.

Anal. Calcd. for $C_{21}H_{24}O_5$: C, 70.77; H, 6.79. Found: C, 70.73; H, 6.59.

This compound depressed the melting points of samples of α- (m. p. 126–126.5°) and β- (m. p. 114–114.5°) dimethyl ester of 2-methyl-2-carbomethoxy-7-methoxy-1,2,3,4-tetrahydrophenanthrene-1-acetic acid.[14]

Summary

The addition of fumaric acid to 1-vinylnaphtha-

(14) Bachmann, Cole and Wilds, THIS JOURNAL, **62**, 824 (1940).

lene gave a higher yield of monomeric adduct than did maleic anhydride.

Citraconic anhydride and mesaconic acid add to 1-vinylnaphthalene and to 1-vinyl-6-methoxynaphthalene to give the *cis* and *trans* forms of adducts in which the methyl group is in the 1-position of the hydrophenanthrene nucleus.

cis–trans Interconversions of the products are described.

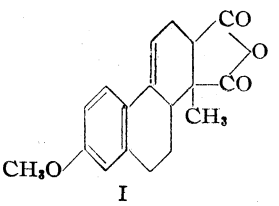
The Diels–Alder Reaction of 1-Vinyl-6-methoxy-3,4-dihydronaphthalene with Citraconic Anhydride[1]

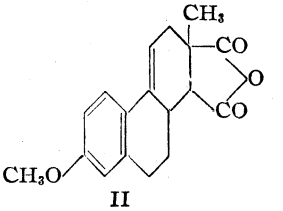
BY W. E. BACHMANN AND J. M. CHEMERDA[2]

1-Vinyl-6-methoxy-3,4-dihydronaphthalene has been allowed to react with a number of dienophiles in order to obtain estrogens or suitable intermediates for the synthesis of estrone.[3,4,5] In 1941 we began an investigation[6] of the reaction of this diene with citraconic anhydride.[7] Theoretically, two sets of products were possible: I, with the methyl group in the 1-position, and II, with the methyl group in the 2-position. In virtue of the three asymmetric carbon atoms, each of the structures can exist in eight stereoisomeric forms (four racemic mixtures). However, the principle of *cis* addition reduces the number to two racemic mixtures for each structure; and, if the rule of the "maximum accumulation of double bonds" prior to addition is applicable, only one racemic mixture for each structural isomer should be obtained. The configuration of the 2-methyl derivative should be IIa; similarly, the single racemic mixture of I would have the H's on C_2 and C_{10a} and the methyl group on C_1 *cis* to each other.

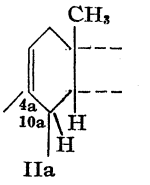
Citraconic anhydride reacted with 1-vinyl-6-methoxy-3,4-dihydronaphthalene in boiling benzene to give a mixture of adducts in 70% yield, from which two pure, crystalline anhydrides were isolated. The anhydrides, m. p. 128° (one part)



I



II



IIa

and m. p. 163° (two parts), comprised at least 60% of the mixture.[8] These results illustrate the pronounced steric selectivity of the Diels–Alder addition. For convenience in isolation, the crude product was hydrolyzed, and the acid portion was separated from neutral material and reconverted to anhydrides by fusion at 190–200°. It was not determined whether the original compounds were regenerated or whether this treatment shifted the double bond (for example, to the 4a-10a position).[9]

The 128° anhydride is *cis*-1-methyl-7-methoxyhexahydrophenanthrene-1,2-dicarboxylic anhydride (I), since treatment of it or the corresponding acid with palladium on charcoal[10] at 315° for a short time yielded 1-methyl-7-methoxyphenanthrene and (after hydrolysis) the *cis*-1-methyl-7-methoxy-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid (V) of Bachmann and Scott.[7] The 163° anhydride is *cis*-2-methyl-7-methoxyhexahydrophenanthrene-1,2-dicarboxylic anhydride (II); it and the acid (IV) derived from it were transformed smoothly into 2-methyl-7-methoxyphenanthrene[11] and the anhydride of

(8) *Cf.* Breitner, *Med. u. Chem.*, **4**, 317 (1942); *Chem. Zentr.*, **114**, I, 2688 (1943); *C. A.*, **38**, 4953 (1944). The German abstract appeared after most of our experimental work had been completed. Breitner obtained a potent estrogen from an anhydride adduct (m. p. 210°) prepared from the diene and citraconic anhydride. Later the Government Intelligence Team (Report No. 248, Pharmaceuticals at the I. G. Farbenindustrie Plant, Elberfeld, Germany, Office of the Publication Board, Department of Commerce, Washington, D. C.) reported that Breitner's product was prepared from an adduct melting at about 125° and at 160° after several recrystallizations.

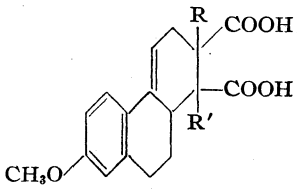
(9) The structures I, II, III, and IV are written with the double bond in the 4–4a position until more information is available.

(10) Hartung, THIS JOURNAL, **50**, 3370 (1928); **66**, 888 (1944).

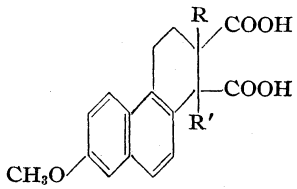
(11) Heer and Miescher, *Experientia*, **3**, 322 (1947), recently reported the formation of 1-methyl- and 2-methyl-7-methoxyphenanthrene from the adducts which they obtained from the diene and citraconic anhydride. An example of a 1-methyl-1-carboxyhydrophenanthrene derivative which has been decarboxylated and dehydrogenated is abietic acid (Ruzicka, *et al.*, *Helv. Chim. Acta*, **6**, 692 (1923); **16**, 842 (1933)) and of a 2-methyl-2-carboxy derivative is estric acid (Butenandt, Weidlich and Thompson, *Ber.*, **66**, 601 (1933)).

cis-2-methyl-7-methoxy-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic anhydride (anhydride of VI).[12] The formation of the 2-methyl- as well as the 1-methylhydrophenanthrene adduct is in contrast to the behavior of 1-vinylnaphthalene and 1-vinyl-6-methoxynaphthalene, which yielded only the 1-methyl derivatives with citraconic anhydride and with mesaconic acid.[7]

The 1-methylhexahydro acid III, derived from the 128° anhydride, was hydrogenated smoothly in the presence of palladium-charcoal to a mixture of stereoisomeric octahydro acids (VIIa) from which a single pure compound was isolated in 70–80% yield *via* the dimethyl ester or more efficiently through the anhydride. It is of interest that a single compound was formed in such a high yield on reduction.

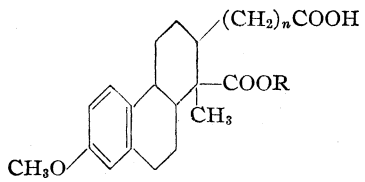


III, R′ = CH_3; R = H
IV, R = CH_3; R′ = H

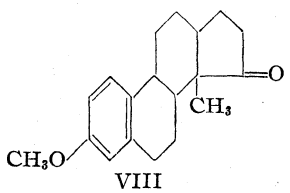


V, R′ = CH_3; R = H
VI, R = CH_3; R′ = H

Two Arndt–Eistert reactions were carried out on the acid ester (presumably VIIb) obtained by half hydrolysis of the dimethyl ester of VIIa. Pyrolysis of the lead salt of the product (presumably VIId) yielded a neutral product, m. p. 100–101°, whose analysis was in fair agreement with that of the methyl ether of an isomer of estrone (VIII). The small amount of material available prevented us from fully characterizing the compound.

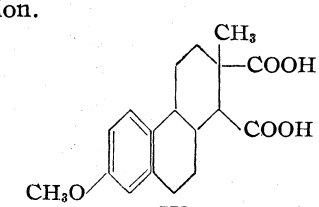


VIIa, n = 0, R = H
VIIb, n = 0, R = CH_3
VIIc, n = 1, R = CH_3
VIId, n = 2, R = H
VIIe, n = 2, R = CH_3



VIII

The 2-methylhexahydro acid IV, derived from the 163° anhydride, absorbed hydrogen rapidly in acetic acid only when a large proportion of Adams catalyst was employed. Whether this is indicative of the double bond lying in the 4a-10a position is left undecided at this time. From the mixture of products a crystalline octahydro acid IX could be isolated but only in low yield. After conversion of the non-crystallizable acids to anhydrides by distillation, a crystalline anhydride of the octahydro acid was isolated readily. Crystalline derivatives of the same octahydro acid were obtained by reduction of the hexahydro acid ester and the dimethyl ester. Various methods suggest themselves for converting these compounds to estrone or its stereoisomers and these are now under investigation.



IX

Experimental

Preparation of 1-Vinyl-6-methoxy-3,4-dihydronaphthalene.—Purified acetylene was bubbled at the rate of 2–3 bubbles per second for twenty-four hours through an ice-cold, ethereal solution of ethylmagnesium iodide (the iodide was used instead of the bromide[3] because of the greater solubility of the acetylene Grignard reagent in ether–benzene) prepared from 28 g. of magnesium and 110 cc. of ethyl iodide in 500 cc. of ether. The ether layer was decanted from the heavy, viscous purple layer of the acetylene-bis-magnesium iodide, which was then dissolved in 300 cc. of dry thiophene-free benzene. To the filtered Grignard solution, 20 g. of 6-methoxy-1-tetralone[13] was added in one portion. After eight hours at room temperature, the reaction mixture was hydrolyzed with ice-cold ammonium chloride solution, and the filtered organic layer was evaporated under reduced pressure at 35–40°. The partly solid residue was filtered and the solid diol, —C(OH)C≡C(OH)C—, on the filter was washed with small amounts of ether; after a second evaporation, a second crop of diol was removed. The filtrate was evaporated in a modified Claisen flask with an 8-inch Vigreux column, and the apparatus was filled with nitrogen and then evacuated before the dehydration was carried out. At 100–110° (0.5–0.6 mm.) the liquid bubbled vigorously as water was evolved; the eneyne, 1-ethynyl-6-methoxy-3,4-dihydronaphthalene, distilled smoothly at 118–123° (0.5–0.6 mm.) (reported, 124–130° at 0.5 mm.[3] and 120° at 0.1 mm.[4] for a purer sample); yield, 10.9 g. (52%). The eneyne reacted instantly with ammoniacal silver nitrate solution and with an alcoholic mercuric chloride solution in the presence of sodium ethoxide.[14]

For best results exposure of the carbinol to air should be avoided throughout. Midway in the distillation of a batch of acetylenic carbinol which had been kept overnight in a refrigerator, a sudden violent reaction set in with the formation of a green tar in the flask and the receiver. This danger can be partially averted by storage of the carbinol in an atmosphere of nitrogen at 0°, but it is better to carry out the entire sequence of steps from the hydrolysis of the Grignard reaction mixture to the distillation without interruption. Because the eneyne oxidized rapidly in the presence of air even at 0°, the partial hydrogenation to the diene was carried out immediately after the distillation.

(12) This compound should prove useful in a project now in progress concerned with the determination of the configuration at C/D ring fusion of equilenin, estrone and other steroids.

(13) Burnop, Elliot and Linstead, *J. Chem. Soc.*, 727 (1940). In place of steam distillation, we distilled under reduced pressure the crude 6-methoxy-1-tetralone obtained by chromic acid oxidation of 6-methoxytetralin.

(14) Shriner and Fuson, "The Identification of Organic Compounds," John Wiley and Sons, Inc., New York, N. Y., 2nd edition, 1940, p. 59.

The eneyne (10.9 g.) in 30–40 cc. of absolute alcohol with 0.5 g. of palladium-charcoal absorbed the equivalent of one mole of hydrogen at slightly more than one atmosphere pressure in one to three hours. After filtration from the catalyst and concentration *in vacuo* at 35–40°, 1-vinyl-6-methoxy-3,4-dihydronaphthalene was obtained as a practically colorless liquid. Since the product gave no test for an ethynyl group, it was used in the Diels-Alder reaction without further purification. A sample reacted instantly with maleic anhydride in benzene to give an adduct melting at 201–202° (reported,[3] 201°) after one recrystallization.

Reaction of the Diene with Citraconic Anhydride.—A solution of 31 cc. of citraconic anhydride and 10.9 g. of the diene in 150 cc. of dry thiophene-free benzene was refluxed for forty-eight hours, the solvent was removed from the mixture in a current of air, and the residual citraconic anhydride was distilled at 100° (0.5 mm.). The sticky, semi-crystalline residue was warmed gently on a steam-bath with 10 cc. of 45% aqueous potassium hydroxide solution and 40 cc. of water until the anhydrides were hydrolyzed (fifteen minutes). After the removal of 1.5 g. of alkali-insoluble material by extraction with ether, the aqueous solution was added with stirring to a solution of 15 cc. of concentrated hydrochloric acid and 15 cc. of water. The precipitated acid, after it had crystallized (on standing or when seeded and scratched) was filtered and washed thoroughly with water. A solution of the product in ethyl acetate deposited crystalline acid (m. p. 174–179°) which on continued recrystallization was transformed to an anhydride (m. p. 161.5–165°). The product was separated more efficiently by recrystallization of the anhydrides (12.3 g. or 70%) which were prepared by fusion of the above mixture of dicarboxylic acids at 190–200° in an atmosphere of nitrogen. Breitner[8] obtained about the same yield of adduct by heating the diene with citraconic anhydride at 50–60° and allowing the temperature to rise to 160–190°.

A hot solution of the anhydrides in 25 cc. of ethyl acetate and 10 cc. of acetone was concentrated and then seeded with the high melting isomer. After one to two hours at room temperature, 4.6 g. of ***cis*-2-methyl-7-methoxyhexahydrophenanthrene-1,2-dicarboxylic anhydride (II)** was obtained as square yellowish tablets, m. p. 158–162°. A colorless, constant-melting product was obtained after evaporative distillation at 160–200° (0.01 mm.) and one recrystallization from ethyl acetate, m. p. 163–163.5°.

Anal.[m15] Calcd. for $C_{18}H_{18}O_4$: C, 72.5; H, 6.1. Found: C, 73.1; H, 6.2.

The anhydride reacted readily with a dilute solution of potassium permanganate in acetone.

The mother liquor from the first crop of high melting anhydride was concentrated to a volume of about 10 cc. and allowed to cool undisturbed. A mixture of crystals was obtained consisting of small yellow tablets (m. p. *ca.* 160°) and large, jagged, rectangular, colorless masses, m. p. 125–150°. The two forms were separated mechanically and 2.6 g. of fairly pure ***cis*-1-methyl-7-methoxyhexahydrophenanthrene-1,2-dicarboxylic anhydride (I)** was obtained. After one recrystallization from ethyl acetate the anhydride melted at 125–128°; yield 2.1 g. After evaporative distillation at 0.01 mm. and recrystallization from ethyl acetate–ligroin, the anhydride melted at 127–128°.

Anal.[m] Calcd. for $C_{18}H_{18}O_4$: C, 72.5; H, 6.1. Found: C, 72.8; H, 6.2.

Additional crops of material were obtained from the mother liquor after removal of the second crop. These usually were rich in the lower melting anhydride. In one experiment there appeared to be some indication of the presence of an additional isomer but complete characterization of this substance has not been accomplished.

(15) Analyses marked "m" are by Dr. T. S. Ma and those marked "k" are by Mr. Fred Kaufmann.

Derivatives and Reactions of 1-Methyl-7-methoxyhexahydrophenanthrene-1,2-dicarboxylic Acid

Proof of Structure of the 128° Anhydride.—Three hundred milligrams of the 128° anhydride (I) and 150 mg. of palladium charcoal[10] were heated in an atmosphere of nitrogen at 310–315° for fifteen minutes when gas evolution ceased. The product after separation from the catalyst was digested with *N* sodium hydroxide. The insoluble portion (10 mg.) gave a yellow trinitrobenzene derivative in alcohol; m. p. 136–138°. Mixed melting point determinations with samples of the trinitrobenzene derivatives of synthetic 1-methyl and 2-methyl-7-methoxyphenanthrene proved conclusively that the neutral material was 1-methyl-7-methoxyphenanthrene.

Acidification of the alkaline filtrate followed by recrystallization of the product from aqueous acetone yielded 150 mg. of an acid as colorless needles, m. p. 196–198° dec. (bath pre-heated to 185°). The dimethyl ester, prepared by means of diazomethane crystallized from methanol in colorless needles, m. p. 168–169° alone and when mixed with dimethyl ester of *cis*-1-methyl-7-methoxy-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid (V).[7]

1-Methyl-7-methoxyphenanthrene was prepared in the following manner. One gram of 1-keto-7-methoxy-1,2,3,4-tetrahydrophenanthrene was added to a solution of methylmagnesium iodide prepared from 0.3 g. of magnesium. After forty-eight hours at 0°, the reaction mixture was hydrolyzed with ice-cold ammonium chloride solution and the desired carbinol, 1-methyl-1-hydroxy-7-methoxy-1,2,3,4-tetrahydrophenanthrene, was isolated by evaporation of the filtered organic layer; yield of product after trituration with ethyl acetate–ligroin, 0.48 g., m. p. 78–92°. More material was isolated from the mother liquor.

A mixture of 480 mg. of the carbinol and 100 mg. of palladium charcoal[10] was heated at 300–320° in an atmosphere of nitrogen for thirty minutes. An acetone extract of the reaction mixture was filtered, concentrated and diluted with alcohol. The 1-methyl-7-methoxyphenanthrene which crystallized in nacreous colorless leaflets (200 mg., m. p. 131–132.5°) was recrystallized from alcohol, purified through the picrate and recrystallized from absolute alcohol; m. p. 135–136° (reported,[16] 133.5–134°).

The **trinitrobenzene derivative** crystallized from hot alcohol–benzene in bright yellow needles, m. p. 143–143.5°.

Anal.[k] Calcd. for $C_{22}H_{17}N_3O_7$: C, 60.69; H, 3.94 Found: C, 60.59; H, 3.93.

Dimethyl Ester of the Acid III.—**The dimethyl ester of *cis*-1-methyl-7-methoxyhexahydrophenanthrene-1,2-dicarboxylic acid,** obtained from the crude diacid and diazomethane, crystallized from aqueous methanol in rectangular prisms; m. p. 83.5–85°.

Anal.[m] Calcd. for $C_{20}H_{24}O_5$: C, 69.7; H, 7.0. Found: C, 69.6; H, 6.8.

Reduction of the Hexahydro Acid.—The crude diacid from 4.3 g. of the 128° anhydride (I) in 75 cc. of acetic acid with 1.5 g. of palladium–charcoal absorbed one mole equivalent of hydrogen in one to two hours at slightly more than one atmosphere pressure. When 10 to 20% of catalyst by weight was used, about twenty-four hours was required for the hydrogenation. The filtered solution was evaporated to dryness and the solid diacid mixture was converted either to the anhydrides or to the dimethyl esters for purification. The anhydrides were obtained by refluxing the diacid with 40 cc. of acetic anhydride and 25 cc. of acetyl chloride for three hours. After removal of the solvents under reduced pressure, 2.85 g. of an anhydride crystallized from ethyl acetate as glistening thick prisms; m. p. 161–163.5°. From the filtrate an additional 0.7 g. of anhydride, m. p. 162–164°, was obtained; total yield, 83%. After one more recrystalliza-

tion, ***cis*-1-methyl-7-methoxy-1,2,3,4,4a,9,10,10a-octahydrophenanthrene-1,2-dicarboxylic anhydride (anhydride of VIIa)** was pure and melted at 163–164°.

Anal.[k] Calcd. for $C_{18}H_{20}O_4$: C, 72.0; H, 6.7. Found: C, 72.0; H, 7.0.

The same dimethyl ester was obtained by diazomethane treatment of the diacid mixture and of the hydrolysis or methanolysis product of the pure anhydride. The **dimethyl ester of *cis*-1-methyl-7-methoxy-1,2,3,4,4a,9,-10,10a-octahydrophenanthrene-1,2-dicarboxylic acid** crystallized from methyl alcohol in colorless needles, m. p. 126–127.5°.

Anal.[m] Calcd. for $C_{20}H_{26}O_5$: C, 69.3; H, 7.6. Found: C, 69.5; H, 7.4.

Hydrolysis of the Dimethyl Ester of VIIa to the Acid Ester.—A solution of 3.7 g. of the above *cis*-dimethyl ester in 50 cc. of methanol and 10.5 cc. of 1.04 *N* sodium hydroxide solution was refluxed for thirty-eight hours. After removal of methanol in a current of air, the residue was treated with water and ether. The ethereal solution contained 0.7 g. of a mixture of *cis* and *trans* esters. Acidification of the aqueous layer gave the acid ester (2.7 g.; m. p. 169–183°) which crystallized from ethyl acetate in colorless prisms; yield, 2.56 g. (85%); m. p. 184–188°. After a few recrystallizations from ethyl acetate the acid ester, presumably ***trans*-1-methyl-1-carbomethoxy-7-methoxy-1,2,3,4,4a,9,10,10a-octahydrophenanthrene-2-carboxylic acid (VIIb)** melted at 186–187° dec.

Anal.[m] Calcd. for $C_{19}H_{24}O_5$: C, 68.7; H, 7.3. Found: C, 69.0; H, 7.3.

The acid ester is assigned the *trans* configuration because on treatment with diazomethane it gave a practically quantitative yield of a **dimethyl ester** (different from the original diester) which crystallized from methanol in colorless rhombs; m. p. 134–135°. A mixture of this ester and the original diester melted at 107°.

Anal.[m] Calcd. for $C_{20}H_{26}O_5$: C, 69.3; H, 7.6. Found: C, 69.7; H, 7.4.

Partial hydrolysis of the *trans*-dimethyl ester gave the same acid ester in 85% yield.

Arndt–Eistert Synthesis on the Acid Ester VIIb.—Oxalyl chloride was found to be superior to thionyl chloride and phosphorus pentachloride for preparing the ester acid chloride. The acid ester (50 mg.) was added to 0.25 cc. of oxalyl chloride in 1 cc. of dry thiophene-free benzene and after two hours at room temperature the solution was evaporated. Treatment of the residual yellow gum with methanol gave 40 mg. of pure *trans*-dimethyl ester; no acidic products were isolated.

After many failures the following procedure was found to be successful for the Arndt–Eistert synthesis. The acid chloride solution, prepared as above from 500 mg. of pure *trans*-acid ester, was evaporated under reduced pressure at room temperature. Twice, the residue was redissolved in benzene and the solution evaporated. A solution of the colorless acid chloride in 15 cc. of dry benzene was added slowly to an ice-cold distilled, ethereal solution of diazomethane (prepared from 4.5 cc. of nitrosomethylurethan). The reaction appeared to be slow. After one day at 0° and another day at room temperature, the reaction mixture was filtered and evaporated to dryness under reduced pressure. The semicrystalline mass yielded 390 mg. (72%) of crystalline diazoketone upon trituration with ether–ligroin, m. p. 131–133° dec.

For the rearrangement, a silver mirror was prepared by refluxing a suspension of 0.1 g. of silver oxide in 15 cc. of methanol for one and one-half hours. To the hot mixture, the diazoketone was added in one portion. After one-half hour of refluxing another portion of silver oxide was added and refluxing was continued for another half-hour. After filtration of the suspension and evaporation of the solvent, the yellow oil was evaporatively distilled at 180–230° (0.03 mm.) and saponified by refluxing with 0.9 cc. of 1.04 *N* sodium hydroxide solution for three hours; weight of acid ester, 270 mg. The acid ester, presumably **1-methyl-1-carbomethoxy-7-methoxy-1,2,3,4,4a,-9,10,10a-octahydrophenanthrene-2-acetic acid (VIIc)**, crystallized from ethyl acetate in glistening prisms; yield 180 mg. (57%), m. p. 182–186°; after several recrystallizations of the compound the m. p. was 186–187°.

Anal.[k] Calcd. for $C_{20}H_{26}O_5$: C, 69.33; H, 7.56. Found: C, 69.95; H, 7.76.

A portion of the pure acid ester with diazomethane gave the **dimethyl ester** which crystallized from methanol in tiny colorless prisms; m. p. 78–79°.

Anal.[k] Calcd. for $C_{21}H_{28}O_5$: C, 70.0; H, 7.8. Found: C, 69.9; H, 8.0.

For the next Arndt–Eistert synthesis, 500 mg. of the acid ester (VIIc) was allowed to react with 3 cc. of oxalyl chloride in 2 cc. of dry benzene for three hours at room temperature. The reaction of the acid chloride with diazomethane at 0° was rapid; after twelve hours at 0°, the suspension of crystalline diazoketone in ether was evaporated to dryness. In this manner 570 mg. of a light cream-colored diazoketone was obtained, m. p. 138–140°.

The crude diazoketone was submitted to a rearrangement in methanol as described, and the product was hydrolyzed by refluxing with 1.45 cc. of 1.03 *N* sodium hydroxide solution in 10 cc. of methanol for one and one-half hours; weight of acid ester, 530 mg.; m. p. 171–180°. The acid ester, presumably **1-methyl-1-carbomethoxy-7-methoxy-1,2,3,4,4a,9,10,10a-octahydrophenanthrene-2-propionic acid (VIIe)**, crystallized from ethyl acetate in small thin plates, yield 380 mg. (70%), m. p. 183–184° with previous sintering; after one more recrystallization the m. p. was 184.5–186°.

Anal.[k] Calcd. for $C_{21}H_{28}O_5$: C, 69.98; H, 7.83. Found: C, 69.52; H, 7.78.

Cyclization of the Diacid VIId.—A mixture of 130 mg. of the acid ester (VIIe), 3 cc. of 45% aqueous potassium hydroxide and 6 cc. of methanol was refluxed for twenty-one hours. Acidification of the alkaline solution gave a crystalline diacid (presumably VIId), m. p. 214–215°, which was used without further purification. In our best experiment, 61 mg. of the diacid was heated in methanol with 60 mg. of lead acetate and the white suspension was evaporated to dryness.[17] The solid was heated at 290–310° at 0.01 mm. until distillation stopped. The distillate was digested with 5% sodium hydroxide solution and the neutral product isolated by extraction with benzene. The compound, presumably **7-methoxy-1′-keto-1-methyl-1,2,3,4,4a,9,10,10a-octahydro-1,2-cyclopentenophenanthrene (VIII)** crystallized from methanol in small prisms, yield 10 mg., m. p. 99–100.5°, unchanged by another recrystallization. In another run, less well-defined crystals were obtained by recrystallization from aqueous methanol, m. p. 100–101°. Both samples were analyzed.

Anal.[k] Calcd. for $C_{19}H_{24}O_2$: C, 80.24; H, 8.51. Found: C, 79.47, 79.93; H, 8.42, 8.54.

Derivatives and Reactions of 2-Methyl-7-methoxyhexahydrophenanthrene-1,2-dicarboxylic Acid

Proof of Structure of 163° Anhydride.—A mixture of 1 g. of the 163° anhydride (or the corresponding acid) and 500 mg. of palladium–charcoal was heated in an atmosphere of nitrogen at 315–320° for fifteen minutes. The filtered acetone extract of the product was treated with Norit, concentrated and diluted with ethyl acetate. Practically colorless rectangular prisms of the **anhydride of *cis*-2-methyl-7-methoxy-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid (VI)** crystallized; yield 610 mg.; m. p. 183–186°. After several recrystallizations from ethyl acetate and benzene the pure anhydride melted at 185–186°.

Anal.[k] Calcd. for $C_{18}H_{16}O_4$: C, 73.0; H, 5.4. Found: C, 73.0; H, 5.5

A mixture of 1.08 g. of the 185–186° anhydride and 50 cc. of methanol was refluxed for twenty-two hours.

(17) Litvan and Robinson, *J. Chem. Soc.*, 1997 (1938).

Upon concentration of the solution chalky prisms of an **acid ester** crystallized; yield, 650 mg., m. p. 186–188°.

Anal.[k] Calcd. for $C_{19}H_{20}O_5$: C, 69.50; H, 6.14. Found: C, 69.56; H, 6.02.

Additional crystalline material could be obtained from the mother liquor, but it was not pure. Both the material from the mother liquor and the pure acid ester above reacted with diazomethane to give the *cis*-**dimethyl ester**, m. p. 100–101°, which crystallized from aqueous methanol in chalky white needles.

Anal.[k] Calcd. for $C_{20}H_{22}O_5$: C, 70.16; H, 6.48. Found: C, 70.22; H, 6.44.

The same dimethyl ester was obtained by the dehydrogenation of the hexahydro dimethyl ester and the octahydro dimethyl ester. The yield of ester was inferior to the yield of the aromatic anhydride because of its less favorable solubility in organic solvents.

Digestion with *N* sodium hydroxide of the material in the filtrate after removal of the anhydride left 47 mg. of solid (m. p. 105–135°), which after two recrystallizations from methanol gave 10 mg. of 2-methyl-7-methoxyphenanthrene, m. p. 141–144° alone and when mixed with a synthetic specimen. The m. p. (141–143.5°) of the trinitrobenzene derivative was not depressed by a sample of known structure.

2-Methyl-7-methoxyphenanthrene was synthesized by reducing 1.2 g. of 1-keto-2-methyl-7-methoxy-1,2,3,4-tetrahydrophenanthrene[18] to the corresponding 1-hydroxy derivative by means of a ten-fold excess of aluminum isopropoxide. The reaction mixture was hydrolyzed with ice-cold dilute sulfuric acid solution, the product extracted with benzene and the benzene extract washed with dilute ammonia. Evaporation of the extract gave 1.2 g. of a stereoisomeric mixture of carbinols, m. p. 102–115°; after one recrystallization from benzene–petroleum ether, the m. p. was 109.5–117°.

A mixture of 500 mg. of the recrystallized carbinols and 100 mg. of palladium–charcoal[10] was heated at 315° in an atmosphere of nitrogen for fifteen minutes. A filtered acetone extract of the product was concentrated, diluted with alcohol. After a few recrystallizations of the plate-like crystals (310 mg., m. p. 142–143.5°) and purification through the picrate, the melting point was not changed significantly but the analysis was low in carbon. The following treatment with alkali removed the impurity and led to an analytically pure sample. The crude product was dissolved in methyl alcoholic potassium hydroxide with the aid of warm acetone and water was added until crystallization began. The **2-methyl-7-methoxyphenanthrene** crystallized from alcohol–acetone in slender rectangular prisms, m. p. 144.5–145.5° (reported,[3] 143–144°).

Anal.[k] Calcd. for $C_{16}H_{14}O$: C, 86.45; H, 6.35. Found: C, 86.57; H, 6.26.

The **trinitrobenzene derivative** crystallized from hot alcohol–benzene in fine orange needles, m. p. 146–147°.

Anal.[k] Calcd. for $C_{22}H_{17}N_3O_7$: C, 60.69; H, 3.94. Found: C, 60.62; H, 3.96.

Dimethyl Ester of the Acid IV.—The 163° anhydride did not appear to react with warm dilute sodium bicarbonate solution but was hydrolyzed rapidly by hot *N* sodium hydroxide solution. Upon acidification of the alkaline solution, the dicarboxylic acid (IV) was obtained which melted at 179–180° after one recrystallization from ethyl acetate.

The **dimethyl ester of 2-methyl-7-methoxyhexahydrophenanthrene-1,2-dicarboxylic acid** prepared from the crude dicarboxylic acid by means of diazomethane, crystallized from aqueous methanol as hexagonal plates, m. p. 90–93°. After two more recrystallizations from aqueous methanol, the pure ester melted at 91–92°.

Anal.[m] Calcd. for $C_{20}H_{24}O_5$: C, 69.7; H, 7.0. Found: C, 69.9; H, 7.0.

(18) Bachmann, Cole and Wilds, THIS JOURNAL, **62**, 824 (1940).

Preparation of the Acid Ester.—A solution of 2.57 g. of the aforementioned dimethyl ester in 30 cc. of methanol containing 7.1 cc. of 1.1 *N* sodium hydroxide was refluxed for forty-six hours. After evaporation of the methanol, addition of water and extraction of the insoluble material (0.08 g.) with benzene, dilute hydrochloric acid was added to the aqueous layer. The product crystallized when stirred with ether and after evaporation of the ether, 2.45 g. of solid was filtered and washed with water, m. p. 117–170° dec. The **acid ester** crystallized from ethyl acetate in silken colorless needles, yield 730 mg., m. p. 185–187° dec. At the melting point the acid ester gave the anhydride (II), m. p. 163°.

Anal.[m] Calcd. for $C_{19}H_{22}O_5$: C, 69.1; H, 6.7. Found: C, 69.1; H, 6.7.

When a solution of 5 g. of the 163° anhydride in methanol was refluxed for twelve hours and concentrated, 2.16 g. of needles was obtained; m. p. 182.5–184° dec. alone and when mixed with the acid ester obtained by alkaline hydrolysis. Both acid esters were converted to the dimethyl ester, m. p. 91°, obtained from the anhydride in the manner described.

Hydrogenation of Derivatives of the 163° Anhydride. (a) **Dicarboxylic Acid.**—Attempts to hydrogenate derivatives of the hexahydro anhydride to octahydro derivatives using 5–10% by weight of Adams catalyst were unsuccessful. When 40–50% by weight of the catalyst was used, hydrogenation was rapid. A mixture of 850 mg. of the diacid IV, 35 cc. of acetic acid, and 300 mg. of pre-reduced Adams catalyst absorbed one mole equivalent of hydrogen at slightly more than one atmosphere pressure in forty-five minutes. On concentration of the filtered solution in a current of air, 56 mg. of the octahydro dicarboxylic acid IX crystallized in colorless prisms, m. p. 202–203° dec. Since it was difficult to obtain more crystalline material from the mother liquor, the residual material was evaporatively distilled at 200–250° (0.01 mm.) to convert the diacids into the corresponding anhydrides. The solution of the distillate in ethyl acetate yielded 335 mg. of anhydrides in two crops, m. p. 165–166° and m. p. 150–155°. *cis*-**2-Methyl-7-methoxy-1,2,3,4,4a,9,10,10a-octahydrophenanthrene-1,2-dicarboxylic anhydride,** the material from the first crop, was recrystallized from ethyl acetate without any change in melting point.

Anal.[k] Calcd. for $C_{18}H_{20}O_4$: C, 71.98; H, 6.71. Found: C, 72.23; H, 6.74.

(b) **Acid Ester.**—Hydrogenation of 1.3 g. of the acid ester of IV was accomplished with 0.45 g. of pre-reduced Adams catalyst in 50 cc. of acetic acid in three hours. The filtered solution was concentrated and the residue crystallized from ethyl acetate, yield 420 mg., m. p. 194–204° dec. The pure **octahydro acid ester** crystallized from ethyl acetate in small cubes, m. p. 206–208° dec. (bath preheated to 180°). The melting point varied markedly with the rate of heating.

Anal.[m] Calcd. for $C_{19}H_{24}O_5$: C, 68.7; H, 7.3. Found: C, 68.8; H, 7.2.

(c) **Dimethyl Ester.**—A mixture of 1.15 g. of the dimethyl ester of IV and 0.4 g. of pre-reduced Adams catalyst in 35 cc. of acetic acid absorbed one mole equivalent of hydrogen at slightly more than one atmosphere pressure in forty-five minutes. A methanol solution of the product deposited colorless needles of the **dimethyl ester of *cis*-2-methyl-7-methoxy-1,2,3,4,4a,9,10,10a-octahydrophenanthrene-1,2-dicarboxylic acid,** yield 470 mg., m. p. 104.5–108.5°; after several recrystallizations the m. p. was 108.5–109.5°.

Anal.[k] Calcd. for $C_{20}H_{26}O_5$: C, 69.3; H, 7.6. Found: C, 69.3; H, 7.6.

The configurations of the derivatives isolated from the three hydrogenations were the same. Both the anhydride and the acid ester were converted to the 109.5° dimethyl ester.

Hydrolysis of the Dimethyl Ester.—Alkaline hydrolysis of the dimethyl ester gave **2-methyl-7-methoxy-1,2,3,4,-**

4a,9,10,10a-octahydrophenanthrene-1,2-dicarboxylic acid (IX) which crystallized from ethyl acetate in colorless prisms, m. p. 211–213° dec.

Anal.[m] Calcd. for $C_{18}H_{22}O_5$: C, 68.0; H, 7.0. Found: C, 68.0; H, 7.1.

Summary

Two structurally isomeric adducts are formed in the reaction of citraconic anhydride with 1-vinyl-6 methoxy-3,4-dihydronaphthalene. One is a derivative of 1-methylhexahydrophenanthrene; the other has the methyl group in the 2-position of the hexahydrophenanthrene nucleus. From one a compound was synthesized whose analysis agreed with that of the methyl ether of an isomer of estrone. Preliminary studies have been carried out on the conversion of the other isomeric Diels–Alder adduct to estrone.

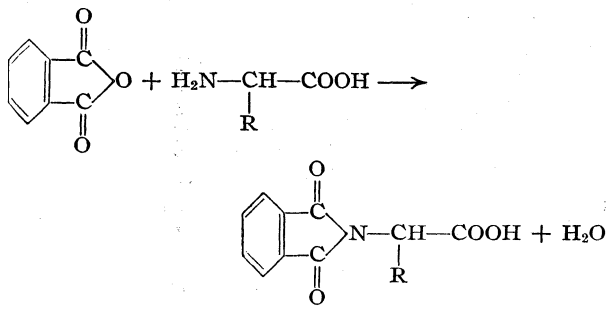
Amino Acids. V.[1] Phthalyl Derivatives

BY JOHN H. BILLMAN[2] AND WILLIAM F. HARTING[3]

Interest in amino acids has increased enormously during recent years mainly because of the many new uses which have been found for these compounds in the nutritional and medicinal fields. Additional reagents for the characterization of amino acids are accordingly useful.

Succinic anhydride and maleic anhydride were investigated as reagents but proved to be unsatisfactory. However phthalic anhydride gives compounds of excellent properties with a large number of amino acids.

Table I contains a list of the phthalyl derivative prepared in these laboratories. Phthalic anhydride condenses with amino acids according to the following general equation, the reaction being complete in fifteen minutes at 180–185°.



The recorded yields are those obtained from 0.2 to 0.5 g. of the amino acid. Much smaller amounts of the amino acid can be used with equal success. Large amounts, such as 5 g. of several of the amino acids were tried and in most cases the yields were considerably higher than those reported in the table. All of the derivatives were easily and

quickly prepared and melted in a convenient temperature range.

Since the basic function of the amino group is suppressed by this reaction, the derivatives behave as ordinary carboxylic acids. The neutral equivalent of the derivative can therefore be used as a criterion of identity. This is particularly useful when the melting points of two derivatives are separated by only a few degrees.

A solution of phthalyl L-leucine when examined polarimetrically was found to be optically active. This confirms the findings of Fox[4] and Reese.[5] Phthalyl L-glutamic acid likewise was found to be optically active. Since racemization does not appear to occur during their preparation, phthalyl derivatives should be valuable for the rapid characterization of optically active amino acids.

Tryptophan, tyrosine, serine and taurine did not give the desired derivatives.

Preparation of Phthalyl Derivatives of Amino Acids.—In a Pyrex test-tube is placed a mixture of 0.5 g. of an amino acid and 1.0 g. of phthalic anhydride. The tube is then placed in an oil-bath, which has previously been heated to 180–185°, for fifteen minutes. During the first ten minutes, the mixture is stirred occasionally and the phthalic anhydride which sublimes and deposits on the walls of the tube is pushed down into the reaction mixture by means of a glass rod. The mixture is left undisturbed during the remaining five minutes. At the end of fifteen minutes, the test-tube is carefully removed and cooled until the liquid mass solidifies. It is then inverted and the excess phthalic anhydride sublimed on the walls is scraped out. The residue is recrystallized from 10% ethyl alcohol or water. Most of the phthalyl amino acids are very soluble in dilute alcohol. When alcohol is used, some of the derivatives oil out if too concentrated a solution of the derivative is made or if the solution is cooled too rapidly.

When working with a specific amino acid it is desirable to use an approximately one to one molar ratio of amino acid to phthalic anhydride.

(5) Reese, *Ann.*, **242**, 9 (1887).

Summary

A series of phthalyl derivatives of amino acids has been prepared by a general procedure and it has been shown that phthalic anhydride is a useful reagent for the identification of most of the simple amino acids.

Condensation of Some Tertiary Octyl Alcohols with Phenol

BY RALPH C. HUSTON, WILLIAM K. LANGDON[1a] AND LOUIS J. SNYDER[1b]

In previous communications from this Laboratory,[2] the condensations of eleven tertiary alcohols with phenol have been described. The present paper reports the condensation of the five tertiary alcohols shown in Table I.

These alcohols were prepared as described by Huston and co-workers[3] and condensed with phenol in the presence of anhydrous aluminum chloride. The yields of the *p-t*-octylphenols varied from 36 to 80%. No isomers or disubstituted products were isolated. In addition to the benzoyl esters and α-naphthylurethans of these *p-t*-octylphenols, the phenylurethans of three of them were prepared.

The position of the alkyl group in each phenol was proven by oxidation of the corresponding nitro-octylbenzene,[4] by heating in a Carius tube with 6 *N* nitric acid at 130°, to yield only *p*-nitrobenzoic acid. The corresponding *t*-octylbenzene[3] was also converted into the phenol by nitration, reduction to the amine, diazotization and hydrolysis.[2] The phenol thus synthesized was shown to be identical with the one obtained through direct condensation of the alcohol and phenol by means of melting point and mixed melting point determinations. The assignment to the alkyl group of the phenol the same structure as that of the alkyl group of the alcohol from which it is formed is based upon the following considerations:

(a) There are theoretically possible seventeen *p-t*-octylyhenols.

(b) In the rearrangement of alkyl groups during processes of condensation, primary groups may change to secondary or tertiary, secondary may change to tertiary, and tertiary may change to tertiary. Instances of the formation of appreciable yields of isomeric primary or secondary groups from tertiary groups are not known.[2b]

(c) Fifteen different *p-t*-octylphenols, corresponding to the fifteen tertiary octyl alcohols, other than 2,3,3-trimethyl-2-pentanol and 2,2,3-trimethyl-3-pentanol, have been described[2,5] or are described in this article.

When 2,3,3-trimethyl-2-pentanol is condensed with phenol, *two* *p-t*-octylphenols are formed, neither of which is identical with any of the other fifteen. The condensation of 2,2,3-trimethyl-3-pentanol with phenol gives the same two *p-t*-octyl-

phenols. These are now being studied in this Laboratory. The only other evidence of rearrangement noted is the formation of some 2,4,4-trimethyl-2-*p*-hydroxyphenylpentane together with 2,3,4-trimethyl-2-*p*-hydroxyphenylpentane when 2,3,4-trimethyl-2-pentanol is condensed with phenol.[5]

(d) Seventeen different *p*-*t*-octylphenols have been formed by the condensation of seventeen isomeric octyl alcohols. In cases where only one phenol is isolated, the assignment of the structure of the alkyl group of the alcohol to the side chain of the octylphenol is justified.

Experimental

Melting points and boiling points are uncorrected.

The alcohols were prepared as indicated by Huston, Goerner, *et al.*,[3] with one exception. Part of the 3-ethyl-3-hexanol was made by adding one mole of chloroacetyl chloride to slightly over three moles of ethyl Grignard reagent. The ether was then removed and the dry reaction mixture heated on the steam-bath for twenty-four hours in order to insure the hydrocarbon type of synthesis on the α-carbon atom. The average yield was 75%.

Condensations with Phenol. (a) Using 3-Ethyl-3-hexanol and 2-Methyl-3-ethyl-3-pentanol.—Thirty-two grams (0.25 mole) of octyl alcohol, 47 g. (0.5 mole) of phenol and 200 ml. of petroleum ether were mixed in a 500 ml., three-neck flask equipped with a thermometer, condenser and mechanical stirrer. Anhydrous aluminum chloride (17 g., 0.125 mole) was added portionwise during the course of an hour. The temperature was maintained between 25 and 30° by external cooling when necessary.

(b) **Using the Other Three *t*-Octyl Alcohols.**—The proportions of reactants were: alcohol, 32.5 g. (0.25 mole); phenol, 23.5 g. (0.25 mole); aluminum chloride, 17 g. (0.125 mole); petroleum ether, 80 ml. The method was the same as in (a).

After the addition of the aluminum chloride, stirring was continued for four hours and the reaction mixture allowed to stand overnight. After hydrolysis by ice and hydrochloric acid, the layers were separated and the aqueous layer extracted with ether. The combined ether–petroleum ether layers were washed with 10% sodium carbonate solution and dried. Distillation through a modified Claisen flask with a 30 to 45 cm. Vigreux column gave the following fractions: (1) b. p. below 65° (5 to 10 mm.), probably unreacted alcohol or the corresponding chloride; (2) b. p. 65 to 100° (5 mm.), chiefly recovered phenol; (3) b. p. 100 to 140° (3 mm.). The last fraction was redistilled until a product with a narrow boiling point range was obtained. 2-Methyl-3-ethyl-3-(*p*-hydroxyphenyl)-pentane, the only solid phenolic product, was recrystallized from petroleum ether.

The benzoyl esters were prepared by the method of Shriner and Fuson.[6] Since the esters did not solidify when poured into water, it was necessary to separate the oil, extract the aqueous layer with ether, wash the ether extract successively with dilute acid and sodium carbonate solution and distil under diminished pressure. The esters crystallized at once or when chilled in the refrigerator. They were recrystallized from petroleum ether or ethyl alcohol.

The phenylurethans and α-naphthylurethans prepared by the method of Bickel and French[7] or by the method of French and Wirtel,[8] were recrystallized from alcohol or petroleum ether.

Summary

1. Five *t*-octyl alcohols have been condensed with phenol in the presence of aluminum chloride.

2. The benzoyl esters and α-naphthylurethans of the resulting *p*-*t*-octylphenols have been prepared. The phenylurethans of three of these phenols were also prepared.

3. The structures of the phenols have been established.

Synthesis of 6-Nitro-6-desoxy-D-glucose and 6-Nitro-6-desoxy-L-idose

BY J. M. GROSHEINTZ AND HERMANN O. L. FISCHER

The synthesis of 6-carbon C-nitrodesoxy-aldoses, in which the hydroxyl group on carbon atom 6 is replaced by a nitro group, thus forming the grouping $-CH_2NO_2$, was of interest, since these compounds represent a new type of sugar derivative and also show, as was anticipated, a remarkable tendency to form cyclic compounds of the cyclohexane and benzene series, on which we shall report in a subsequent paper.

Two of these sugars, 6-nitro-6-desoxy-D-glucose and 6-nitro-6-desoxy-L-idose, have been prepared by the condensation of 1,2-acetone-D-*xylo*-trihydroxyglutaric dialdehyde (II) with nitromethane. Such a condensation reaction of an aldehyde with a nitroparaffin, which dates back to Henry[1] has received much attention in recent years.[2] It has been used previously in this Laboratory for the preparation of nitrolactaldehyde,[3] and recently for the preparation of carbohydrate C-nitroalcohols.[4] In the case under consideration the condensation was effected in ethanol with sodium methoxide in the presence of an excess of nitromethane. When no further change in optical rotation occurred (after eighteen hours), the solution was processed and a crystalline **Mixture A** of the two diastereoisomers III and IV was obtained in a yield of 50% of the theoretical amount (calcd. on the dialdehyde).

The 1,2-acetone-D-*xylo*-trihydroxyglutaric dialdehyde, which is made from monoacetone-D-glucose (I)[5] by oxidation with lead tetraacetate, has been described previously with a rotation of $[\alpha]^{10}D + 20 \pm 3°$.[6] On preparing this compound we obtained products of varying rotations. Therefore, in the experimental part we describe our method of preparing the dialdehyde for our present purpose. Further investigations of the sirupy dialdehyde are being conducted.

It was found impracticable to separate the two isomers from the mixture **A** by fractional crystallization. A very small amount of IV (less than 5%) was obtained on extraction with absolute ether and repeated crystallization from dibutyl ether. However, separation could be effected satisfactorily by a process we would like to call "fractional acetonation." We found that under similar conditions, IV was acetonated to a diacetone derivative in a yield of about 90%, whereas III was acetonated in a yield of only about 25%. Thus acetonation of the mixture **A** resulted in practically complete acetonation of IV and only partial acetonation of III. This mixture could then be separated easily into the monoacetone derivative III, the diacetone derivative VI, and a residual amount of a crystalline mixture of the two diacetone derivatives V and VI, from which V could not be separated. The latter was, however, obtained from acetonation of III.

On desacetonation of III and V, 6-nitro-6-desoxy-D-glucose was obtained as a white powder which crystallized on slow cooling from a mixture of butanol and dibutyl ether. The crystalline 6-nitro-6-desoxy-D-glucose shows a downward mutarotation in water. Acids slightly accelerate the mutarotation, whereas traces of alkali induce secondary reactions. The downward direction of the mutarotation indicates that the 6-nitro-6-desoxy-D-glucose crystallizes in its α-form.[7]

On desacetonation of IV and VI, 6-nitro-6-desoxy-L-idose was obtained as a resinous, slightly colored mass, which so far has resisted crystallization. The initial and final values of the rotation of this amorphous material were considerably dependent on the degree to which it had been previously dried. Acids accelerate the mutarotation whereas traces of alkali induce secondary reactions.

To establish the configuration of III, it was reduced to the known 1,2-acetone-6-amino-6-desoxy-D-glucose,[8] which was isolated in the form of its *p*-toluenesulfonate in a yield of 85%. Further evidence that III and V possess the D-glucose configuration was obtained by the reduction of V to the known 1,2,3,5-diacetone-6-amino-6-desoxy-D-glucose *p*-toluenesulfonate.[9] This establishes the D-glucose configuration for III and for V and for the acetone-free nitrodesoxysugar VII obtained from III and V. It leaves for IV, VI and VIII the L-idose configuration, as indicated in the table.

On reduction of VI, as above, the crystalline *p*-toluenesulfonate of 1,2,3,5-diacetone-6-amino-6-desoxy-L-idose could be isolated in a yield of 80%.

Experimental

(1) **Condensation of 1,2-Acetone-D-xylo-trihydroxyglutaric Dialdehyde with Nitromethane.**—One hundred grams of monoacetone-D-glucose (m. p. 159–160°) was added to 1.6 liters of dry benzene and the suspension just brought to the boil while stirring moderately. Then 205 g. of lead tetraacetate was added in five equal portions at intervals of about three minutes without further heating, and the stirring was continued for an additional quarter of an hour at 70°. Any slight excess of lead tetraacetate

* No ring form has been assigned

was then reduced with a few drops of ethylene glycol and, after cooling to room temperature, the precipitated lead diacetate was filtered off and washed with a little benzene. The combined filtrates, about 2 liters, were quickly extracted four or five times with 25 cc. of ice-water, until no more lead diacetate could be traced in the last aqueous extract, and the benzene solution was cleared from suspended water by filtration. On removal of the benzene under reduced pressure, about one-third of the amount of aldehyde formed remained as a viscous sirup. The optical rotation of this sirup was $[\alpha]^{25}D$ +50 ± 2° (c = 5) in ethanol. The combined aqueous extracts, about 125 cc., were kept at 0° and extracted quickly six to eight times with 25 cc. of chloroform. Thus the remaining aldehyde was almost entirely extracted from the aqueous solution, containing lead diacetate and acetic acid, and was obtained as a viscous sirup after drying and evaporating the chloroform under reduced pressure. The optical rotation of this sirup was $[\alpha]^{25}D$ +40 ± 2° (c = 5) in ethanol. The lower optical rotation of the product recovered from the chloroform solution, as compared with that recovered from the benzene solution, may be due to polymerization or to a partial desacetonation, resulting in an admixture of the optically inactive xylo-trihydroxyglutaric dialdehyde. However, both sirups, which may still contain small amounts of formaldehyde, gave the same mono-phenylhydrazone, m. p. 140.5–141°, $[\alpha]^{25}D$ −42° (c = 5.0) in chloroform, as described by Koichi Iwadare.[6] Over-all yield of the sirupy material was approximately 80%. For all further experiments these sirups were dissolved in ethanol and used together.

One hundred grams of the above 1,2-acetone-D-xylo-trihydroxyglutaric dialdehyde was dissolved in a mixture of 400 cc. of 95% ethanol and 200 cc. of nitromethane. The solution was made alkaline to litmus by the addition of 2 N sodium methoxide. An excess of 20 cc. of 2 N sodium methoxide was then added and the solution left at room temperature for eighteen hours. The solution was then concentrated *in vacuo* to about one-fifth of its volume, and, after addition of about 500 cc. of chloroform, it was extracted five to six times with about 20 cc. of water. The condensation products were then obtained as a viscous residue on evaporation of the organic solvents *in vacuo*. On addition of an equal amount of absolute ether to this residue and stirring until a homogeneous mixture was obtained, crystallization of the condensation products was soon induced and the crystals were filtered with suction and washed twice with absolute ether. The mother liquor and ether washings, containing an appreciable amount of condensation products, were collected and evaporated and the residue treated as above. This crystalline mixture of 1,2-acetone-6-nitro-6-desoxy-D-glucose and 1,2-acetone-6-nitro-6-desoxy-L-idose could be crystallized from dibutyl ether (25 parts), chloroform and ether–petroleum ether (b. p. 40–60°), but no appreciable separation of the isomers took place. The mixture melted between 105 and 120° and showed a specific optical rotation of between −21° and −25°. The yield of this mixture A of colorless crystalline nitrodesoxysugars was about 50% of the theoretical.

(2) **1,2-Acetone-6-nitro-6-desoxy-D-glucose.**—One hundred grams of mixture A, as under (1), was dissolved in 2 liters of absolute acetone, containing 10.0 cc. of concentrated sulfuric acid, and kept at room temperature for four days. The sulfuric acid was then just neutralized with concentrated ammonia (an excess of ammonia being avoided), the ammonium sulfate was centrifuged off, and the solution was concentrated *in vacuo* to about 200 cc. The residue was taken up in 2 liter of ether and extracted twice with 50 cc. and twice with 25 cc. of water and filtered clear. The ether was distilled off, leaving a crystalline sludge from which the remaining solvent was distilled off *in vacuo* at about 60°. The resulting crystalline mass was dissolved in about 150 cc. of hot ethanol and the solution was slowly diluted with 600 cc. of water. Most of the diacetone products crystallized out immediately, and, after standing overnight in the ice-box, the crystals (B) (about 40 g.) were filtered with suction and washed with a little water. The mother liquor was concentrated *in vacuo* to half its volume, heated shortly to 80° with a little charcoal, and filtered. On complete evaporation of the solvents *in vacuo* the unchanged 1,2-acetone-6-nitro-6-desoxy-D-glucose crystallized out and was recrystallized first from benzene and then from

dibutyl ether (1 g. in 25 cc.). In this way 40 g. of the almost pure isomer, m. p. 123–125°, $[\alpha]^{25}D$ −18 to −20°, was obtained. On repeating with this substance the entire acetonation and crystallization procedure as above, the purest isomer we could prepare, m. p. 126–127° and $[\alpha]^{24}D$ −16.8° in water (c = 4.2), was obtained. *Anal.* Calcd. for $C_9H_{15}O_7N$ (249): C, 43.3; H, 6.02; N, 5.62; acetone, 23.3. Found: C, 43.4; H, 6.17; N, 5.64; acetone, 23.1.

(3) **1,2-Acetone-6-nitro-6-desoxy-L-idose.**—On extraction of 5 g. of mixture A, as under (1), with absolute ether in a Soxhlet apparatus, about 0.5 g. of impure 1,2-acetone-6-nitro-6-desoxy-L-idose, m. p. 135–142°, remained undissolved. After three crystallizations from dibutyl ether this substance had a m. p. of 161–162° and $[\alpha]^{24}D$ −39.0° in water (c = 3.32) and no change of these constants was observed on recrystallization. *Anal.* Calcd. for $C_9H_{15}O_7N$ (249): C, 43.3; H, 6.02; N, 5.62; acetone, 23.3. Found: C, 43.6; H, 5.93; N, 5.55; acetone, 23.6.

(4) **1,2,3,5-Diacetone-6-nitro-6-desoxy-D-glucose.**—This was obtained on acetonation of our purest 1,2-acetone-6-nitro-6-desoxy-D-glucose, as under (2) and crystallization from ethanol, and subsequently from 50% aqueous methanol, in a yield of 25%, while 60% of the unchanged starting material was recovered; m. p. 106–107°, $[\alpha]^{23}D$ +18.8° in pyridine (c = 3.56). *Anal.* Calcd. for $C_{12}H_{19}O_7N$ (289): C, 49.8; H, 6.58; N, 4.84; acetone, 40.1. Found: C, 50.0; H, 6.49; N, 4.87; acetone 40.3.

(5) **1,2,3,5-Diacetone-6-nitro-6-desoxy-L-idose.**—On crystallizing the mixture B (40 g. as under (2)), once from 80% ethanol and three times from methanol, 20 g. of diacetone-6-nitro-6-desoxy-L-idose, m. p. 150–151° and $[\alpha]^{25}D$ −30.1° in pyridine (c = 2.80), was obtained. After five recrystallizations from methanol or ethanol the melting point was one-half degree higher, but the optical rotation was unchanged. *Anal.* Calcd. for $C_{12}H_{19}O_7N$ (289): C, 49.8; H, 6.58; N, 4.84; acetone, 40.1. Found: C, 49.7; H, 6.78; N, 4.75; acetone, 40.3. The mother liquors were combined and concentrated *in vacuo*, leaving a crystalline sludge, consisting mainly of the diacetone-glucose derivative. Fractional crystallization of this mixture from ethanol and water yielded further amounts of the diacetone-idose derivative. The main portion of about 15 g., however, could not be separated completely from its isomer and melted from about 95 to 105°.

Acetonation of 1,2-acetone-6-nitro-6-desoxy-L-idose, as under (2), yielded about 90% of diacetone-6-nitro-6-desoxy-L-idose.

(6) **6-Nitro-6-desoxy-D-glucose.**—The 1,2-acetone-6-nitro-6-desoxy-D-glucose (m. p. 124° and higher), was dissolved in five times its weight of 0.1 N sulfuric acid and kept for about seventy-five minutes in a water-bath at 75–80°. The diacetone-6-nitro-6-desoxy-D-glucose was treated in the same manner, except for the addition of about 20% of ethanol to facilitate its solution. The solutions were then freed from the sulfuric acid by careful addition, with stirring, of 80% of the theoretical amount of barium hydroxide solution and balanced out exactly with a 0.1 N solution of barium acetate. This solution should at no time become even slightly alkaline on account of the extreme sensitivity of the free nitrodesoxysugar. The barium sulfate was removed by centrifuging or filtering. On evaporation *in vacuo* of the water, the free sugar was obtained as a white powder, m. p. 152–154°, with an initial optical rotation of $[\alpha]^{23}D$ +40 ± 2° within five minutes after dissolution in water. Ten grams of this substance was dissolved in a boiling mixture of 500 cc. of n-butanol and 500 cc. of n-dibutyl ether and the solution seeded at about 100° with crystalline nitrodesoxyglucose. (Seeds were obtained by dissolving a sample of the nitrodesoxysugar in a mixture of the solvents as above, and letting stand overnight.) Approximately 5 g. of material crystallized in small white needles on slow cooling to 50° within six hours. On further cooling, the remaining substance came out as an amorphous precipitate from the mother liquor, and could be recovered completely by evaporation of the solvents *in vacuo*.

The crystalline 6-nitro-6-desoxy-D-glucose melts at 156–157° and shows the mutarotation (±0.5°).

Time	$[\alpha]^{23}D$ in H_2O (c = 2.90)	$[\alpha]^{23}D$ in 0.1 N H_2SO_4 (c = 2.81)
5 min.	+45° ± 0.5°	+44.6° ± 0.5°
10 min.	44.6°	44.0°
30 min.	43.6°	42.8°
60 min.	43.0°	40.9°
2 hours	41.0°	39.2°
3 hours	39.0°	37.9°
4 hours	37.8°	37.4°
5 hours	37.0°	37.0°
6 hours	36.7°	36.9°
12 hours	36.7°	36.8°
2 days	35.6°	36.8°
5 days	32.6°	36.8°
12 days	29.1°	..
18 days	24.9°	..

The end rotation was thus reached within six to seven hours in water and dilute acid. A very much slower change of the optical rotation was observed after that time in water, indicating that a secondary reaction took place. This was probably due to the slight alkalinity of the glass with which the solution came in contact, since no such change was observed in dilute acid. *Anal.* Calcd. for $C_6H_{11}O_7N$ (209): C, 34.5; H, 5.27; N, 6.70. Found: C, 34.6; H, 5.23; N, 6.94.

(7) **6-Nitro-6-desoxy-L-idose** was prepared from its diacetone derivative, as under (6). So far, it has not been obtained in a crystalline state, but only as a resinous, slightly colored mass. We have been unable, therefore, as yet, to determine accurately the optical properties of this compound, especially since sharp drying in high vacuum over phosphorus pentoxide resulted in a brittle, glassy mass with a very much smaller mutarotation than material dried to a viscous consistency. A representative experiment can be given as follows: 1.503 g. of diacetone-6-nitro-6-desoxy-L-idose, m. p. 150–151°, was dissolved in 20 cc. of boiling ethanol and kept at 75–80° for one hour after the addition of 10.0 cc. of N sulfuric acid; then 15 cc. of warm water was added and the solution kept at the same temperature for an additional hour. After cooling to room temperature and adjusting the volume of the solution to 50.0 cc. with water, the optical rotation was $[\alpha]^{20}D$ −13.8°. After removal of the sulfuric acid and the solvents, as under (6), and drying the residue to a viscous consistency, the initial optical rotation was $[\alpha]^{23}D$ −16.6° in water (c = 3.15), $[\alpha]^{23}D$ −12.3° in 0.1 N sulfuric acid (c = 2.63), and the rotation seven days later $[\alpha]^{23}D$ −20.9° in water, $[\alpha]^{23}D$ −26.0° in 0.1 N sulfuric acid. After drying the same sample to a brittle, glassy mass, which was crushed to a powder, the initial optical rotation was $[\alpha]^{23}D$ −10.4° in water (c = 4.36), $[\alpha]^{21}D$ −12.2° in 0.1 N sulfuric acid, and the rotation forty-eight hours later $[\alpha]^{22}D$ −12.9° in water, $[\alpha]^{22}D$ −14.0° in 0.1 N sulfuric acid.

(8) **1,2-Acetone-6-amino-6-desoxy-D-glucose *p*-Toluenesulfonate.**—1,2-Acetone-6-nitro-6-desoxy-D-glucose (1.01 g., m. p. 126°) was dissolved in 30 cc. of water and reduced with hydrogen at ordinary temperature and pressure in the presence of 8 g. of freshly prepared Raney nickel catalyst. Within the first ten minutes 250 cc. of hydrogen was absorbed and 55 cc. within the next fifty minutes (calcd., 307 cc. at 23° and 753 mm.). (This reduction was also carried out at room temperature and a hydrogen pressure of 20–30 atm. and was then complete in five minutes.) The catalyst was then centrifuged off and the solution neutralized with 0.5 N *p*-toluenesulfonic acid and evaporated to dryness *in vacuo*. The amorphous residue was dissolved in about 6–8 cc. of absolute ethanol and filtered. On gradual addition of about 300 cc. of absolute ether, in portions, 1.2 g. (85%) of the crystalline compound was obtained, m. p. 176–177°, $[\alpha]^{26}D$ −7.0°

in water (c = 3.7). These constants agree with those reported by Ohle[8] for the same compound (m. p. 176–177°, $[\alpha]^{20}D$ −7.02° in water, (c = 5.01)).

(9) **1,2,3,5-Diacetone-6-amino-6-desoxy-D-glucose *p*-Toluenesulfonate.**—An amount of 1.05 g. 1,2,3,5-diacetone-6-nitro-6-desoxy-D-glucose (m. p. 106–107°) was dissolved in 60 cc. of dioxane and reduced as under (8). The reduction was complete within forty-five minutes and the free amine was obtained as a viscous sirup after centrifuging off the catalyst and evaporating the dioxane *in vacuo* at 40°. This sirup was dissolved in 20 cc. of water, neutralized exactly with 0.5 *N* *p*-toluenesulfonic acid and filtered. On evaporating the water *in vacuo*, 1.3 g. (83%) of the salt was obtained and was crystallized once from benzene and once from dry ethyl acetate. *Anal.* Calcd. for $C_{19}H_{29}O_8NS$ (431): C, 52.8; H, 6.72; N, 3.25; acetone, 26.9. Found: C, 52.9; H, 6.62; N, 3.12; acetone, 26.7.

Since the melting point found for this substance did not entirely agree with that reported by Ohle, the physical constants of the salt were thoroughly examined by Mr. D. L. MacDonald of this Laboratory, who reports as follows:

"The melting point of this compound varied considerably with the rate of heating, and melting was accompanied by decomposition; as these characteristics were not reported by Ohle and v. Vargha, the compound was also prepared according to their method from 6-tosyl-1,2-monoacetone-D-glucose *via* 6-tosyl-1,2,3,5-diacetone-D-glucose.[9,10] The amine salt prepared by the two different methods was found to be identical as regards melting point (with decomposition), solubilities in various solvents, crystal form, optical rotation and dependence of melting point on rate of heating, as shown in the table. From the data, it can be concluded that the compound under consideration is identical with Ohle and v. Vargha's

	Prepared according to: Ohle and v. Vargha	Grosheintz and Fischer	Mixed melting point, °C.

Summary

The preparation of a new type of sugar derivative is described. 1,2-Acetone-D-*xylo*-trihydroxyglutaric dialdehyde was condensed with nitromethane to yield a mixture of 1,2-acetone-6-nitro-6-desoxy-D-glucose and 1,2-acetone-6-nitro-6-desoxy-L-idose. Separation of the two diastereoisomers could be effected. The free nitrodesoxysugars were obtained on desacetonation with dilute sulfuric acid.

The constitution and configuration of the glucose derivatives were established by the reduction of the mono- and diacetone-6-nitro-6-desoxy-D-glucose to the known 1,2-acetone-6-amino-6-desoxy-D-glucose and to 1,2,3,5-diacetone-6-amino-6-desoxy-D-glucose and subsequent isolation of their *p*-toluenesulfonates.

This leaves for the other isomer the L-idose configuration.

Cyclization of 6-Nitrodesoxyaldohexoses to Nitrodesoxyinositols

BY J. M. GROSHEINTZ AND HERMANN O. L. FISCHER

When an aldose, in which the primary hydroxyl group is replaced by a nitro group, is exposed to a mild alkali, condensation of the aldehyde group into the $—CH_2NO_2$ group may be expected[1] forming the group $—CH(NO_2)—CH(OH)—$ with two new asymmetric carbon atom centers. Such a reaction, reminiscent of an aldol condensation, could produce either straight-chain or cyclic polymers or produce cyclic monoisomers. In the latter case the aldehyde group would condense with the nitromethylene group of the same molecule. It was with this reaction in mind that we synthesized 6-nitro-6-desoxy-D-glucose and 6-nitro-6-desoxy-L-idose,[2] since we expected intramolecular condensation, *i. e.*, cyclization of these nitrodesoxysugars to a number of nitrodesoxyinositol stereoisomers. We found our expectations confirmed and we were able to isolate some of these nitrodesoxyinositols under certain controlled conditions.

Evidence for the cyclohexane ring structure of our condensation products is shown by the quantitative transformation of these compounds to a known aromatic compound. Thus, on dissolving a pentaacetylnitrodesoxyinositol in warm pyridine

(1) L. Henry, *Compt. rend.*, **120**, 1265 (1895).

(2) Grosheintz and Fischer, THIS JOURNAL, **70**, 1476 (1948).

it is immediately and quantitatively transformed to diacetyl-5-nitroresorcinol. Similarly, on dissolving any of the nitrodesoxy inositols in warm pyridine and acetic anhydride the diacetyl-5-nitroresorcinol is immediately formed in a quantitative yield. This transformation is in principle the same as that of inosose and its pentaacetate to the tetraacetate of 1,2,3,5-tetrahydroxybenzene as described by Posternak.[3] On ring closure the aldehyde group disappears with the formation of a new hydroxyl group. This was evidenced by the preparation of pentasubstituted nitrodesoxyinositol derivatives and by the absence of any carbonyl reaction. Thus, after reduction of the nitro group to an amino group, the amino sugars give a strong Fehling test, whereas the amino inositols give none whatever. Also characteristic for our condensation products is the absence of any optical activity. This property points to the formation of symmetrically built molecules, or the presence of equal amounts of enantiomorphs.

The cyclization process, which was followed polarimetrically, is induced by very small amounts of alkali, as was already observed during the investigation of the mutarotation of 6-nitro-6-desoxy-D-glucose.[2] It takes place, in water, *via* the nitronium salts, as evidenced by an initial (numerical) increase in the optical rotation, and it can be arrested at any stage by acidification of the reaction solution or by precipitation of the nitronium salts; on restoring the initial *p*H of the solution or on redissolving the precipitated salts in water the cyclization continues where it had been interrupted, until the optical activity had disappeared. The rate of cyclization and the end-products are dependent, within limits, on the alkalinity to which the nitrodesoxysugars are exposed.

For one series of experiments the nitrodesoxysugars were dissolved in the calculated amount of 0.1 to 0.16 *N* barium hydroxide. Approximately half of the theoretical amount of barium salts of the cyclic compounds would crystallize overnight and the other half could be precipitated by the addition of ethanol. A slight excess of barium hydroxide solution did not affect the reaction, but tends to discoloration of the barium salts, whereas a great excess and especially greater concentration of the alkali induces strong discoloration and subsequent lower yields of the free nitrodesoxyinositols. On dissolving the barium salts in acetic acid and eliminating the barium in the usual manner, a mixture of the crystalline isomers was obtained in excellent yield. Thus from the cyclization of crystalline nitrodesoxy-D-glucose two individual substances could be isolated in approximately equal amounts. The separation could be effected due to the fact that one isomer, which we shall call **Nitrodesoxyinositol I,** crystallized from pure 1,4-dioxane with one half mole of solvent, was practically insoluble in acetone and could not be acetonated under the usual conditions, whereas the other isomer, which we shall call **Nitrodesoxyinositol II,** crystallized only in very small amounts, when pure, from dioxane, and was very easily acetonated to a diacetone derivative. In a similar manner, but in somewhat smaller yields, two nitrodesoxyinositols could be isolated from the mixture of stereoisomers obtained from the cyclization of amorphous nitrodesoxy-L-idose. These two isomers proved to be identical with those obtained from the cyclization of nitrodesoxyglucose.

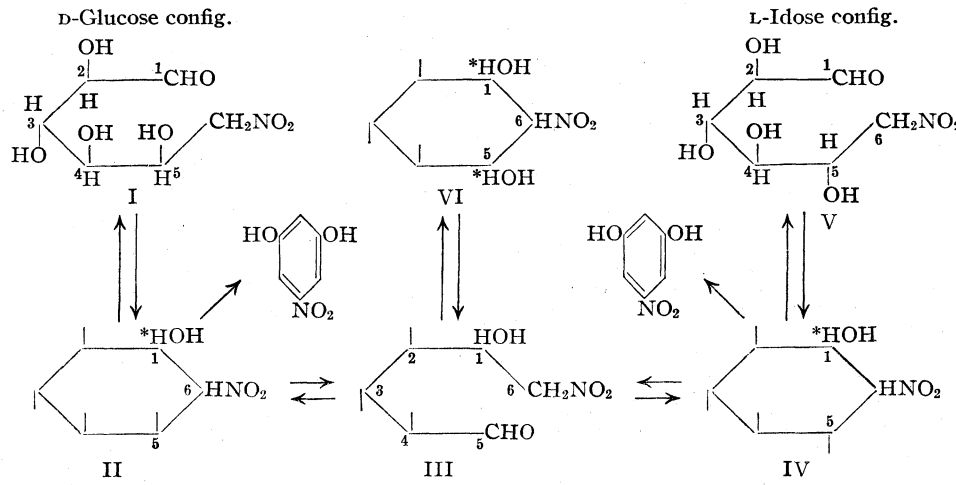
An altogether different mixture of nitrodesoxyinositols was obtained when a molar solution of nitro glucose was made alkaline with one-third of the calculated amount of normal sodium hydroxide. The cyclization proceeded slowly and a main product, which we will call **Nitrodesoxyinositol III,** was obtained in a yield of about 65% of the theoretical. This material did not represent a pure isomer, since products of slightly differing melting points were isolated on fractional crystallization, but no clear separation of individual compounds could be effected. It did not form acetone derivatives under the usual conditions. Moreover, the reaction mixture contained some nitrodesoxyinositol II, which could be isolated due to its ready formation of a diacetone derivative, and we believe, therefore, that it also contained smaller amounts of nitrodesoxyinositol I.

These results lead to the following considerations with regard to the steric configuration of our compounds: on ring closure of 6-nitro-6-desoxy-D-glucose four isomers may be formed theoretically, of which two would possess symmetrical and two asymmetrical molecular structure; the same is the case for 6-nitro-6-desoxy-L-idose. The isomers with asymmetrical molecular structure which would be thus obtained by cyclization of one of the sugars are the enantiomorphs of those to be expected by cyclization of the other sugar, whereas all the expected isomers with symmetrical molecular structure would have a different steric configuration from one another. Therefore, having obtained two nitrodesoxyinositols from one of the sugars under certain experimental conditions, one should expect two different nitrodesoxyinositols from the other sugar under the same experimental conditions, while the absence of optical activity would, in general, indicate the absence of asymmetrical structure in these compounds. Since we obtained only two different compounds in all, under similar experimental conditions, we conclude that, in alkaline medium, an equilibrium is established between the cyclic and open-chain forms of the nitrodesoxysugar derivatives (Table I) resulting in a transformation of these derivatives, whether originally of the D-glucose or L-idose configuration, to an identical mixture of nitrodesoxyinositol isomers.[4] This would therefore not ex-

(3) Th. Posternak, *Helv. Chim. Acta*, **19**, 1333 (1936).

(4) This, of course, does not exclude other reaction mechanisms in the alkaline medium, *e. g.*, cleavage of the nitrohexoses into nitromethane and D-xylo-trihydroxyglutaric dialdehyde, and the recondensation to nitrohexoses and/or nitroinositols.

TABLE I



clude the formation of racemates and one may not rule out any of the eight possible steric configurations on the grounds of optical inactivity. We believe that in the case of cyclization experiments with mild and dilute alkali, such as one-tenth normal barium hydroxide, the reaction indicated in the table is the main reaction. Thus, the conversion into one another of the two nitrodesoxyinositols I and II was easily effected under the same conditions as their preparation from the nitrodesoxysugars. This conversion may, of course, simply indicate an isomerization due to the intermediate formation of a nitronium salt, but we are more inclined to believe that a symmetrical arrangement of the hydroxyl groups is achieved prior to the precipitation of the salts and that upon reconversion of the salts to the free nitro compounds the nitro group is guided into the *trans* position with regard to the neighboring hydroxyl groups. Such an arrangement would agree with all observed reactions as well as with previous experience.[5] In the case of the cyclization experiments which led to the formation of nitrodesoxyinositol III, a much greater concentration of alkali prevailed. Therefore, one cannot dismiss completely the possibility of far reaching enolization such as the sugars are known to undergo in alkaline solution as evidenced in the reduction of glucose at ordinary temperature and *p*H 10–13.[6]

Such a reaction would leave the way open to all theoretically possible steric rearrangements. The non-occurrence of isomers is not surprising in such a labile system where certain molecular structures would naturally be preferred.

From the aforesaid it is evident that for the preparation of these cyclic compounds one need not start from the individual 6-nitro-6-desoxy-D-glucose or 6-nitro-6-desoxy-L-idose, but may use their equimolecular mixture, which is readily available by desacetonation of "mixture A," as described in our previous publication.[2]

All cyclic nitro compounds were reduced and in most cases the corresponding amino compounds could be isolated. The desamination of the amino compounds to the inosityls and the transformation of the nitro compounds to inososes by means of the Nef reaction[7] has not yet been realized.

We wish to stress the fact that the significance of our observations lies not so much in the purity or final identification of individual isomers, but rather in the ease with which ring closure is effected[8] under mild conditions. We feel that such a model experiment gives validity to the belief that inositol is formed in nature through cyclization of glucose.[9] The easy transformation of a sugar *via* an inositol derivative to an aromatic compound as demonstrated by us in the laboratory might well have its counterpart in an enzymatic process in nature.

Experimental

A. Cyclization of 6-Nitro-6-desoxy-D-glucose. (1) **Barium Salts of Nitrodesoxyinositols.**—To a solution of 12.0 g. of nitrodesoxy-D-glucose (m. p. 154–156°)[2] in 100 cc. of water was added 352 cc. of 0.163 *N* barium hydroxide. Crystallization of barium nitrodesoxyinositol started within a few minutes; 8.7 g. or 55% of the theoretical of the salts separated within twelve hours and 7.2 g. or 45% of the theoretical of crystalline salts precipitated on addition, in portions, of 600 cc. of ethanol within the next thirty-six hours. The first crystals formed were colorless, whereas those formed later were usually light brown. *Anal.* Calcd. for $C_{12}H_{20}O_{14}N_2Ba$ (553): Ba, 24.77. Found: Ba, 24.6.

(2) **Nitrodesoxyinositols.**—An amount of 8.65 g. of the above barium salts was dissolved in 40 cc. of 2 *N* acetic acid by shaking at room temperature. The resulting solution was freed from the barium by addition of 95% of the theoretical amount of *N* sulfuric acid and balanced

out exactly with 0.1 *N* sulfuric acid. On evaporation, *in vacuo*, of the filtered solution a mixture of isomeric nitrodesoxyinositols was obtained as a partly crystalline mass. After drying this mixture over phosphorus pentoxide and sodium hydroxide and dissolving it in 50 cc. of boiling 1,4-dioxane, 3.7 g. or 47% of the theoretical of substance (**Nitrodesoxyinositol I**) crystallized with one-half mole of dioxane on cooling to room temperature. Twice recrystallized from the same solvent, this substance melted at 147–148°. *Anal.* Calcd. for $(C_6H_{11}O_7N)_2 \cdot C_4H_8O_2$ (506): C, 37.94; H, 5.93; N, 5.53. Found: C, 38.10; H, 5.97; N, 5.55.

The mother liquors were collected and evaporated *in vacuo* and the residue was dissolved in a little hot methanol. On partial evaporation of the solvent over phosphorus pentoxide 3.0 g. or 46% of the theoretical of crystalline substance (**Nitrodesoxyinositol II**) was obtained. Crystallized from absolute ethanol with addition, in portions, of about 20% of absolute ether this substance melted at 185–186° (dec.). *Anal.* Calcd. for $C_6H_{11}O_7N$ (209): C, 34.5; H, 5.27; N, 6.70. Found: C, 34.5; H, 5.26; N, 6.72.

(3) Nitrodesoxyinositol I.—This substance, as obtained under (2), contained some isomers which could not be eliminated satisfactorily by repeated crystallization. However, separation was partially effected due to the fact that this substance could not be acetonated under standard conditions, whereas the contaminating isomers were easily acetonated. Thus 2 g. of this powdered substance was shaken for five hours in 50 cc. of absolute acetone containing 0.5% of concentrated sulfuric acid, whereupon the undissolved material was filtered off, washed with a few drops of absolute acetone and crystallized from dry 1,4-dioxane. This operation was repeated (3–5 times) until the substance showed a constant melting point. After filtration from the acetonation solution it melted at 182–183° (dec.). *Anal.* Calcd. for $C_6H_{11}O_7N$ (209): C, 34.5; H, 5.27; N, 6.70. Found: C, 34.6; H, 5.23; N, 6.82. After crystallization from 1,4-dioxane the nitrodesoxyinositol I contained one half mole of dioxane and melted at 162–163°. *Anal.* Calcd. for $(C_6H_{11}O_7N)_2 \cdot C_4H_8O_2$ (506): C, 37.94; H, 5.93; N, 5.53. Found: C, 38.10; H, 5.81; N, 5.52. The acetone mother liquor contained some diacetone-nitrodesoxyinositol II, as described under (6), and small amounts of not acetonated nitrodesoxyinositols, which were not further investigated.

(4) Aminodesoxyinositol I Hydrochloride.—An amount of 1.02 g. of nitrodesoxyinositol I, as obtained under (2), was dissolved in 50 cc. of distilled water and reduced with hydrogen at 26° and 752 mm. pressure in the presence of 2 g. of freshly prepared Raney nickel. Within the first ten minutes 250 cc. of hydrogen was absorbed, and 15 cc. within the next fifty minutes (calcd. 263 cc.). The catalyst was centrifuged off and the solution was neutralized with 0.5 *N* hydrochloric acid, and concentrated to about 25 cc., filtered with a little charcoal, and further concentrated to about 10 cc. On addition of about 80 cc. of acetone the solution turned slightly turbid and the hydrochloride crystallized within thirty minutes in long needles with one mole of water in a yield of about 75%. *Anal.* Calcd. for $C_6H_{14}O_5 \cdot HCl \cdot H_2O$ (233.5): C, 30.9; H, 6.85; N, 6.01. Found: C, 31.3; H, 6.80; N, 6.00. This compound sintered at 211° and slowly fused under decomposition on further heating to 230°. It did not reduce Fehling solution, which is a characteristic difference between the aminoinositols and the aminosugars, nitrosugars or nitroinositols.

(5) Nitrodesoxyinositol II.—This substance, as obtained under (2), appeared to be free of isomers, since its melting point did not change on repeated crystallization from ethanol or methanol and ether. Moreover, this procedure is wasteful. Pure substance in best yields is obtained by acetonation of the crude mixture of isomers and subsequent desacetonation, as described under (6).

(6) Diacetone-nitrodesoxyinositol II.—An amount of 2.4 g. of nitrodesoxyinositol II was added to 50 cc. of dry acetone containing 0.25 cc. of concentrated sulfuric acid, in which it dissolved on shaking, within thirty minutes. The solution was kept at room temperature overnight and was then neutralized with the calculated amount of concentrated ammonium hydroxide; the precipitate of ammonium sulfate was centrifuged off and the solution was evaporated, *in vacuo*, to about 5 cc. Then 100 cc. of ether was added and the ethereal solution was washed and dried and the ether was evaporated. Crystallization from *n*-butanol gave 2.8 g. or 85% of the theoretical of the diacetone compound, which showed a constant melting point of 186–186.5° after one more crystallization from the same solvent. *Anal.* Calcd. for $C_{12}H_{19}O_7N$ (289): C, 49.8; H, 6.58; N, 4.84; acetone, 40.1. Found: C, 49.7; H, 6.62; N, 4.74; acetone, 40.4.

Desacetonation of this substance by dissolving 2.0 g. of it in 20 cc. of boiling ethanol, refluxing for one hour with 20 cc. of *N* sulfuric acid, eliminating the sulfuric acid with the exact amount of barium acetate, evaporating the solvent *in vacuo* and crystallizing the residue from ethanol and ether, gave the nitrodesoxyinositol II, m. p. 185–186° (dec.), in a yield of 83% of the theoretical.

(7) Monoacetyl-diacetone-nitrodesoxyinositol II.—This was obtained by acetylating 0.5 g. of diacetone-nitrodesoxyinositol II in a mixture of 2 cc. of pyridine and 2 cc. of acetic anhydride and keeping the reaction mixture at room temperature for two hours, then evaporating the solvents *in vacuo* and crystallizing the residue twice from ethanol; m. p. 226°; yield about 87% of the theoretical. *Anal.* Calcd. for $C_{14}H_{21}O_8N$ (331): C, 50.7; H, 6.35; N, 4.23; acetone, 35.0. Found: C, 50.6; H, 6.35; N, 4.24; acetone, 34.9.

(8) Diacetone-aminodesoxyinositol II *p*-Toluenesulfonate.—An amount of 0.929 g. of diacetone-nitrodesoxyinositol II was dissolved in 25 cc. of 1,4-dioxane and reduced with hydrogen at 28° and 756 mm. pressure in the presence of 1 g. of freshly prepared Raney nickel. Within the first ten minutes 210 cc. of hydrogen was absorbed and 40 cc. within the next twenty minutes (calcd. 248 cc.). The catalyst was centrifuged off, the dioxane was evaporated *in vacuo* to about 5 cc. and 20 cc. of water was added, whereupon the solution was neutralized with 0.5 *N* *p*-toluenesulfonic acid, filtered with a little charcoal and evaporated to dryness *in vacuo*. On dissolving the residue in a little cold absolute ethanol and adding about five times the amount of absolute ether, long colorless needles of the salt formed immediately in a yield of 82% of the theoretical; decomposition point 225°. *Anal.* Calcd. for $C_{19}H_{29}O_8NS$ (431): C, 52.8; H, 6.72; N, 3.25; acetone, 26.9. Found: C, 52.8; H, 6.64; N, 3.22; acetone, 26.9.

(9) Nitrodesoxyinositol III.—To a solution of 12.3 g. of nitrodesoxy-D-glucose in 90 cc. of water was added 30.0 cc. of 1.003 *N* sodium hydroxide. This reaction mixture was kept at room temperature until the optical rotation had disappeared (forty-eight hours), and was then acidified with 32 cc. of *N* acetic acid. After the addition of 1.030 *N* sulfuric acid the solution was evaporated to dryness *in vacuo*. The dry, crystalline residue was extracted three times with 100 cc. of absolute ethanol. On cooling the alcoholic extract, 4.0 g. of nitrodesoxyinositol III, m. p. 215° (dec.) crystallized. From the mother liquor an additional 4.1 g. of the same substance was collected on evaporation of the solvent and boiling the residue in a little dioxane. On dissolving this substance in boiling ethanol only 20% of it crystallized on cooling, m. p. 212–213° (dec.); still less was obtained on using dioxane, from which it crystallized with a m. p. of 218–219° (dec.). *Anal.* Calcd. for $C_6H_{11}O_7N$ (209): C, 34.5; H, 5.27; N, 6.70. Found: C, 34.8; H, 5.14; N, 6.84. This compound did not form acetone derivatives under standard conditions, but some diacetone-nitrodesoxyinositol II, m. p. 184–185°, was isolated on acetonation of the mother liquor residues, as under (6).

(10) Aminodesoxyinositol III.—An amount of 1.04 g. of nitrodesoxyinositol III was dissolved in 50 cc. of distilled water and reduced with hydrogen at 24° and 760 mm. pressure in the presence of freshly prepared Raney nickel; 265 cc. of hydrogen or 71% of the theoretical were absorbed within two and one-half hours. The

catalyst was then centrifuged off and the solution filtered with a little charcoal, and evaporated to about 10 cc. *in vacuo*, whereupon crystallization of the amine began; yield 69% of the theoretical. *Anal.* Calcd. for $C_6H_{13}O_5N$ (179): C, 40.2; H, 7.26; N, 7.82. Found: C, 40.1; H, 7.09; N, 7.74. This substance started decomposing at about 255° and melted under decomposition at 280–285°.

(11) **Pentaacetyl-nitrodesoxyinositol III.**—This was obtained by mixing 0.5 g. of nitrodesoxyinositol III with 10 cc. of acetic anhydride containing one drop of concentrated sulfuric acid and keeping the mixture at 20–22°; the nitrodesoxyinositol went quickly into solution and the pentaacetate crystallized immediately. After standing for two hours the crystals were filtered with suction and washed with water, yielding 90% of the theoretical. After crystallization from dioxane this substance melted at 258–259° (dec.). *Anal.* Calcd. for $C_{16}H_{21}O_{12}N$ (419): C, 45.7; H, 5.01; N, 3.34. Found: C, 45.7; H, 4.88; N, 3.63.

(12) **Sodium Salts of Nitrodesoxyinositols.**—These were isolated in an almost quantitative yield by dissolving 2.0 g. of nitrodesoxyinositol I or nitrodesoxyinositol II in 7 cc. of water and adding the theoretical amount of 2 *N* sodium hydroxide. Small colorless needles formed quickly; 30 cc. of ethanol was added, in portions, and the crystals were filtered with suction and washed with a little ethanol and ether. These salts could be recrystallized from water alone, or better by dissolving 1 g. in 25 cc. of warm water and adding 50 cc. of acetone in portions. *Anal.* Calcd. for $C_6H_{10}O_7NNa$ (231): Na, 9.95. Found: 9.78. From a concentrated aqueous solution of these sodium salts the barium nitrodesoxyinositols could be precipitated quantitatively by a molar solution of the calculated amount of barium chloride.

(13) **Conversion of Nitrodesoxyinositol I into Nitrodesoxyinositol II.**—To a solution of 0.010 mole (2.09 g.) of pure nitrodesoxyinositol I, as obtained under (3), in 64 cc. of water, was added 0.0050 mole of barium hydroxide dissolved in 36 cc. of water. Crystals appeared within two minutes; 2.66 g. of barium nitrodesoxyinositol was isolated after fifteen hours and 0.10 g. from the mother liquor, on addition of 200 cc. of ethanol, or a total of 99.7% of the theoretical. On treating this salt as described under (2), (5) and (6), the diacetonenitrodesoxyinositol II was isolated in a yield of 58% of the theoretical.

(14) **Conversion of Nitrodesoxyinositol II into Nitrodesoxyinositol I.**—On repeating as under (12) with nitrodesoxyinositol II, barium nitrodesoxyinositol was isolated in a nearly quantitative yield. On treating this salt as under (2), nitrodesoxyinositol I was isolated in a yield of 43% of the theoretical.

B. Cyclization of 6-Nitro-6-desoxy-L-idose.—(15) To a solution of 9.2 g. of nitrodesoxy-D-idose[2] in 100 cc. of water was added 188 cc. of 0.235 *N* barium hydroxide. The solution was kept at room temperature for sixteen hours, during which time only a very small precipitate formed.[10] On addition, in portions, of 700 cc. of ethanol, 8.5 g. or 70% of the theoretical of finely precipitated barium nitrodesoxyinositol was obtained. On eliminating the barium, as described under (2), a mixture of nitrodesoxyinositols was obtained in a yield of 83% of the theoretical. From this mixture identical compounds were isolated as described under (2)–(8).

(16) **Change of the Optical Rotation during Cyclization.**—This was observed on the following solutions—**Solution A**: 104.5 mg. crystalline nitrodesoxy-D-glucose, m. p. 156°, dissolved in 5.0 cc. of 0.126 *N* sodium hydroxide. **Solution B**: 2.50 cc. of an 0.20 molar solution of the same sample of nitrodesoxy-D-glucose, prepared twenty hours in advance and made alkaline with 2.50 cc. of 0.252 *N* sodium hydroxide. **Solution C**: 68.7 mg. of crystalline nitrodesoxy-D-glucose dissolved in 0.4 *N* sodium hydroxide. **Solution D**: 5.00 cc. of a solution of nitrodesoxy-L-idose, prepared by deacetonation of 3.563 g. of diacetone-6-nitro-6-desoxy-L-idose with 8.00 cc. of *N* sulfuric acid, as described previously (2), made up to 100.0 cc., made alkaline with 1.00 cc. of 1.20 *N* sodium hydroxide. The following changes in rotation were observed:

TABLE II

C. Cyclization Products Obtained from "Mixture A."[11]—(17) An amount of 50 g. of "Mixture A" was dissolved in 300 cc. of 0.1 *N* sulfuric acid and kept for about seventy-five minutes at 75–80°. The warm solution was then freed from the sulfuric acid by addition of the exact amount of barium acetate; the precipitate was centrifuged off and the solution was concentrated to dryness *in vacuo*. The residue was dissolved in 100 cc. of water and 2100 cc. of 0.1 *N* barium hydroxide was added. Crystallization of barium nitrodesoxyinositols started within a few hours and the optical activity of the supernatant solution disappeared after twenty hours. The solution was acidified with glacial acetic acid and stirred until all crystals had dissolved. On processing this solution, as described under (2), a crystalline mass was obtained from which 25 g. of nitrodesoxyinositol I (50% of the theoretical) was obtained on crystallization from dioxane, and 18 g. of diacetone nitrodesoxyinositol II (31% of the theoretical) was obtained on acetonation of the dioxane soluble material, as described under (5) and (6).

D. Aromatization of the Nitrodesoxyinositols.—(18) Acetylation of any of the foregoing nitrodesoxyinositols by dissolving 0.5 g. of these substances in a mixture of 2 cc. of pyridine and 2 cc. of acetic anhydride and warming the solution to 70° for one minute, then evaporating the solvents *in vacuo* and crystallizing the residue twice from ethanol, gave **diacetyl-5-nitroresorcinol**, m. p. 105°, in an almost quantitative yield. *Anal.* Calcd. for $C_{10}H_9O_6N$

(10) The failure of the barium salts to precipitate directly from the aqueous solution, as in the case of the cyclization of the 6-nitro-6-desoxy-D-glucose, may be due to the fact that the starting material was amorphous and perhaps less pure. This is also indicated by the considerably lower yield in which the mixture of nitrodesoxyinositols was obtained.

(11) This "mixture A" represents the crude mixture of 1,2-acetone-6-nitro-6-desoxy-D-glucose and 1,2-acetone-6-nitro-6-desoxy-L-idose as described in our preceding publication.[2]

(239): C, 50.2; H, 3.76; N, 5.85; CH_3CO-, 36.0. Found: C, 50.1; H, 3.72; N, 5.81; CH_3CO-, 36.9. Propionylation of the nitroinositols gave in a similar manner, the **dipropionyl-5-nitroresorcinol**, m. p. 115°, from 70% ethanol. *Anal.* Calcd. for $C_{12}H_{13}O_6N$ (267): C, 53.9; H, 4.86; N, 5.24. Found: C, 53.7; H, 4.90; N, 5.20. On hydrolysis of the two above substances with 50% alcoholic 0.5 *N* potassium hydroxide, the known 5-nitro resorcinol, m. p. 157–159°, was isolated in the usual manner and gave, on methylation, the known 3,5-methoxynitrobenzene, m. p. 89.5°.

On dissolving 0.5 g. of pentaacetyl-nitrodesoxyinositol III, as described under (11), in 5 cc. of hot pyridine, it was transformed almost quantitatively into diacetyl-5-nitroresorcinol.

Acknowledgment.—The authors wish to express their gratitude to the Nutrition Foundation, Inc., for the support of this work.

Summary

The cyclization of 6-nitro-6-desoxy-D-glucose and 6-nitro-6-desoxy-L-idose to a mixture of nitrodesoxyinositols is described. Starting from either of the nitrodesoxy hexoses, the same mixture of nitrodesoxyinositols was obtained. A reaction mechanism for the cyclization is proposed.

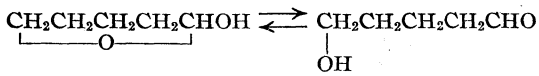
Hydroxylation of 2,3-Dihydropyran and the Application of Desoxyaldopentoses in the Browning Reaction[1]

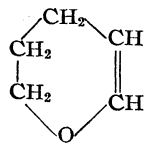
BY CHARLES D. HURD AND CHARLES D. KELSO

The reaction of reducing sugars with amino acids, leading to the evolution of carbon dioxide and the development of an intense brown color was studied by Maillard.[2] This general subject of the "browning reaction" has been one of considerable interest in recent years, since it seems to be intimately associated with the color changes observed in many foodstuffs during processing or storage.

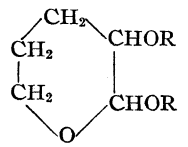
To extend our knowledge of the fundamentals of this reaction, two model aldoses were synthesized for test purposes. One was tetrahydropyran-2-ol, made by hydration of dihydropyran (I), following the directions[3] of Schniepp and Geller. This is stated to exist in equilibrium (95:5) with 5-hydroxypentanal



This material may be regarded as a 2,3,4-tridesoxyaldopentose. The substance is similar to



I



II (R = H)
III (R = Ac)

4-hydroxypentanal, $CH_2CHOHCH_2CH_2CHO$, which was synthesized by Helferich[4] and shown to exist primarily in the cyclic modification

The second model sugar was tetrahydropyran-2,3-diol (II). This substance is new. It may be regarded as a 3,4-didesoxyaldopentose, thereby providing an aldose molecule with inert beta and gamma positions. In solution the cyclic alpha and beta forms of II should be in equilibrium with the open-chain structure, $HOCH_2CH_2CH_2CHOHCHO$, just as the alpha and beta forms of a glycose are in equilibrium with the glyconaldehyde.

Synthesis of II was readily accomplished from I by use of hydrogen peroxide in *t*-butyl alcohol using osmium tetroxide as catalyst. This follows the type of synthesis devised by Milas and co-workers[5] for such syntheses as these: isobutylene glycol from isobutylene, ethylene glycol from ethylene, racemic acid from fumaric acid, glycerol from allyl alcohol, glycolaldehyde from vinyl acetate or vinyl ether, etc. Glycals, according to Hockett and co-workers,[6] behave analogously.

Although hydroxylation of double bonds by hydrogen peroxide ordinarily produces *cis* glycols,[5] it seems reasonable to think that both *cis* and *trans* hydroxyls are present in II because of the equilibration reaction mentioned above. Besides II, the reaction product also contained a considerable C_{10}-fraction revealing both non-reducing and reducing isomers. The non-reducing compound was shown to be 3,4-didesoxyaldopentosyl 3,4-didesoxyaldopentoside (IV). Products II and IV accounted for half of the I used. An additional 10–15% was accounted for by reducing disaccharide and 6% by a fraction, some of which is reducing, which may contain trisaccharide.

IV (R = H)
V (R = Ac)

Structures II and IV are apparent from the following evidence: (1) correct carbon and hydrogen analyses; (2) II reduces Benedict solution, while IV is non-reducing; (3) IV is quantitatively converted to II by dilute hydrochloric acid at 70°. This is proven by the identity of the 2,4-dinitrophenylosazones formed from II and from the hydrolysis product of IV and by the fact that the hydrolysis product reduces Benedict solution; (4) II and IV yield bis-3,5-dinitrobenzoic esters on treatment with 3,5-dinitrobenzoyl chloride in pyridine. Similarly, on acetylation, II gives rise to 2,3-diacetoxytetrahydropyran (III) and IV yields 2-acetyl-3,4-didesoxyaldopentosyl 2-acetyl-3,4-didesoxyaldopentoside (V). II has been obtained only as a thick oil, whereas IV is crystalline (m. p. 142.5–143°).

The crystalline nature of IV suggests that it may be a D,L pair or one *meso* form. Out of four possible D,L pairs and two *meso* forms for IV, only one D,L pair and one *meso* form would be expected if IV was related only to the *cis* forms of II.

In the browning studies it was demonstrated that 2,3,4-tridesoxyaldopentose or tetrahydropyran-2-ol underwent only a slight discoloration when heated with glycine solution, whereas 3,4-didesoxyaldopentose browned more readily even than D-glucose itself. Evidently, therefore, a δ-hydroxy aldehyde does not undergo the browning reaction, whereas an α,δ-dihydroxy aldehyde does do so. It seems that the α-hydroxy group is required for this reaction. Results are shown in Table I. In these experiments the solutions in question were heated at 90–95° under reflux condensers for four hours. Carbon dioxide was evolved from solutions 1 and 3. Initial and final absorptions at 4900 Å. were observed, using a Beckman spectrophotometer. The *p*H was that of the natural, unadjusted solutions. The four-hour samples of solutions 1, 2, and 3 were also taken for absorption spectra measurements between 3300–2550 Å. Solutions 1 and 3 revealed a definite maximum at 2950 Å., whereas solution 2 showed no such maximum.

TABLE I

5. 1.0 *M* 2,3,4-tridesoxyaldopentose alone

Experimental

Hydroxylation of 2,3-Dihydropyran.—2,3-Dihydropyran (196 g., 2.3 moles), obtained from the du Pont Company, and 5 ml. of osmium tetroxide catalyst (0.5 g. OsO_4 in 100 ml. of *t*-butyl alcohol) were placed in a 2-liter, 3-neck flask and 1320 ml. of hydrogen peroxide solution (6% H_2O_2 in *t*-butyl alcohol[5]) was added dropwise with stirring at −10 to +5° over a period of four hours. Additional catalyst solution (3 ml.) was added after two hours and after all of the peroxide solution had been added. The reaction is highly exothermic and care must be exercised not to add the peroxide at too fast a rate. The solution was allowed to stand overnight. The solvent was removed under reduced pressure at a bath temperature of 60° or below. The residue (255 g.) was acetylated by dissolving it in 500 ml. of pyridine and adding 750 ml. of acetic anhydride at 10°. The solution was allowed to warm to room temperature and stand overnight. After destruction of the unused acetic anhydride by addition of excess 75% ethyl alcohol, the solvent was removed at reduced pressure. The residue (335 g.) was allowed to stand overnight, whereupon some crystallization was noted, leading to 53 g. of V, which was collected on a filter. The solid was recrystallized from methyl alcohol: m. p. 132–133°. It sublimes at a pressure of 1 mm. of mercury.

Anal. Calcd. for $C_{14}H_{22}O_7$: C, 55.61; H, 7.34. Found: C, 55.78; H, 7.38.

The filtrate, after separation of V, was distilled at 1 mm., yielding 135 g. of crude 2,3-diacetoxytetrahydropyran (III) (b. p. 96–115°). Redistillation of this material gave 115 g. of product collected at 108–120° and 2–5 mm.

Anal. Calcd. for $C_9H_{14}O_5$: C, 53.46; H, 6.98. Found: C, 53.43; H, 7.74.

The residue (120 g.) after removal of V and III was dissolved in 100 ml. of methanol and cooled to 0°. Another 12 g. of crude V separated and was collected on a filter. Methanol was distilled from the filtrate and the residue was distilled at low pressure[7] into two fractions, VI and VII. At a bath temperature of 150–170° and a pressure of 10^{-6} to 10^{-3} mm., there was collected 48.4 g. of VI, a mixture of V and its isomers (the diacetate of the "disaccharide" portion). At a bath temperature of 170–200° and the same pressure was collected the acetate of the higher-boiling portion (VII); yield, 19.7 g.

The over-all yield data for utilization of 2,3-dihydropyran are as follows: 135 g. or 28.6% of III, 65 g. or 18.5% of V, 48.4 g. or 13.5% of a mixture of V and a diacetate of a reducing disaccharide, 19.7 g. or 6.3% of an acetate of a higher-boiling fraction.

Hydroxylation, Second Method.—The products of another comparable run were processed without the acetylation procedure. In this experiment 70 ml. of dihydropyran was taken and other reagents were used proportionately. After the solvent had been removed under reduced pressure, the resulting sirupy product was subjected to continuous extraction with cyclohexane (100 ml.). Sixteen grams of the product was insoluble in the hot hydrocarbon, whereas 41 g. was extracted. Of this 41-g. portion, 33.6 g. (A) was a sirup soluble in ether, and 7.4 g. (B) was a white solid insoluble in ether. Fraction A was essentially II (37% yield), and fraction B was proved by analysis (Found: C, 55.50; H, 8.76) and m. p. 141° to be IV (8% yield).

Deacetylation of 2,3-Diacetoxytetrahydropyran (III).—Twelve grams of III was dissolved in 100 ml. of absolute

(7) Hurd, Liggett and Gordon, THIS JOURNAL, **63**, 2656 (1941).

methanol and 8 ml. of 0.4 *N* barium methoxide solution was added. After forty-eight hours at 0°, the solution was carbonated by addition of Dry Ice, and the methyl alcohol was evaporated off at room temperature. Treatment of the residue with dry ether resulted in formation of a white amorphous precipitate (barium salts). After filtration and distillation of the solvent, finally at 52° (10 mm.), there remained 6.0 g. (85% yield) of water white, thick liquid. In other runs, yields of II have been 95–97%.

Anal. Calcd. for $C_5H_{10}O_3$: C, 50.88; H, 8.54. Found: C, 51.63; H, 8.54.

This material is soluble in water, ether and most other organic solvents except hexane. It reduces Benedict solution at once at 90° and reacts with phenylhydrazine to give a red oil.

3,4-Didesoxypentose 2,4-Dinitrophenylosazone.—Tetrahydropyran-2,3-diol (0.5 g.) was dissolved in 200 ml. of absolute ethanol and 2.5 g. of 2,4-dinitrophenylhydrazine was added. The reaction mixture was refluxed several minutes. Then 5 ml. of concd. hydrochloric acid was added and the refluxing was resumed, whereupon the color changed to dark brown. After fifteen minutes of refluxing, the reaction mixture was cooled and filtered (yield, 1.1 g.). Three recrystallizations from acetone led to a red-orange, crystalline solid of m. p. 242°.

Anal. Calcd. for $C_{17}H_{16}N_8O_9$: N, 23.52. Found: N, 23.35.

Tetrahydropyran-2,3-diol Bis-3,5-dinitrobenzoate.—One gram of II was dissolved in 10 ml. of pyridine. Three grams of 3,5-dinitrobenzoyl chloride was added. The reaction mixture was allowed to stand overnight at room temperature and was then treated with water and 5% aqueous sodium carbonate. The gummy product weighed 3 g. Three recrystallizations from a 3:1 mixture of ethanol and ethyl acetate led to a crystalline product melting at 174.5–175.5°.

Anal. Calcd. for $C_{19}H_{14}N_4O_{13}$: N, 11.06. Found: N, 10.95.

Deacetylation of 2-Acetyl-3,4-didesoxyaldopentosyl 2-Acetyl-3,4-didesoxyaldopentoside (V) into (IV).—The V (8.5 g., m. p. 132–133°), which had been recrystallized twice from methanol, was dissolved in 200 ml. of absolute methanol and deacetylated as above (dilute sulfuric acid instead of carbon dioxide was used to destroy the barium methoxide). It was necessary to allow the reaction to proceed for six days because of the limited solubility of IV in cold methanol. The product was worked up as above except that the residue was extracted with ethyl acetate instead of ether. The yield was 5.7 g. or 92%. The product was crystallized twice from ethyl acetate and sublimed before analysis (m. p. 141.5–142°).

Anal. Calcd. for $C_{10}H_{18}O_5$: C, 55.03; H, 8.31. Found: C, 55.42; H, 8.35.

This material (IV) is water soluble, is non-reducing to Benedict solution, and does not react with phenylhydrazine. A dinitrobenzoyl derivative of this material may be prepared as above (m. p. 245–246° after three recrystallizations from a 3:1 mixture of ethyl acetate and acetic anhydride).

Anal. Calcd. for $C_{24}H_{22}N_4O_{15}$: N, 9.24. Found: N, 9.35.

Hydrolysis of IV into II.—Acid hydrolysis of IV was carried out by dissolving 1 g. of the solid in 25 ml. of water, adding 1.5 ml. of concd. hydrochloric acid, and heating to 70–80° for thirty minutes. The solution was cooled, neutralized to phenolphthalein with 10% sodium hydroxide solution, and one drop of concd. hydrochloric acid added. This solution reduced Benedict solution, whereas the solution before treatment with acid was non-reducing. The solution was evaporated to dryness at room temperature with the aid of an air jet. The residue was treated with ether and the ether solution decanted from sodium chloride and evaporated, leading to 1 g. of clear sirup. This was placed in reaction with 2,4-dinitrophenylhydrazine as above The product melted at 242–243° after two recrystallizations from acetone and showed no m. p. depression when mixed with the 2,4-dinitrophenylosazone of II described above.

Deacetylation of Fractions VI and VII from High Vacuum Distillation.—These water insoluble acetates were deacetylated as above Fraction VI was first dissolved in methyl alcohol and crystallization was allowed to take place to remove the bulk of V present. The filtrate after removal of the solid was evaporated leaving an oily residue which showed no tendency to crystallize. This residue (8.5 g.) was deacetylated in 90.5% yield (5.8 g.). The product is water soluble and reduces Benedict solution strongly. Attempts to prepare pure derivatives of this material have failed.

Fraction VII showed no tendency to crystallize and was deacetylated in 80% yield to a water soluble, reducing material.

Acknowledgments.—Combustion analyses (C, H, N) were performed by P. Craig, M. M. Ledyard, and N. Mold.

Summary

Mono- and disaccharide-like compounds have been obtained by hydroxylation of 2,3-dihydropyran, using hydrogen peroxide in *t*-butyl alcohol and osmium tetroxide. The implications of the fact that tetrahydropyran-2,3-diol may be regarded as 3,4-didesoxyaldopentose are expounded. This compound gives rise to a strong brown coloration in its reaction with glycine, whereas 2,3,4-tridesoxyaldopentose (tetrahydropyran-2-ol) does not, thereby demonstrating the importance of the α-hydroxy aldehyde function in this reaction.

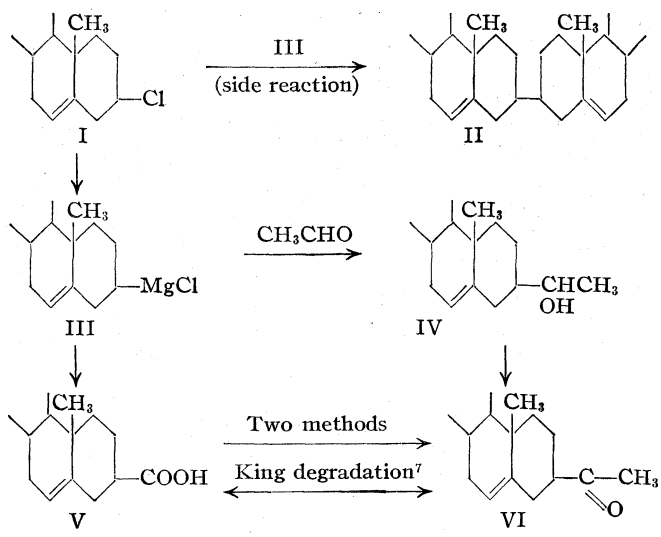
Derived Steroids. I. Cholesteryl Ketones[1]

BY ROBERT H. BAKER AND EDWARD N. SQUIRE[2]

As a model for the preparation of 3-acylsteroids, we have made a study of various methods for preparing methyl cholesteryl ketone, VI. All of the successful methods make use of cholesteryl Grignard reagents. This reagent may be converted into an impure methyl carbinol, IV, which is then oxidized to the ketone or it may be converted into the acid and to the acid chloride which with methyl Grignard or dimethylcadmium yields the ketone.



The preparation of cholesterylmagnesium chloride has been described briefly by Marker.[3] The reaction is carried out in the presence of ethylmagnesium bromide and is very slow in refluxing ethyl ether. Even though the cholesteryl chloride is added slowly over a period of six hours, there is always formed the coupling product, 3-cholesteryl-5-cholestene (biocholesteryl), II. This compound is almost insoluble in ether, and, although it must have been encountered previously, it has not been characterized.[4] We have isolated the compound in yields as high as 12% and have characterized it by physical constants and molecular weight determination. Cholesteryl bromide forms the Grignard reagent more rapidly than does the chloride but offers no advantage as a means of diminishing the production of bicholesteryl.

The reactions of cholesteryl Grignard are quite slow and although it is possible to carbonate it in almost quantitative yield, those reagents which are condensable undergo reaction with the production of large quantities of cholestene.[5] Table I summarizes the Grignard reactions. Cholestene was formed in all of these runs in yields of approximately 50%. In spite of the fact that acetaldehyde probably condenses more rapidly than do the other reagents used, it also reacts more rapidly in the desired way. The products of the acetaldehyde reactions do not crystallize, probably due to the presence of steroisomeric carbinols. The product of the Oppenauer[6] oxidation of the crude carbinol also is difficult to crystallize, but after purification by way of the semicarbazone it crystallizes very well.

Another approach, through the reaction of methylmagnesium bromide or dimethylcadmium on cholesteryl-3-carboxylic acid chloride, has proven to be the best route to the ketone. Although these methods, involving two Grignard reactions, would seem to be longer than the first ones discussed they are actually economical of time since the ketone is produced without an oxidation step and its purity is sufficiently high to allow crystallization without purification by the semicarbazone. An approximately 40% yield of crystalline ketone may be obtained by use of the magnesium or 82% by use of the cadmium reagents.

Diethylcadmium furnishes the ethyl ketone to about the same extent. In early experiments with the cadmium alkyls the reaction was carried out over long periods of time at comparatively low temperature and there resulted high-melting by-products. One of these has been identified as dimethylcholesterylcarbinol by comparison with a sample synthesized from 3-carbomethoxy-5-cholestene and methylmagnesium iodide. Since the color test for methylmagnesium bromide was negative it appears that a large excess of organocadmium reagent is capable of production of tertiary alcohols.

The various methods have thus far produced only one crystalline form of the methyl ketone, m. p. 104–105°; $[\alpha]^{27}D$ − 11°. The assignment of structure is based not only on its method of synthesis but also upon the fact that it has been de-

(1) Presented under the the title "Methyl Cholesteryl Ketone" at the Atlantic City Meeting of the American Chemical Society, April, 1947.

[a] Cholestene accounts for approximately 50% of each yield except the last three. [b] R is 3-cholesteryl.

graded to cholesteryl-3-carboxylic acid. The degradation was accomplished according to the excellent method discovered by Professor Carroll King of these Laboratories.[7] When heated with iodine and pyridine the ketone was converted into the crude pyridinium iodide in 75% yield and this upon cleavage by alkali gave Marker's acid[3] in 86% yield.

The success experienced recently in the replacement of the *p*-toluenesulfonoxy group through the use of sodiomalonic ester[8] led to attempts to effect similar replacements with potassium cyanide. Such a cyanide would probably yield the methyl ketone by reaction with methyl Grignard. The replacement has not been accomplished, but this reaction is of interest because it produces 3,5-cholestadiene in good yield. Suspensions of equimolar mixtures of cholesteryl tosylate and potassium cyanide in xylene do not react at 80° or 100° during twenty-four hours, but refluxing (139°) for eighteen hours produced the easily isolated diene in 70% yield. The diene is also formed (81%) by fusion of cuprous cyanide and cholesteryl bromide at 130° for four hours, but the product is more difficult to purify.

Experimental[9]

Cholesteryl Chloride, I.—This was prepared according to Diels[10] with the exceptions that enough thionyl chloride was used to take all the cholesterol into solution and the reaction product was poured into water. A quantitative yield of crude product was obtained and this was reduced to 63% by crystallization from four times its weight of acetone, m. p. 96–97°. A quantitative yield of crude product, m. p. 84–92°, was also obtained from the reaction of equal weights of cholesterol and phosphorus oxychloride for eighteen hours at room temperature but the product is difficult to purify.

It is necessary that the cholesteryl chloride used in the preparation of cholesterylmagnesium chloride be very pure; the melting point should be as high as 95–96°. The purification has been accomplished by chromatographic adsorption. A solution of 10 g. of crude cholesteryl chloride, m. p. 85–93°, in 100 ml. of petroleum ether (80–100°) was passed through a column containing 18 × 100 mm. of 80–200 mesh activated alumina and 18 × 50 mm. of Norit. The petroleum ether was evaporated off under vacuum and the cholesteryl chloride crystallized from acetone, m. p. 95–96°. The purified compound was then crystallized from absolute ether at −50° and dried *in vacuo* at 78° for four hours.

Cholesteryl-3-carboxylic Acid, V.—This was prepared in 85% yield, m. p. 210–220°, by a modification of Marker's method[3] in which the Grignard solution made from 12 g. of chloride was poured into a flask containing crushed Dry Ice in absolute ether and allowed to stand overnight before working up. One crystallization from benzene gave 90% of the material, m. p. 222–223°, and 10%, m. p. 225–227°.

Cholesterylmagnesium Chloride and Bromide.—To 0.73 g. (0.03 mole) of powdered magnesium there was added 0.7 g. (0.0064 mole) of ethyl bromide in 10 ml. of absolute ether. When this reaction was complete a solution of 9.2 g. (0.023 mole) of pure cholesteryl chloride in 50 ml. of dry ether was added over a period of three hours, gentle reflux being maintained throughout the addition time and for an additional thirty to thirty-five hours. The volume of the solution was maintained at 50–60 ml. by occasional addition of dry ether. Stirring was not used.

The preparation of the bromo Grignard was similarly carried out with the exception of a shorter refluxing period, fifteen to twenty hours.

3-Cholesteryl-5-cholestene, II.—This was isolated from the early experiments by filtration of the ether extracts of acidified reaction mixtures. The suspended material collects at the interface between the aqueous and ether phases, but is re-suspended upon shaking. In later experiments it was removed from the Grignard preparation by filtration prior to addition of the reactant. It was separated from any unreacted magnesium by extraction with hot benzene in which it is only slightly soluble. It crystallizes from benzene in small colorless plates which melt at 267–269° to a cloudy melt with decomposition, $[\alpha]^{24.5}D$ +30° (6.8 mg. made up to 5 ml. with benzene, α + 0.07°; *l*, 2 dm.).

Anal. Calcd. for $C_{54}H_{90}$: C, 87.73; H, 12.27; mol. wt., 739. Found: C, 87.90; H, 12.39; mol. wt. (Rast), 751.

Methyl Cholesteryl Ketone Semicarbazone.—To the Grignard solution prepared from 0.7 g. (0.006 mole) of ethyl bromide and 9.2 g. (0.023 mole) of cholesteryl chloride in 50 ml. of ether was added 50 ml. of an absolute ether solution of dry acetaldehyde (0.077 mole). The addition was made at 0° over a period of two hours and the mixture was allowed to stand, finally reaching room temperature over a period of four hours. The mixture was then hydrolyzed with 5% hydrochloric acid and extracted with ether. The crude bicholesteryl, 1.2 g., was separated by filtration and then the ether solution was evaporated to an oil which was dried *in vacuo* at 100°.

The oil was oxidized by refluxing for fourteen hours in a mixture of 75 ml. of dry acetone and 150 ml. of benzene containing 10 g. of aluminum *t*-butoxide. Upon working up the product there was obtained about 5 g. of a yellow oil which was heated *in vacuo* at 100° for three hours in order to remove the simple condensation products of acetone.

The resulting ketonic oil was refluxed for one hour with 0.9 g. of semicarbazide hydrochloride and 2 ml. of pyridine in 20 ml. of ethanol. The solvent and pyridine were removed by evaporation and the solid was washed with ether and collected on a filter. It was then boiled with 20 ml. of water and filtered hot to remove biurea. The dried **semicarbazone** weighed 1.74 g., (16.3%), m. p. 215–225°. Crystallized from benzene twice the m. p. is 229–231°, dec.

Anal. Calcd. for $C_{30}H_{51}ON_3$: C, 76.70; H, 10.94; N, 8.95. Found: C, 76.87; H, 10.98; N, 9.02.

Methyl Cholesteryl Ketone, VI.—To 194 mg. of the semicarbazone and 20 ml. of 95% ethanol there was added 1 ml. of concentrated sulfuric acid and the mixture heated under reflux. The suspension became homogeneous and when concentrated to 10 ml. after two hours of heating

(7) King, THIS JOURNAL, **66**, 894, 1612 (1944).

and cooled to 0° the ketone crystallized. This was taken up in ether and washed with potassium carbonate solution then water and the ketone was recovered. Crystallization from 5 ml. of 95% ethanol gave 51 mg. (29.8%) of colorless needles, m. p. 104–105°, $[\alpha]^{27}D$ −11° (67 mg. made up to 2.0 ml. with chloroform, α −0.37; l, 1 dm.).

Anal. Calcd. for $C_{29}H_{48}O$: C, 84.40; H, 11.72. Found: C, 84.44; H, 11.76.

Methyl Cholesteryl Ketone (second method).—3-Cholesterylcarboxylic acid, 2.84 g. (0.0069 mole), m. p. 210–220°, was dried for one hour *in vacuo* at 100°. It was then mixed with 2.0 g. (0.0096 mole) of phosphorus pentachloride and the mixture heated *in vacuo* at 100° for an hour. The dark reaction mixture was allowed to stand at room temperature for eighteen hours at the end of which time it was taken up in dry ether and filtered to remove the insoluble residue. The ether solution was then cooled to −10° and to it was added a solution of methylmagnesium iodide prepared from 1.24 ml. (0.02 mole) of methyl iodide and 0.5 g. of magnesium in 10 ml. of ether. The mixture was allowed to stand at −10° for thirty-six hours during which time an oil had settled out. The mixture was then poured into 50 ml. of ice water containing 10 ml. of 10% sulfuric acid. The organic material was then taken up in ether which was dried, filtered, and evaporated to a gum, 0.74 g. The gum was then dissolved in acetone, filtered and crystallized to yield two fractions; 0.138 g., m. p. 107–112°, and 0.280 g., m. p. 98–103°. The latter fraction was recrystallized from acetone to give a product, m. p. 100–103°, which with methylcholesteryl ketone, previously prepared, m. p. 104–105°, gave a mixed m. p. 103–105°.

Methyl Cholesteryl Ketone (third method).—Thionyl chloride was a more suitable reagent than phosphorus pentachloride for the preparation of 3-cholesterylcarboxylic acid chloride. The acid, 1.2 g., was refluxed with 1 ml. of thionyl chloride in 10 ml. of benzene for four hours and allowed to stand overnight. The solvent and excess reagent were then removed *in vacuo* at 100° leaving the crude acid chloride, 96% yield, m. p. 118–120°.

The acid chloride, 0.50 g. (1.15×10^{-3} mole), in 3 ml. of ether was added to 2×10^{-3} mole of dimethylcadmium contained in 5 ml. of ether at 0°. The mixture was refluxed for forty-five minutes and then decomposed by ice water. The product was extracted with ether and washed with 10% hydrochloric acid, saturated sodium bisulfite, 10% potassium hydroxide and then water. Acidification of the alkaline wash afforded 0.10 g. of crude 3-cholesteryl carboxylic acid. The ether solution was dried over sodium sulfate and evaporated to yield 0.39 g. of ketone, m. p. 103–105°, 82% yield.

Variation of this procedure by refluxing the reactants in benzene for two hours[11] led to a product more difficult to purify in 40% yield.

Ethyl Cholesteryl Ketone.—In a manner similar to the third method described above diethylcadmium gave the ethyl ketone, m. p. 133–134°; $[\alpha]^{27}D$ −14 (25.9 mg. made up to 3.61 ml. with chloroform, α −0.10, l, 1 dm.).

Anal. Calcd. for $C_{30}H_{50}O$: C, 84.44; H, 11.82. Found: C, 84.31; H, 11.77.

The **semicarbazone** of ethyl cholesteryl ketone was prepared in order to determine the amount of ketone in an impure fraction of material prepared as above. By use of the pyridine method previously described, 1.45 g. of ketonic material gave 0.58 g. of semicarbazone, m. p. 224–225°, from benzene–ethanol.

Anal. Calcd. for $C_{31}H_{53}N_3O$: C, 76.93; H, 11.03; N, 8.73. Found: C, 77.24; H, 11.08; N, 8.41.

Degradation of Methyl Cholesteryl Ketone.[7]—Methyl cholesteryl ketone, 65 mg. (1.58×10^{-4} mole) was heated with 1 ml. (1.24×10^{-2} mole) of pyridine and 25 mg. (1×10^{-4} mole) of iodine at 100° for twenty-two hours. The pyridine was then removed *in vacuo* at 100° and the product was extracted with three 1-ml. portions of absolute ether which yielded 26 mg. of starting material. The ether insoluble material was then extracted with three 2-ml. portions of warm methanol. By fractional crystallization of the methanol solution there was obtained 43 mg. of the crude pyridinium iodide of methyl cholesteryl ketone, m. p. 190–192° with prior softening (75% yield based on recovered ketone).

The pyridinium iodide, 20 mg. (3.2×10^{-5} mole) in 5 ml. of ethanol containing 0.2 ml. of 10% potassium hydroxide was then refluxed three hours. The reaction mixture was then poured into water and extracted with ether. The aqueous layer upon acidification with sulfuric acid gave a yellow coagulum, which, after cooling to 0° and filtering, yielded 11.5 mg. (86%) of crude acid. Crystallized from benzene the acid melted at 223–225° and showed no depression with mixtures of 3-cholesteryl carboxylic acid.

3-Carbomethoxy-5-cholestene.—Following the method of Marker,[3] 550 mg. (1.3×10^{-3} mole) of 3-cholesterylcarboxylic acid, V, was converted into 559 mg. of the methyl ester, m. p. 93–103°. One crystallization from methanol or chromatographing a cyclohexane solution on alumina followed by elution with benzene yielded crystals, m. p. 100–101°, $[\alpha]^{27}D$ −16 (53 mg. made up to 2 ml. with chloroform, α −0.42, l, 1 dm.). The purified product amounted to 64% of the total ester. The benzene eluate, 33%, melted at 86–90° and this indicates that the 101.5°-melting form of Marker is probably entirely of one configuration.

Dimethylcholesterylcarbinol.—This compound was isolated in about 4% yield from reactions of five-fold excess cadmiumdimethyl (prepared from methyl bromide) with the acid chloride in benzene at 25° for eighteen hours. It was isolated in two ways. Upon adding petroleum ether solutions of the reaction product to ethanol there was obtained as many as three fractions melting variously between 143 and 160°. The filtrate from the third fraction upon evaporation yielded the ketone. When the whole reaction product was absorbed from petroleum ether solution on alumina and eluted with methanol, the ketone was removed first and the carbinol melted as low as 128°. Air-dried crystals from methanol melt about 128° and prolonged drying *in vacuo* at 100° (72 hours) is required to obtain an analytically pure sample, m. p. 159–160°; $[\alpha]^{28}D$ −26 (47.0 mg. made up to 2.0 ml. with chloroform, α −0.62; l, 1 dm.).

Anal. Calcd. for $C_{30}H_{52}O$: C, 84.04; H, 12.23. Found: C, 83.96; H, 12.02.

The melting point was not depressed by mixtures with a sample synthesized as follows:

Methylmagnesium iodide was prepared in the usual way from 0.5 g. (2.06×10^{-2} mole) of magnesium powder and 2.28 g. (1.6×10^{-2} mole) of methyl iodide in 8 ml. of ether. To the Grignard solution, 200 mg. of 3-carbomethoxy-5-cholestene in 2 ml. of ether was added. The reaction mixture was allowed to reflux twenty-four hours with stirring under 800 mm. nitrogen pressure. The ether was evaporated and the residue cooled to 0°. This was hydrolyzed by slow addition of 13 ml. of 10% ammonium chloride solution and the mixture was allowed to stand eighteen hours. The solution was transferred to a separatory funnel, and following acidification with sulfuric acid it was extracted twice with ether. The ether extracts were washed once with water, once with saturated sodium bisulfite, and then four times with water; the ether was then dried over anhydrous sodium sulfate for eighteen hours, filtered and evaporated to dryness *in vacuo* yielding crystals; 200 mg., m. p. 129–130°.

Upon drying *in vacuo* at 100° for seventy-two hours a different form of the carbinol results, m. p. 159–160°.

3,5-Cholestadiene.—Cholesteryl-*p*-toluenesulfonate,[12] 5 g. (0.0093 mole), and 1.2 g. of potassium cyanide (0.0185 mole) were dried and suspended in 20 ml. of xylene. The mixture was refluxed for eighteen hours at which time a heavy white precipitate is obtained. The suspension was cooled and extracted by filtration with 200

(11) Cason, THIS JOURNAL, **68**, 2078 (1946).

(12) Wallis, Fernholz and Gephart, *ibid.*, **59**, 137 (1937).

ml. of dry ether. The clear filtrate was evaporated in a dry air stream at 100° and the product crystallized from 100 ml. of acetone to produce 2.4 g. (70%) of 3,5-cholestadiene, m. p. 73–74°. Crystallization from acetone then absolute ethanol raised the m. p. to 76–77°, $[\alpha]^{22.5}D$ −96.5 (109.8 mg. made up to 5 ml. with chloroform, α, −4.24°; l, 2 dm.); γ_{max} (obs.) 236. These values are in agreement with those of the literature, m. p. 78–79°,[13] $[\alpha]^{20}D$ −97.5,[13] γ_{max} (obs.) mμ 235.[14] The diene gives a 20° depression in m. p. when mixed with *i*-cholestadiene[15] and its ultraviolet spectrum is clearly different from that of the *i*-diene.[16]

Isolation of 5-Cholestene.—Separate experiments generally were made to determine the extent of cholestene formation. The product resulting from the reaction of 0.026 mole of diacetyl with a mixture of 0.024 mole of cholesterylmagnesium chloride was treated so as to remove bicholesteryl. Of the remaining 8.3 g. of oil, 2 g. was dissolved in 50 ml. of petroleum ether (30–60°) and passed through a 17 by 1 cm. column packed with Brockman alumina. The eluate, 45 ml., and the first 15 ml. fraction of petroleum ether washings gave upon evaporation 1.26 g. of product, m. p. 80–84°. Crystallized once from acetone the m. p. was 85–87°, $[\alpha]^{24.5}D$ −53.5°. The literature[17] values are 89–90° and −56.3°.

Summary

1. Methyl cholesteryl ketone has been prepared by the reaction of cholesteryl Grignard reagents with acetaldehyde followed by oxidation of the impure carbinol and by Grignard alkylation of cholesteryl-3-carboxylic acid chloride. Its semicarbazone is described.

2. The ketone has been degraded back to cholesteryl-3-carboxylic acid.

3. 3-Cholesteryl-5-cholestene has been identified as a by-product of the formation of cholesteryl Grignard reagents.

4. 5-Cholestene is formed in large quantity in the reaction of cholesteryl Grignard reagents with a variety of compounds.

5. 3,5-Cholestadiene is conveniently prepared by the reaction of cholesteryl *p*-toluenesulfonate with potassium cyanide.

6. Ethyl cholesteryl ketone, its semicarbazone, and dimethylcholesterylcarbinol have also been prepared.

The Cleavage of Benzyl Ethers with Hydrogen

BY ROBERT H. BAKER, KATHRYN HEROLD CORNELL AND MARTIN J. CRON

Recently it has been shown that vinyl ethers and amines which are so substituted as to activate the alkyloxy or alkylamino group may be cleaved by hydrogen prior to saturation of the double bond which carries the activating effect.[1] It was hoped that the remarkable promoting effects of perchloric and sulfuric acids[2] might allow preferential cleavage of unsaturated benzyl ethers, but the results, Table I, were not promising.

Cyclic ethers bearing phenyl groups on the α carbon atom have been found to undergo hydrogenolysis. 2-Phenyltetrahydropyran[3] yields 5-phenylpentanol and since the starting materials are easily available, a convenient synthesis for 5-arylpentanols is indicated. Phenyldioxane and 2,3-diphenyldioxane[4] reacted, respectively, with one and two moles of hydrogen. The 2-(2-phenylethoxy)-ethanol produced from the former of these demonstrated that the ether linkage β to a phenyl group is quite stable under the conditions which will completely cleave a similar group in the α position.

(4) The aryldioxanes were furnished by Prof. R. K. Summerbell, *cf.* Summerbell and Bauer, THIS JOURNAL, **57**, 2364 (1935).

Two isomeric compounds, m. p. 122 and 174°, to which the structure of *cis* and *trans* 2,5-diphenyldioxane have been tentatively assigned failed to behave in the expected manner.[5] Over palladium–charcoal they showed no reduction in acetic acid; with added hydrochloric acid the reduction was very slow and with added perchloric or sulfuric acids they took up three moles of hydrogen with no diminution of the rate at two moles. This can hardly be due to cleavage of 2-phenylethanol followed by its reduction to ethylbenzene because this would require four moles of hydrogen and repeated values of three would be unexpected. Further evidence against this explanation is seen in the behavior of phenethyl benzyl ether and in the fact that 2-phenylethanol takes up only 4% of one mole of hydrogen in the time and under the conditions required for complete cleavage of the phenyldioxanes.

A liquid described as 2,6-diphenyldioxane was

(5) These compounds were prepared by Aldro Bryan, Ph.D. Thesis, Northwestern University, 1945, by reaction of 2,5-dichlorodioxane with a phenyl Grignard. They were believed to contain no acetal or ketal linkage on the basis of stability to acid hydrolytic conditions. Dibromination followed by hydrolysis and treatment with phenylhydrazine produced the osazone of phenylglyoxal in poor yield. The compound referred to as 2,5-diphenyl-1,4-dioxane, m. p. 147–152°, by Smedley, U. S. Patent 2,414,982; *C. A.*, **41**, 2755 (1947), is in fact the source of these isomers.

TABLE I

HYDROGENATIONS WITH PALLADIUM–CHARCOAL

Compound	Run	Millimoles	Cat., mg.	Solvent[a]	Moles H_2	Time, min.	% Products isolated

[a] Ac–P and –S refer to acetic acid containing 2.5% of 60% aqueous perchloric or 2% sulfuric acid, respectively. The millimolar runs employed 4 ml. and the 0.1 molar 40 ml. of solvent. [b] These runs were stopped short of completion. [c] The unmistakable odor of 2-phenylethanol was observed but no derivatives were obtained. [d] Average values of three identical runs.

kindly furnished by Dr. W. S. Emerson.[6] Two middle fractions of it, b. p. 158–162° and 162–163° (2 mm.), $n^{20}D$ 1.5602, were combined and subjected to incomplete hydrogenation. No product corresponding to the expected diphenethyl ether could be isolated by 3-plate fractionation. The lowest boiling fraction, 75° at 2 mm., $n^{20}D$ 1.5109, was shown to contain 2-phenylethanol.

Benzoin diethylacetal was studied because of its similarity of structure to some of the other compounds in Table I. The compound is very difficult to obtain by the published method,[7] and is obtained only when very dry reagents are used and the reaction mixture is allowed to stand in the cold for twenty-one days. The oil which is obtained slowly produces crystals from petroleum ether, b. p. 60–80°, and after two more crystallizations gives the acetal, m. p. 67–68° in 3% yield. The compound could not be hydrogenated over palladium on charcoal in ethanol even at 70°.

Experimental

Preparation of Compounds.—Benzyl allyl ether has been described previously.[8] It was prepared in 65% yield by reaction of 2.1 moles of benzyl chloride with 2.1 moles of sodium allyloxide in excess allyl alcohol, b. p. 204–205°; $n^{20}D$ 1.5090; d^{25}_4 0.959.

Benzyl methallyl ether was made in a similar manner from 5.4 moles of dry methallyl alcohol, 1.56 moles of sodium and 1.56 moles of benzyl chloride. The crude ether, b. p. 110–118° at 13 mm., was subjected to 10-plate fractionation to give 33% yield, b. p. 113–114° at 12 mm.; $n^{20}D$ 1.5095; d^{25}_4 0.958; M_D calcd., 50.57, found 50.59.

Benzyl 2-phenylethyl ether was similarly prepared but from sodium 2-phenylethyloxide in toluene, b. p. 175–178° at 13 mm., $n^{20}D$ 1.5545.[9]

2-Phenyltetrahydropyran was prepared from dihydropyran according to the method of Paul.[3] The crude product, b. p. 110–114° at 12 mm., from the first distillation was distilled again to duplicate the published physical properties. The sources of other materials are noted in Table I.

Hydrogenations.—The millimolar reactions were carried out at one atmosphere pressure in a shaking vessel of 8-ml. capacity attached to a hydrogen buret. Palladium on charcoal (5%) obtained from Wilkens-Anderson Company, Chicago, was used in all the runs. In the small runs the catalyst was shaken with hydrogen to constant volume before dropping the sample, contained in a thimble, into the reaction mixture. Larger runs were carried out in standard size apparatus at 3 atmospheres. The data are summarized in Table I.

Isolation and Identification of Products.—No attempts to isolate products from the allyl and methallyl ethers were made. The reaction mixtures which were expected to contain alcohols were poured into 10% sodium hydroxide–ice mixtures and were refluxed for thirty minutes to saponify acetate esters which often form in the presence of noble metal catalysts. The neutral materials were extracted from the alkaline saponification mixtures with ether or tetrachloroethane. It was proved independently that tetrachloroethane could be distilled from 2-phenylethanol without loss of the latter.

An analytical procedure was used to determine the quantity of 2-phenylethanol resulting from Run 12 in dry tetrachloroethane, the procedure being standardized with known samples of the alcohol.[10] From other runs similar to 12 the alcohol was identified as its 1-naphthylcarbamate, m. p. 116–117° (lit.[11] 119°). This alcohol was otherwise identified from Run 7 by physical constants, and from Run 16 by its allophanate, m. p. 184–185°, (lit.[12] 186°).

2-(2-Phenylethoxy)-ethanol from Run 9 was also identified as its allophanate, m. p. 148–149° (from toluene), lit.[13] 150°. 1,2-Diphenylethane was purified by sublimation *in vacuo*, m. p. and mixed m. p. with an authentic sample, 51.5–52°, lit.[14] 52°.

Summary

1. In acid solution it is not practical to selectively hydrogenate allyl or methallylbenzyl ethers over palladium–charcoal.
2. The structures of certain aryldioxanes have been proved by hydrogenation.
3. Some compounds isomeric with 2,3-diphenyldioxane do not react with hydrogen in ways consistent with their suspected structures.
4. A convenient synthesis of 5-phenylpentanol has been described.

3-Nitrofluorenone

BY FRANCIS EARL RAY AND JAMES G. BARRICK

Mononitration of fluorene yields only 2-nitrofluorene. As this is easily oxidized to 2-nitrofluorenone the properties of both compounds are well known.[1]

4-Nitrofluorenone also seems to be well known, having first been prepared by Schmidt and Baur,[2] from the known 4-nitrophenanthraquinone by means of the benzilic acid rearrangement followed by oxidation and decarboxylation. Courtot[3] and Bell[4] have confirmed this work.

1-Nitrofluorenone has not been prepared.

3-Nitrofluorenone was first reported by Schmidt and Soll[5] who obtained it by the simultaneous nitration and oxidation of 9,10-diaminophenanthrene to 3-nitrophenanthraquinone. A benzilic acid rearrangement, followed by oxidation and decarboxylation gave a compound melting at 209–210° which was described as 3-nitrofluorenone. Its oxime melted at 240°. As the structure of 3-nitrophenanthraquinone had been proved conclusively by J. Schmidt[6] seven years previously, there seemed no reason to question the identity of Schmidt and Soll's compound. Especially was this true after the appearance of the paper by Eckert and Langecker[7] in 1928.

Using a different method, the simultaneous nitration and oxidation of 2-acetylaminofluorene to 3-nitro-2-amino-fluorenone followed by removal of the 2-amino group, Eckert and Langecker obtained identical melting points, Table I. Eckert and Langecker proved the position of the nitro group by converting their compound to the known 3-hydroxyfluorenone.[8]

Better evidence for the identity of 3-nitrofluorenone could hardly be desired. Nevertheless, in 1931 Bardout[9] reported that his preparation of this compound by essentially Eckert and Langecker's method yielded 3-nitrofluorenone melting, not at 210°, but at 239°. The oxime instead of melting at 240°, as previously reported, melted at 221°, cor. Bardout also converted his compound to the known 3-hydroxyfluorenone as well as to the known 3-bromofluorenone.[10]

In the course of his synthesis Bardout also obtained 3-nitrofluorene melting at 105°. Hayashi and Nakayama[11] repeated the synthesis of 3-nitrofluorene and found the same melting point as Bardout. They did not, however, oxidize it to the fluorenone.

With a view to resolving this difficulty, Scheer[12] attempted to repeat Bardout's synthesis but found great difficulty in isolating pure compounds. Repeating Schmidt and Soll's work, he obtained, supposedly, 3-nitrofluorenone which melted considerably higher than Schmidt and Soll's and Eckert and Langecker's compound but not quite as high as Bardout's. From the two degree range in melting point Scheer concluded that his material was still impure. The significant part remains that even the impure material melted considerably higher than the first investigators reported. A summary of these results will be found in Table I.

It seemed of interest, therefore, to attempt an entirely *new* synthesis of 3-nitrofluorenone in the hope of settling the controversy.

Our starting material was the readily available 2-aminobiphenyl. This was treated with toluenesulfonyl chloride and the product nitrated accord-

ing to the method of Bell[13] and of Jones and Braker[14] to give on hydrolysis 2-amino-5-nitrobiphenyl. The use of the acetyl derivative gives inferior results in nitration.[15] 2-Cyano-5-nitrobiphenyl was obtained in the usual manner. On hydrolysis, 5-nitrobiphenyl-2-carboxylic acid was obtained.

The structure of this compound rests on Sako's[16] proof of structure for 2-amino-5-nitrobiphenyl. Reduction gave the diaminobiphenyl and by conversion to a Lauth's violet, the amino groups were shown to be *para* to each other. An isomeric diamine was shown to be 2,3-diaminobiphenyl by treating it with phenanthraquinone to form the quinoxaline. The 2-amino-4-nitro isomer would yield the well known 2-nitrofluorenone.

5-Nitrobiphenyl-2-carboxylic acid was converted to 3-nitrofluorenone by heating with concentrated sulfuric acid, a method widely used in the preparation of fluorenones[17] as well as other cyclic ketones.[18] The crude 3-nitrofluorenone was obtained on pouring the sulfuric acid solution onto ice. The oxime was prepared by Bardout's method. It melted somewhat higher than Bardout's value but not nearly as high as the value reported by Schmidt and Soll, and by Eckert and Langecker, Table I.

It is possible that the differences in the melting point of the oximes may be due to *cis–trans* isomerism. It is not so easy, however, to explain the low melting point for 3-nitrofluorenone reported by the earlier investigators. If only a single paper were involved one might be tempted to suggest that the melting point values for the ketone and the oxime were interchanged.

In the hope of obtaining further data we reduced our 3-nitrofluorenone to 3-aminofluorenone and prepared the acetyl derivative. Much to our surprise we found the melting points to agree almost exactly with those reported by Eckert and Langecker. We must conclude that the impurities in their 3-nitrofluorenone were eliminated when it was converted into 3-aminofluorenone. These values are also given in Table I.

Experimental

2-Aminobiphenyl.—This dark pink material was Eastman Kodak Co. practical grade and melted at 47–49°. Distillation under reduced pressure removed the color but did not raise the melting point above 49°.

2-*p*-Toluenesulfonamidobiphenyl.—This compound was best prepared by condensing *p*-toluenesulfonyl chloride and 2-aminobiphenyl in the presence of pyridine. From 85 g. of 2-aminobiphenyl, 100 g. of *p*-toluenesulfonyl chloride and 200 cc. of pure pyridine there was obtained 135 g. (84%) of 2-*p*-toluenesulfonamidobiphenyl melting at 98–99°.[14]

5-Nitro-2-*p*-toluenesulfonamidobiphenyl.—Bell's method[13] gave largely the unchanged starting material. It was modified as follows. Sixty grams of 2-*p*-toluenesulfonamidobiphenyl was dissolved in 120 cc. of warm glacial acetic acid, nitric acid (15 cc., sp. g. 1.5) was added slowly and the mixture was heated on the steam-bath to 90°. When the temperature started to rise rapidly, the beaker was removed from the heat and the reaction allowed to continue for three minutes. It was poured into cold water and a red oil precipitated which quickly solidified. When recrystallized from 400 cc. of hot ethyl alcohol, yellow needles were obtained melting at 168–169°; yield 55 g. (80%). When recrystallized a second time the compound melted sharply at 169°.

5-Nitro-2-aminobiphenyl.—A solution of 25 g. of 5-nitro-2-*p*-toluenesulfonamidobiphenyl in 50 cc. of concentrated sulfuric acid was allowed to stand for one hour at room temperature. It was then added dropwise to 200 cc. of an ice slurry. The yellow amine weighed 16 g. (yield quantitative) and was recrystallized twice from alcohol, m. p. 125°.[13]

5-Nitro-2-cyanobiphenyl.—A solution of 16 g. of 5-nitro-2-aminobiphenyl in 100 cc. of concentrated hydrochloric acid was diazotized at 0° with 5.2 g. of sodium nitrite in 50 cc. of water. After one hour urea was added and the solution filtered. This solution was slowly added to a solution of potassium cuprocyanide, prepared from 25 g. of copper sulfate and 28 g. of potassium cyanide and containing 15 g. of sodium carbonate, at 10°. After half of the diazonium solution had been added a further 15 g. of sodium carbonate was added in 50 cc. of water. After one hour the light tan precipitate was removed. It weighed 12 g.; yield, 72%. On recrystallization it melted at 134–135°.[13]

5-Nitrobiphenyl-2-carboxylic Acid.—Twelve grams of 5-nitro-2-cyanobiphenyl was hydrolyzed by boiling with 70 cc. of concentrated sulfuric acid in 100 cc. of water for six hours. After several hours the solid changed to an oil and finally became semisolid. The crude material (10 g.) was dissolved in 100 cc. of 10% sodium hydroxide, 1 g. of Darco added, the mixture boiled for fifteen minutes, filtered and acidified. White platelets weighing 6 g., yield 50%, were obtained melting at 179–180°. Recrystallization from alcohol gave a m. p. of 180°. No m. p. is given by Jones and Braker.[14]

Anal. Calcd. for $C_{13}H_9NO_4$: eq. wt., 243. Found: eq. wt., 244.

3-Nitrofluorenone.—Two grams of 5-nitrobiphenyl-2-carboxylic acid in 10 cc. of concd. sulfuric acid was heated in an oil-bath to 120° and held at this temperature for ten minutes. After cooling this blood red solution to room temperature it was poured into a slurry of ice yielding a yellow precipitate weighing 2 g. It was recrystallized from glacial acetic acid with Darco, then from ethyl alcohol and melted constantly at 235–236° (239–240°, cor.). The same melting point was obtained when samples were recrystallized from benzene and pyridine.

Anal. Calcd. for $C_{13}H_7NO_3$: N, 6.22. Found: N, 6.45.

3-Nitrofluorenone Oxime.—A 0.5-g. sample of 3-nitrofluorenone was heated with 0.25 g. of hydroxylamine in 15 cc. of alcohol and 0.3 g. of oxime was obtained which on recrystallization from alcohol melted at 224–225°, Table I.

3-Aminofluorenone.—Five grams of sodium sulfide was added over a period of two hours to 100 cc. of boiling alcohol containing 1 g. of 3-nitrofluorenone and 2 g. of ammonium chloride. After refluxing for an additional hour it was poured into cold water and extracted with ether. The ether was extracted with dilute hydrochloric acid and on neutralization a deep yellow precipitate was obtained. It was not possible to get a better melting point than 142–146°. Following the procedure of Eckert and Langecker,[7] who encountered similar difficulties, the amine was acetylated. Recrystallization from alcohol gave 3-acetylaminofluorenone.

3-Acetylaminofluorenone was hydrolyzed by boiling with 20% hydrochloric acid. It yielded 3-aminofluorenone, Table I.

Summary

A new synthesis of 3-nitrofluorenone has been described and Bardout's characterization of this compound has been substantially confirmed.

The following melting points, uncorrected unless otherwise stated, have been found for 3-nitrofluorenone and related compounds:

	M. p., °C.
3-Nitrofluorenone	235–236 (239–240, cor.)
3-Nitrofluorenone oxime	224–225
3-Aminofluorenone	157–158
3-Acetylaminofluorenone	215–216

The values of the latter two compounds given by Eckert and Langecker have been confirmed but their values for 3-nitrofluorenone and 3-nitrofluorenone oxime as well as those of Schmidt and Soll are shown to be in error.

The Synthesis and Spectrum of 2-Cyclopropylpyridine*

BY RAYMOND P. MARIELLA, LOWELL F. A. PETERSON[1] AND ROBERT C. FERRIS[2]

Some recent work by Klotz[3] has shown that the cyclopropane ring, when adjacent to an olefinic or carbonyl group, produced spectra which could be interpreted in terms of resonance due to hyperconjugation. This effect had also been observed by Carr and Burt,[4] who examined the spectra of compounds in which the cyclopropane ring was in "conjugation" with both a carbonyl group and the benzene ring. From these spectra it was not possible to secure information regarding the extent of conjugation of the cyclopropane grouping alone with the aromatic nucleus.

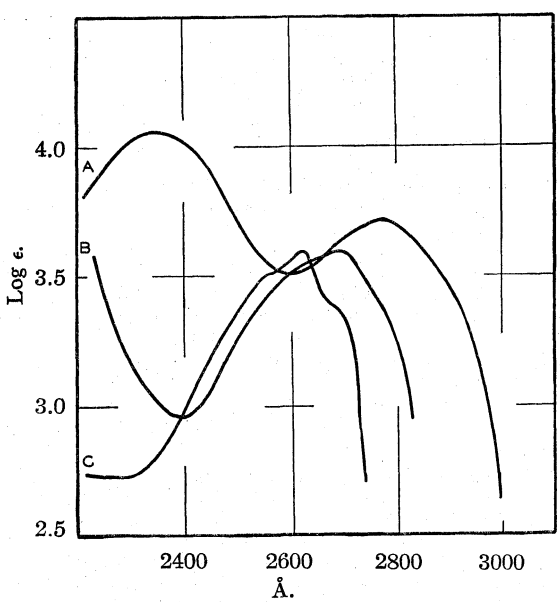

Fig. 1.—Absorption spectra of 2-vinylpyridine, A; 2-cyclopropylpyridine, B; and 2-*n*-propylpyridine, C.

In the present work, 2-cyclopropylpyridine (IX) was synthesized. This compound has the cyclopropane ring alone in conjugation with a highly aromatic nucleus.[5] A comparison of its absorption spectrum with those of 2-*n*-propylpyridine (VIII) and 2-vinylpyridine (X) (Fig. 1), showed the cyclopropane compound to have a maximum (2690 Å.) between that of the similarly conjugated (2775 Å.) and non-conjugated (2620 Å.) system.

Since the maximum for pyridine itself is at 2530 Å.,[6] the presence of an alkyl or alicylic group in the α position causes a shift of the maximum to longer wave lengths. This effect appears greater with the cyclopropyl group than with the *n*-propyl group, and confirms chemical evidence long known[7] that the cyclopropane ring possesses a certain degree of unsaturation. The phenomenon no doubt occurs because the electrons of cyclopropane are rendered especially polarizable by the unusual angle between the bonds.

If the shift to longer wave lengths is to be interpreted as a "hyperconjugation" effect, then in the case of 2-cyclopropylpyridine we can postulate that certain ionic structures exist, which in addi-

(5) After the initial submission of this manuscript a paper appeared (Rogers, *ibid.*, **69**, 2544 (1947)), in which the absorption spectrum of cyclopropylbenzene was given. This compound also showed a shift in the maximum toward longer wave lengths when compared with propylbenzene, which was interpreted as a hyperconjugation effect.

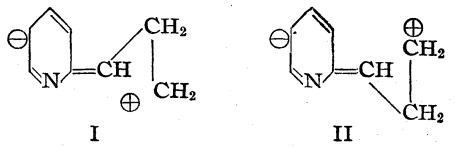
(7) Kohler and Conant, THIS JOURNAL, **39**, 1404, 1699 (1917).

tion to the usually written hyperconjugation forms, contribute to the excited structure. Two of the twelve possible additional forms are listed below (I and II).



I II

Since the three-membered ring is not necessarily coplanar with the pyridine ring these resonance forms probably do not contribute as much as expected, causing the shift from *n*-propyl to cyclopropyl to be small but still measurable.

The maximum due to the cyclopropane ring itself, probably about 2100 Å., was beyond the range of the instrument used.

The flow sheet for the synthesis of 2-cyclopropylpyridine and related compounds is shown in Fig. 2.

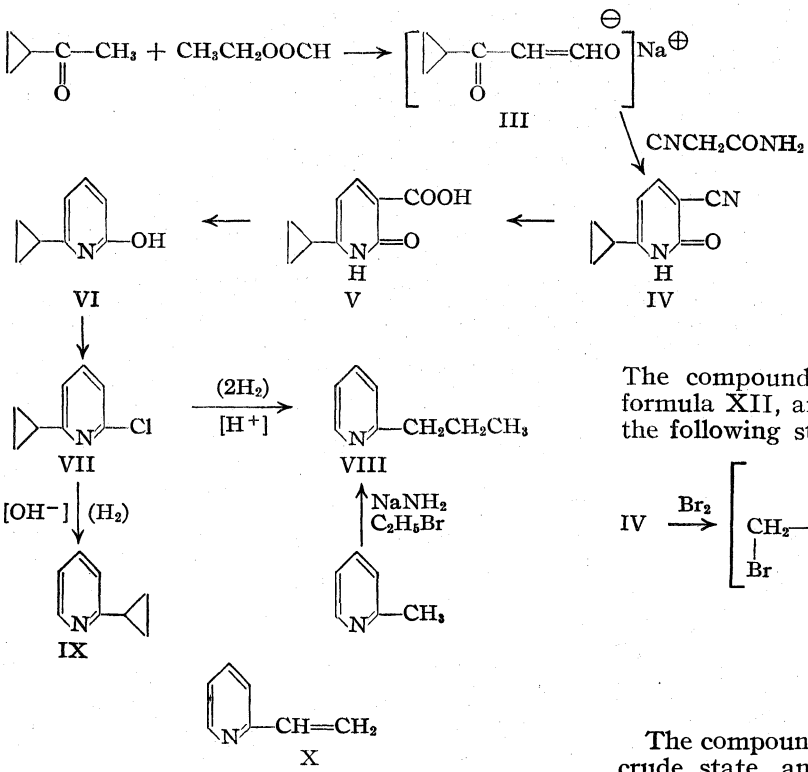


Fig. 2.

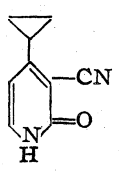
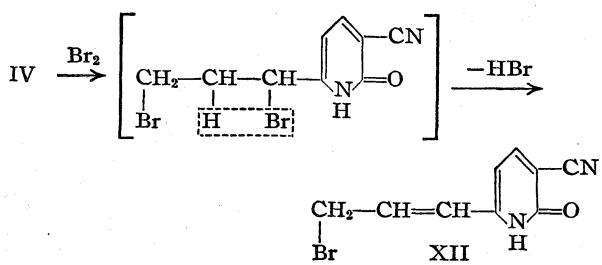
The sodium salt (III) was reported recently,[8]



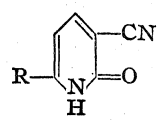
XI

but no yield was given. The condensation of III with cyanoacetamide could have yielded XI instead of IV, but this possibility was eliminated by the isolation of the known compound (VIII), in the acidic reduction of VII. In all steps, the yields were lower than in similar reactions of compounds[9,10] in which the cyclopropyl ring was replaced by a simple alkyl group. In many of the reactions, there was evidence of considerable decomposition and tar formation. This was particularly noticeable in the decarboxylation of V to VI, which succeeded only in small runs of one and a half grams each.

The cyclopropane ring remained fairly stable to reagents such as concentrated hydrochloric acid and phosphorus pentachloride, as evidenced by the isolation of V and VII, which still possessed the alicyclic ring intact. Treatment with bromine, however, immediately destroyed the cyclopropane ring in IV to give a compound containing only *one atom* of bromine, instead of two. The compound, $C_9H_7BrN_2O$, probably has the formula XII, and its formation is postulated by the following steps.



The compound (XII) was quite unstable in the crude state, and purification by crystallization was very difficult. Bromination was assumed to attack the cyclopropane ring because compounds having the general formula XIII, where R is a simple aliphatic group, do not react with bromine in glacial acetic acid.[11]



XIII

The 2-*n*-propylpyridine (VIII) (conyrine) was made by a method similar to that of Chichibabin,[12] and the 2-vinylpyridine was a product obtained from the Reilly Tar and Chemical Corporation.

The authors acknowledge a grant from the

Graduate School, which made some of the work possible.

Experimental[13]

Sodium Salt of Hydroxymethylene Methyl Cyclopropyl Ketone (III).—To 58 g. of sodium metal ribbon in one liter of absolute ether was added a mixture of 185 g. of ethyl formate[14] and 210 g. of methyl cyclopropyl ketone,[15] dropwise over a period of two hours. The reaction mixture was protected from moisture, cooled in an ice-bath, and stirred during the addition. When about one-fourth of the addition mixture had been added, the tan-colored precipitate first appeared, and increased in amount as the addition continued. Stirring was continued for one-half hour after the addition was completed. The cooling bath was then removed, and stirring continued, at room temperature, for an hour and a half. The brown solid was then filtered and dried in a vacuum desiccator. Additional product was obtained by filtering the solid which developed in the filtrate. The combined solids weighed 219 g. (65% yield).

3-Cyano-6-cyclopropylpyridone-2 (IV).—A solution of 115 g. of the sodium salt (III), 84 g. of cyanoacetamide, and piperidine acetate catalyst in 250 ml. of water was refluxed for two hours. (The catalyst was prepared by adding piperidine to a solution of 9 ml. of glacial acetic acid in 25 ml. of water until basic to litmus.) The solution was then diluted with 250 ml. of water, acidified with glacial acetic acid, and cooled in an ice-bath for an hour. The yellow solid, which had formed, was filtered and dried, 73 g. (53% yield). Purification by a carbon treatment and several recrystallizations from alcohol gave a white powder, m. p. 239–240° (dec.).

Anal. Calcd. for $C_9H_8N_2O$: C, 67.48; H, 5.04; N, 17.5. Found: C, 67.39; H, 5.06; N, 17.2.

Bromination of 3-Cyano-6-cyclopropylpyridone-2.—A solution of 0.50 g. of IV in 10 ml. of glacial acetic acid heated to 60° was treated with a solution of 0.3 ml. of bromine in 5 ml. of glacial acetic acid. A copious evolution of hydrogen bromide gas ensued, as the solution was kept at 60° for ten minutes. The solution was then poured on 50 g. of cracked ice, and the yellow solid, which immediately formed, was filtered and dried, 0.69 g. (93% yield). The crude material soon developed a green color and finally turned black. A pure sample was obtained by treating the yellow solid with Norit in alcohol, followed by five recrystallizations from alcohol and six recrystallizations from benzene. The white solid, so obtained, remained colorless, m. p. 221–222°.

Anal. Calcd. for $C_9H_7BrN_2O$: C, 45.21; H, 2.95; N, 11.7. Found: C, 45.09; H, 3.04; N, 12.0.

6-Cyclopropane-2-oxo-3-pyridine Carboxylic Acid (V).—A solution of 73 g. of IV in 250 ml. of concentrated hydrochloric acid was refluxed for four hours. The solution was then poured into 250 ml. of water, cooled in an ice-bath for an hour, and the gray solid filtered and dried, 44 g. (54% yield). After a carbon treatment and seven recrystallizations from 3:1 water–glacial acetic acid, the pure white solid was obtained, m. p. 248–250° (dec.). The compound was only slightly soluble in cold water and gave a negative ferric chloride test.

Anal. Calcd. for $C_9H_9NO_3$: N, 7.8. Found: N, 7.8.

2-Cyclopropyl-6-pyridol (VI).—A test-tube containing powdered V was heated to 290°. The solid melted and decomposed as carbon dioxide was evolved. A cold finger was then inserted in the test-tube to collect the product which sublimed in the form of white plates. The yields varied, depending upon the amount and purity of the starting material. A maximum of 70% yield was obtained when 1.5 g. of V, purified by two crystallizations from alcohol, was used. The yields fell off sharply if more material was used in the decarboxylation. Additional purification was achieved by a vacuum sublimation at 0.05 mm. and at a temperature of 110–120°, m. p. 165–166°. The white solid gave a deep red ferric chloride test.

Anal. Calcd. for C_8H_9NO: N, 10.4. Found: N, 10.4.

2-Cyclopropyl-6-chloropyridine (VII).—To a solution of 10.5 g. of VI in 16 ml. of phosphorus oxychloride heated to refluxing was added 20 g. of phosphorus pentachloride, in small portions, over a period of one-half hour. The oil-bath temperature was then raised to 165° and kept there for one hour. The phosphorus oxychloride was removed under reduced pressure, 50 g. of ice then added, and the mixture made strongly basic by adding a concentrated potassium hydroxide solution. When this was steam distilled, a colorless heavy oil was obtained, which was separated by two extractions with 100-ml. portions of ether. The ether was dried and removed, and the residue distilled, giving a colorless oil, 4.0 g. (34% yield), b. p. 107–108° (16 mm.), $n^{25}D$ 1.5512. The liquid darkened very slowly when exposed to light.

Anal. Calcd. for C_8H_8ClN: N, 9.1. Found: N, 9.1.

Reduction of VII in Acidic Solution.—To a solution of 0.193 g. of VII in 15 ml. of absolute alcohol were added a solution of 100 mg. of palladium chloride in one ml. of concentrated hydrochloric acid, one ml. of 15% hydrogen chloride in absolute alcohol, 0.50 g. of Norit and hydrogen. The reduction proceeded at room temperature and atmospheric pressure and stopped in fifty minutes, at which time two moles of hydrogen had been absorbed. There was no distinct break in the hydrogenation curve during the reduction. The mixture was filtered and the liquid filtrate concentrated to a colorless oil. The chloroplatinate of this material did not depress the m. p. 163° of an authentic sample of the chloroplatinate of 2-*n*-propylpyridine.

Reduction of VII in Basic Solution: 2-Cyclopropylpyridine (IX).—To a solution of 1.26 g. of VII in 25 ml. of 3% alcoholic potassium hydroxide was added 4.0 g. of 5% palladium on charcoal. The hydrogenation proceeded at room temperature and atmospheric pressure and was complete in thirty minutes, at which time 0.90 mole of hydrogen had been absorbed. The mixture was filtered, made faintly acid with hydrochloric acid and concentrated. The addition of concentrated potassium hydroxide liberated the free base, which was taken up in ether. The solution was dried, ether removed *in vacuo*, leaving an oil, which on distillation gave 0.65 g. (67% yield), b. p. (750 mm.) 174–175°, $n^{25}D$ 1.5110, d^{29}_4 0.956. The material possessed the characteristic alkyl pyridine odor. It was observed that the liquid caused a temporary numbing effect when brought in contact with the skin.

The picrate was isolated as pale yellow needles, m. p. 115–117°.

Anal. Calcd. for $C_{14}H_{12}N_4O_7$: C, 48.28; H, 3.47. Found: C, 48.19; H, 3.48.

The chloroaurate was prepared as a yellow powder, m. p. 111–113°.

Anal. Calcd. for $C_8H_{10}Cl_4NAu$: Au, 43.0. Found: Au, 43.0.

The chloroplatinate came down very slowly when a solution of chloroplatinic acid was added to the 2-cyclopropylpyridine hydrochloride in water. The orange solid melted at 159–160°. The mixed m. p. with the chloroplatinate of 2-*n*-propylpyridine was depressed to 140°.

Anal. Calcd. for $C_{16}H_{20}Cl_6N_2Pt$: Pt, 30.1. Found: Pt, 30.1.

2-*n*-Propylpyridine (Conyrine) (VIII).—To 300 ml. of liquid ammonia containing 0.3 g. of ferric nitrate, was added 35 g. of sodium metal. The excess ammonia was allowed to escape and 83 g. of α-picoline (b. p. 128°) was

(16) Chichibain, ref. 12, reports a b. p. 173° and a m. p. 76° for the picrate.

(17) Ladenburg, *Ann.*, **247**, 21 (1888), reports a m. p. of 159–160°.

(18) Ladenburg, *Ber.*, **22**, 2585 (1889), reports a b. p. 79–82° (29 mm.).

The chloroplatinate melted at 174–175°, and the chloroaurate melted at 143°.[19]

Spectra.—The ultraviolet absorption spectra were obtained with a Beckmann quartz spectrophotometer. All physical constant measurements of the above alkyl pyridines were performed immediately after their isolation. Solutions of known concentrations were made by dissolving weighed quantities of compound in absolute alcohol in a volumetric flask. Dilutions were made volumetrically to give suitable density readings. The solutions were poured into one of two matched silica absorption cells and the second cell was filled with the solvent. Extinction coefficients were calculated from the equation

$$\epsilon = d/cl$$

where c is the concentration of the solute, in moles per liter, l is the thickness of the cell, in centimeters, and $d = \log_{10}(I_0/I)$. I_0 is the intensity of light passing through the solvent, and I is the intensity of light passing through the solution.

Summary

2-Cyclopropylpyridine was prepared and its ultraviolet absorption spectrum compared with those of 2-*n*-propylpyridine and 2-vinylpyridine. The maximum of 2-cyclopropylpyridine falls in a position between the two comparison compounds. This effect can be interpreted in terms of additional resonance due to hyperconjugation.

(19) Ladenburg, *ibid.*, reported the chloroplatinate m. p. 174°, and the chloroaurate, m. p. 144°.

An Electron Diffraction Investigation of the Structure of Adamantane

BY WERNER NOWACKI AND KENNETH W. HEDBERG

The crystal structure of adamantane ($C_{10}H_{16}$, see Fig. 1) has been investigated by Nowacki,[1] who found a C–C bond distance of 1.54 ± 0.02 Å. on assumption of tetrahedral bond angles, and by Giacomello and Illuminati,[2] who obtained similar results by Fourier methods. A significant difference has been found between C–N distances in the crystal[3] and vapor[4] of hexamethylenetetramine, a molecule whose configuration is closely similar to that of adamantane, and although no such difference would be expected in adamantane, it seemed worth while to study it by electron diffraction in the vapor phase.

The photographs obtained show twelve maxima and shelves extending to q values of about 90 ($q = (40/\lambda) \sin \varphi/2 = (10/\pi)s$).

Experimental

The sample of adamantane, which had been synthesized by Prelog and Seiwerth,[5] was vaporized by use of a high temperature nozzle[6] in the apparatus described by Brockway.[7] The camera distance was about 11 cm. and the electron wave length[8] about 0.06 Å. Corrections were made for film expansion.

Radial Distribution Curve

The radial distribution curve (Fig. 2) was calculated from the equation[9,10] by use of punched

$$rD(r) = \sum_{q=1,2\ldots}^{q\ max} I(q) \exp.(-aq^2) \sin\left(\frac{\pi}{10} q\, r\right)$$

cards[10,11]; the quantities $I(q)$ were taken from the visual curve (Fig. 2) drawn to represent the

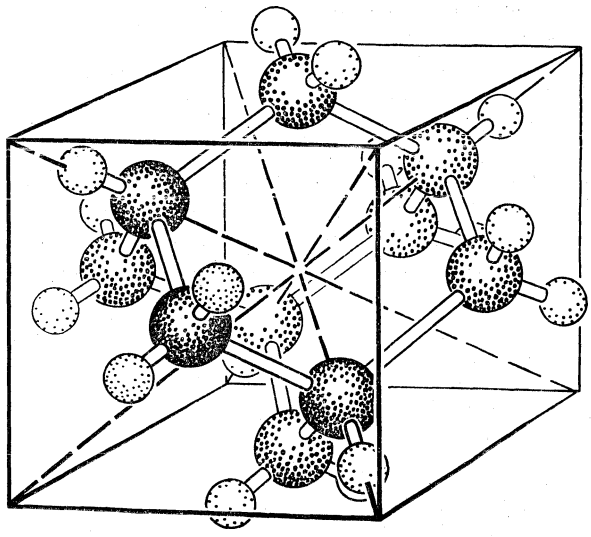

Fig. 1.—Adamantane.

appearance of the photographs, and the constant a was chosen to give exp $(-aq^2) = 1/10$ at $q = 90$. The resulting curve shows major peaks at 1.53 and 2.52 Å. which correspond to the bonded and to the shortest non-bonded C···C distances in a model such as C with tetrahedral bond angles; in model C these distances are 1.540 and 2.515 Å. There are additional peaks at 1.00, 2.92 and 3.46 Å., and a broad feature at 2.20 Å. With the exception of the first none of these is sufficiently well resolved for a determination of interatomic distances, though they agree well with our final model, as shown by the vertical lines. The heavy lines denote the C···C distances and the light, the C···H; the lengths of the lines indicate the relative weights of the distances.

The deviation of the peak at 1.00 Å. from the value 1.09 Å. normally obtained from bonded C···H interactions closely parallels the result obtained by Schomaker and Shaffer[4] in their study of hexamethylenetetramine.[12]

Correlation of Visual and Intensity Curves

Intensity curves were calculated[10,11] from the

$$I(q) = \sum_{i,j}{}' \frac{Z_i Z_j}{r_{i,j}} \exp.\ (-a_{i,j}q^3) \sin\left(\frac{10}{\pi} qr\right)$$

equation[9] for a model of symmetry $T_d - \bar{4}3m$ assuming C–C = 1.54 Å. throughout, C–H = 1.09 Å. except for model G, and ∠HCH 109°28′ except for model H. In models A to F the $C_2C_3C_2$ bond angle is varied from 106°28′ to 112°28′. Models G and H, which have tetrahedral C–C–C angles, are characterized by a shortened C–H distance (1.05 Å.) and an increased H–C–H angle (114°28′), respectively. Terms representing all bonded and non-bonded atomic interactions except H···H were included in the calculations. An effective value of $Z = 1.2$ was employed for hydrogen in order to approximate better its scattering power relative to carbon for small q. The coefficient $a_{i,j}$ was given the value 0.00016 for bonded C–H, 0.00030 for all non-bonded C···H interactions,[13] and zero otherwise.

TABLE I

ELECTRON DIFFRACTION DATA FOR ADAMANTANE

Max.	Min.	$q_{obsd.}$	$q_{calcd.}$ (Model C)	$q_{calcd.}/q_{obsd.}$[a]
	1	6.5	5.3	(0.815)
1		9.6	8.5	(0.885)
	2	13.3	12.6	(0.947)
2		17.8	17.8	1.000
	A	21.9	22.2	1.014
A		25.1	25.5	(1.016)
	3	27.8	27.2	(0.798)
3		30.3	29.3	(0.967)
	4	32.8	33.7	[1.027]
4		35.7	35.3	[0.989]
	5	38.7	38.1	0.984
5		42.2	42.0	0.995
	6	45.8	46.2	1.009
6		49.3	49.8	1.010
	7	53.3	53.2	0.998
7		57.4	57.0	0.993
	8	61.4	61.2	0.997
8		66.0	67.3	(1.020)
	9	70.6	72.3	[1.024]
9		74.2	75.2	[1.013]
	10	77.7	78.1	1.005
10		81.7	82.2	1.006
	11	85.5	86.7	1.014
11		90.1	90.5	1.004
			Average	1.004
			Average deviation	0.008

[a] Parenthesized values were omitted in evaluation of averages, bracketted values were given half weight.

Comparison of the calculated curves with the visual curve shows model A to be unacceptable; minimum 8 appears in the calculated curve as far too broad and the relative depths of minima 9 and 10 are inverted. Curve B is somewhat better than A but the disagreement in the relative depths of minima 9 and 10 is still present. Curve C is generally satisfactory.[14] Curve D is acceptable

(12) The visual curve for adamantane was drawn without previous knowledge of the appearance of the hexamethylenetetramine photographs or of the corresponding intensity curves, although subsequently the photographs of the two substances were carefully compared and found to be closely similar. The errors in the two visual curves which correspond to the errors at 1.0 Å. in the two radial distribution functions are evidently nearly alike. Perhaps this is because they represent errors of interpretation which are in some way peculiar to the types of features shown by hexamethylenetetramine and adamantane.

(13) Because of the relative rigidity of the carbon skeleton of adamantane we believe the value 0.00030 for $a_{i,j}$ to be a reasonable one for all the non-bonded C···H interactions.

(14) The main points of disagreement in the correlation of model C with the observed intensity distribution are seen to involve (1) the relative depths of minima 1 and 2, (2) the strength of shelf A, (3) the shape of maximum 8, and (4) the relative depths of minima 5 and 6. The first two items do not appear to be serious; estimates of the depth of the first minimum are subject to considerable error, and a

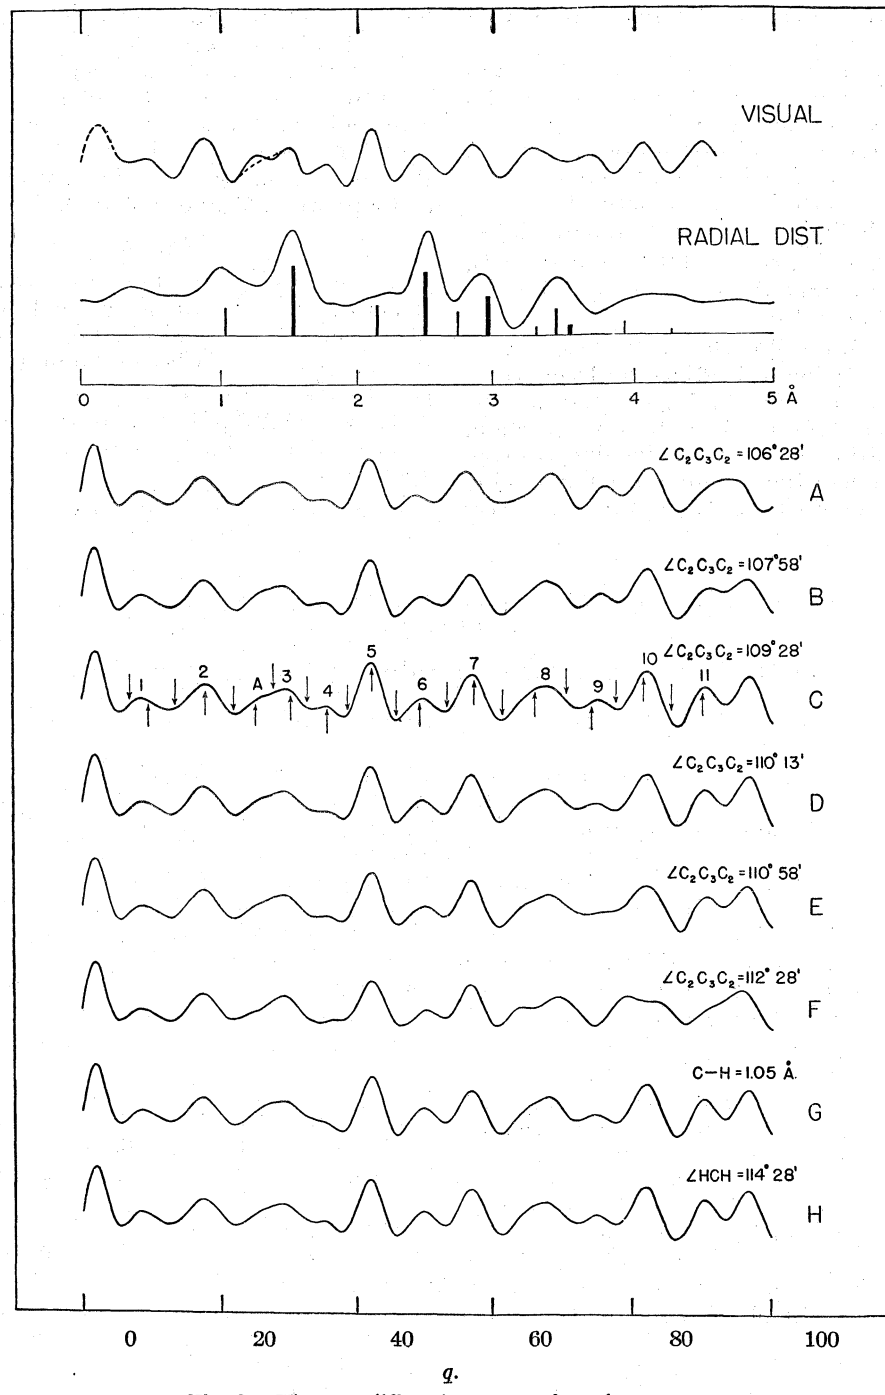

Fig. 2.—Electron diffraction curves for adamantane.

reexamination of the photographs indicates the exaggeration of shelf A to be a simple misinterpretation (the dotted line is felt to be a more accurate representation of this feature). Item (3) also arises from errors of interpretation, as shown by comparing photographs of adamantane and hexamethylenetetramine; the appearance of maximum 8 is closely similar and was satisfactorily represented by Schomaker and Shaffer[4] in their visual intensity curve for hexamethylenetetramine. It is difficult to explain the reversal of minima 5 and 6 (item (4)). Perhaps the trouble is due to a tendency to compensate incorrectly for the background intensity, which is difficult to estimate in patterns as complicated as that of adamantane.

although maximum 4 is a poorer representation of the appearance of the photographs than the same maximum in C. Curves E and F are unsatisfactory. Curves G and H are both acceptable although G is not as satisfactory as C in the region of maximum 4. We conclude that in the adamantane molecule in the gas phase $\angle C_2C_3C_2 = 109.5 \pm 1.5°$, the upper limit of this determination being especially conservative. The ∠HCH and C–H/

C–C determinations cannot be made to within sizable limits of error.

A comparison (Table I) of the observed q values with those calculated for model C (all bond angles tetrahedral, C–C = 1.54 Å., C–H = 1.09 Å.), a consideration of the radial distribution function, and comparisons of visual and calculated intensity curves lead to the following structural parameters and probable limits of error: symmetry $T_d - \bar{4}3m$ (assumed), $\angle$HCH = 109°28′ (assumed), C–H = 1.09 Å. (assumed), C–C = 1.54 ± 0.01 Å., $\angle C_2C_3C_2$ = 109.5 ± 1.5°.

Acknowledgment.—We thank Professor Verner Schomaker for helpful advice and constructive criticism, Professor V. Prelog (Zürich) for the sample of adamantane used in the investigation, and the International Business Machines Corporation for the loan of the machines used in making calculations. One of us (W. N.) wishes to express his gratitude to Professor Linus Pauling for the many kindnesses extended him; he is also indebted to the American-Swiss Foundation for Scientific Exchange (Montclair, N. J.), to the Stiftung zur Förderung der wissenschaftlichen Forschung an der Bernischen Hochschule, and to the Government of the Canton of Berne for financial support and leave of absence.

Summary

An electron diffraction investigation of the structure of the adamantane molecule in the gas phase has led to values for the structural parameters in agreement with those found in the crystal. On the assumption of symmetry $T_d - \bar{4}3m$, of C–H = 1.09 Å., and of $\angle$HCH = 109.5°, the results are C–C = 1.54 ± 0.01 Å., and $\angle C_2C_3C_2$ = 109.5 ± 1.5°.

[CONTRIBUTION FROM THE DEPARTMENT OF CHEMISTRY AND CHEMICAL ENGINEERING OF THE UNIVERSITY OF WASHINGTON]

The System Cesium Fluoride–Hydrogen Fluoride

BY R. VIRGINIA WINSOR AND GEORGE H. CADY

Mathers and Stroup[1] have shown that solutions made by melting acid fluorides of cesium may be used at approximately room temperature as electrolytes for the preparation of fluorine. They found that the acid fluorides of cesium have lower melting points than the corresponding salts of potassium, but in their work identified only the previously known compound, CsF·HF. A more thorough study of the system comprises the subject matter of the present article.

Experimental

A 36.0-g. sample of cesium fluoride was prepared from pulverized pollucite following a procedure based upon work of Wells[2] and recommended by Geo. McPhail Smith. The mineral was digested with an equal weight of 6 N hydrochloric acid at about 95° for approximately three days. Solid remaining undissolved was separated by filtration and the filtrate was evaporated to dryness. The product was then dissolved in four times its weight of 4 N hydrochloric acid and, after filtering, one gram atom of iodine was added for each mole of cesium chloride present. The liquid was then heated while an excess of chlorine was passed. As the resulting solution was allowed to cool, the compound $CsICl_2$ crystallized. This salt was purified by three recrystallizations in the presence of a little ICl in solution. Cesium chloride was produced by the thermal decomposition of $CsICl_2$. The chloride was converted to the nitrate which was fused with oxalic acid to form the carbonate. Aqueous hydrofluoric acid was allowed to react with the carbonate and the resulting solution was poured into the silver vessel shown in Fig. 1. Evaporation of the solution left the fluoride. Hydrogen fluoride was then added. The vessel was heated and hydrogen fluoride was removed by vacuum distillation. This process of adding and then removing hydrogen fluoride was repeated a few times with the result that the vessel plus the cesium fluoride came to constant weight.

Hydrogen fluoride was obtained as the vapor by distillation from a cylinder of the commercial anhydrous acid. About half of the material originally present in the cylinder had been removed by evaporation before starting the work on the system.

Cooling or warming curves were determined using the apparatus shown in Fig. 1. This comprised a silver cylinder, A, of 105 ml. capacity equipped with a thermocouple well, B, and a monel metal tube, C, through which materials were added or removed. The composition of the charge was determined by weighing the vessel and its contents. Temperatures were measured with a calibrated copper–constantan thermocouple connected to a potentiometer. Each cooling curve was established by first heating the vessel and then allowing it to cool slowly while being held firmly in a Dewar flask or other well-insulated vessel which was moved rapidly back and forth in a mechanical shaker. Temperatures below that of the room were reached by placing solid carbon dioxide in the Dewar vessel in such a location that the

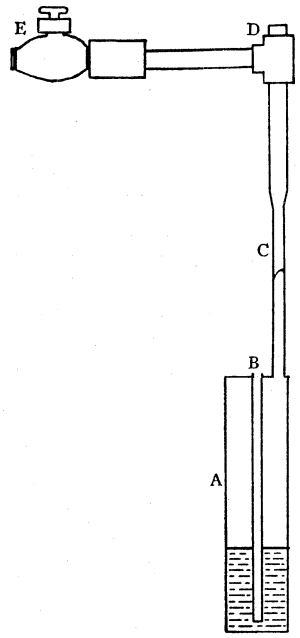

Fig. 1.

refrigerant did not touch the silver cylinder. In a number of cases, both cooling and warming curves were determined.

The temperatures of the observed significant breaks in the curves are shown in Fig. 2. From this diagram the data presented in Table I were selected.

Discussion

The data indicate the existence of four acid fluorides: CsF·HF, CsF·2HF, CsF·3HF and CsF·6HF. The first of these exists in two or perhaps three forms within the temperature range 30° to the melting point 176°. Several attempts were made to determine the number of forms and the transition temperatures, but the experiments gave ambiguous results.

TABLE I

SYSTEM CsF–HF

Mole fraction of HF in solution	Temp., °C.	Type of point	Solid phases present
0.500	176.0	Freezing	CsF·HF
.667	50.2	Freezing	CsF·2HF
.750	32.6	Freezing	CsF·3HF
.857	−42.3	Freezing	CsF·6HF
.453	151.5	Eutectic	CsF·HF and CsF
.639	38.3	Eutectic	CsF·HF and CsF·2HF
.709	16.9	Eutectic	CsF·2HF and Cs·F3HF
.828	−49.5	Eutectic	CsF·3HF and CsF·6HF
< .61	34.4 to 58.8	One or two transition points	Two or perhaps three forms of CsF·HF

In general, an abrupt change in slope in the cooling curve for a sample containing solid CsF·HF occurred at about 56.5°. The corresponding break in the warming curve usually occurred at about 42°. The proximity of the latter temperature to the eutectic point, 38.3°, for CsF·HF and CsF·2HF added to the difficulty of interpreting the experimental observations.

It is almost certain that no additional acid fluorides of cesium will be discovered by extending the study of the system beyond the concentration limits used in this research. In the case of mixtures rich in cesium fluoride, the thermal effect resulting from the freezing of CsF·HF and another solid, probably cesium fluoride, was still readily detected at a mole fraction of hydrogen fluoride of 0.205. It is also the case that the thermal decomposition of molten CsF·HF leaves

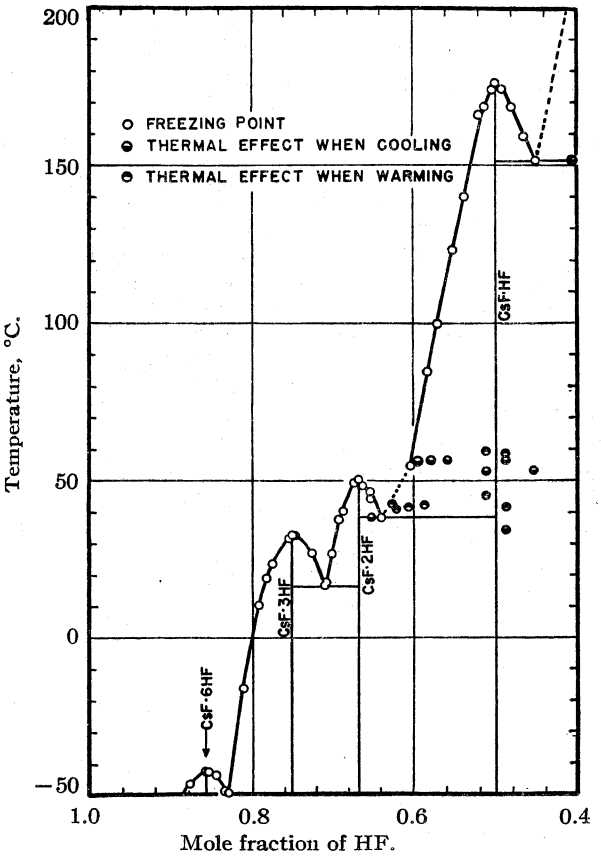

Fig. 2.—The system CsF–HF.

solid cesium fluoride rather than an acid fluoride. These two facts strongly suggest that no acid fluorides exist which are richer in cesium fluoride than the salt CsF·HF. Since the most dilute solution studied (mole fraction of hydrogen fluoride equal to 0.876) showed no thermal effect due to eutectic freezing down to temperatures as low as −83° and since no other acid fluorides containing over six moles of hydrogen fluoride per mole of metal fluoride are known, it is unlikely that additional compounds exist in this part of the system.

A comparison of the acid fluorides of the alkali metals reveals the following trends with increasing atomic number of the metal: (1) The melting points of corresponding compounds decrease. (2) The corresponding compounds become more stable. (3) The maximum number of moles of hydrogen fluoride capable of combining with one mole of metal fluoride apparently increases. Item (1) is illustrated by the fact that NaF·HF melts at some as yet undetermined temperature above 278°,[3] while the corresponding acid fluorides of potassium,[4] rubidium[5] and cesium melt congruently at 239.0, 205 and 176.0°, respectively. This trend is comparable with that existing for the

(3) Froning, Richards, Stricklin and Turnbull, *Ind. Eng. Chem.*, **39**, 275 (1947).

(5) E. B. R. Prideaux and K. R. Webb, *J. Chem. Soc.*, 1 (1937).

normal fluorides whose freezing points are reported to be: lithium fluoride, 870°; sodium fluoride, 980–997°; potassium fluoride, 880°; rubidium fluoride, 760°; cesium fluoride, 684°. Item (2) is illustrated by the heats of formation of the acid fluorides of the type MF·HF from the solid fluorides of the type MF·HF from the solid fluoride of the metal and gaseous hydrogen fluoride. Values given by de Forcrand[6] for the salts progressing from that of sodium to that of cesium are in calories per mole: 17.10, 21.56, 22.58, 23.57. Further evidence for increasing stability is furnished by the temperatures at which the MF·HF compounds decompose to give solid MF and hydrogen fluoride vapor at one atmosphere pressure. The lithium and sodium salts decompose without melting at "below 200°"[7] and at 278°,[3] respectively. Potassium acid fluoride, KF·HF, melts, and the liquid must be heated to about 400°,[4,8] to cause the vapor pressure of hydrogen fluoride to be one atmosphere. The corresponding salts of rubidium and cesium require still higher, but at present unknown, temperatures. Item (3) is illustrated by the formulas for the highest known acid fluorides: LiF·HF, NaF·HF, KF·4HF, RbF·3HF (others may yet be found), CsF·6HF.

Both KF·HF and CsF·HF undergo transitions involving large heat effects. In the case of the former, the heat of transition is larger than the heat of fusion and the modification existing above the transition point is much softer than the low temperature form. The cause of the transition is not known, but it may possibly involve rotation of the HF_2^- ion.

Summary

Cesium fluoride and hydrogen fluoride form the compounds: CsF·HF, CsF·2HF, CsF·3HF and CsF·6HF.

SEATTLE 5, WASHINGTON RECEIVED AUGUST 8, 1947

[CONTRIBUTION NO. 9 FROM THE THERMODYNAMICS LABORATORY, PETROLEUM EXPERIMENT STATION, BUREAU OF MINES]

The Heat Capacity, Heat of Fusion and Entropy of Benzene[1]

BY GEORGE D. OLIVER, MARGARET EATON AND HUGH M. HUFFMAN

Because of the importance of benzene in organic chemistry and in industry the Bureau of Mines has considered it desirable to include this material in its research program involving determination of the thermodynamic properties of hydrocarbons and their derivatives.

Low-temperature measurements have been made on benzene by several investigators. Nernst[2] made measurements over the temperature range 20 to 80°K. Huffman, Parks and Daniels[3] made measurements over the temperature range 92 to 300°K. More recently Ahlberg, Blanchard and Lundberg[4] made measurements from 4 to 93°K. These authors used their data, combined with those of Huffman, Parks and Daniels,[3] to calculate the entropy of liquid benzene at 298.1°K. Hence the best experimental value of the entropy of benzene is the resultant of measurements made in different laboratories. It seemed desirable to obtain the value of the entropy from a single set of precise data in order to make a reliable comparison with the entropy calculated from spectroscopic and molecular data.

The Apparatus.—The measurements were made in the apparatus described by Ruehrwein and Huffman.[5] Very briefly, the method is as follows: About 0.6 mole of the material under investigation was contained in a sealed copper calorimeter, which was mounted in the adiabatic calorimetric system. A measured amount of electrical energy was supplied to the calorimeter, and at all times the temperature of the environment was maintained at that of the calorimeter to prevent heat interchange. The initial and final temperatures of the calorimeter were measured by means of a platinum resistance thermometer. The electrical measurements required for determination of the resistance of the thermometer and for electrical energy were made on a "White" double potentiometer in conjunction with a high-sensitivity galvanometer and accurately calibrated resistances. The potential was in terms of a bank of six saturated cadmium cells which had been certified by the National Bureau of Standards. Time measurements were made with an electric stop clock driven by alternating current, the frequency of which was controlled to about 0.001%. The precision of the measurements was in general better than 0.1%, and above 30°K. it is believed that the accuracy uncertainty should not be greater than 0.2%. The energy measurements were made in terms of the NBS international joule and were converted to calories by dividing by 4.1833.

Experimental

The Material.—The benzene used in this investigation was purified at the Laramie station of the Bureau of Mines[6] and supplied to this Laboratory for a check of its purity by a calorimetric melting point determination.

In July, 1944, a melting point study was made on this material but heat capacity measurements were not made at that time, since the laboratory hydrogen liquefier was not yet in operation. The material was left in the sealed calorimeter from July, 1944, until June, 1947, when the measurement of the heat capacity was undertaken. Due to a change in calorimetric technique it was necessary to

transfer the benzene to another calorimeter. The transfer was made by distillation at room temperature in an air-free glass system.

During the heat capacity measurements, a second study of the melting point was made, and the amount of impurity found was approximately three times as great as in the original investigation. This finding suggests that benzene stored in copper is not stable, although it is possible that the benzene may have been contaminated in the transfer process.

[a] These points used to obtain calculated values. [b] These points obtained from freezing expt.

The melting point studies were made in the way described by Todd, Oliver and Huffman.[7] The results of the investigations are summarized in Table I. As discussed in the above reference,[7] a plot of the melting point against the reciprocal of the fraction melted should yield a straight line if Raoult's law is obeyed. The data are plotted in Fig. 1, and it is apparent that the observed points do not follow the theoretical linear relationship. It may be argued that the departure from linearity is due to experimental error. This is quite possible, but it is believed that it is not due to the thermometry, as in general the thermometry is precise to a few ten thousandths of a degree. The fact that the departure from linearity is qualitatively the same in both sets of measurements is a substantial argument in favor of the observations being characteristic of the benzene solution. If the observed curvature is not characteristic of the benzene solution under equilibrium conditions, it is a resultant of the combination of benzene, the calorimetric system, and the method employed. This latter statement is made because, in similar studies of other compounds using the same calorimetric system, a linear relation, within the thermometric error, has been found.

The data have been used in the usual way to obtain the melting point of the pure material by an extrapolation of the straight line, through the points at approximately 90 and 50% melted, to $1/F$ equals zero. The slope of this line times the cryoscopic constant gives the mole fraction of impurity.

It is obvious that, in this case, the above procedure is

(7) S. S. Todd, G. D. Oliver and H. M. Huffman, THIS JOURNAL, **69**, 1519 (1947).

arbitrary, since the data do not show conclusively that Raoult's law is obeyed. These observations will emphasize the conclusion of Todd, Oliver and Huffman[7] that the interpretation of melting point data obtained in the ordinary specific heat calorimeter should be made with caution.

Results

In Table II are given the results of the experimental heat capacities and in Table III are listed the values of the molal heat capacity at integral temperatures as selected from a smooth curve drawn through the experimental data. The smoothed heat capacity data of Ahlberg, Blanchard and Lundberg[4] and of Huffman, Parks and Daniels[3] have also been listed in Table III for comparison.

Two measurements of the heat of fusion were made. The values found were 2357.6 and 2358.6 calories per mole, mean 2358.1 ± 0.5 calories per mole. The uncertainty given is the precision uncertainty; the accuracy uncertainty may be considerably greater than this due to lack of knowledge of the exact amount of premelting, of the exact composition, and of the behavior of the impurity when the material was crystallized.

ing point. Hence it should be noted that the values listed in the tables are for the saturated liquid. The difference between C_p and $C_{satd.}$ may become barely significant at the higher temperatures.

The heat capacity measurements of Ahlberg, Blanchard and Lundberg[4] showed no regular deviation from those of this research but were both lower and higher in the temperature range 15 to 90°K. The differences ranged from −8.7 to +3.2%. They calculated a value of 10.89 cal./degree for the molal entropy at 90° compared with 10.82 cal./degree obtained in this research.

The entropy of gaseous benzene has been calculated by Taylor, Wagman, Williams, Pitzer and Rossini,[8] who used the vibrational assignment of Pitzer and Scott.[9] They calculated $S_{gas\ 298.16°}$ = 64.34 and $S_{gas\ 353.26°}$ = 67.98 cal./degree/mole. A similar calculation using the more recent vibrational assignment of Herzfeld, Ingold and Poole[10] and the same values for the moments of inertia and fundamental constants used by Taylor, *et al.*,[8] gives values of 64.33 and 67.97 cal./degree/mole. The vapor heat-capacity data of Scott, Waddington, Smith and Huffman[11] indicate significant anharmonicity in the vibrations of the benzene molecule. The correction for anharmonicity increases the calculated entropy by 0.02 and 0.04 cal./degree/mole at 298.16° and 353.26°K., respectively. These calculated values are shown in Table V. The agreement between the experimental and calculated values is within the estimated experimental error.

Summary

The heat capacity of benzene has been measured over the temperature range 12 to 341°K. From these and other data the entropy of the liquid and vapor at 298.16 and 353.26°K. were calculated. The experimental values of the entropy were found to be in good agreement with those calculated from spectroscopic and molecular data.

The Entropy of Ethyl Chloride. Heat Capacity from 13 to 287°K. Vapor Pressure. Heats of Fusion and Vaporization

BY JOSEPH GORDON AND W. F. GIAUQUE

This paper presents the results of a low temperature calorimetric investigation on ethyl chloride. Linnett[1] has calculated the entropy of the gas for several assumed atomic distances and the cases of completely free and completely restricted internal angular motion about the carbon–carbon bond. In the absence of more complete molecular data these calculations leave an uncertainty of the order of one or two cal. deg.$^{-1}$ mole^{-1} in the entropy.

Ethyl Chloride.—Ethyl chloride, C_2H_5Cl, was obtained from the Eastman Company in five 100 g. ampoules. The material was purified by the following procedure: Two fractional crystallizations were carried out in a bulb equipped with a side arm. The resulting material was pumped to remove air and then dried by condensing it in a bulb of phosphorus pentoxide. Following this the material was alternately solidified and melted several times and a vacuum of 10^{-6} mm. was pumped on the solid after each such crystallization to insure the removal of air or any other volatile material. The ethyl chloride was then distilled in two lots in a silvered, vacuum-jacketed column about 1.3 cm. i.d., which was packed for a length of 50 cm. with small glass helices. A reflux ratio of the order of 30:1 was used. The rate of removal was controlled by means of a system of capillaries which led to a receiving vessel where the product was obtained as a solid by condensation in liquid air. As usual the glass receiving vessel was protected from the liquid air by means of a metal sheath in case of breakage. The condenser of the fractionating column was cooled by ice. The two middle fractions were combined to give about 100 cc. of the final product.

The small amount of heat due to premelting observed in connection with heat capacity measurements just below the melting point was used to estimate the liquid-soluble solid-insoluble impurity as of the order of 0.02 mole per cent.

Method and Apparatus.—The measurements were made in a calorimeter which has been described previously[2,3,4] and given the laboratory designation Gold Calorimeter II. The most detailed description of this type of calorimeter has been given by Giauque and Egan.[5] An accident to the apparatus necessitated winding a new gold resistance thermometer-heater which was practically the same as had been used previously. A small platinum well was fused to the bottom of the gold calorimeter and filled with Rose's metal to facilitate contact with the junction of the standard thermocouple.

The standard thermocouple which has the laboratory designation W was, as usual, compared with the triple and boiling points of hydrogen and the vapor pressure of liquid oxygen by liquefying these substances in the calorimeter. The comparison served to emphasize the importance of considering a standard thermocouple and the potentiometer used to measure its e. m. f. as a unit to be calibrated together. The potentiometer had been returned to the manufacturer for reconditioning prior to its use in this research. In terms of temperature the comparison using the reconditioned potentiometer indicated that the thermocouple read high by 0.70° at the triple point of hydrogen, 13.95°K., and 0.45° high at the boiling point of hydrogen 20.37°K. Since two other standard thermocouples compared under similar conditions showed almost identical deviations it was clearly evident that the absolute reading of the potentiometer had been altered. At 72°K. the apparent change was 0.04° high and at 78°K., 0.05° high. As nearly as the change could be allocated between thermocouple and potentiometer it appeared that the actual change of the thermocouple was in the direction to read about 0.1° low at liquid hydrogen temperatures if the potentiometer had not been altered. It was of course not necessary to allocate the change in using the thermocouple to determine temperature.

Vapor Pressure of Ethyl Chloride.—The vapor pressure was measured by means of a mercury manometer with an inside diameter of 1.6 cm., and a standard meter bar suspended between the manometer tubes. A Société Génévoise cathetometer with a precision of 0.002 cm. was used as a comparison instrument.

The manometer line was connected to the calorimeter which provided almost ideal temperature control. The data of Cawood and Patterson[6] were used to correct for capillary depression. The data were corrected to international cm. by means of the thermal expansion of mercury as given in the "I.C.T."[7] and the acceleration of gravity[8] which was taken as 979.973 cm. sec.$^{-2}$ for this location. The standard acceleration used was 980.665 cm. sec.$^{-2}$.

The vapor pressure data covering the range 217 to 286°K. are represented by the equation

(1) Linnett, *Trans. Faraday Soc.*, **36**, 527 (1940).

$$\log_{10} P \text{ (int. cm. Hg)} = (-1777.378/T) - 0.0115789T + 1.06734 \times 10^{-5}T^2 + 10.54417$$

The observations are compared with the above equation in Table I. The temperatures are given to thousandths of a degree to permit the calculation of accurate derivatives from the precise remometer data although the absolute temperatures may be in error by as much as 0.05°.

The equation gives the value of the boiling point as 285.37°K.

[a] Premelting.

eter, melted. The data are given in Table II. Each of the temperatures given was obtained by waiting a long period for equilibrium after each addition of heat to alter the fraction melted. The observations extended over a period of 35 hours.

The melting and boiling point observations of other observers are given in Table III for comparison with those found in the present research.

Heat Capacity of Ethyl Chloride.—The heat capacity from 13°K. to the boiling point was measured in the same manner as has been used in many similar researches[3] in this Laboratory.

The value 4.1833 international joules was taken equal to one calorie. The amount of ethyl chloride in the calorimeter was 89.978 g., equivalent to 1.3946 moles, using 64.517 as the molecular weight. Correction was applied for the small amount of heat used in vaporization into the gas space above the liquid in the calorimeter.

Values of the heat capacity read at even values of the temperature from a smooth curve through the observations are given in Table V. It is estimated that the smooth curve represents the heat capacity to within 0.2% above 35°K., within 1% at 20°K. and within 3% at 15°K. due to the low temperature coefficient of the resistance thermometer.

TABLE V

HEAT CAPACITY OF ETHYL CHLORIDE

134.80	23.23 (liquid)		

Heat of Fusion of Ethyl Chloride.—Three determinations of the heat of fusion of ethyl chloride were made in the usual way. Heat input started somewhat below the melting point and ended at a temperature somewhat above. A correction was made for the small amount of premelting which had occurred below the starting temperature. The results are summarized in Table VI.

TABLE VI

HEAT OF FUSION OF ETHYL CHLORIDE

Melting point 134.80°K.; molecular weight 64.517

Temperature interval, °K.	Total heat added cal. mole^{-1}	Pre-melting cal. mole^{-1}	$\int C_p\,dT$ cal. mole^{-1}	ΔH fusion cal. mole^{-1}
130.109–135.698	1181.6	1.5	119.0	1064.1
131.837–138.162	1203.1	2.4	141.0	1064.5
132.242–136.095	1145.1	2.7	84.6	1063.2
			Average	1064 ± 1

Heat of Vaporization of Ethyl Chloride.—The heat of vaporization was measured by vaporizing the material from the calorimeter into a bulb where it was condensed by means of liquid air. The pressure was maintained constant during vaporization at approximately 1 atmosphere by means of a system of capillary tubes, which could be used in various combinations, between the calorimeter line and the condensation bulb. Only the heater on the lower half of the calorimeter was used in these measurements and only liquid in the upper half of the calorimeter was evaporated. This avoided possible superheating of the gas following vaporization.

The temperature of vaporization was obtained by observing the vapor pressure during the heat input. The rate of vaporization used in such measurements in this Laboratory is kept low enough so that vaporization occurs quietly at the surface with no bubble formation Since some superheat occurs toward the bottom of the liquid the final temperature after heating and condensation is ended will be somewhat different than the initial temperature or the vaporization temperature. Accordingly correction was applied for the heat capacity, heat leak and vaporization into the known gas volume, including the volume previously occupied by the liquid. A small correction was applied to correct the values of the heat of vaporization to the exact temperature 285.37°K., the normal boiling point of ethyl chloride.

The experimental observations are given in Table VII. The value calculated from the vapor pressure equation and the assumption that the gas volume may be calculated by assuming a Berthelot gas is in excellent agreement but is given no weight in comparison with the direct observations.

TABLE VII

HEAT OF VAPORIZATION OF ETHYL CHLORIDE

Boiling point, 285.37°K.

Run	Moles evaporated	Time of energy input, minutes	ΔH vaporization cal. mole^{-1}
1	0.15210	40	5894
2	.14240	40	5898
3	.13736	40	5897
4	.13379	40	5891
5	.17709	45	5886
6	.17732	45	5885
			Average 5892 ± 6

Value calculated from vapor pressure equation 5875 cal. mole^{-1}.

The Entropy of Ethyl Chloride.—The calculation of the entropy of ethyl chloride from the calorimetric data is summarized in Table VIII.

TABLE VIII

CALCULATION OF THE ENTROPY OF ETHYL CHLORIDE

	Cal. deg.$^{-1}$, mole^{-1}
0–15°K., Debye extrapolation	0.50
15–134.80°K., graphical	18.725
Fusion, 1064/134.80	7.893
134.80–285.37°K., graphical	17.401
Vaporization, 5892/285.37	20.647
Entropy of actual gas at boiling point	65.17 ± 0.10
Correction for gas imperfection	0.14
Entropy of ideal gas at boiling point	65.31

The correction for gas imperfection given in Table VIII was calculated by assuming that Berthelot's equation of state represented the gas imperfection. For this case the equation $(\partial S/\partial P)_T = -(\partial V/\partial T)_P$ gives

$$S_{\text{ideal}} - S_{\text{actual}} = (27RT_c^3P)/(32T^3P_c)$$
$$= 0.14 \text{ cal. deg.}^{-1} \text{ mole}^{-1}$$

The values $T_c = 460.3$°K. and $P_c = 52$ atm. were taken from the "International Critical Tables."

Entropy Calculations Based on Molecular Data.—Since the potential barrier for internal rotation of ethyl chloride has not been observed spectroscopically the entropy could not be completely calculated from molecular data. However, the data are otherwise sufficiently complete so that the entropy due to internal rotation may be evaluated by difference. "I.C.T." values of natural constants were used in the calculations.

The following distances were adopted as a basis for the calculation C–C, 1.54 Å.; C–H, 1.09 Å.; C–Cl, 1.75 Å. Tetrahedral angles were assumed in the absence of definite information since the error due to this assumption should not have much effect on the entropy calculation. The vibrational assignment given by Linnett[1] was adopted except that we accepted a suggestion of Professor K. S. Pitzer to delete the values 1000 and 1120 cm.$^{-1}$, and add 1319 and 1385 cm.$^{-1}$ although the change has little effect on the vibrational entropy at the boiling point since this is principally due to the lower frequencies. The assignment used is 337, 655, 790, 970, 1050, 1070, 1290, 1319, 1385, 1400, 1450(2), 3000(5).

The principal moments of inertia were calculated to be $I_1 = 30.20 \times 10^{-40}$, $I_2 = 159.7 \times 10^{-40}$ and $I_3 = 178.5 \times 10^{-40}$ g. cm^2., where I_3 is perpendicular to the plane of symmetry. The angle between the C–C direction and the principal axis of I_1 was found to be $45°48' = \theta$. The reduced moment of inertia was calculated from the formula

$$I_{\text{red.}} = I_{CH_3}\left[1 - I_{CH_3}\left(\frac{\cos^2\theta}{I_1} + \frac{\sin^2\theta}{I_2}\right)\right]$$

given as Formula (1a) by Pitzer and Gwinn.[15] $I_{\text{red.}}$ was found to be 4.73×10^{-40} g. sq. cm.$^{-2}$.

The entropy calculation for the gas at the boiling point is summarized in Table IX.

TABLE IX

CALCULATION OF THE ENTROPY OF ETHYL CHLORIDE GAS FROM MOLECULAR DATA AT ITS BOILING POINT, 285.37°K.

	Calories degree^{-1} mole^{-1}
Translation	38.20
Rotation (rigid molecule)	23.58
Vibration	1.98
	63.76
Total entropy, measured	65.31
Entropy due to internal rotation	1.55

The potential barrier may be evaluated from the tables prepared by Pitzer and Gwinn.[15] If the internal rotation were completely free the entropy corresponding to the reduced moment of inertia given above would be 3.46 cal. deg.$^{-1}$ mole^{-1} at 285.37°K. $S_{\text{free}} - S_{\text{restricted}} = 3.46 - 1.55 = 1.91$ cal. deg.$^{-1}$ mole^{-1}. In the present case there are three potential minima per revolution and the potential barrier corresponding to the suppression of internal rotation by 1.91 cal. deg.$^{-1}$ mole^{-1} is found to be 4700 cal. mole^{-1}.

A summary of the entropy calculation for 298.1°K. is given in Table X.

TABLE X

ENTROPY OF ETHYL CHLORIDE GAS AT 298.1°K.

	Calories degree^{-1} mole^{-1}
Translation	38.42
Rotation (rigid molecule)	23.70
Vibration	2.19
Internal rotation	1.60
	65.91

The entropy value 65.91 cal. deg.$^{-1}$ mole^{-1} does not include the effects of isotopes and nuclear spin since these effects should be ignored in ordinary thermodynamic calculations.

We thank Dr. W. M. Jones for assistance with some of the experimental measurements.

Summary

The heat capacity of ethyl chloride has been measured from 13 to 287°K.

The melting and boiling points were found to be 134.80 and 285.37°K., respectively.

The heat of fusion was determined to be 1064 cal. mole^{-1} and the heat of vaporization 5892 cal. mole^{-1}.

The vapor pressure was measured and represented by the equation $\log_{10} P(\text{inter. cm. Hg}) = (-1777.378/T - 0.0115789T + 1.06734 \times 10^{-5}T^2 + 10.54417$ which applies over the range 217 to 286°K.

The entropy of the gas at the boiling point was found to be 65.31 cal. deg.$^{-1}$ mole^{-1} of which 1.55

(15) Pitzer and Gwinn, *J. Chem. Phys.*, **10**, 428 (1942).

cal. deg.$^{-1}$ mole^{-1} was shown to be due to internal rotation, corresponding to a potential barrier of 4700 cal. mole^{-1}.

The entropy at 298.1° K. and 1 atmosphere was found to be 65.91 cal. deg.$^{-1}$ mole^{-1}.

The Chlorophyll-sensitized Photooxidation of Phenylhydrazine by Methyl Red. II. Reactivity of the Several Forms of Methyl Red[1]

BY ROBERT LIVINGSTON AND RUDOLPH PARISER

In a previous study[2] of this reaction a mechanism was suggested which led to the prediction that the quantum yield should increase with increasing concentration of phenylhydrazine. Direct measurements, in the range from 0.01 to 0.20 *M* phenylhydrazine, showed a definite although small decrease in the yield with increasing concentrations. Since it was noticed that the color of methyl red was also affected by this change in concentration, a series of measurements using varying mixtures of phenylhydrazine and phenylhydrazine hydrochloride were made. Both the concentration of a "red" form of the methyl red and the yield of the reaction increased with increasing acidity of the solution, the yield approaching a limiting value of about 0.5. Since methyl red has three colored forms,[3] it was necessary to determine the absorption spectra of each of these forms, before it was possible to analyze the solutions spectrophotometrically. Using this method of analysis, it was found that only the intermediate form of methyl red reacted in the solutions used. Making allowance for the variation of quantum yield with dye concentration, it can be shown that the yield is also a (symbatic) function of the phenylhydrazine concentration. The yield appears to be independent of intensity. A relatively simple reaction mechanism is consistent with these observations.

Part I. Spectrophotometric Analysis of Methyl Red

Experimental Methods and Materials

Materials.—The methanol was purified by treating synthetic methanol with an amount of sodium estimated to be three times as much as was required to react with the water present, refluxing with an excess of methyl phthalate,[4] and then distilling through an efficient packed column. The purification of the methyl red has been described.[2] Alcoholic hydrochloric acid was prepared by bubbling dry hydrogen chloride into methanol. Sodium methylate solutions were prepared by allowing weighed quantities of clean sodium to react completely with methanol. The concentrations of the acid and base solutions were checked by titration with aqueous standard solutions.

The several solutions were made from stock solutions of methyl red and of either sodium methylate or alcoholic hydrochloric acid. All measurements were made with 2×10^{-5} *M* methyl red. As only ordinary precautions were taken to keep the solutions out of contact with laboratory air, it is probable that the sodium methylate solutions contained some carbonate and hydroxide.

Methods.—The photometric measurements were made with a Beckmann spectrophotometer at room temperature (24 to 27°). Measurements were made at 100 Å. intervals in the range from γ 3600 to 6000 Å. Duplicate preparations and measurements were made for each solution studied.

Experimental Results

The solutions studied were made up to contain, in addition to 2×10^{-5} *M* methyl red, the following added substances: (1) 0.40 *M* HCl, (2) 10^{-3} *M* HCl, (3) 10^{-4} *M* HCl, (4) 10^{-5} *M* HCl, (5) 10^{-6} *M* $NaOCH_3$, (6) 10^{-5} *M* $NaOCH_3$, (7) 2×10^{-5} *M* $NaOCH_3$, (8) 5×10^{-5} *M* $NaOCH_3$, and (9) 10^{-3} *M* $NaOCH_3$.

Further increase of the hydrochloric acid concentration above 0.40 *M* did not affect the extinction curve. At the other end of the range, use of concentrated sodium methylate results in a fading of the yellow color. This fading is reversible. It is not complete even in very basic solutions. The extinction coefficients at wave lengths near the maximum decrease about 30% as the concentration of methylate is increased from 10^{-3} to 1 *M*. The absorption spectrum of the dye is practically unchanged in the range from 2×10^{-4} to 5×10^{-3} *M* $NaOCH_3$.

The extinction curves for solutions 1, 3, 6, 7, and 9 are plotted in Fig. 1. The curves corresponding to solutions 4, 5 and 8 have been omitted from the plot to simplify it. They belong to the same family of curves as those plotted. It should be noted that the curves intersect at one of two points, corresponding to either λ 4360 or 4800 Å. One curve, number II, passes through both points of intersection.

It is apparent that the dye can exist in three different colored forms. From the variation of the absorption curves with the acidity of the solutions, it may be safely assumed that curves 9 and 7 correspond, respectively, to the pure forms I and III.[5] It is impossible to calculate exactly the extinc-

(4) We are indebted to Dr. R. Arnold of the Organic Division of this department for suggesting this method.

(5) It is possible that solution 9 contains a trace of the colorless form. However, the practical independence of the curve from the methylate concentrations over a wide range is evidence that the percentage of the dye present in the colorless form is small.

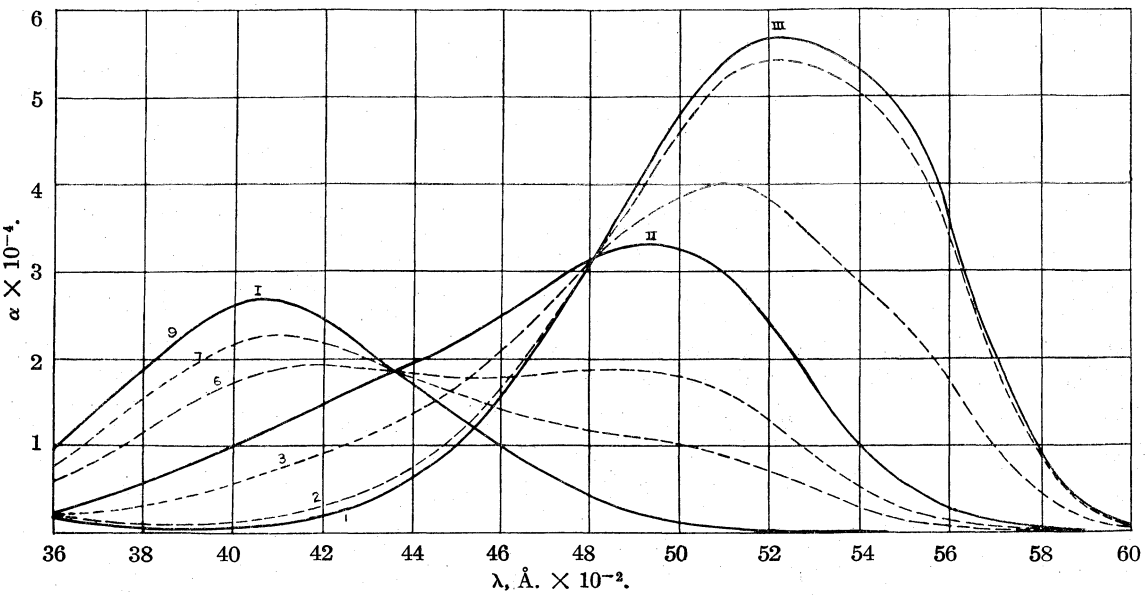

Fig. 1.—Extinction coefficients of methyl red dissolved in methanol containing acid or base.

tion curve of the third form from the curves for the two pure forms and from any number of curves for mixtures.[6] However, a reasonably precise numerical approximation, to the curve of form II, may be readily obtained.[3,6] The curves which pass through the point at 4360 Å. correspond to solutions which are free from form III; and those which cross at 4800 Å. represent solutions free from form I. The analysis of the data was simplified by the fact that one curve (for solution number 4) which is not shown on Fig. 1 passes very close to both points of intersection. Accordingly this solution must contain chiefly form II of the dye. For those solutions whose curves cross at 4360 Å. the observed extinction coefficient β_i equals

$$\beta_{i,\lambda} = \alpha_{1,\lambda}C_1 + \alpha_{2,\lambda}C_2$$

when C_1 and C_2 are the concentrations of form I and II in the ith solution and $\alpha_{1,\lambda}$ and $\alpha_{2,\lambda}$ are the extinction coefficients of the pure form I and II at the wave length λ. Similarly for curves crossing at 4800 Å.

$$\beta_{i,\lambda} = \alpha_{2,\lambda}C_2 + \alpha_{3,\lambda}C_3$$

Approximately the values of $\beta_{4,\lambda}$ are equal to those of $\alpha_{2,\lambda}$. Curve II has been obtained from the values of solution No. 4 by a process of successive approximations, as follows. Minor adjustments were made in these approximate values of $\alpha_{2\lambda}$ until all of the mixture curves (2, 3, 5, 6, 7 and 8) could be fitted in terms of the preceding two equations and a series of values of $\alpha_{1,\lambda}$, $\alpha_{2,\lambda}$ and $\alpha_{3,\lambda}$. It is assumed that these values are close approximations to the true values for the extinction coefficients of the three pure forms of the dye. The three solid curves of Fig. 1 are plots of these values which are listed in Table I.

It is interesting to compare these results with those obtained by Thiel, Dassler and Wülfkin (ref. 3, Fig. 13) for aqueous solutions of methyl

red. The data of Table II[7] suggest that, while two of the colored forms are chemically identical in methanol and in water, the remaining forms differ.

Acidic	5170	5.25	5210	5.71

Part II. Photochemical Measurements

Experimental Methods and Materials

The reagents used were similar to those described by Livingston, Sickle and Uchiyama.[2] The method of purifying methanol is described in the first part of the paper. The apparatus, described by them,[2] was slightly improved mechanically and by the use of a voltage stabilizer with the light source. Cylindrical reaction vessels, 12 mm. in length, were used in all of the present experiments.

Except for the analytical method, the experimental procedure and the routine computations were similar to those previously described.[2] All solutions were analyzed for methyl red concentration, before and after illumination, with the Beckmann spectrophotometer. Two or more wave lengths were used and the measured values were corrected for the (small) absorption due to chlorophyll. Control experiments showed that this method of analysis did not produce any change in the concentration and that it gave results consistent with the analytical method used in the earlier measurements.[2]

The results of a number of determinations of the quantum yield, in terms of the disappearance of methyl red, are presented in Table III. Chlorophyll A at a concentration of 5×10^{-6} M was used in all experiments. The solvent was methanol. The experiments were performed at room temperature, which varied between 25 and 28°. The actinic light was a red band, having a maximum at 6200 Å., cutting off sharply at 6000 Å., and tailing off gradually to about 7300 Å. The special symbols used in the table have the following significance: I, number of quanta absorbed per second in the reaction cell, (Ph), molarity of phenylhydrazine, (PhHCl), molarity of phenylhydrazine hydrochloride, $(D)_0$, initial molarity of the total methyl red, and $(D'')_0$, initial molarity of the intermediate form of methyl red. The quantum yield, $\bar{\varphi}$, is the average value and is defined by the equation

$$\bar{\varphi} = \frac{[(D_0) - (D)_{final}](\text{moles/liter})}{I\ (\text{quanta/sec.})\ [T_0 - T_{final}]\ (\text{sec.})}\ V(l) \times N\ (\text{molecules/mole})$$

The significance of the values tabulated in the last three columns is discussed in a later section of the paper.

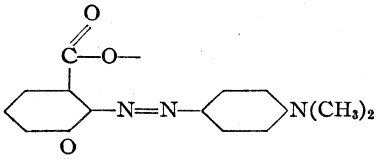
The average value of the quantum yield, $\bar{\varphi}$, corresponding to those solutions in which there was no phenylhydrazine hydrochloride, is 0.14. This is in reasonable agreement with the value of 0.12 obtained by Livingston, Sickle and Uchiyama.[2] The statement by these latter authors, that the yield is independent of the methyl red concentration, was based upon preliminary unpublished experiments and appears to be in error.

Attempts to make quantum yield measurements in more acid solutions were unsatisfactory, due partly to the instability of chlorophyll in acid solutions, and partly to a dark reaction between phenylhydrazine and methyl red, which becomes appreciable as the phenylhydrazine is completely neutralized with hydrogen chloride.[8] A few experiments were performed with solutions which contained 0.10 M phenylhydrazine hydrochloride but no free base. In these solutions, the dye was partly in form II and partly in form III. The quantum yields obtained were lower than in less acid solutions, and suggest that form III (like form I) of methyl red is incapable of undergoing a photosensitized reaction with phenylhydrazine.

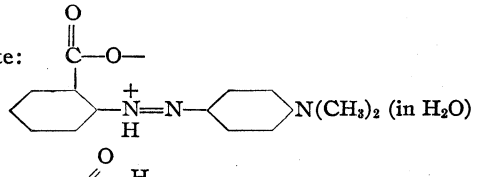
When purified methylaniline is substituted for phenylhydrazine no detectable reaction occurs.

(7) As was pointed out by Thiel in 1924,[3] the probable structures of methyl red in aqueous solutions are as follows.

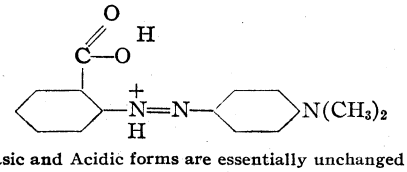
Basic:



Intermediate:

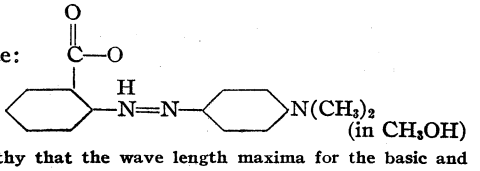


Acidic:



While the Basic and Acidic forms are essentially unchanged in going from aqueous to alcoholic solution, the zwitterion form of the intermediate is probably replaced by an uncharged molecule which is stabilized by an internal hydrogen bond.

Intermediate:



It is noteworthy that the wave length maxima for the basic and intermediate forms are shifted strongly to the violet when the solvent is changed from water to methanol. In both of these cases the principal resonance of the excited states involves a separation of charges. In the acid form where a similar resonance can occur without a separation of charge, the effect of the solvent upon the wave length of the extinction maximum is slight. As a result of these shifts, the maximum of the Acidic form lies between the maxima of the Basic and intermediate forms in aqueous solution, but to the red side of that of the Intermediate form in alcoholic solution.

[a] Contained 10^{-4} M $NaOCH_3$.

Two experiments were performed with solutions containing 5×10^{-6} M chlorophyll A, 2×10^{-5} M methyl red, and 0.050 M methylaniline. If any reduction of methyl red occurred its quantum yield was less than 0.005. In contrast to this result, hydrazobenzene undergoes a reaction comparable to that obtained with phenylhydrazine. Quantum yields of 0.17 and 0.19 were obtained with solutions containing 5×10^{-6} M chlorophyll A, 1×10^{-4} M methyl red, and 0.050 M hydrazobenzene. In these (four) experiments the solvent was methanol, and the light intensity and temperature were comparable to those reported in Table III.

Discussions and Computations

The data presented in Table III are consistent with any of several different mechanisms. The following series of steps has been adopted for purposes of discussion. It is as simple as any and has the further advantage that it is in agreement with the interpretation of the reversible bleaching of chlorophyll which was recently suggested by McBrady and Livingston.[9,10] The special symbols used have the following significance: GH, chlorophyll, HG, long-lived activated chlorophyll, D″, methyl red in form II, and DH_2, reduced methyl red. Making the usual assumption that a

$$GH + h\nu \longrightarrow GH^* \quad (1)$$

$$GH^* \longrightarrow GH + h\nu_f \quad (2)$$

$$GH^* \longrightarrow HG \quad (3)$$

$$HG \longrightarrow GH \quad (4)$$

$$D'' + HG \longrightarrow HGD \quad (5)$$

$$HGD \longrightarrow GH + D'' \quad (6)$$

$$C_6H_5N_2H_3 + HGD \longrightarrow GH + DH + C_6H_5N_2H_2 \quad (7)$$

$$2DH \longrightarrow D'' + DH_2 \quad (8)$$

$$2C_6H_5N_2H_2 \longrightarrow (C_6H_5N_2H_2)_2 \quad (9)$$

steady state exists, an equation for the steady-

(9) J. McBrady and R. Livingston, *J. Phys. Colloid Chem.*, **52**, in press (1948).

(10) Unpublished results on the quenching of fluorescence, obtained recently in this Laboratory by Dr. W. Watson, indicate that the photochemical properties of chlorophyll are modified by methyl red due to the formation of an addition compound. If this postulate is confirmed, the present mechanism can be modified to conform to it.

state can be obtained[11]

$$\varphi_{-D} = \frac{1}{2} \times \frac{k_3}{k_2 + k_3} \times \frac{k_7\,(C_6H_5N_2H)}{k_6 + k_7\,(C_6H_5N_2H_3)} \times \frac{k_5\,(D'')}{k_4 + k_5\,(D'')} \quad (1)$$

For the concentrations used in the present experiments, the factor involving the concentrations of phenylhydrazine as well as the ratio of (D″) to (D) remain sensibly constant during each run, and therefore we write

$$\varphi_{-D} = -\frac{1}{I'} \times \frac{d(D)}{dt} = -\frac{1}{I'} \times \frac{(D)_0}{(D'')_0} \times \frac{d(D'')}{dt} \quad (2)$$

and

$$-\frac{d(D'')}{dt} = \frac{(D'')_0}{(D)_0} I'A \frac{(k_5/k_4)(D'')}{1 + (k_5/k_4)(D'')} \quad (3)$$

where I' is the intensity of the absorbed light expressed in Einsteins per liter per second and

$$A = \frac{k_7(C_6H_5N_2H_3)}{k_6 + k_7(C_6H_5N_2H_3)}$$

The definite integral corresponding to equation (3) is

$$\frac{k_4}{k_5} \ln \frac{(D'')_0}{(D'')} + (D'')_0 - (D'') = \frac{(D'')_0}{(D)} AI't \quad (4)$$

Introducing the experimentally determined average value for the quantum yield

$$\bar{\varphi} = \frac{(D)_0 - (D)}{I't} = \frac{(D)_0}{(D'')_0} \frac{(D'')_0 - (D'')}{I't} \quad (5)$$

we obtain

$$\frac{k_4}{k_5} \frac{\ln (D'')_0 - \ln (D'')}{(D'')_0 - (D'')} + 1 = \frac{A}{\bar{\varphi}}$$

Rearranging and introducing the symbol $(\bar{D}'')$ for the logarithmic mean[12]

$$\frac{(D'')_0 - (D'')}{\ln (D)_0/(D'')}$$

we obtain equation (5) for the mean quantities, which has the same form as equation (1) relating to the instantaneous values.

$$\bar{\varphi} = \frac{1}{2} \times \frac{k_3}{k_2 + k_3} \times \frac{k_7/k_6(C_6H_5N_2H_3)}{1 + k_7/k_6(C_6H_5N_2H_3)} \times \frac{k_5/k_4\,(\bar{D}'')}{1 + k_5/k_4\,(\bar{D}'')} \quad (6)$$

Assuming the validity of this equation, we may compute $\bar{\varphi}'$, the values which $\bar{\varphi}$ would approach at high concentrations of phenylhydrazine.

$$\bar{\varphi}' = \bar{\varphi}\left[1 + \frac{k_6}{k_7} \times \frac{1}{(C_6H_5N_2H_3)}\right] \quad (7)$$

The values of $\bar{\varphi}'$, listed in the eighth column of Table III, were computed in this way, using an empirical value of k_7/k_6 of 1.0×10^2 (liter/mole). In making this correction, the total concentration of phenylhydrazine, rather than the concentration of the free base, was used. While this procedure seems to be in better agreement with the data, they are not sufficiently precise to prove that it is correct.

Figure 2 is a plot of $1/\bar{\varphi}'$ against $1/(\bar{D}'')$. While the points show considerable scatter, they unmistakably conform to the expected linear relation. The values of the constants, corresponding to the line drawn in the figure, are $k_5/k_4 = 5.0 \times 10^4$ (liter/mole) and $\Phi = 1/2 \times k_3/k_2 + k_3) = 0.46$ (molecules/quantum). The latter quantity is the maximum value for the quantum yield and corresponds to a value of $k_3/(k_2 + k_3)$ of 0.92. If the electronically excited chlorophyll, GH*, is incapable of directly sensitizing the reaction (as is assumed in the mechanism), this value is in close agreement with the commonly quoted value of 0.08 for the fluorescence efficiency of chlorophyll in solution.

The values of Φ, listed in the last column of Table III, were computed from the corresponding values of $\bar{\varphi}'$ and of $(\bar{D}'')$ by means of equation (8).

$$\Phi = \varphi'\left[1 + \frac{k_4}{k_5} \frac{1}{(\bar{D}'')}\right] \quad (8)$$

The mean of the tabulated values of Φ is 0.45, with a standard deviation of the mean of 0.06. The several values of Φ show no significant correlation with any of the experimental variables (concentrations or intensity). In other words equation (6) fits the data within the limit of their random variation. It was not found possible to fit to the data any *simple* equation which contained, in place of (D″), the total concentration of the dye, the concentration of its basic form or the concentration of its acidic form. Accordingly, we are forced to the conclusion that only the intermediate form of the dye enters, directly, into the reaction. This result, which was unexpected, is probably related to the relative stabilities of the semiquinones of the several forms of the dye.

The mechanism proposed here is based as much upon the reversible bleaching data (5) as it is upon the kinetics results. Therefore, the values of the rate constants of the individual reaction steps must be consistent with both sets of data. The mean life of the activated state, HG, was determined[13] from the reversible bleaching measurements to be equal to or less than 4×10^{-5} seconds. Combining this with the present value for k_5/k_4, we obtain

$$k_5 \lesssim 10^9 \text{ (liter/moles) per sec.}$$

In terms of the simple collision theory, the value for k_5 corresponds to a collision efficiency of about 1%. In other words, step 5 would require little or no heat of activation, and its rate would be practically independent of temperature.

(11) It is interesting to note that the preceding mechanism and the derived equation for the quantum yield are formally similar to those presented by Ghosh and Sen Gupta.[8] The chief differences are the nature of the activated chlorophyll molecule, the restriction of the reaction to the intermediate form of the dye, and the postulated final products. The latter differences lead to a limiting quantum yield of one-half in the present case and of unity in the earlier paper.

(12) We are indebted to Dr. B. Crawford, Jr., for pointing out that the function $(x_1 - x_2)/\ln x_1/x_2$ is known as the *logarithmic* mean and is commonly used in engineering problems.

(13) R. Livingston, *J. Phys. Chem.*, **45**, 1312 (1941).

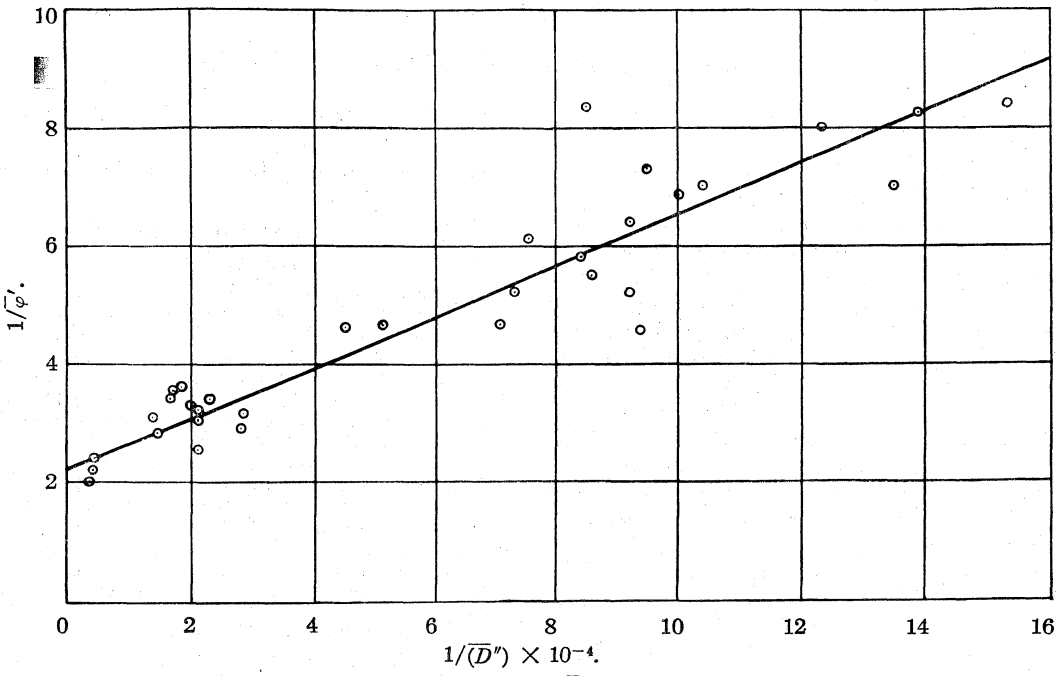

Fig. 2.—The reciprocal of the (corrected) average quantum yield, $\bar{\varphi}'$, plotted as a function of the reciprocal of the logarithmic mean, $\bar{D}''$, of the dye concentration.

The mean life of the complex, HGD, was not determined[9] at all precisely, but is approximately 1 second. If we identify HGD with the bleached form of chlorophyll in solutions containing methyl red and further assume[9] that its disappearance is due to a monomolecular reaction (step 6), we may conclude that $k_6 \simeq 1$ sec.$^{-1}$. The corresponding value of k_7 is apparently 10^2 (liter/mole) per second. Since this is smaller than the maximum value for a second order rate constant, it indicates that step 7 must require a considerable energy of activation. It is to be expected, therefore, that the reaction should exhibit a marked dependency upon temperature when the phenylhydrazine concentration is low, but not when it is high.

The simple form of equation (1) or (2) is a direct consequence of the use of the analytically determined concentration of the intermediate form of methyl red. An equation containing the stoichiometric concentration of methyl red would be of much more complex form. It would contain a function of the concentration of phenylhydrazine hydrochloride as well as of the free base.

The present case is the first chlorophyll-sensitized photoöxidation which has been studied quantitatively over a wide range of experimental conditions. It is, therefore, particularly gratifying that it can be represented by a relatively simple empirical relation. The available facts do not determine a mechanism uniquely, but they do constitute a definite step in that direction and suggest that further measurements of this type may be of real aid to our understanding of the "inner mechanism" of photosynthesis.

Summary

Methyl red can exist in three colored forms in methanol. The relative concentration of these forms depends upon the acidity of the solution. The absorption coefficients for each of these pure forms has been determined in the range λ3600 to 6000 Å.

In the chlorophyll-sensitized photoöxidation of phenylhydrazine, only the intermediate form of methyl red reacts.

The maximum quantum yield for the reaction is about 0.5.

The quantum yield, φ, is an empirical function of the stoichiometric concentration of phenylhydrazine, (Ph), and of the concentration of the intermediate form of methyl red, (D″)

$$\varphi = 0.46 \frac{10^2(\mathrm{Ph})}{1 + 10^2(\mathrm{Ph})} \times \frac{5 \times 10^4(\mathrm{D}'')}{1 + 5 \times 10^4(\mathrm{D}'')}$$

Over a fairly wide range, φ is independent of the light intensity and of the concentration of chlorophyll.

A relatively simple mechanism is proposed which is consistent with the preceding facts and with recently published results[9] on the reversible photobleaching of chlorophyll.

Photochemical Decomposition of *t*-Butyl Nitrite

BY CLARENCE S. COE AND THOMAS F. DOUMANI

The photochemical decomposition of *t*-butyl nitrite has been studied in the vapor phase using a quartz mercury vapor lamp as a source of ultraviolet radiation. Some of the experimental technique and methods of analysis employed in these laboratories for the study of the determination of the primary products from the thermal cracking of hydrocarbons have been applied to this photochemical decomposition. This study involves distinguishing between the initial and the secondary reaction products by determining the composition of the products formed when only small percentages of the compound studied are decomposed at relatively low pressures. The mass spectrometer pattern for the gaseous decomposition products free of undecomposed *t*-butyl nitrite was obtained by subtracting the mass number contributions of the latter compound from the total pattern of the decomposition products. To determine which decomposition products were present, the mass spectrometer patterns for a large number of possible compounds were examined. Chemical tests were made on the residue in the quartz flask after each experiment and, where possible, solid derivatives were prepared for identification.

The initial photochemical decomposition products are acetone and nitrosomethane. During the decomposition this latter compound is constantly removed from the gas phase forming colorless long needles of m. p. 122° in dimeric form on the surface of the quartz reaction flask. Nitrosomethane and its dimer are believed to be new compounds. The initial reaction in the photochemical decomposition of *t*-butyl nitrite appears to be as follows

$$(CH_3)_3CONO \longrightarrow (CH_3)_2CO + CH_3NO$$

Dimerization of nitrosomethane appears to occur rapidly

$$2CH_3NO \longrightarrow (CH_3NO)_2$$

The progress of this decomposition was followed by mass spectrometer analysis and manometrically by determining the total gas pressure in the irradiation quartz flask after various reaction times.

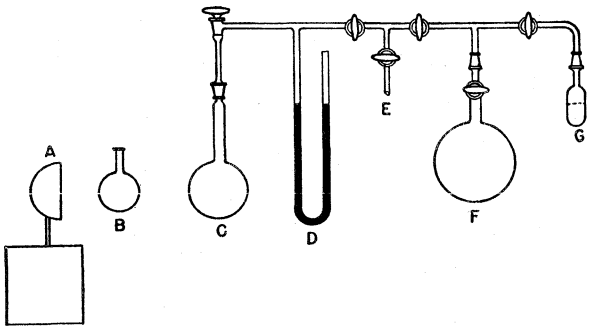

Fig. 1.—Diagram of apparatus.

Experimental

Materials Used

t-Butyl Nitrite.—Technical *t*-butanol was purified by fractional distillation followed by fractional crystallization. Five moles (370.6 grams) of *t*-butanol, m. p. 25.0–25.1°, was mixed with a solution of 5.5 moles (379.5 g.) of sodium nitrite dissolved in 1500 ml. of distilled water. Three moles (667 ml.) of 35% sulfuric acid was added during two hours to the bottom of the previous solution at 0° with stirring. The oil layer which was less dense than the aqueous layer was washed with water, aqueous sodium bicarbonate solution (5%), again with water, and finally dried with anhydrous sodium sulfate. The crude *t*-butyl nitrite (400 g.) was fractionated *in vacuo* in a packed column of about 10 theoretical plates. The composited fractions used in the irradiation studies had a b. p. of 34.0° (250 mm.), $n^{20}D$ 1.3687 and sp. gr. $^{20}_{4}$ 0.867_1.

Acetone.—J. T. Baker analyzed, C. P. was used.

Nitromethane.—The product from Commercial Solvents Corporation was fractionated, b. p. 101–102°, $n^{20}D$ 1.3821.

Nitrogen Dioxide and Nitrous Oxide.—These gases were obtained in cylinders from the Matheson Company in 98% purity.

Nitric Oxide.—The method of Johnson and Giauque[1] was used.

Irradiation

The apparatus (Fig. 1) used for the irradiation experiments was assembled in a dark room which could be maintained at 25 ± 1°. The radiation from a quartz mercury vapor lamp[2] (A) was passed through a quartz flask (B) containing distilled water and then into the quartz flask (C) of 350 ml. capacity filled with vapors of *t*-butyl nitrite. The quartz flask containing distilled water served to filter out infrared wave lengths and helped to focus the ultraviolet beam on the sample. The distance from "Uviarc" to focusing flask was 21.7 cm. and from the center of the latter to the center of the sample flask was 16.1 cm. The quartz flask (C) was connected to a mercury manometer (D) which was used to determine the total pressure therein. To introduce the *t*-butyl nitrite into the flask (C) the entire system was evacuated with a mercury diffusion pump through stopcock (E) in the presence of a few ml. of liquid *t*-butyl nitrite which was surrounded by liquid nitrogen in (G). The nitrite was then allowed to warm until the desired pressure was reached in the system. Gas samples were taken after varying irradiation times directly into evacuated 2-liter glass bulbs (F) which were covered with black tape to eliminate photochemical decomposition due to daylight. All samples were analyzed in a mass spectrometer within eight hours after collection.

In following the pressure change in the system during the photochemical decomposition the mercury manometer was replaced by a more sensitive combination mercury–oil manometer.

To prepare sufficient amounts of dimeric nitrosomethane for a determination of some of its properties the following procedure was found effective. About one milliliter of liquid *t*-butyl nitrite was condensed into the bottom of the

[a] Detailed data for the spectrometer analyses may be obtained from the authors on request.

evacuated quartz flask. The reaction vessel was then irradiated with the "Uviarc," shielding the liquid from direct radiation. The liquid *t*-butyl nitrite served as a reservoir for the production of the gaseous nitrite. The crystals were deposited in much larger quantities in the quartz flask than when the homogeneous nitrite vapors were irradiated.

Results

Data on the photochemical decomposition of *t*-butyl nitrite vapor at various pressures and irradiation times are given in Table I. A plot showing the decrease in the *t*-butyl nitrite and the increase in the acetone percentages with time is given in Fig. 2.

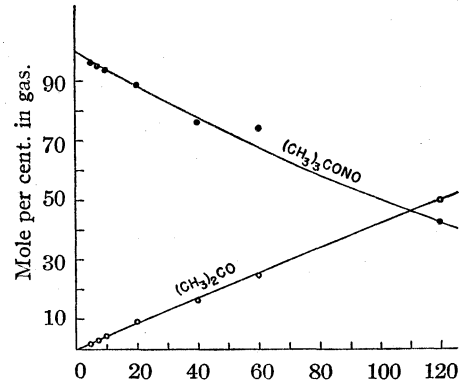

Fig. 2.—Effect of irradiation time.

A pressure–time curve for the photochemical decomposition of *t*-butyl nitrite is shown in Fig. 3. This first irradiation period of about 200 minutes is characterized by the production of predominantly initial decomposition products. Secondary decomposition products are principally formed during the second reaction period from 200 to about 320 minutes. The practically constant pressure state is finally reached after about 400 minutes when compounds substantially stable to the ultraviolet light are present. For this experiment small crystals of nitrosomethane dimer were noticeable with the naked eye after about 120 minutes of irradiation. These crystals grew to well-defined needles until after about 290 minutes they commenced to be transformed to an amorphous deposit of trimeric formaldoxime. Continued irradiation caused a practically complete conversion of the dimeric nitrosomethane to the latter compound after about 420 minutes. A photograph of some crystals of nitrosomethane dimer in the quartz irradiation flask is shown in Fig. 4.

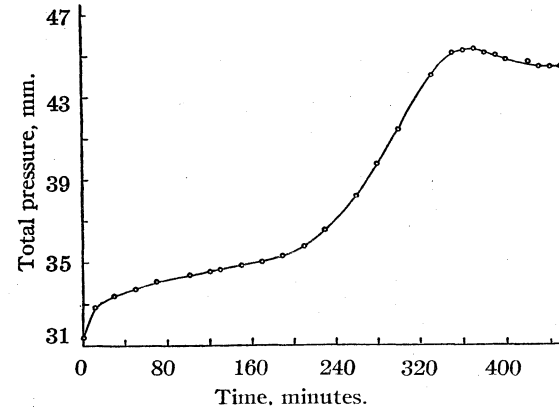

Fig. 3.—Total pressure–time plot.

The irradiated vapors of *t*-butyl nitrite in the quartz flask was shaken with an aqueous solution of 2,4-dinitrophenylhydrazine hydrochloride forming the hydrazone of m. p. 125.6° (cor.). Mixed m. p. with pure acetone 2,4-dinitrophenylhydrazone was the same.

Anal. Calcd. for $C_9H_{10}N_4O_4$; C, 45.38; H, 4.23. Found: C, 45.41; H, 4.50.

Some Properties of Dimeric Nitrosomethane.—Several grams of crystals was collected from a series of the irradiation experiments and crystallized from ethanol as colorless needles, m. p. 122.0–122.2° (cor.). This compound is very soluble in ethanol, moderately soluble in water or acetone, slightly soluble in ethyl ether, benzene or carbon tetrachloride, and insoluble in pentane.

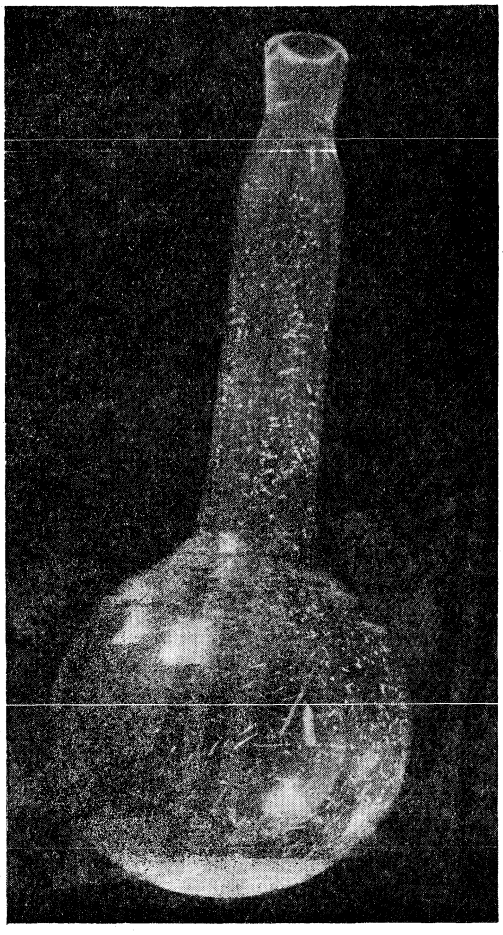

Fig. 4.—Crystals of dimeric nitrosomethane in quartz reaction flask.

Anal.[3] Calcd. for $(CH_3NO)_2$: C, 26.66; H, 6.71; N, 31.10; mol. weight, 90.1. Found: C, 26.94; H, 7.01; N, 31.15; mol. weight, 93.4 (benzophenone as solvent).

The mass spectrometer numbers for this dimer were obtained by admitting vapors from the finely crushed powder at room temperature into the head of the mass spectrometer at low pressure. The mass numbers 90, 75, 60, 45, 30, and 15 were obtained.

When nitrosomethane dimer is heated above its melting point a blue color is noticeable, especially in the vapor. Likewise, when this dimer is heated in organic solvents, such as toluene, a blue color is produced. The colorless solution is restored by cooling. This reversible color change may be represented by the equation

$$(CH_3NO)_2 \rightleftharpoons 2CH_3NO$$

Colorless Blue

Prolonged heating of dimeric nitrosomethane above its melting point converts it to trimeric formaldoxime, insoluble in ethanol

$$3(CH_3NO)_2 \longrightarrow 2(CH_2NOH)_3$$

Nitrosomethane dimer forms a blue color when tested with diphenylamine in concentrated sulfuric acid.

Discussion

Both the experimental data and the proposed mechanism for the photochemical decomposition of *t*-butyl nitrite of Thompson and Dainton[4] are at variance with the results of the present investigation. Their mechanism involving the formation of hyponitrous acid does not explain the formation of nitrosomethane or acetone. None of the products propylene, formaldehyde, ethane or ethylene required by their mechanism could be found in the gaseous decomposition products.

The complete absence of ethane in the decomposition products seems to indicate that the nitrosomethane is probably formed intramolecularly. If the nitrosomethane were formed by the combination of free methyl radicals with nitric oxide the formation of at least some ethane might be expected.

The mass spectrometer pattern for nitrosomethane dimer serves as further evidence for its constitution. Loss of a methyl radical of mass 15 from dimeric nitrosomethane of mass 90 leaves a mass of 75. Removal of a second methyl radical leaves 60, whereas depolymerization of the dimer produces two molecules of monomeric nitrosomethane of molecular weight 45. Removal of a methyl radical from the monomer produces the 30 mass.

Previous workers[5] have postulated the existence of nitrosomethane in explaining the inhibition of some chain reactions by nitric oxide. Isolation of this compound serves to substantiate some of these mechanisms.

The development of alternative methods for the synthesis of nitrosomethane dimer is being considered as well as its isomerization to trimeric formaldoxime. The photochemical decomposition of some other organic nitrites is being checked to determine whether nitroso compounds are involved.

Acknowledgment.—We wish to thank the management of the Union Oil Company of California for permission to publish this paper. We are especially grateful to our analytical department for their generous assistance.

Summary

1. The photochemical decomposition of *t*-butyl nitrite has been studied in the vapor phase at 25° and at pressures of about 50 mm. using a quartz mercury vapor lamp.

(3) Low N values are obtained by the usual micro-Dumas or micro-Kjeldahl methods. Friederich's micro-Kjeldahl method with hydriodic acid was used (Pregl-Grant, "Quantitative Organic Microanalysis," The Blakiston Co., Philadelphia, Pa., 1946, p. 82).

(4) H. W. Thompson and F. S. Dainton, *Trans. Faraday Soc.*, **33**, 1551 (1937).

(5) H. A. Taylor and H. Bender, *J. Chem. Phys.*, **9**, 761 (1941).

2. Acetone and nitrosomethane were found to be initial products of the decomposition. The latter new compound was identified as the hitherto unknown crystalline dimer.

3 Some of the properties of nitrosomethane and its dimer have been determined.

Copolymerization. IV. Effects of Temperature and Solvents on Monomer Reactivity Ratios

BY FREDERICK M. LEWIS, CHEVES WALLING, WILLIAM CUMMINGS,[1] EMORENE R. BRIGGS[2] AND FRANK R. MAYO

Previous papers from this Laboratory and elsewhere[3] have shown that the behavior of monomers in free radical type copolymerizations may be described accurately by the copolymerization equation[3a,4,5]

$$\frac{d[M_1]}{d[M_2]} = \frac{[M_1]\,r_1[M_1] + [M_2]}{[M_2]\,r_2[M_2] + [M_1]} \qquad (1)$$

where $[M_1]$ and $[M_2]$ are concentrations of unreacted monomers, r_1 is the ratio of the rate constants for the reaction of an M_1-type radical with M_1 and M_2, respectively, and r_2 is the ratio for reaction of an M_2-type radical with M_2 and M_1, respectively. The quantities r_1 and r_2 have been designated *monomer reactivity ratios*, and it should be noted[3b] that a comparison of the *reciprocals* of a series of monomer reactivity ratios for a particular radical with a number of monomers yields the *relative reactivities* of the monomers toward that radical. If such series for all radicals were the same, *i. e.*, if, in general, $r_1r_2 = 1$, Equation (1) would reduce to the simpler form earlier proposed by Wall.[6] However, a striking feature of free radical copolymerizations is that, in many pairs, each monomer prefers to react with the opposite type radical. This "alternating effect," which can be discussed qualitatively in terms of r_1r_2 products (r_1r_2 being zero for complete alternation), appears to be an additional effect superimposed upon a fundamental order of monomer reactivity,[3b] and Price[7] has suggested, on the basis of the data available at the time, that it arises from polar interaction between radical and monomer. The present series of nine papers increases five-fold the number of monomer pairs for which monomer reactivity ratios are available. The results give partial support to Price's suggestion and permit a much more detailed discussion of copolymerization phenomena than has hitherto been possible.

The present paper discusses refinements in techniques and in the treatment of data which have been developed in this Laboratory during the past three years and presents measurements of the temperature coefficients of monomer reactivity ratios for five monomer pairs. It also reports more precise measurements of the effects of solvents on the monomer reactivity ratios for styrene and methyl methacrylate.

The next three papers, V–VII, describe new experiments on twenty-nine monomer pairs. In VIII, all of these data are reviewed and the theoretical implications discussed in terms of monomer activity and polarity series. Copolymerization IX presents and discusses experiments on the relative reactivities in copolymerization of *cis* and *trans* isomers. The last three papers, X–XII, are a study of the effect of nuclear substitution on the reactivity of styrene in copolymerization. Here, measurements on thirty-six systems throw further light on the nature of the "alternating effect" in copolymerization.

Experimental

Materials.—Diethyl maleate and diethyl fumarate were Eastman Kodak Co. materials, melting points −12 to −11 and 0 to 1°, respectively. They were used without further purification. Styrene, methyl methacrylate and methyl acrylate were commercial materials, fractionally distilled and stored in the ice-box until used. *p*-Chlorostyrene was prepared by the decarboxylation of *p*-chlorocinnamic acid. Its preparation and physical properties are described elsewhere.[8]

Polymerization Technique.—Polymerizations were carried out in duplicate or triplicate on 1:4 and 4:1 molar ratios of monomers in sealed tubes in absence of air, essentially as described in previous papers in this series.[3a] At 60°, 0.1 mole % benzoyl peroxide was used as catalyst, at 131°, no catalyst except for the styrene–methyl methacrylate system where 0.1% acetone peroxide was added. All polymers were soluble in benzene and were isolated by the frozen benzene technique.[9] Results of all experiments reported here are listed in Tables I and II.

Experimental Errors.—Extensive experience in this laboratory has shown that, although any set of experiments may give a very small intersection in the graphical

[a] Per volume total monomers.

solution of the copolymerization equation, these intersections shift appreciably from set to set. In early work many of these shifts proved to be due to inadequate techniques of polymer isolation. With more refined methods, they now appear to be usually the result of small systematic errors in polymer analysis. The temperature coefficients of monomer reactivity ratios discussed in this paper represent, at best, small differences between experimentally measured quantities. Accordingly, the highest attainable accuracy in determination of monomer reactivity ratios is important. Further, since the desired quantities are *differences*, the presence of a small systematic error (so long as it is the same for the experiments at both temperatures) causes no trouble.

In order to "freeze" this error as nearly as possible, each set of experiments at two temperatures reported here was carried out and worked up by the same operator at the same time and using the same techniques. The relative experimental error at each temperature was then calculated as the standard deviation of duplicate experiments, and the errors in heats and entropies of activation were determined by the usual formulas for propagation of error. In the most fortunate cases, for example, styrene–methyl acrylate, the relative experimental error in monomer reactivity ratios determined in this way is considerably smaller than the probable *absolute* error. However, for the reasons outlined above, we consider it the proper one to use in the subsequent calculations. The styrene–methyl methacrylate system was studied before this procedure was adopted. The experimental error in this case was taken as that arising from a 0.1% error in carbon analysis (see below). An idea of the agreement obtained between experiments and the magnitude of the change in monomer reactivity ratios arising from a 70° change in temperature may be gotten from Fig. 1 in which the graphical solutions of the copolymerization equation for the styrene–methyl acrylate system are illustrated.

In the case of the styrene–diethyl maleate system, the monomer reactivity ratio for the maleate-type radical is indistinguishable from zero. Accordingly, only 4:1 styrene–maleate experiments were carried out at 131°, and the heats and entropies of activation differences for the reaction of the styrene type radical calculated from the shift of the intersection of the high styrene experiments with the zero axis.

It is of course important to have an idea, as well, of the magnitude of the *absolute* experimental error in the measurement of monomer reactivity ratios. Since, with suitable technique in polymer isolation, this error arises chiefly from errors in polymer analysis, we have adopted the following technique for its estimation, based upon the observation that blank carbon analyses run in

our analytical laboratory on known samples deviate from calculated results by over 0.2% less than one time in five. For a given monomer pair two representative experiments, one at 1:4 and the other at 4:1 monomer ratios are chosen and $[M_1]$ and $[M_2]$ recalculated assuming +0.2% and −0.2% errors in analysis. The results are then replotted on a r_1 *vs.* r_2 plot, yielding a parallelogram about the former intersection. This parallelogram is now shifted so that its center coincides with the best value of r_1 and r_2 determined by the whole set of experiments carried out on the given monomer pair, and the absolute experimental error is taken as the range of values of r_1 and r_2 lying within the parallelogram. The best justification for the method, aside from the arguments just outlined, is that with sufficient care sets of experiments can generally be obtained in which all of the lines corresponding to the individual experiments pass through the parallelogram. In the case that they do not, and it does not appear feasible to run additional polymerizations, the standard deviation is taken as the absolute experimental error. However, this difficulty has not arisen with any of the monomer pairs reported here. In the cases where $[M_1]$ and $[M_2]$ are determined by nitrogen or chlorine analysis, calculations are based upon a 0.1% experimental error. In the case of the system styrene–methyl methacrylate, blanks of pure polymeric styrene and methyl methacrylate were analyzed simultaneously with the copolymers and the empirical carbon contents used in calculating copolymer compositions. Although the experiments are those described in the first paper of this series,[3a] this changes the values of the momomer reactivity ratios slightly from the values previously reported.[10] For styrene–diethyl maleate, polymer compositions lay very close to pure polystyrene. Accordingly, a sample of pure polystyrene to which diethyl maleate monomer had been added was worked up together with the copolymers and analyzed. The result (92.24% C) was used in calculations and served as a check both on the isolation procedure and the accuracy of carbon analysis (calcd. 92.26%). In view of the employment of these precautions, the use of 0.1% error in carbon seemed justified in calculating the experimental errors in this system.

Results and Discussion

Measurements at Two Temperatures.—Previous measurements of monomer reactivity ratios in copolymerizations have been limited to a single temperature. Measurement at two temperatures are of obvious practical interest. Further, since a monomer reactivity ratio represents the ratio of two rate constants which may be expressed in the form

$$r_1 = e^{\frac{\Delta S_{11}^{\ddagger} - \Delta S_{12}^{\ddagger}}{R} - \frac{\Delta H_{11}^{\ddagger} - \Delta H_{12}^{\ddagger}}{RT}} \qquad (2)$$

where $\Delta S_{11}^{\ddagger}$, $\Delta H_{11}^{\ddagger}$, $\Delta S_{12}^{\ddagger}$, and $\Delta H_{12}^{\ddagger}$ are, respectively, the entropies and heats of activation for the reaction of M_1 type radical with M_1 and M_2, measurement of r_1 at two temperatures permits the calculation of the differences in the heats and entropies of activation for the two reactions of the radical. These differences, for the monomer pairs of Table I, are listed in Table III. Since $(\Delta S_{11}^{\ddagger} - \Delta S_{12}^{\ddagger})/R = \ln (P_{11}Z_{11}/P_{12}Z_{12})$ in the Arrhenius treatment, and since this ratio perhaps provides a simpler way of visualizing the magnitude of a "steric" effect, it has been calculated as well, and is included in Table III.

(10) Although blanks were run indicating slightly low (0.1–0.3%) carbon analyses, the original calculations were based on theoretical carbon analyses. We have since frequently based calculations on actual instead of theoretical analyses and this procedure is now extended to our earlier work; *cf.* Nozaki, ref. 11.

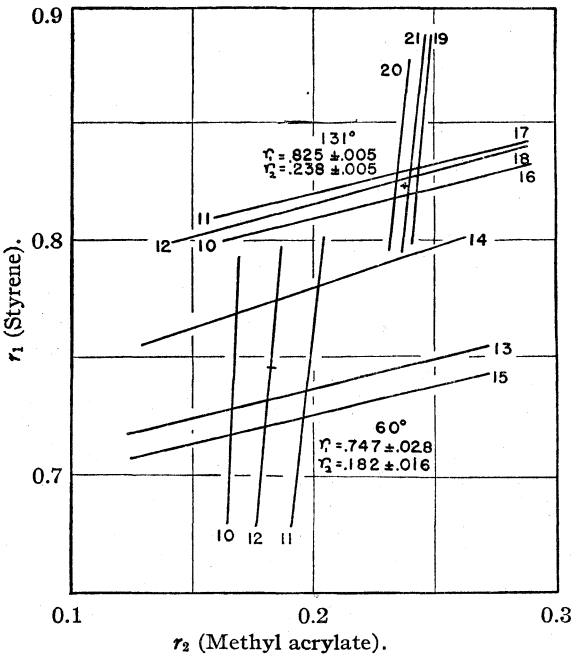

Fig. 1.—Copolymerization of styrene and methyl acrylate at 60° and 131°. Numbers of lines correspond to order of experiments in Table I.

Two conclusions may be safely drawn from the data of Table III. The first is that, despite the care with which the experiments were carried out, the resulting uncertainties in heat and entropy of activation differences are still quite large. The second is that, for most of the pairs, entropy of activation differences do not differ significantly from zero, and the major source of the differences in reactivity of monomers in polymerization lies in heats of activation. Accordingly, the practice of discussing these differences as due to resonance stabilization of complexes, polar interaction, etc., is in general justified. The only case where the entropy difference clearly differs from zero is that of the reaction of the fumarate type radical with styrene and diethyl fumarate. Although the reason for the difference, corresponding to a threefold difference in PZ factors, cannot be stated unequivocally, it lies in the direction which would be expected if the second carboethoxy group of diethyl fumarate offered steric hindrance toward the attack of the radical on the double bond. If this were the case, a similar difference should be anticipated for the styrene radical in the same copolymerization and in the system styrene–diethyl maleate. Although in both cases the entropy difference does lie in the right direction, it is smaller and, in the first, within experimental error of zero.

Another result of these measurements is that in general the temperature coefficients of the monomer reactivity ratios are rather small. This

[a] Each monomer of the pair being considered as M_1 in turn.

is, indeed, a necessary consequence from the observed small differences in entropies of activation, and may be generalized to the statement that the composition of the copolymer obtained from systems in which neither monomer reactivity ratio differs greatly from unity will be quite insensitive to temperature. This conclusion is of some practical importance.

Absolute Values of Monomer Reactivity Ratios.—Using the procedure described in the Experimental Part, absolute experimental errors for monomer reactivity ratios for the monomer pairs studied here have been calculated, and results are summarized in Table IV, together with the results of other workers on the same systems. The agreement between work in this Laboratory and elsewhere will be seen to be quite satisfactory.

TABLE IV

MONOMER REACTIVITY RATIOS AT 60° WITH CALCULATED EXPERIMENTAL ERRORS

[a] Nozaki, *J. Polymer Sci.*, **1**, 455 (1946). Results of two sets of experiments have been averaged. [b] Alfrey, Merz and Mark, *ibid.*, p. 37. The experimental errors have been estimated by plotting their data on a r_1 *vs.* r_2 plot and by taking the axes of the smallest ellipses through which all the lines corresponding to their experiments would pass. [c] Marvel and Schertz, THIS JOURNAL, 65, 2054 (1943), prepared and analyzed samples of this copolymer but monomer compositions were not varied sufficiently for a calculation of monomer reactivity ratios.

Effect of Solvents.—Copolymerizations of styrene with methyl methacrylate in benzene and acetonitrile (solvents of low and high dielectric constant, respectively) and in methanol (a solvent from which the polymer precipitates) are listed in Table II and the graphical solutions illustrated in Fig. 2. Since experiments were carried out using better techniques than in the first paper, intersections are smaller and render more certain the conclusion[3a,11] that solvents have no detectable effect on monomer reactivity ratios. This conclusion is also in agreement with the results of other workers who have found identical monomer reactivity ratios for the systems styrene–methyl methacrylate[12] and styrene–acrylonitrile[3e] studied under homogeneous conditions and in emulsion.

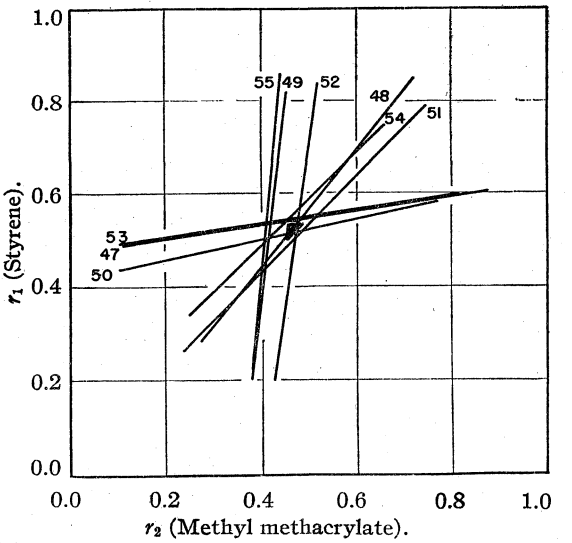

Fig. 2.—Constancy of monomer reactivity ratios for styrene–methyl methacrylate in various solvents at 60°: 47–49, benzene; 50–52 acetonitrile; 53–55, methanol. Numbers of line correspond to order of experiments in Table II. Black triangle represents intersection in absence of solvent.

Acknowledgment.—The inception of work on copolymerization in these laboratories is largely due to the early decision by Dr. Robert T.

(11) Nozaki, *J. Polymer Sci.*, **1**, 455 (1946).
(12) Smith, THIS JOURNAL, **68**, 2069 (1946).

Armstrong that a study of copolymerization would be one of the best approaches to a fundamental understanding of polymerization as a whole, a decision which we feel has been amply justified. We are also indebted to Dr. Oscar W. Lundstedt who was in charge of analytical work while most of the work in this series of papers was in progress. The consistency of analytical results discussed in this paper is largely the result of his efforts. Finally, we wish to acknowledge the considerable contributions of Mrs. Charles J. Pennino and Miss Lucille Librizzi, who have carried out much of the actual experimental work described in this series.

Summary

1. By carrying out copolymerizations at 60 and 131°, heat and entropy of activation differences for the reaction of each radical with the two monomers have been determined for the systems styrene–methyl methacrylate, styrene–methyl acrylate, styrene–diethyl maleate, styrene–diethyl fumarate and styrene–*p*-chlorostyrene.

2. In every case the difference in reactivity of the two monomers is found to be due, primarily, to differences in heat of activation. Only in the reaction of the diethyl fumarate radical with styrene does the difference in entropies of activation clearly differ from zero by more than experimental error.

3. Further data are presented showing that solvents (benzene, acetonitrile or methanol) are without effect on the monomer reactivity ratios of the system styrene–methyl methacrylate.

Copolymerization. V.[1] Some Copolymerizations of Vinyl Acetate

BY FRANK R. MAYO, CHEVES WALLING, FREDERICK M. LEWIS AND W. F. HULSE[2]

This paper presents experiments on the copolymerization of vinyl acetate with eight representative monomers. The double bond of vinyl acetate proves to be one of the least reactive of any common monomers toward free radical attack.

Experimental

Materials.—Vinyl bromide was prepared from ethylene bromide by the action of alcoholic sodium hydroxide. After washing with water and drying with potassium carbonate, the fraction used boiled at 15.5–16.0° at 761 mm. Vinyl chloride, obtained from the Dow Chemical Co., was used without purification. The other monomers were commercial materials fractionally distilled before use and stored in a refrigerator.

Procedure.—With the exceptions noted below, reaction mixtures were prepared as described previously[1] and products were isolated by the frozen benzene technique.[3] In the trichloroethylene experiments (5.00 g. of total monomers and 6.1 mg. of benzoyl peroxide) air was displaced from the reaction tubes by flushing with nitrogen and the polymers obtained by distilling off the monomers and heating the residue for sixteen hours at 90–100° and 2 mm. pressure. The acrylonitrile runs were carried out in the presence of 5 cc. of acetonitrile. The low nitrile runs remained homogeneous. These polymers were precipitated twice from acetone solution with petroleum ether and were then pressed out into thin sheets and dried for twenty hours at 60° and 1 mm. pressure. The high acrylonitrile runs gave a very fine suspension of polymer which at first gave no indications of coagulating or settling. As soon as these indications appeared, heating was stopped. The mixtures were diluted with benzene and petroleum ether; the polymer was collected on a filter as a white powder, washed with the latter solvent and dried for twenty hours at 60° and 1 mm. pressure.

The vinyl halides were measured out approximately by volume; their exact weights were determined by difference from the weights of the total contents of the reaction tubes. Copolymers containing large proportions of vinyl halide were insoluble in the reaction mixture (except when chlorobenzene was used as solvent) and in benzene. The excess vinyl halide was allowed to escape and the polymers were precipitated twice from chloroform (bromide) or a chloroform–acetone mixture (chloride) and petroleum ether. The chloride polymers were broken up and heated for about twenty-four hours at 60° and 1 mm. pressure. Solvent was removed from the bromide polymers by twenty-four hours of evacuation at 0° and 1 mm. pressure. They were finally warmed cautiously for a few minutes in warm water. Longer or stronger heating led to very rapid discoloration.

Analyses for acetic acid[4] were carried out by determining hydrolyzable acetoxy groups as acetic acid. The polymer sample (0.3–0.8 g.) was weighed into a flask, dissolved in 30 ml. of benzene, and treated for forty-eight hours at room temperature with 50 ml. of 0.5 *N* alcoholic sodium hydroxide. Benzene and alcohol were then removed by steam distillation, adjusting heat and steam input to maintain about the same volume of solution. The mixture was next acidified with 15 ml. of phosphoric acid and 500 ml. of steam distillate collected. The steam distillate was gently aerated for twelve minutes to remove carbon dioxide and titrated to phenolphthalein end-point using decinormal sodium hydroxide. A blank correction (~0.3 ml.) was applied and the results calculated as per cent. acetic acid in the original polymer sample.

Data on experiments are summarized in Table I. In the copolymerization with vinyl ethyl ether, the monomer reactivity ratio for the ether was assumed to be zero and the vinyl acetate monomer reactivity ratio calculated from two duplicate experiments.

Discussion

Monomer reactivity ratios obtained from the data of Table I are summarized in Table II. Since data on the eight systems were gathered at scattered times over four years, during which analytical precision has varied, the standard deviation

of separate experiments is taken as the experimental error.[1] The outstanding feature of the results is the low reactivity toward free radicals of vinyl acetate as compared with other monomers: except for vinyl ethyl ether, the vinyl acetate radical prefers to react with the other monomer of the pair. A similar conclusion, based on α-values[5] derived from single experiments, has been reached by Nozaki.[6] Although the unconjugated monomers (unsaturated halides) have the same order of

(5) Wall, THIS JOURNAL, **63**, 1862 (1941).

(6) Nozaki, *J. Polymer Sci.*, **1**, 455 (1946).

reactivity as vinyl acetate, the monomers with conjugated phenyl, ester, or nitrile groups are so much more reactive than vinyl acetate that the monomer reactivity ratios for the vinyl acetate radical are indistinguishable from zero and it is therefore impossible to compare the reactivities of these monomers.

TABLE II

SUMMARY OF MONOMER REACTIVITY RATIOS IN COPOLYMERIZATIONS OF VINYL ACETATE (M_2)

M_1	r_1	r_2
Styrene	55 ± 10	0.01 ± 0.01
Methyl methacrylate	20 ± 3	.015 ± .015
Methyl acrylate	9 ± 2.5	.1 ± .1
Acrylonitrile	4.05 ± .3	.061 ± .013
Vinyl bromide	4.5 ± 1.2	.35 ± .09
Vinyl chloride	1.68 ± .08	.23 ± .02
Vinyl ethyl ether	0	3.0 ± .1
Trichloroethylene	.01 ± .01	0.66 ± .04

Vinyl ethyl ether not only is less reactive than vinyl acetate with both the latter and with styrene, it retards the polymerization of vinyl acetate. Thus a 4:1 ether–acetate feed gives <3% polymer in two-hundred fifty-eight hours. This retardation may be due to the formation of a less reactive α-vinyloxyethyl radical by chain transfer, the α-hydrogen of the ethyl group being easily susceptible to free radical attack, or to as rapid decomposition and inefficient utilization of the catalyst.[7]

Experiments on the vinyl chloride–vinyl acetate system indicate a possible effect of precipitation of the polymer on its composition. The polymers from the high vinyl chloride feeds precipitated as they formed, yielding a highly swollen but fairly stiff gel. Such experiments failed to give reproducible results, although the homogeneous runs gave good checks. The monomer reactivity ratios here obtained are consistent with the observation of Staudinger and Schneiders[8] that fractionation of a 1:1 copolymer gave fractions containing as much as three chlorine atoms per acetate group. The difficulty encountered by Marvel and coworkers[9] in obtaining consistent α-values with these monomers may have been partly due to precipitation of polymer.

The vinyl bromide results are subject to considerable uncertainty because of analytical difficulties. The lowest values of the monomer reactivity ratios are the most probable because otherwise the product of the ratios exceeds unity by an unexpected margin. Even so, the results indicate that, in comparison with a chlorine atom, a bromine atom gives much less tendency to alternate with vinyl acetate, but a considerably higher average activity.

A comparison of the reactivity of several chloroethylenes with vinyl acetate[10] and a discussion of rate phenomena in the styrene–vinyl acetate system[11] will be given in later papers in this series.

Summary

Copolymerizations of eight monomers with vinyl acetate have been examined. The data show that, in comparison with monomers with conjugated substituents, the double bond in vinyl acetate is unreactive.

Copolymerization. VI.[1] The Copolymerization of Chloroethylenes with other Monomers

BY KENNETH W. DOAK

This paper presents a comparison of the reactivities of all the chlorinated ethylenes with each of two or more other radicals. Some data have been taken from other papers in this series; the new data include the systems vinyl chloride and trichloroethylene with styrene, tetrachloroethylene with styrene, vinyl acetate and acrylonitrile, and vinylidene chloride with vinyl acetate and diethyl fumarate. More precise data for the system styrene and vinylidene chloride have been obtained.

The relative reactivities of 1,1- and 1,2-dichloroethylenes with some other monomers have been reported by Nozaki[2] on the basis of single experiments, but strong alternation tendencies[3] involved in some of the systems make the present method more reliable.

The monomers were commercial samples which had been carefully refractionated. Except as indicated, the experimental procedure was similar to that of Mayo and Lewis.[3a] The copolymers of acrylonitrile and tetrachloroethylene and of vinylidene chloride (80 mole % in reaction mixture)

(1) For the preceding paper in the series, see Mayo, Walling, Lewis and Hulse, THIS JOURNAL, **70**, 1523 (1948).

(3) (a) Mayo and Lewis, THIS JOURNAL, **66**, 1594 (1944); (b) Lewis, Mayo and Hulse, *ibid.*, **67**, 1701 (1945); (c) Bartlett and Nozaki, *ibid.*, **68**, 1495 (1946).

with vinyl acetate and diethyl fumarate precipitated from the reaction mixtures as finely divided powders which were washed with ethanol and dried at 65° and 1 mm. All other copolymers were purified by the frozen benzene technique of Lewis and Mayo.[4]

The monomer reactivity ratios were determined graphically from the data in Table I. For the systems containing tetrachloroethylene, it was assumed that the reactivity ratio for the tetrachloroethylene radical is zero, since this monomer did not homopolymerize under the experimental conditions. The other reactivity ratio was considered to be the intersection of the calculated lines with the r_1 axis. Monomer reactivity ratios, together with literature data necessary for the discussion, are given in Table II.

Results and Discussion

Relative reactivities of the chloroethylenes with four radicals were determined from the reciprocals[3,5] of r_1, and are recorded in Table III. The values for vinyl chloride are taken as unity.

The relative reactivities of the chloroethylenes depend upon the reference radical, presumably because of the alternating tendency, although qualitatively the general order, with one possible exception, is the same for different radicals. As shown qualitatively by Nozaki,[2] unsymmetrical substitution of a second chlorine increases the reactivity, since extra resonance forms are possible. These data show the increase to vary from a factor of 3.6 to 10.5 or greater. Symmetrical substitution of the second chlorine decreases the reactivity, presumably because of steric interference with the approaching radical. The difference in the *cis*- and *trans*-dichloroethylenes is discussed by Lewis and Mayo in a later paper in this series.[6] Trichloroethylene, in which the effects are opposed, has a reactivity intermediate between that of the symmetrical and unsymmetrical dichloroethylenes. Tetrachloroethylene offers additional steric hindrance, and is much less reactive than trichloroethylene.

A comparison of the r_1r_2 products[5] in Table II shows that vinyl chloride alternates better than vinylidene chloride with the electron acceptors diethyl fumarate and acrylonitrile but less readily with the electron donors vinyl acetate and styrene. With vinyl acetate, all the dichloroethylenes alternate better than vinyl chloride. All these results are consistent with the idea that dichloroethylenes should be better electron acceptors[7] than vinyl chloride. Trichloroethylene, tetrachloroethylene, and the 1,2-dichloroethylenes, in comparison with vinyl chloride, are about three times as reactive toward the styrene radical as toward the vinyl acetate radical. If this result were wholly due to donor–acceptor effects, it would mean that styrene is a better donor than vinyl acetate, a conclusion which seems to be contradicted by the weight of other evidence.[7c]

Summary

Monomer reactivity ratios have been determined for several new systems of chloroethylenes with other monomers. The data are correlated with other available data to give the following reactivity series: vinylidene chloride > vinyl chloride > trichloroethylene > *trans*-dichloroethylene > *cis*-dichloroethylene and tetrachloroethylene. This series can be accounted for qualitatively by a consideration of steric effects and of the ease of formation of di- and trisubstituted radicals. Differences in alternating tendencies in various systems are consistent with existing theories of alternation.

Copolymerization. VII.[1] Copolymerizations of Some Further Monomer Pairs

BY FREDERICK M. LEWIS, CHEVES WALLING, WILLIAM CUMMINGS,[2] EMORENE R. BRIGGS[3] AND W. J. WENISCH[4]

This paper presents experimental data on the copolymerization of eight monomer pairs needed to supplement our series of relative reactivities of monomers with radicals. The monomer reactivity ratios calculated from these data are summarized in Table I. Since the data were gathered over an interval of four years, the standard deviations of the separate experiments rather than any established analytical error[5] have usually been used to determine the stated experimental errors. Also included in this paper are some less reliable mono-

Correlation and discussion of the results of Table I and II will be given in a subsequent paper in this series.[6]

Experimental

Materials.—**Isobutylene** and **butadiene** were obtained from the Matheson Company and used without purification other than drying. **Methacrylonitrile,** from the Shell Chemical Company, was fractionated just prior to use; $n^{20}D$ 1.4003. **β-Chloroethyl acrylate** was prepared by acid-catalyzed ester interchange from methyl acrylate and ethylene chlorohydrin in the presence of an inhibitor. The crude product was fractionated *in vacuo* under nitrogen; b. p. 94.1–95 at 18.5 mm.; $n^{20}D$ 1.4490. **Methyl vinyl ketone** was obtained from E. I. du Pont de Nemours and Co. as an azeotrope with water containing 85% ketone. Upon saturating with potassium carbonate and distilling through a packed column the pure ketone was collected as a fraction boiling at 80.5–81.0° at one atmosphere. Since it was unstable and polymerized readily, it was stored in the ice-box and used as soon as possible. Other monomers, usually fractionated commercial materials, were those described in previous papers in this series.

Polymerizations.—Except as noted, experiments were carried out and polymers isolated as described in previous papers. Results are tabulated in Table III.

In styrene–butadiene experiments, styrene charges were first weighed accurately into tubes, then butadiene was added in approximate amounts to the chilled tube. The exact weights of butadiene used were then determined from the weights of the charged and sealed, and empty reaction tube.

Since both isobutylene and vinyl chloride are low boiling monomers, a manifold was constructed with stopcocks leading to a vacuum line, to a standard taper joint and to two graduated tubes for measuring the monomers. Tubes containing pure monomer were attached by the standard taper joint and the monomers were degassed and distilled into the respective graduated tubes. By suitable manipulation of the stopcocks the monomers could then be separately distilled *in vacuo* into the reaction tube attached to the ground joint. The graduated tubes were adjusted to approximately −50° for volume readings, the exact temperature noted, and the corresponding density read from graphs. Weights of single monomers measured from this apparatus showed that their densities were a linear function of temperature, varying from 0.949 g./ml. at 0° to 1.018 at −48° for vinyl chloride; and from 0.619 at 0° to 0.664 at −40° for isobutylene.

[a] Millimoles of unreacted monomer; zero subscripts indicate initial quantities.

Isobutylene–vinyl chloride polymers were precipitated from acetone solution with methanol. Nitrile polymers were dissolved in dimethylformamide or acetonitrile, precipitated with petroleum ether or methanol, and dried for several days at 60° *in vacuo*.

Polymer compositions were determined by standard analytical methods except for styrene–butadiene systems. Several attempts to determine the monomer reactivity ratios for this pair by combustion analysis or by separation and analysis of the unreacted monomer mixture were unsatisfactory. The data given in Table I are based on polymer analysis by index of refraction. Since, for emulsion copolymers of styrene and butadiene, other

factors being constant, the index of refraction of the copolymers is a linear function of composition,[7] the same relation has been assumed here for oil-phase copolymers, using for the pure polymers of styrene and butadiene, made under the same conditions as the copolymers, $n^{20}D$ 1.5935 and 1.5160, respectively. The high-styrene polymer was quite hard and an optical surface was generated by pressing the polymer against a hot glass plate and allowing it to cool in contact. Optical contact of the resulting surface with the prism of an Abbe refractometer was made with a saturated aqueous solution of cadmium borotungstate and the refractive index was measured by reflected light. The intermediate-styrene polymer was soft enough to make optical contact with the prism directly under pressure, allowing measurement by reflected light. The low-styrene polymer was soft enough to squeeze between the two prisms of the refractometer for measurement by transmitted light. All readings were reproducible to ±0.0002.

(7) "Analyses by Refractive Index," Lundstedt and Hampton, Akron Copolymer Research Group Meeting, June 12–13, 1944.

Summary

1. Copolymerization data and monomer reactivity ratios at 60° are given for eight new monomer pairs.

2. Monomer reactivity ratios of lower precision are given for six additional pairs.

Copolymerization. VIII. The Relation Between Structure and Reactivity of Monomers in Copolymerization[1]

BY FRANK R. MAYO, FREDERICK M. LEWIS AND CHEVES WALLING

The first papers in this series[2] showed that series of copolymerizations make possible the determination of the relative reactivities of monomers toward certain radicals, and that such relative reactivities are independent of the feed composition, conversion, solvents, regulators, sources of free radicals used and rates of polymerization. On the other hand, such relative reactivities do appear to depend upon the particular attacking radical, and the results indicate a general order of monomer reactivity toward radicals on which is superimposed a tendency of certain monomers to alternate in copolymerization. In some monomer pairs this alternating effect appears to be negligible; relative reactivities of the monomers are the same toward both types of radicals and the monomer reactivity ratio product, r_1r_2, $\cong$ 1. Such systems, of which styrene–butadiene is an example (r_1r_2 = 1.08) have been termed "ideal" by Wall.[3] In other systems the "alternating effect" appears dominant, $r_1r_2 \cong 0$, and the initial copolymer from any feed consists of regularly alternating units of the two monomers (*e. g.*, styrene–maleic anhydride $r_1r_2 \leq 0.001$).[4] In the great majority of copolymerizations, however, both effects appear of importance and monomer reactivity ratios have intermediate values: styrene–methyl methacrylate, r_1r_2 = 0.26; acrylonitrile–methyl methacrylate, r_1r_2 = 0.24.

The purpose of the present paper is to discuss these phenomena in more detail using the extensive experimental data recently presented from this Laboratory,[5] and also making reference to additional material to appear in subsequent papers in this series.[6]

The Alternation Tendency in Copolymerization.—An earlier paper[2b] stated that the alternating effect "seems sometimes to be due to steric effects, at other times to dipole effects or specific interactions (compound formation) between monomers." This section will amplify this statement in the light of the work cited above.[5,6] Price[7] has proposed that substitutents in a radical or monomer may withdraw or supply electrons from the site of reaction, resulting in effective charges on the trivalent or doubly bound carbon atoms. The alternating effect then arises from an attraction between a negative double bond and a positive radical, or *vice versa*. Alfrey and Price[8] have since attempted to place this suggestion on a general and quantitative basis, describing the reactivity of each monomer in terms of two parameters, referring to the "general monomer reactivity" (Q) and "polarity factor" (e). Bartlett and Nozaki[9] have mentioned the possibility that electron transfer from a donor radical to an acceptor monomer, or *vice versa*, in the activated complex may account for alternation tendencies, and we have developed and discussed this concept further in later papers in this series.[10]

TABLE I

PRODUCTS OF MONOMER REACTIVITY RATIOS IN COPOLYMERIZATIONS AT 60°

Vinyl acetate							
	Butadiene						
	1.08	Styrene					
0.3			Allyl acetate				
.39		0.34		Vinyl chloride			
<.3	0.19	.26			Methyl methacrylate		
<.1		.16			0.61	Vinylidene chloride	
		.14					Methyl acrylate
		.10					Methyl vinyl ketone
		.054	<.3			.8	β-Chloroethyl acrylate
		.05			.43		Methacrylonitrile
.25		.02		.07	.24	.34	1.1 Acrylonitrile
.004		.02		.06		.56	Diethyl fumarate

Both of these schemes lead to the prediction that the larger the *difference* in polarity or donor-acceptor properties between two monomers, the greater will be the alternation tendency, a conclusion which is given qualitative support by Table I. In this table, monomers have been arranged approximately in order of their increasing tendency to alternate with styrene, as measured by the decreasing products of monomer reactivity ratios. The monomers are then seen to be arranged approximately in order of the tendency of the substituents to accept electrons from the double bonds (*i. e.*, decrease the rate of substitution in the benzene ring). The acetoxy, vinyl and phenyl groups seem to be the best donors and poorest acceptors, followed by substituted alkyl, chlorine, carbalkoxy, carbonyl and nitrile groups. The effects of substituents are roughly additive. Considering the rather large experimental errors in some of the products, Table I is surprisingly consistent and gives strong support to the qualitative notion: in each horizontal row, the monomer reactivity ratio products tend to increase from a minimum value at the left margin to unity at the right end, and the products in each column tend to decrease from unity at the top to a minimum value at the bottom.

On the other hand, there are enough inconsistencies in Table II to suggest that such a scheme will not work quantitatively. For example, using the Q and e values of Alfrey and Price[8] for styrene, methyl methacrylate and acrylonitrile, Q and e values for methyl vinyl ketone and methacrylonitrile[5d] were each calculated from two independent sets of data. Styrene data give for methyl vinyl ketone, $Q = 0.75$ and $e = 0.51$, while the acrylonitrile data give $Q = 0.59$, $e = 1.00$. For methacrylonitrile, our styrene data give $Q = 0.59$, $e = 0.74$ while our methacrylate data give $Q = 0.95$, $e = 0.914$. Clearly some other factors must be considered. One of these is the existence of specific resonance interactions between certain radicals and monomers, often large, and perhaps involving actual electron transfer.[9,10] Another is the effect of differences in entropies of activation, or steric effects, most striking in the case of copolymerization of a 1- or 1,1-substituted ethylene with a 1,2-substituted derivative (as with styrene–diethyl fumarate[5a]), where alternation results (in half the steps) in more crowding of substituents. Such an effect may account for the abnormally low alternation tendency (large r_1r_2) in the diethyl fumarate-vinylidene chloride system (Table I) and for the high alternation tendency in the vinyl acetate–trichloroethylene system.[5b] In the latter case, polyvinyl acetate and the copolymer may be constructed from Fisher–Hirschfelder models while polytrichloroethylene cannot: an alternation tendency should be expected in general when a radical from a small monomer prefers to react with a more highly substituted monomer which cannot polymerize with itself. Further, comparison of *cis* and *trans* isomers in copolymerizations shows that even configurations of substituents in the activated complex are important in determining reactivity.[6a] While the above examples are all concerned with 1,2-substituted ethylenes, where steric effects were anticipated by Alfrey and Price,[8] there is good evidence of steric hindrance in the polymerization of 1,1-disubstituted ethylenes where these workers neglect steric effects: heats of polymerization of 1,1-substituted ethylenes (methyl methacrylate, 11.6 kcal./mole, isobutylene, 12.8 kcal./mole)[11] are significantly lower than for 1-substituted ethylenes (styrene, 16.1 kcal./mole,[12] acrylic acid, 18.3 kcal./mole[11]).

Average Activities of Monomers in Copolymerization.—The reciprocals of a series of monomer reactivity ratios for a reference radical with a number of monomers are the relative reactivities of the monomers toward the reference radical.[2] Table II summarizes data on monomers which have been tested in enough combinations to be of interest. The first column of figures gives the relative reactivity of monomers toward the vinyl acetate-type radical, taking the relative reactivity of vinyl acetate as one. Similarly, the second column gives the relative reactivity of monomers toward the styrene-type radical, taking the relative reactivity of styrene as one, *etc.* Since

[a] Italic values have been calculated from α-values obtained from single experiments in a preliminary survey carried out largely by Mr. W. F. Hulse. The results have not been reported elsewhere, but, except when starred, are probably accurate within a factor of two. [b] Alfrey and Harrison, THIS JOURNAL, **68**, 299 (1946) (70°). [c,d,e] Calculated from Moffett and Smith, U. S. Patent 2,356,871. Reactions at 80°, 45°, 40°, respectively. [f] Ref. (9), 35°. [g] Doak and Walling, unpublished work.

the reactivities in various columns are related by the ratios of the rate constants for chain growth of the standard monomers, relations between columns must await determinations of these constants.

The radicals at the top of Table II are arranged in order of decreasing electron-donor tendencies, increasing electron-acceptor tendencies, as listed in Table I. Except that 1,2-disubstituted ethylenes have been arbitrarily grouped at the bottom for later discussion, the order of the monomers in the first column is a compromise arranged so that the reactivities decrease in each column. The decrease in each column is sufficiently uniform, within the often considerable experimental error, that the order approximates the average activities of the monomers. The lack of uniformity can be correlated qualitatively with the alternating tendency. For example, the monomers immediately below styrene are more reactive toward the styrene-type radical for this reason. Similarly, the relative reactivities of vinyl chloride and vinyl acetate change as the electron-accepting properties of the attacking radical increase. Quantitative changes in relative reactivities, without change in order, in other addition reactions of double bonds suggest that the order of stability of radicals is tertiary > secondary > primary.[13] Thus, those addition reactions to double bonds are preferred where the new radical formed is the most stabilized by resonance. However, the conjugation and hyperconjugation which stabilize the radicals should also stabilize the double bonds (but to a lesser extent since there will be a greater energy difference between the main and resonating structures), making the double bonds less reactive. Since the conjugated double bonds are actually more reactive, the conjugation must stabilize the activated complex more than the monomer, a conclusion consistent with the expectation that the resonance stabilization in the activated complex should be intermediate between the initial and final states. In other words, direct attachment of a vinyl, phenyl, carbonyl, carboxyl, nitrile or alkyl group to a double bond reduces the activation energy required for formation of the activated complex when any radical approaches. This conclusion is consistent with the proposal to be developed later[10] relating alternation effects to resonance contributions to the activated complex.

It follows from the above conclusions about

(13) Wheland, "The Theory of Resonance," John Wiley and Sons, Inc., New York, N. Y., 1944, p. 238; Mayo and Walling, *Chem. Rev.*, **27**, 373 (1940).

resonance stabilization in monomers and radicals that, in general, the most reactive monomers are converted, in polymerization, to the least reactive radicals and the least reactive monomers yield the most reactive radicals.

Effects of Substituents.—The conclusions of the last two sections on the copolymerization of the 1- and 1,1-substituted ethylenes are summarized in Table III. The "average activity series," based on Table III, shows the effects of substituents on the ease with which an ethylene derivative reacts with an average radical and on stabilizing the radical which will be formed. The electron "donor-acceptor series," based on Table I, is a measure of the abilities of the substituents to serve as donors or acceptors in radical monomer interactions. The effects of a second α-substituent are roughly additive in both series.[14]

TABLE III

THE EFFECTS OF SUBSTITUENTS ON THE COPOLYMERIZATION OF MONOSUBSTITUTED ETHYLENES, R'—CH=CH$_2$

	Decreasing donor ability ↓

[a] As pointed out to us by Dr. T. Alfrey, although butadiene is about four-thirds as reactive as styrene, it contains two vinyl groups, each of which must be two-thirds as reactive as the vinyl group in styrene.

When two monomers lie close together in the donor–acceptor series then the copolymer will be the "ideal" or random type. If the monomers are also close together in the average activity series (example, styrene–butadiene),[5d] the composition of the copolymer will approximate the composition of the feed. The greater the separation of the monomers in the average activity series, the greater will be the tendency of the more reactive monomer to predominate in the copolymer; the less reactive monomer may be practically excluded (example, styrene–vinyl acetate[5b]).

When two monomers are well-separated in the donor-acceptor series, then they will have a marked tendency to alternate in copolymerization. If neither monomer polymerizes easily by itself (*e. g.*, stilbene–maleic anhydride),[6a] or if they lie close together in the average activity series (*e.g.*, styrene–acrylonitrile)[2b] then the products will approximate a 1:1 copolymer as long as the feed permits. These are the conditions under which a system is most likely to form an azeotropic copolymer, the only requirement being that both monomer reactivity ratios be less than unity.[3] On the other hand, if the monomers are well separated in both series, then the more reactive monomer will predominate to an extent such that the alternating effect will be apparent only from the monomer reactivity ratios or their product (example, acrylonitrile–vinyl acetate).[5b]

Copolymerization of 1,2-Disubstituted Ethylenes.—Toward the styrene-type radical, diethyl fumarate is 2.5 times as reactive as methyl acrylate[5a] and fumaronitrile[6a] is twice as reactive as acrylonitrile, but these bifunctional monomers have two equally probable sites of reaction. The fumaric ester is about ten times as reactive as the acrylic ester toward the vinyl acetate-type radical. Toward the radicals which are poorer donors, however, the acrylate seems more reactive than the fumarate. These results show that a 2-carbethoxy group enhances the reactivity of ethyl acrylate toward donor monomers but decreases activity toward acceptor monomers. However, results in the polychlorinated ethylenes[5c] reveal only a retarding effect of 2-substituents.

Rates of Polymerization and Copolymerization.—Comparison of some over-all rates of polymerization of single monomers has yielded the following order of decreasing rates with 0.1 mole % of benzoyl peroxide at 60°: methyl acrylate, acrylonitrile, vinyl acetate, methyl methacrylate, vinyl chloride, vinylidene chloride, styrene, α-methacrylonitrile, allyl chloride, allyl acetate, isobutylene, vinyl ethyl ether.[15] This order has no relation to the order of activity of these monomers in copolymerization, or to conjugation, since over-all rates are determined primarily by the competition between chain growth and chain termination reactions and since they involve the rate of reaction of a different radical with each monomer, not the relative reactivities of monomers toward a common radical. Over-all rates in copolymerization are even more complex, and can be discussed quantitatively only if absolute rate constants are known.[16] Although such a discussion will be presented shortly from this Laboratory, some qualitative generalizations are worth mention here. First, copolymerization of two monomers far apart on the polarity series will frequently lead to much higher rates than are obtained for either monomer alone. This effect is observed in most copolymerizations of maleic anhydride with donor monomers[9] and arises because the rate of the chief growth step for each radical is greatly increased. Second, addition of a small amount of a reactive monomer may markedly inhibit the polymerization of an unreactive monomer close to it in the polarity series, as in the inhibition by styrene of the polymerization of vinyl acetate. A series

(14) An interesting observation is that even rather remote substitution may change monomer reactivity ratios appreciably. Thus values for styrene–methyl acrylate, 0.75 and 0.18,[5a] are changed to 0.54 and 0.10, respectively, for styrene–β-chloroethylacrylate.[5d]

(15) Experiments in this Laboratory by R. Van Meter and D. M. Alderman.

(16) Melville, Noble and Watson, *J. Polymer Sci.*, **2**, 229 (1947).

of experiments[17] showed that the inhibition depended on the catalyst concentration. Below about 0.4 mole % of styrene, one molecule of catalyst per molecule of styrene would permit the formation of a hard polymer in twenty-four hours at 70° while less catalyst (although ample to polymerize vinyl acetate alone) gave little polymer. At higher styrene concentrations, a higher ratio of catalyst to styrene was required unless much longer reaction times and addition of fresh catalyst were allowed. The result was then a mixed polymer. Copolymerization data show that styrene is at least fifty times as reactive as vinyl acetate toward both radicals. Hence with about 0.1% styrene in vinyl acetate, although the vinyl acetate radicals can add rapidly to vinyl acetate, they have a strong preference for styrene and are rapidly converted to styrene-type radicals. While these styrene radicals can add readily enough to styrene, this monomer is present only in very low concentration and the vinyl acetate is unreactive, acting like a rather inert diluent. As a result, relatively little chain growths occurs before two radicals meet and destroy each other, but if enough catalyst is supplied to sweep out the last traces of styrene, then the vinyl acetate can polymerize normally.

(17) Unpublished results by Drs. R. T. Armstrong and D. W. Sherwood, obtained in these laboratories in 1942.

Summary

Survey of the extensive new data from this laboratory is shown to support the conclusion that the reactivities of monomers in copolymerization are determined by an order of average monomer activity on which is superimposed a tendency toward alternation. The average activity of monomers depends largely on conjugation, *i. e.*, on the possibilities of resonance stabilization of the activated complex and resulting radical. The alternation tendency seems to result from several factors which are roughly summarized as the ability of one monomer (or radical) of a pair to donate electrons to the other radical (or monomer) of the pair. Tables show the effects of substituents on both the average activity and electron-donating ability of monomers.

Limited data on symmetrically substituted ethylenes show that the behavior of these monomers is more complicated than that of the 1- and 1,1-substituted monomers.

The qualitative relations between reactivity in copolymerization and over-all polymerization rates are discussed.

Copolymerization. IX. A Comparison of Some *cis* and *trans* Isomers[1,2]

BY FREDERICK M. LEWIS AND FRANK R. MAYO

As a study of the principles governing copolymerization was getting under way in this Laboratory, the paper by Marvel and Schertz[3] called our attention to the fact that dimethyl fumarate had a greater tendency than dimethyl maleate to enter a copolymer with *p*-chlorostyrene. Since any general scheme of copolymerization must account for such differences, we have compared the behavior of six pairs of geometrical isomers with a total of four other monomers. The results support our previous conclusion[1] that the possibilities of resonance stabilization of the activated complex is a critical factor determining the activity of a monomer toward a free radical.

Experimental

Materials.—Stilbene, maleic anhydride and methyl fumarate and maleate esters were Eastman Kodak Co. materials used without purification. The half esters were prepared according to the directions of Shields.[4] Eastman Kodak Co. mixed dichloroethylenes were separated by fractional distillation through a packed column: *trans*, b. p. 48.0 at 752 mm., $n^{20}D$ 1.4454; *cis*, b. p. 60.6 at 772 mm., $n^{20}D$ 1.4486. Wood and Dickinson[5] give: *trans*, b. p. 47.2° at 745 mm.; *cis*, b. p. 59.6 at 745 mm. Isostilbene was prepared by Mr. R. W. Strassburg by the partial hydrogenation of tolane. It distilled at 82.5° at 0.5 mm. and melted at −28 to −26°, although the melt was slightly cloudy up to 0°. This clearing point indicates that the product contains less than 3% *trans*-stilbene.[6]

Fumaronitrile was prepared from fumaramide and phosphorus pentoxide.[7] The nitrile was then partially isomerized to maleonitrile with hydrogen chloride in ether.[8] From 24 g. of crude product were obtained, by fractional distillation and crystallization, 12.6 g. fumaronitrile (m. p. 96–97°), 3.1 g. maleonitrile (m. p. 23–27°) and 2.10 g. chlorosuccinonitriles. These yields are in fair agreement with determinations of equilibrium mixtures. Mommaerts[9] isomerized the *cis* isomer thermally to a 50% *cis-trans* mixture in 1180 hours at 105–110° but apparently did not reach equilibrium. We have heated the *trans* isomer in a sealed, evacuated tube at 140° for seventy

hours with a trace of iodine and apparently obtained an equilibrium mixture containing 76% fumaronitrile as determined from the melting point phase diagram.

Other materials have been described in previous papers.

Procedure.—Except as indicated, experiments were put up and polymers isolated as described previously. When a polymer was of low molecular weight, the solution above the precipitate was concentrated and examined for polymer, which was combined with the main lot when found in appreciable quantities. This procedure permitted distillation of the monomer from a small fraction of the polymer instead of from the whole product.

Results are summarized in Tables I and II.

TABLE I

RATES OF COPOLYMERIZATION OF EQUIMOLECULAR MIXTURES OF MALEIC ANHYDRIDE AND STILBENE AT 60°

Moles of each monomer	Stilbene isomer	Chloroform, cc.	Reaction time, hr.	Yield, wt. %
0.0250	*trans*	7.00	15.3	61.0[a]
.0250	*cis*	7.00	15.3	35.6[b]
.0100	*trans*	2.80	3	21.9[c]
.0100	*cis*	2.80	3	13.3[c]

[a] Stiff polymer cut into thin slices, extracted twice with boiling methyl ethyl ketone, washed with petroleum ether, dried, ground, and heated to 100° at 1 mm. pressure for two to three hours. [b] Soft polymer broken up and soaked in methyl ethyl ketone for three days, washed on filter with petroleum ether and dried as in *a*. [c] Reaction products heated slowly at 3 mm. pressure up to 175°. Residue taken as polymer.

[a] Millimoles of unreacted monomers; zero subscripts indicate initial concentrations. [b] Contained 5.00 cc. chlorobenzene. [c,d,e] Contained 10,[c] 2.5,[d] or 3.75[e] cc. of chloroform, respectively. [f] The % acetic acid was determined by the method described by Mayo, Walling, Lewis and Hulse, THIS JOURNAL, 70, 1523 (1948), corrected empirically from the error in the nearest known sample: copolymers of diethyl fumarate and vinyl acetate, known to contain 10.97, 21.06 and 28.24% acetic acid, analyzed for 11.45, 20.90 and 27.95% acetic acid.

Vinyl acetate runs containing a high proportion of dichloroethylene were not precipitated at all but were heated slowly at 1 mm. pressure to remove monomer, finally for a minute or two at 150–175°. These residues were then analyzed directly.

The high vinyl chloride runs with diethyl maleate gave a precipitate of polymer and chlorobenzene was therefore added to some to keep them homogeneous. In low vinyl chloride runs, monomer reactivity ratios for the maleate radical varied with the isolation procedure although checks were obtained with each procedure: (a) simply distilling off the monomer from the soft liquid polymer at 150–200° and 2 mm. pressure gave 0.10; (b) precipitating the polymer three times, concentrating the liquors at reduced pressure and combining this residue with the polymer gave 0.05; (c) distilling off the bulk of the unreacted diethyl maleate first, then treating as in (b) with repeated washings of precipitated polymer with petroleum ether gave 0.009, the recorded results. The high vinyl chloride runs showed little difference between procedures (b) and (c), the polymers being harder and less readily soluble.

Chloroform was used as a solvent for all the dinitrile runs because fumaronitrile was immiscible with styrene. The polymers precipitated from solution as highly swollen gels; they were precipitated three times from methyl ethyl ketone with methanol and were then swollen in benzene

TABLE III

COMPARISON OF *Cis* AND *Trans* ISOMERS IN COPOLYMERIZATION

Reference monomer (M_1)	r_1	*cis–trans* isomer (M_2)	r_2	More reactive isomer	Less stable isomer	Planar *cis* form hindered

[a] Experimental errors for ethyl esters are based on a possible 0.1 or 0.2% error in carbon analyses.[10] Experimental errors in other instances represent the areas of the intersections obtained in graphical solutions of the copolymerization equation. [b] From rates of polymerization, Table I. [c,d,e] From copolymerizations with vinyl chloride, vinyl acetate, and styrene, respectively. [f] Ratio of reactivities of two isomers toward reference radical.

and subjected to the freezing procedure, or dried in powder form when obtainable.

The copolymers formed from all maleic anhydride–stilbene feeds were 1:1 copolymers within experimental error. The *rates* of copolymerization of the two isomers were therefore compared. Even in chloroform the polymers formed a gel, including all the reaction mixture and becoming stiffer as the reaction progressed. Data are summarized in Table I.

Discussion

Results of comparisons of *cis* and *trans* isomers are summarized in Table III. The experimental errors given were, in general, obtained from the standard deviation of individual experiments.[10] In the cases of some of the maleic and fumaric esters, however, the low volatility of these monomers and their high solubility in the polymer made their complete removal difficult and actual errors may be larger. This is especially likely for the vinyl acetate–maleate and fumarate and styrene–methyl maleate and fumarate systems with which special precautions[10] (see Experimental part, also ref. 10) were not taken.

The addition of a free radical to either a *cis* or *trans* isomer presumably results in the formation of the same free radical with the three attached substituents in the same plane[11] or with a pyramidal configuration which is easily reversible. Accordingly, addition to the isomer which is less stable thermodynamically might be expected to require less activation energy, so that this isomer should be the more reactive. However, the data show that dialkyl fumarates are 6–20 times as reactive as the maleates toward the styrene, vinyl chloride, and vinyl acetate radicals. Our previous conclusion that the possibilities of resonance in the activated complex[1] is a major factor governing the reactivity of double bonds toward free radicals suggests a probable explanation for such results. When a radical adds to these monomers, the activated complex can be stabilized by resonance between forms I–III only if the oxygen of the carbonyl group involved lies in the same plane as the other atoms attached to the doubly-bound carbon atoms.

Consideration of models shows that the two ester groups in maleic esters cannot be coplanar simultaneously and interference between them is such that a coplanar configuration for either is not very probable. On the other hand, in the fumaric esters either or both ester groups may be coplanar. Such an interpretation also suggests a reason for the high reactivity of the double bond of maleic anhydride[1] in which both carbonyl groups are constrained to a coplanar configuration by the five-membered ring. Price[12] has proposed that purely steric effects can account for the observed differences without considering resonance.

Similarly, in *cis*-stilbene, both rings cannot be

III

simultaneously coplanar and the possibilities of activation of the double bond by the phenyl groups are less favorable than in *trans*-stilbene. The rate data show that the *trans* form is 1.5–2 times as reactive as the *cis* form toward the maleic anhydride radical.[13] The half esters of maleic and fumaric esters did not differ significantly. Here the smaller size of the substituent and the possibilities (at least) of hydrogen bonding and ring formation in the *cis* form reduce the difference found between the normal esters.

In the cases of the dichloroethylenes and the dinitriles, no steric inhibition of resonance can be involved. Although the ratio of *cis* to *trans* forms in the equilibrium mixture of the dichloroethylenes is about 3.5, the *trans* form reacts 6–7 times as fast with both the styrene and vinyl acetate radicals. Thus the difference in free energy of activation is greater than the free energy difference in the monomers. The equilibrium *trans*:*cis* ratio in the dinitriles is about 3.0, but there is no difference in reactivity. Here the difference in rate of reaction is less than would be anticipated. These results show that the isomer pairs do not yield the same activated complex (whether or not they are eventually converted to the same radical) and that there is no consistent relation between the free energies of the isolated monomers and their free energies of activation. The results further suggest that the dipole and resonance effects and energy levels which determine the relative stabilities of the pure monomers lead to larger differences in the stabilities of the activated complexes.

Our data show that coplanarity of conjugated groups is an important factor determining the relative reactivities of *cis–trans* isomers in copolymerization. The general principle that the less stable isomer should be more reactive is only a qualitative guide in other cases, showing that other factors must be considered. Factors such as general availability of electrons in the double bonds[14] or dipole moment have not led to useful correlations in these compounds. The present work suggests also that the steric inhibition of resonance should be important in the copolymerization of 1,1-disubstituted ethylenes: vinylidene chloride is considerably more reactive than vinyl chloride and 1,1-dicyanoethylene should be much more reactive than acrylonitrile, but because of interference between the 1-substituents, considerably less difference should be expected between 1,1-diphenylethylene and styrene, or between methylenemalonic esters and acrylic esters.

(13) This comparison of rates assumes that the rate of chain initiation is the same in both monomer mixtures, and that both isomers yield the same free radical, so that the rates of reaction of this radical with maleic anhydride and the rates of chain termination are the same in both experiments.

Summary

The relative reactivities of the *cis* and *trans* forms of six pairs of isomers have been compared with radicals from a total of four monomers. The order of decreasing activity, maleic anhydride, fumaric esters, maleic esters, parallels the decreasing ability of these monomers to assume a planar configuration and thus to stabilize the activated complex by resonance with the carbonyl groups. Similarly, the inability of both phenyl groups in isostilbene to resonate with the double bond accounts for the higher reactivity of stilbene.

Of the 1,2-dichloroethylenes, the less stable *trans* form is more reactive, while maleonitrile and fumaronitrile are equally reactive. Thus, steric inhibition of resonance, when it occurs, seems to determine the relative reactivities of geometrical isomers, and the relative stabilities of the isomers has only a qualitative relation to reactivity in other cases.

Copolymerization. X. The Effect of *meta*- and *para*-Substitution on the Reactivity of the Styrene Double Bond

BY CHEVES WALLING, EMORENE R. BRIGGS,[1a] KATHERINE B. WOLFSTIRN[1b] AND FRANK R. MAYO

Although previous work has established the validity of the copolymerization equation[2] as a description of the free radical copolymerization of a large number of systems,[3] interpretation of the monomer reactivity ratios observed has been neither simple nor unequivocal. Thus, the reactivities of monomers in copolymerization depend both upon a general order of reactivity, apparently independent of the attacking radical and related to the resonance stabilization of the radical resulting from reaction, and a specific tendency of certain monomers to alternate in copolymerization. This "alternating tendency" has proved to be of particular interest, and polar interaction,[4,5] electron donor–acceptor properties[6] and actual compound formation,[4] have been suggested as possible causes. Still further factors appear to be involved in the interpretation of the relative reactivities of *cis-trans* isomers,[7] and in some systems, where monomer reactivity ratios appear to depend upon differences in both heats and entropies of activation[8] the situation is still further complicated.

Since any attempt to identify or evaluate all of these factors in the copolymerization of the usual monomers appeared to us a formidable undertaking, we have looked for a simpler system. We have chosen the *meta* and *para*-substituted styrenes since the effect of *meta* and *para* substitution on the rates and equilibria of (polar) side-chain reactions of benzene appear to be particularly simple and well understood. Thus, Hammett, who has surveyed available data on a wide variety of such side-chain reactions of benzene,[9] has found that, in general, the effect of *meta*- or *para*-substituents can be expressed by the relation $\log K_0/K = \sigma\rho$, where K_0 and K are the rate or equilibrium constants for the reaction of the unsubstituted and substituted compound, σ a parameter having a single value for each substituent and ρ a constant for any particular reaction. The parameters σ and ρ are probably best interpreted as measures, respectively, of the ability of the substituent to withdraw electrons or make them available at the site of reaction and the effect of such electron-availability on the reaction considered.

If a given monomer (M_1) is copolymerized in turn with a series of substituted styrenes (M_2's), the reciprocals of the monomer reactivity ratios for the radical corresponding to that monomer ($1/r_1$'s) are the relative reactivities of the substituted styrenes with that radical. Such series, obtained with several radicals, might permit the assigning of a value to each substituent analogous to Hammett's σ value, but applying now to *radical* reactions rather than to ones proceeding through "polar" intermediates. In particular, it was hoped that such a series might throw light on the nature and magnitude of the "alternating effect" in copolymerization.

Experimental

Materials.—Styrene and methyl methacrylate were commercial materials, distilled before use and stored in the ice-box. *p*-Methoxy, *p*-chloro, *m*-chloro-, *o*-chloro- and *m*-bromostyrene were prepared by the decarboxylation of the corresponding cinnamic acids. Their preparation and properties are described elsewhere,[10] as are the preparation and properties of the samples of *p*-iodo, *p*-nitro and *p*-dimethylaminostyrene.[11] *p*-Bromostyrene was prepared by the aluminum isopropoxide reduction of *p*-bromoacetophenone followed by dehydration over potassium bisulfate essentially as described by Brooks.[12] An over-all yield of 32.8% of product was obtained, b. p. 49.5–50.0° (2.5 mm.), $n^{20}D$ 1.5952 (lit. gives b. p. 83.5–84.5 (11 mm.), $n^{20}D$ 1.5961).[13] By similar procedures were prepared *p*-methylstyrene in over-all yield of 34.7%, b. p. 59.3–59.5° (15.5 mm.), $n^{20}D$ 1.5425 (lit. gives b. p. 65–66 (18 mm.), $n^{25}D$ 1.5402[14]), and *p*-cyanostyrene in over-all yield of 15.2%, b. p. 69–71 (2 mm.), $n^{20}D$ 1.5795 (lit. gives b. p. 102–4 (9 mm.), $n^{20}D$ 1.5781[15]). *m*-Methylstyrene was a sample supplied by Dr. Schoene of the Naugatuck Chemical Co. Refractionated here, it had an index of refraction $n^{20}D$ of 1.5402 (lit. $n^{20}D$ 1.5410[16]).

Copolymerization Technique.—Polymerizations were carried out at 60° in sealed evacuated tubes essentially as described in the first paper in this series,[2b] using 0.05 to 0.10 mole total monomers and 0.1 mole % benzoyl peroxide in each experiment. In general two experiments each at 1:4 and 4:1 molar ratios were carried out on each

(16) Marvel, Overberger, Allen and Saunders, *ibid.*, **68**, 736 (1946). The sample from Dr. Schoene was obtained by the steam distillation of unreacted monomers from a butadiene-*m*-methylstyrene copolymer and is believed to have come originally from the University of Illinois.

monomer pair, as this provides a better check on experimental error than several experiments each with different monomer compositions. Polymers, whenever possible, were worked up by the frozen benzene technique.[17a] *p*-Cyanostyrene copolymers made from high *p*-cyanostyrene feeds and all *p*-nitrostyrene copolymers however, were insoluble in benzene. *p*-Nitrostyrene copolymers from high *p*-nitrostyrene feeds were insoluble in all solvents tried and were freed from monomer as well as possible by repeated swelling in chloroform and shrinking in petroleum ether, followed by drying for a week at 70° *in vacuo*. The other benzene-insoluble polymers were repeatedly dissolved in chloroform and precipitated with petroleum ether, followed by vacuum drying at 70°. Polymer compositions were determined by elementary analysis and the quantities of unreacted monomers then calculated by difference. Experimental data for four typical systems are given in Table I.[17b]

Calculation of Results and Experimental Errors.—Monomer reactivity ratios were determined graphically[2b] for each monomer pair, the results for the four pairs for which data are listed in Table I being illustrated in Fig. 1. Results for all of the systems are tabulated in Tables II, III and IV, together with a number of derived quantities. Experimental errors were calculated as described previously[8] using the assumed analytical errors listed in the tables. In all but four cases all lines corresponding to individual experiments passed through the calculated parallelograms (*cf.* Fig. 1.). In the four showing a larger scatter, the standard deviation of duplicate experiments was taken as the experimental error.[8]

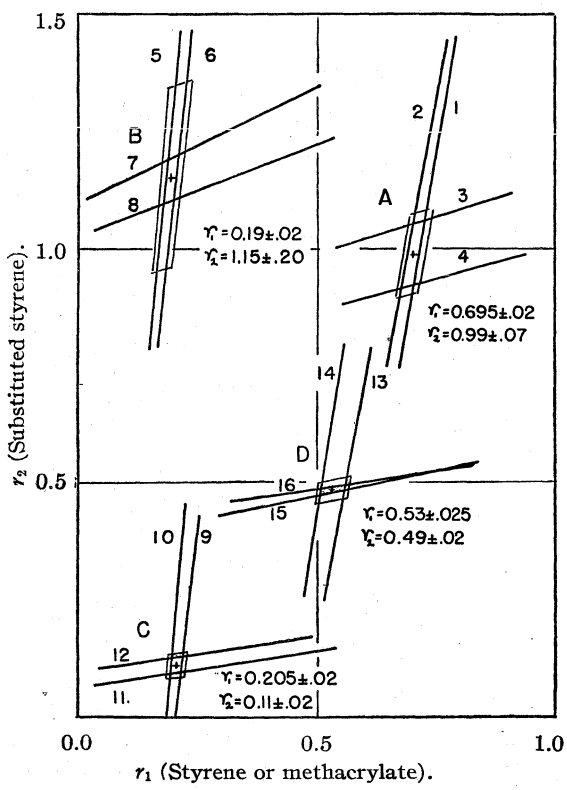

Fig. 1.—Graphical solutions of copolymerization equation for representative systems listed in Table I: A, styrene–*p*-bromostyrene; B, styrene–*p*-nitrostyrene; C, methacrylate–*p*-dimethylaminostyrene; D, methacrylate–*m*-methylstyrene. Numbers of lines correspond to experiments in table.

[a] Millimoles of initial monomers. [b] Millimoles of unreacted monomers.

The median % of the measured values of r_1 for the errors in r_1's listed in Tables II and III is 7%. For r_2's, it is larger, 11.6%, and could probably be improved somewhat by using lower than 4:1 feeds in the high substituted styrene experiments since analyses in these runs usually involved determining small amounts of M_1 in the polymer by difference. The main subject of this paper, however, is concerned with the consideration of r_1 values, and their accuracy appears to lie close to the limits of our experimental techniques.

Experiments on Complexes.—Absorption coefficients for violet light for maleic anhydride-substituted styrene complexes were measured using a Cenco photelometer with a Corning #511 filter. Chloroform solutions giving 30–70% transmission (approximately 3 molar in styrene and 2 molar in maleic anhydride for most of the styrenes) were employed and $\log_{10} I_0/I$ calculated for a solution 1 molar in each component, assuming a highly dissociated 1:1 complex following the law $\log I_0/I = K$ [styrene][maleic anhydride]. The high dissociation and obedience to the above law was established for styrene–maleic anhydride

by Dr. F. M. Lewis in another study in this Laboratory.

Complexes with chloranil were much more stable and showed appreciable color in concentrations ranging from 0.008 *M* chloranil in 0.35 *M* styrene for the styrene–chloranil complex to 0.000003 *M* chloranil in 0.05 *M* *p*-dimethylaminostyrene for the *p*-dimethylaminostyrene complex.

Trinitrobenzene complexes were prepared by dissolving 1,3,5-trinitrobenzene in the styrenes and appeared to show intermediate intensity of color.

Results and Discussion

Relative Reactivities toward Styrene-type Radicals.—Monomer reactivity ratios and some derived quantities for the copolymerizations described in Table I are listed in Table II. In Figure 2 the logarithms of the relative reactivities of the substituted styrenes toward the unsubstituted styrene radical are plotted against Ham-

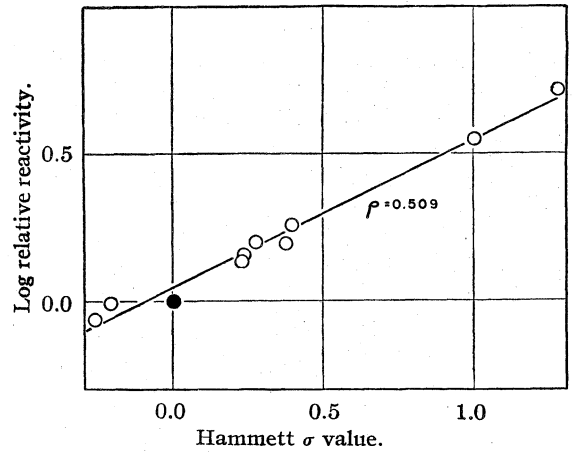

Fig. 2.—Plot of log relative reactivity toward the styrene type radical *vs.* Hammett σ value of substituent for various substituted styrenes.

mett's σ values for the same substituents. Strikingly, excellent correspondence is observed between the relative reactivities and Hammett's σ values. The median deviation of points from the best straight line (drawn by the method of least squares) is only 0.024 log unit, less than the average experimental error, and better than all but six of the 52 polar reactions originally investigated by Hammett.[9] In short, this radical reaction behaves like an ordinary polar reaction with a ρ value (the slope of the line in Fig. 1) of 0.509, approximately the same as that for the ionization of phenylacetic acids.[9,18]

If the Hammett σ values may be interpreted as measures of electron density at the site of reaction (here the substituted styrene double bond) this result suggests that polar interaction between reactants, perhaps of the sort suggested by Price and Alfrey,[5] may be of primary importance in determining reactivity in this series. Further, since ρ is positive and dipole measurements[19] show the styrene double bond to possess an absolute negative charge, the styrene-type *radical* must possess an effective negative charge as well as it approaches the monomer.[20]

If such a polar interaction were here the primary factor in determining relative reactivity, it would be predicted that substituting the styrene radical with negative (electron-attracting) groups should decrease the magnitude and possibly even change the sign of its charge. As a result, the reactions of styrenes with negatively substituted styrene radicals should have decreasing and perhaps even negative ρ values. In Fig. 3 are plotted relative reactivities taken from the more reliable data of Tables II and IV *vs.* σ values for the reactions of some substituted styrene radicals with substituted styrenes. Although the prediction is realized, the ρ values seem to fall into two sharp classes, positive and roughly equal for styrene and positively substituted styrenes, and close to zero for those with negative substituents.

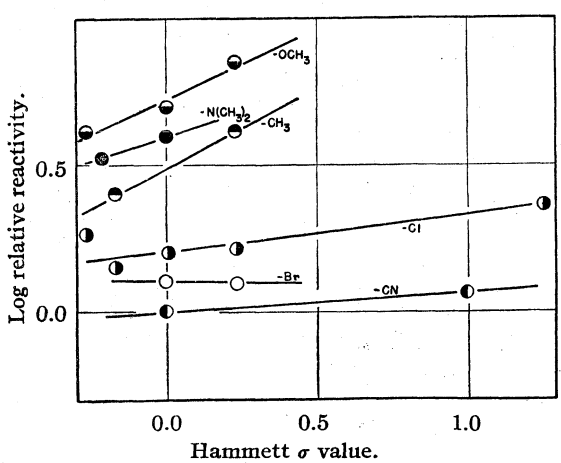

Fig. 3.—Plot of log relative reactivities toward indicated *para*-substituted styrene radicals *vs.* Hammett σ values for various substituted styrenes. Height of ordinate scale is arbitrary.

The interpretation given above fails to take into account any contribution from the differing resonance stabilizations of the resulting substituted styrene radicals to the reactivities of the substituted styrenes.[3,4,5,21] On the other hand, if the results illustrated in Fig. 3 are to be ascribed entirely to such differential stabilization, the close agreement with the Hammett series must be partly coincidental, and the decreased reactivities of the *p*-methoxy- and *p*-dimethylaminostyrenes (for which plausible additional resonance forms can be drawn) are surprising. Furthermore, there then seems to be no simple way of accounting for the observed reactivities toward substituted styrene radicals (*cf.* Fig. 3).

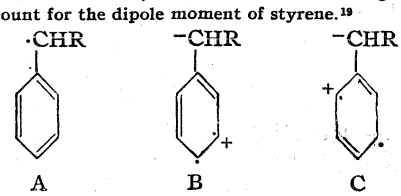
That resonance stabilization of the resulting radicals may, however, play some role in the observed reactivities is suggested by a closer inspection of Fig. 2, where it will be noted that the (black) point corresponding to styrene lies appreciably below the best square line. Since all other points were determined by comparison with styrene, purely random scatter would be expected to put the styrene point on the line. On the other hand, such a result may be due to increased reactivity of all the substituted styrenes due to additional resonance stabilization of their resulting radicals above that arising from polar interaction. It is likely that both factors are involved to some degree, but a determination of their relative magnitudes is not as yet possible.

Relative Reactivities toward the Methyl Methacrylate Radical.—Monomer reactivity ratios for the reaction of methyl methacrylate with eleven substituted styrenes are listed in Table III, and, in Fig. 4, logarithms of relative reactivities are plotted against the Hammett σ values for the substituents. It can be immediately seen that, unlike the case for reaction with the styrene radical, no simple linear relation is evident and no generally applicable value of ρ can be selected. In short, in the case of this radical, derived from the class of carbonyl-conjugated monomers which tend to alternate in copolymerization with sty-

(18) Kindler, *Ann.*, **452**, 90 (1927).

(19) Styrene has a dipole moment of 0.37 debye unit, opposite in direction to toluene, Otto and Wenzke, THIS JOURNAL, **57**, 294 (1935).

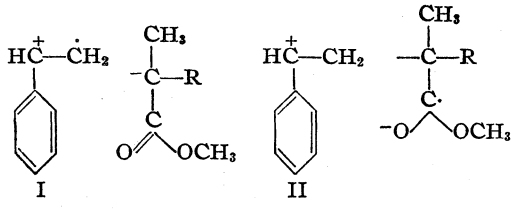
(20) Since both reactants would possess like charges, this could hardly represent an induced polarization, but must correspond to either a general inductive effect of the ring or contributions from structures such as B and C, similar to those which might be called upon to account for the dipole moment of styrene.[19]



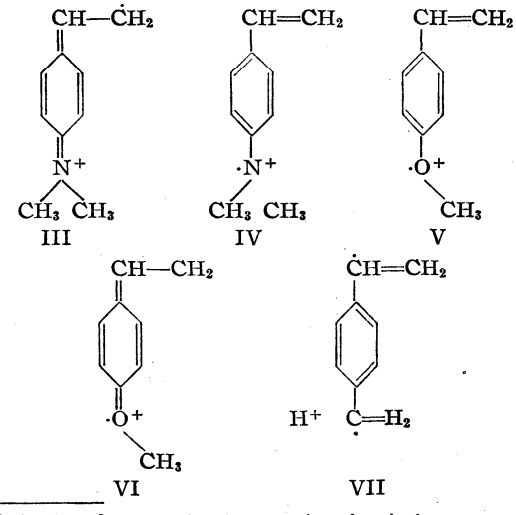
(21) Wheland, "The Theory of Resonance," John Wiley and Sons, Inc., New York, N. Y., 1944, Chap. 8.

rene,[2b,3] some additional factor besides those considered in the preceding section must be at work determining the effect of substituents on reactivity.

Other cases of deviation from the usual Hammett series can sometimes be accounted for by special resonance forms available to one of the reactants in the transition state.[22] Here, since the respective electron accepting and donating properties of carbonyl-conjugated and aromatic systems are well recognized, it seems reasonable to consider the possible contributions of non-bonded and bonded structures such as I and II.[23] Since transfer of an electron to give the non-bonded structure I transforms the methacrylate radical to the relatively stable enolate ion, while the styrene radical carbonium ion may resonate through some twenty-six more or less equivalent forms, structure I appears to have considerable plausibility. Similarly, the energy difference gained in forming a C–C bond while opening a carbonyl group and by the shifting of a negative charge to oxygen suggests that contributions from II might also be important. Inspection of Fig. 4, however, indicates that the chief problem in this discussion lies in accounting for the high reactivities of *p*-dimethylamino-, *p*-methoxy- and, to a lesser degree, *p*-methylstyrene. By this interpretation, there should be available to them additional forms not possessed by the styrene radical carbonium ion. A number of such structures can be drawn, of which III–VII are examples.



I II



III IV V VI VII

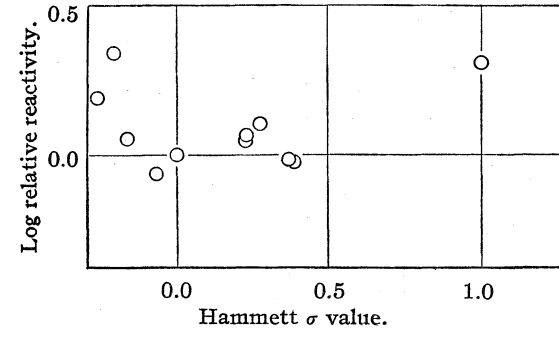


Fig. 4.—Plot of log relative reactivity toward the methyl methacrylate type radical *vs.* Hammett σ value of substituent for various substituted styrenes.

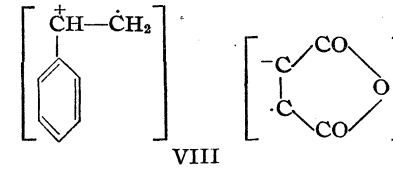
An interesting property of unsaturated carbonyl compounds and similar materials (maleic anhydride, quinones, polynitrobenzenes, etc.) is that they form colored molecular complexes with styrenes and other aromatic compounds. A suggested structure of these materials is one consisting of pairs of radical ions in which the aromatic compound has donated an electron to the conjugated carbonyl system,[24] for styrene–maleic anhydride, the hybrid resulting from the resonance between various forms of VIII.



VIII

Inspection of VIII shows the styrene portion to be identical with I. It is thus evident that, if the unbonded resonance forms are important, a relation should exist between the complex forming tendency of substituted styrenes and their tendency to copolymerize with acceptor radicals.[25] Some observations on such complexes are listed in Table V in which the nature of light absorption of complexes of substituted styrenes with maleic anhydride, 1,3,5-trinitrobenzene, and chloranil is compared with their reactivity toward the methacrylate radical. Maleic anhydride yields rather unstable complexes, highly dissociated in solution and, since all are yellow in dilute solution, their relative absorption of violet light has been com-

(22) Thus, for example, the necessity of assigning two σ values to the *p*-nitro group, one for the reactions of amines and phenols, in all probability arises from the heightened resonance possibilities between nitro and —OH or —NH_2 groups. Physical evidence of such interaction has long been available from dipole moments, increased color, etc.

(23) The possibility of the importance of special resonance structures in the transition state as a means of interpreting alternation in coplymerization was first made to us by Prof. Saul Winstein of the University of California at Los Angeles, and we are indebted to him for several discussions which have been most helpful in formulating the viewpoint expressed here.

(24) Weiss, *J. Chem. Soc.*, 245 (1942).

(25) A relation between the complex forming and copolymerizing tendencies of maleic anhydride has been suggested by Bartlett and Nozaki, ref. 6. Also Woodward, THIS JOURNAL, **64**, 3058 (1942), has postulated the existence of structures similar to VIII in the transition state of the Diels–Alder reaction.

pared. Chloranil complexes are more stable (preliminary measurements indicate dissociation constants of 1–5 and heats of dissociation of 0 to −1500 cal./mole) and have absorption maxima in the visible spectrum, while trinitrobenzene complexes have intermediate properties. Examination of the data of Table V shows a very reasonable correlation between increasing depth of color (shade or intensity) and reactivity, and lends strong support, in general, to the idea of a relation between the complex forming tendency of styrenes and their ease of copolymerization with radicals conjugated with a carbonyl system, and in particular, to the idea of the importance of special forms in the transition state of such copolymerizations.

TABLE V

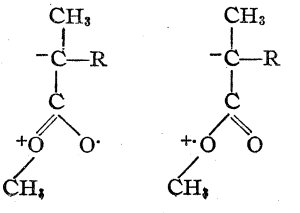
Even though special resonance forms are of primary importance in determining the reactivities of styrenes toward the methacrylate radical, some contribution might still be expected from the resonance structures of the resulting radical and (unless the methacrylate radical is just electrically neutral) polar interactions. Some evidence for such contribution is gained from Fig. 4, for, if the points for *p*-methyl-, *p*-dimethylamino-, and *p*-methoxystyrenes (the monomers showing the highest complex-forming tendencies) are omitted, a line can be drawn through the remaining points corresponding to a ρ value of 0.33 with the reasonable median deviation of 0.04 log unit. Differences in reactivities of these styrenes may thus be due to the same factors as govern reactivity toward the styrene radical.[26] Consideration of these factors also aids in interpreting the r_2 values in Table III. Thus, negatively substituted styrene radicals show little preference in reaction with their own monomers or methacrylate, paralleling their behavior toward styrene. On the other hand, the styrene radicals with electron-supplying groups show heightened reactivity toward methacrylate, as might be anticipated since structures analogous to I–VII can be drawn in which an electron has been donated from the styrene radical to the methacrylate double bond.

The necessity of considering special resonance forms related to those involved in molecular complex formation in interpreting the copolymerization of styrenes with even such a weakly alternating monomer as methyl methacrylate (r_1r_2 = 0.24) makes it appear likely that they, rather than some sort of simple electrostatic interaction, are primarily responsible for the "alternating effect" in copolymerization. Accordingly, it seems doubtful to us that the equation of Alfrey and Price[5b] has any real theoretical justification.[27] The determination of the relative reactivities of styrenes with a more strongly electron accepting radical is described in Paper XII of this series, and will be the subject of future communications.

(26) The same difficulties arise, however, in assessing the importance of differences in the resonance stabilization of the resulting radical. If such differences are minor, incidentally, and the effects primarily polar, we are led to the conclusion that the methacrylate radical possesses a partial negative charge. Since the ester group would usually be expected to attract rather than donate electrons, this conclusion is surprising and suggests the possibility of resonance forms such as



Summary

1. Copolymerizations of methyl methacrylate and styrene with eleven *meta* and *para* substituted styrenes have been carried out and the monomer reactivity ratios calculated.

2. The relative reactivities of the substituted styrene radical closely follow the order found by Hammett for "polar" side-chain reactions of benzene, with a ρ value of 0.509. Negatively substituted styrene radicals show lower ρ values. These results are interpreted as being due to the effect of substituents on the polar interaction between the styrene and the radical as they approach the transition state and on the resonance stabilization of the resulting radicals.

3. Relative reactivities of substituted styrenes toward the methyl methacrylate type radical fail to follow a Hammett series. These results are interpreted as being due to the effect of contributions of non-bonded resonance forms to the transition state in which the radical has accepted an electron, superimposed upon factors similar to those involved in reaction with the styrene radical.

4. Molecular complexes between substituted styrenes and maleic anhydride, trinitrobenzene and chloranil have been investigated and a relation between complex forming tendency and abnormal reactivity toward the methacrylate radical noted and interpreted on the basis of the importance of non-bonded resonance structures.

PASSAIC, NEW JERSEY RECEIVED JULY 22, 1947

(27) Attempts to calculate *Q*'s and *e*'s by Alfrey and Price's equation for the systems reported here have not given very satisfactory agreement with experiment and have fallen down particularly in the cases where strong alternation occurs.

Copolymerization. XI. Copolymerizations Involving α-Vinylpyridine, α-Vinylthiophene, o-Chlorostyrene and α-Methylstyrene

BY CHEVES WALLING, EMORENE R. BRIGGS[1a] AND KATHERINE B. WOLFSTIRN[1b]

In the preceding paper of this series,[2] the copolymerization of styrene and methyl methacrylate with a series of *meta* and *para*-substituted styrenes was reported. At the same time it appeared of interest to investigate the copolymerization of these same two monomers with some other vinyl aromatics which were available.

This paper describes the copolymerization of styrene with α-vinylpyridine, α-vinylthiophene, and *o*-chlorostyrene and of methyl methacrylate with α-vinylpyridine, *o*-chlorostyrene, and α-methylstyrene. The series is not complete since it did not appear possible to analyze a styrene–α-methylstyrene copolymer accurately, and insufficient α-vinylthiophene was available for further experiments.

Due to space limitations, the ultimate experimental data on the systems have been omitted, but are available from the American Documentation Institute.[3] An idea of the accuracy of the work can, however, be gained from the graphical solutions of the copolymerization equation[4] illustrated in Figs. 1 and 2. Experimental errors (represented by the parallelograms around each intersection in the Figs.) have been calculated assuming analytical errors of 0.2% C, 0.1% N and 0.1% Cl as described previously.[5] Since all the lines corresponding to individual experiments pass through the parallelograms, the precision of the experiments may be seen to be appreciably greater than their assumed accuracy.

In Table I the relative reactivities towards the styrene and methyl methacrylate type radicals of the monomers are listed compared with styrene,[6]

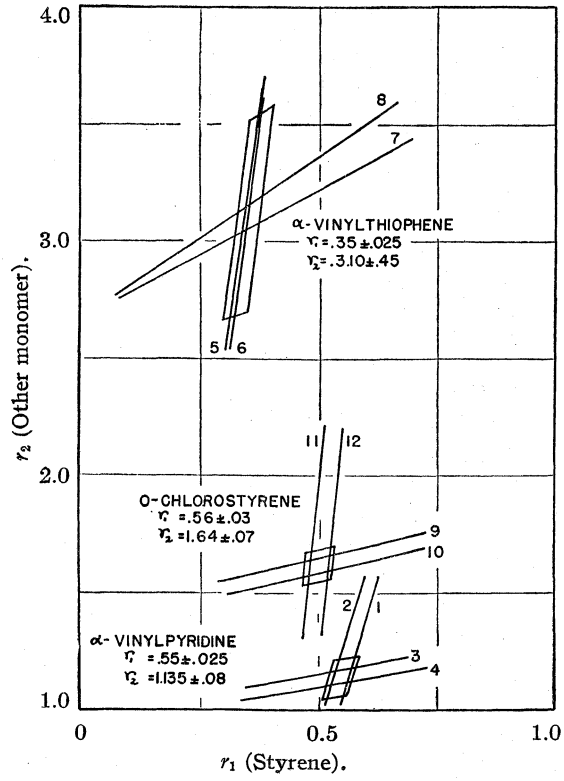

Fig. 1.—Determination of monomer reactivity ratios for some copolymerizations of styrene.

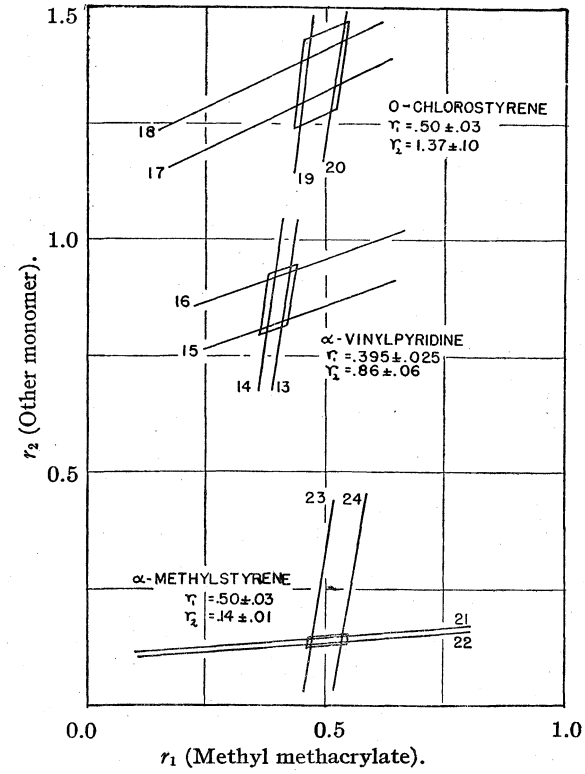

Fig. 2.—Determination of monomer reactivity ratios for some copolymerizations of methyl methacrylate.

(6) *i. e.*, $1/r_1$'s for the styrene radical and $0.46/r_1$'s for the methacrylate radical, since the best value for the monomer reactivity ratio for styrene with the methacrylate radical has been found to be 0.46.[4,5]

TABLE I

RELATIVE REACTIVITIES AND MONOMER REACTIVITY RATIO PRODUCTS (r_1r_2)

Monomer	Relative reactivities toward Styrene radical	Relative reactivities toward Methacrylate radical	(r_1r_2) With styrene	(r_1r_2) With methacrylate
Styrene	1.00	1.00	1.00	0.24 ± 0.01
α-Vinylpyridine	1.82 ± 0.08	1.17 ± 0.08	0.625 ± 0.052	.340 ± .035
α-Vinylthiophene	2.86 ± .20	.....	1.09 ± .18	.....
o-Chlorostyrene	1.78 ± .06	.97 ± .06	.919 ± .063	.685 ± .065
α-Methylstyrene	.....	.97 ± .06	.....	.070 ± .007

and also the monomer reactivity ratio products (r_1r_2's) which serve as qualitative measures of the tendencies of the two monomers to alternate in copolymerization.

It may be seen from Table I that the monomers are all more reactive toward the styrene-type radical, than styrene and lie in the order styrene < o-chlorostyrene < α-vinylpyridine < α-vinylthiophene. Further, only α-vinylpyridine shows an appreciable tendency to alternate with a r_1r_2 value significantly smaller than unity. It is of interest that, of the three chlorostyrenes, the o-chloro is the most reactive, reactivities[2] lying in the order p-Cl (1.35) < m-Cl (1.56) < o-Cl (1.78). In reactivity toward the methacrylate radical, the three styrenes are indistinguishable and α-vinylpyridine is slightly more reactive. Apparently, the greater reactivity of α-vinylpyridine and o-chlorostyrene (as shown in copolymerization with styrene) is counteracted by a lesser tendency to alternate in copolymerization with methacrylate (larger r_1r_2 values) than is shown by styrene. The very small r_1r_2 value for α-methylstyrene is probably due to its reluctance to polymerize alone (a 1:4 methacrylate-α-methylstyrene mixture yields only 7–10% polymer in six hundred hours) rather than to an unusually high reactivity toward the methyl methacrylate type radical.

Experimental

Styrene, methyl methacrylate, α-methylstyrene and α-vinylpyridine were commercial materials, distilled *in vacuo* and stored in the ice-box before use. The preparation and properties of the samples of o-chlorostyrene[7] and α-vinylthiophene[8] are described elsewhere.

Polymerizations were carried out at 60° in sealed tubes in absence of air, using, usually, 0.08 mole total monomers and 0.5 mole % benzoyl peroxide. All polymers were benzene soluble, and were worked up by the frozen benzene technique[9] using petroleum ether as a precipitant.

Summary

1. Monomer reactivity ratios have been determined for the copolymerization at 60° of styrene with α-vinylpyridine, α-vinylthiophene, and o-chlorostyrene and of methyl methacrylate with α-vinylpyridine, o-chlorostyrene and α-methylstyrene, and the results are discussed.

Copolymerization. XII. The Effect of m- and p-Substitution on the Reactivity of α-Methylstyrene toward the Maleic Anhydride Type Radical

BY CHEVES WALLING, DEXTER SEYMOUR AND KATHERINE B. WOLFSTIRN[1]

A study[1a] of the copolymerization of methyl methacrylate with a series of m- and p-substituted styrenes has shown that, for most of the styrenes studied, relative reactivities toward the methyl methacrylate type radical followed quite well the order found by Hammett[2] for ionic-type side-chain reactions with a small positive rho value, *i. e.*, increasing reactivity with the introduction of increasingly electron withdrawing groups. However, anomalously high reactivities were observed (in increasing order) for p-methyl-, p-methoxy- and p-dimethylaminostyrenes.

These enhanced reactivities were shown to parallel the increased tendencies of these styrenes to form colored complexes with molecules such as maleic anhydride and chloranil, and it was suggested that they were due to the availability of additional resonance forms in the transition state of the copolymerization reaction in which an electron had been transferred from the styrene to the attacking carbonyl-conjugated radical. Existence of similar forms in the complexes in which an electron has been transferred to the conjugated carbonyl system has already been proposed by Weiss.[3]

Since these observations throw valuable light on the nature of the "alternating tendency" in

copolymerization[4,5,6] it seemed desirable to carry out further studies with a monomer showing a greater tendency to alternate with styrene, in which such resonance forms might be even more important. This paper reports such a study, using substituted α-methylstyrenes and maleic anhydride, probably the extreme type of such a monomer.[6,7,8]

Due to the high tendency of styrenes and maleic anhydride to alternate in copolymerization, both monomer reactivity ratios are essentially zero. Accordingly, it is not possible to investigate relative reactivities by simple copolymerization experiments, and recourse must be had to competitive reactions in three-component systems composed of two styrenes and maleic anhydride. In such a system, since four of the six monomer reactivity ratios are very small, the polymer consists of chains in which maleic anhydride residues alternate regularly with one or the other styrene and the complex terpolymerization equation[9] can be greatly simplified.[10] Under such conditions virtually the only[11] reaction which consumes either styrene is attack by the maleic anhydride type radical. Designating the two styrenes as M_1 and M_2 and the rate constants for their respective reactions with maleic anhydride as k_1 and k_2, this condition leads to the simple differential equation

$$\frac{d[M_1]}{d[M_2]} = \frac{k_1[M_1]}{k_2[M_2]} \qquad (1)$$

which on integration yields

$$\log [M_1]_0/[M_1] = k_1/k_2 \log [M_2]_0/[M_2] \qquad (2)$$

with zero subscripts indicating initial concentrations. Carrying out such a polymerization to partial conversion, determining $[M_1]$ and $[M_2]$ by analysis of either the polymer, or, as proves more convenient in these systems, the unreacted styrenes, and substituting these values into (2) permits a calculation of k_1/k_2, the desired ratio of reactivities of the two styrenes toward the maleic anhydride type radical. By comparing a series of substituted α-methylstyrenes with one selected as a standard, the relative reactivities of the whole series toward the maleic anhydride type radical may thus be determined.

(10) The simplification arising when one or two monomer reactivity ratios are zero has been already discussed by Alfrey and Goldfinger, *J. Chem. Phys.*, **14**, 115 (1946).

(11) When this project was undertaken preliminary measurements on the system styrene–maleic anhydride had indicated a monomer reactivity ratio for the styrene radical of 0.15, too small for the comparison of ordinary copolymerizations, but enough to introduce errors into the kinetics described above. Accordingly, a series of α-methylstyrenes were employed since the α-methylstyrene radical shows very little tendency to add to its own monomer (*cf.* Walling, Briggs and Wolfstirn, THIS JOURNAL, **70**, 1543 (1948). Subsequent work[6] has shown that the monomer reactivity ratio is actually less than 0.01, making the precaution unnecessary.

Experimental

Materials

Maleic anhydride was Eastman Kodak Co. material, m. p. 54.0–57.0°, used without further purification.

α-Methylstyrene was purified by fractionating commercial material through a 14-cm. column packed with glass helices. The fraction used had the following constants: b. p. 69.0–69.2° at 27 mm., $n^{20}D$ 1.5383. The material was always used shortly after distillation since it tended to oxidize to acetophenone and formaldehyde even when stored in a stoppered bottle in the refrigerator.

α-*p*-Dimethylstyrene was purified by fractionating commercial material through a 45-cm. helices-packed column. The fraction used had b. p. 72–3° at 11.5 mm. $n^{20}D$ 1.5334.

Substituted α-Methylstyrenes.—The syntheses and properties of the other α-methylstyrenes are described elsewhere.[12]

Polymerizations and Analyses

Polymerizations were carried out by heating mixtures of two α-methylstyrenes and maleic anhydride in sealed tubes at 60° in the presence of benzoyl peroxide and absence of air.[4] In general 0.1 mole of mixed styrenes (in 1:2, 1:1, or 2:1 molar ratios), 0.05 to 0.1 mole maleic anhydride, and 0.16–0.18 millimole of benzoyl peroxide were used in each experiment, and heating times were adjusted to consume 50–90% of the maleic anhydride. As might be expected, the products under these conditions yielded viscous solutions and had the properties of high polymers rather than Diels–Alder adducts.[13]

Although reactivities were ultimately related to α-methylstyrene, most reactions were actually run on mixtures of α-methylstyrenes with α,*p*-dimethylstyrene, since this compound proved to be more stable to storage than our sample of α-methylstyrene. Due to its high reactivity, it was found necessary to compare *p*-dimethylamino-α-methylstyrene with *p*-methoxy-α-methylstyrene and also to dilute the reaction mixture with 15 cc. of acetic anhydride to moderate the reaction.

Analyses were carried out by determining the amount and composition of the unreacted styrenes. After removal from the 60° bath, tubes were frozen in liquid nitrogen, wrapped in cellophane, crushed, and dropped into a one l. flask containing 200 cc. of 1 *N* sodium hydroxide solution and 0.5 g. hydroquinone. After shaking for an hour at room temperature, during which time the polymer usually dissolved, the residual styrenes were steam distilled into a graduated water separator (Dean and Stark trap) modified so that liquids either lighter or heavier than water could be separated. When distillation was complete, the volume of styrenes was noted and they were separated from the water layer, dried over anhydrous potassium carbonate, and analyzed. In the case of the systems containing *p*-cyano-α-methylstyrene, sodium bicarbonate was substituted for sodium hydroxide to minimize hydrolysis of the nitrile. For the system *p*-dimethylamino-α-methylstyrene–*p*-methoxy-α-methylstyrene, the unreacted monomers were steam-distilled into a 500-cc. flask which was next attached to a liquid–liquid extractor and the styrenes extracted for twenty-four hours with ether containing a little *t*-butylcatechol. Following removal of the ether (first at atmospheric pressure and then by freezing the mixture at −5° and pumping for five hours at 2 mm.) the styrenes were analyzed for nitrogen.

Compositions of the unreacted styrene mixtures containing chlorine, bromine or nitrogen were determined by

(12) Seymour and Wolfstirn, THIS JOURNAL, **70**, 1177 (1948).

(13) Tomayo-Viguera, *Anales fis. chim.*, **38**, 184 (1942). By heating maleic anhydride and α,*p*-dimethylstyrene in the presence of 1% trinitrobenzene as a polymerization inhibitor, we were able to isolate, besides considerable dioxane-soluble polymer, a small amount of a high-melting (>230°) material relatively insoluble in dioxane and giving solutions of low viscosity ($[\eta] = 0.07$). This may represent the Diels–Alder type product.

elementary analysis. Mixtures of α,p-dimethylstyrene with p-fluoro- or p-methoxy-α-methylstyrene were analyzed by index of refraction, the linear relation between index and volume fraction having been established from known mixtures.

α-Methylstyrene and α,p-dimethylstyrene differ too little in index of refraction for accurate analysis and so mixture compositions were determined by melting point using a melting-point curve constructed from the data of Table I.

TABLE I

MELTING POINTS OF KNOWN α-METHYLSTYRENE–α,p-DIMETHYLSTYRENE MIXTURES

Vol. % dimethylstyrene	M. p., °C.	Vol. % dimethylstyrene	M. p., °C.
0.0	−24.5	55.6	−52.0
16.6	−31.8	62.5	−47.7
28.6	−36.8	71.4	−43.0
37.5	−42.4	83.2	−36.6
44.5	−49.5	100.0	−28.0
50.0	−52.8		

All melting points were taken as the "flats" observed in the warming curve of styrene mixtures measured with a Leeds and Northrup potentiometer using a copper–constantan thermocouple with a melting ice reference junction. This combination gives readings to ±0.2°.

Calculation of Experimental Errors.—The accuracies of the analytical methods were tested for the systems α-methylstyrene–p-chloro-α-methylstyrene and α-methylstyrene–α,p-dimethylstyrene by putting up tubes similar to those used in the polymerizations, but working them up without heating. Results are listed in Table II.

TABLE II

BLANK EXPERIMENTS ON α-METHYLSTYRENE MIXTURES

Total monomer volume, cc. Calcd.	Found	Vol. % α-Methylstyrene Calcd.	Found
With α,p-Dimethylstyrene			
13.6	13.4	46.8	45.0
13.6	13.4	47.2	52.5
13.8	13.8	46.8	44.5
With p-Chloro-α-methylstyrene			
11.9	11.7	47.6	47.2
11.6	11.5	48.0	49.0
12.0	11.9	48.9	49.4

Results of actual terpolymerization experiments are listed in Table III. Relative reactivities were calculated from each experiment by Equation (2) and averaged for each pair. Experimental error was taken as the standard deviation of the separate experiments for each pair from this mean. Results, all referred to α-methylstyrene as standard,[14] are listed in Table IV. The given experimental errors, in general, correspond to 1–5% errors in monomer isolation and analysis, in reasonable agreement with the blank runs of Table II. In the case of the p-cyano-α-methylstyrene system, however, errors were definitely larger. Whether the difficulty was due to the analytical method or other causes was not determined before the sample of p-cyano-α-methylstyrene was exhausted.[15] The high reactivity of p-dimethylamino-α-methylstyrene, and the rather complex isolation technique which was necessary permit only the assignment of a minimum value for its relative reactivity.

[a] In millimoles. [b] Monomer contained 2 wt. % p-fluorobromobenzene, and results have been corrected accordingly. [c] Experiment was intended as blank, but polymerization occurred on standing at room temperature.

Discussion

In Table IV are listed relative reactivities of the eight α-methylstyrenes toward the maleic anhydride type radical compared with the relative reactivities of the corresponding styrenes toward the methyl methacrylate and styrene type radicals reported previously.

The striking feature of Table IV is the high reactivity of the first three styrenes, which paral-

(14) In the case that the original comparison was not with α-methylstyrene, the experimental errors in both of the ratios involved were taken into account, using the usual formulas for the propagation of error.

(15) If the difficulty is analytical, it most probably results from failure to recover all of the unreacted p-cyano-α-methylstyrene. In this case the apparent reactivity of this monomer is too high and the true value may be near the lower limit indicated in Table IV.

TABLE IV

RELATIVE REACTIVITIES OF STYRENES AND α-METHYLSTYRENES TOWARD VARIOUS RADICALS IN COPOLYMERIZATION

Substituent[a]	Attacking radical: Maleic anhydride	Methyl methacrylate	Styrene

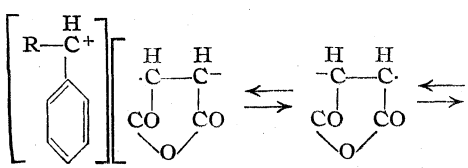
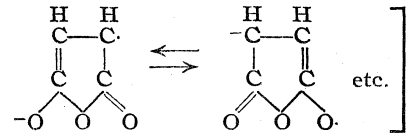
[a] On α-methylstyrene in second column, on styrene in third and fourth.

lels, but is much larger than, that noted previously in connection with reactivity toward the methacrylate radical.[1a] Thus, this increased reactivity, which parallels the tendencies of these styrenes to form colored molecular complexes with carbonyl conjugated systems, appears to be general for carbonyl-conjugated radicals and to increase with the "alternating tendency" of the monomer from which the attacking radical is derived.

This lends much support to the suggestion made earlier[1a] that the driving force for "alternation" arises from the presence of resonance structures in the transition state similar to those of molecular compounds.

Possible structures of such forms, in which an electron has been transferred from styrene monomer to attacking radical, were suggested previously,[1a] but it should be pointed out that similar structures may be drawn to explain as well the great reactivity of carbonyl conjugated double bonds with styrene type radicals, and thus to account for both "halves" of the alternating copolymerization reaction.





Further, it should be noted that relative reactivities of all α-methylstyrenes toward the maleic anhydride type radical now show little relation to the Hammett sigma values of the substituents, again indicating the dominant importance of special resonance forms in the transition state of this reaction, rather than some general property of electron density or availability at the double bond, as required by any "electrostatic" interpretation.[5]

The parallel drawn between the transition state of polymerization and molecular compound formation again brings up the possibility that alternation in copolymerization may actually involve attack of a radical on a molecular complex, particularly in a pair such as styrene–maleic anhydride where appreciable concentrations of actual colored complex exist. It should be pointed out, however, that by the interpretation given above the transition from a weakly alternating system such as styrene–methyl methacrylate where participation of such a complex can be excluded[16,17] to a strongly alternating system where its role is equivocal[16] becomes one in degree, not in kind. Thus, while participation of an actual complex in the reaction would still be of importance in the over-all reaction kinetics, it would not be in our understanding of the nature of the reaction.

Summary

1. The relative reactivity of eight *meta-* and *para-* substituted α-methylstyrenes toward the maleic anhydride type radical have been determined.

2. Further evidence has been obtained that the major driving force leading to alternation in copolymerization is the presence in the transition state of polar resonance forms resembling those in the colored "molecular complexes."

Difluoromalonic Derivatives from Difluoropentane

BY ALBERT L. HENNE AND EARL G. DEWITT

To prepare a fluorinated compound containing an oxygenated function, we have consistently introduced the fluorine atoms in a non-oxygenated compound first, then created the oxygenated function afterwards. In so doing, we have frequently been able to take advantage of the directing power of the fluorinated cluster. The syntheses of CF_3CO_2H, and of $HO_2C(CF_2)_nCO_2H$, are examples of this procedure.[1,2]

We have now prepared difluoromalonic acid and some of its derivatives by the following sequence. Diethyl ketone was transformed into 3,3-difluoropentane; due to the directing effect of the CF_2 group away from the alpha hydrogen atoms,[3] moderate chlorination gave preferentially the 1,5-dichloro derivative $CH_2ClCH_2CF_2CH_2CH_2Cl$. Aided by the stronger acidity of the hydrogen atoms in 2 and 4 positions, the removal of two molecules of hydrogen chloride proved quite easy and yielded a diene $CH_2{=}CHCF_2CH{=}CH_2$. Alkaline permanganate oxidation of the diene gave difluoromalonic acid which, although fairly stable, was nevertheless handled as its di-ester and characterized as its crystalline diamide.

In the process of chlorinating 3,3-difluoropentane, the various mono- and di-chloro derivatives were isolated and characterized; their relative abundances were determined, and agreed with the expectations based on the directing influence of the CF_2 group. All chlorides beyond the dichlorinated stage were further treated for complete transformation into the perchlorinated form $C_2Cl_5CF_2C_2Cl_5$, a well crystallized product. From this, the non-conjugated pentadiene $CCl_2{=}CCl\text{-}CF_2CCl{=}CCl_2$ was prepared, and its formula demonstrated by oxidation to difluoromalonic acid. It is proposed to use this diene as an intermediate toward $CF_2{=}CFCF_2CF{=}CF_2$, a perfluorinated non-conjugated diene, the polymerization of which may offer new characteristics.

Experimental

Synthesis of $C_2H_5CF_2C_2H_5$.—Diethyl ketone was treated with phosphorus pentachloride to obtain a mixture of $C_2H_5CCl_2C_2H_5$ and $C_2H_5CCl{=}CHCH_3$. Since the latter is more advantageous for the subsequent treatment with hydrogen fluoride, operations were adjusted to obtain as favorable a ratio as possible. In a five-liter, three-necked flask maintained at 12 to 14° by a water-bath was placed 1342 g. (6.45 moles) of phosphorus pentachloride; this was agitated by a Hershberg stirrer driven by a motor strong enough to plow through the dry material. From a dropping funnel, 500 g. (5.8 moles) of diethyl ketone was fed over a period of two to two and one-half hours; the mixture was stirred overnight, then progressively brought to boiling under constant stirring, and maintained at the boiling point for forty-five minutes. After cooling, the reaction mixture was delivered dropwise into vigorously boiling water, held in a five-liter, three-necked flask. Superheated steam was supplied continuously to the bottom through one neck, and the vapors were led from the other neck to a condensing system adequately cooled. The organic material steamed over was decanted, neutralized, and dried to yield 582 g. of product. Distillation gave 439 g. b. 87–95° ($CH_3CH_2\text{-}CCl{=}CHCH_3$) and 110 g. b. 127–135° ($C_2H_5CCl_2C_2H_5$). The average yield was 73% of chloropentene, and 14% of dichloropentane or 88% of usable material. The dichloride was transformed into more chloro-olefin by treating its boiling alcoholic solution (2.4 moles in 600 cc.) with a solution of 2.6 moles of potassium hydroxide in 700 cc. of alcohol; this treatment gave a 36% conversion and a 55% recovery of unreacted dichloride, which was treated again.

The chloro-olefin was treated with hydrogen fluoride in a manner which would minimize the formation of the mere addition product ($C_2H_5CClFC_2H_5$) in favor of the desired $C_2H_5CF_2C_2H_5$. In a 1500-ml. steel vessel were placed 700 g. (6.7 moles) of chloro-olefin cooled to −80°, then 660 g. (33 moles) of liquefied hydrogen fluoride also cooled to −80°. A 45-cm. length of pipe bearing the customary thermometer well, pressure gage, and releasing needle valve was screwed on; the pipe was cooled by means of a sleeve through which cold water was passed. Warming to room temperature caused the pressure to rise rapidly to 12 atmospheres, due to formation of hydrogen chloride. This was reduced to 8 atmospheres by slow release of the gases through a wash train. The temperature was progressively raised to 60° and held there as long as the pressure could be kept around 8 atmospheres while slowly bleeding off the hydrogen chloride formed in the reaction. After cooling, the remaining pressure was released, then the contents of the vessel were poured into a slurry of 30% sodium hydroxide–ice, washed three times by siphoning, steam-distilled and dried, giving 579 g. of organic material. Distillation gave 524 g. (4.85 moles) b. 55–65° ($C_2H_5CF_2C_2H_5$); 5 g. b. 65–85°; 12 g. b. 85–95° (recovered $C_2H_5CCl{:}C_2H_4$); 15 g. b. 95–105° ($C_2H_5CFClC_2H_5$) and 18 g. of residue. Average yields were similarly between 67 and 73%, an appreciable improvement over those in the literature.[4,5]

Monochlorination of $C_2H_5CF_2C_2H_5$.—Chlorine was led into liquid difluoropentane floating over water, in a Pyrex flask equipped with a reflux condenser, until the increase in weight corresponded to about 70% of monochlorination. A 480 g. batch (4.6 moles) took about ten hours to reach this stage (585 g.). Distillation gave 160 g., b. 54–67° (recovered $C_2H_5CF_2C_2H_5$); 7 g., b. 67–97°; 91 g., b. 97–101° ($C_2H_5CF_2CHClCH_3$); 13 g., b. 101–114°; 198 g., b. 114–119° ($C_2H_5CF_2CH_2CH_2Cl$) and 115 g. of higher chlorides. The average of several such operations gave a ratio $C_2H_5CF_2CH_2CH_2Cl/C_2H_5CF_2CHClCH_3$ of about 2. The formula of the two monochlorides was derived from chlorine analysis, differences of boiling points similar to those observed in the butane series[3,6] and reactions with alcoholic potassium hydroxide, which was much stronger for the higher boiling isomer.[3,6]

Dehydrochlorination of $C_2H_5CF_2CH_2CH_2Cl$ was performed by dripping into its hot alcoholic solution a very concentrated alcoholic solution of potassium hydroxide, and adjusting the reflux in such a way as to allow only the olefin $C_2H_5CF_2CH{=}CH_2$, b. 51° to distil out of the reaction mixture. This olefin was used successfully to

synthesize $C_2H_5CF_2CHClCH_2Cl$, needed for contrast with other dichlorides, and also $C_2H_5CF_2CO_2H$ to test its response to oxidation.[2]

Chlorination of $C_2H_5CF_2CH_2CH_2Cl$.—Chlorination was carried out to 60% of the next stage in the same manner as above. Fractionation of 598 g. of reaction product gave 91 g., b. up to 140°; 48 g., b. 140–148°, $C_2H_5CF_2CHClCH_2Cl$, calcd. Cl, 40.4, found, Cl, 39.3; 12 g., b. 148–150°; 91 g., b. 150–155°, $CH_2ClCH_2CF_2CHClCH_3$, calcd. Cl, 40.4, found, Cl, 40.4; 34 g., b. 155–170°; 220 g., b. 170–173°, $CH_2ClCH_2CF_2CH_2CH_2Cl$, calcd. Cl, 40.4, found Cl, 41.0; 20 g., b. 173–179°, and 78 g. of residue (higher chlorides). By averaging, the following proportion of the possible dichlorides was found to be: $C_2H_5CF_2CH_2CHCl_2$ / $C_2H_5CF_2CHClCH_2Cl$ / $CH_3CHClCF_2CH_2CH_2Cl$ / $CH_2ClCH_2CF_2CH_2CH_2Cl$ 0/1/4/10. The tendency to affect the hydrogen *beta* to the CF_2 group is thus evident.

Chlorination of $C_2H_5CF_2CHClCH_3$.—Carried out in the same manner as above the results were, for 353 g. of chlorinated material: 70 g., b. up to 118°; 19 g., b. 118–122° ($CH_3CHClCF_2CHClCH_3$ or $C_2H_5CF_2CCl_2CH_3$); 26 g., b. 122–149°; 165 g., b. 149–154° ($CH_2ClCH_2CF_2CHClCH_3$); 10 g., b. 154–166°; 35 g., b. 166–171° (a trichloride isomer); 6 g., b. 171–174°; and 20 g. of residue. Chlorination of $C_2H_5CF_2CHClCH_3$ proceeds almost exclusively to $CH_2ClCH_2CF_2CHClCH_3$, by preferred action on the hydrogen beta to the CF_2 group.

The identity of $CH_2ClCH_2CF_2CHClCH_3$ is derived from the facts that (1) it is obtained from both possible monochlorides, and (2) it differs from $C_2H_5CF_2CHClCH_2Cl$ obtained by chlorine addition to the olefin.

Perchlorination.—Perchlorination was performed with a source of ultraviolet light immersed in the organic material, as shown before.[7] The chlorinator was, however, redesigned to permit its use at varied temperatures without risk of breakage due to the different coefficients of expansion of quartz and Pyrex glass (Fig. 1). The operation was carried out around 60°. Chlorination was pushed as fast as the consumption of the chlorine would permit. It was noted that after a period of continued chlorination the rate of absorption dropped very markedly. When this happened, the material solidified at room temperature. The crystals were separated from the oil by suction, and a sample, after repeated crystallization from alcohol, melted sharply at 62.3–62.8°, and analyzed for 72.6% chlorine. This is midway between $C_5F_2H_2Cl_8$ and $C_5F_2H_3Cl_7$. The formula was not further investigated. With alcoholic KOH, removal of two moles of hydrogen chloride occurred without loss of fluorine. The reaction product, b. 95–100° at 2 mm., d^4_{20} 1.7751, $n^{20}D$ 1.5162, was presumed to be mostly $CCl_2{=}CClCF_2CCl{=}CCl_2$, and on this basis the computed value for AR_F was 0.9, an acceptable value. Chlorine addition was performed at 70–80° and quantitatively yielded a solid material, which after recrystallization from absolute alcohol melted at 89.4–89.8° and analyzed for 78.6% chlorine; calculated for $C_5F_2Cl_{10}$, 78.4%.

Synthesis of $CH_2{=}CHCF_2CH{=}CH_2$.—An alcoholic solution of $CH_2ClCH_2CF_2CH_2CH_2Cl$ (277 g. or 1.56 moles in 450 ml. absolute alcohol) was treated with a solution of 3.42 moles of potassium hydroxide in one liter of alcohol, the addition and reflux being controlled in such a way as to permit only the diene to distil off. The distillate, after washing off alcohol and drying, amounted to 148 g. of which 110 g. was good diene, 30 g. was $CH_2ClCH_2CF_2CH{=}CH_2$ and the remainder unreacted dichloride. This is a conversion of 63% and a recovery of 83%. *Anal.* Calcd.: F, 36.4. Found: F, 35.0.

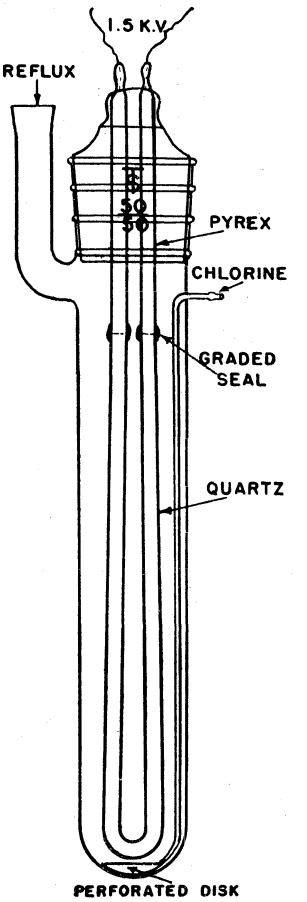

Fig. 1.—Ultra-violet light chlorinator.

Synthesis of $CCl_2{=}CClCF_2CCl{=}CCl_2$.—The treatment of an alcoholic solution of $C_2Cl_5CF_2C_2Cl_5$ with zinc is too vigorous. However, if methylene chloride is added, its refluxing keeps the reaction at a temperature no higher than 40°, and the desired removal of four chlorine atoms takes place efficiently (91%). The reaction product boils at 101–102° under 13 mm., and analyzes for 68.3% chlorine, while theoretical for $C_5F_2Cl_6$ is 68.4%.

Difluoromalonic Acid and Derivatives.—In a small preliminary run, $CH_2{=}CH{-}CF_2{-}CH{=}CH_2$ was oxidized with alkaline permanganate in our conventional way.[1,2] Ether extraction gave a few grams of mushy material, from which filtration gave grayish crystals with a neutral equivalent of 77, while the mother liquid had an equivalent of 90; the calculated value for difluoromalonic acid is 70 and for difluoroacetic acid is 96. On standing the crystals became liquid; this was interpreted as a slow decarboxylation of difluoromalonic acid to difluoroacetic acid, and in further tests the free acid was avoided.

The oxidation of the diene (21 g. or 0.2 mole) was exceedingly vigorous and exothermic, necessitating cooling of the oxidation mixture during addition to maintain the temperature at 60°. Within fifteen minutes after completion of the addition, oxidation was complete. Treatment of the reaction mixture with sulfur dioxide followed the conventional practice, and so did the ether extraction. However, at this point, the free acid was esterified by dripping its ether solution into an ether solution of diazomethane. Fractional distillation under reduced pressure gave 7 g. of a lighter boiling material, presumed to be

(7) Henne and Zimmerschied, THIS JOURNAL, **67**, 1235 (1945).

methyl difluoroacetate, and 24 g. of dimethyl difluoromalonate (*Anal.* Calcd.: F, 22.6. Found: F, 22.5), a 67% yield. A solution of 2 g. of this ester in 8 g. of ethyl ether was treated at 0° with anhydrous ammonia. White crystals formed at once, and 1.6 g. of amide, m. 206.5–206.7°, was collected, the theoretical yield. Nitrogen analysis indicated 20.1% (calculated, 20.3%).

The same amide (as determined by mixed melting point) was also obtained by oxidation of CCl_2=$CClCF_2CCl$=CCl_2 but this oxidation was slow; it required long heating, and the yield was poor. Better operating conditions were not worked out.

Summary

Diethyl ketone was transformed into 3,3-difluoropentane and the latter subjected to chlorination. The directing effect of the CF_2 group upon the first two chlorine atoms entering the organic molecule was ascertained, before perchlorination was allowed to proceed. From saturated derivatives, two non-conjugated dienes were prepared, CH_2=$CHCF_2CH$=CH_2 and CCl_2=$CClCF_2CCl$=CCl_2, both of which were oxidized to difluoromalonic acid. The latter was transformed into its dimethyl ester by means of diazomethane, and characterized as its crystalline diamide.

Polyfluoro Alkyl Ethers and their Preparation

BY J. D. PARK, D. K. VAIL, K. R. LEA AND J. R. LACHER

Alkyl ethers containing fluorine were previously prepared by Swartz[1-3] by the action of alcoholic caustic or metallic carbonate on polyfluorohaloethanes. This procedure was later modified by Gowland.[4] Aryloxy alkanes containing fluorine also were prepared by McBee and Bolt[5] by a similar reaction. In the present work, alkoxy-2-chloro-1,1,2-trifluoroethanes were prepared by the base-catalyzed addition of alcohol to chlorotrifluoroethylene carried out at room temperature and atmospheric pressure. This type of addition to fluoroölefins was first carried out by Hanford and Rigby[6] under autogenous pressure and at elevated temperatures in the presence of sodium alkoxide as a catalyst.

Starting Materials.—The various alcohols and chemicals used in this study were of technical grade. When deemed necessary they were purified by distilling before using. The compound, CF_2ClCCl_2F, used as an intermediate in the preparation of chlorotrifluoroethylene was of "refrigerant-grade" furnished us through the courtesy of Mr. R. J. Thompson of the Kinetic Chemicals, Inc. Chlorotrifluoroethylene was obtained by dehalogenation of CF_2ClCCl_2F with ethanolic zinc according to a known method.[7]

Fractionation of the product showed the pure olefin to boil at −34 to −35° at 630 mm. pressure.

Preparation of Ethers.—The general reaction involved is

$$ROH + CF_2{=}CFCl \longrightarrow ROCF_2CHFCl \quad (1)$$

According to Pauling's[8] bond energies, the vapor phase reaction should be exothermic to the extent of 5.7 kcal. The entropy change is not known but may be estimated by analogy with similar reactions,[9-12] to be around −28 e. u. The free energy change at 298°K. is +2.6 kcal. and becomes zero at 200°K. It is apparent, therefore, that an equilibrium would be favored by low temperatures and high pressures. Since the reaction was quite rapid at room temperature and slightly above, it was not necessary to employ high pressures. An excess of alcohol was used in all cases.

In the experimental arrangement finally chosen, the olefin, CF_2=$CFCl$, from a cylinder was bubbled through a dispersion disk at the bottom of a long vertical tube filled with a potassium hydroxide saturated solution of the alcohol. The outlet end of the tube was connected to an upright water condenser. The unreacted olefin escaping through the condenser was led into a second potassium hydroxide–alcohol solution. The flow of organic through the disk was so regulated that most of the reaction took place in the first reactor. The reaction was quite slow at first. However, as soon as some ether was formed, the rate increased quite rapidly with a resultant rise in temperature. After the necessary amount of olefin had reacted with the alcohol, the reaction mixture was poured into water. The excess alcohol was completely removed by washing with water and the heavier ether layer separated. The ether was then dried over "Drierite" and fractionated in a laboratory precision column.

The addition of alcohols to chlorotrifluoroethylene may proceed to give the product listed in equation I or the structure may be $ROCClFCHF_2$. It is believed that the structure containing the —CHFCl group is the more probable. This is indicated by the formation of CHFCl-COOH in the catalytic hydrolysis of the ethyl ether in the presence of silica gel.[6] The second structure is not consistent with the relative stabilities of the ethers (with the possibile exception of the isopropyl derivative). This structure would permit the elimination of hydrochloric acid quite easily with the formation of $ROCF{=}CF_2$. Such a compound was not isolated under our reaction conditions. If the addition of alcohols to chlorotrifluoroethylene leads to the thermodynamically most stable product, then considerably more heat must be liberated when the isomer containing the —CHFCl group is formed, in which case tables of bonding energies will not be sufficiently precise to determine the course of the reaction.

[a] Determinations made with a Pulfrich refractometer. [b] MR denotes molecular refraction calculated by the Lorentz–Lorenz formula. [c] AR_F denotes the atomic refraction for fluorine obtained from MR by subtracting the customary increments for C, H, Cl, O, and the ether linkage. [d] This compound has also been prepared by Miller, *et al.*, THIS JOURNAL, **70**, 432 (1948).

The fact that the ethers were obtained in yields between 70 and 85% indicates that the heat of reaction is greater than that calculated.

Physical Properties.—Some physical properties of the ethers are listed in Table I. The boiling points, densities, and refractive indices are in line with what one might expect for an homologous series. The atomic refraction for fluorine is reasonable for compounds of this type.

The absorption spectra of the ethers were measured using a Beckman quartz spectrophotometer model DU. Pure cyclohexane was used as a reference liquid and the experiments were carried out in a 10-mm. quartz cell. The ethers were transparent from 9000 to about 3600 Å. Below this wave length they absorb strongly. The curves in the ultraviolet region are given in Figs. 1 and 2. In order to bring out the details of the curves, the logarithm of the extinction coefficient, log E, is given as a function of wave length in Ångstrom units.

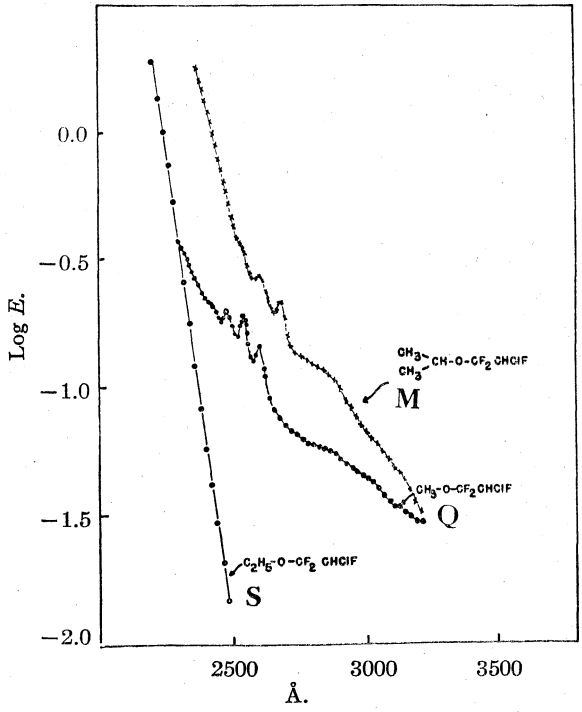

Fig. 1.—Ultraviolet absorption spectra of some alkyl fluoroethers. Logarithm of the extinction coefficient against wave length in Ångström units.

In case of the ethyl ether, absorption sets in sharply below 2500 Å. The logarithm of the extinction coefficient as a function of the wave length is a straight line and no structure is evident. Both the methyl and isopropyl ethers show vibrational fine structure. In case of the methyl compound the peaks occur at 2420, 2480, 2540 and 2600 Å. giving separations between them of 1000, 950 and 900 cm.$^{-1}$, respectively. The isopropyl ether shows peaks of 2535, 2605, and 2685 Å. with separations of 1050 and 1150 cm.$^{-1}$. These frequencies may be reliable to ±10% and could correspond either to a C–F or C–C stretching vibration.[13] It is also possible for a bending motion in the molecule to have a frequency in this range.

The isopropyl compound shows a slight shoulder between 2800 and 2900 Å., which, in case of the n-propyl derivative, is a distinct broad band. The n-butyl ether gives only a shoulder. Absorption in this region may be due to unresolvable fine structure or to the presence of small amounts of the isomer formed by the reverse addition of the alcohol to chlorotrifluoroethylene. We plan to extend absorption studies to longer wave lengths using our infrared spectrometer.

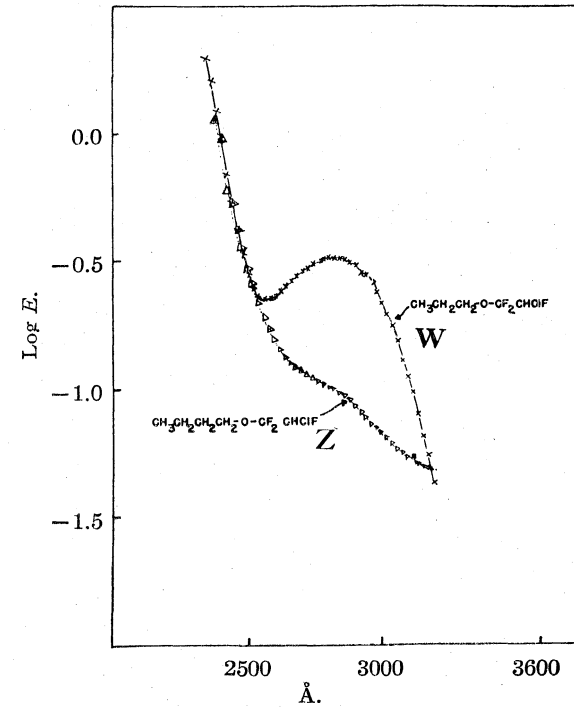

Fig. 2.—Ultraviolet absorption spectra of some alkyl fluoroethers. Logarithm of the extinction coefficient plotted against wave length in Ångström units.

Summary

This paper reports the base-catalyzed addition

(13) G. Herzberg, "Infrared and Raman Spectra," D. Van Nostrand Co., New York, N. Y., 1945.

of alcohols to chlorotrifluoroethylene resulting in the formation of ethers of the type $ROCF_2CFClH$, which in general are quite stable. The reaction is carried out at room temperature and atmospheric pressure. Some of the physical properties of the ethers, along with their ultraviolet absorption spectra are discussed.

BOULDER, COLORADO RECEIVED NOVEMBER 21, 1947

[CONTRIBUTION FROM THE RESEARCH LABORATORIES, HOUSTON REFINERY, SHELL OIL COMPANY, INCORPORATED]

Alkylation of Thiophene with Olefins[1]

BY W. G. APPLEBY, A. F. SARTOR, S. H. LEE, JR.,[2] AND S. W. KAPRANOS[3]

In connection with other work in these laboratories, it was necessary to prepare several alkyl thiophenes. When the experimental work was started in 1943, no method of preparation of the desired compounds which would meet our needs was found in the literature. It seemed worthwhile, consequently, to investigate the possibility of the direct alkylation of thiophene with appropriate olefins. This paper presents the results of our investigation of the alkylation of thiophene with propylene and isobutylene.

In the intervening time, the direct alkylation of thiophene by olefins and alcohols was reported by Kutz and Corson.[4] These authors reported the results of two experiments on the direct alkylation of thiophene with propylene and isobutylene under conditions considerably removed from those to be presented here. It is remarkable that in these experiments no evidence was presented for the formation of 3-isopropyl- and 3-*t*-butylthiophene, whereas in the experiments described below a considerable reaction to the 3-isomer was observed with each olefin. An explanation of the discrepancy will be presented in following sections of this paper.

Experimental

Purity of Chemicals.—The catalyst was phosphoric acid on kieselguhr (50–60%) manufactured by Universal Oil Products Company. The commercial 1/4-inch pellets were cut into 1/8-inch pellets. A fresh sample of catalyst was used for each experiment.

Synthetic thiophene was obtained from the Eastman Kodak Company. Satisfactory purity of the sample was indicated by a comparison of its properties with those reported in the literature: our sample, $n^{20}D$ 1.5287, d^{20}_4 1.0646; literature,[5] $n^{20}D$ 1.5286, d^{20}_4 1.0642.

Technical isobutylene from the Phillips Petroleum Corporation and propylene from the Ohio Chemical Company were used. The propylene had a purity of 98%, and the isobutylene contained a maximum of 4% isobutane as the only impurity.

Apparatus.—The alkylation reactions were carried out under continuous flow conditions in an 18–8 stainless steel reactor with a one-inch diameter. The unit was pressured with nitrogen prior to the introduction of thiophene and the olefin. For experiments in which 1:1 thiophene to olefin mole ratios were used, the liquids were charged from separate cylinders of a dual displacement pump. Higher thiophene to olefin ratios were obtained by dissolving the liquid olefin in the thiophene and maintaining the mixture at a low temperature until it was charged to the pump.

Alkylation of Thiophene with Propylene.—The alkylation of thiophene with propylene was carried out at 288°, 21.5 atmospheres, 1.1 thiophene to propylene mole ratio, and a flow rate of 3.6 g. of liquid charge per gram of catalyst per hour (WHSV). Under these conditions 70% of the thiophene and 50% of the propylene reacted to give an 80% by weight yield of liquid product which contained 40% mono-isopropylthiophene and significant amounts of di-isopropylthiophenes. This was equivalent to 30–35% conversion of propylene to the mono-isopropylthiophene. The amount of mono-isopropylthiophene recovered in each experiment was too small for analysis. The combined monoalkylate fractions from several experiments were therefore distilled and then hydrogenated over a catalyst of mixed tungsten and nickel sulfides[6] at 288°, 33 atmospheres pressure, 0.1 WHSV and a hydrogen/alkylate molal ratio of 15. The resulting paraffin hydrocarbons, as determined by physical properties and infrared spectra, consisted by weight of 38% 2,3-dimethylpentane, 54% 2-methylhexane and 8% of lower boiling hydrocarbons (perhaps from the propylene polymerization reaction). These values correspond to a relative distribution by weight of the mono-isopropylthiophenes in the liquid product of 41% 3-isopropylthiophene and 59% 2-isopropylthiophene.

Although the isopropylthiophenes were not purified as efficiently as the *t*-butylthiophenes (see below), the physical properties of selected distillation cuts were as follows: 2-isopropylthiophene,[7] b. p. 152.0°, $n^{20}D$ 1.5037, d^{20}_4 0.9673; 3-isopropylthiophene,[7] b. p. 155.5°, $n^{20}D$ 1.5060, d^{20}_4 0.9722.

Infrared analysis of the C_{10} hydrocarbons resulting from the hydrogenation of the di-isopropylthiophenes showed that the principal product was 2,7-dimethyloctane (from 2,5-di-isopropylthiophene). The presence of the other three possible decanes (2,3,4,5-tetramethylhexane, 2,3,6-trimethylheptane, and 2,5-dimethyl, 3-ethylhexane) was also indicated.

Alkylation of Thiophene with Isobutylene.—No physical properties were available in the literature for *t*-butylthiophene. Consequently, in order to have this information for identification of the products in later experiments, it was necessary to prepare pure samples of these compounds for such determinations. The liquid product for this purpose was prepared by alkylating thiophene with isobutylene (1:1 mole ratio) at 21.5 atmospheres, 270°, and a WHSV of 4.3.

The liquid product from this experiment was distilled in a column having nine theoretical plates at total reflux. This distillation separated the product roughly into three fractions: (1) unreacted thiophene, (2) mono-alkylthio-

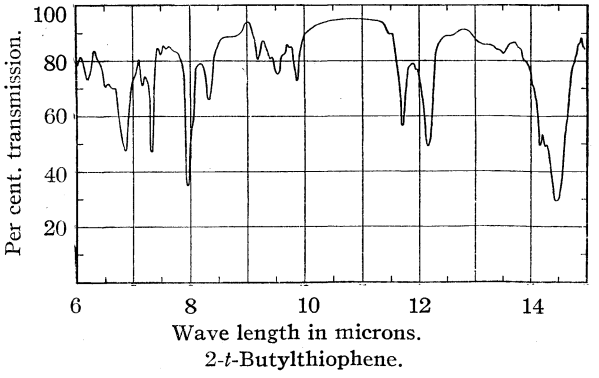
phene, and (3) di-alkylthiophene and heavier. The last fraction was vacuum distilled to separate the di-alkylthiophene from the heavier residue.

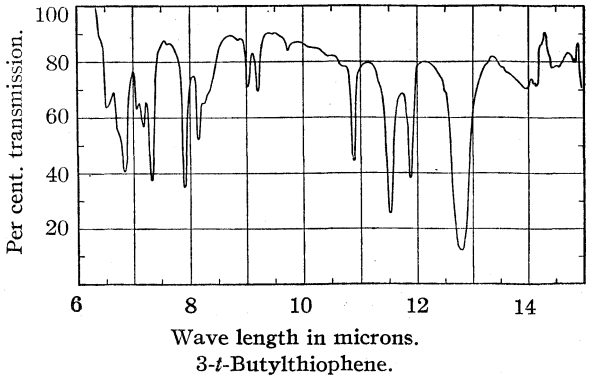
The isomeric mono-*t*-butylthiophenes were separated and purified by a series of precision distillations which were carried out at a 49:1 reflux ratio in a Stedman column having 60 theoretical plates at total reflux.

As a final check of the purity of the two isomers, time *versus* temperature freezing curves were obtained by a method similar to that of the Bureau of Standards.[8] These curves indicated a minimum purity for each isomer of 97%.

Hydrogenation of the higher boiling *t*-butylthiophene yielded principally 2,2,3-trimethylpentane, thus establishing the identity of that isomer as 3-*t*-butylthiophene. The lower boiling isomer was shown to be 2-*t*-butylthiophene by the formation of 2,2-dimethylhexane upon hydrogenation. These designations are analogous to those of other substituted thiophenes and the picolines; *i. e.*, the 3-isomers have the higher boiling points and densities. The paraffins resulting from the hydrogenation of the pure *t*-butylthiophenes were identified by determination of their infrared spectra.



2-*t*-Butylthiophene.



3-*t*-Butylthiophene.

Fig. 1.—Infrared absorption spectra.

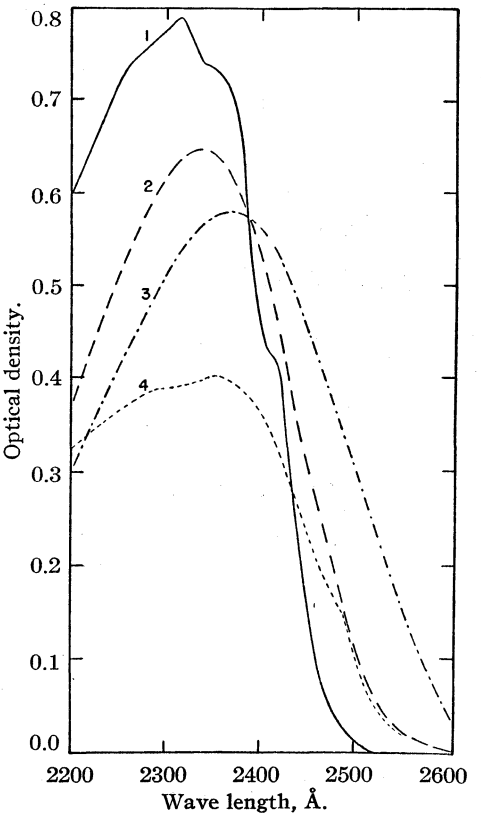
(8) Glasgow, Streiff and Rossini, *J. Research Nat. Bur. Standards*, **35**, 355 (1945).

The di-*t*-butylthiophene, which was separated from the heavy residue, was pure only as regards the removal of the residue and mono-*t*-butylthiophene. Actually, at least two isomers were present. These were partially separated by precision distillation, but not enough of either of the isomers was available for further identification.

A summary of the physical properties and analytical values which were determined on the pure compounds and fractions discussed above is presented in Table I.

The residue left after removal of the di-*t*-butylthiophene showed, in addition to the analytical data of Table I, values of % C and % H of 70.3 and 7.6, respectively. These values correspond closely to the calculated values for a mixture containing about 70% di-*t*-butyldithienyl and 30% di-*t*-butylthiophene.

A very small amount of material boiling below thio-



1—Eastman thiophene
2—2-*t*-Butylthiophene
3—Mixed di-*t*-butylthiophenes
4—3-*t*-Butylthiophene

Fig. 2.—Ultraviolet absorption spectra—dilution 1:100,000 in cyclohexane.

phene and a small amount boiling between thiophene and the monoalkylate and possessing lower refractive indexes were indicated in the distillation of the liquid product. This material could have been formed in the course of a small amount of isobutylene polymerization followed by polymer disproportionation.

There was also noted a small amount of material with a high refractive index boiling between the monoalkylate and dialkylate. A substituted thiophene with a double bond in the side chain could have these properties, but it is not clear how a compound of that type could be formed under the conditions investigated here.

From the foregoing distillation and analytical data, the following approximate liquid product composition by weight can be written—37% 2-*t*-butylthiophene, 23% 3-*t*-butylthiophene, 33% di-*t*-butylthiophenes, 5% di-*t*-butyl-dithienyl and 2% unidentified.

Infrared and ultraviolet absorption spectra of several of the compounds of Table I are shown in Figs. 1 and 2. The marked differences between the spectra of the 2- and 3-*t*-butylthiophenes support the freezing point purity data mentioned above.

Thermal Alkylation.—Thiophene and isobutylene (1.2/1 mole ratio) were passed over glass beads at 267°, 21.5 atmospheres, and 4.4 WHSV. Distillation of the product from this experiment gave an overhead material which was thiophene. Since the sulfur content of the distillation residue was lower than that of thiophene, the residue may have contained two or more of the following products: thiophene, alkythiophenes, isobutylene polymer and polythienyls. If it is assumed that only thiophene and monoalkyl thiophenes were present, the maximum amount of thermal alkylation possible at these conditions is approximately 5%. A small amount of thiophene thermal decomposition was indicated by the presence of hydrogen sulfide in the product.

Catalytic Decomposition of Thiophene.—The catalytic decomposition of thiophene, as determined by passing thiophene over the phosphoric acid catalyst at 281°, 21.5 atmospheres, and 2.8 WHSV, amounted to 6.7%. In addition to the decomposition reaction, indicated by the amount of hydrogen sulfide formed, there was evidence of a considerable amount of some other reaction to form heavier compounds, possibly dithienyl. Distillation of the liquid product was stopped at 76.3% by volume overhead because of excessive kettle temperature. The overhead product was thiophene, but the remainder of the product solidified upon cooling to room temperature. Since 2,2′-dithienyl and 3,3′-dithienyl melt at 33° and 132°, respectively, it is possible that these materials constituted a major part of the residue.

Discussion

The results of the experiments above indicate that the reactions of major importance in the alkylation of thiophene with isobutylene over phosphoric acid are

(I) Thiophene ⟶ H_2S + carbonaceous material
(II) Thiophene ⟶ dithienyl
(III) Thiophene + isobutylene ⟶ 2- and 3-*t*-butylthiophene
(IV) *t*-Butylthiophene + isobutylene ⟶ di-*t*-butylthiophene
(V) *t*-Butylthiophene ⟶ di-*t*-butyldithienyl
(VI) Isobutylene ⟶ polymer
(VII) Disproportionation of the isobutylene polymer

On the basis of the liquid product compositions and the ratios of moles of isobutylene reacted/moles of thiophene reacted, it was possible to deduce the effects of the reaction variables on the above reactions.

Increase of the pressure in the range 7.8 to 21.5 atmospheres caused increases in the amounts of all reactions, particularly reactions I, II, III and IV. The relative amounts of 2- and 3-*t*-butylthiophenes were not affected appreciably by changes in operating pressure.

In the range of 235 to 302°, increases in the reaction temperature caused increases in the amounts of reactions I, II, IV, V, VI and VII. Although less monoalkylate was produced at the higher temperature, the ratio of the 3-isomer to the 2-isomer was greater than at the lower temperature.

Increase of the thiophene/isobutylene mole ratio in the range 1.2 to 6.1 caused decrease of the amounts of all reactions except I and II, and also a decrease of the ratio of 3-*t*-butylthiophene to the 2-isomer. Reaction I was not markedly affected by the change in mole ratio. The composition of the residue indicated that the amount of reaction II increased, relative to reaction V, at the higher mole ratio.

Increase of the weight space velocity from 2.9 to 9.9 caused decreases in the amounts of all reactions except III. The amount of reaction III increased, but the relative amounts of the 2- and 3-isomers remained approximately constant. Part of the differences in product composition and yields between our results and those of Kutz and Corson can undoubtedly be attributed to the differences in experimental conditions and the physical states of the catalysts used. It does not seem reasonable, however, that no 3-*t*-butylthiophene was formed in their work. An examination of their data on the physical properties of mono-*t*-butylthiophene (assumed by them to be the 2-isomer) reveals that the refractive index and density are intermediate between the values listed in Table I for the 2- and 3-isomers, suggesting that some 3-*t*-butylthiophene was formed in their work. A rough value of the amount may be estimated from these properties to be 21% of the monoalkylate fraction on the basis of the density and 22% on the basis of the refractive index, assuming a linear blending relation in these properties for the isomers. These values are to be compared to a value of 38% from our data reported above.

In the homogeneous reactions of thiophene it has been established[9] that substitution occurs almost entirely in the 2-position. The production of relatively high yields of 3-isopropyl- and 3-*t*-butylthiophenes in the heterogeneous reactions described above must, therefore, be attributed either to (1) some effect of the catalyst on the "normal" orientation influence of the sulfur atom or to (2) isomerization of the 2- to the 3-isomer. If the latter explanation is correct, both the temperature and the space velocity would be expected to have considerable influence on the relative yields of the two isomers. The influence of space velocity was shown to be negligible in the range 3–10 The 3-/2-*t*-butylthiophene ratio varied over a re-

(9) Steinkopf, "Die Chemie des Thiophenes," Theodor Steinkopf, Dresden and Leipzig, 1941; Edwards Brothers, Inc., Ann Arbor, Michigan, 1944.

markably small range in all of the experiments and was below about 0.6 only in the experiments involving lower temperature and low yields of mono-alkylate. This suggests that an isomerization equilibrium between the two isomers was established under all of the conditions except those under which the low concentration of mono-alkylate prevented the attainment of equilibrium at the space velocities used.

The possibility that the catalyst influences the "normal" action of the sulfur atom in controlling the point of substitution should not be overlooked, however, since our data show that appreciable thiophene decomposition (evolution of hydrogen sulfide) occurred in all experiments. This suggests that the thiophene molecule, during the heterogeneous reaction, is not in the state corresponding to that of the aforementioned homogeneous reactions and, therefore, is not subject to the orientation rules of the homogeneous reactions. A study of the activity of the phosphoric acid catalyst for isomerization of the 2- to the 3-isomer should show which of the above two hypotheses is correct.

The complicated array of simultaneous and consecutive reactions which appear to be involved in the over-all reaction make it impossible to obtain an adequate theoretical treatment of the reaction kinetics which can be tested by the experimental data herein presented.

Acknowledgments.—We wish to express our thanks to the following people for their contributions to the work: Messrs. M. P. L. Love and L. L. Lovell at whose suggestion the larger project, of which this work was a part, was carried out; Mr. W. K. Meerbott who carried out the hydrogenation of the alkylates; and Dr. R. A. Friedel for his interpretation of the infrared spectra of the decanes.

Summary

Alkylthiophenes were prepared by direct alkylation of thiophene with isobutylene and propylene over a phosphoric acid polymerization catalyst. Alkylation was predominantly in the 2-position, although remarkably high yields of the 3-isomer were obtained. The physical properties and absorption spectra of several of the alkylthiophenes were determined. A study was made of the influence of several reaction variables on the alkylation with isobutylene.

3-Substituted Thiophenes. I

BY E. CAMPAIGNE AND WILLIAM M. LESUER[1]

A great deal of work has been reported in the recent literature on the preparation and pharmacological evaluation of thiophene compounds.[2-5] Due to the fact that 3-substituted thiophene derivatives have not been available in the desired quantities, this work has been limited, by necessity, to thiophene compounds substituted in the 2-position.

It has been shown repeatedly that replacement of the 2-thienyl radical for the benzene nucleus in pharmacologically active compounds leads to products of similar activity.[3,4,6] In some cases the thiophene analog has been toxic to a lesser degree.[7] It therefore seemed of interest to prepare some 3-substituted thiophene compounds in order that their pharmacological properties might be compared with those of the 2-substituted derivatives and the benzene analogs. The work described in this paper deals with the synthesis of intermediate compounds required in the preparation of some 3-substituted thiophene derivatives with possible pharmacological activity.

The synthesis of 3-thenaldehyde (V)[8] has been previously carried out in poor yield in a reaction utilizing the difficultly obtainable 3-iodothiophene.[9] 3-Thenoic acid (VII) has been prepared in small amounts by numerous methods: oxidation of 3-methylthiophene (I)[10,11]; chlorination of I followed by hydrolysis, oxidation and finally reduction[12]; treatment of 3-iodothiophene with potassium cyanide and water in a sealed tube[13];

(8) The recent literature contains various names for the same thiophene compound. For instance, thiophenecarboxylic acid, 2-thienoic acid, 2-thiophenoic acid, and thenoic acid are all used to designate the same compound. We have used the system which seems simplest, based on the analogy between thiophene and benzene compounds. In this system the prefix "then" corresponds to the prefix "benz"; *i. e.*, "benzyl chloride," "2-thenyl chloride," "benzaldehyde," "3-thenaldehyde," "benzoic acid," "3-thenoic acid," "2-thenoyl chloride," etc. The prefix "thienyl" corresponds to "phenyl" and we have "2-thienylacetic acid," "3-acetothienone," etc. This system fits into the framework of the large group of useful trivial names which has been established in the benzene series, and saves much space. Thus 1-hydroxy-2-keto-1,2-di-(3-thienyl)-ethane becomes 3,3'-thenoin, and thiophene-3-aldehyde becomes 3-thenaldehyde.

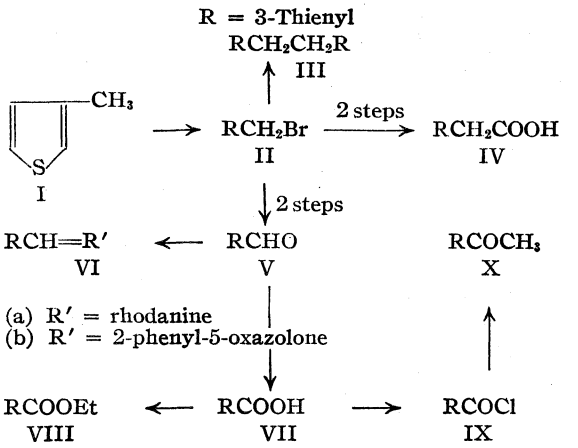
and by the Grignard reaction with carbon dioxide on 3-iodothiophene.[9]

We have used N-bromosuccinimide as a bromination agent in the preparation of 3-thenyl bromide (II) from 3-methylthiophene. Buu-Hoi and Lecocq[14] described the preparation of α-bromomethylnaphthalene by the action of N-bromosuccinimide on α-methylnaphthalene, but Buu-Hoi[15] was unable to prepare benzyl bromide



from toluene by the same procedure. Schmid and Karrer[16] reported that the latter reaction yielded benzyl bromide in 64% yield in the presence of small amounts of benzoyl peroxide. In the absence of the peroxide catalyst we have obtained only nuclear substitution in the reaction of N-bromosuccinimide with 3-methylthiophene, but when benzoyl peroxide was added to the reaction mixture side chain bromination predominates, yielding mainly II along with a small amount of nuclear substituted material. The latter material is probably 2-bromo-3-methylthiophene. Some difficulty has been experienced in the separation of the side chain and nuclear substituted products. 3-Thenyl bromide decomposes on distillation at atmospheric pressure and a sharp separation of the two isomers could not be effected by distillation under reduced pressure. The presence of the nuclear substituted material caused no trouble as it was removed in the next step in the sequence of reactions leading to the aldehyde. The aldehyde was prepared from II by the method of Sommelet.[17] The mixture of bromides was treated with hexamethylenetetramine in chloroform and the salt formed with II separated from solution while the nuclear substituted material remained in solution. Steam-distillation of a water solution of the salt yields V in 30–40% yield.

The aldehyde was converted to 3-thenoic acid (VII) in nearly quantitative yield by silver oxide oxidation, but only to the extent of 40–60% by alkaline permanganate. The aldehyde undergoes the usual aromatic aldehyde reactions. Treatment with sodium cyanide in alcoholic solution yielded the benzoin analog, 3,3′-thenoin. Normal condensation products were obtained with hippuric acid and rhodanine, namely, 2-phenyl-4-(3-thenal)-5-oxazolone and 3-thenalrhodanine, respectively.

The acid was converted to several esters for characterization. From the acid chloride[9] we have prepared 3-acetothienone (X) employing cadmium methyl, by the method of Gilman and Nelson.[18]

An attempt was made to prepare 3-thienylacetic acid (IV) from II through the Grignard reaction with carbon dioxide. In this preparation the same difficulty reported by Blicke and Burckhalter[2] in a Grignard reaction on 2-thenyl chloride was encountered. Coupling occurred giving rise to the formation of a dithienylethane, in our case *sym*-di-3-thienylethane (III). 3-Methyl-2-thenoic acid[19] was also isolated from this reaction. This may have been formed from a small amount of 2-bromo-3-methylthiophene which contaminated the starting material. The yield of 3-methyl-2-thenoic acid was somewhat higher than expected, considering the purity of the starting material as calculated from the yield of hexamethylenetetramine salt. It is not impossible that some rearrangement has occurred giving rise to the formation of 3-methyl-2-thenoic acid. Such a rearrangement does not occur in the benzene series when benzylmagnesium bromide is treated with carbon dioxide,[20] but the high activity of the alpha position in the thiophene nucleus must be considered in dealing with thiophene compounds substituted in the beta position such as II. Further work is being carried out on the possibility of rearrangement in this reaction.[21]

3-Thienylacetic acid was prepared by conversion of II to the nitrile and hydrolysis of the latter product.

Experimental[22]

N-Bromosuccinimide.—This compound was prepared by the method of Ziegler, *et al.*[23] A good grade of succinimide should be employed in this preparation; that described by Clarke and Behr[24] being satisfactory. Some commercial materials give a poor product which reacts unsatisfactorily in brominations. The product should be thoroughly washed with water to remove any excess bromine. It was found that storing the material open to the air, allowing traces of bromine to escape, gives the most active brominating agent.

3-Thenyl Bromide (II).—To a solution of 55 g. (0.56 mole) of 3-methylthiophene in 150 ml. of carbon tetra-

chloride was added 88.5 g. (0.50 mole) of N-bromosuccinimide and 0.2 g. of benzoyl peroxide. The mixture was shaken vigorously and then heated. During the first ten minutes an additional 0.2 g. of benzoyl peroxide was added. The flask and contents were shaken vigorously at frequent intervals during the first hour, then refluxed for five additional hours. After cooling in an ice-bath the succinimide was removed by filtration and washed with 50 ml. of carbon tetrachloride. The solutions from two identical experiments were combined at this point and the carbon tetrachloride removed at reduced pressure. The remaining highly lachrymatory oil was distilled in vacuum and 114 g. of faintly tan material was collected at 70–100° (2 mm.). This material was unstable and darkened slowly. The best sample contaminated by a small amount of 2-bromo-3-methylthiophene was collected at 75–78° (1 mm.); d^{20}_4 1.635, $n^{20}D$ 1.604.

Hexamethylenetetramine Salt of 3-Thenyl Bromide.—Hexamethylenetetramine (90 g.) was added to a solution of 114 g. of 3-thenyl bromide in 200 ml. of chloroform. The mixture was refluxed for one hour, cooled, and the salt filtered. Distillation of the chloroform filtrate yielded a small amount of 2-bromo-3-methylthiophene, b. p. 173–175° (745 mm.). The salt was washed with 100 ml. of ether; yield, 150 g. This material may be purified by crystallization from absolute ethanol, yielding white needles. It softens at 120°, becomes brown and melts completely at 150°. *Anal.* Calcd. for $C_{11}H_{17}N_4SBr$: S, 10.10. Found: S, 9.80.

3-Thenaldehyde (V).—The hexamethylenetetramine salt (150 g.) was dissolved in 500 ml. of hot water and rapidly steam-distilled, one liter of distillate being collected. The distillate was acidified with hydrochloric acid and extracted with three 100-ml. portions of ether. The ether solution was dried over drierite and the ether removed on a steam-bath. Distillation of the residue at atmospheric pressure yielded 35.8 g. (32%, based on N-bromosuccinimide) of 3-thenaldehyde, b. p. 195–199° (744 mm.); d^{24}_4 1.2800, $n^{20}D$ 1.5860.

The phenylhydrazone,[25] previously reported,[7] melted at 136–137° after recrystallization from dilute alcohol.

The **2,4-dinitrophenylhydrazone** crystallized as deep orange needles from nitromethane, m. p. 236–237°.

Anal. Calcd. for $C_{11}H_8O_4N_4S$: S, 10.97. Found: S, 11.09.

The **semicarbazone** crystallized from a water–ethanol solution as white leaflets, m. p. 233–234°.

Anal. Calcd. for $C_6H_7N_3OS$: S, 18.95. Found: S, 19.25.

3-Thenoic Acid (VII).—To the brown silver oxide, formed from 150 g. of silver nitrate and 70 g. of sodium hydroxide in 600 ml. of water, was added 47.5 g. (0.424 mole) of 3-thenaldehyde in small portions with cooling. The addition was completed in twenty minutes and the oxidation was completed in thirty minutes as evidenced by the disappearance of the characteristic aldehyde odor. The silver was removed and washed with 200 ml. of water. The solution was acidified with concentrated hydrochloric acid and cooled for twelve hours; yield 49.3 g.; m. p. 136–137°. Concentration of the mother liquors to 50 ml. yielded an additional 3.2 g. of acid; total yield, 52.5 g. (97%); m. p. 137–138° after recrystallization from water.

The ***p*-bromophenacyl ester** was crystallized from ethanol; m. p. 129–130°.

Anal. Calcd. for $C_{13}H_9O_3SBr$: S, 9.86. Found: S, 9.99.

The **amide**[9] was recrystallized from water; m. p. 179–180°.

3-Thenoyl Chloride (IX).[9]—This material was prepared from VII, employing thionyl chloride, in 88% yield; b. p. 203–204° (748 mm.), 110–111° (36 mm.); m. p. 51–52°.

Ethyl-3-thenoate (VIII).—The ester was prepared from IX in 76.7 yield; b. p. 207–208° (736 mm.); d^{27}_4 1.1799, $n^{20}D$ 1.5230.

Anal. Calcd. for $C_7H_8O_2S$: S, 20.53. Found: S, 20.77.

3-Acetothienone (X).—The procedure of Gilman and Nelson,[18] used in the preparation of *p*-methoxyacetophenone, was employed in this preparation; yield 81%; b. p. 208–210° (748 mm.). After recrystallization from petroleum ether (30–60°) this material melted at 57°.

Anal. Calcd. for C_6H_6OS: S, 25.41. Found: S, 26.08.

The **2,4-dinitrophenylhydrazone** crystallized as red needles from chloroform, m. p. 265°.

Anal. Calcd. for $C_{12}H_{10}O_4N_4S$: S, 10.47. Found: S, 10.80.

The **semicarbazone** crystallized from water as white leaflets, m. p. 174–175°.

Anal. Calcd. for $C_7H_9N_3OS$: S, 17.50. Found: S, 17.27.

***sym*-Di-3-thienylethane** (III).—To a mixture of 200 ml. of anhydrous ether and 12.2 g. (0.5 mole) of magnesium was added dropwise with stirring 30 g. of the bromide mixture (3-thenyl bromide and 2-bromo-3-methylthiophene) in 75 ml. of ether. After the addition was complete and refluxing had subsided the mixture was stirred at room temperature for one-half hour and was then poured into a beaker containing 200 g. of crushed Dry Ice. The mixture was stirred vigorously and a stiff mass resulted which finally solidified. Water, followed by concentrated hydrochloric acid, was added with stirring. When all the solid material had dissolved the ether solution was removed, washed with water, and extracted twice with sodium bicarbonate solution. Acidification of the bicarbonate solution yielded 3 g. (12.5%) of 3-methyl-2-thenoic acid[19]; m. p. 144–145° after recrystallization from water.

Anal. Calcd. for $C_6H_6O_2S$: neut. equiv., 142.17. Found: neut. equiv., 142.20.

The ether solution was dried and the ether removed on a steam-bath. Vacuum distillation of the oil yielded 8 g. (48%) of *sym*-3,3′-dithienylethane; b. p. 120–130° (2 mm.); m. p. 64–65° after recrystallization from methanol.

Anal. Calcd. for $C_{10}H_{10}S_2$: S, 33.00. Found: S, 33.31.

3-Thienylacetic Acid (IV).—A mixture of 100 ml. of water, 100 ml. of ethanol and 15 g. (0.3 mole) of sodium cyanide was stirred and refluxed while a solution of 54 g. of the mixture of bromides dissolved in 50 ml. of ethanol was added dropwise. After refluxing for three hours, the sodium bromide was removed by filtration. To the alcoholic filtrate was added 30 g. of potassium hydroxide and the solution was refluxed for fifteen hours. The alcohol was then removed by distillation. The basic solution was extracted with ether and the aqueous layer acidified with concentrated hydrochloric acid. The acid separated as an oil which was extracted with ether, dried and the ether removed on a steam-bath. The crystalline acid was recrystallized from petroleum ether (90–130°); m. p. 79–80°; yield 9.7 g. (25%).

Anal. Calcd. for $C_6H_6O_2S$: S, 22.54; neut. equiv., 142.17. Found: S, 23.10; neut. equiv., 142.00.

3,3′-Thenoin.—A solution of 50 ml. of ethanol containing 2 g. of sodium cyanide and 3 g. of 3-thenaldehyde was refluxed for one hour. The reaction mixture was poured into 150 ml. of water, the mixture thoroughly shaken, and cooled overnight; yield 1 g. (33%) after recrystallization from water; m. p. 116–117°.

Anal. Calcd. for $C_{10}H_8O_2S$: S, 28.59. Found: S, 28.59.

3-Thenalrhodanine (VIa).—This compound was prepared following the procedure of Julian and Sturgis[26]

(25) All derivatives were prepared by the methods described by Shriner and Fuson, "Identification of Organic Compounds," John Wiley and Sons, Inc., New York, N. Y., 2nd ed., 1940.

(26) Julian and Sturgis, THIS JOURNAL, **57**, 1126 (1935).

for veratralrhodanine, in a yield of 98%. Yellow needles were obtained from a water–acetone mixture, m. p. 212–213°.

Anal. Calcd. for $C_8H_5ONS_3$: S, 42.31. Found: S, 42.27.

2-Phenyl-4-(3-thenal)-5-oxazolone (VIb).—This material was prepared, following the procedure described by Gillespie and Snyder[27] for the preparation of 2-phenyl-4-benzal-5-oxazolone, in a yield of 63.5%. Yellow needles were obtained on crystallization from benzene, m. p. 188–190°.

Anal. Calcd. for $C_{14}H_9O_2NS$: S, 12.56. Found: S, 12.62.

Acknowledgment.—The authors wish to thank Dr. George A. Harrington of the Socony Vacuum Oil Company for the generous gift of 3-methylthiophene used in this investigation.

Summary

A synthesis, based on the side-chain bromination of 3-methylthiophene with N-bromosuccinimide, has been described for a number of 3-substituted thiophenes.

New compounds which have been prepared in this investigation are 3-thenyl bromide, 3-thienylacetic acid, 3-acetothienone, *sym*-di-3-thienylethane, 3-thenalrhodanine, 2-phenyl-4-(3-thenal)-5-oxazolone, 3,3′-thenoin, and some esters of 3-thenoic acid.

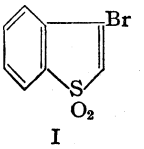
Studies in the Thianaphthene Series. I. Reactivity of the Bromine Atom in 3-Bromothianaphthene-1-dioxide

BY F. G. BORDWELL AND C. J. ALBISETTI, JR.[1]

Komppa[2] found that the bromine atom in 3-bromothianaphthene was inert to boiling alcoholic alkali and 30% aqueous alkali. In contrast, 3-bromothianaphthene-1-dioxide (I) liberates bromide ion rapidly when treated with hot alkaline



I

solutions, and several reactions in which the bromine atom of I was replaced with other groups were found to occur readily. By oxidation of 3-bromothianaphthene[2] with 30% hydrogen peroxide in acetic acid–acetic anhydride solution I was obtained in good yields.

The reaction of I with piperidine in refluxing alcoholic solution was rapid, a 96% yield of 3-(1-piperidino)-thianaphthene-1-dioxide being obtained within thirty minutes. In a similar manner excellent yields of 3-butylaminothianaphthene-1-dioxide and 3-diethylaminothianaphthene-1-dioxide were obtained. When I was dissolved in liquid ammonia no reaction occurred at −38°, but heating the reaction mixture at 110° for one and one-half hours in a pressure vessel gave 3-aminothianaphthene-1-dioxide. Aqueous ammonia at 110° gave only highly colored non-crystalline material. Less basic amines including aniline, 2-aminopyridine and 2-aminopyrimidine did not react with I in refluxing alcoholic solution.[3] Refluxing I with 2-aminopyridine in phenol also failed to effect the desired replacement; instead a small quantity of 3-phenoxythianaphthene-1-dioxide was obtained.

The hydrolytic behavior of 3-diethylaminothianaphthene-1-dioxide was tested in a few experiments. In refluxing solution hydrolysis to 3-hydroxythianaphthene-1-dioxide occurred within ten minutes in the presence of 10% sulfuric acid. 3-Aminothianaphthene-1-dioxide was also hydrolyzed rapidly in acidic solutions. In neutral or basic solutions 3-diethylaminothianaphthene-1-dioxide was more stable to hydrolysis.

It seems probable that the bromine atom in I can be replaced by reaction with nucleophilic reagents other than aliphatic amines. Thus far, the reaction with only one other class of reagents has been investigated. By refluxing I in methanol solution in the presence of an equimolar quantity of potassium hydroxide an excellent yield of 3-methoxythianaphthene-1-dioxide was obtained. When phenol was included in the reaction mixture 3-phenoxythianaphthene-1-dioxide was isolated. Refluxing a methanol solution of I for thirty minutes with an equimolar portion of sodium cyanide also gave 3-methoxythianaphthene-1-dioxide.

To test quantitatively the activity of the bromine atom, I was refluxed in benzene solution with excess piperidine as described by Spitzer and Wheland[4] for the determination of the activity of the bromine atoms in *p*- and *o*-nitrobromobenzenes

(1) Du Pont Fellow, 1946–1947. Present address: Du Pont Experimental Station, E. I. du Pont de Nemours and Company, Wilmington, Delaware. Abstracted from the Ph.D. dissertation of C. J. Albisetti, Jr.

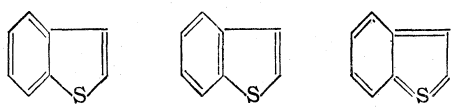
(2) Komppa, *J. prakt. Chem.*, **122**, 319 (1929).

(3) The bromine atom in I is less active than that in 3-bromoindone, since Schlossberg, *Ber.*, **33**, 2426 (1900), found that the latter reacts readily in alcoholic solution with aniline to give 3-anilinoindone.

(4) Spitzer and Wheland, THIS JOURNAL, **62**, 2995 (1940).

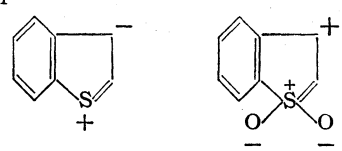
and related compounds. The authors[4] report the reaction of *p*-nitrobromobenzene to be about 52% complete in eight hours, whereas with *o*-nitrobromobenzene the reaction was about 82% complete in one hour. With I, the reaction was found to be essentially complete under these conditions even when the reaction time was shortened to one-quarter hour.[5] It is impossible from these data to calculate a rate constant to compare with those given,[4] but the bromine atom in I must be at least four times as reactive as that in *o*-nitrobromobenzene. Since Todd and Shriner[6] found that an *o*-methylsulfonyl group is only about one-fifteenth as effective as an *o*-nitro group in activating an aryl halogen atom in a similar type of reaction, the bromine atom in I must be much more easily replaced than that in *o*-methylsulfonylbromobenzene.

For thianaphthene, resonance structures, II, III and IV, may be written, comparable to those



II III IV

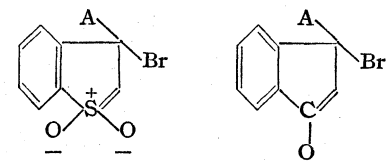
for naphthalene. In view of the lower aromaticity of thianaphthene[7a] it is probable, however, that IV contributes less to the structure of the molecule than does II or III.[7b] For thianaphthene-1-dioxide no structure comparable to IV may be written, since the sulfur atom has no unshared electrons. Charge separation structures such as V and VI,



V VI

may be written for thianaphthene and its 1-dioxide, but in structures for the latter the sulfur atom must again be given ten electrons. It seems likely, therefore, that the hetero ring in the dioxide has less aromatic character than that in thianaphthene. The chemical evidence indicates that the 2–3 bond in thianaphthene-1-dioxide is olefinic in type, since it will add bromine,[8a,b] ethyl alcohol[8b] and hydrogen[8b] under conditions similar to those used for α-β-unsaturated sulfones.

The relative inertness of aryl halides in replacement reactions initiated by nucleophilic reagents has been ascribed[9] to the inability of the reagent to approach the carbon atom holding the halogen atom in such a way as to give a reasonable transition state, unless the Kekulé-type resonance is disrupted in the process. The activation of the halogen of aryl halides by substitution of *meta*-directing groups in *o*- and/or *p*-positions, is accounted for by increased resonance stabilization in the transition state. The fact that 2,4-dinitro-1-chloronaphthalene reacts about twenty times as rapidly with methoxide ion as does 2,4-dinitrochlorobenzene[10] is understandable since more structures can be written for the transition state in the naphthyl halide. The effective activation of the bromine atom in I and in 3-bromoindone has a similar explanation, since resonance structures of the type VII and VIII can be



VII VIII

written for the transition state of a displacement reaction involving the attack of the anion, A^-. The higher order of activity of the bromine atom in 3-bromoindone,[3] despite the greater electron attracting power of a sulfonyl group, can be accounted for by a smaller amount of resonance stabilization by structures such as VII due to the ten electrons around the sulfur atom.

Acknowledgment.—The authors wish to thank Professor Ralph Pearson for helpful suggestions.

Experimental[11]

3-Bromothianaphthene-1-dioxide (I).—A mixture of 8.0 g. (0.037 mole) of 3-bromothianaphthene,[2,12] 50 ml. of acetic anhydride and 50 ml. each of acetic acid and hydrogen peroxide (30%) was brought carefully to reflux temperature. The initial ebullition was very vigorous. The mixture was refluxed for one hour, 200 ml. of water was added, and the solution thoroughly cooled. By filtration there was obtained 6.5 g. (70.6%) of 3-bromothianaphthene-1-dioxide, m. p. 180–182°. The compound crystallized as short white needles from alcohol; m. p. 183.5–184°.

Anal. Calcd. for $C_8H_5O_2SBr$: C, 39.20; H, 2.06. Found: C, 39.07; H, 1.85.

3-(1-Piperidino)-thianaphthene-1-dioxide.—A mixture of 1.2 g. (0.005 mole) of I, 25 ml. of 85% alcohol and 1.3 g. (0.015 mole) of piperidine was refluxed for thirty minutes and cooled. There separated 1.20 g. (96%) of a yellow crystalline solid, m. p. (dec.) 223–227°. After three crystallizations from alcohol the material decomposed at 246° with gas evolution.

Anal. Calcd. for $C_{13}H_{15}O_2NS$: C, 62.23; H, 6.07. Found: C, 62.04; H, 5.85.

A similar reaction of I with diethylamine gave a 67% yield of **3-diethylaminothianaphthene-1-dioxide.** Crystallization from alcohol and twice from ethyl acetate gave long yellow needles, m. p. 186.5–187°.

(12) We wish to thank the Texas Company, Beacon, New York, for a generous supply of thianaphthene.

Anal. Calcd. for $C_{12}H_{15}O_2NS$: C, 60.73; H, 6.37. Found: C, 60.58; H, 6.46.

The reaction of I with butylamine gave 83% of **3-butylaminothianaphthene-1-dioxide**, which was obtained as fine white needles, m. p. 145°, after crystallization from methanol–water and twice from ethyl acetate.

Anal. Calcd. for $C_{12}H_{15}O_2NS$: C, 60.73; H, 6.37. Found: C, 60.91; H, 6.47.

The kinetic experiments[5] were run essentially by the method described by Spitzer and Wheland,[4] except that silver bromide was determined gravimetrically. In one hour 99% of the bromine was liberated from I and in one-fourth hour 97% of the theoretical amount of silver bromide was obtained.

Attempted Preparation of 3-(2-Pyridylamino)-thianaphthene-1-dioxide.—After refluxing an alcoholic solution of I and 2-aminopyridine for eighteen hours I was recovered unchanged. No reaction occurred when an alcoholic solution of I and aniline was refluxed for thirty minutes or when an alcoholic solution of I and 2-aminopyrimidine was refluxed for eighteen hours.

Refluxing a solution of I and 2-aminopyridine in phenol for three hours gave a very small amount of 3-phenoxythianaphthene-1-dioxide (properties reported below).

3-Aminothianaphthene-1-dioxide.—A mixture of 3.7 g. (0.015 mole) of I and 25 ml. of liquid ammonia was heated at 110° for one and one-half hours in a glass liner in a pressure vessel. After evaporation of the ammonia the product was washed from the liner with absolute ethanol. There was obtained 1.5 g. (53%) of a yellow powder which melted at 200–205° with the evolution of gas. The gas evolved by heating a small amount of the material in a shallow tube turned litmus paper blue. Purified from absolute ethanol, the material melted at 211–213°.

Anal. Calcd. for $C_8H_7O_2NS$: C, 53.03; H, 3.90; N, 7.73. Found: C, 53.22: H, 4.13; N, 7.25.

Hydrolysis of 3-Diethylaminothianaphthene-1-dioxide.—A mixture of 0.1 g. of 3-diethylaminothianaphthene-1-dioxide and 10 ml. of 10% sulfuric acid was refluxed for ten minutes. On cooling there separated 0.05 g. of 3-hydroxythianaphthene-1-dioxide, m. p. 132–133°. The most recent reference to this compound[13] gives the melting point as 133.5–134°. From a similar experiment with 10% potassium hydroxide the starting material was recovered almost quantitatively.

(13) Weston and Suter, THIS JOURNAL, **31**, 389 (1939).

3-Methoxythianaphthene-1-dioxide.—A solution of 2.45 g. (0.01 mole) of I and 0.56 g. (0.01) mole of potassium hydroxide in 30 ml. of dry methanol was refluxed one hour and cooled. By filtration there was obtained 1.5 g. (77%) of small white crystals, m. p. 208–210°. Several purifications from boiling ethanol gave large white flat blades, m. p. 220°.[14]

Anal. Calcd. for $C_9H_8O_3S$: C, 55.10; H, 4.11. Found: C, 55.11; H, 4.27.

An 84% yield of 3-methoxythianaphthene-1-dioxide was obtained in a somewhat less pure state by substituting sodium cyanide for potassium hydroxide in the above experiment.

3-Phenoxythianaphthene-1-dioxide.—A mixture of 2.45 g. (0.01 mole) of I, 1.0 g. (0.01 mole) of phenol and 0.56 g. (0.01 mole) of potassium hydroxide was dissolved in 20 ml. of absolute ethanol and the solution refluxed for one hour and cooled. The crude material melted at 110–124°. Several purifications from ethanol gave a small quantity of clear plates, m. p. 137°. The yield could undoubtedly be improved.

Anal. Calcd. for $C_{14}H_{10}O_3S$: C, 65.00; H, 3.87. Found: C, 64.80; H, 3.98.

Summary

1. Excellent yields of 3-alkylamino-, 3-amino- and 3-methoxythianaphthene-1-dioxides were readily obtained by the reaction of 3-bromothianaphthene-1-dioxide (I), respectively, with primary and secondary amines, anhydrous ammonia, and methanol in the presence of potassium hydroxide. Aryl amines did not react with I under comparable conditions.

2. The bromine atom in I was displaced at least four times as rapidly as that in *o*-nitrobromobenzene in the reaction with excess piperidine in benzene solution.

3. The reactivity of the bromine atom in I and related compounds is discussed on the basis of current theory.

Preparation and Polymerization of *m*-Cyanostyrene

BY RICHARD H. WILEY AND NEWTON R. SMITH

Many substituted styrenes, including *p*-cyanostyrene[1,2] and *o*-cyanostyrene[2] have been described in a number of recent papers[3] but no mention has been made of *m*-cyanostyrene. We have prepared *m*-cyanostyrene by the decarboxylation of *m*-cyanocinnamic acid. Poly-*m*-cyanostyrene resembles poly-*p*-cyanostyrene in that both are insoluble in aromatic hydrocarbons and are soluble in nitromethane. The principle of vinylogy which by reference to polyacrylonitrile predicts the insolubility of poly-*p*-cyanostyrene does not apply to the meta isomer. The relative insolubility of each is undoubtedly caused by the polarity of the cyano group but it is not possible, with the meta isomer, to relate this effect vinylogously to the behavior of the polyacrylonitrile.

Experimental

***m*-Cyanobenzaldehyde.**—*m*-Tolunitrile (Eastman Kodak Co.) was converted to the aldehyde by the procedure used in "Organic Syntheses" for the preparation of *p*-

bromobenzaldehyde.[4] Eight to ten hours were required to complete the bromination of the nitrile. The dibromide was hydrolyzed with calcium carbonate. The aldehyde was separated by steam distillation and, after cooling, was collected on a filter. The yield of dried *m*-cyanobenzaldehyde was 45%, m. p. 76–77°.[5]

m-Cyanocinnamic Acid.—The procedure of Walling and Wolfstirn[6] was followed. A solution of 48.0 g. (0.37 mole) of crude *m*-cyanobenzaldehyde and 42.5 g. (0.41 mole) of malonic acid (E.K. Co.) in 5 ml. of pyridine and 50 ml. of 95% alcohol was heated for ten hours on a steam-bath. The precipitate was collected and recrystallized from alcohol to give 45.3 g., 71.4% of the theoretical amount, of *m*-cyanocinnamic acid, m. p. 247° cor.

Anal. Calcd. for $C_{10}H_7NO_2$: eq. wt., 173.2; N, 8.08. Found: eq. wt., 174.5; N, 8.04, 8.09.

m-Cyanostyrene.—*m*-Cyanocinnamic acid was decarboxylated by the method of Walling and Wolfstirn.[6] To 125 g. of boiling quinoline and 2 g. of copper powder in a 250-ml. Claisen flask was added 40 g. of *m*-cyanocinnamic acid in 10-g. portions. Twenty five ml. of distillate was collected after each addition. The distillate was taken up in ether, extracted with 3 *N* hydrochloric acid, and dried over anhydrous sodium sulfate. After removing ether from the dried solution, the residue was fractionated to give 16.2 g., 51% of the theoretical amount, of *m*-cyanostyrene, b. p. 81–5° (3.5 mm.). Refractionation of 22 g. of crude styrene gave 19.6 g. of purified *m*-cyanostyrene, b. p. 83° (3.5 mm.), $n^{20}D$ 1.5630.

Anal. Calcd. for C_9H_7N: N, 10.85. Found: N, 11.03, 11.05.

The dibromide was prepared by adding bromine to a solution of *m*-cyanostyrene in carbon tetrachloride. The crystals obtained on evaporation of the carbon tetrachloride were recrystallized from alcohol, m. p. 71–72°.

Anal. Calcd. for $C_9H_7NBr_2$: N, 4.96. Found: N, 5.01.

Polymerization of m-Cyanostyrene.—A solution of 0.002 g. (*ca.* 0.1% by weight) of benzoyl peroxide in 1.71 g. of purified monomer was prepared in a test-tube, stoppered, and heated with protection from the air for twenty-four hours at 80° to form a hard, brittle, transparent, slightly yellow solid. A control without benzoyl peroxide did not polymerize. The polymer softens at 100°, sticks at 135°, and turns into a thick gum at 190°. It is soluble in nitromethane and acetone and swells in hot toluene and benzene. Relative viscosity 1.270 for concentration of 0.400 g. in 100 ml. of nitromethane; 2.835 for 2.000 g. in 100 ml. of nitromethane.

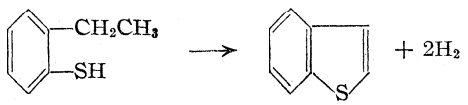
The Vapor Phase Catalytic Synthesis of Thianaphthenes

BY CORWIN HANSCH AND WILLIAM A. BLONDON

The synthesis of thianaphthenes from *o*-alkylbenzenethiols was undertaken in this Laboratory as a part of a general investigation of the vapor phase catalytic synthesis of hetrocyclic compounds. Preparation of thianaphthene itself was taken as the model reaction on which the catalysts and apparatus were developed. The following equation gives the over-all reaction.



The arylthiols used in this work were prepared from the corresponding hydrocarbons (ethylbenzene, *n*-propylbenzene, isopropylbenzene) by treating them with chlorosulfonic acid and reducing the resulting sulfonyl chloride with sulfuric acid and zinc dust. The pure sulfonylchlorides were not isolated, in fact the propylbenzenesulfonyl chlorides were found to be quite unstable to heat. Attempts to distill these compounds, even under reduced pressure, resulted in explosive decompositions.

The apparatus used in this work was similar to that described by Hoog, Verheus and Zuiderweg.[1]

(1) Hoog, Verheus and Zuiderweg, *Trans. Faraday Soc.*, **35**, 995 (1939).

Experimental

Catalyst Preparations. I. Chromium on Aluminum Oxide.—To a boiling solution of 36.4 g. of chromic anhydride in 400 ml. of distilled water, was added 200 g. of ALORCO alumina,[2] H-40 Grade R2200, 8–14 mesh. The solution was allowed to stand for two minutes and filtered, then the product was dried at 100°.

II. **Molybdenum Sulfide.**—One hundred grams of alumina was added to a boiling solution of 60 g. of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ in 200 ml. of distilled water. The mixture was allowed to stand for a few minutes and then a rapid stream of hydrogen sulfide was passed into the catalyst for twenty minutes. The catalyst was filtered, washed repeatedly with water and dried at 100°.

III. **Platinum on Charcoal.**—To 75 ml. of distilled water was added 5 g. of chloroplatinic acid containing 40% platinum. The solution was heated to boiling and 12 g. of activated charcoal[3] was added. This mixture was boiled for five minutes and then the catalyst was filtered and dried at 100°.

Preparation of Ethylbenzenethiol.—To 2300 g. of chlorosulfonic acid, cooled to 0° in an efficient ice-bath, 652 g. of ethylbenzene was added, with stirring. The temperature of the mixture was held at 0° during the addition, after which the reaction mixture was stored in a refrigerator at 0° for eighteen hours. After this period of standing, the product was poured, with vigorous stirring, onto 6 liters of crushed ice. The lower oily layer was then separated and divided into three equal portions to facilitate reduction.

(2) This type of alumina was used exclusively in this research.

(3) The activated charcoal used in this work was Type B15P, 6–8 mesh, obtained from the Pittsburgh Coke & Chemical Co.

Three 5-liter round-bottom flasks were fitted with efficient stirrers and surrounded with ice–salt mixtures. Into each flask was placed 4 liters of crushed ice and 1300 g. of concd. sulfuric acid. When the temperature of this mixture had reached 0°, the sulfonyl chloride was allowed to drop into the mixture, with rapid stirring. After the addition of the sulfonyl chloride, 650 g. of zinc dust was added to each flask in small portions so that the temperature never rose above 5°. When all of the zinc had been added, the flasks were fitted with reflux condensers and permitted to come to room temperature slowly. After the initial evolution of hydrogen had ceased, the reaction mixtures were boiled for six hours. The upper oily layer was then separated, washed and dried. Distillation gave 621 g. (68%) of *o*-ethylbenzenethiol, b. p. 207–209° (730 mm.).

o-Propylbenzenethiols.—*o,n*-Propylbenzenethiol and *o*-isopropylbenzenethiol were synthesized by the above procedure, giving 76% yield of the former, b. p. 219–221° (730 mm.) and 70% yield of the latter, b. p. 225–227° (730 mm.).

	Calcd. C, %	Calcd. H, %	Found C, %	Found H, %
Ethylbenzenethiol	69.50	7.25	69.50	7.59
n-Propylbenzenethiol	71.05	7.89	70.96	7.97
Isopropylbenzenethiol	71.05	7.89	71.03	7.89

α-(o-Carboxyphenylmercapto)-propionic Acid.—In 300 ml. of boiling water were dissolved 10 g. of anhydrous sodium carbonate and 20 g. of *o,o'*-dithiodibenzoic acid.[4] When all of the acid had dissolved, 30 g. of sodium hydrosulfite was added slowly, with stirring. The reactants were refluxed for fifteen minutes and then cooled to room temperature. To this cooled solution was added 49 g. of α-bromopropionic acid (previously neutralized with sodium bicarbonate) in 150 ml. of water. This mixture was boiled for fifteen minutes and then acidified to congo red paper while hot. On cooling, the α-(*o*-carboxyphenylmercapto)-propionic acid crystallized and was filtered and dried; yield 20 g. Recrystallization from 700 cc. of boiling water gave 15 g. of product, m. p. 192–194° (dec.).

2-Methylthianaphthene.—Ten grams of α-(*o*-carboxyphenylmercapto)-propionic acid, 5 g. of anhydrous sodium acetate and 25 ml. of acetic anhydride were placed in a round-bottom flask and slowly warmed to 75°, at which temperature the evolution of carbon dioxide began. After the gas evolution had subsided somewhat, the temperature was raised to 140° and held there for twenty minutes. Excess 50% sodium hydroxide was then added and the solution refluxed for one hour. It was then acidified with phosphoric acid and steam-distilled, giving a yellow oil: 2-methyl-3-thianaphthenol. Five grams of this oil was dissolved in 50 ml. of acetic acid, the resulting mixture being refluxed for two hours with 10 g. of zinc dust, then made basic with sodium hydroxide and steam-distilled. About 1 g. of a water-white oil distilled and solidified on cooling; m. p. 42–47°. Recrystallization from an alcohol–water mixture gave a product which melted at 51–52°.

Anal. Calcd. for C_9H_8S: C, 72.96; H, 5.41. Found: C, 72.73; H, 5.90.

2-Methylthianaphthene, formed by catalytic dehydrogenation of *o*-isopropylbenzenethiol, possessed the same melting point. A mixed melting point of the two substances showed no depression. Both preparations yielded picrates; m. p. 108–109°.

Anal. Calcd. for $C_{15}H_{11}N_3O_7S$: C, 47.75; H, 2.92. Found: C, 47.90; H, 3.28.

Catalytic Preparation of Thianaphthene.—The following is an example of a typical dehydrogenation run made in this research, using *o*-ethylbenzenethiol and chromium on alumina (I) catalyst. Ten milliliters of catalyst (I) was reduced *in situ* with a slow stream of hydrogen at a temperature of 400° for one hour, after which the catalytic tube was swept free of hydrogen with a stream of nitrogen. Then, 82 g. of *o*-ethylbenzenethiol was passed over the catalyst during a period of two hours. The temperature of the catalyst was held at 475 ± 3° during this reaction. The condensate (72 g.) was extracted with dilute sodium hydroxide, and by this means 4.5 g. of unchanged mercaptan was recovered. The alkali insoluble portion was distilled through a 1.5 ft. column using a variable take-off head with a reflux ratio of 5 to 1. Twenty-six grams boiled at 132–140° and was identified as mainly ethylbenzene. The 5 g. distilling at 140–210° was ethylbenzene with some thianaphthene. Twenty-two grams, which distilled between 210–230°, solidified on cooling; m. p. 22–24°. Crystallization from alcohol gave a product, m. p. 31–32°, the temperature at which thianaphthene melts.

Catalytic Preparation of 2-Methylthianaphthene.—2-Methylthianaphthene was prepared in the same manner, using 10 ml. of chromium oxide catalyst. Thirty grams of *o,n*-propylbenzenethiol was processed at 450° during a one-hour period, yielding 8 g. of oil insoluble in dilute sodium hydroxide. Fourteen grams of unchanged mercaptan was recovered. Distillation of the alkali insoluble fraction gave 3 g., b. p. 220–265°. This fraction was heated under reflux with 0.5 g. of sulfur for four hours to dehydrogenate any dihydromethylthianaphthene, then steam-distilled from an alkaline solution. The white solid collected was crystallized from alcohol; yield 1.6 g., m. p. 51–52°.

Attempted Catalytic Preparation of 3-Methylthianaphthene.—*o*-Isopropylbenzenethiol (65 g.), processed over 10 ml. of catalyst (I) at a temperature of 425° during a ninety-minute period, yielded 16 g. of isopropylbenzene and 7.5 g. of a substance which distilled at 235–250°. Fifteen grams of unchanged thiol was recovered. Considerable decomposition occurred on the catalyst. Attempts to purify the material boiling at 235–250°, by crystallization of its picrate, were unsuccessful. A sharp melting point could not be obtained with the picrate in spite of repeated crystallizations from various solvents. Attempts to crystallize the thianaphthene itself were also unsuccessful.

Discussion

It should be pointed out that although over fifty runs were made (mostly with *o*-ethylbenzenethiol) using various catalysts and conditions, the authors feel that by continued study the yield of thianaphthenes could be improved. It has been shown recently,[5] however, that thianaphthene may be made in good yield by the vapor phase catalytic reaction of styrene and hydrogen sulfide. Preliminary work in this Laboratory has shown that ethylbenzene and hydrogen sulfide may be catalytically converted into thianaphthene. At present, work is in progress to develop a general method of synthesis from alkylbenzenes and hydrogen sulfide.

The catalysts employed in this work which were at all effective were: chromium oxide on alumina (I), molybdenum sulfide on alumina (II), platinum on charcoal (III), and type J-2 dehydrogenation catalyst obtained from Universal Oil Products. Of the above catalysts, the platinum was the least effective because of rather rapid poisoning. The molybdenum sulfide, although effective in cyclization and resistant to poisoning, was not practical because of its great tendency to desulfurize the thiols to the corresponding hydro-

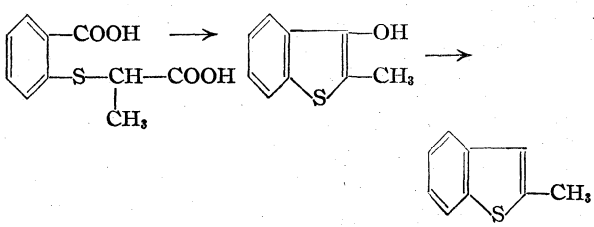
carbons. Apparently, hydrogen, formed during the dehydrogenation, reacted with the thiols to convert them to hydrocarbons and hydrogen sulfide. This side reaction occurred with all catalysts used but was most pronounced with molybdenum sulfide. The best catalyst found in this work was chromium oxide (I), although the J-2 catalyst from Universal Oil Products was almost as active.

Table I summarizes below the results of a series of comparable runs, and shows the effect of temperature and space velocity on the dehydrogenation of *o*-ethylbenzenethiol, using chromium on alumina catalyst (I).

TABLE I

Temp., °C.	Space vel., ml./ml. cat./hr.	% Conversion to thianaphthene
350	600	10
400	600	32
450	800	42
500	600	35
450	1500	28
450	900	40
450	800	42
450	200	42

In an attempt to extend the reaction to other alkylbenzene thiols, several runs were made using *o,n*-propylbenzenethiol. Conversions of 10–12% of 2-methylthianaphthene were obtained. Since its synthesis had not been reported previously, this compound was prepared by a known procedure[6] to check its identity.



The 2-methylthianaphthene prepared catalytically was identical with that made by the method illustrated.

The ultraviolet absorption spectrum determined for 2-methylthianaphthene followed closely that of thianaphthene (Fig. 1), with maxima at 288.5 and 297 mμ, and a minimum at 299 mμ. The absorption spectrum for thianaphthene was in close agreement with that previously reported,[7] with maxima at 288 and 297.5 mμ, and a minimum at 295 mμ. All of the absorption measurements were made with methanol solutions at dilutions of 1/100,000, by means of a Beckman quartz spectrophotometer.

An attempt to prepare 3-methylthianaphthene was not completely successful. A liquid was obtained which had the expected boiling point, but attempts to purify it by distillation or crystallization of the picrate were unsuccessful. It is interesting to note that this substance possessed an absorption spectrum (Fig. 1) closely resembling that of thianaphthene and 2-methylthianaphthene.

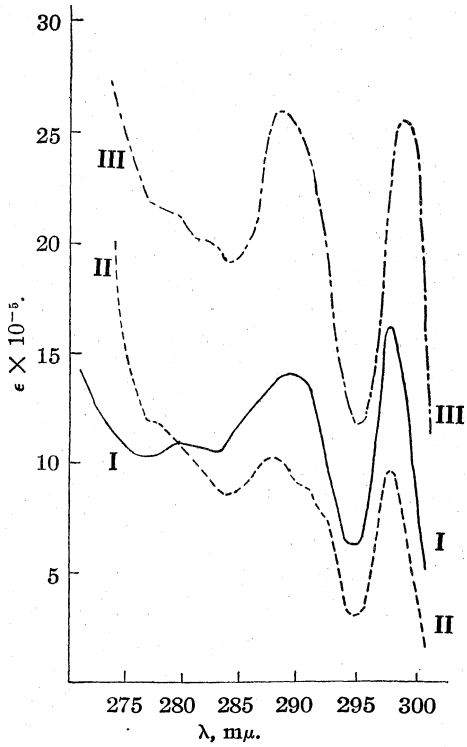

Fig. 1.—Ultraviolet absorption spectra of thianaphthene and 2-methylthianaphthene:

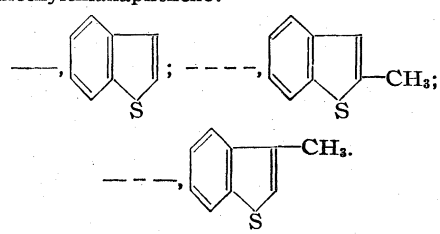

Acknowledgment.—The authors are very much indebted to the Research Corporation for a Frederick Gardner Cottrell grant-in-aid which supported this research. We also wish to acknowledge a generous gift from the Signal Oil Company which made possible the purchase of the Beckman spectrophotometer used in this work.

Summary

1. The preparation of two new alkylbenzenethiols is described.

2. A study of the cyclodehydrogenation of the thiols to the corresponding thianaphthenes is discussed.

3. The ultraviolet absorption spectra are reported for the thianaphthenes.

4. A special synthesis for 2-methylthianaphthene is reported.

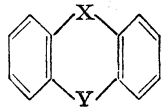
The Use of Fluoro Compounds in the Determination of Valency Angles by Electric Dipole Moment Measurements

BY NELSON J. LEONARD AND LESLIE E. SUTTON

Our initial aim in this investigation was to determine bond angles from electric dipole substitution, using methods previously developed[1,2,3,4] but using fluorine as the substituent atom. Evaluations of the interaction moments between halogens and the NH_2- or CH_3O- grouping indicated that these are least with fluorine,[5] and therefore that this cause of error in bond angle determinations should be least if fluorine is used. Our results caused us to investigate more thoroughly the magnitudes of such interaction moments in fluorine compounds, and to compare them with those for other halogens.

We applied information so obtained about bond angles in the discussion of the configuration of molecules of the type I, when X and Y are divalent atoms or groups, *e. g.*, O, S, Se, NH, and we augmented the dipole moment data for such compounds by measuring phenoxthine and phenthiazine.



I

Experimental

Preparation and Purification of Materials.—Benzene (British Drug Houses "AnalaR") was purified by freezing three times, boiling under reflux over phosphorus pentoxide, and finally distilling in a dry air stream. It was stored under dry air until used.[2] Diphenylamine (B. D. H.) was recrystallized four times from dry petroleum ether (b. p. 40–60°), m. p. 53°. Di-*p*-tolylamine (B. D. H.) was recrystallized twice from dry petroleum ether, m. p. 79°.

The following compounds were prepared by methods previously described: fluorobenzene,[6] *p*-fluoroaniline,[7] *p*-fluoroanisole,[8] *p*-fluorobenzaldehyde,[9] *p*-fluorobromobenzene,[10] *p*-fluoronitrobenzene,[11] *p*-fluorobenzophenone,[13] *p*-fluorophenol,[12] *p*-fluorotoluene,[11] *p,p'*-difluorobenzophenone,[13] phenyl-*p*-tolylamine,[14] phenyl-*p*-tolylnitrosamine, m. p. 82°,[15] di-*p*-tolylnitrosamine, m. p. 100–101°,[15] phenoxthine,[16] phenthiazine,[17] and triphenylamine.[18]

The compounds described below are, with one exception, new compounds, prepared specifically for the presently described dipole moment investigation.

***p*-Fluorodimethylaniline.**—This compound had previously been prepared by Schiemann and Pillarsky[19] from *p*-aminodimethylaniline, but a better yield was obtained by methylation of *p*-fluoroaniline. A mixture of 20 g. of dimethyl sulfate and 17 g. of *p*-fluoroaniline was sealed in a pressure tube and heated at 200° for one hour. The oily product was treated with aqueous sodium hydroxide and the resultant mixture was extracted with ether. After drying the ethereal solution, the ether was removed and the residue was distilled *in vacuo*, b. p. 86–87° (18 mm.), 79.5° (16 mm.); yield, 15 g. (71.5%).

***p*-Fluorodiphenyl Ether.**—A method similar to that used for *p*-tolyl- and di-*o*-tolyl ether by Reilly, Drumm and Barrett[20] was employed. A mixture of 12 g. of potassium *p*-fluorophenoxide, 12 g. of bromobenzene, and 0.5 g. of copper–bronze was heated at 200° for four hours under an air condenser. The product was subjected to steam distillation and the distillate was extracted with ether. The ethereal solution was dried and the ether was removed. The liquid residue was fractionated at atmospheric pressure. The portion boiling above 200° was retained and twice fractionated. Seven grams (47%) of colorless liquid, b. p. 247–249° (760 mm.), was finally collected.

Anal. Calcd. for $C_{12}H_9FO$: C, 76.59; H, 4.79. Found: C, 76.25; H, 4.82.

***p,p'*-Difluorodiphenyl Ether.**—Twelve grams of potassium *p*-fluorophenoxide, 15 g. of *p*-fluorobromobenzene, and 0.5 g. of copper–bronze were mixed and the mixture was heated under reflux for six hours at 200°. The product was isolated by the same method as employed for *p*-fluorodiphenyl ether. The colorless liquid boiled at 239–240° (743 mm.); yield, 9.0 g. (56%).

Anal. Calcd. for $C_{12}H_8F_2O$: C, 69.88; H, 4.01. Found: C, 70.08; H, 3.94.

***p*-Fluorodiphenyl Sulfide.**—A method similar to that used by Mauthner[21] for analogous sulfides was employed. Fourteen grams of potassium thiophenoxide, 29 g. of *p*-fluoroiodobenzene, and 0.5 g. of copper–bronze were heated together under reflux at 235–240° for four hours. The reaction product was treated with warm ethanol and acidified with dilute sulfuric acid. After the addition of zinc dust, the mixture was steam-distilled. The distillate was extracted with ether, the ethereal solution was dried and the ether was removed. The colorless product was distilled once with fractionation at atmospheric pressure, then twice at reduced pressure, b. p. 147–148° (15 mm.), 141–142° (11 mm.); yield, 18 g. (66%).

Anal. Calcd. for $C_{12}H_9FS$: C, 70.58; H, 4.44. Found: C, 70.25; H, 4.35.

***p,p'*-Difluorodiphenyl Sulfoxide.**—This compound was prepared successfully by the method which Colby and McLoughlin[22] used for diphenyl sulfoxide. Sixty grams of fluorobenzene and 16 g. of thionyl chloride were mixed in

an ice-cooled flask to which a reflux condenser was attached. Anhydrous aluminum chloride was added in small portions; hydrogen chloride ceased to be evolved after 40 g. had been added. The mixture was heated on a water-bath for thirty minutes, after which it was cooled and poured into ice-water. The thick oil which separated on the surface was washed with water and was then heated to remove excess fluorobenzene. A yellow, wax-like solid remained which was recrystallized three times from petroleum ether (b. p. 40–60°). A yield of 23 g. (72%) of colorless crystals, m. p. 50.5°, was obtained.

Anal. Calcd. for $C_{12}H_8F_2OS$: C, 60.47; H, 3.39. Found: C, 60.26; H, 3.55.

p,p'-Difluorodiphenyl Sulfide.—This compound was prepared by a method analogous to that of Gazdar and Smiles[23] for di-*p*-cresol sulfide. *p,p'*-Difluorodiphenyl sulfoxide (17 g.) was boiled for four hours under reflux with 6 g. of powdered zinc in glacial acetic acid. When the filtered solution was diluted with water, the sulfide separated as a colorless oil, which was twice fractionally distilled *in vacuo*, b. p. 136–137° (9 mm.); yield, 15 g. (90%).

Anal. Calcd. for $C_{12}H_8F_2S$: C, 64.83; H, 3.63. Found: C, 64.71; H, 3.51.

p,p'-Difluorodiphenyl Sulfone.—*p,p'*-Difluorodiphenyl sulfide (5 g.) was dissolved in a ten-fold quantity of glacial acetic acid and oxidized with 3 g. of potassium permanganate. After dilution of the reaction mixture with water, the precipitate was twice recrystallized from ethanol as colorless needles, m. p. 98–98.5°; yield, 4 g. (80%).

Anal. Calcd. for $C_{12}H_8F_2O_2S$: C, 56.67; H, 3.17. Found: C, 56.34; H, 3.18.

p-Fluorodiphenyl Sulfone.—This compound was prepared in the same manner, using 8.5 g. of *p*-fluorodiphenyl sulfide, 80 g. of glacial acetic acid, and 6 g. of potassium permanganate. After dilution of the reaction mixture with water, the precipitate was twice recrystallized from ethanol as colorless needles, m. p. 109.5–110°; yield, 6 g. (70%).

Anal. Calcd. for $C_{12}H_9FO_2S$: C, 60.98; H, 3.84. Found: C, 60.97; H, 3.76.

p-Fluorodiphenylamine.—This compound, b. p. 164–166° (17 mm.), m. p. 34°, was made from *p*-fluoroacetanilide and bromobenzene essentially by the method of Goldberg,[24] which is general for the preparation of diarylamines.

Anal. Calcd. for $C_{12}H_{10}FN$: C, 76.99; H, 5.38. Found: C, 76.89; H, 5.32.

p,p'-Difluorodiphenylamine.—This compound, b. p. 165–166.5° (17 mm.), m. p. 37.5°, was likewise prepared from *p*-fluoroacetanilide and *p*-fluorobromobenzene by the general method of Goldberg.[24]

Anal. Calcd. for $C_{12}H_9F_2N$: C, 70.24; H, 4.40. Found: C, 70.37; H, 4.46.

p-Fluorotriphenylamine.—A method similar to that for triphenylamine[18] was employed. A mixture of 8 g. of diphenylamine, 13 g. of *p*-fluoroiodobenzene, 8 g. of potassium carbonate, and 2 g. of copper–bronze in 50 ml. of nitrobenzene was boiled under reflux for ten hours. The nitrobenzene was removed by steam distillation and the residue was extracted with benzene. The benzene extract was dried by partial distillation of benzene, saturated with dry hydrogen chloride gas in the cold, and allowed to stand for three hours. The precipitated diphenylamine hydrochloride was removed by filtration and the benzene by distillation. The residue was distilled under reduced pressure, b. p. 187–189° (8 mm.), when the distillate solidified. Three recrystallizations from ethanol, followed by centrifuging and drying, gave 7 g. (60%) of colorless needles, m. p. 98–98.5°.

Anal. Calcd. for $C_{18}H_{14}FN$: C, 82.09; H, 5.32. Found: C, 82.22; H, 5.31.

(24) Godberg, *Ber.*, **40**, 4541 (1907).

Physical Measurements.—Electric dipole moments were determined from measurements of the dielectric constant, refractive index and density of benzene solutions of varying concentration at the same temperature. Dielectric constants were determined by a heterodyne beat method using an apparatus and a technique essentially the same as described before.[2,25] The solution condenser was similar to that described by Jenkins and Sutton.[26]

Densities were determined with a 10-ml. Sprengel–Ostwald pyknometer.

Refractive indices were measured relative to the solvent with a Pulfrich refractometer fitted with a divided cell; the mercury green line (5461 Å.) was used for illumination. For three of the compounds (fluorobenzene, *p*-fluorodiphenyl sulfide, and *p*-fluorotriphenylamine) it was not possible to obtain the molecular refractivities experimentally, due to temporary instrumental disorder, but they were calculated from the most acceptable values for the refractivities of the constituent atoms.

The dielectric constant of pure dry benzene was taken to be 2.2727 at 25°, that of dry air 1.0000. The square of the refractive index of pure dry benzene at 25° was taken to be 2.25714.

Atom polarizations, for the moments recorded in Table I, were allowed by adding 5% to the electron polarization.

Results

All measurements are in benzene solution at 25°. Moments are expressed in Debye units (1 D = 10^{-18} e. s. u.).

[a] The values of θ are derived from dipole moments based on an allowance for ${}_AP = 5\%_EP$. [b] Very sensitive to changes in the value of μ_0; 3.97 used for this calculation. [c] The angle ω, between the unsubstituted moment μ_0 and the perpendicular to the plane of the benzene rings,[1] is 16°. [d] The angle between the N-phenyl bond and the axis of symmetry in triphenylamine is $\phi = \cos^{-1}(\mu_T^2 - \mu_0^2 - \mu_s^2)/2\mu_0\mu_s$; $\sin\theta/2 = \sqrt{3/2}\sin\phi$, where θ is the C–N–C angle.

Discussion

From the preceding data, we evaluated the valence angles in diphenyl ether, sulfide, sulfoxide, sulfone, ketone, amine and in triphenylamine. In Table II are given the results when interactions between the central group and the substituent group or groups are ignored. In Table III are the angle values corrected for these, together with the interaction moments themselves. These will be discussed *seriatim*.

TABLE III

C–X–C ANGLES, CORRECTED FOR INTERACTION MOMENTS

		$d_1\mu_s = d_2\mu_s$		$d_1\mu_s = 2d_2\mu_s$	
${}_AP = 5\%_EP$	X	θ	$d_2\mu_s$	θ	$d_2\mu_s$
Diphenyl ether	O	117°	0.11	115°	0.07
Diphenyl sulfide	S	106°	.17	103°	.12
Diphenyl sulfone	SO_2	93°	− .16	106°	.08
Benzophenone	CO	128°	− .06	132°	.04

The value of 115–117° calculated for ∠C–O–C in diphenyl ether is lower than the value 124 ± 5° obtained by Coop and Sutton[4] from measurements on bromo derivatives in the gas-phase, but agrees well with the value of 118 ± 3° ascribed by Maxwell, Hendricks and Mosley[36] from an electron diffraction investigation. The probable range may be given as 115–124°. This is distinctly greater than the values for ∠C–O–C in aliphatic compounds, *viz.*, 111 ± 4° in dimethyl ether[37] and 108° in 1,4-dioxane.[38] The earlier differentiation[3] between the aromatic and the aliphatic ethers is therefore confirmed and its explanation in terms of resonance may still be regarded as valid.

The value of 103–106° found for ∠C–S–C in diphenyl sulfide is also lower than the earlier value, 113 ± 3° from the dipole moments of the *p*-chloro- and *p*-methyl-derivatives.[3] Toussaint,[39] from an X-ray investigation of the *p,p'*-dibromo-derivative, has obtained a value 109.5 ± 0.5°. In aliphatic compounds, the values reported for ∠C–S–C are, in dimethyl sulfide 100°[40] and 100–110°,[41] in 1,4-dithian 100°,[38] in *sym*-trithian 106.5°,[38] and in α- and β-trithioacetaldehyde also 106.5°.[38] The angles in this case are not, therefore, clearly different in the aromatic and aliphatic compounds, so there is no conclusive evidence from this source for resonance between the normal structure for diphenyl sulfide and others with positive, tricovalent sulfur. Toussaint[39] reports, however, that the C–S distance is 1.75 Å., *i. e.*, that it is shorter than the sum of the covalent radii (1.81 Å.) and that it therefore indicates some resonance of the type mentioned.

The value for ∠C–S–C in diphenyl sulfoxide (Table II) cannot be regarded as accurate since it is very sensitive to the moment value taken for diphenyl sulfoxide itself.

That in diphenyl sulfone, of 93–106°, or more probably 100–104°, is in good agreement with the 100° reported by Toussaint[39] from an X-ray diffraction examination of the *p,p'*-dibromo-derivative, though less than the 109° reported by Bergmann and Tschudnowsky.[42] Toussaint's value for the C–S distance is 1.84 Å., which should be compared with that of 1.90 Å. found by Lister and Sutton[43] in dimethyl sulfone. There is, therefore, some evidence of conjugation between the phenyl groups and the SO_2-group. Toussaint observes that the benzene rings are turned into planes at right angles to the C–S–C plane, but Koch[44] has

	O	S	0.34	0.53	0.83	1.10	1.35	1.54	1.70	1.83
	S	S	0	0.46	0.87	1.19	1.49	1.71	1.92	2.10
	S	NH	1.75	1.86	2.00	2.08	2.15	2.20	2.24	2.28
	Se	Se	0	0.42	0.80	1.12	1.39	1.60	1.82	1.92
	Te	Te	0	0.33	0.66	0.94	1.17	1.35	1.50	1.61

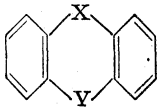
suggested that this need not necessarily preclude resonance between them and the SO_2-group.

The large angle, 128–132°, calculated in benzophenone agrees with that of 131–133° derived by Sutton and Hampson[3] (*cf.*, however, Coomber and Partington,[45] who consider 125 ± 3° to be more accurate, from considerations of interaction), and with the 135° reported by Banerjee and Jaque.[46] It is a clear indication that there is resonance involving structures with double bonds between the benzene rings and the carbonyl group.

The value of 113° for ∠C–N–C found in diphenylamine and that of 114° in triphenylamine are probably real, and they are larger than the value observed in trimethylamine, 108 ± 4°, by Brockway and Jenkins.[41] The inference is that, in accordance with the expectations of current theory, there is resonance involving structures with the grouping $\overset{+}{\diagdown\!\!\diagup}\!\!\mathrm{N}\!\!\diagdown$, but that neither molecule is coplanar.

Some moment values for N-nitrosodiphenylamino compounds were determined (Table I) in the hope that this group might be sufficiently rigid for the treatment applicable to diphenylamine to be suitable. The C–N–C angle calculated is, however, unreal, so the configuration of the N-nitroso group is evidently not simple. It is interesting to note that phenyl-*p*-tolylnitrosamine has a moment 3.59 D nearly equal to that of N-nitrosomethylaniline (3.62 *D*).[34]

The moments of molecules of type I have been measured by various authors and have been dis-



I

cussed in relation to the folding of the molecule along the X-Y line.[3,31,42,47,48,49,50] It is possible to show that the moments calculated when X = Y

TABLE IVb

OBSERVED MOMENT VALUES IN COMPOUNDS OF TYPE I

X	*Y*	$\mu_{obs.}$			
O	O	0.64[50]	0[51]		
O	S	0.92[52]	1.09[50]		
S	S	1.68[42]	1.41[53]	1.54[54]	1.57[47]
S	NH	2.13[52]			
Se	Se	1.41[47]			
Te	Te	...			

are close to those observed if it be assumed that the angle C–X–C is approximately the same in these compounds as in C_6H_5–X–C_6H_5, that the moments of the C–X–C segments are likewise equal to those of the diphenyl compound, and that the valences of carbon in the benzene rings are all coplanar and at 120° to each other.[47,50] This treatment may be extended to the case where X ≠ Y by taking a common mean value for both angles.

In Table IVa, β is the angle C–X–C or C–Y–C in the tricyclic compound, 2α is the supplement of the angle between the benzene ring planes, ω is the angle between the C–X–C (or C–Y–C) segment and the X–Y line; $\mu_{calcd.}$ is the moment evaluated on the preceding assumptions for various values of β. For the particular case of phenthiazine, we assumed that ω is 90° for the C–NH–C segment. In Table IVb, the observed values ($\mu_{obs.}$) are given.

By comparison of these two tables, we see that agreement between calculated and observed values of the moments is obtained for the following values of β:

TABLE V

X	*Y*	β	180–2α
O	O	117–120°	160–180°
O	S	113–116°	150–160°

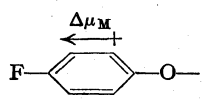
[a] Calculated by the method of Marsden and Sutton.[5] A negative value is one with its negative end away from the halogen atom. Moment values derived from the "Table of Dipole Moments" of Sidgwick and collaborators (*Trans. Faraday Soc.*, 30, 1934) are: for toluene, 0.40; phenol, 1.61; aniline ($\theta_2 = 56°$), 1.53; anisole ($\theta_2 = 76°$), 1.23; dimethylaniline ($\theta_2 = 38°$), 1.58; nitrobenzene, 3.95; chlorobenzene, 1.56; bromobenzene, 1.52; iodobenzene, 1.30. [b] Series of Marsden and Sutton[5] recalculated. [c] Calculated simultaneously with bond angles.

pected, because the conditions which determine them are somewhat different in the two cases. The value which we derive for 180-2α in thianthrene, *ca.* 140°, is the same as that reported by Wood and Crackston,[55] from X-ray investigations. We find that 180-2α in selenanthrene also is *ca.* 140°, a value which agrees with the earlier one of Wood and Crackston, but which is higher than the revised one of 127° given by Wood and Williams.[56]

The phase-rule investigations made by Cullinane and Plummer[57] agree with there being a marked difference of configuration between diphenylene dioxide on the one hand and either thianthrene or selenanthrene on the other; likewise, Cullinane and Rees[58] find evidence of a difference between diphenylene dioxide and phenoxthine and a similarity between phenoxthine and phenthiazine.

The interaction moments between the substituent atoms and the central atoms in the ether and sulfides are perhaps less when fluorine is used (Table III) than when chlorine is used (Table VI), and, as expected, they are certainly less than with bromine. The sign of the interactions is such as to indicate that when fluorine is substituted *para* to the phenoxy group, the mesomeric moment of the former is diminished (see diagram II). According to the sign convention adopted (see Table VI) this is termed a positive change.

Examination of the interaction moments of halogens with other groups in *para* positions shows that they are less positive (using the preceding



II

convention) the less polarizable the halogen, and are actually negative for fluorine. Therefore, although there is a difference between the actual sign for the interaction moments in the fluoro-substituted diphenyl ethers or sulfides and those in the other fluoro compounds listed, the algebraic changes in these moments, as the polarizability of the halogen increases, are the same.

Groves and Sugden[59] showed that the mesomeric effect of the fluorine atom is such that it drives electrons into the benzene ring and that it does this to a greater extent than does any other halogen. Our results show that fluorine has unique power to suppress the mesomeric effect of groups *para* to it if they conflict with its own.

This mesomeric effect of fluorine with benzene has been attributed to resonance between the structure with neutral monovalent fluorine and others with positive divalent fluorine (III) (*vide, e. g.*, Kenner[60]). In view of the great electronegativity of fluorine and its unwillingness to form single dative bonds, some doubts have been ex-

III

pressed about the validity of this explanation.[61] We suggest that an alternative should be considered, in which it is not necessary to postulate a change in multiplicity of the C–F bond, nor a positive charge on fluorine. The general problem is to discover the most stable state possible for the whole molecule, and this means discovering the most favorable electron distribution. It seems improbable that this will involve a considerable reduction in electron density around the fluorine atom; rather the reverse. Now, if we suppose that the key to the problem is that the electron density around the fluorine atom shall be increased, it is possible to propose a means by which this may happen, by which the C–F bond may be shortened and strengthened, and by which electrons may be driven into the benzene ring.

The carbon and fluorine atoms have some permitted range of atomic orbitals available for bond

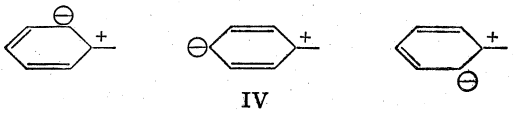
formation. These would vary in the degree of overlap which they would give in the bond, and therefore in the concentration of the negative cloud charge which they would give between the nuclei. At large internuclear distances, the orbitals giving greatest overlap would be least favored because they would require the removal of the negative centroid somewhat from each nucleus. If, however, either or both the atoms have high electronegativities, the high axial concentration resulting from these orbitals would increase stability, because the positive nuclei would be better shielded from each other, *i. e.*, the nuclei would be better "cemented" together, so they could approach more closely, the electrostatic potential energy of the system would be reduced, and accordingly, the total energy would also be lowered. There might, in fact, be opposing tendencies: on the one hand, for the electrons to remain held in the configurations which are best in the fields of the separate nuclei, and on the other hand, for them to move from these into others that are most favorable in the joint, binuclear field. We think it possible that in the C–F link a considerable degree of such redistribution might occur, with the results indicated, *viz.*, a shortening and strengthening of the C–F bond and a reduction in its dipole moment. Furthermore, if the bond shortens, the density of electronic charge on the carbon atom might actually increase, with the result that electronic distributions in the neighborhood might be repelled; *i. e.*, driven into the nucleus. If this field effect occurs by resonance with polar structures (IV) (as has previously been postulated[62]) the appearance of *o,p*-direction in fluorobenzene might be expected.



IV

Summary

The valence angles (C–X–C) in diphenyl ether, sulfide, sulfone, ketone, amine and in triphenylamine have been determined from the dipole moments in benzene solution of the unsubstituted and the *p*-fluoro-substituted compounds. They are, in the same order: 116 ± 4°, 106 ± 4°, 102 ± 4°, 130 ± 4°, 113 ± 3° and 114 ± 3°. The relation of these to other reported values, and their significance, have been discussed.

The moments of phenoxthine and phenthiazine have also been measured. They are 0.92 and 2.13 *D*, respectively. These agree with angles of 155 ± 5° and 145 ± 5° between the planes of the benzene rings, the molecules being folded along the OS and NS lines.

The moments resulting from the interaction between fluorine atoms substituted on benzene, with other groups *para* to them, show that fluorine has unique power to suppress mesomeric effects which conflict with its own.

The origin of the mesomeric effect in fluorobenzene has been discussed.

Search for Elements 94 and 93 in Nature. Presence of 94^{239} in Pitchblende[1]

BY GLENN T. SEABORG AND MORRIS L. PERLMAN[1a]

The discovery[2] of a rather easily prepared form of radioactive element 94 and the subsequent determination of the chemical properties[3] of 94 with the help of this isotope as tracer make it possible to conduct a search for 94 in natural minerals. It is convenient to search for 93, whose chemical properties[3,4] are also known, at the same time. The hope would be to discover a very long-lived 94 or 93 and that this be present in an amount large enough so that useful quantities should be extracted from the minerals. Alpha and beta radioactivity is to be tested for in the final very thin sample which, in view of the chemical procedure, would contain the 94 or 93. In case the 94 or 93 is not alpha or beta active, a test for fissions with neutrons should be made since it appears likely that any isotopes of these elements will undergo fission either with slow or with fast neutrons. The presence of an amount of the order of one microgram can be established by the neutron tests; therefore, starting with about 1 lb. of the pitchblende, the sensitivity for the detection of these elements can be about 1 part in 10^8 or 10^9.

This report describes a careful search for elements 94 and 93 in a sample of pitchblende concentrate obtained from the Great Bear Lakes region of Canada. Since this pitchblende, which is

said to contain some 40 different elements, seems to offer more hope to contain 94 and 93 than does any other mineral, it was decided to make an extremely careful search in this mineral. Great care was taken to be sure that all the material was dissolved, even down to the last few milligrams, and the most sensitive means of detection for 94 and 93 in the final fraction, including tests for alpha and beta radioactivity and neutron induced fissions, were employed.

Another reason that seemed to make it definitely worth while to extend the sensitivity of the method to the limit was the possibility of establishing the presence of the 30,000-year 94^{239} [5] in this material. From the spontaneous fission rate of uranium, one can calculate the amount of 94^{239} which might be formed as a result of the absorption by U^{238} of the neutrons emitted in the spontaneous fission process. In an amount of pitchblende of the order of one pound, there might be expected to be present an amount of 94^{239}, formed from spontaneous fission neutrons, corresponding to an alpha counting rate of several thousand counts per hour, provided an appreciable fraction of these neutrons were absorbed by U^{238} ultimately forming 94^{239}. Even if only a small percentage of the neutrons leads to the formation of 94^{239} from U^{238} in this manner, it still should be possible to detect the 94^{239}, since alpha counting rates of the order of a few counts per hour are readily determinable. Our experiments indicate that we have discovered the presence of 94^{239} in pitchblende.

Experimental

Four hundred grams of the pitchblende concentrate was treated successively with a number of reagents, and after each treatment the solution which was obtained was set aside and the residue was subjected to the action of the next reagent. The reagents, in the order in which they were used, were (1) boiling concentrated hydrochloric acid followed by boiling aqua regia, (2) hot 6 *N* sodium hydroxide, (3) hot aqua regia, (4) boiling 6 *N* hydrochloric acid, (5) boiling 27 *N* hydrofluoric acid followed by nitric acid extraction, (6) fuming hot sulfuric acid followed by water extraction, (7) sodium hydroxide fusion followed by dilute sodium hydroxide extraction, (8) boiling 6 *N* hydrochloric acid, and (9) hydrofluoric acid solution followed by sulfuric acid, sodium carbonate and nitric acid solutions. After this series of treatments the final undissolved matter was entirely negligible, perhaps of the order of a few milligrams in weight.

The acidity of each of these solutions was adjusted to the range from 1 to 6 *N*, sulfur dioxide was added, and hydrofluoric acid was added to each in order to remove a fluoride precipitate. When necessary, lanthanum and cerium carrier material was added before the addition of the hydrofluoric acid.

(5) J. W. Kennedy, G. T. Seaborg, E. Segrè and A. C. Wahl, *Phys. Rev.*, **70**, 555 (1946) (submitted May 29, 1941).

The various fluoride precipitates were all combined and dissolved in concentrated sulfuric acid, and after dilution with water and the addition of dilute nitric acid (to oxidize any uranous uranium to the uranyl form) the rare earth fluorides were again precipitated by the addition of hydrofluoric acid. This rare earth and thorium fluoride precipitate, which amounted to about 20 g. and which would contain, in their reduced forms, any 94 or 93 which might have been present in the original pitchblende, was dissolved in sulfuric acid and reprecipitated as the fluoride. It was now necessary to go through a chemical procedure designed to isolate any such 94 or 93 into a very thin layer (0.3 mg./sq. cm.) of rare earth carrier material, special care being taken to eliminate all the elements in the uranium, thorium and actinium radioactive series which would interfere with the detection of the 94 or 93 in the final sample.

This rare earth and thorium fluoride precipitate was dissolved in sulfuric acid and after the addition of a few grams of potassium peroxydisulfate, $K_2S_2O_8$, and a few tenths of a gram of silver nitrate, hydrofluoric acid was again added to precipitate the rare earth and thorium fluoride. In this procedure, the 94 and 93 remain in solution, present in their higher oxidation states. This solution, after the removal of the fluoride preicpitate by centrifugation, was boiled in order to remove the hydrofluoric acid and decompose the peroxydisulfate and it was then treated with sulfur dioxide to reduce the 94 and 93 to their lower (fluoride-insoluble) oxidation states. About 120 mg. of lanthanum and cerium carrier was then added and the fluoride precipitated by the addition of hydrofluoric acid.

This 120 mg. fluoride precipitate was then dissolved in sulfuric acid and taken through another identical cycle in which the amount of rare earth was reduced to about 5 mg. The 5 mg. of rare earth, which would contain the 94 or 93, was then dissolved in sulfuric acid and, after the addition of peroxydisulfate and silver ion, the rare earths were removed from solution by precipitation as the fluoride. The hydrofluoric acid was removed by boiling the solution until the white fumes of sulfur trioxide appeared and after dilution another 0.2 mg. of rare earth carrier was added. After treatment with peroxydisulfate and silver ion, this 0.2 mg. of rare earth was precipitated as fluoride. The purpose of this last precipitation, which was made just before the final isolation of the material which would contain the 94 and 93 was to establish that there was a negligible amount of isotopes of thorium (UX_1, Io) present in the solution at this stage. This 0.2 mg. of precipitate showed no detectable beta activity, above the background of the Geiger–Müller counter, and an alpha counting rate of about 45 per hour when placed on one electrode of an ionization chamber in which the calibrated counting efficiency amounted to about 45 per cent.

The hydrofluoric acid was removed from the solution by boiling until the dense white fumes of sulfur trioxide appeared, and after dilution and reduction with sulfur dioxide, another 0.2 mg. of rare earth was added. This was precipitated as fluoride by the addition of hydrofluoric acid, and centrifuged onto a platinum disk for final measurements. This sample would contain any 94 or 93 which was present in the original pitchblende. (Calibration experiments, starting with 20 g. of rare earth and ending with 0.2 mg. of rare earth fluoride in an identical chemical procedure, in which the 50-year alpha-emitting 94 was added as tracer to the original 20 g., proved that the yield of 94 in this rather lengthy chemical procedure amounted to about 80 per cent.) Previous careful counting experiments had proved that the rare earth carrier material and the platinum, upon which the final sample was mounted, were free from alpha-emitting contamination.

Results

This final sample showed no detectable beta-activity, above the background of the Geiger–Müller counter. It showed an alpha counting rate of about 90 per hour when placed on one electrode of an ionization chamber in which the calibrated counting efficiency was about 45 per cent. Since it is likely that any isotopes of 94 or 93 would undergo fission with slow or fast neutrons, a test for fissions with neutrons was made by placing the final sample on one electrode of an ionization chamber connected to a linear amplifier and recording system adjusted to record the impulses due to fissions. When slow neutrons were used, from a 300-mg. radium-beryllium source with paraffin between the chamber and neutron source and around the chamber and neutron source, there was recorded zero fissions in seven hours of counting. When the sample was replaced by a "standard" 200-microgram uranium sample, containing therefore 1.4 microgram of U^{235}, the fission counting rate due to slow neutrons amounted to about 15 counts per hour. Therefore, assuming that the slow neutron fission cross section of the 94 or 93 would be of the same order of magnitude as that of U^{235}, there was present in the final sample no more than a small fraction of a microgram of any isotope of 94 or 93 capable of undergoing fission with slow neutrons. So far as fast neutrons are concerned our experiments place an upper limit of the order of a microgram on the amount of any isotope of 94 or 93 which was present and capable of undergoing fission with fast neutrons; therefore, we can say that there was not present in this pitchblende as much as one part in 10^8 or 10^9 of 94 or 93.

On the other hand, the alpha counting rate might very well be due to the presence of 94^{239} in view of the expectation that some of this isotope would be present as the end-product formed as the result of absorption of spontaneous fission neutrons by U^{238}. The chemical procedure is very stringent and specific for the isolation of 94 (and 93). A counting rate of about 90 per hour, amounting to some 10^{-6} microcuries, would correspond to the order of 10^{-5} microgram of 30,000-year 94^{239}. This would correspond to something like one part in 10^{14} of 94^{239} in the original pitchblende concentrate. This amounts to only a few per cent. of the amount to be expected if a large proportion of the spontaneous fission neutrons were absorbed by the U^{238}, but this is not surprising in view of the number of other neutron absorbing materials which might be present in the pitchblende.

Summary[6]

A chemical method for separating and concentrating elements 94 and 93 from uranium and thorium has been applied to a sample of pitchblende concentrate from the Great Bear Lakes region of Canada. A final fraction of 94 and 93 precipitated with rare earth carrier has been counted for fissions with slow and with fast neutrons, and an upper limit of 1 part in 10^8 to 10^9 has been set for the amount of these elements in the sample. Based on the number of alpha-particle counts in the sample, 1 part in 10^{14} is estimated as the amount of 30,000-year 94^{239} in the original pitchblende concentrate.

A Study of the Distribution of Arsine in Impregnated Charcoal by Means of Radioactive Tracers

BY JOSEPH W. HICKEY[1] AND EDWIN O. WIIG

The object of the present work, which formed part of an investigation of the mechanism of arsine removal by impregnated charcoals, was to study the distribution of arsine in beds of charcoal using a radioactive tracer. The various experiments were carried out in the light of certain facts that had already been ascertained concerning arsine removal. Of chief interest were the effects of the time of exposure to the toxic gas, the water content both of the charcoal and of the air stream, the concentration of arsine in the air stream, and the nature of the absorbent. In conjunction with the arsine distribution, the distribution of water was also determined in an attempt to find some correlation with the effect of water in the removal process.

Experimental Details

Absorbent.—The absorbent, supplied by Edgewood Arsenal, was a 12–16 mesh (U. S. Standard Sieve Series), activated coconut shell charcoal which had been impregnated to contain cupric oxide. It was dried by heating for three hours at 150°. In some experiments the charcoal was previously equilibrated to a definite relative humidity.

Radioactive Arsine.—The radioactive arsenic employed was obtained by bombarding Ge^{73} with deuterons in a cyclotron to give As^{74} with a half-life of seventeen days.

Since the radioactive material was obtained from a germanium dioxide target, it was necessary to separate arsenic from germanium and also from copper from the bombardment chamber. Treatment of the radioactive material with aqua regia followed by a sodium carbonate fusion of the residue rendered the sample soluble. After addition of pure sodium arsenite as a carrier, a large part of the germanium was removed as volatile germanium chloride by evaporating the solution nearly to dryness twice with hydrochloric acid. Removal of copper was effected by precipitation with hydrogen sulfide and subsequent treatment with polysulfide reagent. After this separation the arsenic was fairly pure except for a small amount of germanium which might conceivably form germane during the reduction of the arsenic to arsine. The separation of the remaining germanium was carried out after the method of Abrahams and Müller,[2] using a double precipitation of arsenic sulfide to ensure complete removal of germanium. The pure radioactive arsenic sulfide was dissolved in aqua regia, evaporated with a small amount of sulfuric acid and diluted in a volumetric flask. Both procedures for the removal of germanium chloride by boiling and the separation of arsenic from germanium by precipitation of the sulfide were checked using samples of radio-arsenic and radio-germanium. It was found that practically all of the germanium was lost by boiling with a hydrochloric–nitric acid mixture while the arsenic stayed in the solution. Also, it was shown that no appreciable amount of germanium came down in the second precipitation of arsenic sulfide while the arsenic was obtained in good yield.

Radio-arsine was prepared by reaction of metallic zinc with a solution of dilute sulfuric acid and sodium arsenate to which some of the radio-arsenic solution had been added. The arsine and hydrogen evolved were passed through anhydrous calcium sulfate and a dry ice–ether trap to remove water vapor. Thence the gases were led through two liquid air traps to freeze out arsine and the non-condensable gases removed with a Hyvac pump. The pure arsine was later allowed to expand into a storage bottle.

Absorption Apparatus.—The set-up used to expose the absorbent bed consisted essentially of an apparatus for obtaining an air–arsine stream of known concentration, temperature and humidity, at a constant flow rate of 500 cm. per minute through the empty absorption tube. The main air stream was split into two streams, one of which flowed through two bottles of distilled water and a glass wool trap and thence to a mixing chamber while the second passed through concentrated sulfuric acid, a glass wool trap and into the wet air stream. Any desired relative humidity could be obtained by varying the ratio of the two streams. The entire humidifying system was placed in a thermostat at 25.0° to insure constant humidity. The humidified air passed on through a calibrated wet and dry bulb psychrometer enclosed in an insulated box, the pressure being kept constant by a small overflow in a hydrostatic regulator. The air stream was then mixed with arsine in a mixing chamber.

Arsine was forced out of the storage vessel at a constant rate by allowing sodium chloride solution to run slowly into the vessel under a constant head. The amount introduced into the air stream was determined by passing the arsine through a flowmeter before entering the mixing vessel. The flowmeter was calibrated by actual chemical analysis of the air–arsine stream and the proper flowmeter setting checked by analysis at the beginning of each run. From the mixing vessel the air–arsine stream passed through a second flowmeter, kept constant to insure a constant arsine concentration, and into the manifold. A small excess flow was allowed to escape through a stopcock into the hood.

Attached to the manifold were six absorption tubes, each preceded by its own flowmeter and constant temperature coil. Water jackets, through which a rapid flow of water at 25° was maintained, surrounded both the coil and the absorption tube. A three-way stopcock inserted after the flowmeter permitted diversion of the flow either to a waste line or an analysis train. The analysis for arsine was carried out by allowing a known flow, as measured by the tube flowmeter, to pass for a measured length of time, through two bubbler tubes containing a mercuric chloride–gum arabic solution. The latter quantitatively absorbs arsine, which was then determined by the method of Cassil.[3]

The absorption tube, shown in detail in Fig. 1, was a uniform Pyrex tube of internal diameter 19.0 ± 0.1 mm. with a semi-ball joint at each end. In order that the absorption tube might be attached and detached without using rubber connections, a U-tube with a ground glass joint at each end was placed between the bottom of the absorption tube and the rest of the system. About half way up the absorption tube on the inside and held by a ring seal was a glass ring with a ground surface. This ring served as a seat for a perforated porcelain disk which in turn was the support for the charcoal bed. The disk (of the type used as small filtering plates) had about sixty-three regularly spaced holes, and its diameter was such that it could be just slipped in and out of the tube. The

(3) Cassil, *J. Assoc. Official Agr. Chem.*, **24**, 196 (1941).

sealed-in ring support decreased channeling of the gas stream at the periphery of the disk. This design of the absorption tube was necessary so that the entire bed (5.0 ± 0.1 cm. in depth and introduced by the standard Chemical Corps procedure) could be pushed up the tube as a unit after exposure to arsine. The absorbent could then be progressively removed in layers of known size at the top of the tube. To carry this out, the tube was removed from the system, the joints carefully cleaned with ether to remove the grease and the tube mounted vertically. The bed was raised up the tube by means of a rod pressing against the bottom of the supporting porcelain disk. This rod was moved by a screw shown at the bottom in the diagram. When the top of the bed was exactly level with the top of the tube, a millimeter scale attached to the rod was read. The rod was then moved up gradually for a measured distance (usually 3 mm.). The absorbent thus forced up beyond the top of the tube was removed, collected in a rubber mat surrounding the tube and placed in a small corked tube. The procedure was repeated until the entire bed had been sectioned. No mixing or appreciable contraction of the bed was ever noticed in using this method of layer separation. This was checked by coloring some of the charcoal particles.

The breakpoint indicator apparatus followed the absorption tube. A three-way stopcock was used in order that the flow might be changed instantly to either of two bubbler tubes. The absorbent was considered "broken" to arsine when a faint brown color appeared in a 2% silver nitrate solution in three minutes. This corresponds to 0.02% transmission of arsine by the absorbent for an initial arsine concentration of 4.15 mg. per liter.

Geiger Counter Assembly.—The separated layers of charcoal were weighed and, in most cases, dried to determine their moisture content after the run. It was found experimentally that the drying procedure had no effect on the counting rate of the sample. Then a 0.350-g. portion of each layer was placed evenly in a circular brass counting cup and covered with thin aluminum foil. This size sample proved satisfactory for the absorbent used and for the counter tube.

The Geiger–Müller tube, the quenching circuit and the assembly for holding the counting cup in place were enclosed in a grounded brass housing. The counting cup was placed in a fixed position on a support that could be moved up and down directly beneath the window of the counting tube. With the cup raised to a fixed distance from the window the average counting rate of the sample was determined. One sample was kept and counted from time to time during a set of experiments in order to measure the rate of decay of the radioactivity. Using the decay data, the counting rates of the various samples were calculated back to the time of starting the experiments.

The counting tube, with a thin mica window sealed on the bottom, was filled to a pressure of 8 cm. with a mixture of 90% argon and 10% ethanol and had a background of about thirty counts per minute. The counter itself consisted of a Neher–Harper type quenching circuit, a high voltage supply, a counting rate meter circuit capable of counting up to 20,000 counts per minute and a Cenco mechanical counter for low counting rates. The counting rate meter circuit was calibrated frequently by means of a standard pulse generator. In actual operation the rate meter was used for all the samples except those with counting rates less than 100 counts per minute.

Calculations.—The counting rates measured were for a 0.350-g. (or 0.300-g. in some cases) portion of the layer. The total counting rate per layer was found by simple weight proportion. It was observed by actual experiment that the counting rate was proportional to the weight of a given sample over the range used. Since the layers of absorbent obtained by the sectioning method were small and sometimes different in size, the data were expressed as weight of arsine absorbed per gram of dry absorbent at a given depth. It was assumed that the dried layers contained only the dried absorbent and arsenic trioxide. The latter has been found[4] present by X-ray analysis of similar absorbents exposed to a dry air–arsine stream. Also, Pierce[5] observed in some experiments on the change in weight of the same type of absorbents on exposure to arsine that this oxide was a strong possibility.

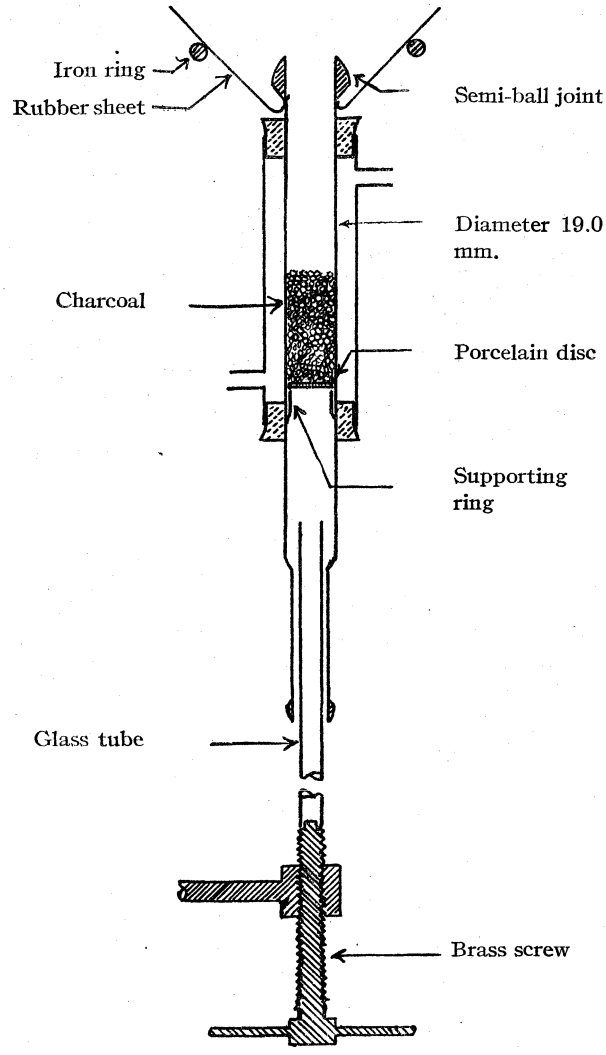

Fig. 1.—Apparatus for sectioning.

In order to obtain the amount of arsine absorbed in any layer, it was necessary to know the counting rate per unit weight of arsenic trioxide. The total number of counts in an entire bed was found by adding together the counting rates of all the layers. This total count divided by the weight of arsenic trioxide in the whole bed, calculated from the known amount of arsine absorbed during the run, gave the desired ratio. In actual practice the value used was an average for all the samples exposed to the same batch of radioactive arsine and not run beyond the breakpoint. Using this factor, the weight of arsenic oxide in each layer was obtained. The amount of dry absorbent in each layer was found by subtracting the weight of arsenic trioxide from the total weight of the dried layer. This method of finding the amount of absorbent in each layer was verified by adding together the weights of all the layers of a given sample and comparing with the weight of absorbent as calculated from the apparent density and the volume of the char used. These two values agreed to within 1–4%, including several samples

(4) H. F. Johnstone, NDRC Informal Report, 1941.

(5) W. C. Pierce, NDRC Formal Report, 1941.

that had absorbed almost 2 g. of arsine. Finally, the weight of arsine originally absorbed per gram of dry absorbent in each layer was calculated and plotted against the bed depth (the distance from the influent end to the center of the layer).

As a matter of allied interest, the weight of water (equal to the loss in weight on drying) per unit weight of dry absorbent was calculated for the various layers and plotted as a function of bed depth.

Results and Discussion

A study of the distribution curves in Figs. 2–6 shows the marked influence of water on arsine removal. With dry absorbent as much arsine is removed by the very first layers in ninety-three

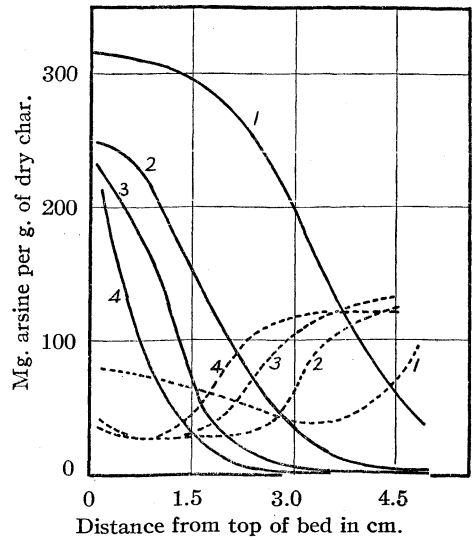

Fig. 4.—Variation of arsine distribution with time using char equilibrated to 50% relative humidity and air at 50% relative humidity. 1–300 min., 2–130 min., 3–80 min., 4–48 min. Dotted curves represent water distribution. Original water content about 100 mg. per g. of dry char.

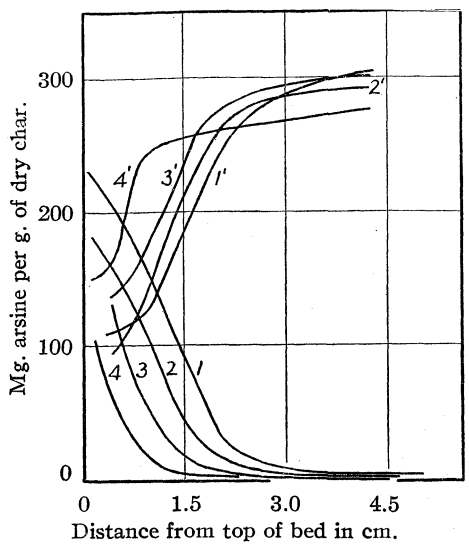

Fig. 5.—Variation of arsine distribution with time using char equilibrated to 70% relative humidity and air at 70% relative humidity. 1–80 min., 2–60 min., 3–40 min., 4–20 min. Upper primed curves represent water distribution. Original water content = 325 mg. per g. of dry char.

minutes from 50% relative humidity air as is taken up in three hundred minutes from dry air. Water vapor in the air stream is obviously accelerating the removal. In the former case, however, the amount of arsine drops sharply through the bed whereas with dry air it falls more slowly. This indicates that water also inhibits the removal of arsine. Water vapor, which is incompletely absorbed by charcoal, moves ahead of the arsine wave and poisons the more active centers.

This inhibiting effect of water is seen in comparing Figs. 3, 4 and 5. Using 50% relative humidity air more arsine is removed at the influent end in ninety-three minutes by dry char than is absorbed in one hundred thirty minutes by char equilibrated to 50% relative humidity. The inhibiting effect is very marked in experiments with air at 70% relative humidity and absorbent equilibrated to this humidity. In the latter case the amount of arsine removed at the influent end still remains greater than for dry char and dry air, as may be seen in Fig. 6. The rate of removal of arsine at lower concentrations as it passses through the bed is evidently less for the equilibrated char as indicated by the appreciable amount at the effluent end.

From the longest runs it appears that the arsine saturation value depends upon the amount of water present in the gas stream and on the charcoal. The highest value obtained for the dry absorbent using dry air was about 270 mg. of arsine per gram of char while values of over 400 mg. were found using dry charcoal and air at 50% relative humidity. The highest value for the absorbent equilibrated to 50% relative humidity and run at this humidity was intermediate at about 315 mg. of arsine per gram of dry charcoal. Since the apparent density of the absorbent was 0.50, the value obtained with dry air corresponds to 135 mg. of arsine per cc. of charcoal. This latter value agrees quite well with values of about 130 mg. per cc. reported by Pierce[5] from the results of his experiments on the change in weight of the same absorbent on absorption of arsine. Yost,[6] using a different base charcoal impregnated with copper oxide, found 120 mg. of arsine absorbed per cc. of absorbent by a radioactive method similar to the one used here. The difference in the saturation values with dry absorbent using in one case dry air and in the other air at 50% relative humidity may be correlated with the observation[7] that the breaktime for arsine using dry absorbent varies with the relative humidity of the air stream, gradually rising to a maximum at about 30% humidity and then falling off to low values at very high humidities.

The rate of approach toward a saturation value in the first layers of a bed varies considerably with conditions and presumably with the gas being absorbed. In the case of the inorganic gas cited by Klotz[8] (which was done in this Laboratory) the approach toward a saturation value proceeds at a slowly decreasing rate. The behavior of arsine with 70% relative humidity char and air stream (Fig. 5) or with dry char and 50% relative humidity air (Fig. 3) is somewhat similar. With 50% relative humidity char and air stream (Fig. 4) or dry char and dry air (Fig. 2), however, practically the same large amount of arsine is removed

by the influent end of the bed for exposures of fifty to one hundred thirty minutes and then the amount removed increases very slowly.

The reaction of arsine with oxygen is known to be highly exothermic (arsine is endothermic to the extent of 43.5 kcal.). The effect of the heat liberated can be readily traced by a study of the water distribution curves in Figs. 2–5. As arsine is removed at the influent end, the heat generated results in local desorption of water and an increase further down the bed. There is a distinct minimum in the water curves in most cases at a point corresponding roughly to the steep part of the arsine distribution curve where most of the adsorption was taking place. On continued exposure as the rate of accumulation of arsine at the influent end and the heat effects decrease, the amount of water present increases again. Experiments with and without water jackets on the absorption tube (Fig. 7) show that this heat also results in a displacement of the arsine distribution. As the air stream is warmed by the heat of reaction at the influent end evidently the rate of removal (oxidation of arsine) is increased a short distance down the bed.

Three runs with dry char and dry air at different concentrations of arsine for such lengths of time that the total amount of arsine passed through was the same in each case gave distribution curves similar to those in Fig. 2. The distributions at 4.15 and 7.18 mg. of arsine per liter were identical within experimental error, but at 1.67 mg. per liter the arsine was spread more throughout the bed. These observations can be correlated with the product of the breaktime and

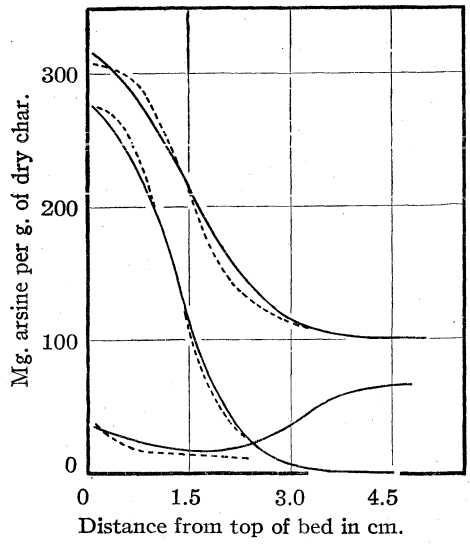

Fig. 7.—Effect on the arsine distribution of water cooling the absorption tube. Full curves — shows water jacket. Dotted curves --- have no water jacket. Top two curves with dry char and dry air have been displaced upward 100 mg. Other four curves are for dry char and 50% relative humidity air. Lowest two curves represent corresponding water distribution.

initial concentration (C_0T) that have been found at these concentrations:

C_0 (mg./liter)	1.67	4.15	7.18
C_0T	2.82	3.28	3.38

It would seem that only the more active catalyst centers are effective at low concentrations, and of course this is also shown by the tailing off of all the distribution curves. It suggests that if this charcoal were exposed to a very low concentration of arsine for some time to use up the more active centers throughout the bed, the breaktime toward a higher concentration would be much less than expected.

No attempt was made in this investigation to make a complete study of the distribution of arsine in various absorbents. One experiment was performed with an activated, zinc chloride-treated, wood charcoal impregnated with cupric oxide. This absorbent had a breaktime of fifty minutes as compared to ninety minutes for the other, using dry char and air at 50% relative humidity. A comparison of the two absorbents run for the same time at the same concentration (Fig. 8) shows that the coconut char apparently had a higher saturation value. The water distributions were similar except that the amount absorbed by the wood char was greater, in agreement with the observation that the latter also absorbed more water, 13% compared to 10%, when equilibrated to 50% relative humidity.

The actual mechanism of arsine removal cannot be assumed on the basis of this investigation, but it does involve the oxidation of arsine mainly to arsenic trioxide and water with copper oxide as a catalyst. It is necessary to have both charcoal and copper oxide present since copper oxide alone will not remove arsine, and unimpregnated charcoal removes it for only a very short time. Furthermore, it is evident from the highest values obtained for the amount of arsine accumulated in the top layer that arsine is not removed by reacting directly with copper oxide since there is only 58 mg. of copper present per gram of absorbent. It seems quite probable that the first step in the removal is adsorption of arsine followed by the oxidation reaction. The role that small amounts of water play is not at all certain, but it might be mentioned that even in the gas phase arsine and oxygen undergo practically no reaction in the absence of water.[9] The presence of large amounts of water on the charcoal and covering the copper oxide may decrease the initial adsorption of arsine to such an extent that little arsine is removed until some of this water is driven off by the heat of a small amount of reaction.

Acknowledgment.—The authors wish to express their thanks to the National Defense Research Committee of the OSRD who sponsored this research, to the Edgewood Arsenal Laboratories for their coöperation and to Drs. John H. Raley and Herbert Scoville, Jr., for their assistance with some of the experimental work.

Summary

The distribution of arsine on a charcoal bed has been followed as a function of the humidity of the air stream and the absorbent, concentration of ar-

(9) W. C. Johnson, private communication.

sine, time of exposure and cooling, by the use of radioactive arsenic. The distribution curves show a marked accelerating effect of small amounts of water and an inhibiting effect of larger amounts. A constant saturation value for arsine at the influent end of the bed is apparently not reached even after long exposure.

Determination of the Product of the Constants for the Overlapping Dissociation of Weak Acids by Electromotive Force Methods

BY ROGER G. BATES

The exact determination of the thermodynamic dissociation constants of many weak dibasic and tribasic acids is complicated by the "overlapping" of the successive ionization steps. When the ratio of the thermodynamic constants for the primary and secondary steps, K_1/K_2, is less than 500 to 1000, as it is for most of the common aliphatic dicarboxylic acids[1] and many substituted benzoic acids,[2] the ionic and molecular concentrations cannot be established with sufficient accuracy by consideration of a single equilibrium. Hence, a determination of the constants often requires laborious arithmetical approximations.[3,4,5,6]

The constant for the second overlapping step in the dissociation of a dibasic acid can often be determined by the thermodynamic method of Harned and Ehlers[7] from measurements of cells without liquid junction. The determination is facilitated through choice of buffer solutions on the alkaline side of the midpoint of the neutralization curve for the second group, with a decrease in the correction for the first dissociation equilibrium. A buffer ratio of 5:1 appears not to be excessive.[8] However, the advantage of a similar procedure is sometimes offset in the evaluation of the first constant by the enhanced correction for hydrogen ion, the concentration of which must be established by successive approximations or, at a sacrifice of accuracy, derived from a pH measurement.[9]

When conditions cannot readily be chosen to isolate each of the individual equilibria in turn, solutions of the acid salt, where overlapping of the two equilibria is at a maximum, can be used to advantage in establishing the product of the constants for two overlapping equilibria. A thermodynamic method for the determination of this product from measurements of the electromotive force of cells without liquid junction is described. If one dissociation constant of an overlapping pair is known, this procedure usually permits the other to be determined accurately.

Method

The electromotive force, E, of the cell

$$\text{Pt; } H_2\text{, acid salt } (m)\text{, MCl } (m_2)\text{, AgCl; Ag} \qquad \text{I}$$

where M represents an alkali metal and the acid salt is of one of the three types: MHA, MH_2A, or M_2HA, is given by

$$\frac{F(E - E^0)}{2.3026\ RT} + \log m_{Cl} = -\log (f_H f_{Cl} m_H) \equiv pwH \qquad (1)$$

For convenience, this experimental quantity will be termed pwH. In equation (1), f is an activity coefficient on the scale of molality (m), F is the faraday, and the other symbols have their usual significance. The hydrogen-ion concentration, m_H, is readily expressed in terms of dissociation constants, molalities, and activity coefficients. The product of the thermodynamic constants for the two overlapping steps is obtained by extrapolation of an appropriate function of E, with the aid of the Debye–Hückel formula,[10] to infinite dilution, where the estimated activity coefficients are exact. To simplify the treatment, the following discussion is restricted to solutions of acid salts with pH < 8, in which the concentration of hydroxyl ion can be ignored.

Case I. Acid Salt of a Dibasic Acid, $K_1/K_2 < 500$.—The molecular and ionic species participating in the equilibria are H^+, H_2A, HA^-, and $A^=$. The concentration of hydrogen ion, m_H, in solutions of the acid salt is given by

$$m_H^2 = \frac{K_1 K_2 m_{H_2A}}{m_A} \times \frac{f_{H_2A}}{f_H^2 f_A} \qquad (2)$$

Inasmuch as

$$m_A = m_{H_2A} + m_H \qquad (3)$$

we obtain, by combination of equations (1) and (2)

(9) The simultaneous evaluation of overlapping K_1 and K_2 from pH-titration data obtained from cells with liquid junction has been described by J. C. Speakman, *J. Chem. Soc.*, 855 (1940).

(10) P. Debye and E. Hückel, *Physik. Z.*, **24**, 185 (1923).

$$-\frac{1}{2}\log(K_1K_2) = pw\mathrm{H} - \frac{1}{2}\log\frac{m_{\mathrm{H_2A}} + m_{\mathrm{H}}}{m_{\mathrm{H_2A}}} - \frac{1}{2}\log\frac{f_{\mathrm{A}}}{f_{\mathrm{H_2A}}f_{\mathrm{Cl}}^2} \quad (4)$$

To aid in the extrapolation, the Debye–Hückel equation may be employed for the ionic activity coefficients and unity assumed for the activity coefficient of the uncharged molecule. In this way an expression for the "apparent" value of the product of K_1 and K_2, namely $(K_1K_2)'$, is obtained

$$-\frac{1}{2}\log(K_1K_2)' = pw\mathrm{H} - \frac{1}{2}\log\frac{m_{\mathrm{H_2A}} + m_{\mathrm{H}}}{m_{\mathrm{H_2A}}} + \frac{A\sqrt{\mu}}{1 + Ba^*\sqrt{\mu}} \quad (5)$$

where A and B are constants of the Debye–Hückel theory,[11] μ is the ionic strength, and a^* is the so-called ion-size parameter. The limiting value of $(K_1K_2)'$ at zero ionic strength is K_1K_2.

Case II. Primary Acid Salt of a Tribasic Acid, $K_1/K_2 < 500$, $K_2/K_3 > 1000$.—The ionic and molecular species concerned are H^+, H_3A, H_2A^-, and $HA^=$. The molality of hydrogen ion is given by

$$m_{\mathrm{H}}^2 = \frac{K_1K_2m_{\mathrm{H_3A}}}{m_{\mathrm{HA}}} \times \frac{f_{\mathrm{H_3A}}}{f_{\mathrm{H}}^2 f_{\mathrm{HA}}} \quad (6)$$

Inasmuch as the third dissociation step need not be considered

$$m_{\mathrm{HA}} = m_{\mathrm{H_3A}} + m_{\mathrm{H}} \quad (7)$$

By combination of equations (1), (6) and (7), an expression is obtained that differs from equation (4) only in substitution of H_3A for H_2A and of HA for A in the subscripts of m and f. This expression can be written in a form suitable for extrapolation as follows

$$-\frac{1}{2}\log(K_1K_2)' = pw\mathrm{H} - \frac{1}{2}\log\frac{m_{\mathrm{H_3A}} + m_{\mathrm{H}}}{m_{\mathrm{H_3A}}} + \frac{A\sqrt{\mu}}{1 + Ba^*\sqrt{\mu}} \quad (8)$$

Case III. Secondary Acid Salt of a Tribasic Acid, $K_1/K_2 > 1000$, $K_2/K_3 < 500$.—The ionic species are H^+, H_2A^-, $HA^=$, and $A^{\equiv}$. The square of the concentration of hydrogen ion is

$$m_{\mathrm{H}}^2 = \frac{K_2K_3m_{\mathrm{H_2A}}}{m_{\mathrm{A}}} \times \frac{f_{\mathrm{H_2A}}}{f_{\mathrm{H}}^2 f_{\mathrm{A}}} \quad (9)$$

Equations (3) and (4) are valid for Case III as well as for Case I, with the substitution of the product K_2K_3 for K_1K_2. The charges of H_2A and A are, of course, now -1 and -3 instead of 0 and -2 as in Case I. By combination with the Debye–Hückel equation, an expression suitable for extrapolation is obtained

$$-\frac{1}{2}\log(K_2K_3)' = pw\mathrm{H} - \frac{1}{2}\log\frac{m_{\mathrm{H_2A^-}} + m_{\mathrm{H}}}{m_{\mathrm{H_2A^-}}} + \frac{3A\sqrt{\mu}}{1 + Ba^*\sqrt{\mu}} \quad (10)$$

(11) G. G. Manov, R. G. Bates, W. J. Hamer and S. F. Acree, THIS JOURNAL, **65**, 1765 (1943).

Case IV. Primary Acid Salt of a Tribasic Acid, $K_1/K_2 < 500$ and $K_2/K_3 < 500$.[12]—The ionic and molecular species of concern in Case IV are H^+, H_3A, H_2A^-, $HA^=$, and $A^{\equiv}$. All three steps in the dissociation of the acid must be considered, and

$$m_{\mathrm{HA}} = m_{\mathrm{H_3A}} + m_{\mathrm{H}} - m_{\mathrm{A}} \quad (11)$$

Formula (6) applies here, and equation (8) of Case II accordingly takes the form

$$-\frac{1}{2}\log(K_1K_2)' = pw\mathrm{H} - \frac{1}{2}\log\frac{m_{\mathrm{H_3A}} + m_{\mathrm{H}} - m_{\mathrm{A^{\equiv}}}}{m_{\mathrm{H_3A}}} + \frac{A\sqrt{\mu}}{1 + Ba^*\sqrt{\mu}} \quad (12)$$

Case V. Secondary Acid Salt of a Tribasic Acid, $K_1/K_2 < 500$ and $K_2/K_3 < 500$.—The molalities of the molecular acid and of the primary and tertiary ions in a solution of the secondary salt are related by

$$m_{\mathrm{A}} = m_{\mathrm{H_2A}} + m_{\mathrm{H}} + 2m_{\mathrm{H_3A}} \quad (13)$$

The hydrogen-ion concentration is given by equation (9). Hence, an expression analogous to equation (10) is obtained:

$$-\frac{1}{2}\log(K_2K_3)' = pw\mathrm{H} - \frac{1}{2}\log\frac{m_{\mathrm{H_2A^-}} + m_{\mathrm{H}} + 2m_{\mathrm{H_3A}}}{m_{\mathrm{H_2A^-}}} + \frac{3A\sqrt{\mu}}{1 + Ba^*\sqrt{\mu}} \quad (14)$$

Compositions of the Solutions

Only two overlapping dissociation steps are involved in Cases I, II and III. The evaluation of the second terms on the right of equations (5), (8) and (10) requires that the concentration of only one ionic or molecular species in addition to that of hydrogen ion be established. In equations (12) and (14) of Cases IV and V, the concentration of a second species, fortunately considerably smaller than that of the first, must be estimated. In each instance the hydrogen-ion concentration, m_{H}, can be computed from the equation

$$-\log m_{\mathrm{H}} = pw\mathrm{H} + \log f_{\mathrm{H}}f_{\mathrm{Cl}} = pw\mathrm{H} - \frac{2A\sqrt{\mu}}{1 + Ba^*\sqrt{\mu}} \quad (15)$$

In the following discussion of the exact and approximate methods of computing these concentration terms, it will be convenient to employ the classical dissociation constants, k_n, for the three steps. For a weak tribasic acid

$$k_1m_{\mathrm{H_3A}} = m_{\mathrm{H}}m_{\mathrm{H_2A}};\ k_2m_{\mathrm{H_2A}} = m_{\mathrm{H}}m_{\mathrm{HA}};\ k_3m_{\mathrm{HA}} = m_{\mathrm{H}}m_{\mathrm{A}} \quad (16)$$

If, further, it is assumed that each activity coefficient is given by the Debye–Hückel equation, we may write

$$k_n = \bar{K}_n / f^{2n} \quad (17)$$

(12) The formulas of Cases IV and V have been applied successfully to the resolution of the three overlapping constants of citric acid by Miss Gladys D. Pinching and the author (unpublished work). For citric acid, each ratio is about 44, and K_1/K_2 is about 1900. If K_1/K_2 were less than 1000, the separation would doubtless be more difficult.

where

$$-\log f^n = nA\sqrt{\mu}/(1 + Ba^*\sqrt{\mu}) \qquad (18)$$

and n is 1, 2, or 3. The symbol K_n represents the thermodynamic dissociation constant.

Complete or Exact Treatment, Cases I, II, and III.—When the acid salt of a dibasic acid with overlapping constants (Case I) is dissolved in water the interaction

$$2HA^- \rightleftarrows H_2A + A^= \qquad (19)$$

may proceed rather extensively. This reaction is usually considerably more important than the normal acidic dissociation of the intermediate ion. When K_1/K_2 is 4 (the theoretical lower limit for a symmetrical dibasic acid[13]), as much as half of the acid anion may be converted into H_2A and $A^=$.[13,14]

From the mass law and equations (3), (17) and (19) we have

$$\frac{k_2}{k_1} = \frac{K_2}{K_1 f^2} = \frac{m_{H_2A}(m_{H_2A} + m_H)}{(m - m_H - 2m_{H_2A})^2} \qquad (20)$$

Even though m_H is obtained by equation (15) and the ratio of constants is known, equation (20) cannot readily be solved for m_{H_2A}. The desired quantity can, however, be obtained graphically or by trial.

Two features of this method are noteworthy. First, the second terms on the right of equations (5), (8), (10), (12) and (14) are of the form $^1/_2 \log [(a + b)/a]$, where a is large relative to b. Hence, the values of these terms are rather insensitive to small changes in a. The higher the pH of the solution of the acid salt the smaller is b, and the larger is the permissible error in a. Secondly, although the evaluation of both m_H and k_2/k_1 rests upon an assumed value of a^*, the ion-size parameter, the second terms on the right of these five extrapolation formulas are but little influenced by the choice of a^*, when the same value is used in both equation (15) and equation (18). This point will be illustrated later in this paper. The value of a^* used in the extrapolation equations themselves is immaterial, so long as the plots of $^{-1}/_2 \log (K_1K_2)'$ as a function of ionic strength display the convergence at infinite dilution demanded by theory.

The treatment of Cases II and III is entirely analogous to Case I. For Case II the principal equilibrium is

$$2H_2A^- \rightleftarrows H_3A + HA^= \qquad (21)$$

In equation (20), m_{H_2A} is replaced by m_{H_3A}. The extrapolation is performed with the aid of formula (8) instead of with (5). For Case III the principal ionic equilibrium is

$$2HA^= \rightleftarrows H_2A^- + A^{\equiv} \qquad (22)$$

Hence, equation (20) becomes

$$\frac{k_3}{k_2} = \frac{K_3}{K_2 f^2} = \frac{m_{H_2A^-}(m_{H_2A^-} + m_H)}{(m - m_H - 2m_{H_2A^-})^2} \qquad (23)$$

(13) R. Wegscheider, *Monatsh.*, **16**, 153 (1895); E. Q. Adams, THIS JOURNAL, **38**, 1503 (1916); N. Bjerrum, *Z. physik. Chem.*, **106**, 219 (1923).

(14) C. W. Davies, *J. Chem. Soc.*, 1850 (1939).

The extrapolation is made, of course, with equation (10)

Complete Treatment, Cases IV and V.—Formula (21) represents the principal equilibrium in solutions of the primary salt of a tribasic acid with three overlapping constants (Case IV). The secondary anion, $HA^=$, formed in this reaction is capable of further acidic dissociation, as is the primary anion. Contrary to the situation in Case II, where K_3 was too small to require consideration, three equilibria are involved here. Inasmuch as

$$m_{H_2A} = m - m_{H_3A} - m_{HA} - m_A \qquad (24)$$

we have, from equation (11) and the mass-law expression for equilibrium (21)

$$\frac{k_2}{k_1} = \frac{m_{H_3A}(m_{H_3A} + m_H - m_A)}{(m - m_H - 2m_{H_3A})^2} \qquad (20a)$$

The analogy with equation (20) is evident. The molality of $A^{\equiv}$ appearing in the numerator of (20a) is small (slightly less than 1% of m_{H_3A} in solutions of potassium dihydrogen citrate[12]). It is readily computed with an accuracy exceeding the experimental error in the electromotive force by

$$m_A = k_3 m_{HA}/m_H = K_3 m_{HA}/(m_H f^6) \qquad (25)$$

from a first estimate of m_{HA} and a value of pK_3 accurate to ± 0.1. Otherwise, the evaluation of K_1K_2 parallels Case I.

The principal equilibrium in solutions of the secondary salt of a tribasic acid with three overlapping constants (Case V) is (22). Acidic dissociation of the secondary anion must be considered as well as the reaction of the primary anion formed in (22) with a part of the hydrogen ion liberated by dissociation of $HA^=$

$$H_2A^- + H^+ \rightleftarrows H_3A \qquad (26)$$

From equations (13), (24), and the mass law

$$\frac{k_3}{k_2} = \frac{m_{H_2A}(m_{H_2A} + m_H + 2m_{H_3A})}{(m - m_H - 2m_{H_2A} - 3m_{H_3A})^2} \qquad (23a)$$

The molality of H_3A, like m_A in Case IV, is a correction of secondary importance. It is obtained with sufficient accuracy from the approximate K_1 and m_{H_2A} by

$$m_{H_3A} = m_H m_{H_2A}/k_1 = m_H m_{H_2A} f^2/K_1 \qquad (27)$$

Approximate Treatment.—If the pH of the solution of acid salt is higher than 3.5 to 4.0, m_H is usually small with respect to m_{H_2A} and m_{H_3A} in equations (5), (8), (10), (12) and (14), and the treatment can be simplified. Fortunately, the acid salts of most dicarboxylic acids with overlapping fall in this category.

If m_H in equation (3) approaches zero, it is easy to show that the molality of molecular acid produced by reaction (19) is approximately

$$m_{H_2A} \approx \frac{1}{2}(mx - m_H) \qquad (28)$$

where

$$x \equiv \frac{2(k_2/k_1)^{1/2}}{1 + 2(k_2/k_1)^{1/2}} \qquad (29)$$

Hence, the concentration term of equation (5) is readily obtained and, by a similar procedure, also that of equation (8)

Cases I and II.—

$$\frac{m_{H_2A} + m_H}{m_{H_2A}} \approx \frac{mx + m_H}{mx - m_H}$$
$$\frac{m_{H_3A} + m_H}{m_{H_3A}} \approx \frac{mx + m_H}{mx - m_H} \quad (30)$$

Similarly, from equation (23), we have

$$m_{H_2A^-} \approx \frac{1}{2}(my - m_H) \quad (31)$$

where

$$y \equiv \frac{2(k_3/k_2)^{1/2}}{1 + 2(k_3/k_2)^{1/2}} \quad (32)$$

Hence, the concentration term of formula (10) is given by

Case III.—

$$\frac{m_{H_2A^-} + m_H}{m_{H_2A^-}} \approx \frac{my + m_H}{my - m_H} \quad (33)$$

By the same reasoning, the second term on the right of formula (12) can be expressed in terms of x

Case IV.—

$$\frac{m_{H_3A} + m_H - m_{A^{\equiv}}}{m_{H_3A}} \approx \frac{mx + m_H - 2m_A}{mx - m_H} \quad (34)$$

In Case V the situation is slightly different, for a part of the primary anion, H_2A^-, produced by (22) is converted into H_3A. Hence

$$m_{H_2A} \approx \frac{1}{2}(my - m_H) - m_{H_3A} \quad (35)$$

The second term on the right of equation (14) is thus given by

Case V.—

$$\frac{m_{H_2A^-} + m_H + 2m_{H_3A}}{m_{H_2A^-}} \approx \frac{my + m_H + 2m_{H_3A}}{my - m_H - 2m_{H_3A}} \quad (36)$$

Ionic Strength.—Whether the complete or approximate treatment is used, sufficiently accurate values of the ionic strength can ordinarily be obtained with the aid of x and y

Case	Mixture	Ionic Strength	
I	MHA (m), MCl (m_2)	$m\,(1 + 0.5x) + 1.5m_H + m_2$	(37a)
II	MH_2A (m), MCl (m_2)	$m\,(1 + 0.5x) + 1.5m_H + m_2$	(37b)
III	M_2HA (m), MCl (m_2)	$m\,(3 + 0.5y) + 2.5m_H + m_2$	(37c)
IV	MH_2A (m), MCl (m_2)	$m\,(1 + 0.5x) + 1.5m_H + 2.5m_A + m_2$	(37d)
V	M_2HA (m), MCl (m_2)	$m\,(3 + 0.5y) + 2.5m_H + 2m_{H_3A} + m_2$	(37e)

Evaluation of K_1K_2 and K_2K_3

The determination of K_1K_2 for a dibasic acid is made as follows. Values of x are computed by equation (29) from a reasonable estimate of k_2/k_1, and a first estimate of the ionic strength is obtained by equation (37a). The hydrogen-ion concentration can be ignored or estimated from the approximate pH of the solution. Equation (15) yields a value of m_H when the ionic strength has been estimated, and the second term on the right of equation (5) is computed with the aid of equation (20) or the approximation, equation (28). It is suggested that a value of 4.0 be assigned to a^* in equations (15) and (18). A first approximation of K_1K_2 is obtained by extrapolation of the right-hand side of equation (5) to infinite dilution. The plots of $-{}^1/_2 \log (K_1K_2)'$ as a function of ionic strength will dictate the value of a^* in equation (5) necessary to provide an accurate extrapolation, although 4.0 is a reasonable first choice.

A value of K_2/K_1 results from combining K_1K_2 with K_1 or K_2, whichever is available from independent determinations, and a new k_2/k_1 is obtained with the assistance of equations (17) and (18). The process is then repeated. Inasmuch as m_{H_2A} need not be known accurately, a third approximation is usually unnecessary.

For the solution of Cases IV and V an approximate value of m_A or m_{H_3A} is calculated as described in an earlier section. In other respects, K_1K_2 and K_2K_3 are evaluated in Cases II, III, IV, and V exactly as is K_1K_2 in Case I.

The extrapolation of the right side of equations (12) and (14) to infinite dilution is illustrated in Fig. 1 with data for the acid salts of citric acid. The two sets of curves were computed from the electromotive force of cells of type I. The upper lines represent mixtures of secondary potassium citrate and potassium chloride, whereas the lower set was derived from studies of mixtures of primary potassium citrate and potassium chloride.[12,15] The approximate formulas (34) and (36) were used in evaluating the second terms on the right of equations (12) and (14). Curves a, b, c, d, e, and f were computed with a^* values of 5.0, 5.5, 6.0, 2.0, 3.0 and 4.0, respectively. As mentioned earlier, altering a^* in formulas (15) and (18) has little effect on the plotted points.

Limitations of the Approximation.—In Figure 2, the differences between the true ${}^1/_2 \log [(m_{H_2A} + m_H)/m_{H_2A}]$ of formula (5) and approximate values computed by equation (30) are plotted as a function of the molality of the acid salt. To enhance the accuracy of the determination of the constants for the overlapping steps, the concentration of acid salt should preferably not be lower than 0.01 molal. The lower limit of $-\log m_H$ (pcH), below which the error of the approximation exceeds 0.0005 in ${}^1/_2 \log (K_1K_2)'$ (0.03 mv. in the electromotive force), is a function of the magnitude of k_1/k_2, that is, of the extent of overlapping. The approximate treatment is adequate above pcH 3.25 when k_1/k_2 is 10, above 3.70 when k_1/k_2 is 100, and above 3.95 when k_1/k_2 is 215.

K_1K_2 for *o*-Phthalic Acid

The two dissociation constants of *o*-phthalic acid have been determined accurately by electromotive-force methods.[5,6] These constants can be employed to illustrate the application of the equa-

(15) These curves were plotted from preliminary data. They serve, nevertheless, to illustrate the nature of the extrapolation.

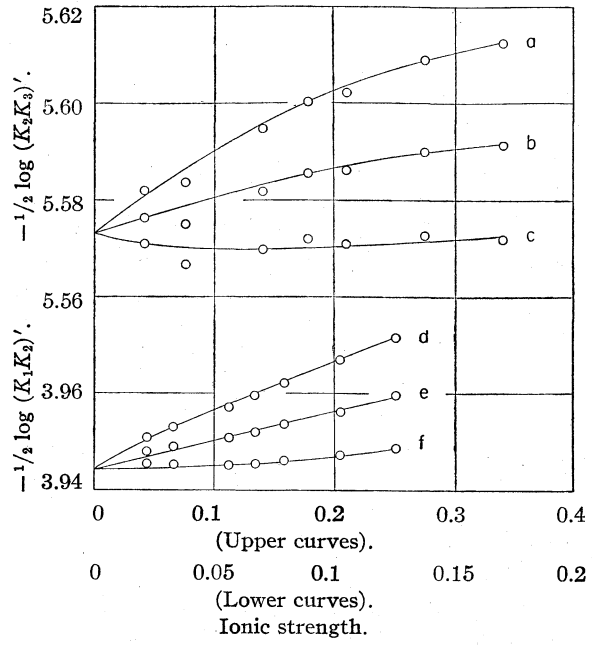

Fig. 1.—Determination of K_1K_2 and K_2K_3 for citric acid from the electromotive force of cell I at 25°.

tions of the foregoing sections and to test this method of determining K_1K_2.

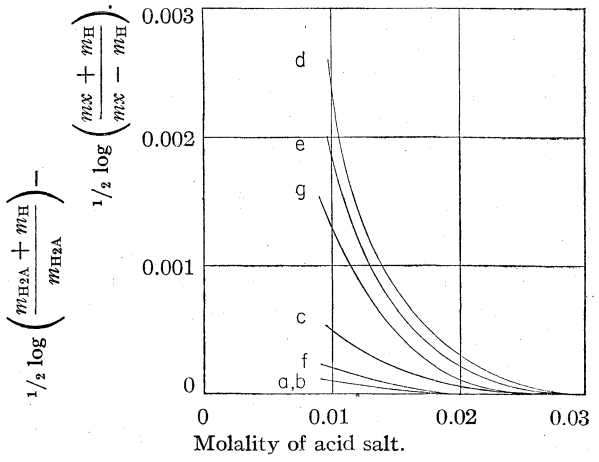

Fig. 2.—Error of the approximation plotted as a function of the molality of the acid salt:

Curve	k_1/k_2	$-\log m_H$
a	7	3.43
b	10	3.50
c	10	3.25
d	10	3.00
e	20	3.15
f	100	3.80
g	100	3.50

The electromotive force of 19 cells of type I was measured at 25° with mixtures of acid potassium phthalate[16] and potassium chloride (m_2 = 0.01). Palladium electrodes were substituted for platinum.[17] The molality of acid salt varied from 0.01 to 0.07. The electromotive force in int. v. appeared to be a linear function of log m in this range

$$E_{25} = 0.57662 - 0.00476 \log m \qquad (38)$$

The reproducibility and stability of the cells with 0.01 m to 0.02 m acid potassium phthalate were not good, and an uncertainty of nearly 0.2 mv. must be assigned to the electromotive force at 0.01 m. The uncertainty is indicated in Fig. 3 by the varying sizes of the circles which represent the values of $-1/2 \log (K_1K_2)'$. The approximate treatment was employed throughout. The error of the approximation is only 0.0002 in $-1/2 \log (K_1K_2)'$ for the 0.01 m solution, the most dilute studied.

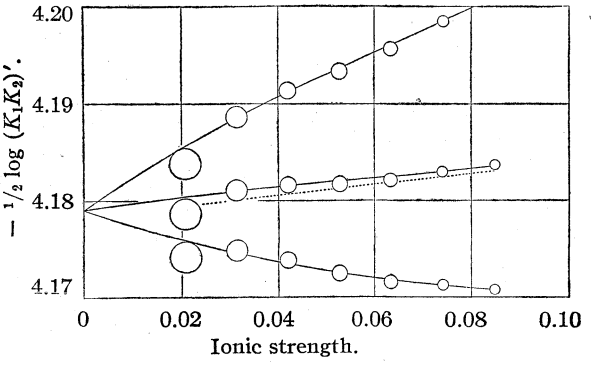

Fig. 3.—Determination of K_1K_2 for phthalic acid from the electromotive force of cell I at 25°: from top to bottom, the lines represent a^* values of 2.0, 4.0, and 6.0, equation (5). The curves are drawn to intersect at 4.179, the known value of $-1/2 \log (K_1K_2)$.[5,6]

From top to bottom of Fig. 3, the three lines represent a^* values of 2.0, 4.0, and 6.0 in the last term of formula (5). In each instance, 4.0 was used for a^* in equations (15) and (18). When a^* was set equal to zero in these two equations, the middle curve in Fig. 3 took the position indicated by the dotted line. It is evident, therefore, that the final result is altered by only 0.001 if the Debye–Hückel limiting law ($a^* = 0$) is used in these two formulas. The three lines are drawn to intersect at 4.179, the value of $-1/2 \log (K_1K_2)$ at 25°.[5,6]

It should be noted that the electromotive force of cell I containing a solution of primary or secondary acid salt is rather sensitive to variations in the composition of the salt. For example, the change in the electromotive force of the cell containing 0.05 m acid potassium phthalate and 0.01 m potassium chloride that results from a change of 0.1% in the titration value of the acid salt is about 0.17 mv. For phthalic acid, K_1/K_2 is 288.[5,6] The electromotive force is somewhat less sensitive to the purity of the salt when the extent of overlapping is greater. A change of 0.03 mv. in

(16) National Bureau of Standards Standard Samples 84a and 84c.

(17) W. J. Hamer and S. F. Acree, *J. Research Natl. Bur. Standards*, **33**, 87 (1944).

E corresponds to 0.001 in $pK_1 + pK_2$. Hence, the uncertainty in pK caused by experimental errors is twice that of the conventional method where a single dissociation step is involved.

Summary

The use of electromotive-force measurements of hydrogen–silver chloride cells without liquid junction in resolving the constants for the overlapping dissociation steps of weak dibasic and tribasic acids is discussed. When one constant of an overlapping pair is known, the second can be derived from studies of solutions of the appropriate primary or secondary acid salt with added alkali chloride. The equations for the five possible cases of overlapping have been developed. A simple means of estimating the molalities needed in the computation is described. The method has been applied to a determination of the product of the constants of phthalic acid at 25°. The result is consistent with earlier determinations of the two constants.

Synthesis of Products Related to Vitamin A. IV. The Application of the Darzens Reaction to β-Ionone[1a]

BY NICHOLAS A. MILAS, S. WARREN LEE,[2] EMILE SAKAL,[3] HERBERT C. WOHLERS,[4] NORMAN S. MACDONALD,[5] FRANK X. GROSSI[6] AND HERBERT F. WRIGHT[7]

One of the key intermediates in the synthesis of several biologically active vitamin A products[8] was produced by the application of the Darzens synthesis to β-ionone.[9] The structure of this product presented a special problem in view of the anomalous results obtained in the early stages of our investigation. When β-ionone was condensed with ethyl chloroacetate at low temperatures (−30 to −60°) in anhydrous ether or toluene using alcohol-free sodium ethoxide or methoxide as the condensing agents, the glycidic ester I was produced which upon hydrolysis presumably gave a glycidic acid of similar structure. When the crude glycidic ester was hydrolyzed and the crude glycidic acid decarboxylated in the presence or absence of powdered glass or by passing it under a reduced pressure downwards through a hot tube (140–160°) packed with freshly reduced copper powder on pumice, the decarboxylation product had slightly different properties from that obtained by the decarboxylation of the pyridine salt of the same glycidic acid. Furthermore, decarboxylation under similar conditions of the two glycidic acids, one crystalline and the other highly viscous liquid both derived from pure glycidic ester, yielded products still different in physical and chemical properties. Table I shows the main fractions of decarboxylation products obtained by various methods from crude as well as from crystalline glycidic acids. Upon careful fractionation of a large sample of the decarboxylation product obtained from the crude glycidic acid using a four-foot packed fractionation column, three fractions were obtained: a small low-boiling fraction with a high index of refraction; a large fraction with an intermediate b. p. and an index of refraction ranging from 1.5133 (20°) to 1.5155 (25°); and a small high-boiling fraction with a high index of refraction. It may be seen from the table that the low-boiling fraction resembles in properties the main product obtained from the decarboxylation of the crystalline glycidic acid. The high-boiling fraction, on the other hand, has several properties in common with the main product resulting from the crude glycidic acid, except that it exhibits a secondary absorption maximum at 3000 Å.

The results shown in Table I raise the question whether the purified glycidic ester and the glycidic acids derived from it have the same structure as the corresponding crude compounds. The purified glycidic ester was found to have one active hydrogen (Zer.), while the crystalline glycidic acid showed the presence of two active hydrogens. Both the ester and the acid gave a strong ferric chloride reaction, and upon catalytic hydrogenation showed the presence of approximately three double bonds. Furthermore, the ultraviolet spec-

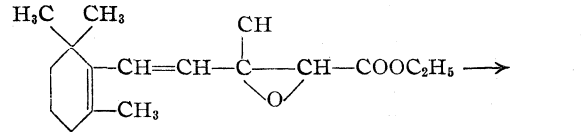
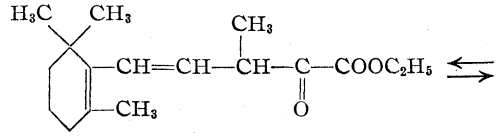
[a] From purified glycidic ester. Decarboxylation was accomplished via the pyridine salt. [b] Same as in (a) except that decarboxylation was accomplished in the presence of copper chips. [c] From crude glycidic acid derived from the condensation without first isolating the pure glycidic ester. [d] Inflection.

trum of both the ester and the acid ($\lambda_{max.}$, 2860 Å.) indicates the presence of three double bonds in conjugation with the ester or carboxyl groups.[10] That spectroscopically the epoxide group is not equivalent to a double bond as Heilbron, *et al.*,[9b] assumed is shown by the spectra of several epoxides (*cf.* structure V)[11] which exhibit maxima in the neighborhood of 2300 Å. In view of these facts we feel that the crude reaction product should be represented by structures I, II and III. The crude glycidic ester and the acids derived from it may be represented mainly by structures I and II while that of the pure glycidic ester and its acids may be represented by structure III. Structure III accounts for all the observed facts for the "crystalline glycidic acid" as well as the large amount of resin produced during its decarboxylation.

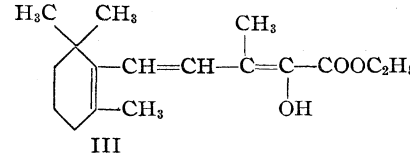
These views are in accord with the original assumption of Darzens[12] who found that under certain conditions even the simple glycidic esters rearrange into the α-ketoesters.



I



II



III

The only product used in the synthesis of biologically active vitamin A substances[13] was that represented by the main fraction from a fractionation of the decarboxylation product of the crude glycidic acid, as it was felt that this, being the largest portion, represented the main product of the reaction. It was therefore essential that the structure of this key intermediate be established with some degree of certainty in order to assign structures to products synthesized in the subsequent steps. The structure of this substance is not very easy to establish since it can be represented by four possible isomeric structures (IVa, IVb, IVc and IVd). Of these, structures IVd can be eliminated since a substance represented by this structure should absorb in the region of 2600–2900 Å.,[14] and no maximum was observed in this region. The fact that our substance responds slowly to the fuchsin aldehyde test and forms phenylhydrazones should place it in the aldehyde class, although isomeric compounds having structures similar to IVa or even isobutylene oxide were found to respond similarly to these reactions. Even the spectrum of IVa, IVb and IVc might conceivably be similar, although that of IVc should have, in addition to a band in the region of 2300 Å., a second or even a third band of higher wave lengths and of lower intensity as observed in the spectra of the known α,β-unsaturated aldehydes.[15] No such a band was found in the purified decarboxylation product which was used in our synthetic experiments, although a small high boiling fraction with an abnormally high index of refraction was found to have an additional band

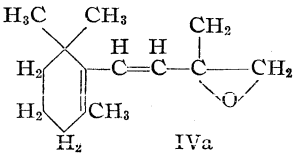
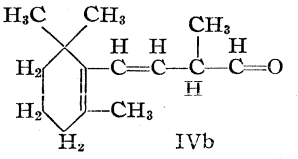
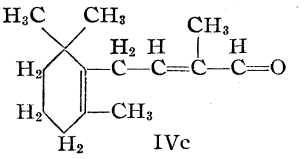
at 3000 Å. It is this fraction which may have structure IVc.



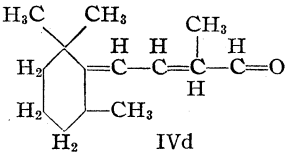
IVa



IVb



IVc



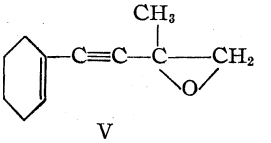
IVd

If our decarboxylation product had structure IVc, as proposed by Heilbron, *et al.*,[9b] it should yield on ozonization 3,3-dimethyloctanedione-2,7, or if the reaction of Böeseken and Jacobs[16] operates in this case, 2,2-dimethyl 6-heptanol-1, both of which are neutral products. No such products were found, but instead, geronic acid was obtained in a yield of about 40%. Since the intermediate product formed upon hydrolysis of the ozonization product should theoretically be a derivative of acetoacetic acid which may oxidize[17] under the conditions of our hydrolytic reaction using small amounts of 30% hydrogen peroxide, we determined the stability of both acetoacetic ester and ethanol under these conditions by measuring the hydrogen peroxide consumed. We have found that the amount of hydrogen peroxide consumed is very small to account for the production of geronic acid from the theoretically possible acetoacetic acid derivative. Furthermore, alcohols are not oxidized rapidly with hydrogen peroxide in the absence of catalysts, and even in the presence of catalysts, glycols have been isolated in good yields.[18] Therefore, if we assume that ozonolysis is a reliable method for determining the structure of organic compounds, we are forced to the conclusion that our main decarboxylation product must have either structure IVa or IVb.

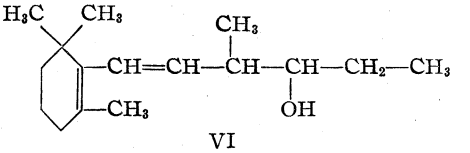
In order to obtain more reliable information concerning the structure of our product, it was necessary to stabilize its functional group by some simple reactions, thereby preventing a possible rearrangement during ozonization. For example, if our product had structure IVc, the addition of lithium acetylide or that of ethylmagnesium bromide should destroy the conjugation, and the ultraviolet absorption spectrum of the resulting carbinols should be that of two isolated double bonds acting individually. Furthermore, both carbinols should yield on ozonolysis 3,3-dimethyloctanedione-2,7 or 2,2-dimethyl-6-heptanol-1 rather than geronic acid. Actually, both carbinols exhibited absorption maxima in the neighborhood of 2260 Å., which indicates the preservation of conjugation. On ozonolysis, both carbinols yielded geronic acid rather than the neutral products mentioned. Again we are forced to the conclusion that the substance from which the carbinols were made must have either structure IVa or IVb.

To decide between structures IVa and IVb, two methods were employed. The synthesis of the epoxide V structurally analogous to IVa was first undertaken.[11] This was found to have similar but not identical properties with those of our key intermediate. It exhibited an absorption maximum at 2320 Å., indicating the presence of a triple and a double bond in conjugation. It responded to the fuchsin-aldehyde test in the same manner but was more reluctant to form a 2,4-dinitrophenylhydrazone than the decarboxylation product. Several attempts to prepare a semicarbazone of the epoxide were entirely unsuccessful. In spite of the fact that some properties of the epoxide resemble those of the decarboxylation product, the evidence is not convincing that the latter has the epoxy structure.

The oxidation of the carbinols derived from the decarboxylation product by the Oppenauer reagent[19] would establish the nature of the hydroxyl group in these carbinols as well as in the vitamin A intermediates.[13] If the carbinols were secondary, ketones would be formed while if they were tertiary no oxidation would be expected to occur. When the unsaturated carbinol VI and its perhydro derivative were actually oxidized with a large excess of aluminum *t*-butoxide, the corresponding ketones were obtained in yields of 79 and 70%, respectively. These results, together with the ozonolysis, seem to establish the structure of the carbinol VI and that of its perhydro derivative.



V



VI

If the decarboxylation product had structure IVb, the acetylene carbinol VII should also be a secondary carbinol and form easily an acid phthalate.[20] Actually, only a small amount could be converted into the acid phthalate, the bulk of the product either remained unchanged or dehydrated into the polyvinylacetylene VIII. Similarly, when 3-nitrophthalic anhydride was used, only a small amount of the acid 3-nitrophthalate was obtained; the remaining product had two bands in

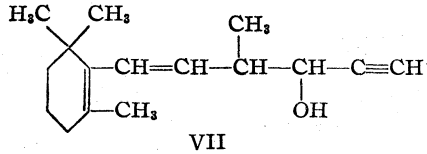
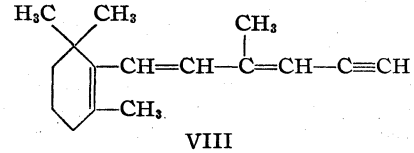
the ultraviolet, one at 2860 Å. and the other at 2260 Å. Even the crude preparation of the acetylene carbinol showed two bands, the 2260 Å. band attributed to the acetylene itself and a band of low intensity at 2860 Å. with an $E^{1\%}_{1\text{ cm.}}$ value of 18–78 attributed to the polyvinylacetylene. The ease with which the acetylene carbinol dehydrates suggests the possibility of the hydroxyl group being tertiary. However, in accordance with the



VII



VIII

Saytzev rule[21] the same polyvinylacetylene will result by the dehydration of either the acetylene VII or its isomer which is derived from the epoxy IVa. Direct dehydration of the acetylene carbinol using various dehydrating agents produced the polyvinylacetylene mixed with isomeric products which were difficult to remove. Dehydrohalogenation of the acetylene halide using quinoline to remove the hydrogen halide failed to remove all of the halogen, indicating that a small portion of the latter was probably attached to the double bond through an allylic shift to the acetylene bond. The pure polyvinylacetylene was obtained only when the chloroacetylene was treated with alcoholic potash and the acetylene hydrocarbon subsequently purified through its silver derivative. The polyvinylacetylene had an $E^{1\%}_{1\text{ cm.}}$ value at 2860 Å. of 760 and showed normal hydrogenation and other properties.

Some of the properties of the acetylene carbinol, however, are not consistent with those expected of a secondary carbinol. For example, when its perhydro derivative was treated with acetyl bromide, it was partly converted into a bromide, indicating the presence of a loosely bound hydroxyl group. Although this derivative resembled in physical properties the perhydro carbinol prepared from the carbinol VI, its chemical properties were somewhat different. When it was treated with excess aluminum *t*-butoxide or with chromic acid in acetic acid solution, a product was obtained which failed to form a solid semicarbazone, phenylthiosemicarbazone, or 2,4-dinitrophenylhydrazone. In spite of the fact that the product underwent a change in some of its properties, such as reduction of active hydrogen, increase of unsaturation (with aluminum *t*-butoxide), it was difficult to isolate any pure component from it other than recovering the original product. Therefore, the perhydroacetylene carbinol seems to show properties which cannot be entirely reconciled with the view that the hydroxyl group in this derivative is a secondary hydroxyl, in spite of the fact that the original acetylene carbinol formed a 3-nitrophthalate, which is not usually formed by tertiary carbinols under the conditions employed. At present we cannot explain this anomaly.

Heretofore, the decarboxylation of glycidic acids in general has always led to the production of aldehydes or ketones; the epoxy intermediates which are theoretically possible have never been isolated.[22] Furthermore, authentic epoxides[11] related to structure IVa have been found to have somewhat different properties than those shown by the main decarboxylation product. Therefore, we feel strongly at present that of all the structures considered, structure IVb seems to account best for the properties of our main decarboxylation product, although on standing for long periods of time, it may slowly rearrange to the structure IVc.

Table II summarizes the spectroscopic data of the important substances mentioned in this investigation.

TABLE II

SUMMARY OF ULTRAVIOLET ABSORPTION SPECTRA DATA (IN ALCOHOL)

Compound	$\lambda_{max.}$, Å.	$E^{1\%}_{1\text{ cm.}}$	log $\epsilon_{mol.}$

Experimental

β-Ionone.—Three different methods have been used in this Laboratory for the purification of β-ionone. Although the bisulfite and semicarbazone methods were used for small quantities, fractionation under reduced pressure was resorted to for the purification of larger quantities. The commercial grade (Maywood) of β-ionone (n^{25}D 1.5155–1.5162) was fractionated in quantities

(21) Saytzev, *Ann.*, **179**, 300 (1875); Thoms and Mannich, *Ber.*, **36**, 2544 (1903).

of 1–2 kg. under a constant reduced pressure maintained between 10 and 18 mm. through a four-foot packed fractionating column of about 25 theoretical plates using a reflux ratio of about 5:1. The purity was followed by measuring the index of refraction of every fraction. Those between 1.5168–1.5180 (25°) were collected and refractionated and the fractions boiling 124–126° (10 mm.), or 133–134° (13 mm.), or 135–137° (15 mm.), or 142–143° (18 mm.), collected. These had $n^{25}D$ between 1.15172 and 1.5182 and d^{20}_4 of 0.944 and 0.9442 and $\epsilon_{mol.}$ (2950 Å.) between 10,500–11,000. In the majority of our syntheses, the β-ionone used had an $n^{25}D$ >1.5175. Recently through the courtesy of the du Pont Company we received a generous sample with an $n^{25}D$ 1.5185.[23]

1-[2′,6′,6′-Trimethylcyclohexen-1′-yl]-3-methyl-4-hydroxypentadien-1,3-oic Ethyl Ester-5 (I, II, III).—This compound was prepared over fifty times under a variety of conditions by several members of our group. A representative procedure embodying our latest modifications follows: A mixture of 184 g. (1.5 moles) of ethyl chloroacetate (b. p. 142–143° at 750 mm.), 96 g. (0.5 mole) of β-ionone and 135 g. of dry thiophene-free toluene was cooled between −50 and −60° in a three-necked flask supplied with a stirrer, a dropping funnel, a thermometer, a nitrogen inlet and a long Gooch tube attached to a flask containing 56.7 g. (1.05 moles) of alcohol-free sodium methoxide.[24] A little over one-half of the sodium methoxide was slowly added with vigorous stirring in the course of one-half hour, then an additional 96 g. (0.5 mole) of β-ionone was added dropwise in the course of one-half hour alternately with the remainder of the sodium methoxide. The mixture was then packed at −50° and allowed to stir gently overnight at the same time warming up slowly to room temperature. The mixture was then heated in nitrogen on the water-bath for four hours, then cooled quickly to −5° and maintained at this temperature while the aqueous solution of 500 cc. of tartaric acid containing 90 g. of the latter was added to it. The toluene layer was separated, washed with water, dried, and the toluene and excess ethyl chloroacetate removed on the water-bath under reduced pressure. The brown residue was fractionated in nitrogen and the fraction (190 g.) boiling at 152–157° (2 mm.) refractionated and the final fraction (178 g.) boiling at 154–156° (2 mm.) collected; $n^{25}D$ 1.5293; $E^{1\%}_{1\ cm.}$ (2860Å.), 793; log $\epsilon_{mol.}$ 4.34.

Anal. Calcd. for $C_{17}H_{26}O_3$: C, 73.18; H, 9.39; unsaturation, 3 ⌐¬; active hydrogen (Zer.), 1. Found: C, 73.5, 73.3; H, 8.80, 9.61; unsaturation, 3.19 ⌐¬ (Pt); active hydrogen (Zer.), 1.08.

In alcoholic solution, the ester gives an immediate green color with ferric chloride, indicating the presence of an enol form.

Crystalline Hydroxy Acid from Ester (III).—The pure hydroxy ester (158 g.) was hydrolyzed in the usual manner with alcoholic potash, then the mixture diluted with two volumes of water and extracted several times with petroleum ether to remove non-saponifiable materials. The water layer was then neutralized with dilute phosphoric acid and extracted with ether. Since the ester is strongly enolic, it can be retained by the alkali in the aqueous layer. The ethereal solution was therefore extracted with excess sodium bicarbonate solution, and the hydroxy acid recovered by acidification with dilute phosphoric acid. The crude acid thus obtained was dissolved in the least volume of ether and to the solution was added enough petroleum ether until a cloudiness resulted. The mixture was allowed to stand at 0° for several days, whereby a solid acid separated out. By repeating the process several times and recrystallizing the solid each time from similar solvent mixtures, a total of 44 g. of crystalline acid m. p. 150–150.2° (dec.),[25] and 78 g. (combined total of 86% yield) of liquid acid from which no more crystals could be obtained by any means tried. The crystalline acid is also strongly enolic; it gives a greenish coloration with ferric chloride and has two (1.99, 2.09, 2.15) active hydrogen atoms (Zer.), and an unsaturation of 2.74 double bonds. It also has an $E^{1\%}_{1\ cm.}$ (2850 Å.) value of 1363; log $\epsilon_{mol.}$ 4.53. Calcd. N. Eq. for $C_{15}H_{22}O_3$, 250. Found: 255, 256.

The liquid acid showed similar properties.

Decarboxylation of the Crystalline Acid (Pyridine Method).—In a Claisen flask attached to a 6 inch Vigreux was placed 50 g. of crystalline glycidic acid and to it was added 60 cc. of pure anhydrous pyridine. Some of the excess pyridine was removed by distillation under reduced pressure, then decarboxylation was allowed to proceed in nitrogen and under ordinary pressures at 130–135° for about one to two hours. The mixture was then subjected to a vacuum distillation and the product distilling at 80–125° (2 mm.) collected. A large amount of resin was also formed. The crude distillate was washed in petroleum ether several times with sodium bicarbonate solution, then fractionated under reduced pressure and the fraction boiling at 91–98° (2–3 mm.) collected; $n^{25}D$ 1.5450. This product failed to give the fuchsin-aldehyde test except on long (two to three hours) standing when a faint purplish color developed. It slowly reduced ammoniacal silver nitrate solution, and gave no solid semicarbazones or phenylhydrazones. It gave a negligible (0.12) active hydrogen (Zer.) and showed an unsaturation of 4.1 double bonds. The ultraviolet absorption spectrum showed two bands; one at 2380 Å., $E^{1\%}_{1\ cm.}$ .978, and one at 3150 Å., $E^{1\%}_{1\ cm.}$ 856.

A less pure product was obtained when 10 g. of the crystalline acid was decarboxylated in the presence of clean copper chips. This product had exactly the same properties as the one above except its $E^{1\%}_{1\ cm.}$ value at 2380 Å. was 661 and at 3150 Å., 221.

Decarboxylation of the Liquid Acid.—The liquid acid (124 g.) separated from the crystalline acid was mixed with 150 cc. of pyridine and after removal of the excess pyridine, decarboxylation was effected at 130 to 135°. When decarboxylation was over, the mixture was distilled in nitrogen at 76–135° (2–3 mm.). The crude product was shaken several times with sodium bicarbonate solution, and, after drying, fractionated twice using a 6-inch Vigreux column and a fraction boiling at 98–105° (2–3 mm.) or 49–53° (10^{-4} mm.) collected. This product had the following properties: $n^{25}D$ 1.5320, negligible active hydrogen (0.07) and an unsaturation of 2.32 double bonds. It gave a fair fuchsin-aldehyde test and reduced ammoniacal silver nitrate solution. It showed a band in the ultraviolet at 2350 Å. with an $E^{1\%}_{1\ cm.}$ value of 741.

Decarboxylation without Isolation of the Glycidic Ester (Commonly used in the Various Syntheses).—In the preparation of the glycidic acid, the crude ester prior to its fractionation was dissolved in 10% alcoholic potash and the mixture allowed to stand in nitrogen overnight, then heated on the water-bath for two hours under slightly reduced pressure to remove about one-third of the alcohol. The mixture was then cooled and diluted with three volumes of water and extracted several times either with ether or petroleum ether[26] to remove unsaponifiable matter. The aqueous layer was then acidified with 10% phosphoric acid and extracted several times with ether. The ether extracts were dried and the ether removed under reduced pressure. The crude glycidic acid was then mixed with excess pyridine (2 moles per mole of glycidic acid) and decarboxylated at 130–135°

(23) Determined in our Laboratory.

(24) Best results were obtained when the residual methanol in sodium methoxide was removed under reduced pressure at about 70–80°. Sodium ethoxide treated the same way gives identical results. Sodamide gives much lower yields of the final product.

(25) The decomposition point was determined by the method of Cocker and Lapworth, *J. Chem. Soc.*, 1398 (1931).

(26) β-Ionone dissolves in alkali to give red solutions, but it can be extracted to the extent of 98% with petroleum ether or ethyl ether.

in the usual manner. When decarboxylation was over, the resulting mixture was fractionated under reduced pressure and the fraction boiling up to 135° (2–3 mm.) collected and treated several times with sodium bicarbonate; yield of crude product, 40–60%, a variation of several experiments. The crude product was refractionated twice using a 6-inch Vigreux and the largest fraction with an acceptable index of refraction was used for synthetic purposes. The results of a representative final fractionation are given in Table III.

TABLE III

FINAL FRACTIONATION OF THE DECARBOXYLATION PRODUCT FROM THE CRUDE GLYCIDIC ACID

Wt., g.	B. p. (≤ 1 mm.) °C.	$n^{24}D$
32	<86	1.5330
74	86–89	1.5144
7	90–137	1.5234

The middle fraction was used for synthetic and analytical purposes. Yields of the pure product varied from 19–30% not including products obtained from refractionations of the low and high boiling fractions. The specific fraction given above had a d^{25}_{25} 0.956, and an $E^{1\%}_{1\ cm.}$ (2320 Å.) value of 967.

Anal. Calcd. for $C_{14}H_{22}O$: C, 81.50; H, 10.75; unsaturation, 2.0 ⌐; active hydrogen (Zer.), 0.0. Found: C, 81.90, 81.49; H, 11.2, 10.75; unsaturation, 3.38, 3.01, 3.43 (Pt), 1.91 (Pd) ⌐; active hydrogen (Zer.), 0.12, 0.07.

This product gave a strong fuchsin-aldehyde test only after fifteen minutes to one hour of standing, and reduced alcoholic ammoniacal silver nitrate solution. The semicarbazone, m. p., 149.5–150.5° (from 50% alcohol), $E^{1\%}_{1\ cm.}$ (2660 Å.), 1375; the thiosemicarbazone, m. p., 156–159° (from alcohol); and the 2,4-dinitrophenylhydrazone, m. p., 169–170° (from alcohol), $E^{1\%}_{1\ cm.}$ (2560 Å.), 550, $E^{1\%}_{1\ cm.}$ (3800 Å.), 859 were prepared from this product. In all cases the production of these derivatives was slow and the yields were low.

When appreciable quantities of the low and high boiling fractions were collected, they were fractionated several times and the main fractions separated. They had the following properties.

Low Boiling Fraction.—B. p., 79–82° (2 mm.); $n^{26}D$ 1.5450; $E^{1\%}_{1\ cm.}$ (2380 Å.), 923, $E^{1\%}_{1\ cm.}$ (3150 Å.), 645. It gave a negative fuchsin-aldehyde test (faint purple color developed after two to three hours). After long standing it reduced alcoholic ammoniacal silver nitrate solution. It failed to form solid semicarbazone and nitrophenylhydrazones. This product was not investigated further.

High Boiling Fraction.—B. p. 113–115° (1.5 mm.), 55–60° (10^{-4}–10^{-5} mm.), $n^{25}D$ 1.5202; $E^{1\%}_{1\ cm.}$ (2310 Å.), 737, $E^{1\%}_{1\ cm.}$ (3000 Å.), 402. It gave a positive fuchsin-aldehyde test (one to two hours) and reduced alcoholic ammoniacal silver nitrate solution. 2,4-Dinitrophenylhydrazone, m. p. 161–162° (from alcohol); mixed m. p. with 2,4-dinitrophenylhydrazone of the main fraction, 160.5–166°. Like the 2,4-dinitrophenylhydrazone of the normal decarboxylation product, this derivative showed two maxima in the ultraviolet with values of $E^{1\%}_{1\ cm.}$ (2560 Å.), 506 and $E^{1\%}_{1\ cm.}$ (3800 Å.) 853, respectively. The parent product gave the following analyses:

Anal. Calcd. for $C_{14}H_{22}O$: C, 81.50; H, 10.75; unsaturation, 2.0 ⌐; active hydrogen (Zer.), 0.0. Found: C, 81.2, 81.3; H, 10.4, 10.4; unsaturation, 2.27 ⌐; active hydrogen (Zer.), 0.12.

Ozonization of Aldehyde (main product IV).—About 4 g. of aldehyde IV was ozonized following the method of Strain[27] and the 2,4-dinitrophenylhydrazone precipitated. The precipitate was almost completely soluble in sodium bicarbonate solution from which the crude 2,4-dinitrophenylhydrazone of geronic acid was precipitated by the addition of 20% potassium bisulfate. A yield of about 40% calculated as geronic acid was obtained at this stage, having a m. p. of 115–120°. This was recrystallized several times from aqueous acetic acid, from aqueous methanol and finally from cyclohexane; m. p. 131–132.5° (cor.). A mixed m. p. with an authentic sample of the geronic acid derivative gave a m. p. of 132–133.5° (cor.).

1-[2′,6′,6′-Trimethylcyclohexen-1′-yl]-3-methylhexen-1-ol-4 (VI).—A Grignard was prepared from 5.8 g. of ethyl bromide and 1.3 g. of magnesium in about 150 cc. of anhydrous ether. To this was added 10 g. of the normal decarboxylation product ($n^{24}D$ 1.5144). When the Grignard reaction mixture was hydrolyzed and the product fractionated under a reduced pressure using a 6-inch Vigreux, a carbinol (8 g.) was obtained which boiled at 66–68° (10^{-4}–10^{-5} mm.); $n^{25}D$ 1.5020; $E^{1\%}_{1\ cm.}$ (2260 Å.) 264.

Anal. Calcd. for $C_{16}H_{26}O$: C, 81.29; H, 11.94; unsaturation, 2.0 ⌐; active hydrogen (Zer.), 1.0. Found: C, 81.00, 81.30; H, 11.80, 12.00; unsaturation, 2.3, 2.4 ⌐; active hydrogen (Zer.), 0.90, 0.95, 0.97.

Ozonization of Carbinol VI.—About 2.8 g. of carbinol VI was ozonized as before and the 2,4-dinitrophenylhydrazone precipitated, extracted with sodium bicarbonate and reprecipitated; yield of the crude bicarbonate soluble product, about 35%. This was purified as in the previous case, m. p. 133.5–134.5° (cor.). A mixed m. p. with an authentic sample of the geronic acid derivative showed no significant depression.

Oxidation of Carbinol VI with Aluminum *t*-Butoxide.—The carbinol (2.8 g.) was oxidized in a mixture of 70 cc. of anhydrous, thiophene-free benzene and 40 cc. of pure, freshly distilled acetone with 4 g. (large excess) aluminum *t*-butoxide[16] by refluxing the mixture on the water-bath in an atmosphere of nitrogen for fourteen hours. The crude product was isolated in the usual manner and distilled at a pressure of 10^{-4} mm. in a molecular still of the falling film type using a heating liquid (mixture of ethanol and carbon tetrachloride) which boiled at 65.2°. The largest fraction (79%) obtained had the properties: $n^{25}D$ 1.5033; $E^{1\%}_{1\ cm.}$ (2340 Å.), 469; active hydrogen (Zer.), 0.19, 0.22. A semicarbazone was prepared from it, m. p. 167.5–169° (from 50% alcohol); $E^{1\%}_{1\ cm.}$ (2660 Å.), 1019.

Anal. Calcd. for $C_{17}H_{29}ON_3$: C, 70.06; H, 10.03. Found: C, 70.11; H, 10.05.

Reduction of Carbinol VI to the Perhydrocarbinol.—To avoid hydrogenolysis with platinum oxide as catalyst, the carbinol (8 g.) was first reduced in alcohol using Raney nickel (0.16 g.) for sixteen hours under a hydrogen pressure of 7–12 pounds. Complete hydrogenation was effected in the same solvent (minimum hydrogenolysis is known to occur in alcohol) for several days using platinum oxide as catalyst. The product was finally recovered and fractionated using a 6-inch Vigreux and the fraction boiling at 58–59° (10^{-4}–10^{-5} mm.) collected; $n^{25}D$ 1.4838; active hydrogen (Zer.), 0.96.

Oxidation of the Perhydrocarbinol with Aluminum *t*-Butoxide.—When this carbinol was oxidized with excess aluminum *t*-butoxide using the same procedure as above, a product was obtained boiling at 44–50° (10^{-4}–10^{-5} mm.); $n^{25}D$ 1.4855; active hydrogen (Zer.), 0.25; semicarbazone, m. p. 165–166° (from 75% ethanol, 25% water); 2,4-dinitrophenylhydrazone, m. p. 111–114° (from alcohol).

1-[2′,6′,6′-Trimethylcyclohexen-1′-yl]-3-methyl-4-hydroxyhexen-1-yne-5 (VII).—After a number of trials using calcium and sodium acetylide in liquid ammonia, and sodamide in ether, it was found that lithium acetylide gave the best yields of the acetylene carbinol VII. Into a 3-necked, round-bottomed flask provided with a stirrer, a dropping funnel and an inlet tube and externally cooled

(27) Strain, *J. Biol. Chem.*, **102**, 137 (1933).

to −60°, was condensed 1.5 liters of ammonia. The liquid ammonia was then saturated with dry acetylene and, while stirring and the latter passing through the solution, 3.1 g. of small pieces of metallic lithium was added in the course of two hours. When the color of the mixture turned gray, the latter was cooled to −70° and to it was added dropwise in the course of one hour 80 g. of the aldehyde IV in 80 cc. of dry ether while acetylene was still passing through the solution. Stirring and cooling to −70° was continued overnight then the cold-bath was removed, the ammonia slowly expelled and the mixture allowed to warm up to 0°. At this temperature 500 cc. of dry ether was added and the mixture acidified with 80 g. of tartaric acid in 120 cc. of water. The ether layer was then separated, washed with a 10% salt solution, dried and the ether removed. The residue was fractionated twice under reduced pressure using a 3-inch Vigreux and the fraction (67 g., 83.8% yield) boiling at 69–72° (10^{-4} mm.) collected; $n^{25}D$ 1.5122; d^{25}_{25} 0.9538; M_D (calcd.), 72.48; found, 73.02; $E^{1\%}_{1\ cm.}$ (2260 Å.), 407. Crude samples of the acetylene carbinol had an additional band of low intensity with a maximum at 2860 Å.; $E^{1\%}_{1\ cm.}$, 18–78.

Anal. Calcd. for $C_{16}H_{24}O$: C, 82.70; H, 10.41; unsaturation, 4.0 ⌐; active hydrogen (Zer.), 2.0. Found: C, 82.28; H, 10.30; unsaturation, 4.01, 4.07, 4.39 ⌐ (Pt), 3.83, 3.95 ⌐ (Pd); active hydrogen (Zer.), 2.01, 2.06, 1.91, 1.99.

The acetylene carbinol formed a silver derivative which exploded on rubbing and on the hot plate. This derivative was purified from benzene by precipitation with methanol.

Anal. Calcd. for $C_{16}H_{23}OAg$: Ag, 31.8. Found: Ag, 31.5.

The acetylene carbinol also formed a solid acid 3-nitrophthalate[17] in low yields (7–10%); m. p. 149.5–150° (methanol); $E^{1\%}_{1\ cm.}$ (2260 Å.), 746.

Anal. Calcd. for $C_{24}H_{27}O_6N$: C, 67.76; H, 6.40; unsaturation (including benzene ring and nitro group), 9.0 ⌐. Found: C, 68.14; H, 6.61; unsaturation, 9.24 ⌐ (Pt).

The recovered product from this reaction had a spectrum with maxima at 2260 Å., $E^{1\%}_{1\ cm.}$ 254, and at 2860 Å., $E^{1\%}_{1\ cm.}$ 141.

With phosphorus tribromide in pyridine at 0° the acetylene carbinol formed a bromide which retained its acetylene properties; b. p. 53–56° (10^{-4}–10^{-5} mm.); $n^{25}D$ 1.5413; d^{25}_{25} 1.076.

Anal. Calcd. for $C_{16}H_{23}Br$: Br, 27.12. Found: Br, 27.0.

The acetylene carbinol also formed a chloride with thionyl chloride in pyridine at 0°. This reaction, however, caused a slight dehydrochlorination since the percentage of chlorine was found to be slightly lower than the theoretical and the product gave, in addition to the 2260 Å band, the 2860 Å. band which is characteristic of the polyvinyl acetylene.

Anal. Calcd. for $C_{16}H_{23}Cl$: Cl, 14.13; active hydrogen (Zer.), 1.0. Found: Cl, 12.64, 12.57; active hydrogen (Zer.), 0.74.

Ozonization of Acetylene Carbinol VII.—About 4.97 g. of acetylene carbinol was ozonized as in the previous cases and the 2,4-dinitrophenylhydrazone precipitated. The precipitate was extracted with sodium bicarbonate and reprecipitated with 20% potassium acid sulfate solution. A yield of about 41% of the crude product calculated as geronic acid was obtained, m. p. 118–123°. This was recrystallized as before, using aqueous acetic acid, aqueous methanol and cyclohexane; m. p. 133–134° (cor.). A mixed m. p. with an authentic derivative of geronic acid showed no depression.

Perhydroacetylenecarbinol.—Acetylene carbinol (10 g.) was hydrogenated in 200 cc. of absolute ethanol in the presence of Raney nickel (0.2 g.) with shaking and under a 15-lb. hydrogen pressure for two days. The product was recovered and found to be still unsaturated, so it was further hydrogenated for several days in alcohol with shaking using platinum oxide (0.12 g.) as catalyst. Finally, the completely saturated carbinol was recovered and fractionated and the fraction (8.5 g.) boiling at 62–66° (10^{-4} mm.) collected and analyzed; $n^{25}D$ 1.4830.

Anal. Calcd. for $C_{16}H_{32}O$: C, 79.93; H, 13.40; active hydrogen (Zer.), 1.0. Found: C, 79.50; H, 13.03; active hydrogen (Zer.), 0.91, 0.81, 0.94.

Oxidation of Perhydroacetylenecarbinol with Aluminum *t*-Butoxide.—A solution of perhydroacetylenecarbinol (0.8 g.) in 25 cc. of anhydrous acetone and 30 cc. pure benzene was heated to 85° then a solution of 2.5 g. of aluminum *t*-butoxide in 25 cc. of benzene was quickly added and the mixture refluxed for eighteen hours. The product was then recovered in the usual manner and distilled under a reduced pressure, b. p. 38–42° (10^{-5} mm.); $n^{25}D$ 1.4848; active hydrogen (Zer.), 0.48; unsaturation, 1.53 ⌐. This product failed to give a solid semicarbazone, phenylsemicarbazone or 2,4-dinitrophenylhydrazone.

Oxidation of Perhydroacetylenecarbinol with Chromic Acid.—About 3 g. of the perhydroacetylenecarbinol was oxidized with chromic acid (1.1 g.) in glacial acetic acid (60 cc.) and 7 cc. of water at 35–40°. The product was recovered and fractionated and the fraction (2.5 g.) boiling at 37–43° (10^{-5} mm.) collected. This had an active hydrogen of 0.21 and an unsaturation of 1.64 ⌐. This product failed to yield a solid semicarbazone, phenylsemicarbazone, or 2,4-dinitrophenylhydrazone. These results seem to indicate that this perhydroacetylenecarbinol is not identical with the perhydrocarbinol obtained from the carbinol VI.

1-[2′,6′,6′-Trimethylcyclohexen-1′-yl]-3-methylhexadien-1,3-yne-5.—Attempts to make this polyvinylacetylene by the direct dehydration of the acetylene carbinol VII using aluminum phosphate at 250–300° or distilling it from small amounts of *p*-toluenesulfonic acid or mixtures of this acid with various anhydrides (acetic, succinic, etc.), or with *p*-toluenesulfonic acid in toluene at 110°, gave very poor yields and much polymerization. Even when the salt-Grignard of the acetylene carbinol was treated with one mole of anhydrous *t*-butyl alcohol and the resulting product distilled under a highly reduced pressure, the yields of the polyvinylacetylene were poor.

Dehydrobromination of the acetylene bromide with quinoline under various conditions failed to remove all of the bromine from the molecule. Even when the acetylene bromide was refluxed with quinoline for long periods of time, the product formed, when fractionated, contained from 6 to 7% bromine. The bromine could easily be removed by refluxing with alcoholic potash, but the product formed had rather low active hydrogen (Zer.).

Dehydrochlorination of the acetylene chloride with alcoholic potash was much more successful. Into 200 cc. of 95% alcohol containing 23 g. of potassium hydroxide under a gentle reflux in an atmosphere of nitrogen was added in the course of fifteen minutes 51.5 g. of acetylene chloride in an equal volume of alcohol. Gentle refluxing was continued for one and one-half hours longer, then about one-third of the alcohol was removed under reduced pressure and the mixture cooled and diluted with two volumes of water. It was then extracted with 3 × 100 cc. of olefin-free petroleum ether and the extract dried and the solvent removed. The residue was distilled under a highly reduced pressure and a product (33 g.) was obtained boiling at 53–56° (10^{-4}–10^{-5} mm.). This was free from chlorine and had an active hydrogen (Zer.) of 0.7 and a hydrogenation number of 4.34 ⌐. Further purification was effected by preparing its silver derivative in alcoholic ammoniacal silver nitrate solution. The silver derivative of the polyvinylacetylene precipitates rapidly while that of the acetylene carbinol comes down very slowly, and this difference in the precipitation rate made the separation of the two possible. The polyvinylacetylene was recovered from its silver derivative by sus-

pending the latter in petroleum ether and either passing through it hydrogen sulfide or adding ammonium thiocyanate. The polyvinylacetylene was recovered and distilled under reduced pressure and the fraction boiling at 55–60° (10^{-4}–10^{-5} mm.) collected and analyzed. It had an ultraviolet absorption spectrum with a maximum at 2860 Å., $E^{1\%}_{1\ cm.}$ 760 and an inflection at 3050 Å., $E^{1\%}_{1\ cm.}$, 404.

Anal. Calcd. for $C_{16}H_{22}$: C, 89.65; H, 10.35; active hydrogen (Zer.), 1.0; unsaturation, 5.0 ⊨. Found: C, 88.5; H, 10.1; active hydrogen (Zer.), 0.96; unsaturation, 4.78, 4.95 ⊨.

The polyvinylacetylene is very unstable and darkens on standing, even under nitrogen.

Acknowledgment.—The authors are indebted to Mrs. Alice R. Lowry, Mrs. Silvia P. Solar, Miss Margaret A. Campbell, Miss Zelma Weiss, and Mr. S. M. Nagy for the analyses given in this paper, also to Drs. Henry Rapoport and John N. Ingraham for assistance in some of the early experiments, and to Miss Therese M. Harrington for assisting in the ozonolysis experiments. This article is a part of a research program on the synthesis of vitamins A and D, support of which was derived in part through contributions from Abbott Laboratories, Eli Lilly and Company, Merck and Company, Inc., Parke, Davis and Company, The Upjohn Company, and the United Drug Company, such contributions being made through the Research Corporation of New York.

Summary

1. The application of the Darzens synthesis to β-ionone gives 1-[2′,6′,6′-trimethylcyclohexen-1′-yl]-3-methylbuten-1-al-4 as the main decarboxylation product.

2. Ozonolysis of the main decarboxylation product and other products derived from it yielded geronic acid, showing the presence of the β-ionone ring and a double bond in conjugation with this ring.

3. 1-[2′,6′,6′-Trimethylcyclohexen-1′-yl]-3-methylhexen-1-ol-4, its perhydro derivative and their corresponding ketones have been synthesized from the main decarboxylation product.

4. 1-[2′,6′,6′-Trimethylcyclohexen-1′-yl]-3-methyl-4-hydroxyhexen-1-yne-5, its perhydro derivative and 1-[2′,6′,6′-trimethylcyclohexen-1′-yl]-3-methylhexadien-1,3-yne-5 were also synthesized.

5. The absorption spectra of all the products synthesized were determined and correlated with their structure.

Synthesis of Products Related to Vitamin A. V. The Synthesis of [1-(2′,6′,6-Trimethylcyclohexen-1′-yl)-3,7-dimethyldeca-1,3,5,7-tetraenyl]-10-ethyl Ether[1]

BY NICHOLAS A. MILAS, S. WARREN LEE,[1a] CONRAD SCHUERCH, JR., RICHARD O. EDGERTON,[2] JOHN T. PLATI,[3] FRANK X. GROSSI,[4] ZELMA WEISS[5] AND MARGARET A. CAMPBELL[6]

The synthesis of [1-(2′,6′,6′-trimethylcyclohexen-1′-yl)-3,7-dimethyldeca-1,3,5,7-tetraenyl]-10 ethyl ether[7] or simply homovitamin A ethyl ether (I) and [1-(2′,6′,6′-trimethylcyclohexen-1′-yl)-3,7-dimethyldeca-1,3,5-trien-5-ynyl]-10-ethyl ether or simply 5-dehydrohomovitamin A ethyl ether (II) was undertaken in the early days of our investigation in this field to provide model studies for the corresponding derivatives of the vitamin A itself.

In the first step of this synthesis, 5-ethoxypentanone-2 was prepared from acetoacetic ester by a modification of the procedure of Clarke and Gurin,[8] and was then converted, in liquid ammonia with sodium acetylide or in *t*-butyl alcohol with potassium acetylide, to 3-methyl-6-ethoxyhexa-1-yn-3-ol (III) which was dehydrated over hot aluminum phosphate to 3-methyl-6-ethoxyhexa-3-en-yne-1 (IV).

For the synthesis of 5-dehydrohomovitamin A ethyl ether, the acetylene carbinol (III) and the vinylacetylene (IV) were allowed to react via their Grignard reagents[9] with 1-[2′,6′,6′-trimethylcyclohexen-1′-yl]-3 methylbuten-1-al-4 (V)[10] to produce, in the first case, the glycol (VI) and, in the second case, the carbinol (VIII). Both of these compounds were successfully dehydrated, with small amounts of *p*-toluenesulfonic acid in toluene, to 5-dehydrohomovitamin A ethyl ether.

The acetylene glycol (VI) had an absorption maximum at 2200–2230 Å. characteristic for a

(1) Since this and other work related to the synthesis of vitamin A was under confidential classification during the War, we wish to point out for purposes of priority the existence of two documents deposited in the Office of the Committee on Medical Research of the O. S. R. D. and describing the synthesis of biologically active vitamin A products using the Darzens aldehyde made from β-ionone as the key intermediate. These documents were dated March 6, 1942.

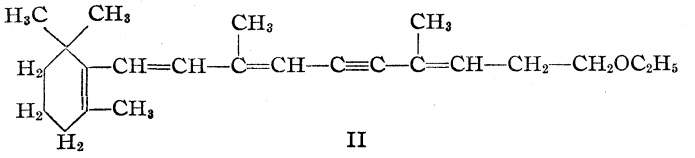
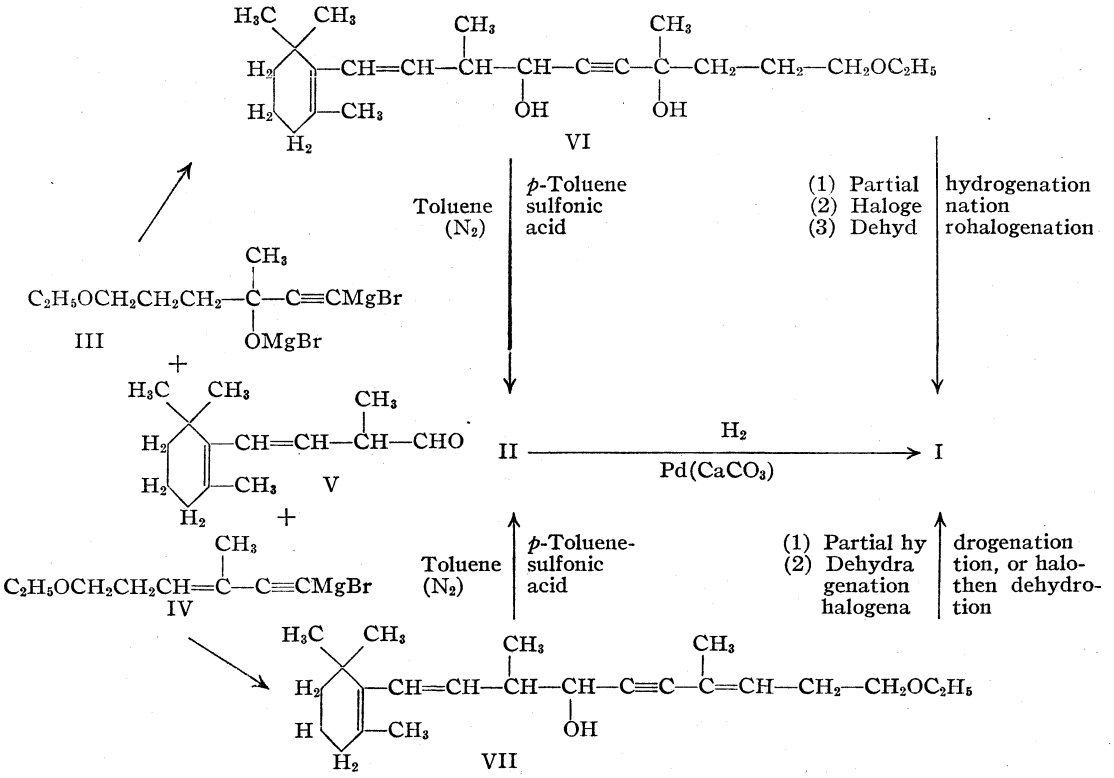
[a] The nomenclature and numbering adopted in this and all subsequent papers of this series is so chosen as to indicate the increase in the carbon side chain and to keep the same numbers present in this chain, irrespective of the increase in the number of carbon atoms, thus facilitating the naming of the intermediate compounds in this field.



II

conjugated system of two double bonds. The existence in the carbinol (VII) of two conjugated systems separated by saturated groups does not seem to have any appreciable effect on the position of the absorption band[11] which appears at 2330 Å.

acid. The crude product obtained from both the glycol VI and carbinol VII, upon a single distillation at pressures $10^{-4}-10^{-5}$ mm., exhibits two bands; one at 3160–3200 Å. and another at 2850–2900 Å. If distillation as a method of purification was repeated several times, the final distillate showed only the 2850–2900 Å. band, and each distillation produced considerable resinification. Other methods were therefore resorted to for the purification of the final products. After a single distillation, the dehydrated product from the carbinol VII was first partitioned between petroleum ether and 90% methanol followed by chromatographic adsorption of the petroleum ether soluble portion on activated alumina. The unadsorbed portion showed a single band at 3210 Å. (Fig. 1, curve A) and gave a blue color with antimony trichloride with absorption maxima at 6220 and 5800 Å. A sample of 5-dehydrohomovitamin



The absorption spectrum of 5-dehydrohomovitamin A ethyl ether (Fig. 1, curves A and C) bears a strong resemblance to that of vitamin A except that it is displaced toward the ultraviolet by about 40 Å., if we take 3250 Å. as the value for the maximum band of natural vitamin A. Both of these substances have been made by dehydration in toluene using catalytic amounts of *p*-toluenesulfonic

(11) Lewis and Calvin, *Chem. Rev.*, **25**, 273 (1939).

A ethyl ether obtained by the dehydration of the carbinol VII and distilled once under high vacuum was tested biologically by Professor Robert S. Harris of the Nutritional Laboratories of this Institute. He reported that when fed to vitamin A deficient rats in doses of 98γ per day, it cured xerophthalmia and caused an average weight increase per rat of 32 g. for the 28-day test period.

Similarly, the dehydrated product from the gly-

col VI, after a single distillation, was partitioned and the petroleum ether soluble portion fractionated at low temperatures using absolute methanol as the solvent. The fraction insoluble in methanol below −30° solidified at about −40° but failed to remain solid at higher temperatures. This product exhibited a single band at 3210 Å. (Fig. 1, curve C), while the methanol soluble portion had both the 2850–2900 and the 3160–3200 Å. bands.

When one mole of hydrogen was added to glycol VI in alcohol using 1% palladium hydroxide on calcium carbonate, the ethylenic glycol VIII was produced. This glycol was treated with pyridine hydrobromide in a large excess of pyridine and the product formed dehydrobrominated with alcoholic potash. The final product was partitioned and the petroleum ether portion chromatographed using activated alumina. The unadsorbed portion was distilled once through a molecular still of the falling film type, and the largest fraction showed an absorption maximum at 3280 Å. (Fig. 1, curve B), and a faint inflection at 3670 Å. From the experimental evidence on hand, it is difficult to decide, at present, whether this product is identical in every respect with the homovitamin A ethyl ether produced by other methods used in this investigation.

Early in our work the glycol VIII was treated in pyridine with either thionyl chloride or phosphorus tribromide and the products formed dehydrohalogenated with alcoholic potash, or, as in one case, with sodamide in liquid ammonia. The crude product from one dehydrobromination experiment was found biologically active in doses of about 0.06 mg. per day, but its stability under feeding experiments was low. The products formed by the dehydrohalogenations when further purified by first partitioning, then by low temperature fractionation in methanol, showed a single absorption band between 3210 and 3220 Å. They also gave a deep blue color with antimony trichloride with bands at about 6220 and 5800 Å.

When one mole of hydrogen was added to carbinol VII in the presence of 1% palladium hydroxide on calcium carbonate, the carbinol IX was produced, and was dehydrated in toluene using catalytic amounts of *p*-toluenesulfonic acid. After molecular distillation, followed by low temperature fractionation in methanol, a product was obtained which showed an absorption maximum at 3210 Å. (Fig. 1, curve D).

The addition of one mole of hydrogen in the presence of palladium to 5-dehydrohomovitamin A ethyl ether did not materially change its ultraviolet absorption spectrum except that the extinction coefficient was slightly lowered, but not appreciably enough to indicate a large percentage of 1,4-addition or some other addition which would radically alter the position of the maximum. It may be of interest to note that in all of the above cases, the 5-double bond formed in the final product may be a *cis*-double bond, although in natural carotenoids and vitamin A, according to Zechmeister,[12] this double bond exists only in the *trans*-form.

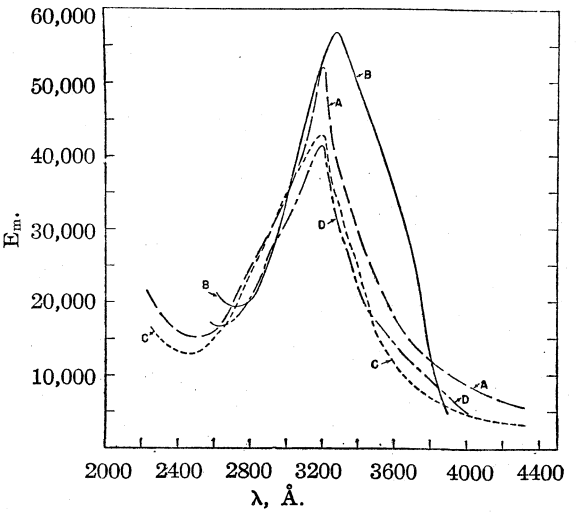


Fig. 1.—Absorption spectra in ethanol of: (A) 5-dehydrohomovitamin A ethyl ether from (VII); (B) homovitamin A ethyl ether via dehydrobromination (pyridine hydrobromide) of partially hydrogenated (VI); (C) 5-dehydrohomovitamin A ethyl ether from (VI); (D) homovitamin A ethyl ether via dehydration of partially hydrogenated (VII).

The ultraviolet absorption spectra of the various compounds reported in this investigation are summarized in Table I.

Experimental

β-Ethoxyethyl Bromide.—This product was prepared in 59–65% yields, b. p. 125–127°, by a method[13] essentially

(12) Zechmeister, *Chem. Rev.*, **34**, 267 (1944).

(13) Schuerch, B.S. Thesis, M. I. T., 1940.

the same as that published later by Harrison and Diehl[14] except that olefin-free petroleum ether was used as a solvent.

5-Ethoxypentanone-2.—This ketone was obtained in a yield of 26.4% using the procedure described by one of us elsewhere.[7] It had a b. p. of 170.5–171° (763 mm.); $n^{20}D$ 1.4176.

Anal. Calcd. for $C_7H_{14}O_2$: C, 64.62; H, 10.77. Found: C, 64.60, 64.50; H, 10.80, 10.80.

Semicarbazone of 5-Ethoxypentanone-2.—This product was recrystallized from ethanol, m. p. 86–87.5°.

Anal. Calcd. for $C_8H_{17}O_2N_3$: N, 22.4. Found: N, 21.7, 22.2.

3-Methyl-6-ethoxyhexa-1-yn-3-ol (Carbinol of III).—This product was also prepared by a procedure described elsewhere[7] and fractionated using a packed column of about 20 theoretical plates; yield, 83%; b. p. 94–95° (15 mm.); $n^{24}D$ 1.4466; $n^{20}D$ 1.4482; MR_D, 44.61; calcd., 44.86; d^{20}_4 0.938.

Anal. Calcd. for $C_9H_{16}O_2$: C, 69.24; H, 10.26; unsaturation, 1 ≡; active hydrogen, 2.0; $-OC_2H_5$, 28.8[4] Found: C, 69.23, 69.37; H, 9.77, 9.60; unsaturation, 0.94, 1.06 ≡; active hydrogen (Zer.), 1.9; $-OC_2H_5$, 28.2.

With alcoholic silver nitrate solution the acetylene carbinol forms a white precipitate which explodes on the hot plate.

This acetylene carbinol was also prepared in a somewhat lower yield (30%) by an adaptation of the method of Gould and Thompson.[15] It was identical with that obtained in liquid ammonia with sodium acetylide.

3-Methyl-6-ethoxyhexa-3-en-yne-1 (Vinylacetylene of IV).—Twenty grams of 3-methyl-6-ethoxyhexa-1-yn-3-ol was passed upward under a reduced nitrogen pressure (11 mm.) through a tube containing a mixture of aluminum phosphate and pumice and maintained at temperatures between 270 and 290°. The crude dehydrated mixture was then dried and fractionated under a reduced nitrogen pressure and the fraction boiling at 55–55.5° (12 mm.) collected; yield, 36% per pass; $n^{20}D$ 1.4522; d^{20}_4 0.8538; MR_D, 43.74; calcd., 42.95.

Anal. Calcd. for $C_9H_{14}O$: C, 78.26; H, 10.14; unsaturation, 3 ═; active hydrogen, 1; $-OC_2H_5$, 32.6. Found: C, 77.99, 77.71; H, 10.60, 9.86; unsaturation, 3.07 ═; active hydrogen (Zer.), 0.93, 0.94; $-OC_2H_5$, 30.4, 33.4.

[1-(2′,6′,6′-Trimethylcyclohexen-1′-yl)-3,7-dimethyl-4-hydroxydeca-1,7-dien-5-ynyl]-10-ethyl Ether (VII).—A Grignard reagent was prepared in about 300 cc. of anhydrous ether from 3.9 g. of magnesium and 17.5 g. of ethyl bromide freshly distilled from phosphorus pentoxide. The mixture was then cooled to 0° and added to it dropwise with rapid stirring and in a stream of nitrogen, 22.1 g. of 3-methyl-6-ethoxyhexa-3-en-yne-1 in 25 cc. of anhydrous ether in the course of one-half hour. Stirring was continued at room temperature overnight, then the mixture was cooled to 0° and to it was added dropwise with rapid stirring 30 g. of the aldehyde (V) in an equal volume of anhydrous ether. The mixture was finally stirred overnight in nitrogen at room temperature, then hydrolyzed with an ammonium chloride–ice mixture and the ether layer recovered, dried and the ether removed under reduced pressure. The residue was subjected to a high vacuum, 10^{-4}–10^{-5} mm., at 100° to remove low boiling constituents, leaving a light-yellow, highly viscous liquid. Attempts to crystallize it were unsuccessful. An absorption spectrum of the final product showed a band at 2330 Å.; log $\epsilon_{mol.}$ 4.33.

Anal. Calcd. for $C_{23}H_{36}O_2$: C, 80.18; H, 10.54; unsaturation, 5 ═; active hydrogen, 1. Found: C, 80.0, 79.9; H, 10.3, 10.5; unsaturation, 5.68, 5.15 ═ (Pt), 5.28 ═ (Pd); active hydrogen (Zer.) 1.00, 1.23.

(14) Harrison and Diehl, "Organic Syntheses," John Wiley and Sons, Inc., New York, N. Y., 1943, Vol. XXIII, p. 32.

(15) Gould and Thompson, THIS JOURNAL, **57**, 340 (1935).

Since all of the semimicrohydrogenations were done in aldehyde-free glacial acetic acid, the high values are probably due to a slow hydrogenolysis of the hydroxyl groups.

[1-(2′,6′,6′-Trimethylcyclohexen-1′-yl)-3,7-dimethyl-4,7-dihydroxydeca-1-en-5-ynyl]-10-ethyl Ether (VI).—A Grignard reagent was prepared from 2.1 g. of magnesium and 9.5 g. of ethyl bromide in about 200 cc. of anhydrous ether. The mixture was then cooled to 0° and added to it dropwise with rapid stirring and in a stream of nitrogen, 8 g. of 3-methyl-6-ethoxyhexa-1-yn-3-ol in 40 cc. of dry ether in the course of one-half hour. A thick finely divided semi-solid separated out. The mixture was refluxed gently for about six hours then cooled to 0° and added to it dropwise 8 g. of the aldehyde (V) in 20 cc. of dry ether. To complete the reaction, the mixture was refluxed overnight in an atmosphere of nitrogen, then cooled and hydrolyzed with an ammonium chloride–ice mixture. The ether extract was dried and the ether removed under reduced pressure. To remove the low boiling constituents, the residue was subjected to a high vacuum 10^{-4}–10^{-5} mm. at 100°. A highly viscous amber-colored liquid remained; yield 13 g. (93%). A semimicrohydrogenation (Pt) of this product showed the presence of 5.6 ═. Spectroscopically it had a prominent band at 2230 Å. and indications at 2400–2500, 2700–2800 and 3200–3300 Å., respectively. Further purification of this glycol was effected by partitioning it between equal volumes of petroleum ether and 90% methanol. The glycol went predominantly into the methanol layer from which it was recovered by diluting with water and extracting with petroleum ether. The final product had a single band at 2200–2230 Å.; log $\epsilon_{mol.}$ 3.65. Semimicrohydrogenation, 4.24 ═.

When this glycol was dissolved in dry petroleum ether and the solution allowed to stand at −20° for several weeks, a small amount of white solid separated out. Successive fractionations of the non-crystallizable product from −20 to −78° yielded only a small additional amount of the white solid. After several crystallizations from hot petroleum ether, the white solid had a m. p. of 74.5–75°, a semimicrohydrogenation of 5.53 ═ and a band at about 2200 Å., log $\epsilon_{mol.}$ 3.575. The non-crystallizable highly viscous liquid analyzed as follows:

Anal. Calcd. for $C_{23}H_{28}O_2$: C, 76.19; H, 10.56; unsaturation, 4 ═; active hydrogen, 2. Found: C, 76.5, 76.3; H, 10.8, 10.7; unsaturation, 4.22, 4.46 ═ (Pt); active hydrogen (Zer.), 1.96. Found (crystalline): C, 75.95; H, 10.42.

[1-(2′,6′,6′-Trimethylcyclohexen-1′-yl)-3,7-dimethyldeca-1,3,5-trien-5-ynyl]-10-ethyl Ether (II) via Dehydration of Carbinol (VII).—About 0.3 g. of *p*-toluenesulfonic acid monohydrate was dehydrated in 300 cc. of toluene (thiophene-free) by distilling 75 cc. of the latter. The mixture was then cooled in nitrogen and 10 g. of [1-(2′,6′,6′-trimethylcyclohexen-1′-yl)-3,7-dimethyl-4-hydroxydeca-1,7-dien-5-ynyl]-10-ethyl ether in 200 cc. of toluene was added to it and distillation resumed in a stream of nitrogen until about 200 cc. of toluene was distilled over in the course of twenty minutes. The residual liquid which had turned deeply reddish-brown was cooled to room temperature and shaken in nitrogen with 2 × 50 cc. of 10% sodium hydroxide solution, washed with water, dried and the toluene removed under reduced pressure. The greenish viscous residue (8 g.) was dissolved in absolute methanol and the solution treated with about 1 g. of solid potassium hydroxide which caused the green color to disappear and the solution assumed a yellowish-orange tinge. Enough water was then added to make the methanol 95% and the mixture extracted with two volumes of olefin-free petroleum ether. The solution was washed with water, dried and the solvent removed. The crude light-brown viscous residue was subjected to a vacuum of about 0.01 mm. at 40–50° for about one hour to remove low boiling constituents. This product gave a deep blue color in chloroform with antimony trichloride;

it showed a negligible active hydrogen (Zerewitinoff) and had an unsaturation equivalent to 5.88 double bonds. When 0.0000956 g. was fed to a group of vitamin A deficient rats per day, a weight increase of 32 g. in twenty-eight days resulted, as compared with an increase of 44 g. in a positive control group fed 3 U. S. P. units of Reference Cod Liver Oil per day. All negative controls died.

The crude product was then fractionated once from a specially designed shallow flask sealed on to it a thermometer well and proper receivers to take cuts, and the largest fraction (light orange oil) boiling at 94–106° (10^{-4}–10^{-5} mm.) collected and examined spectroscopically. It showed two bands; one at 2850–2900 Å. and the other at 3160–3200 Å. Repeated fractionations caused considerable decomposition of the chromogen having the 3160–3200 Å. band.

In subsequent preparations, the crude product was fractionated once at 10^{-4}–10^{-5} mm. and the main fraction partitioned between equal volumes of petroleum ether and 90% methanol. Most of the product went into the petroleum ether layer. This fraction was chromatographed in nitrogen through a column 110 cm. long and 10 mm. bore, packed with 40–60-mesh activated alumina, and washed with about 2 liters of petroleum ether. A small yellowish-brown band 2 cm. long developed on the top of the column while the rest of the column was light orange-yellow. The unadsorbed product in petroleum ether was light orange, and when the petroleum ether was removed and the residue fractionated once, the main fraction (light orange oil) boiled at 100–104° (10^{-5} mm.). This had a single band at 3210 Å. and an $\epsilon_{mol.}$ value of 52,000. It also gave a blue color with antimony trichloride.

Anal. Calcd. for $C_{23}H_{34}O$: C, 84.60; H, 10.49; unsaturation, 6 ⌐¬. Found: C, 83.99, 84.06; H, 10.46, 10.25; unsaturation, 5.98 ⌐¬.

The adsorbed material was eluted with absolute alcohol and a small amount of a product recovered in petroleum ether. This was found to have a strong band at 2850–2900 Å. and a weaker one at 3160–3200 Å. All operations in this and subsequent experiments were carried out in a stream of purified nitrogen.

Partial Hydrogenation of Compound VII to Compound IX.—To 16.6 g. of the carbinol VII in 300 cc. of absolute alcohol and an equal weight of 1% palladium hydroxide deposited on calcium carbonate was added the calculated amount of hydrogen to convert the acetylene bond into an olefin bond taking also into consideration the amount of hydrogen necessary to reduce the palladium hydroxide into palladium black. The product was recovered from this solution and used in the dehydration experiment.

Dehydration of Compound IX.—The product from the previous experiment was dehydrated in 300 cc. of toluene containing about 0.4 g. of *p*-toluenesulfonic acid. The dehydrated product was recovered as in the previous case and treated in absolute methanol with solid potassium hydroxide (2 g.); the methanol diluted with water to 95% and extracted with two volumes of petroleum ether, the latter washed with water, dried, and the petroleum ether removed; yield of the crude product, 11 g. The highly viscous reddish-brown residue was dissolved in about 100 cc. absolute methanol and fractionated in nitrogen at successively lower temperatures, using 10° intervals from 0 to −78°. After a number of such fractionations, the entire product was obtained in three fractions: (1) a very small amorphous resinous fraction insoluble in methanol at 0°; (2) a methanol soluble fraction at −40°; (3) a methanol insoluble fraction at −40° or below which exists as a light orange solid below −50°. Fraction (2) was found to have an absorption band with two maxima; one at 2850–2900 Å., $E^{1\%}_{1\ cm.}$ 994, and the other at 3220 Å., $E^{1\%}_{1\ cm.}$ 710. Fraction (3) had only one maximum at 3210 Å., $\epsilon_{mol.}$. 41,250. The last fraction was also analyzed.

Anal. Calcd. for $C_{23}H_{36}O$: C, 84.08; H, 11.05; unsaturation, 5 ⌐¬. Found: C, 83.22; H, 10.78; unsaturation, 4.88 ⌐¬.

Dehydrochlorination of Compound IX.—A small sample of the carbinol IX (1.1 g.) was treated at 0°, in a mixture of 10 cc. petroleum ether, 10 cc. ethyl ether and 0.25 g. anhydrous pyridine, with 0.4 g. of thionyl chloride for fifteen minutes. It was then allowed to warm to room temperature for one-half hour, then heated in nitrogen under reflux for an additional one-half hour. The mixture was then cooled and filtered off the solid pyridine hydrochloride. Finally the solvent was removed under reduced pressure and the residue taken up in 20 cc. hot 95% ethanol containing 1 g. of potassium hydroxide. To complete dehydrochlorination, the mixture was heated in nitrogen for one-half hour at 60–80°, then cooled, diluted with three volumes of water and extracted with petroleum ether. The petroleum ether extract was once partitioned with an equal amount of 95% methanol, washed with water, dried and examined spectroscopically. It showed two bands; one at 2820–2900 Å., $E^{1\%}_{1\ cm.}$ 406, and the other at 3220–3230 Å., $E^{1\%}_{1\ cm.}$ 313.

[1-(2′,6′,6′-Trimethylcyclohexen-1′-yl)-3,7-dimethyldeca-1,3,5-trien-5-ynyl]-10-ethyl Ether via Dehydration of Glycol VI.—About 150 cc. of anhydrous toluene was mixed with 0.03 g. of *p*-toluenesulfonic acid monohydrate, and a little over 50 cc. of toluene was distilled to cause the dehydration of *p*-toluenesulfonic acid. The mixture was then cooled and to it was added about 1 g. of the glycol VI in 25 cc. of toluene. About 50 cc. of toluene was then distilled in nitrogen and the mixture (deep orange) was cooled, the product recovered as in the previous dehydrations and treated with methyl alcoholic potash. It was recovered from this mixture with petroleum ether and distilled (temperature of boiling cyclohexanone) once, using a molecular still of the falling film type. In addition to a small amount of residue, a dark orange-brown viscous liquid (about 0.6 g.) was obtained which had an absorption band at 3200–3210 Å., $E^{1\%}_{1\ cm.}$ 723. This was further purified by fractionation from absolute methanol at temperatures between 0 and −78°. The fraction insoluble in methanol below −40° was recovered and examined spectroscopically. It was found to have a band with a maximum at 3210 Å., $\epsilon_{mol.}$ 42,500. A semimicrohydrogenation showed the presence of 5.93 double bonds.

Partial Hydrogenation of Glycol VI to Glycol VIII.—To 10.8 g. of glycol VI in 200 cc. of absolute alcohol and 11 g. of 1% palladium hydroxide deposited on calcium carbonate was added the calculated amount of hydrogen necessary to convert the acetylene bond into an olefin bond, and the product recovered and used in the dehydrohalogenation experiments.

Dehydrohalogenation of Glycol VIII. (a) Via Phosphorus Tribromide.—A mixture of 6.9 g. of freshly distilled tribromide, 25 cc. of dry benzene and a few drops of pyridine was cooled to −5°. A solution of 4.62 g. of the glycol VIII, 25 cc. of dry benzene and 6.5 g. of pyridine was then added dropwise with shaking in the course of one-half hour. The mixture was then allowed to stand at room temperature in nitrogen for two hours, heated to 70° for twenty minutes, then cooled and poured on cracked ice and immediately extracted with ether. The ether extract was shaken with two 50-cc. portions of cold phosphoric acid, then once with cold water and dried over anhydrous magnesium sulfate. After filtration, the solvent was removed and to the residue was added 80 cc. of hot methyl alcoholic potash containing 10 g. of potassium hydroxide. The mixture was further heated in nitrogen for one-half hour at 70° then cooled, diluted with two volumes of water and extracted with petroleum ether. This crude product was found biologically active in doses of 0.06 mg. per day, but the activity was not maintained until the end of the test, showing considerable instability. This product was further purified by partitioning between equal volumes of petroleum ether and 90% methanol and the product in the petroleum ether layer analyzed spectroscopically. A yield of about 2 g. was obtained at this stage. It showed two maxima in the ultraviolet; one at

2800–2900 Å. and the other at 3210–3230 A. With antimony trichloride in chloroform, it gave two bands; one at 6220 Å. and the other at 5800 Å., the latter being more prominent.

(b) **Via Pyridine Hydrobromide.**—To 30 g. of dry pyridine was added 1.5 g. of dry hydrogen bromide (Dow Chemical Co.) and the mixture cooled to room temperature while nitrogen was allowed to bubble through it. A solution of 2.5 g. of the glycol VIII in 50 cc. of dry benzene was then added to the above mixture and heated on the water-bath in nitrogen for two hours. All of the benzene and most of the pyridine were then removed under reduced pressure, and to the residue, with nitrogen still flowing through the system, was added 100 cc. of hot 95% alcohol containing 10 g. of potassium hydroxide. The mixture was then heated on the water-bath for one-half hour, then cooled, diluted with two volumes of water and extracted with petroleum ether. About 1.8 g. of a yellowish-brown viscous liquid was recovered which, unlike any other crude dehydrohalogenation product, had a single broad absorption band in the ultraviolet between 3200 and 3400 Å. It also gave a deep blue color with antimony trichloride in chloroform. To purify this product further, it was partitioned between equal volumes of petroleum ether and 90% methanol and the petroleum ether portion chromatographed in nitrogen through a column 110 cm. × 1 cm. packed with activated alumina. The column was then washed with 1.5 liters of petroleum ether and the unadsorbed portion (light yellow) was removed from petroleum ether and fractionally purified at 0 to −78° from absolute methanol. A yellow, highly viscous product (*ca.* 1 g.) was finally obtained and to free it completely from methanol, it was dissolved in petroleum ether and the solution extracted with water, dried and examined spectroscopically. It showed an absorption band at 3280 Å., $\epsilon_{mol.}$ 56,750 and a possible inflection at 3670 Å., $\epsilon_{mol.}$ 30,000. Semimicrohydrogenation showed the presence of 4.85 double bonds.

Anal. Calcd. for $C_{23}H_{36}O$: C, 84.08; H, 11.05. Found: C, 82.32; H, 10.90.

This product was highly unstable and easily autoxidizable and in spite of the precautions taken to obtain pure samples for combustions, the carbon analyses were always from 1.5 to 2% low. This difficulty was also encountered in the early stages of the natural vitamin A purifications.

The adsorbed portion was eluted from alumina with absolute alcohol and, after diluting with water, extracted with petroleum ether. It was found to have two bands in the ultraviolet; one at 3440 Å., $E^{1\%}_{1\ cm.}$ 250, the other at 3670 Å., $E^{1\%}_{1\ cm.}$ 188. The amount of this product was too small for further investigation.

Partial Hydrogenation of 5-Dehydrohomovitamin A Ethyl Ether.—A sample of 0.1271 g. of 5-dehydrohomovitamin A ethyl ether having an $E^{1\%}_{1\ cm.}$ (3210 Å.) value of 1250 was placed in a wafer glass capsule sealed flat on one end and, after weighing, drawn into an open capillary on the other end. The sample was placed into a glass key attached to a rod revolving around a ground glass stopper and sealed on to a specially designed vessel of a semimicro-hydrogenation apparatus.[16] The vessel contained an alcoholic suspension of 0.254 g. of 1% palladium hydroxide on calcium carbonate. After the palladium hydroxide was reduced with hydrogen and equilibrium was established in the system, the capsule was crushed and exactly one mole equivalent of hydrogen was allowed to be absorbed. Hydrogenation was discontinued and the hydrogen in the apparatus was quickly replaced with pure nitrogen. The product was then recovered in the usual manner and analyzed spectroscopically. It was found to have an absorption band at 3200–3210 Å., $E^{1\%}_{1\ cm.}$ 1000 with a faint inflection at 2900 Å. (?).

These results seem to indicate that the addition of hydrogen on the en-yne system had taken place mainly on the acetylene bond, since 1,4-addition would have produced an allene which should be optically equivalent to 5.5 double bonds[17] and its absorption maximum should have been in the region of about 3400 Å. However, the possibility of a rearrangement of the allene into an en-yne with one less double bond should not be excluded. Such an en-yne should have a prominent absorption band in the region of 2900 Å. The fact that a faint inflection was found in this region indicates that some of the hydrogen had actually added 1,4 with a subsequent rearrangement of the allene formed.

Acknowledgment.—The authors are indebted to Mrs. Alice R. Lowry, Mrs. Silvia P. Solar, Mrs. C. K. Fitz and Mr. S. M. Nagy for several of the analyses, and to Professor Robert S. Harris for the biological tests. This article is a part of a research program on the synthesis of vitamins A and D, support of which was derived in part through contributions from Abbott Laboratories, Eli Lilly and Company, Merck and Company, Inc., Parke, Davis and Company, the Upjohn Company, and the United Drug Company, such contributions being made through the Research Corporation of New York.

Summary

1. The synthesis of [1-(2′,6′,6′-trimethylcyclohexen - 1′ - yl) - 3,7 - dimethyldeca - 1,3,5,7 - tetraenyl]-10 ethyl ether, or homovitamin A ethyl ether, and [1-(2′,6′,6′-trimethylcyclohexen-1′ - yl) - 3,7 - dimethyldeca - 1,3,5 - trien - 5 - ynyl]-10-ethyl ether, or 5-dehydrohomovitamin A ethyl ether, and that of several new intermediates has been described. Crude preparations of both homovitamin A and 5-dehydrohomovitamin A ethyl ethers have been found to possess antixerophthalmic (vitamin A) activity.

Synthesis of Products Related to Vitamin A. VI. The Synthesis of Biologically Active Vitamin A Ethers[1]

BY NICHOLAS A. MILAS, EMILE SAKAL,[2] JOHN T. PLATI,[3] JOSEPH T. RIVERS,[4] JEAN K. GLADDING,[5] FRANK X. GROSSI,[6] ZELMA WEISS,[7] MARGARET A. CAMPBELL[8] AND HERBERT F. WRIGHT[9]

Following a scheme originally suggested by Milas and McAlevy,[10] Kipping and Wild[11] were the first to claim the synthesis of vitamin A methyl ether. Since no experimental details, analyses or biological results were given, it is difficult to evaluate this synthesis. Soon after the original announcement of the synthesis of various biologically active vitamin A products[12] developed in this Laboratory during the war, Oroshnik,[13] claimed in a note the synthesis of vitamin A methyl ether, but experimental details as well as biological activity of the final product are lacking.

The present paper describes the synthesis of four biologically active vitamin A ethers. Only two, the methyl and the ethyl and their corresponding 5-dehydrovitamin A derivatives were obtained in relatively pure form, while the isopropyl and the *t*-butyl ethers were obtained in much less pure state.

One of the important intermediates in the synthesis of vitamin A ethers is 4-alkoxybutanone-2 (I). Attempts to prepare this alkoxybutanone, in which R represents methyl or ethyl groups, by the direct alkylation of 4-hydroxybutanone-2 with dimethyl or diethyl sulfates were entirely unsuccessful. Rivers[14] prepared 4-ethoxybutanone-2 from β-ethoxypropionyl chloride and cadmium dimethyl[15] but the yields were low and the method could not be adapted easily for the preparation of the various alkyl ethers of 4-hydroxybutanone-2. Killian, Hennion and Nieuwland[16] prepared 4-methoxybutanone-2 from anhydrous methanol and methyl vinyl ketone in the presence of boron trifluoride-etherate. This method was found satisfactory in the preparation of 4-methoxy, 4-ethoxy, 4-isopropoxy and 4-*t*-butoxybutanone-2's. 4-Alkoxybutanone-2 (R = methyl or ethyl) was then condensed in liquid ammonia with lithium acetylide to give 3-methyl-5-alkoxy-pentyn-1-ol-3 (II) which was dehydrated at 250–280° over aluminum phosphate to 3-methyl-5-alkoxy-3-pentenyne-1 (III).

These three intermediates were used in the study of three different routes for the synthesis of vitamin A ethers (see flow sheet). In the first route the aldehyde (IV)[17] was condensed in liquid ammonia with lithium acetylide to give the acetylene carbinol (V) which was then condensed via the Grignard reaction with 4-alkoxybutanone-2 to give the acetylene glycol (VI) in yields of 70–80%. This glycol was also obtained in somewhat higher yields by the condensation of the Grignard of the acetylene (II) with the aldehyde (IV). This glycol has been obtained in two forms; a crystalline and a highly viscous liquid form. Since the double bond between carbon atoms one and two can exist only in the *trans* form,[18] the difference between the crystalline and the liquid glycols may be one of racemic and *meso* forms.[19] The partial hydrogenation of the acetylene glycol (VI) to give the glycol (VII) was found to be selective when 1% palladium deposited on calcium carbonate was used as the catalyst.

Several methods were employed in the conversion of the glycol ether (VII) (R = methyl) into the vitamin A methyl ether (XI). Using phosphorus tribromide in the presence or absence of pyridine, the glycol was converted into the dibromide which was dehydrobrominated with alcoholic potash. The reaction was also studied with phosphorus trichloride, phosphorus triiodide and thionyl chloride. With thionyl chloride partial dehydrochlorination occurred as was indicated by the appearance in the spectrum of the dichloride of a broad band between 3000 and 3300 Å. Of all the halogenating agents, phosphorus tribromide and thionyl chloride gave the best results. In all

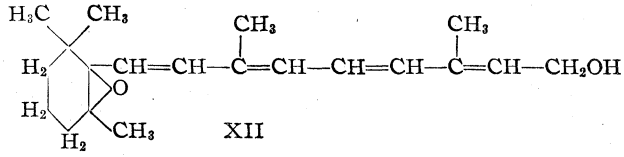
of the cases, however, the product obtained (a pale yellow oil) after a single high vacuum distillation, was found to have two bands in the ultraviolet; one with a maximum at 3250 Å. and the other at 2850–2900 Å. With antimony trichloride in chloroform, it gave a blue color which also showed two bands (Fig. 1, curves with broken lines); one with a maximum at 5800 Å. and another at 6180–6200 Å. Repeated distillation from a shallow vessel at 10^{-5} mm. was detrimental to the chromogen responsible for the absorption band at 3250 Å., which disappeared after five successive distillations.

During the early part of our work we made several preparations through the halogenation of the glycol (VII) (R = methyl, isopropyl, or *t*-butyl) and the dehydrohalogenation of the resulting dihalide. Many of these were assayed biologically on vitamin A deficient rats and a summary of the results is presented in Table I. The glycol (VII) was also tested biologically in order to find out whether the animal organism would cause dehydration, but the results were negative even when very large doses were fed. Preparation (6) was also tested by several other laboratories and all reported appreciable vitamin A activity but not as high as that shown in Table I. Spectroscopically, this sample showed two bands; one at 3250 Å., $E^{1\%}_{1\,cm.}$ 535, the other at 2850 Å., $E^{1\%}_{1\,cm.}$ 655

with feeble indications at 3450 and 3710 Å., respectively. With antimony trichloride in chloroform, it gave a blue color which exhibited two bands at 5800 and 6170 Å., respectively, with the former being the more intense. The product is a light yellow oil boiling at 90–95° (10^{-5} mm.) having negligible active hydrogen (Zer.) and an unsaturation equivalent to 5.08 double bonds. The ultimate analysis, however, gave percentages of carbon varying from 1.5 to 2.0% low. Attempts to purify this product by fractionation at low temperatures were unsuccessful, although the $E^{1\%}_{1\ cm.}$ (3250 Å.) of other samples was raised to 1090 by this method.

The high intensity of the 5800 Å. band (Fig. 1, broken line) suggests the possibility that the vitamin A methyl ether as prepared through the above dehydrohalogenation method is a mixture of the methyl ether and its epoxide. This reasoning finds some support in the recent work of Karrer and Jucker,[20] who found that the chromogen responsible for the 5800 Å. band of the Carr–Price reaction is the epoxide of vitamin A (XII) and not vitamin A, which is responsible only for the 6200 Å. band. From their findings, Karrer and Jucker advanced the hypothesis that in fishliver oils as well as in animal-liver oils, the vitamin A epoxide coexists with vitamin A, and is formed by the auto-oxidation of the latter.[21] The epoxide of vitamin A has also been obtained by treating vitamin A with phthalic acid peracid[22] in a manner similar to that used for the preparation of α- and β-carotene epoxides.[23]



XII

That auto-oxidation of vitamin A is responsible for the 2850–2900 Å. chromogen was shown recently in this Laboratory when an auto-oxidized sample of pure vitamin A was examined spectroscopically. It was found to have a single band at 2850 Å. This is in close agreement with the spectrum of the epoxide of the synthetic methyl ether, the structure of which has not yet been definitely established. Furthermore, both resemble the 5800 Å. chromogen of van Eekelen[24] and the subvitamin A of Embree and Shantz[25] and of Hawkins and Hunter.[26]

Identical results were obtained when the carbinol (X) was treated with phosphorus tribromide and the bromide formed dehydrobrominated with

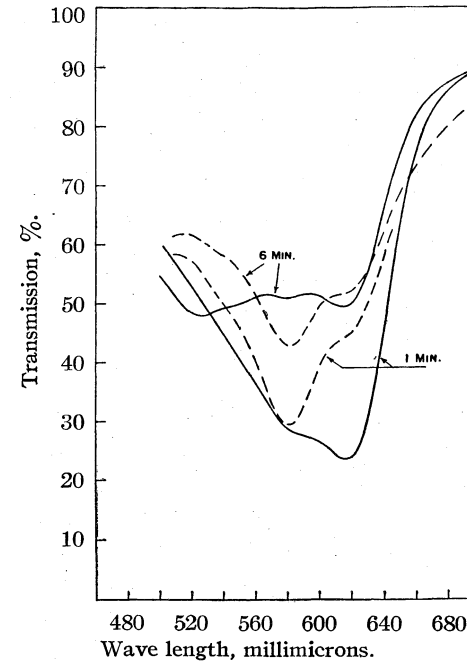


Fig. 1.—Transmission spectra of the antimony trichloride color reaction in chloroform of: (broken line) distilled dehydrobrominated glycol methyl ether (VII), concn., 0.000394%; (solid line) selectively hydrogenated 5-dehydrovitamin A methyl ether (VIII), concn., 0.000192%, taken by the Hardy color analyzer.

alcoholic potash. Since our original publication,[12] Isler, *et al.*,[27] used a similar procedure for the synthesis of vitamin A methyl ether from the carbinol (X) except that the dehydrobromination was carried out with potassium carbonate in acetone. In a more complete publication[28] the same authors used iodine as a catalyst in toluene or ligroin at 95–100° to effect the dehydration of the carbinol (X). The spectroscopic properties of the crude product were similar to those reported by us in the present and earlier publications. The Swiss workers obtained a yellow oil b. p. 90–95° (10^{-5} mm.) having a single band at 3250–3280 Å.; $E^{1\%}_{1\ cm.}$ 1415. When fed to vitamin A deficient rats in doses of 0.8γ and 1.6γ, it was found to be equivalent to 1.1γ and 1.8γ of β-carotene, respectively. Judging from these results, this preparation was not 100% pure vitamin A methyl ether, since the latter has been prepared recently from natural vitamin A by Hanze, *et al.*,[29] who reported a m. p. for this ether of 33–34°, an $E^{1\%}_{1\ cm.}$ (3260 Å.) value of 1660 and a biological potency of about 3,000,000 U.S.P. XXII units per gram.

Sample (10) shown in Table I was prepared by the dehydration in toluene of the methyl ether glycol (VII) using catalytic amounts of *p*-toluene-

TABLE I

SUMMARY OF BIOLOGICAL ASSAYS[a]

MEVA = Methyl ether of vitamin A. iso-PEVA = Isopropyl ether of vitamin A. *t*-BEVA = *t*-butyl ether of vitamin A. DHMEA = 5-Dehydromethyl ether of vitamin A.

	Vitamin preparation	Dose fed per day, γ	Average gain in wt. per rat per 28 days, g.	Remarks[d]
1	MEVA (crude) via dehydrochlorination (PCl_3) of (VII)	331.0[b]	92.0	
2	MEVA (crude) via dehydrobromination (PBr_3) of (VII)	232.0[b]	95.0	
3	Repeat of (2) after standing at 0° in olive oil for one month	531.0[b]	40.0	
4	Repeat of (2), new preparation	176.0[b]	25.0	
5	Repeat of (4), simultaneously	190.0[b]	35.0	
6	Same as (2) distilled three times	3.0[b]	14.0	
7	Repeat of (6) after standing at 0° in olive oil for one month	6.0[b]	−1.5	All rats survived the test
8	Same as (2) distilled four times	3.0[c]	1.6	One out of eight rats died
9	Repeat of (8)	1.5[c]	7.0	Three out of seven rats died on 6th day of test
10	MEVA (distilled) via dehydration of (VII) with *p*-toluenesulfonic acid as catalyst	189.0[b]	45.0	
11	iso-PEVA (distilled) via dehydrobromination (PBr_3)	183.0[b]	57.0	
12	Same as (11) distilled twice	3.0[c]	11.0	One out of six rats died on 10th day of test
13	*t*-BEVA (distilled) via dehydrobromination (PBr_3)	7.4[b]	4.0	Six out of ten rats died during test
14	DHMEA (distilled)	111.0[c]	17.0	
15	Same as (14) distilled twice	6.0[b]	19.0	Only two rats were used for this test

[a] These results were reported to one of us (N. A. M.) during 1941–1942 by Professor Robert S. Harris (M. I. T.). [b] These samples were prepared in olive oil in which the air was replaced by pure nitrogen. To each sample was also added 0.1% of hydroquinone based on the vitamin concentration. [c] These samples were prepared in corn oil in which the air was replaced by pure nitrogen. To each sample was added 0.05% of hydroquinone and 0.05% of lecithin based on the vitamin concentration. [d] All positive control rats were fed 3 U. S. P. units of Reference Cod Liver Oil per day, and showed an average weight increase of 33–44 g. per rat per 28 days. All negative control rats were fed doses of olive or corn oil containing only the antioxidants, and died in the first period of the test.

sulfonic acid. When distilled from a shallow vessel at 10^{-5} mm., the distillate exhibited both the 3250 and the 2850 Å. bands, and gave a blue color with antimony trichloride in chloroform. Hydrogenation showed the presence of 4.98 double bonds and a Zerewitinoff determination showed negligible active hydrogen.

Vitamin A methyl ether was also synthesized by the selective hydrogenation of 5-dehydrovitamin A methyl ether (VIII) which was prepared by the dehydration of the glycol (VI) (R = methyl) using catalytic amounts of *p*-toluenesulfonic acid. The crude 5-dehydrovitamin A methyl ether was purified by partitioning between petroleum ether and 95% methanol followed by low temperature fractionation from methanol and molecular distillation. The ultraviolet absorption of the purest specimen obtained is shown in Fig. 2, curve A. Although the crude product showed two broad bands, one at 3100–3300 Å. and the other at 2800–2900 Å., the purified product showed a single maximum at 3220 Å.; $E^{1\%}_{1\,cm.}$ 1600, and gave the expected unsaturation. Upon ozonization, it yielded geronic acid, indicating the presence of the β-ionone ring in the molecule. When one mole of hydrogen was added to it in the presence of 1% palladium deposited on calcium carbonate, and the product purified by low temperature fractionation from methanol followed by molecular distillation, a specimen [yellow oil, b. p. 90–95° (10^{-4} mm.)] was obtained which had an ultraviolet spectrum [$E^{1\%}_{1\,cm.}$ (3230 Å.), 1560; Fig. 2, curve B] which was very similar to that of the 5-dehydrovitamin A methyl ether. The spectrum of the antimony trichloride color reaction in chloroform is shown in Fig. 1 (solid line curves) taken one minute and six minutes after mixing, respectively. The one-minute curve shows a principal maximum at 6180 Å.; $E^{1\%}_{1\,cm.}$ 3284. Ozonization of this vitamin A methyl ether gave geronic acid, again indicating the presence of the β-ionone ring.

5-Dehydrovitamin A ethyl ether (VIII) (R = ethyl) was also synthesized by the dehydration of either the glycol (VI) or the carbinol (IX) in the presence of *p*-toluenesulfonic acid. The crude product had similar properties to the corresponding 5-dehydrovitamin A methyl ether and was purified by the same procedure. The purest specimen obtained had an ultraviolet absorption spectrum shown in Fig. 2, curve C. Selective hydrogenation did not change appreciably the shape of the band or the position of the maximum.

Since it is well known[18,30] that selective catalytic hydrogenation of an acetylene leads predominantly to a *cis* olefin, and chemical reduction

(30) Campbell and Campbell, *Chem. Rev.*, **31**, 77 (1942).

usually leads to a *trans* olefin, it was thought advisable to study the chemical reduction of 5-dehydrovitamin A ethyl ether and compare the product formed with that obtained from the catalytic hydrogenation. The following chemical methods of selective reduction have been tested with 5-dehydrovitamin A ethyl ether: (1) zinc–copper couple in alcohol[31]; (2) zinc dust in alcoholic potassium hydroxide[32]; (3) zinc and acetic acid in alcohol; (4) "Devarda's" alloy (aluminum–copper–zinc alloy) in aqueous alcoholic potassium hydroxide; (5) Raney alloy in aqueous alcoholic potassium hydroxide; (6) metallic calcium in 90% ethanol; (7) sodium in liquid ammonia.[33] The ultraviolet absorption spectrum and unsaturation were taken before and after each reduction. No reduction was observed, even after prolonged treatment with methods (3) and (6), while method (7) caused complete polymerization of the 5-dehydrovitamin A ethyl ether. Of all the other methods, zinc dust in aqueous alcoholic potassium hydroxide gave the most satisfactory results. A product was obtained by this method which after purification by low temperature fractionation from methanol had an ultraviolet absorption band shown in Fig. 2, curve D. The product also showed an unsaturation of 4.85–5.2 double bonds as compared with the original of 6.0–6.19 double bonds. Although the intensity of the ultraviolet maximum was increased, an increase which might be due to further purification, the position of the maximum was essentially the same (3230 Å.). Moreover, the shape of the absorption curve is somewhat the same as that obtained from the catalytically hydrogenated 5-dehydrovitamin A methyl ether (curve B).

Partially purified specimens of both the methyl and ethyl ethers of vitamin A made by the selective catalytic hydrogenation of the corresponding 5-dehydroethers of vitamin A (VIII) were found biologically active when tested on vitamin A deficient rats. For example, samples with an $E^{1\%}_{1\,cm.}$ (3200–3230 Å.) of about 400 to 500 gave potencies in the neighborhood of 100,000 U.S.P. units per gram. The final purified products have not yet been assayed biologically.

In an attempt to convert the glycol (VII) (R = ethyl) and the carbinol (X) (R = ethyl) into their corresponding bromides with pyridine hydrobromide in excess pyridine followed by treatment with alcoholic potash, we obtained a product (80–90% yield) which showed a broad band in the ultraviolet of very high intensity between 3000 and 3700 Å. and one of low intensity at 2850–2900 Å. and gave a deep blue color with antimony trichloride in chloroform. When partitioned between equal volumes of 83% ethanol and petroleum ether, most of it went into the petroleum ether layer which was chromatographed on activated alumina. The greater part of the product passed through the alumina unadsorbed. This portion was fractionated through a molecular still of the falling film type at 10^{-5} mm. and the largest fraction (80%), a light yellow oil, was analyzed spectroscopically. It was found to have a fine structure of three bands in the ultraviolet (Fig. 3): one at 3300 Å.; $E^{1\%}_{1\,cm.}$ 1690, a second at 3480 Å.; $E^{1\%}_{1\,cm.}$ 1830, and a third at 3670 Å.; $E^{1\%}_{1\,cm.}$ 1520. The shape and position of these bands are identical with similar bands observed recently by Shantz[34] for a hydrocarbon related to vitamin A and containing five double bonds in conjugation. That our substance was not a hydrocarbon was shown by the fact that it still possessed the ethoxyl group. Furthermore, molecular weight determinations and hydrogenation gave values in remarkable agreement with those expected for the vitamin A ethyl ether, although carbon and hydrogen analyses were slightly lower than the theoretical. On standing under nitrogen at 0° for over six months, it partially crystallized into light yellow crystals which melted at about 28–30°. Upon ozonization it yielded geronic acid (as 2,4-dinitrophenylhydrazone) indicating the presence in the molecule of the β-ionone ring. No biological results are as yet available for this substance.

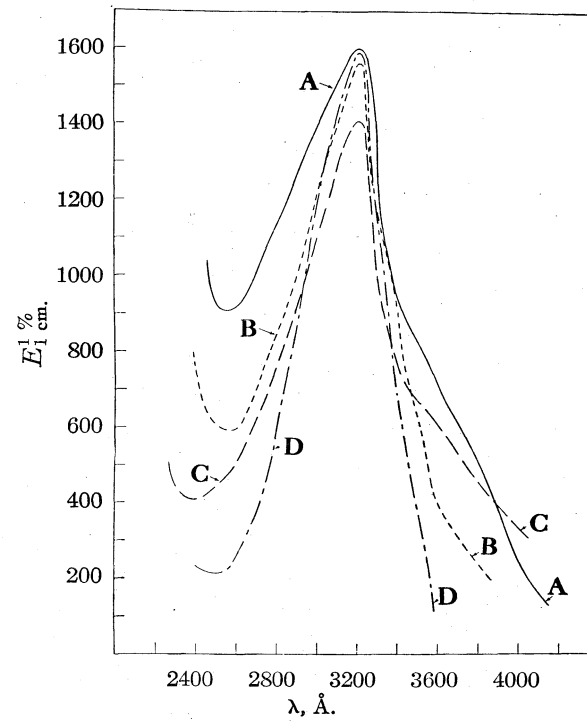

Fig. 2.—Absorption spectra in ethanol of: (A) 5-dehydromethyl ether of vitamin A from (VI); (B) methyl ether of vitamin A via partial hydrogenation of (VIII); (C) 5-dehydrovitamin A ethyl ether via dehydration of either (VI) or (IX); (D) ethyl ether of vitamin A by reduction of (VIII) using zinc dust and alkali.

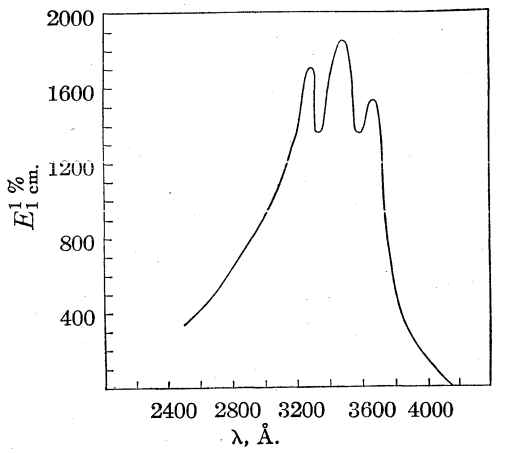

Fig. 3.—Absorption spectrum in ethanol of dehydrobrominated (pyridine hydrobromide) glycol ethyl ether (VII)—"*allo*-vitamin A ethyl ether."

In view of the peculiar nature of its spectrum, one cannot state unequivocally at present that this substance is the normal ethyl ether of vitamin A, in spite of the fact that other evidence seems to point strongly to this conclusion. For this reason, the term "*allo*-vitamin A ethyl ether" is suggested.

A summary of the spectroscopic data of the important compounds discussed in this paper is given in Table II.

TABLE II

SUMMARY OF ULTRAVIOLET ABSORPTION SPECTRA OF ETHERS AND 5-DEHYDROETHERS OF VITAMIN A (IN ALCOHOL)

Vitamin A ether	$\lambda_{max.}$ Å.	$E^{1\%}_{1\,cm.}$	$\epsilon_{mol.}$	log $\epsilon_{mol.}$

[a] 5-Dehydromethyl ether of vitamin A from VI. [b] Methyl ether of vitamin A from VIII. [c] Methyl ether of vitamin A via dehydrobromination of either the dibromide of VII or the bromide of X purified by fractionation at temps. between 0 and −78°. This sample exhibits also the 2850–2900 A. band. [d] 5-Dehydroethyl ether of vitamin A prepared by dehydration of either VI or IX purified via low temperature fractionation and chromatography + molecular distillation. [e] Ethyl ether of vitamin A from VIII via reduction with Zn dust + aqueous alcoholic alkali. [f] Ethyl ether of vitamin A via dehydration of the carbinol X with *p*-toluenesulfonic acid, purified by low temperature fractionation. [g] *allo*-Vitamin A ethyl ether via the dehydrobromination (pyridine hydrobromide) of either VII or X purified by chromatography + molecular distillation.

Experimental

Methyl Vinyl Ketone.—Methyl vinyl ketone was made by the dehydration of β-hydroxyethyl methyl ketone which was prepared by the condensation of acetone with formaldehyde in the presence of small amounts of sodium hydroxide. β-Hydroxyethyl methyl ketone (1150 g.) was best dehydrated by dropping it slowly into hot (160°) *n*-dibutyl phthalate (160 g.) containing 3 g. of iodine and 3 g. of hydroquinone. A yield of 590 g. of crude methyl vinyl ketone was obtained. This was further purified by distilling it from 190 g. of acetic anhydride,[35] followed by fractionation from a six-plate Podbielniak column; b. p. 81°; d^{25}_4 0.842; $n^{22}D$ 1.4095; $n^{15}D$ 1.4120. A yield of 10–15% was obtained based on the formaldehyde used. Pure methyl vinyl ketone is stable for long periods of time over hydroquinone at 0°, but should be freshly distilled as needed.

4-Methoxybutanone-2.—All attempts to make this ketone by the methylation of 4-hydroxybutanone-2 were unsuccessful. It was finally prepared by the method of Killian, Hennion and Nieuwland[16] from methyl vinyl ketone, anhydrous methanol and boron trifluoride-etherate.[36] A yield of 45–51% was obtained based on the amount of methyl vinyl ketone used; b. p. 142–143°; $n^{23}D$ 1.4045. This product had a negligible active hydrogen (Zer.), 0.08.

Anal. Calcd. for $C_5H_{10}O_2$: C, 58.82; H, 9.8. Found: C, 58.73; H, 9.8.

4-Ethoxybutanone-2.—This ketone was made by two independent methods: (1)[14] From β-ethoxypropionyl chloride [b. p. 43–45° (10 mm.)] and cadmium dimethyl.[15] Best results were obtained when the cadmium dimethyl was prepared from methylmagnesium chloride rather than from the corresponding iodide. A yield of 20% of the ketone was obtained; b. p. 43–45° (16 mm.); 2,4-dinitrophenylhydrazone, m. p. 89–90° (from alcohol).

Anal. Calcd. for $C_{18}H_{16}N_4O_5$: N, 18.95; OC_2H_5, 15.23. Found: N, 19.0, 19.0; OC_2H_5, 15.6.

(2) The second procedure was based on the addition of absolute ethanol to methyl vinyl ketone in the presence of boron trifluoride-etherate. This method was employed several times for the preparation of this ketone, and yields were obtained from 52 to 77%; b. p. 149–150° (764 mm.); 74° (50 mm.); 61–62° (23 mm.).

Anal. Calcd. for $C_6H_{12}O_2$: C, 62.04; H, 10.32. Found: C, 62.44, 61.98; H, 10.46, 10.28.

4-Isopropoxybutanone-2.—Using the boron trifluoride-etherate method, this ketone was prepared in 33.5% yield; b. p. 72–75° (37 mm.).

Anal. Calcd. for $C_7H_{14}O_2$: C, 64.63; H, 10.74. Found: C, 64.63, 64.88; H, 9.90, 10.00; active hydrogen (Zer.), 0.1.

4-*t*-Butoxybutanone-2.—This ketone was prepared by the same method as the previous ketone: b. p. 54–57° (15 mm.); $n^{20}D$ 1.4137.

Anal. Calcd. for $C_8H_{16}O_2$: C, 66.7; H, 11.1. Found: C, 66.83, 66.89; H, 12.19, 11.17; active hydrogen (Zer.), 0.14. A semicarbazone was prepared, m. p. 127–129°.

3-Methyl-5-ethoxypentyn-1-ol-3 (II, R = ethyl).—The preparation of this acetylene carbinol from 4-ethoxybutanone-2 and sodium acetylide in liquid ammonia or potassium acetylide in *t*-butyl alcohol resulted in low yields of the desired product and large amounts of resinous produets. However, with lithium acetylide in liquid ammonia, yields of 30–40% of the desired product were obtained in accordance with the following procedure. A liter of liquid ammonia was saturated with dry acetylene and while the latter was passing through the solution, 7.6

(35) White and Howard, *J. Chem. Soc.*, 25 (1943).

(36) Hennion, Hinton and Nieuwland, THIS JOURNAL, **55**, 2858 (1933).

g. of lithium was added with stirring in the course of one hour. Stirring was continued until the solution was decolorized. The mixture was then cooled to −70° and 116 g. of 4-ethoxybutanone-2 was added dropwise in the course of one and one-half hours with acetylene passing through the solution. Stirring was continued for two hours longer, then the ammonia was allowed to evaporate and the residual product acidified with concentrated solution of tartaric acid. Finally, the mixture was extracted several times with ether, the ethereal extracts dried and the ether removed. The crude product was fractionated under reduced pressure and the fraction (46–50 g.) boiling at 67° (7 mm.) collected and analyzed; $n^{25}D$ 1.4370; *MR*, 40.41; calcd. *MR*, 40.32; d^{25}_4 0.922.

Anal. Calcd. for $C_8H_{14}O_2$: C, 67.58; H, 9.93; unsaturation, 2.0 ⌐; active hydrogen (Zer.), 2.0. Found: C, 67.59, 67.83; H, 9.44, 9.55; unsaturation, 2.11 ⌐ (Pd); active hydrogen (Zer.), 2.06, 1.95.

Following the same procedure, the corresponding 5-methoxyacetylene carbinol was prepared in 25% yield, b. p. 80–81° (25 mm.).

3-Methyl-5-ethoxy-3-pentenyne-1 (III).—This enyne was prepared by passing upwards through a hot tube (270–280°) charged with a mixture of aluminum phosphate (17 g.) and pumice (37 g.) the acetylene carbinol (II) at the rate of about 0.6 g. per minute and under a nitrogen pressure of 35 mm. A yield of 50% was obtained per pass; b. p. 68–70° (37 mm.); $n^{25}D$ 1.4448; *MR*, 39.4; calcd. 38.33; d^{25}_4 0.839. An absorption spectrum showed a maximum at 2250 Å., log $\epsilon_{mol.}$, 4.095.

Anal. Calcd. for $C_8H_{12}O$: unsaturation, 3.0 ⌐; active hydrogen, 1.0. Found: unsaturation, 3.1 ⌐; active hydrogen (Zer.), 1.01.

1-[2′,6′,6′-Trimethylcyclohexen-1′-yl]-3,7-dimethyl-9-methoxy-1-nonen-yne-5-diol-3,7 (VI, R = methyl).—A Grignard was prepared in 800 cc. of anhydrous ether from 9.8 g. of magnesium and 43.9 g. of freshly distilled ethyl bromide. The mixture was then cooled to 0° in an atmosphere of nitrogen and to it was added, in the course of thirty minutes with rapid stirring, 48.1 g. (active hydrogen, 1.94) of the acetylene carbinol (V) in 50 cc. of anhydrous ether. The mixture was then refluxed gently in nitrogen for five hours, cooled to 0° and to it added, in the course of twenty minutes, 23.3 g. of 4-methoxybutanone-2 in 20 cc. of anhydrous ether. A whitish precipitate separated out immediately. To complete the reaction the mixture was stirred in nitrogen for twenty-four hours, then cooled and hydrolyzed with a mixture of ice (480 g.) and ammonium chloride (48 g.) and the resulting product extracted several times with ether. The combined ether extracts were washed once with 50 cc. of 10% salt solution, dried with anhydrous magnesium sulfate, and the ether removed. The residue was then subjected to a high vacuum (10^{-5} mm.) at 100° for two hours to remove low boiling constituents. A yield of 63.7 g. (88%) of a yellowish highly viscous product was obtained.

Heating the glycol under high vacuum failed to remove entirely the unreacted acetylene carbinol, so further purification was effected by removing the latter as its silver salt. To a solution of 63.7 g. of the crude glycol in 140 cc. of absolute ethanol was added 35.2 g. of silver nitrate in 240 cc. of absolute ethanol and 120 cc. of concentrated ammonia (d = 0.901). The mixture was protected from light and shaken in nitrogen for twenty minutes, then centrifuged to remove the silver salt of the acetylene carbinol. The clear alcoholic layer was then diluted with an equal volume of water and extracted several times with petroleum ether. The combined petroleum ether extracts were washed with water and dried over anhydrous magnesium sulfate. The mixture was then filtered, the petroleum ether removed and the pale yellow residue subjected to a vacuum of 10^{-5} mm. at 50° for one hour. A yield of 49.5 g. of a gummy product was obtained. Attempts to crystallize this glycol were not successful. Analyses are recorded in Table III.

1-[2′,6′,6′-Trimethylcyclohexen-1′-yl]-3,7-dimethyl-9-ethoxy-1-nonen-yne-5-diol-3,7 (VI, R = ethyl; left → right).—This glycol ether was prepared in the same manner as the corresponding glycol methyl ether except that the Grignard of the acetylene glycol (V) was added to an ethereal solution of 4-ethoxybutanone-2 instead of the reverse. A yield of 92% of the crude product was obtained. This was purified by removing the unreacted acetylene carbinol as its silver salt and the glycol ether obtained partitioned between equal volumes of 90% methanol and petroleum ether. The glycol ether was recovered from the methanol layer by adding two volumes of 10% salt solution and extracting with petroleum ether. A yield of 85% of the purified product was obtained as a pale yellow gum. An ultraviolet absorption spectrum of this substance showed a principal band with a maximum at 2260 Å.; log $\epsilon_{mol.}$, 4.044. Analytical data are given in Table III.

When this glycol (31 g.) was dissolved in petroleum ether and the solution allowed to stand under nitrogen at −20° for several weeks, a white crystalline product (9.2 g.) separated out, m. p. 41–42°. Further successive coolings of the mother liquor from −20 to −78° failed to produce any more crystalline product. The solid was recrystallized several times from petroleum ether at −10 to −20° until a constant m. p. of 68–69° was obtained. An ultraviolet absorption spectrum of this product showed a band with a maximum at 2260 Å.; log $\epsilon_{mol.}$, 4.12. Analytical data are given in Table III.

1-[2′,6′,6′-Trimethylcyclohexen-1′-yl]-3,7-dimethyl-9-ethoxy-1-nonen-yne-5-diol-3,7 (VI, R = ethyl; right → left).—A Grignard was prepared from 19.5 g. of magnesium and 87.5 g. of ethyl bromide. The mixture was cooled to 0° in an atmosphere of nitrogen and to it was added dropwise 57 g. (7.5% excess) of the acetylene carbinol (II, R = ethyl) in the course of one hour. The mixture was then allowed to stir in nitrogen for ten hours, then cooled to 0° and to it was added dropwise 77 g. of the aldehyde (IV) in 100 cc. of ether in the course of one and a half hours. Stirring was continued at room temperature for twenty-four hours, then the mixture was hydrolyzed with a saturated solution of ammonium chloride containing 80 g. of the latter. A yield of 120 g. of the crude glycol was obtained which was purified in the same manner as the glycol prepared from left to right. A yield of 112 g. of the purified product was obtained as a pale yellow gum which had an ultraviolet spectrum with a maximum at 2260 Å.; log $\epsilon_{mol.}$, 3.992. Other analytical data are given in Table III.

When 112 g. of this glycol was dissolved in a liter of petroleum ether and the solution allowed to stand under nitrogen at −20° for several weeks, a white solid (60 g.) separated out which had a m. p. of 41–47°. This was recrystallized several times from petroleum ether at −10 to −20° until a constant m. p. of 67–68° was obtained. An ultraviolet absorption spectrum showed a maximum at 2260 A., log $\epsilon_{mol.}$, 4.018. Other analytical data are given in Table III.

5-Dehydroglycol isopropyl and 5-dehydroglycol *t*-butyl ethers were synthesized in the same manner as the 5-dehydroglycol methyl ether from the Grignard of the acetylene carbinol (V) and 4-isopropoxybutanone-2 and 4-*t*-butoxybutanone-2, respectively. The products were purified only to the stage of removing the volatile constituents by heating at 100° (10^{-4} mm.) for one hour.

The high hydrogenation values shown in Table III are due to partial hydrogenolysis of the hydroxyl groups in the presence of a large excess of catalyst usually required for obtaining quick and accurate estimation of unsaturation with an especially designed semicrohydrogenation apparatus[37] which was thoroughly tested with several known unsaturated compounds.

1-[2′,6′,6′-Trimethylcyclohexen-1′-yl]-3,7-dimethyl-9-ethoxy 1,7-nonadien-yne-5-ol-3 (IX).—A Grignard was prepared in 300 cc. of anhydrous ether from 1.4 g. of magnesium and 6.0 g. of ethyl bromide. The Grignard was cooled to 0° in nitrogen and to it was added dropwise 6.8 g. of 3-methyl-5-ethoxy-3-pentyne-1 (III). The

[a] (1 → r) indicates the preparation of the glycol by adding the Grignard of the acetylene carbinol (V) to the corresponding 4-alkoxybutanone-2. [b] (r → 1) indicates the preparation of the glycol by adding the Grignard of the acetylene carbinol (II) to aldehyde (IV).

mixture was allowed to stir overnight at room temperature, then cooled to 0° and to it added dropwise in the course of one hour 10.8 g. of the aldehyde (IV) in equal volume of ether and again allowed to stir in nitrogen at room temperature overnight. Finally, the mixture was hydrolyzed with excess cold concentrated ammonium chloride solution and the product recovered and heated for one hour at 100° (10^{-4} mm.) to remove low boiling products; yield, 13.5 g., (75%). This was further purified by distillation in a molecular still of the falling film type and the fraction (almost all of the product) distilling at 156° (0.005 mm.) collected and analyzed; $n^{25}D$ 1.5169. An ultraviolet absorption spectrum showed a maximum at 2320 Å.; log $\epsilon_{mol.}$, 4.315.

Anal. Calcd. for $C_{22}H_{34}O_2$: C, 79.94; H, 10.36; unsaturation, 5 ⌐¬; active hydrogen (Zer.), 1.0. Found: C, 79.67, 79.80; H, 10.2, 10.16; unsaturation, 5.31 ⌐¬ (Pt), 5.20 (Pd) ⌐¬; active hydrogen, (Zer.), 1.15, 1.1.

Selective Hydrogenation of 5-Glycol Ethers.—Attempts to add two hydrogen atoms to the acetylene bond of the 5-dehydroglycol ethers chemically were not successful. For example, the solid 5-dehydroglycol ethyl ether, m. p. 68–69°, was treated in methanol or in liquid ammonia with sodium or lithium, or with a large excess of calcium in 90% ethanol and in every case the product was recovered unchanged; *e. g.*, melting point, hydrogenation and active hydrogen determinations were identical with the original; even mixed melting point with the original showed no depression. Catalytic hydrogenation in alcohol, however, using 1% palladium deposited on calcium carbonate showed a high degree of selectivity, so that all of our preparations, including that of 1-[2′,6′,6′-trimethylcyclohexen-1′-yl]-3,7-dimethyl-9-ethoxy-1,7-nonadien-yne-5-ol-3 (IX) were partially hydrogenated by adding one mole equivalent of hydrogen to each. In most of the cases the products recovered were checked by hydrogenation and active hydrogen estimations.

Conversion of the Glycol Ethers (VII) into the Dihalides.—Phosphorus trichloride, tribromide and triiodide were first tried as halogenating agents both in the presence and absence of pyridine. Phosphorus tribromide was found to give the best results. To 100 cc. of dry benzene was added 25 g. of freshly distilled phosphorus tribromide and dry purified nitrogen was allowed to bubble through the solution for five to ten minutes to displace any free hydrogen bromide present. The mixture was then cooled to 0° and, while nitrogen was bubbling through it, 15.3 g. of the glycol (VII, left → right) in 100 cc. of benzene and 22 cc. of dry pyridine was added dropwise in the course of fifteen minutes. The mixture was allowed to stand at 0° for one-half hour, then heated to 60–80° for one hour. The mixture was then cooled, diluted with water and the layers separated. The organic layer was extracted several times with a 5% solution of phosphoric acid, dried and the solvent removed under reduced pressure. The residue was subjected to a high vacuum (10^{-4} mm.) at 50° for one hour; yield of a highly viscous brownish residue, 13 g.

Anal. Calcd. for $C_{21}H_{34}OBr_2$: Br, 34.57. Found: Br, 31.61, 31.60.

The low bromine was due to a partial hydrolysis of the tertiary bromine and to a slight dehydrobromination, since the dibromide showed a small amount of active hydrogen and bands of low intensity at 2850 and 3250 Å.

Dehydrobromination of the Dibromides.—Ordinarily the dehydrobromination was accomplished without isolating the dibromide. Following the above experiment as a typical example, the benzene and other volatile products were removed at the end of the reaction under reduced pressure and to the residue was added 400 cc. of hot 95% alcohol containing 40 g. of potassium hydroxide. Heating was continued in nitrogen at 60–80° under a slightly reduced pressure for one hour, then most of the alcohol was removed and the residue cooled, diluted with six volumes of water and extracted with 4 × 100 cc. of olefin-free petroleum ether. The extract was shaken several times with 5% phosphoric acid solution, then with 10% salt solution, and dried with magnesium sulfate. When the petroleum ether was removed, a yield of 10.9 g. (82%) of the crude product was obtained. This was distilled under a highly reduced pressure and the pale yellow fraction (8 g.) boiling at 90–95° (10^{-4}–10^{-5} mm.) was collected and analyzed. Spectroscopically, this sample had two prominent bands in the ultraviolet, one at 3250 Å.; $E^{1\%}_{1\ cm.}$ 535, the other at 2850 Å.; $E^{1\%}_{1\ cm.}$ 655, and two feeble indications at 3450 and 3710 Å., respectively. With antimony trichloride in chloroform, it gave a deep blue color with maxima at 5800 and at 6180–6200 Å., respectively (Fig. 1, curves with broken lines). Biological results of products prepared by this method are given in Table I, assays 1–9.

Anal. Calcd. for $C_{21}H_{32}O$: C, 83.93; H, 10.73; OCH_3, 10.33; unsaturation, 5 ⌐¬; active hydrogen, 0.0. Found: C, 81.88, 82.09; H, 10.95, 11.12; OCH_3, 11.2; unsaturation, 4.96 (Pd), 5.11, 5.17 (Pt) ⌐¬; active hydrogen (Zer.), negligible.

Repeated distillation of a sample having an $E^{1\%}_{1\ cm.}$ (3250 Å.) value of 1000 at 10^{-5} mm. from a shallow vessel caused considerable decomposition of the vitamin ether. In fact, after five consecutive distillations the band at 3250 Å. had vanished completely. Another sample from a single distillation was fractionated in absolute methanol at temperatures between 0 and −78° and the product (pale yellow solid) insoluble below −40° separated and analyzed spectroscopically. It was found to have a prominent band at 3250 Å.; $E^{1\%}_{1\ cm.}$ 1090.

Dehydrochlorination of the Glycol Methyl Ether (VII, left → right) via Thionyl Chloride and Alcoholic Potash.—A solution of 5.96 g. of freshly distilled thionyl chloride in 10 cc. of ether was added dropwise in the course of fifteen minutes to a well-stirred mixture of 8.5 g. of the glycol methyl ether (VII), 3.96 g. of anhydrous pyridine and 20 cc. of ether, maintained at 0° with nitrogen passing through the solution. The mixture was allowed to come to room temperature, then heated on the water-bath to 60–80° for three hours. During this time all the ether had evaporated, and the residue was cooled and extracted with petroleum ether, the latter removed and the residue (7 g.) analyzed. It gave a deep blue color with antimony trichloride in chloroform and a broad band in the ultraviolet between 3000 and 3300 Å. with an $E^{1\%}_{1\ cm.}$ (3250 Å.) value of 350, showing definite spontaneous dehydrochlorination.

To completely dehydrochlorinate the above product, it was mixed with 60 cc. of methanol containing 3 g. of potassium hydroxide and the mixture heated on the water-bath in an atmosphere of nitrogen for two hours, then cooled, diluted with three volumes of water and extracted with petroleum ether, the extract washed with 10% tartaric acid solution and dried over magnesium sulfate. The final product was free from chlorine, and was purified further by fractionation at low temperatures from a 50–50 mixture of absolute methanol and petroleum ether. A small amount of brown solid separated at −70° which had an ultraviolet spectrum in the region of 3100–3300 Å. and gave a deep blue color with antimony trichloride in chloroform, but was discarded because it was found to contain sulfur. The filtrate yielded a product free from sulfur and chlorine and was found to exhibit two maxima in the ultraviolet; one at 2830 Å.; $E^{1\%}_{1\ cm.}$ 650; the other at 3250–3280 Å.; $E^{1\%}_{1\ cm.}$ 502. When fed to vitamin A deficient rats, it was found biologically active in doses of 10 to 28 γ. Other analytical data of this product were no different from those obtained by the dehydrobromination method using phosphorus tribromide. Similar results were obtained by the dehydrochlorination of the glycol ethyl ether (right → left) using thionyl chloride and alcoholic potash.

The dehydrobromination of the glycol isopropyl (VII, R = isopropyl) and the glycol *t*-butyl (VII, R = *t*-butyl) ethers (left → right) was effected in the same manner as that of the corresponding glycol methyl ether using the phosphorus tribromide method. Yields of about 50–60% were obtained. After preliminary purification from methanol at low temperatures, the isopropyl ether was distilled from a shallow vessel and the product, a yellow viscous liquid, boiling at 87–90° (10^{-5} mm.) was collected and tested spectroscopically and biologically. Table I (assays 11 and 12) gives the biological results of this ether. Spectroscopically it exhibited the usual two broad bands; one at 2800–2900 Å. and the other at 3100–3300 Å. The spectrum of the antimony trichloride color also showed two maxima; one at 5800 Å.; $E^{1\%}_{1\ cm.}$ 506, and the other at 6180 Å.; $E^{1\%}_{1\ cm.}$ 367.

The *t*-butyl ether could not be distilled without appreciable decomposition, so it was fractionated at low temperatures from methanol and the fraction which separated out below −30° was tested biologically and spectroscopically. Assay 13 of Table I gives the biological test on rats of this crude sample of vitamin A *t*-butyl ether. Spectroscopically it also gave the two usual broad bands in the ultraviolet. The spectrum of the antimony trichloride color gave the usual two maxima: one at 5800 Å.; $E^{1\%}_{1\ cm.}$ 388 and the other at 6180–6200 Å.; $E^{1\%}_{1\ cm.}$ 200. This work was done during the early part of the war and no further attempt was made to purify these ethers. However, an attempt was made to convert both of these ethers by the method of Rigby[38] into the corresponding palmitic and acetic esters of vitamin A by treating them with palmityl or acetyl chloride in the presence of traces of anhydrous zinc chloride. Partial conversion was actually accomplished, as it was indicated by the saponification number of the esters produced. With acetyl chloride, the acetate produced had a saponification number between 270 and 300, as against the theoretical of 328. In view of the difficulty encountered in the purification of these esters no further work was done along these lines.

Direct Dehydration of Glycol Methyl Ether (VII, left → right).—Preliminary investigation on the direct dehydration of 1,4-glycol model compounds of the type of the glycol (VII) led to the production of dihydrofurans. However, when 5.7 g. of the glycol methyl ether (VII) was dehydrated in toluene (190 cc.) in the presence of 0.3 g. of *p*-toluenesulfonic acid, by distilling in nitrogen 60 cc. of toluene, a product was obtained which behaved like that obtained by the dehydrobromination process. When distilled from a shallow vessel, a yellow oil (2 g.) was obtained boiling at 90–95° (10^{-4}–10^{-5} mm.). It gave a deep blue color with antimony trichloride in chloroform and exhibited the usual dual maxima in the ultraviolet. Upon hydrogenation it absorbed 4.98 moles of hydrogen as against the theoretical of 5 for the methyl ether of vitamin A. A Zerewitinoff determination showed less than 0.1 active hydrogen, indicating the absence of hydroxyl groups. The preliminary assay 10, Table I, shows the biological activity of this product.

Dehydrobromination of Glycol Ethyl Ether (VII, right → left) via Pyridine Hydrobromide and Alcoholic Potash.—To 40 g. of dry pyridine was added 4.5 g. of dry gaseous hydrogen bromide. The partly solid-partly liquid mixture was cooled in nitrogen and to it was added 8.5 g. of solid glycol ethyl ether (VII) in 50 cc. of anhydrous benzene and heated on the water-bath for three hours while nitrogen was slowly bubbling through it. Most of the solvent was then removed under reduced pressure and to the residue was added 100 cc. of 10% hot alcoholic potash, and the mixture again heated on the water-bath for one-half hour. It was then cooled in nitrogen, diluted with three volumes of water and extracted with petroleum ether. The petroleum ether extract was shaken with 5% phosphoric acid solution, then with water and dried over magnesium sulfate. From the final solution was obtained a yellowish-brown viscous liquid (6.5 g.) which gave a deep blue color with antimony trichloride in chloroform, and exhibited two bands in the ultraviolet: one of very high intensity at 3000–3700 Å. and the other of very low intensity at 2850–2900 Å. For further purification, it was partitioned between equal volumes (100 cc.) of 83% ethanol and petroleum ether, the latter was washed with water, dried and passed through a column 4′ × 1″ filled with 40–60 mesh activated alumina (ALORCO). The column was further washed with a total of 1500 cc. of petroleum ether and the latter removed from the washings; a yellow residue (4.5 g.) remained. This was distilled in a molecular still of the falling film type and the largest fraction (3.5 g.), a clear yellow highly viscous liquid, boiling at 95–98° (10^{-4}–10^{-5} mm.) (bath temperature 145–150°), collected and analyzed. This gave a deep blue color with antimony trichloride and a fine structure

(38) Rigby, Ph.D. Thesis, M. I. T., 1930.

in the ultraviolet of three bands (Fig. 3): one at 3300 Å.; $E^{1\%}_{1\ cm.}$ 1690; a second at 3480 Å.; $E^{1\%}_{1\ cm.}$ 1830; and a third at 3670 Å.; $E^{1\%}_{1\ cm.}$ 1520. No distinct bands developed on the alumina, and the product eluted from it with hot ethyl alcohol exhibited the usual two bands in the ultraviolet, but with lower intensity.

Anal. Calcd. for $C_{22}H_{34}O$: C, 84.00; H, 10.89; OC_2H_5, 14.03; unsaturation, 5.0 ═; mol. wt., 314.5. Found: C, 82.78, 83.32; H, 10.50, 10.90; OC_2H_5, 13.26; unsaturation, 4.94, 5.06 ═ (Pt); mol. wt. (in benzene), 313.7, 310.3, 310.2.

After standing at 0° in nitrogen for over six months, it partially crystallized into pale yellow needles which had a m. p. of 28–30°.

The dehydrobromination of the glycol ethyl ether (left → right) by the above method gave similar results, except much lower yields of the desired product. Similarly, the dehydrobromination of the carbinol (X) by the same procedure yielded a product which in its crude form showed two bands in the ultraviolet; one with a low intensity at 2800–2900 Å., and another with a high intensity at 3000–3700 Å.

Dehydration of the Carbinol (X).—To 150 cc. of thiophene-free toluene was added 0.09 g. of *p*-toluenesulfonic acid and 25–30 cc. of toluene distilled to remove traces of water present in the mixture. The toluene solution was then cooled in nitrogen and to it was added 4.5 g. of the carbinol (X) in 60 cc. of toluene. Enough toluene (50–60 cc.) was then distilled in nitrogen until the distillate was completely free from cloudiness. The contents (reddish-brown) of the flask was cooled and treated with 50 cc. of methanol containing 2.5 g. of potassium hydroxide. Enough water was then added to separate the layers, the organic layer removed, washed with water, and dried over magnesium sulfate. When the toluene was completely removed, a reddish-brown viscous liquid (3.8 g.) remained. This gave a blue color with antimony trichloride in chloroform and exhibited two broad bands in the ultraviolet; one at 2800–2900 Å. and the other at 3000–3400 Å., the latter being more intense. To further purify this product, it was partitioned between 100 cc. of petroleum ether and 100 cc. of 90% methanol. Most of the product went into the petroleum ether which was washed with water, dried, and the solvent removed under reduced pressure. The residue was taken up in absolute methanol and fractionated at temperatures between −10 and −78°, the product (a yellow semi-solid) which separated out in various fractions below −40° recovered in methanol and extracted from it with petroleum ether by adding 5% salt solution. From the petroleum ether a product was obtained which gave a deep blue color with antimony trichloride in chloroform and exhibited a single band in the ultraviolet with a well-defined maximum at 3250–3270 Å.; $E^{1\%}_{1\ cm.}$ 1500 and log $\epsilon_{mol.}$ 4.67 (see Table II).

Dehydration of 5-Dehydroglycol Methyl Ether (VI left → right) to 5-Dehydrovitamin A Methyl Ether (VIII).—The 5-dehydroglycol methyl ether (31.5 g.) was dehydrated in toluene (400 cc.) using *p*-toluenesulfonic acid (0.7 g.) in the usual manner. The dehydrated product was first treated with 5% methyl alcoholic potash followed by partitioning between equal volumes of petroleum ether and 90% methanol. The petroleum ether layer was washed with water, dried and the solvent removed; yield, 24 g. This product gave a purplish-blue color with antimony trichloride in chloroform and two broad bands in the ultraviolet: one with a high intensity at 3000–3300 Å., the other with a low intensity at 2800–2900 Å. When distilled under a high vacuum from a shallow vessel, a clear light orange liquid came over at 85–95° (10^{-4}–10^{-5} mm.). This was tested biologically and the results are given in Table I, assay 14. Hydrogenation of this sample showed the presence of 6.35 double bonds and showed negligible active hydrogen (Zer.). Although the hydrogen analysis was close to the theoretical value the carbon was about 2% low. Further purification was effected by alternate distillation and low temperature fractionation from absolute methanol. The results are given in Table IV. The product from the second distillation was again tested biologically (Table I, assay 15).

The final product (see Table IV) was a light orange viscous oil, having the following analytical data:

Anal. Calcd. for $C_{21}H_{31}O$: C, 84.50; H, 10.13; OCH_3, 10.39; unsaturation, 6.0 ═. Found: C, 83.87, 83.60; H, 10.34, 9.92; OCH_3, 11.25; unsaturation, 6.3, 6.08, 6.1 ═ (Pt).

A freshly distilled sample of 5-dehydrovitamin A methyl ether (7.8 g.) with an $E^{1\%}_{1\ cm.}$ (3200 Å.) value of 1000 was selectively hydrogenated in absolute ethanol by adding to it one mole-equivalent of hydrogen in the presence of 1% palladium deposited on calcium carbonate (using one-half the weight of the sample). The crude product was recovered and analyzed spectroscopically. It was found to have a peak at 3220–3230 Å.; $E^{1\%}_{1\ cm.}$ 886. This was further purified by low temperature fractionation from absolute methanol and the fraction insoluble below −30° recovered and distilled under high vacuum. A product (yellow oil) boiling at 90–95° (10^{-4} mm.) was collected and analyzed. It gave a blue color with antimony trichloride in chloroform, the transmission spectrum of which is shown in Fig. 1 (solid line curves). In this case the 6180 Å. maximum is much more intense than that of the 5800 Å. with an $E^{1\%}_{1\ cm.}$ value of 3284. The ultraviolet absorption spectrum showed a single well-defined band with a maximum at 3230 Å.; $E^{1\%}_{1\ cm.}$ 1560 (Fig. 2, curve B). Hydrogenation showed the presence of 5.15 (Pt) double bonds.

TABLE IV

THE EFFECT OF ALTERNATE HIGH VACUUM DISTILLATION AND LOW TEMPERATURE FRACTIONATION ON 5-DEHYDROVITAMIN A METHYL ETHER

No. of distillations (10^{-4}–10^{-5} mm.) and low temp. fractionations	$\lambda_{max.}$, Å	$E^{1\%}_{1\ cm.}$ max.
Second distillation	3180	1300
Third distillation	3180	1200
Fourth distillation	3200	844
First fractionation (methanol) of distilled product (4th time)	3190	1090
Second fractionation	3200	1120
Third fractionation	3200	1140
Distillation of final fractionated sample	3220	1600 (Curve A, Fig. 2)

Ozonization of Vitamin A Methyl Ether (XI).—A sample (1.81 g.) of the vitamin A methyl ether prepared by the foregoing method and kept under nitrogen at −20° for over two years was ozonized by the method of Strain.[39] It yielded about 0.5 g. (26%) of crude sodium bicarbonate soluble geronic acid 2,4-dinitrophenylhydrazone. This was recrystallized several times from aqueous acetic acid and from aqueous methanol; m. p. 133.5–134.5° (cor.). Mixed m. p. with an authentic sample of geronic acid 2,4-dinitrophenylhydrazone showed no depression; 134–134.5° (cor.).

Dehydration of 5-Dehydroglycol Ethyl Ether (VI, left → right).—The 5-dehydroglycol ethyl ether (22 g.) was dehydrated in toluene (550 cc.) in the presence of 0.45 g. of *p*-toluenesulfonic acid using the general procedure adopted in this paper. The crude product was treated with 5% methyl alcoholic potash, then partitioned between equal volumes (200 cc.) of petroleum ether and 90% methanol. The fraction taken by the petroleum ether was recovered (15.5 g.) and fractionated several times in

(39) Strain, *J. Biol. Chem.*, **102**, 137 (1933).

absolute methanol between 0 and −78° and the fractions insoluble below −30° (orange-yellow solid) were combined and distilled from a shallow vessel under a high vacuum. A light orange oil boiling at 95–98° (10^{-4}–10^{-5} mm.) was collected and analyzed. The ultraviolet spectrum showed a single, well-defined band with a maximum at 3210–3220 Å.; $E^{1\%}_{1\,cm.}$ 1400.

Anal. Calcd. for $C_{22}H_{32}O$: C, 84.55; H, 10.33; unsaturation, 6.0 ⌐═; active hydrogen, 0.0. Found: C, 84.58, 85.22; H, 10.90, 11.00; unsaturation, 6.1, 6.2 ⌐═ (Pt), 6.05 ⌐═ (Pd); active hydrogen (Zer.), 0.05 (within experimental error).

Dehydration of 5-Dehydroglycol Ethyl Ether (VI, right → left).—This glycol ethyl ether (20 g.) was dehydrated in the same manner as the previous sample in 500 cc. of toluene and in presence of 0.4 g. of *p*-toluenesulfonic acid. After washing with 5% methyl alcoholic potash and partitioning between petroleum ether and 90% methanol, a product (14 g.) was obtained which had an $E^{1\%}_{1\,cm.}$ (3210 Å.) value of 1320. Further purification was effected by dissolving the product in petroleum ether and passing it with nitrogen through a 4′ × 1″ column packed with 40–60 mesh of activated alumina (ALORCO). The column was then washed with 1.5 liters of petroleum ether and the unadsorbed portion (11–12 g.) was recovered from the petroleum ether and fractionated once at low temperatures from absolute methanol. The fractions insoluble below −30° were collected and distilled under a high vacuum. An orange-yellow oil boiling at 95–100° (10^{-4}–10^{-5} mm.) was collected and analyzed. It had a single, well-defined band with a maximum at 3220 Å.; $E^{1\%}_{1\,cm.}$ 1410 (Fig. 2, curve C). Upon catalytic hydrogenation (Pt) it absorbed 6.1 moles of hydrogen. Molecular weight determinations in benzene by the freezing point method gave the following values: Calcd. for $C_{22}H_{32}O$: 312.5. Found: 310.7, 308.3, 313.

Dehydration of 5-Dehydrocarbinol Ethyl Ether (IX).—About 10 g. of 5-dehydrocarbinol ethyl ether (IX) was dehydrated in 400 cc. of toluene in the presence of 0.2 g. of *p*-toluenesulfonic acid. The resulting mixture was treated with 5% methyl alcoholic potash and the product recovered from it partitioned between petroleum ether and 90% methanol. The fraction (7.5 g.) taken up by the petroleum ether was recovered and fractionated at low temperatures from absolute methanol. The fractions insoluble below −30° were combined and distilled under high vacuum. An orange-yellow oil was obtained boiling at 95–98° (10^{-4}–10^{-5} mm.). This had a single band with a maximum at 3210–3220 Å.; $E^{1\%}_{1\,cm.}$ 1350.

Anal. Calcd. for $C_{22}H_{32}O$: C, 84.55; H, 10.33; unsaturation, 6.0 ⌐═; active hydrogen, 0.0. Found: C, 83.67, 83.38; H, 10.54, 10.31; unsaturation, 6.10, 6.28 ⌐═ (Pt); active hydrogen (Zer.), 0.03 (negligible).

Ozonization of 5-Dehydrovitamin A Ethyl Ether (VIII).—About 1.5 g. of 5-dehydrovitamin A ethyl ether prepared by the dehydration of 5-dehydroglycol ethyl ether (right → left) was ozonized in the usual manner and the 2,4-dinitrophenylhydrazone precipitated. The bicarbonate soluble portion was recrystallized once from aqueous methanol; m. p. 126.5–127.5° (cor.); yield, 0.3 g. (20%). This was again recrystallized from aqueous methanol three times, and a final m. p. of 134–134.5° (cor.) was obtained. Mixed m. p. with an authentic sample of geronic acid 2,4-dinitrophenylhydrazone gave no depression.

Selective Chemical Reduction of 5-Dehydrovitamin A Ethyl Ether.—The selective chemical reduction of the acetylene bond in 5-dehydrovitamin A ethyl ether was studied using the estimation of unsaturation and the extinction coefficient in the ultraviolet as guides in estimating the degree of reduction. No appreciable reduction was observed when zinc dust and acetic acid in ethanol or calcium in 90% ethanol were used as reducing agents. Sodium in liquid ammonia brought about complete destruction of the molecule. Partial reduction was observed with zinc–copper couple in absolute ethanol and with "Devarda's" (Baker) and Raney alloys in 2% of aqueous (1:9) alcoholic potassium hydroxide. The most successful results were obtained with zinc dust in aqueous alcoholic potassium hydroxide. The following is a representative experiment: 5-Dehydrovitamin A ethyl ether (2.03 g.; unsaturation 6.19 ⌐═ (Pt); $E^{1\%}_{1\,cm.}$ 1350) was dissolved in 90 g. of absolute ethanol and to the solution added, with cooling and purified nitrogen slowly bubbling through it, 10 cc. of water, 6 g. of solid potassium hydroxide and 0.6 g. of zinc dust. Nitrogen was allowed to bubble slowly through the mixture for twenty hours, then 20 cc. of water was added and the reaction allowed to proceed five hours longer. Finally, the mixture was diluted with 20 cc. of water and extracted with petroleum ether, the extract washed with water, dried, and the solvent removed under vacuum. The residue (2 g.) was fractionated at low temperatures from 20 cc. of absolute methanol and the fractions (1.5 g., pale yellow solid) separating below −30° combined and analyzed. An ultraviolet absorption spectrum showed a well-defined band with a maximum at 3230 Å.; $E^{1\%}_{1\,cm.}$ 1590 (Fig. 2, curve D). Hydrogenation (Pt) showed the presence of 4.85–5.2 double bonds. The combined filtrates from the above purification exhibited a band at 3220–3230 Å.; $E^{1\%}_{1\,cm.}$ 1215. This experiment was repeated several times, in some cases with a large excess of zinc dust, and the results were identical.

Acknowledgment.—The authors are indebted to Mrs. Alice R. Lowry, Mrs. Silvia P. Solar, and Mr. S. M. Nagy for most of the analyses; to Mrs. Ruth B. Pitt for assistance in some of the tedious purification experiments; to Miss Therese M. Harrington for assistance in the ozonization and other experiments; and to Professor Robert S. Harris for the biological assays. This article is a part of a research program on the synthesis of vitamins A and D, support of which was derived in part through contributions from Abbott Laboratories, Eli Lilly and Company, Merck and Company, Inc., Parke, Davis and Company, the Upjohn Company, and the United Drug Company, such contributions being made through the Research Corporation of New York.

Summary

1. The synthesis of biologically active vitamin A ethers has been achieved via several routes, using 1-[2′,6′,6′-trimethylcyclohexen-1′-yl]-3-methylbuten-1-al-4 as the key intermediate.

2. Synthetic methyl and ethyl ethers of vitamin A have been obtained in relatively pure form. The isopropyl and *t*-butyl ethers have been obtained in less pure form.

3. Several new intermediates used in the various syntheses are described with complete analytical data for the first time.

The Organic Reactions with Aluminum Chloride. XX. The Action of Aluminum Chloride upon Ethylene Chloride

BY KEIITI SISIDO AND YOSIO YOSIKAWA

In our previous communications[1] in which the Friedel–Crafts reaction of dihalogenoalkanes with benzene were investigated, many anomalies, particularly shifts and splitting off of halogen atoms, were observed. During these researches we were impressed with the need for the fundamental studies of the behavior of these alkylene dichlorides alone in the presence of aluminum chloride, in order to clarify our understanding of the complicated reaction of condensation. The present paper deals with the change of ethylene chloride, one of the simplest homologs of the series, in the absence of an aromatic hydrocarbon, under the ordinary conditions of the Friedel–Crafts reaction.

It was astonishing that, when we treated ethylene chloride with 15% of its weight of aluminum chloride at 80°, a violent reaction ensued and the whole reactant, after only four hours of heating, solidified. In order to study the mechanism of the formation of solid material, it was decided to carry out the experiments under milder conditions. The reaction was now carried out with ethylene chloride and 10% of aluminum chloride at 26 ± 1°, and it was interrupted when the greater part of the dichloride still remained unreacted, so that the distillable intermediate products could be obtained. The reaction was continued for seventy-five minutes and the mass was poured into iced water to decompose aluminum chloride; after recovering the unchanged material, the products were fractionated in the usual way. By this procedure we have isolated the same compounds as the intermediates of a polycondensation product of benzene and ethylene chloride,[2] which we have described in a previous paper,[3] namely, bibenzyl and *m*-bis-(β-phenylethyl)-benzene were identified by analyses and by mixed melting points with authentic specimens. It should be noted that the latter substance was a new compound which we had found just before the War among the intermediates of the above mentioned high molecular material; the constitution was ascertained by the decomposition[3] as well as by the synthesis.[4] The mechanism of the formation of these substances from benzene and ethylene chloride as well as the *meta*-orientation of the reaction were discussed in the previous papers.

The present facts are explained only by the assumption that benzene was formed from ethylene chloride by the action of aluminum chloride; this benzene condenses with the excess of ethylene chloride in the presence of aluminum chloride in the same way as the synthesis of the elastomer by the Friedel–Crafts reaction. During the reaction a considerable amount of hydrogen chloride was liberated, but it was not accompanied by acetylene, ethylene, vinyl chloride or any other unsaturated compound according to qualitative analyses. As these compounds are therefore not regarded as stable intermediates, the route from ethylene chloride to benzene is not certain. It is easy to surmise that an elimination of two moles of hydrogen chloride from ethylene chloride produces a free radical —CH=CH—, three moles of which form a benzene molecule by cyclization. But rigorous proof is lacking.

The formation of benzene from ethylene chloride during the Friedel–Crafts reaction was not observed previously by us, although many investigations were carried out on the condensations of ethylene chloride and aromatic hydrocarbons other than benzene by the action of aluminum chloride. Particularly, we could not find benzene derivatives among the reaction products of ethylene chloride and toluene,[5] ethylbenzene,[6] chlorobenzene,[7] bromobenzene,[8] cymene,[8] biphenyl,[8] naphthalene,[8] phenol,[9] anisole,[9] diphenyl ether,[9] etc., respectively.

Experimental[10]

Ethylene chloride used in this investigation was carefully redistilled and the fraction boiling at 82–83° was submitted to the reaction.

In an ordinary three-necked flask 1190 g. of ethylene chloride was maintained at 25° and 119 g. of newly pulverized anhydrous aluminum chloride was thrown in at once. During the addition, which required one minute, scarcely any elevation of the temperature was remarked. The mixture was stirred for seventy-five minutes at 26 ±

Fraction	Boiling range, °C.	Yield, g.

1°, and then was poured into iced water acidified with hydrochloric acid. The organic layer was separated and after drying over calcium chloride the unchanged ethylene chloride, which weighed 755 g., was removed by distillation. The residue was now fractionally distilled under vacuum of 10 mm. and several fractions were obtained.

The fractions I and III crystallized after a day.

The crystals obtained from fraction I were recrystallized three times from alcohol until the melting point was fixed at 51.7–52.0°. This compound was proved to be identical with bibenzyl by a mixed melting point with a known sample.

Anal. Calcd. for $C_{14}H_{14}$: C, 92.26; H, 7.74. Found: C, 92.00; H, 7.87.

The repeated recrystallizations of the crystals from the fraction III afforded a sample of a melting point of 56.7–57.4°. This agrees in properties with *m*-bis-(β-phenylethyl)-benzene and, when admixed with an authentic specimen, did not depress the melting point, thus proving the identity.

Anal. Calcd. for $C_{22}H_{22}$: C, 92.26; H, 7.74. Found: C, 92.27; H, 7.49.

Summary

By the action of anhydrous aluminum chloride ethylene chloride yields bibenzyl, *m*-bis-(β-phenylethyl)-benzene and finally a polycondensation product.

This phenomenon is explained that at first benzene is formed from ethylene chloride. The resultant benzene then condenses with the excess of ethylene chloride in the sense of the Friedel–Crafts reaction.

The Organic Reactions with Aluminum Chloride. XXI. The Cycli-alkylation of Benzene with 1,4-Dibromo-2-butene and the Disproportionation of Hydrogen Atoms

BY KEIITI SISIDO AND HITOSI NOZAKI

The Friedel–Crafts reactions of poly-functional alkylating agents with benzene are often associated with various anomalies, for example, the "cycli-alkylation"[1] and the shift or reduction of halogen atoms.[2] The former reaction may be of unusual interest as a simple method of synthesizing the compounds of polynuclear structures. In continuation of the studies in this field, we have investigated the condensation of 1,4-dibromo-2-butene with benzene.

The dibromobutene dissolved in a large excess of benzene was treated with aluminum chloride at ordinary temperature. Upon fractional distillation of the reaction products, tetralin and 2-phenyl-1,2,3,4-tetrahydronaphthalene were found to have been formed along with a considerable amount of tarry matter. Neither naphthalene nor dihydronaphthalene was produced. Phenyl-substituted butanes which might be expected as a result of the ordinary Friedel–Crafts reaction also failed to be detected.

These observations may indicate that the first stage of the reaction consists in the condensation of one mole of benzene with one mole of the dibromobutene forming 1,4-dihydronaphthalene under the cyclization by the 2-butene residue. As 1,4-dihydronaphthalene rearranges, however, easily into 1,2-dihydro-compound, for example, by the action of sodium ethylate,[3] the hydrogen atoms at the 1,4-position are supposed to be labile. It seemed to us, therefore, necessary to examine the action of aluminum chloride upon 1,4-dihydronaphthalene in order to clarify the mechanism of this condensation.

To a solution of the dihydronaphthalene in benzene was added aluminum chloride and the mixture was allowed to react at ordinary temperature. It was noted that only small quantities of 2-phenyl-1,2,3,4-tetrahydronaphthalene were produced. The main product was found to be a mixture of about equal amounts of naphthalene and tetralin. We have repeated the same experiment introducing hydrogen chloride gas into the reaction mixture and achieved the same result. Treating 1,4-dihydronaphthalene alone with aluminum chloride we obtained also naphthalene and its tetrahydride.

We have also investigated the reaction of aluminum chloride with 1,2-dihydronaphthalene. In addition to considerable amounts of higher-boiling substances there resulted also in this case naphthalene and tetralin in almost equal quantities. Scott and Walker,[4] who studied the nature of the polymerized dihydronaphthalene as a synthetic resin, stated that 1,2-dihydronaphthalene gave, upon treatment with aluminum chloride, a red brittle resin having a molecular weight of 388 as well as a viscous oil, apparently a dihydronaphthalene dimer. We have found that the 1,2-isomer gives more resinous matter than the 1,4-compound.

Among the reaction products of the 1,4-dihydronaphthalene was a higher-boiling fraction, whose elementary analysis indicated the formula $C_{20}H_{20}$, from which, after a week, crystals of composition $C_{20}H_{18}$ separated. As the original fraction upon sulfur-dehydrogenation, gave 2,2′-binaphthyl in a good yield, it is supposed that the fraction consists of a mixture of 1,2,3,4-tetrahydro-2,2′-binaphthyl, $C_{20}H_{18}$, and 1,2,3,4,1′,2′,3′,4′ - (or 1,2,3,4,5′,6′,7′,8′) - octahydro - 2,2′ - bi-

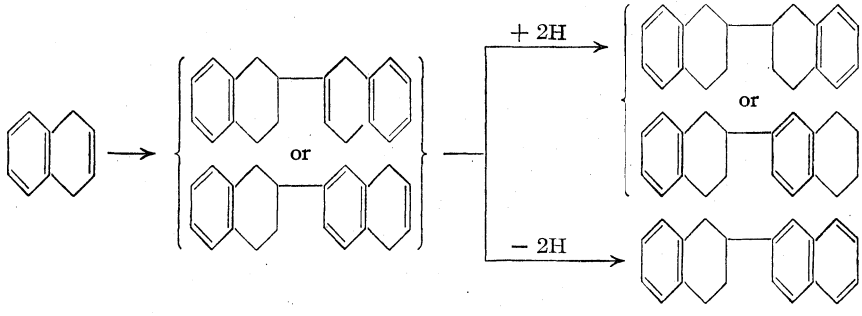
naphthyl,[5] $C_{20}H_{22}$. This mixture may arise, in our opinion, from the dimer of 1,4-dihydronaphthalene by the disproportionation of hydrogen atoms as shown in the figure. As we could, however, neither isolate the octahydrobinaphthyl nor establish the constitution of the tetrahydro compound, this mechanism has not been proved.

Although we have not characterized the polymers of 1,2-dihydronaphthalene, bisdialin, *i.e.*, tetralino-1,2;2′,1′-(or 1,2;1′,2′)-tetralin of v. Braun and Kirschbaum[5] obtained by the sulfuric acid treatment of this dihydronaphthalene, is to be noticed.



In the Friedel–Crafts reaction of allyl chloride with benzene Nenitzescu and Isacescu[6] obtained 1-phenylpropane as well as 1,2-diphenylpropane and they supposed the formation of 2-chloro-1-phenylpropane as an intermediate. The present condensation of 1,4-dibromo-2-butene with benzene bears a close resemblance to this reaction: in both cases the reduction takes place only at the olefinic double bond and such a reaction product, as, for example, chloroisopropylbenzene or dibromobutylbenzene, respectively, in which only an addition of benzene at the double bond occurred, is not obtained.

As to these facts Nenitzescu and others explained that in the case of the transference of hydrogen by the effect of aluminum chloride the double bond does not act immediately as the acceptor. At first hydrogen chloride adds to the double bond and the chlorine atom is replaced by phenyl radical or by hydrogen atom. This statement holds also for the elucidation of the mechanism of the condensation of 1,4-dibromo-2-butene with benzene. But, since the reaction of dihydronaphthalenes and aluminum chloride consists, at least partly, in the disproportionation of labile hydrogens and since hydrogen chloride plays apparently no role in this case, the possibility that the double bond does act as a hydrogen acceptor, contrary to the opinion of Nenitzescu and others,[6] should be considered.

Experimental[7]

The Friedel–Crafts Reaction of 1,4-Dibromo-2-butene with Benzene.—To a suspension of 12 g. of freshly powdered aluminum chloride in 90 g. of benzene at 24–27° was added with stirring during about four hours a solution of 38 g. of 1,4-dibromo-2-butene prepared from butadiene and bromine, in 50 g. of benzene. The resulting mixture was stirred for an additional three hours at the same temperature. On working up the product in the usual way, there were obtained several fractions:

Fraction	B. p., °C.	Pressure, mm.	Yield, g.	Appearance
I_1	95–115	34	4.3	Colorless oil
II_1	145–175	6	4.9	Yellowish oil
III_1	190–230	6	5.3	Yellow, viscous sirup
IV_1	Residue	..	8.7	Reddish brown resin

Tetralin.—Upon redistillation under ordinary pressure Fraction I_1 came over at 200–210°.

Anal. Calcd. for $C_{10}H_{12}$: C, 90.85; H, 9.15. Found: C, 90.57; H, 9.50.

This fraction gave no picrate and did not add bromine at −20°; hence, it was concluded that it contained neither naphthalene nor dihydronaphthalene.

When a mixture of 1.3 g. of fraction I_1 and 0.7 g. of sulfur was heated to 200–230° for three and a half hours, there was obtained 0.9 g. of naphthalene, m. p. and mixed m. p. 80°; picrate, m. p. and mixed m. p. 151°.

A solution of 0.4 g. of fraction I_1 in 10 cc. of carbon disulfide was added to 0.8 g. of aluminum chloride and 0.4 g. of phthalic anhydride. The mixture was refluxed for three hours on a water-bath. There resulted 0.5 g. of *o*-(1,2,3,4-tetrahydro-6-naphthoyl)-benzoic acid, m. p. and mixed m. p. 153–155°.[8]

Anal. Calcd. for $C_{18}H_{16}O_3$: C, 77.12; H, 5.75. Found: C, 77.03; H, 6.06.

2-Phenyl-1,2,3,4-tetrahydronaphthalene.[9]—Fraction II_1 gave analytical figures which agreed with $C_{16}H_{16}$; d^{20}_4 1.0436.

Anal. Calcd. for $C_{16}H_{16}$: C, 92.26; H, 7.74. Found: C, 92.58; H, 7.70.

When 1.2 g. of Fraction II_1 was heated to 220° with 0.4 g. of sulfur for four hours and the resulting melt was distilled under reduced pressure, there was obtained 0.7 g. of substance, m. p. 101°. A mixture of this product and 2-phenylnaphthalene of m. p. 101°, prepared from β-naphthylamine according to Hey and Lawton[10] melted without depression.

Anal. Calcd. for $C_{16}H_{12}$: C, 94.08; H, 5.92. Found: C, 93.75; H, 6.05.

In further identification of the dehydrogenation product it was oxidized with chromic anhydride and acetic acid to 2-phenyl-1,4-naphthoquinone,[11] which was obtained as yellow needles, m. p. 109–110°.

Anal. Calcd. for $C_{16}H_{10}O_2$: C, 82.04; H, 4.30. Found: C, 81.84; H, 4.61.

To a boiling mixture of 4.0 g. of fraction II_1, 125 cc. of water and 25 cc. of concentrated sulfuric acid was added under stirring a solution of 12.2 g. of potassium permanganate in 400 cc. of water. After twenty-two hours of stirring the product was extracted with ether. The ethereal solution was washed with dilute sodium hydroxide solution, the aqueous layer separated and acidified with hydrochloric acid. The precipitates were dissolved in ether and this ethereal solution was dried and distilled to

remove the solvent. The residue was treated with chloroform. The insoluble portion was separated, sublimed and recrystallized from carbon tetrachloride. There were obtained colorless needles, m. p. 127–129°. A mixture of this product and phthalic anhydride melted at 129–131°. Recrystallizations of the chloroform-soluble portion after removing the solvent gave benzoic acid, m. p. and mixed m. p. 122°.

These results indicated that fraction II_1 was 2-phenyl-1,2,3,4-tetrahydronaphthalene.

Fractions III_1 and IV_1 were not investigated.

The Reaction of 1,4-Dihydronaphthalene with Aluminum Chloride.—1,4-Dihydronaphthalene was prepared by the method of Cook and Hill[12] and purified through its addition product with mercuric acetate.[13]

To 14.2 g. of 1,4-dihydronaphthalene was added at 25° under stirring 1.1 g. of aluminum chloride in small portions. The reaction temperature rose spontaneously to about 90°. After two and a half hours of stirring at 30–40° the mixture was poured onto crushed ice acidified with sulfuric acid. The product was subjected to fractional distillation.

Fraction	B. p., °C.	Pressure, mm.	Yield, g.	Appearance
I_2	202–208	760	4.6	Deposited
II_2	70–110	8	1.0	crystals
III_2	205–220	7	1.1	Yellow
IV_2	300–320	6	0.6	sirup
V_2	Residue	...	...	Black mass

Separation of Naphthalene and Tetralin.—Fractions I_2 and II_2 were combined and the mixture was cooled in ice-salt mixture. The crystals separated were collected. These were found to be naphthalene, m. p. and mixed m. p. 80°; yield 2.0 g.

Anal. Calcd. for $C_{10}H_8$: C, 93.71; H, 6.29. Found: C, 93.97; H, 6.54.

To the mother liquor was added a hot alcoholic solution of picric acid. After removing naphthalene picrate thus separated as yellow needles, m. p. and mixed m. p. 151°, the filtrate was concentrated and dissolved in ether. The ethereal solution was washed with aqueous ammonia and water. When a mixture of this solution, 5 g. of mercuric acetate and 50 cc. of water was stirred for four hours, there could not be obtained the addition product of 1,4-dihydronaphthalene with mercuric acetate. The ethereal layer was separated and washed with water. After removing ether the residue was distilled. At 200–210° tetralin came over, yield 2.1 g.

Anal. Calcd. for $C_{10}H_{12}$: C, 90.85; H, 9.15. Found: C, 91.01; H, 9.48.

A Friedel-Crafts condensation product of this oily substance with phthalic anhydride melted at 156–157°. A mixture of this product with an authentic specimen of *o*-(1,2,3,4-tetrahydro-6-naphthoyl)-benzoic acid melted without depression.

These observations show that Fractions I_2 and II_2 are a mixture of naphthalene and tetralin which does not contain 1,4-dihydronaphthalene.

The Reaction of 1,4-Dihydronaphthalene and Benzene in the Presence of Aluminum Chloride.—To a suspension of 15 g. of aluminum chloride in 100 g. of benzene at 10° was added with stirring during about two and a half hours a solution of 28 g. of 1,4-dihydronaphthalene in 73 g. of benzene. No remarkable rise of temperature was noticed. After an additional thirty minutes the stirring was stopped. The reaction product separated into two layers. The upper layer was decanted, washed and dried. After distilling off of benzene the residue was subjected to fractional distillation.

Fraction	B. p., °C.	Pressure, mm.	Yield, g.	Appearance
I_3	195–217	760	8.0	Deposited
II_3	–145	7	1.1	crystals
III_3	145–170	6	1.6	Colorless oil
IV_3	200–230	6	2.0	Yellow
V_3	Residue	...	0.5	sirup

Hydrolysis of the lower layer of the reaction product gave chiefly tarry matter from which nothing could be identified.

Similar results were obtained when the reaction was carried out in a stream of hydrogen chloride gas.

Naphthalene and Tetralin.—From Fractions I_3 and II_3 were isolated and identified 3.3 g. of naphthalene as well as 3.0 g. of tetralin in the same way as described above.

2-Phenyl-1,2,3,4-tetrahydronaphthalene.—Fraction III_3 gave analytical figures which agreed with $C_{16}H_{16}$.

Anal. Calcd. for $C_{16}H_{16}$: C, 92.26; H, 7.74. Found: C, 92.71; H, 8.07.

Dehydrogenation of this fraction with sulfur yielded 2-phenylnaphthalene and these observations may indicate that Fraction III_3 is 2-phenyl-1,2,3,4-tetrahydronaphthalene.

The Reaction of 1,2-Dihydronaphthalene with Aluminum Chloride.—1,2-Dihydronaphthalene was prepared by the method of v. Braun and Kirschbaum.[5] The product melted at −8° and proved to be quite free from naphthalene.

To 13.1 g. of 1,2-dihydronaphthalene cooled at −5° was added 1.0 g. of aluminum chloride and the reaction temperature was allowed to rise; after an hour it reached 15° and after additional thirty minutes 30°. When the reaction product was treated as usual, the following fractions were obtained.

Fraction	B. p., °C.	Pressure, mm.	Yield, g.	Appearance
I_4	65–80	7	2.0	Deposited crystals
II_4	200–240	7	1.5	Yellow viscous oil
III_4	Residue	..	*ca.* 6	Yellow resin

Fraction I_4 was separated into 0.5 g. of naphthalene and 0.6 g. of tetralin. Naphthalene was identified by a mixed melting point with a known sample. Tetralin was analyzed.

Anal. Calcd. for $C_{10}H_{12}$: C, 90.85; H, 9.15. Found: C, 90.47; H, 9.32.

When this product was condensed with phthalic anhydride, there was obtained *o*-(1,2,3,4-tetrahydro-6-naphthoyl)-benzoic acid, m. p. and mixed m. p. 153–155°.

The fractions II_4 and III_4 were not investigated.

Hydrogenated Derivatives of Binaphthyl.—Fractions III_2 and IV_2, that is, the fractions boiling about 200° under 6 mm. pressure of the above-mentioned aluminum chloride treatment of 1,4-dihydronaphthalene, were found to consist of the same components. Their analysis gave a figure near $C_{20}H_{20}$.

Anal. Calcd. for $C_{20}H_{20}$: C, 92.26; H, 7.74. Found: C, 92.79; H, 7.43.

When 1.2 g. of the fraction was heated at 190–240° with 0.6 g. of sulfur for five and one-half hours and the resulting mass was distilled under reduced pressure, there was obtained 1.0 g. of substance, which soon solidified. After triturating with ether to remove a small quantity of oily matter, it was recrystallized from benzene; m. p. 182°. The mixed m. p. with 2,2′-binaphthyl, prepared previously in our Laboratory, showed no depression.

Anal. Calcd. for $C_{20}H_{14}$: C, 94.45; H, 5.55. Found: C, 94.57; H, 5.98.

The picrate, orange needles, m. p. and mixed m. p. 183–184°.

The fraction became a crystalline mass after about a week of standing, which was freed from oily substance and after five recrystallizations from a mixture of alcohol and benzene gave colorless plates of m. p. 85–88°.

(12) Cook and Hill, THIS JOURNAL, **62**, 1995 (1940).

(13) Sand and Genssler, *Ber.*, **36**, 3705 (1903).

Anal. Calcd. for $C_{20}H_{18}$: C, 92.98; H, 7.02. Found: C, 93.30; H, 6.91.

From these results we concluded that the fraction consisted perhaps of a mixture of 1,2,3,4,1′,2′,3′,4′- (or 1,2,3,4,5′,6′,7′,8′) - octahydro - 2,2′ - binaphthyl and 1,2,3,4-tetrahydro-2,2′-binaphthyl in nearly equal quantities.

Summary

1. The Friedel–Crafts reaction of 1,4-dibromo-2-butene with benzene yielded tetralin as well as 2-phenyl-1,2,3,4-tetrahydronaphthalene.

2. 1,4-Dihydronaphthalene was found to change into naphthalene and tetralin in the presence of aluminum chloride.

3. An analogous reaction was observed also in the case of 1,2-dihydronaphthalene.

KYÔTO, JAPAN RECEIVED APRIL 29, 1947

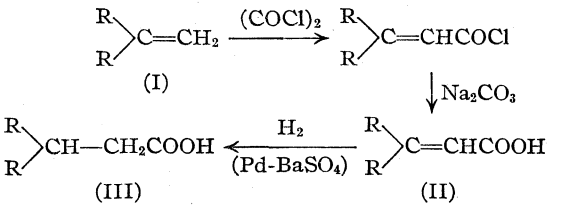
CONTRIBUTION FROM THE DANIEL SIEFF RESEARCH INSTITUTE AND THE DEPARTMENT OF ORGANIC CHEMISTRY OF THE HEBREW UNIVERSITY, JERUSALEM]

β,β-Diarylacrylic Acids.[1] I. Synthesis and Properties of Symmetrical and Unsymmetrical β,β-Diarylacrylic Acids.

BY FELIX BERGMANN, MOSHE WEIZMANN, ELCHANAN DIMANT,[1] JOSEF PATAI[1] AND JACOB SZMUSKOWICZ

The reaction of 1,1-diphenylethylene with oxalyl chloride to form β,β-diphenylacrylyl chloride was discovered by Kharasch and co-workers.[2] As part of a program on the investigation of diarylethylenes, we have applied this reaction to a series of symmetrically and unsymmetrically substituted diphenylethylenes (I).

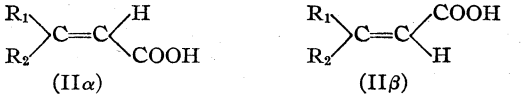
The reaction was found to be a general one; by the use of excess oxalyl chloride (3 to 5 moles) and subsequent hydrolysis of the acid chloride produced, nearly quantitative yields of β,β-diarylacrylic acids (II) were obtained. The application of the reaction to a group of symmetrical and unsymmetrical 1,1-diarylethylenes is summarized in Tables I and II. The corresponding β,β-diarylpropionic acids (III) were easily accessible by catalytic hydrogenation of the acrylic acids (Table III).



The speed of reaction was markedly influenced by the substituents present in the phenyl groups. 1,1-Di-(*p*-anisyl)-ethylene (I,3) reacted completely at room temperature within a half hour, 1,1-diphenylethylene (I,1) had to be refluxed with oxalyl chloride for about two hours, and 1,1-di-(*p*-bromophenyl)-ethylene (I,6) required about eighteen hours for completion of the reaction. The susceptibility of dianisylethylene to substitution by the —COCl group was so great that phosgene in boiling benzene converted it to the dianisylacrylic acid.

The electronic influence of the substituents also influenced the uncatalyzed decarboxylation of the diarylacrylic acids: while the β,β-diphenylacrylic acid (II,1) was stable at 200° and suffered only very slow decarboxylation at 250°, the β,β-di-(*p*-anisyl)-acrylic acid (II,3) was slowly decarboxylated by boiling a solution of it in acetic acid or even by boiling its aqueous suspension. The β-phenyl-β-*p*-anisylacrylic acid was intermediate in stability; carbon dioxide was eliminated from it at about 200°. These results give an explanation of the observation of Bergmann and Bondi[3] that dianisylethylene does not yield a phosphinic acid with phosphorus pentachloride.

When unsymmetrical 1,1-diarylethylenes were refluxed with oxalyl chloride and the mixture hydrolyzed, the two possible isomers (IIα and IIβ) were obtained in most cases.



The use of a large excess of the chloride produced this mixture in good yields, but unavoidable losses during the laborious separation procedures permitted only an approximate estimate of the relative proportion of the two isomers (Table II).

1-Phenyl-1-(*p*-fluorophenyl)-ethylene (I,8) gave rise to a single form of β-phenyl-β-(*p*-fluorophenyl)-acrylic acid (II,8) in nearly quantitative yield; 1-(*p*-tolyl)-1-(*p*-fluorophenyl)-ethylene (I, 11) likewise yielded only one form of the corresponding acid (II,11). On the other hand, the *p*-chloro and *p*-bromo derivatives (II,9 and II,10) were obtained as nearly equimolar, sharply melting mixtures of the two isomers. Resolution of each mixture into the individual isomers showed that the individual melting points lay close to each other and were both higher than that of the mixture.

[a] The anisidide of this acid, prepared from the acid chloride and two equivalents of *p*-anisidine in ether solution, crystallized in white needles, m. p. 163°. *Anal.* Calcd. for $C_{22}H_{19}NO_2$: C, 80.2; H, 5.8; N, 4.3. Found: C, 80.1; H, 6.0; N, 4.5. [b] Kharasch (ref. 2) obtained a 50% yield from equimolar proportions of the two reactants. [c] The anisidide, prepared as above, crystallized from methanol in colorless needles, m. p. 153°. *Anal.* Calcd. for $C_{24}H_{23}NO_2$: N, 3.9. Found: N, 4.0. [d] Bergmann, Hoffmann and Meyer, *J. prakt. Chem.*, **135**, 245 (1932), reported a melting point of 168–170°. [e] The melting point of the acid (142°) was almost identical with that of 1,1-di-(*p*-anisyl)-ethylene (141–142°), Linnel and Shaikmahamud, *Quart. J. Pharm. Pharmacol.*, **14**, 64 (1941); *C. A.*, **35**, 6252 (1941). A mixture of the ethylene and the corresponding acid was depressed to 115–120°. Keeping the acid at its melting point converted it to the ethylene.

Except for 1-phenyl-1-(*p*-tert-butylphenyl)-ethylene (I,15), the *p*-alkyldiphenylethylenes produced both forms of the acids (II,12; II,13 and II,14). One of the *t*-butyl isomers, m. p. 178°, was isolated in pure form as needles. What may have been the second isomer, recognized by its rod-like crystals, could not be purified satisfactorily because it changed to the first isomer during recrystallization. No decision was made whether the two forms represented dimorphic modifications or whether one of the isomers was unstable.

The β-phenyl-β-(*p*-tolyl)-acrylic acid (II,12) has been described by v. Braun,[4] who prepared it by a Reformatsky reaction and reported the melting point as 140°. This is the melting point which we observed for an equimolar mixture of the two isomers (m. p. 172° and 159°) and constitutes clear evidence that the Reformatsky reaction may yield an isomeric mixture.

The question of formation of isomeric acids in Reformatsky's reaction cannot yet be answered satisfactorily. In the way the reaction is carried out by Natelson and Gottfried,[5] an ester of substituted β-chloropropionic acid is always the intermediate. An analogous intermediate, *i. e.*, the chloride of a substituted β-chloropropionic acid, could be formed in the oxalyl chloride reaction if addition to the double bond were the primary step. There is, however, another possibility, *viz.*, that the COCl— group directly substitutes hydrogen at the terminal carbon atom of a diarylethylene. The basic assumption for further work on the mechanism of these two reactions must, therefore, be that identical results point to identical reactions mechanisms, whereas a difference in the reaction products would indicate a different course for Kharasch's reaction.

1-Phenyl-1-(*p*-anisyl)-ethylene (I,17) yielded a mixture of isomeric acids which were both obtained in pure form. However, the lower-melting form appeared to be unstable and to pass into the higher-melting acid upon prolonged heating in organic solvents. In general, *para* substituents with a very strong mesomeric effect, such as methoxyl or fluorine, brought about a fast reaction and favored the formation of one isomer over the other.

β-Phenyl-β-(*o*-anisyl)-acrylic acid (II,18) was isolated in small yield; however, if the reaction time was doubled, 4-phenylcoumarin (IV) was produced in about 60% yield. The reaction, in this case, paralleled exactly the observations of Stoermer[6] concerning the dealkylating action of acetyl chloride or phosphorus pentachloride on the acid.

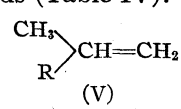
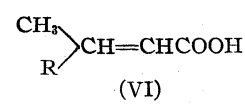
proportions of the isomeric acids were obtained. 1-Phenyl-1-(α-naphthyl)-ethylene (I,20) gave only a very small amount of the high-melting isomer, m. p. 222°. This was in sharp contrast to the result obtained when the acid was made by the Reformatsky reaction, which has been found by various investigators to yield only the high-melting isomer.[7]

The oxalyl chloride reaction was applied to a series of 1-methyl-1-arylethylenes (V) but in no case were two isomeric β-arylcrotonic acids (VI) isolated. Yields were low and the method was inferior to the Reformatsky preparation of these acids (Table IV).



(V)



(VI)

When it was hydrogenated, β-phenyl-β-(*p*-chlorophenyl)-acrylic acid (II,9) absorbed about 150% of the calculated amount of hydrogen and produced a mixture of neutral and acidic products. The neutral substance was identified as 1,1-diphenylethane; the acidic portion yielded about 23% of β,β-diphenylpropionic acid and about 16% of the expected β-phenyl-β-(*p*-chlorophenyl)-propionic acid (III,9).

Similar results were obtained with β,β-di-(*p*-chlorophenyl)-acrylic acid (II,5). In this case

(7) Pirrone, *Chem. Centr.*, **105**, II, 2078 (1934), claims to have evidence for the formation of both isomers of II, 20—although not isolated—in the dehydration of ethyl β-phenyl-β(1-naphthyl)-β-hydroxypropionate. This claim is based on the conversion of the hydroxy ester into a mixture of two indones. However, both of the indones are derived from the same (α-) form of acid II,20. De Fazi, *Gazz. chim. ital.*, **49**, I, 242 (1919); Lipkin and Stewart, THIS JOURNAL, **61**, 3295 (1929).

[a] Various methods of separation are described in the Experimental Part. [b] Alexander, Jacoby and Fuson, THIS JOURNAL, 57, 2208 (1935), describe one form of this acid, prepared by Reformatsky's method, with a melting point of 168°. Prof. Fuson kindly compared both isomers with his preparation and found our α-form to be identical with his. [c] Compare ref. 4. [d] After ten hours of reflux a neutral substance was isolated which crystallized from benzene–petroleum ether in prismatic plates, m. p. 104–105°. It was identical with 4-phenylcoumarin. *Anal.* Calcd. for $C_{15}H_{10}O_2$: C, 81.1; H, 4.5. Found: C, 80.9; H, 4.4. [e] Stoermer (ref. 5) reported a melting point of 153°. [f] Compare ref. 6. Proof of structure of this isomer was given by Koelsch, *J. Org. Chem.*, 6, 558 (1941), who cyclized it to perinaphthindone. [g] v. Braun (ref. 4) gave the melting point as 217°

the neutral portion was 1,1-di-(*p*-chlorophenyl)-ethane with probably a small amount of diphenylethane. The only acid obtained was β,β-di-(*p*-chlorophenyl)-propionic acid.

These observations indicated that partial decarboxylation occurred, probably under the influence of hydrochloric acid which was formed by catalytic dehalogenation of the aromatic ring. This was surprising since the *p*-chlorophenyl-substituted acids have been found to be stable even under the influence of boiling hydrochloric acid. It is also remarkable that the chlorine atoms in the dichloro acid and in the dichloroethane appeared to be much more stable than the corresponding monochloro derivatives.

Experimental[8]

Synthesis of 1,1-Diarylethylenes (I) and 1-Methyl-1-aryl-methylenes (V).—Most of the ethylenes were prepared as described in earlier papers of this series[9] or else-

(8) All melting points are uncorrected.

[a] Kharasch, THIS JOURNAL, **64**, 333 (1942), prepared the acid but did not give experimental details. [b] Because of difficulties encountered in attempts to purify the product, the crude acid was converted to the anilide which crystallized readily from benzene in long needles, m. p. 187°. *Anal.* Calcd. for $C_{20}H_{17}NO$: C, 83.6; H, 5.9; N, 4.9. Found: C, 83.9; H, 6.1; N, 5.2. [c] Banchetti, *Gazz. chim. ital.*, **69**, 398 (1939); *C. A.*, **33**, 8602 (1939), reported a melting point of 170°.

where in the literature. 1,1-Di-(*p*-tolyl)-ethylene (I, 2), which we prepared previously from *p*-methylacetophenone and *p*-tolylmagnesium bromide, was more conveniently synthesized by the method of Bistrzycki[10] in about 60% yield. 1-Phenyl-1-(*p*-cyclohexylphenyl)-ethylene (I,16) and 1-methyl-1-(*p*-xenyl)-ethylene (V,2) are new compounds and were made as follows:

1-Phenyl-1-(*p*-cyclohexylphenyl)-ethylene (I,16): *p*-Cyclohexylbenzophenone[11] (45 g.) in 100 cc. of benzene was added to methylmagnesium iodide (from 38 g. of methyl iodide) in 200 cc. of a 1:1 ether–benzene mixture, and the solution was refluxed for four hours. The crude carbinol was dehydrated by heating to 150–160° for one hour, and the ethylene was purified by distillation, b. p. 181° (0.05 mm.); yield, 100%.

Anal. Calcd. for $C_{20}H_{22}$: C, 91.6; H, 8.4. Found: C, 91.7; H, 8.6.

1-Methyl-1-(*p*-xenyl)-ethylene (V, 2): This ethylene was prepared in an analogous way from 4-acetylbiphenyl and methylmagnesium iodide. The intermediate carbinol was dehydrated at 210–220°. The ethylene crystallized spontaneously and was recrystallized from ethanol. It melted at 108–109°; yield, 60%.

Anal. Calcd. for $C_{15}H_{14}$: C, 92.8; H, 7.2. Found: C, 92.5; H, 7.4.

Synthesis of β,β-Diarylacrylic Acids (II).—As a standard procedure, one mole of ethylene and 3 to 5 moles of oxalyl chloride were refluxed until the evolution of hydrogen chloride ceased. In the case of 1,1-di-(*p*-anisyl)-ethylene (I,3) the reaction was virtually over after one-half hour at room temperature and was completed by refluxing for fifteen minutes.

Excess oxalyl chloride was removed *in vacuo* and the sirupy residue was stirred into an ice-cold sodium carbonate solution. The acid chlorides required from one to two hours for hydrolysis.

The mixture then was boiled with a large amount of water (about one liter per 50 g. of substituted ethylene) to dissolve the sodium salt and to separate it from tars formed as by-products. Charcoal was added and the solution filtered. Part of the sodium salt crystallized from the cooled filtrate; this portion, upon acidification, immediately yielded a pure sample of the desired acid. The remainder of the acid was recovered from the filtrate by acidification and was purified by recrystallization. It was essential in some cases, *e. g.*, with β,β-di-(*p*-anisyl)-acrylic acid (II,3), to avoid high-boiling solvents, because of the possibility of decarboxylation.

The ethylenes containing halogenated phenyl groups

(10) Bistrzycki and Reintke, *Ber.*, **38**, 839 (1905).

(11) Kleene, THIS JOURNAL, **62**, 3523 (1940).

were partially converted into tarry material by the long reflux time necessary to cause them to react. Because of this a lower yield was obtained in these cases.

Details of the conversion of 1,1-diarylethylenes into β,β-diarylacrylic acids are given in Tables I and II.

Reaction of 1,1-Di-(*p*-anisyl)-ethylene and Phosgene.—A slow stream of phosgene was bubbled during ten hours through a boiling solution of 10 g. of 1,1-di-(*p*-anisyl)-ethylene in 50 cc. of benzene. The solvent was distilled *in vacuo* and the residue decomposed with cold sodium carbonate solution. The sodium salt of the acid (II,3) was dissolved by heating and filtered from the insoluble, neutral material. Acidification of the filtrate precipitated 3.5 g. (30%) of β,β-dianisylacrylic acid, m. p. 139–140°.

The dianisylethylene was recovered unchanged when refluxed in a solution of ethyl or amyl chlorocarbonate.

Separation of Isomeric, Unsymmetrical β,β-Diarylacrylic Acids.—Method A—Separation of the acid chlorides: It was found that in the case of β-phenyl-β-(*p*-anisyl)-acrylic acid (II,17), the isomeric acid chlorides differed considerably in their hydrolysis rates. A benzene solution of the mixed chlorides was shaken with water; the solid which separated was the α-isomer, m. p. 181°. After separation of the layers, the benzene solution was shaken with aqueous sodium carbonate. This converted the β-acid chloride into the sodium salt of the β-acid, contaminated with some of the α-acid.

Method B—Separation of the free acids: The mixture of isomers was separated in a few cases by fractional crystallization. This method was especially applicable when the two aryl groups differed appreciably in their molecular weight or in the polar character of the substituent.

Method C—Separation of the sodium salts: In most cases it was observed that on cooling slowly the hot solution of the mixed sodium salts, the salt of the higher-melting acid separated in a fairly pure state. The filtrate upon acidification then gave a mixture enriched in the low-melting isomer, which usually could be separated by fractional crystallization in a Dewar. The separation temperature proved to be critical in some cases. Thus, the α-form of β-phenyl-β-(*p*-chlorophenyl)-acrylic acid (II,9) crystallized in a fairly pure condition at 30–35°. However, at about 15° the β-form also precipitated as its sodium salt. It was important for securing satisfactory separations that very dilute solutions of the sodium salts were used.

Method D—Mechanical separation of the free acids: In some cases Methods A, B and C failed. The mixture of acids was then dissolved in an organic solvent, and the solution was cooled very slowly in a Dewar. The crystals which formed were separated by passing them through a sieve or picking them out with the help of forceps.

Other methods tried, such as chromatographic adsorption on calcium sulfate, fractional acidification or separation of the methyl esters, either were unsuccessful or did not possess any advantage over the four methods outlined.

β-Arylcrotonic Acids (VI).—The reaction of oxalyl chloride with 1-methyl-1-arylethylenes (V) was much more sluggish than with 1,1-diarylethylenes (I), and the products were much more difficult to purify. β-(α-Naphthyl)-crotonic acid (VI,3) was obtained only as an amorphous mass, and was therefore characterized as its anilide. The preparation of five β-arylcrotonic acids is summarized in Table IV.

β,β-Diarylpropionic Acids (III).—The diarylacrylic acids were hydrogenated in ethanol over palladium–barium sulfate at room temperature and normal pressure. Yields were almost quantitative. In a few cases two isomeric acids (IIα and IIβ) were hydrogenated separately in order to prove the existence of geometrical isomerism. When the crude, yellow acrylic acids were used for catalytic reduction, the color faded in the initial phase of the hydrogenation, and the diarylpropionic acids were obtained in an excellent state of purity. Results are given in Table III.

Hydrogenation of β-Phenyl-β-(*p*-chlorophenyl)-acrylic Acid (II,9).—When 4.3 g. of 1-phenyl-1-(*p*-chlorophenyl)-acrylic acid (II,9) was reduced, 50% more hydrogen was absorbed than was calculated for the reduction of the double bond. The reaction mixture smelled strongly of hydrogen chloride and formed a heavy precipitate with silver nitrate. The ethanol was evaporated, the oily residue dissolved in benzene and extracted with warm sodium carbonate solution. The neutral portion was distilled, b. p. 135–140° (0.8 mm.).

Anal. Calcd. for $C_{14}H_{14}$: C, 92.3; H, 7.7. Found: C, 92.1; H, 7.7.

The alkaline extract was boiled with charcoal and filtered. Upon slow cooling a precipitate formed and was filtered; on acidification it yielded 0.7 g. of β-phenyl-β-(*p*-chlorophenyl)-propionic acid (III,6), m. p. 108° (see Table III).

When the sodium carbonate filtrate was acidified, 1 g. of β,β-diphenylpropionic acid precipitated. It crystallized from benzene–petroleum ether in long rods, m. p. 153°; mixed m. p. with authentic sample (m. p. 155°), 154–155°.

Hydrogenation of β,β-Di-(*p*-chlorophenyl)-acrylic Acid (II,5).—The reduction of 6 g. of β,β-di-(*p*-chlorophenyl)-acrylic acid (II,5) was stopped after one molar equivalent of hydrogen had been absorbed. The reaction mixture fumed strongly and was shown to contain hydrogen chloride. It was separated into a neutral and an acidic portion.

The neutral product, after a small forerun at 145° (3 mm.), boiled at 195° (3 mm.). It gave a positive Beilstein test.

Anal. Calcd. for $C_{14}H_{12}Cl_2$: C, 67.0; H, 4.8. Found: C, 66.6; H, 5.0.

The hot sodium carbonate extract was boiled with charcoal, filtered and left overnight. The precipitate was separated and acidified; it proved to be unchanged starting material.

The alkaline filtrate, when acidified, yielded about 1 g. of oily β,β-di-(*p*-chlorophenyl)-propionic acid which solidified when triturated with petroleum ether. It recrystallized from benzene–petroleum ether in flat, rhombic prisms, m. p. 187°. Fuson reported 188–189°.[12]

Anal. Calcd. for $C_{15}H_{12}Cl_2O_2$: C, 61.0; H, 4.1. Found: C, 61.3; H, 4.2.

Summary

The reaction between 1,1-diarylethylenes and oxalyl chloride represents a general method for the preparation of β,β-diarylacrylic acids. The influence of substituents on the speed of the reaction indicates that oxalyl chloride attacks the terminal carbon atom like an electrophilic reagent.

With unsymmetrical 1,1-diarylethylenes a mixture of isomeric β,β-diarylacrylic acids is produced in most cases. Substituents which increase strongly the electron density at the β-carbon atom of the diarylethylenes either yield one isomer only or tend to make the second isomer unstable.

Catalytic hydrogenation of halogenated β,β-diphenylacrylic acids causes partial dehalogenation and decarboxylation.

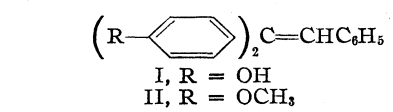
β,β-Diarylacrylic Acids. II. A New Synthesis of Triarylethylenes

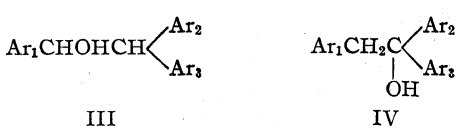
BY FELIX BERGMANN, ELCHANAN DIMANT AND HELENE JAPHE

Triphenylethylene (I) and its derivatives have acquired new interest since the discovery of Robson and Schönberg[1] that the hydrocarbon (I) itself, its dimethoxy derivative (II)[2] and their α-halogen derivatives are endowed with estrogenic activity of prolonged duration. The classical method of synthesis for derivatives of I is the Grignard reaction,[3] in which the carbinols of type III or IV are intermediates. When Ar_2 and Ar_3 represent different aryl groups, two geometrical isomers are possible. However, only very few cases are known where both forms have actually been isolated.[4] There exist also some other, less well known methods of formation of triphenylethylene, *e. g.*, rearrangement of β,β,β-triphenylethylammonium nitrite[5] or condensation of diphenylketene with substituted benzaldehydes[6] in quinoline (with elimination of carbon dioxide).

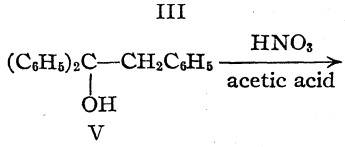
Triphenylethylene itself is unsuitable for direct substitution in a ring, because the common cationoid reagents first attack the central double bond.[7] We observed that 1,1,2-triphenylethanol (V), too, is converted by fuming nitric acid in acetic acid solution into 1,1,2-triphenyl-2-nitroethylene (VI). Apparently dehydration to I precedes nitration at the α-position. When the nitration is carried out without use of a solvent, I and V give a good yield of a tetranitro derivative of the probable structure VII. One nitro group must replace the α-hydrogen, because the α-nitro derivative VI, too, can be converted into the tetranitro compound (VII).



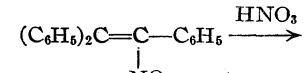
I, R = OH
II, R = OCH_3



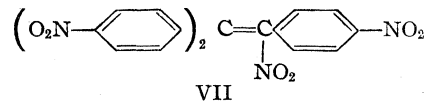
III IV



V



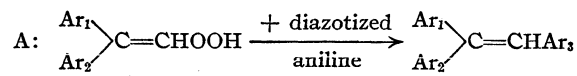
VI



VII

We have been unable to isolate intermediates between the mono- and tetra-nitro derivatives.

A new method of wide applicability was found in the coupling of β,β-diarylacrylic acids VIII with diazotized anilines, in analogy to the Meerwein synthesis of stilbenes from cinnamic acids[8] (scheme A). The data represented in Table I show that meta- and para-substituted anilines give comparable results. The method failed, however, when ortho-substituents were present.



It is noteworthy that under the experimental conditions used, the diarylacrylic acids concerned undergo partial decarboxylation prior to the coupling reaction. Thus, the dianisylacrylic acid (Expt. 2 in Table-I) gave besides the expected 1,1-di-(*p*-anisyl)-2(*p*-nitrophenyl)-ethylene about 50% of dianisylethylene, although we reported previously that the acid loses carbon dioxide in aqueous suspension only upon prolonged boiling.[9]

The Meerwein synthesis of stilbenes yields exclusively the *trans* forms. However, no conclusion about the sterical specificity of the reaction can be drawn from this fact, because only *trans*-cinnamic acids have been used.[10] It was therefore of interest to investigate the coupling of isomeric β,β-diarylacrylic acids (VIII, $Ar_1 \neq Ar_2$). The two forms of β-phenyl-β(*p*-bromophenyl)-acrylic acid (X),[9] upon reaction with diazotized *p*-nitroaniline, yielded the same product (XI). It is evident that in one case isomerization has taken place. In this connection it may be mentioned that α-phenylcinnamic acid, which upon decarboxylation yields *cis*-stilbene,[11] does not undergo a Meerwein coupling, but under the conditions of the experiment yields exclusively *trans*-stilbene.

The most interesting of the new compounds are the nitro derivatives in view of the versatility of the aromatic nitro group, and of the inaccessibility of these derivatives by any other method. It was shown previously,[12] that it is impossible to reduce

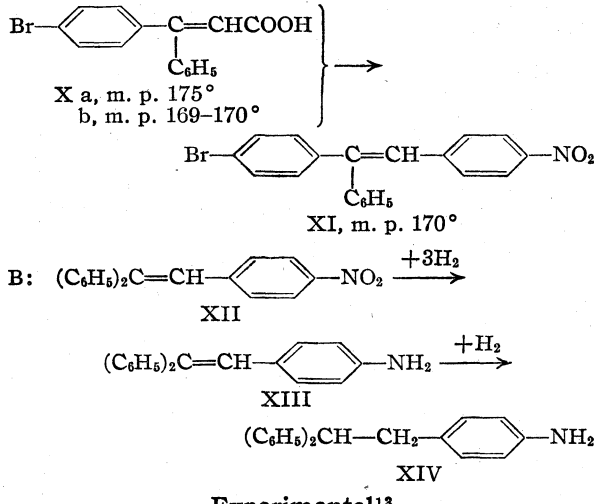
[a] Coupling temp., 25–35°. [b] Coupling temp., 32–45°. [c] Coupling temp., 27–28°. [d] Coupling temp., 27–35°. [e] Coupling temp., 25–50°. [f] Yield calculated on acid consumed. About 50% of the acid was recovered from the alkaline washings by acidification.

catalytically the nitro group of various nitrostilbenes without attack on the double bond. In the nitro-triphenylethylenes, however, the reactivity of the ethylenic bond is lowered so much that the hydrogenation can be interrupted exactly after absorption of three moles of hydrogen to yield about 70% of the unsaturated amine (see scheme B).



Experimental[13]

Meerwein Coupling—General Procedure.—The method used for the coupling reactions may be exemplified for the first case, reaction of diphenylacrylic acid with *p*-nitroaniline. The general results are summarized in Table I.

To a solution of diphenylacrylic acid (9.5 g.) in acetone (200 cc.), cooled to +5°, was added a clear solution of diazotized *p*-nitroaniline (5.8 g.). Solid sodium acetate (11 g.) and a solution of cupric chloride (2 g.) in a little water were added immediately. The temperature was allowed to rise slowly, until at 25° reaction set in. After the strong evolution of gas was over (about fifteen minutes), the mixture was heated to 35° for one hour. Acetone and a small amount of *p*-chloronitrobenzene were removed by steam distillation. The remaining sirup was dissolved in benzene, washed with alkali, dried and distilled *in vacuo*, b. p. 193–194° (1.5 mm.). The yellow-red distillate crystallized upon trituration with ethanol. Recrystallization from butanol or butyl acetate gave brown, polyhedric columns of 1,1-diphenyl-2-(*p*-nitrophenyl)-ethylene (XII), m. p. 148°. The substance is dimorphic and appears sometimes in small yellow prisms of m. p. 158–160°, especially from dilute solutions.

(13) All melting points are uncorrected.

When di-(*p*-anisyl)-acrylic acid was used in the reaction, distillation of the neutral portion gave first a large amount (about 50% of theoretical) of dianisylethylene, b. p. 185–195° (1.2 mm.), followed by the expected coupling product.

In experiment 8, the higher-melting form of β-phenyl-β-(*p*-bromophenyl)-acrylic acid (Xa), m. p. 175°, gave a 30% yield of 1-phenyl-1-(*p*-bromophenyl)-2-(*p*-nitrophenyl)-ethylene (XI), m. p. 170°. The isomeric acid (Xb), m. p. 169–170°, reacted under exactly the same conditions, but only 11% of the expected ethylene was obtained. This compound showed no depression of m. p. with the foregoing reaction product.

Reactions of 1,1-Diphenyl-2-(*p*-nitrophenyl)-ethylene (XII). (a) Bromination.—The ethylene (XII) in chloroform solution showed no visible reaction with bromine at room temperature. Upon heating on a water-bath, strong evolution of hydrogen bromide set in. After five minutes the mixture was cooled and petroleum ether added to precipitate the reaction product. 1,1-Diphenyl-2-(*p*-nitrophenyl)-2-bromoethylene crystallized from butyl acetate in prisms, m. p. 178°.

Anal. Calcd. for $C_{20}H_{14}O_2NBr$: N, 3.7. Found: N, 3.9.

(b) **Catalytic Reduction.**—The ethylene XII (1 g.) was suspended in ethyl acetate (35 cc.) and reduced in the presence of Raney nickel. After absorption of 240 cc. of hydrogen (calcd. for 3 moles, 242 cc.; $T = 239°$; $p = 754$ mm.), the reaction was interrupted. A yellowish oil was isolated, which showed no tendency to crystallize and was therefore acetylated directly. The acetyl derivative of XIII crystallized from butanol in lancets or from toluene–petroleum ether (1:1) in long flat tetragonal prisms, m. p. 169–170°; yield 0.7 g. (70%).

Anal. Calcd. for $C_{22}H_{19}ON$: N, 4.5. Found: N, 4.6.

When the hydrogenation was continued to completion, the speed of the reaction slowed appreciably after the absorption of the first three moles of hydrogen. The oily reduction product (XIV) was transformed again into its acetyl derivative. It crystallized from benzene–petroleum ether in big flat prisms, m. p. 128–129°.

Anal. Calcd. for $C_{22}H_{21}ON$: C, 83.8; H, 6.7; N, 4.4. Found: C, 83.6; H, 6.8; N, 4.7.

Nitration of Triphenylethylene (I) and 1,1,2-Triphenylethanol (V).—(a) In acetic acid: The carbinol V (2 g.) was dissolved in acetic acid (20 cc.) and fuming nitric acid (d. 1.51) (0.55 g., 1.2 equiv.) added dropwise at room temperature. An exothermic reaction took place and the temperature rose to 50°. The mixture was then heated to 65° for twenty minutes and poured onto ice. The granular precipitate was dried and recrystallized from butyl acetate as yellow prisms, m. p. 172° (VI); yield 0.7 g.

Anal. Calcd. for $C_{20}H_{15}O_2N$: C, 79.7; H, 5.0. Found: C, 79.9; H, 5.3.

The same product, but in higher yields, was obtained by the use of 2.2 or 3.2 equivalents of nitric acid. The

product is identical with the substance resulting from nitration of triphenylethylene itself.

(b) Without solvent: The carbinol V (15 g.) was added in small portions to fuming nitric acid (75 cc.) with stirring. A violent reaction took place, which raised the temperature to 70°. The reaction was completed by heating the mixture to 80° for one and one-half hours. Upon standing for several days, the reaction product crystallized out. It was filtered off, washed with nitric acid, then with water and dried; crude yield, 20 g., 83%. The tetranitro derivative (VII?) crystallized from benzene or butyl acetate in yellow prisms, m. p. 205°.

Anal. Calcd. for $C_{20}H_{12}O_8N_4$: C, 55.0; H, 2.8; N, 12.8. Found: C, 55.4; H, 2.6; N, 12.5.

The same product was obtained, but in a less satisfactory form, by nitration of triphenylethylene or α-nitrotriphenylethylene (VI) with fuming nitric acid.

Summary

The coupling of β,β-diarylacrylic acids with diazotized anilines opens a new route to substituted triarylethylenes. Geometrical isomers of the acids yielded identical coupling products.

Under the experimental conditions of this reaction, α-phenylcinnamic acid is decarboxylated to *trans*-stilbene. Decarboxylation is also a side-reaction for β,β-diarylacrylic acids.

1,1-Diphenyl-2-(*p*-nitrophenyl)-ethylene can be reduced catalytically stepwise first to the unsaturated, then to the saturated, amine. Nitration of triphenylethylene, the corresponding carbinol or its α-nitro derivative with fuming nitric acid in the absence of a solvent produces a tetranitro derivative.

Reactions of Mustard-type Vesicants with α-Amino Acids[1]

BY VINCENT DU VIGNEAUD, CARL M. STEVENS,[2] HAROLD F. MCDUFFIE, JR.,[3] JOHN L. WOOD[4] AND HERBERT MCKENNIS, JR.[5]

Early in World War II it was considered that reactions between mustard gas (H) and certain enzymes possibly played a role in the mechanism of vesication by H-type compounds. As part of a collaborative effort to uncover the mechanism of vesication by chemical warfare agents, reactions between H-type compounds and proteins were studied in a number of laboratories. Prior to our investigations, published work[6] and available unpublished British reports[7] indicated that the properties of several proteins were altered by treatment with mustard gas. To gain insight into the protein-H reactions, this Laboratory and others investigated the preparation and nature of compounds formed by the reaction of H-type vesicants with amino acids. This report covers part of this one aspect of the larger problem.

From the chemical standpoint, studies on mustard gas are complicated by the fact that H contains two reactive halogens. Since it was already known[8] that several compounds of the type $RSCH_2CH_2Cl$ possess vesicant action, we sought to simplify the problem by employing these "one-handed" vesicants in our chemical studies. Although these compounds containing only one β-chloroethyl group are potent vesicants, they are quantitatively much less vesicant than H itself. Qualitatively their physiological action parallels that of H. The "one-handed" agents, therefore, must be capable of entering into the chemical reactions essential to vesication. The fact that the structures and properties of the molecules closely resemble those of H itself makes it highly probable that the mechanism of vesication is essentially the same in each case. These considerations caused us to focus our attention largely on the one-handed vesicants, which for convenience are designated as follows:

$C_6H_5CH_2SCH_2CH_2Cl$	Benzyl-H
$CH_3SCH_2CH_2Cl$	Methyl-H
$CH_3CH_2SCH_2CH_2Cl$	Ethyl-H
$CH_3CH_2CH_2CH_2SCH_2CH_2Cl$	Butyl-H

A survey of the general literature[9] indicated that H-type vesicants reacted readily with sulfhydryl, amino and phenolic hydroxyl groups in alkaline solution. Furthermore, a derivative of an α-amino acid had been reported. It was the product formed by the reaction[10] of H and glycine ethyl ester, having the structure I.[11]

$$S(CH_2CH_2NHCH_2COOC_2H_5)_2 \qquad I$$

In our experiments we studied the reactions of most of the naturally occurring amino acids with vesicants of the type $RSCH_2CH_2Cl$, where R has the structures indicated above.

[a] The N-acetyl derivative was prepared in 75% yield and recrystallized from dilute alcohol; m. p. 148–149°. *Anal.* Calcd. for $C_{13}H_{17}O_3NS$: C, 58.4; H, 6.41. Found: C, 58.3; H, 6.48. [b] Based on amount of vesicant used. [c] The N-acetyl derivative was prepared in 80% yield and recrystallized from water; m. p. 120–121°. *Anal.* Calcd. for $C_{14}H_{19}O_3NS$: C, 59.8; H, 6.81. Found: C, 60.0; H, 6.43. [d] Based on amount of amino acid used.

A series of crystalline derivatives of the amino acids was obtained, demonstrating reaction of the one-handed vesicants with sulfhydryl, amino, phenolic hydroxyl and imidazolyl groups under the conditions employed. No evidence was found to indicate reaction with alcoholic hydroxyl, guanido or indolyl groupings. The methods of preparation and study of the compounds are presented not only for the intrinsic interest of the compounds themselves, but also for their possible importance in establishing the nature of protein vesicant reactions. In this latter capacity some of the derivatives can be considered as model substances and as reference compounds in cases where it is desirable to isolate the components of hydrolysates from vesicant-treated proteins.

Simple α-Amino Acids.—Other investigators[12] have demonstrated the facile esterification of the free carboxyl group of amino acid derivatives by H-type compounds. In our work we investigated the alkylation of amino groups with particular reference to the actual isolation of derivatives. It appeared likely that the amino groups would be susceptible to mono-, di- or trialkylation by the $RSCH_2CH_2$- radicals. In practice, treatment of the amino acids in alkaline solution did lead to the formation of a mixture of products from which it was possible to isolate crystalline N$^{\alpha}$-alkyl derivatives, N$^{\alpha}$-dialkyl derivatives in some instances, but no N$^{\alpha}$-trialkyl derivatives (quaternary ammonium compounds). After N,N-bis-(β-benzylmercaptoethyl)-glycine was treated with benzyl-H, it was recovered unchanged in 80% of the theoretical yield. This indicates that the formation of a quaternary ammonium compound is probably not a major reaction under the experimental conditions. The alkylation of α-amino groups by H has been discussed in two recent papers[10,12c] covering work done in the war period by other laboratories.

The monosubstituted derivatives of glycine and alanine were readily acetylated in 75–80% yield by treatment in alkaline solution with acetic anhydride. In contrast, the monosubstituted derivatives of valine, leucine and phenylalanine were recovered unchanged in good yield. This difference in behavior held true both for the butyl-H and the benzyl-H series.

The several procedures for preparation of the derivatives are described in the Experimental part and pertinent data are compiled in Table I.

Lysine.—This amino acid was of particular interest since it is known[13] that the ε-amino group is reactive in many proteins. Kurtz[14] showed that treatment of the copper salt of

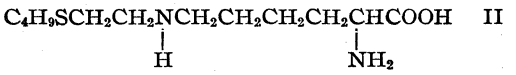
(14) Kurtz, *ibid.*, **140**, 705 (1941).

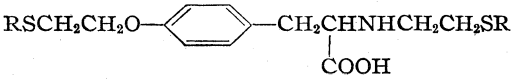
lysine in alkaline solution with benzoyl chloride yielded the N^{ϵ}-benzoyl derivative. The copper salt of lysine was, therefore, treated with butyl-H. A crystalline monosubstituted derivative of lysine was isolated. This is presumably the hydrochloride of structure II.



II

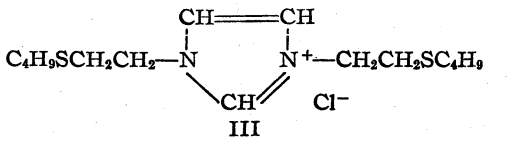
Mercaptoamino Acids.—We were interested particularly in preparing S-substituted vesicant derivatives of mercaptoamino acids because of the possible reactivity of protein sulfhydryl groups with vesicants.[15] The benzyl-H derivatives of the sulfhydryl group of cysteine and homocysteine were obtained in good yield by alkylation with the aid of sodium and liquid ammonia.[16]

Tyrosine.—The phenolic hydroxyl group of tyrosine is stated to be chemically reactive in proteins.[17] The reaction of this group with the vesicants was, therefore, of interest. Treatment of L-tyrosine in strongly alkaline solution with either benzyl-H or butyl-H yielded a mixture of products from which was isolated in each case a disubstituted derivative in 20% yield. The compounds show negative tests for phenolic hydroxyl groups[18] and are, therefore, believed to be O,N-disubstituted derivatives.

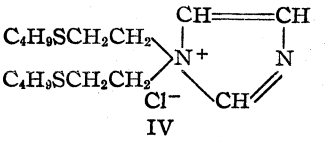


Histidine.—Preliminary studies of the reaction of vesicants with L-histidine and with N^{α}-benzoyl-L-histidine were made using a colorimetric method[19] based on the Pauly diazo reaction.[20] The results indicated a reaction of the vesicant with the imidazole ring. Evidence had been obtained by Moritz and co-workers[21] that the imidazole group of histidine reacted with H, and Ball and co-workers[22] suggested that the effect of H on the oxygen dissociation curve of hemoglobin might be interpreted as indicating a reaction with the imidazole groups of histidine in the intact protein.

We, therefore, studied the reaction of histidine and its derivatives further. Treatment of L-histidine in 0.5 *M* sodium bicarbonate solution with an excess of butyl-H yielded a crystalline substance, the composition of which corresponded to a trialkyl derivative. Treatment of imidazole under similar conditions yielded a disubstituted derivative. By analogy with other alkylation products of imidazole[23] structure III was considered likely for the imidazole derivative, although dialkylation of one N (IV) was not excluded. The

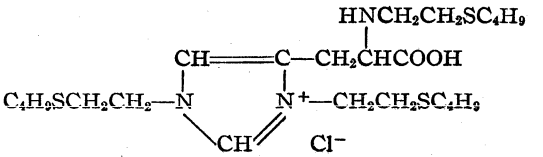


III



IV

structure analogous to structure III, in the case of the histidine derivative, would be structure V.



V

The compound yields no nitrogen in the Van Slyke procedure for the estimation of free amino nitrogen,[24] and is stable to heating under reflux in strong acid.

Using a smaller quantity of butyl-H under slightly different conditions, it was also possible to isolate a monosubstituted derivative of imidazole, and monoalkylation of the imidazole nitrogen alone was also apparently achieved by using N^{α}-benzoylhistidine.

Experimental[25,26]

Derivatives of Simple α-Amino Acids. These derivatives were prepared by one of the following procedures: **A.**—The amino acid (1 mole) was dissolved in 50% ethanol containing 3 moles of sodium carbonate or sodium hydroxide and treated with 2 moles of vesicant. The mixture was stirred for several hours at 30–50°, and then extracted with ether. Neutralization of the aqueous solution with hydrochloric acid precipitated the crude derivative which was recrystallized from the appropriate solvent.

B.—The amino acid was dissolved in slightly more than 3 equivalents of 1 *N* sodium hydroxide in 95% methanol. Two equivalents of vesicant were added and the mixture was allowed to stand for at least twenty-four hours. The solution was then decanted from the precipitated sodium chloride and concentrated *in vacuo*. The residue was dissolved in water. The solution was extracted with ether and then neutralized with hydrochloric acid. The precipitated derivative was collected and recrystallized from the appropriate solvent.

(26) The authors are indebted to Dr. Julian R. Rachele and Mr. Roscoe C. Funk, Jr., for the microanalyses.

C.—The amino acid was dissolved in 1 equivalent of 1 *N* sodium hydroxide in 95% methanol and an equal volume of water was added. The vesicant (0.25 equivalent) was added, the mixture was stirred until homogeneous and then was allowed to stand overnight. When glycine was treated under these conditions and the reaction products were isolated by the method described under procedure B, crystalline disubstituted derivatives were obtained. Concentration of the mother liquors to a small volume yielded crystalline monosubstituted derivatives.

The methods of preparation and the properties of the various derivatives are recorded in Table I.

It seems certain that the derivatives prepared from L-tryptophan involve the α-amino group.[27] To check the possibility of a reaction of the indole group with the vesicants, the α-amino group was covered by acetylation. No evidence was found of the reaction of the vesicants with the indole group of N^{α}-acetyl-L-tryptophan.

Derivative of Lysine.—L-Lysine dihydrochloride (2.17 g.) was dissolved in 50 cc. of 2.5% sodium tetraborate. Copper carbonate was added in excess and the solution was heated to boiling and filtered. The solution was brought to *p*H 9.2 with 5 *N* sodium hydroxide and 4 g. of sodium tetraborate was added. Butyl-H (1.7 cc.) was added, and the solution was stirred for twenty-four hours. Then the precipitated copper salt was filtered and washed with water. A suspension of the copper salt (*p*H 9) was treated with hydrogen sulfide and, after removal of copper sulfide, the solution was acidified to litmus with acetic acid. The solvent was removed *in vacuo* leaving a sirup which crystallized on addition of concentrated hydrochloric acid. The material was recrystallized three times from a minimum amount of hot water by addition of ethanol. The yield of this purified product decomposing at 240° was 0.46 g. (15% of the theoretical amount).

Anal. Calcd. for $C_{12}H_{26}O_2SN_2 \cdot HCl$: S, 10.73; Cl, 11.86. Found: S, 10.33; Cl, 11.25.

Derivatives of Cysteine and Homocysteine.—L-Cystine (24 g.) and sodium were added in portions to 400 cc. of liquid ammonia, just enough sodium being added at the end to give a blue color persisting for ten minutes. Then 32.4 cc. of benzyl-H was added dropwise. The liquid ammonia was allowed to evaporate. The solid residue was stirred well with crushed ice until the ice melted. The resulting precipitate was collected. The filtrate was extracted with ether and then neutralized with concentrated hydrochloric acid. A second precipitate resulted. The combined precipitates were recrystallized from hot water. The yield was 25 g. of material melting at 187–189° and having the composition of the expected S-(β-benzylmercapto)-ethylcysteine.

Anal. Calcd. for $C_{12}H_{17}O_2NS_2$: C, 53.1; H, 6.31. Found: C, 53.3; H, 6.21.

The compound was characterized further by conversion to the acetyl derivative which melted at 125° and had the expected neutral equivalent (313).

Under similar conditions, DL-homocystine yielded S-(β-benzylmercapto)-ethylhomocysteine, m. p. 225°.

Anal. Calcd. for $C_{13}H_{19}O_2NS_2$: N, 4.91; S, 22.46. Found: N, 4.60; S, 22.79.

This compound was characterized further by conversion to the acetyl derivative which melted at 70–72°. The neutral equivalent of the acetyl derivative was 324 (calculated, 327).

Derivatives of Tyrosine.—Experiments indicated that the vesicants did not react appreciably with phenolic groups in neutral solution. However, in a strongly alkaline solution it was possible to prepare O,N-disubstituted derivatives of tyrosine. L-Tyrosine (1.81 g.) was shaken for twenty-four hours with 40 cc. of 1 *N* sodium hydroxide, 40 cc. of methanol, and 4.5 cc. of butyl-H. The reaction product was then isolated according to procedure B. An amorphous product weighing 2.4 g. was obtained. On recrystallization from 70% acetic acid, 1.0 g. of a crystalline derivative melting at 208–210° was obtained. The compound gave a negative Millon test, and yielded no color with Folin phenol reagent.[18]

Anal. Calcd. for $C_{21}H_{35}O_3NS_2$: N, 3.39. Found: N, 3.34.

Treatment of L-tyrosine (1.81 g.) with benzyl-H (procedure B) yielded an amorphous product weighing 3.1 g. This product was dissolved in 150 cc. of 50% ethanol containing 3 g. of sodium bicarbonate. The cooled solution deposited 1.0 g. (20%) of the pure O,N-disubstituted derivative. It gave a negative Millon's test and melted at 203–205°. It formed plates on recrystallization from 80% acetic acid.

Anal. Calcd. for $C_{27}H_{31}O_3NS_2$: C, 67.3; H, 6.48. Found: C, 67.6; H, 6.54.

Derivatives of Histidine and Related Compounds. L-**Histidine.**—L-Histidine monohydrochloride monohydrate (10.2 g.) was dissolved in 500 cc. of 0.5 *M* sodium bicarbonate and the solution was stirred vigorously with 36 cc. of butyl-H for twenty-four hours. About 30 cc. of a brown oil separated. This material was extracted three times with 150-cc. portions of ether. The ether-insoluble residue was diluted with 3 volumes of chloroform, and the solution was washed with 10% hydrochloric acid and with water. Evaporation of the chloroform left a sirupy residue which did not crystallize. The sirup was dissolved in chloroform (80 cc.) and stirred for half an hour with Brockmann alumina. The mixture was filtered and the chloroform was removed *in vacuo*. Addition of 10 cc. of acetone to the residue caused slow crystallization.[28] The yield of crystalline material was 0.9–1.4 g. Several recrystallizations from methylene chloride gave a sample melting at 187–188° and having the composition of a trisubstituted histidine derivative.

Anal. Calcd. for $C_{24}H_{46}O_2N_3S_3Cl$: C, 53.4; H, 8.58; N, 7.78; S, 17.80; Cl, 6.56. Found: C, 53.4; H, 7.87; N, 7.65; S, 18.05; Cl, 6.41.

The derivative was recovered quantitatively after being heated in water at 100° for twenty-four hours, and in 75% yield after treatment for twelve hours in refluxing 20% hydrochloric acid.

Imidazole.—Imidazole (0.136 g.) and butyl-H (0.153 g.) were dissolved in 218 cc. of 0.7 *N* potassium hydroxide in 95% methanol. After the solution had been allowed to stand overnight, another 0.153 g. of butyl-H was added, and the resulting mixture was allowed to stand for four hours. The solvents were removed *in vacuo*, 2 cc. of water was added to the residue, and the solution was extracted with 5 cc. of benzene. The benzene layer was evaporated *in vacuo* and 6 cc. of water was added to the residue. A saturated aqueous solution of picrolonic acid was added to the aqueous solution. Seventy-two milligrams of yellow crystalline material melting at 140–155° (dec.) was obtained. The compound, after recrystallization from water, melted at 154–156° (dec.) and had the composition of the picrolonate of a monosubstituted imidazole derivative.

Anal. Calcd. for $C_9H_{16}N_2S \cdot C_{10}H_8O_5N_4$: C, 50.9; H, 5.39. Found: C, 50.0; H, 5.66.

A disubstituted derivative of imidazole was prepared as follows: A solution of imidazole (1.36 g.) in 300 cc. of 0.5 *M* sodium bicarbonate was stirred with 15 cc. of butyl-H for twenty-four hours. The mixture was acidified to congo red with concentrated hydrochloric acid and extracted 3 times with 50-cc. portions of ether. The

(27) In the course of the study of these derivatives, it was observed that the disubstituted derivative of L-tryptophan gives approximately twice the color given by an equimolar amount of L-tryptophan when treated with the Folin phenol reagent.[18] Further study showed that all of the N^{α}-disubstituted vesicant derivatives of the amino acids gave a blue color with the reagent.

(28) If the material did not crystallize at this point, it was washed with ether, dissolved in 30 cc. of methylene chloride and washed with water. Evaporation of the solvent left a sirup which crystallized on addition of acetone.

aqueous solution was then extracted 3 times with chloroform. The combined chloroform extracts were dried over anhydrous magnesium sulfate. The chloroform solution upon evaporation gave a light yellow oil which crystallized upon addition of ether. The yield was 0.23 g., and additional material was obtained by further chloroform extractions. For analysis the crude product was crystallized from a mixture of benzene and acetone. After the product had been dried at 3 mm. over potassium hydroxide for twenty minutes, it had the approximate composition of a monohydrate, m. p. 50–52°.

Anal. Calcd. for $C_{15}H_{29}N_2S_2Cl \cdot H_2O$: C, 50.8; H, 8.80. Found: C, 51.4; H, 8.62.

On long drying *in vacuo* at 40°, the above material lost 93% of the calculated weight for 1 molecule of water of hydration. It then melted at 56–57°.

Anal. Calcd. for $C_{15}H_{29}N_2S_2Cl$: C, 53.5; H, 8.67; N, 8.31; S, 19.03; Cl, 10.52. Found: C, 53.1; H, 8.79; N, 8.00; S, 19.50; Cl, 10.14.

N^{α}-Benzoyl-L-histidine.—Three grams of N^{α}-benzoyl-L-histidine[29] was dissolved in 25 cc. of water by addition of 1 *N* sodium hydroxide with stirring. Then 1.5 cc. of butyl-H was added, and the mixture was stirred for five hours. The *p*H was maintained at 8–9 by gradual addition of 1 *N* sodium hydroxide. Methanol (10 cc.) was also added portionwise to increase the solubility of the vesicant. The reaction mixture was evaporated to about one-half volume *in vacuo* and then extracted with ether. The aqueous layer was acidified to *p*H 4 with 11 cc. of 1 *N* hydrochloric acid. The oil which separated was removed. The aqueous solution was acidified with 1 cc. of 1 *N* hydrochloric acid and extracted with chloroform. Evaporation of the chloroform left an oil which was crystallized from ethanol by addition of ether. Recrystallization of the compound from water yielded 200 mg. of rosettes, m. p. 188–190°.

Anal. Calcd. for $C_{19}H_{25}O_3N_3S$: S, 8.54. Found: S, 8.37.

Summary

1. A series of N-substituted derivatives of the simple α-amino acids with benzyl-H (benzyl β-chloroethyl sulfide) and butyl-H (butyl β-chloroethyl sulfide) has been prepared by treatment of the various amino acids in alkaline solution with the corresponding vesicant. The following derivatives have been prepared: N-monosubstituted benzyl-H derivatives of glycine, DL-alanine, DL-valine, L-leucine, DL-leucine, DL-isoleucine, DL-threonine, DL-phenylalanine and DL-methionine; N^{α}-monosubstituted butyl-H derivatives of glycine, DL-leucine, DL-phenylalanine and L-tryptophan; N^{α}-disubstituted benzyl-H derivatives of glycine and L-tryptophan; N^{α}-disubstituted butyl-H derivative of glycine.

2. Treatment of the copper salt of L-lysine in alkaline solution with butyl-H yielded a crystalline monosubstituted derivative. By analogy with benzoylation data this compound is believed to be the N^{ϵ}-substituted derivative.

3. S-Substituted derivatives of L-cysteine and DL-homocysteine with benzyl-H have been prepared by reaction of the vesicant with the corresponding sodium mercaptides in liquid ammonia solution.

4. O,N-Disubstituted derivatives of L-tyrosine with benzyl-H and butyl-H have been prepared.

5. A trisubstituted butyl-H derivative of L-histidine was obtained by treatment of the amino acid in alkaline solution with the vesicant. Under similar conditions imidazole yielded mono- and disubstituted derivatives, and N^{α}-benzoyl-L-histidine yielded a monosubstituted derivative.

6. The data provide a further and direct demonstration that the following groups in amino acids are capable of reacting with H-type vesicants: α-amino group, ϵ-amino group, imidazolyl group, sulfhydryl group and phenolic hydroxyl group.

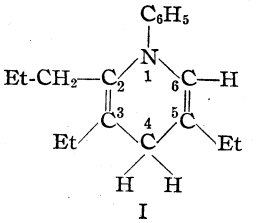
N-Phenyl-3,5-diethyl-2-propyl-1,4-dihydropyridine

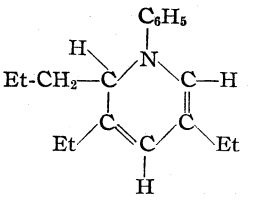
BY DAVID CRAIG, LAURA SCHAEFGEN AND WILLARD P. TYLER

During a study of the reaction of butyraldehyde with aniline in the presence of acetic acid, it has been found possible to isolate a weak base having the formula $C_{18}H_{25}N$. The present paper deals with the structure of this base.

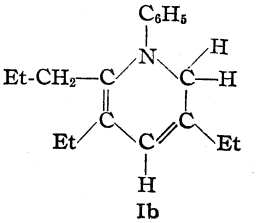
The empirical formula and the method of synthesis suggest dihydropyridine structures I, Ia, or Ib or the open chain anil structure II. The pyrolysis of the compound in the presence of cobaltous chloride forms aniline and 1,3,5-triethylbenzene. The formation of triethylbenzene, $C_{12}H_{18}$, supports these formulations since the linking together of three butyraldehyde residues is thereby indicated. Hydrogenation, depending on conditions, yields di, tetra and decahydro derivatives, in accord with the N-phenyldihydropyridine formulas, but thus far has given no evidence of the



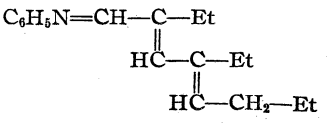
I



Ia

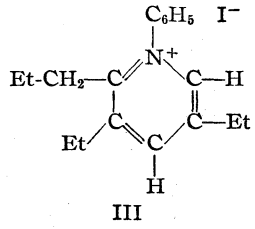


Ib



II

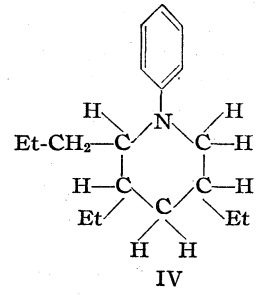
formation of hexahydro or dodecahydro derivatives required of formula II. Dehydrogenation of the new compound occurs upon contact with reduced platinum oxide in acetic acid solution. The product is the corresponding acetate of III. Oxidation with iodine or sulfur in acidic media, containing appropriate anions, produces quaternary salts, *e.g.*, the iodide III. This type of oxidation would be expected of structures I, Ia, or Ib, but would not be expected of the anil II. The anil in such media would be expected to yield hydrolysis products, *i.e.*, aniline and an unsaturated aldehyde. Neither these nor their oxidation products have been observed in the reaction mixtures. Thus oxidation as well as hydrogenation of the new compound supports a dihydropyridine structure and eliminates from consideration an open chain anil structure such as II.



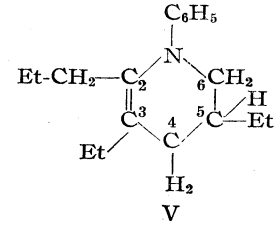
III

Karrer[1] has studied the formation and behavior of N-phenyl-1,2-dihydropyridine, a compound closely related to the $C_{18}H_{25}N$ base. His assignment of structure was based in part on the prompt reaction of his compound with maleic anhydride[2] although a well characterized reaction product was not reported. In contrast, the reaction of one molecule of the $C_{18}H_{25}N$ base with one of maleic anhydride is comparatively sluggish and a well characterized adduct[3] may be isolated. The N-phenyl-1,2-dihydropyridine also reacted rapidly and irreversibly with hydrochloric acid to form unidentified products. Again in contrast, the $C_{18}H_{25}N$ base reacts immediately only as a weak organic base. However, on long contact with hydrochloric acid it dissolves and then irreversibly undergoes disproportionation. The products are the quaternary chloride corresponding to III and the dihydro derivative obtained by hydrogenation. The N-phenyl-1,2-dihydropyridine is unstable in the atmosphere whereas the $C_{18}H_{25}N$ base has been kept for ten years or more substantially unchanged. The $C_{18}H_{25}N$ base is yellow. Karrer reported and we have confirmed that the 1,2-dihydropyridine is colorless. Neither of these dihydropyridines is fluorescent. The differences and similarities in their behavior constitute the chemical basis for the assignment of the 1,4-dihydro structure I to the $C_{18}H_{25}N$ base.

Knowledge of the structure of the $C_{18}H_{25}N$ base facilitates the identification of some of its derivatives. Thus the decahydro derivative is N-cyclohexyl-3,5-diethyl-2-propylpiperidine and the tetrahydro derivative is the corresponding N-phenylpiperidine IV. The dihydro derivative has been assigned structure V on the basis, (a) that it reacts as a vinylamine toward hydrochloric acid, and (b) that there would be less hindrance to the addition of hydrogen to the Δ^5 double bond than to the Δ^2 bond of compound I.



IV



V

The study of the ultraviolet absorption spectra of compound I and its derivatives supports the assigned structures. Figure 1 shows that the spectrum for compound I is very different from that of N-phenyl-1,2-dihydropyridine but very similar to that of the methyl derivative prepared by the reaction of methylmagnesium iodide with the pyridinium salt III. Compound I and the methyl derivative are therefore considered to be 1,4-dihydropyridines, the methyl group in the latter compound being in the 6 or 4-position.

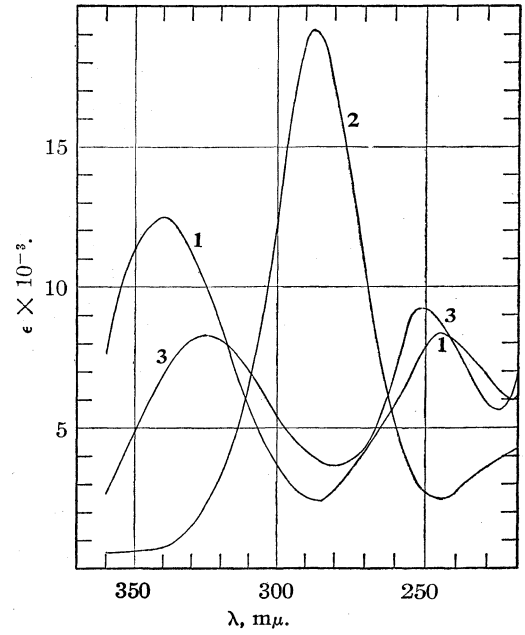


Fig. 1.—Spectra of I (1), N-phenyl-1,2-dihydropyridine (2), and the methyl derivative of I (3).

Figure 2 compares the spectrum of the pyridinium ion of III with the spectra of 3,5-diethyl-2-propylpyridinium ion and N-phenylpyridinium ion. They resemble each other closely. Evidently the tetracovalent nitrogen atom effectively insulates the conjugation of the benzene ring from

(1) Karrer, *Helv. Chim. Acta*, **20**, 72 (1937).

(2) Mumm and Diederichsen, *Ann.*, **538**, 198 (1939), reported that 1,2-dihydro-1,2,6-trimethyl-4-phenyl-3,5-dicarbethoxypyridine reacted with maleic anhydride to form a 1:1 adduct and that the corresponding 1,4-dihydro isomer did not react.

(3) The structure of this adduct is the subject of a second paper.

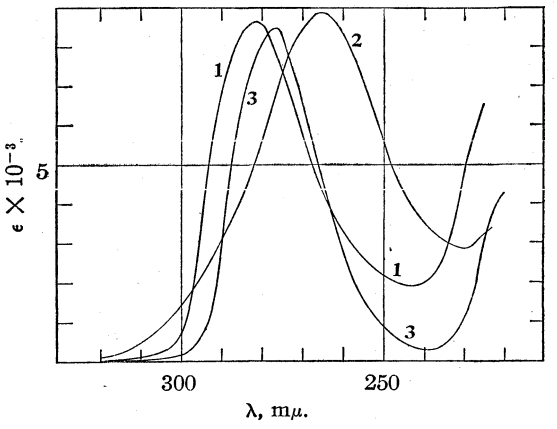

Fig. 2.—Spectrum of the cation of III, obtained by subtraction of the absorption of KI from that of III, (1); spectrum of N-phenylpyridinium chloride (2); spectrum of 3,5-diethyl-2-propylpyridinium ion (3) in 1.2 *N* HCl in 90% methanol.

that of the pyridine ring. The maxima for the trialkyl pyridinium salts appear at longer wave lengths because of the usual bathochromic effects of the alkyl groups on the pyridine nucleus.

Figure 3 presents the spectrum of N-phenyl-3,5-diethyl-2-propylpiperidine IV along with that of N-phenylpiperidine and di-*n*-butylaniline. It is of interest to note the similarities and differences among these spectra. The piperidines are, in one sense, dialkylanilines and would be expected to possess a well-defined fundamental band such as the long wave length band of di-*n*-butylaniline. Extension of the discussion of Remington[4] on steric effects caused by hindrance to ease of formation of a planar configuration can explain the somewhat distorted shape of the fundamental band in the piperidines. This follows as a result of the tendency of the piperidine ring to be puckered. Further comparison shows the similarity between the spectra of N-phenylpiperidine and of IV which supports the structure assigned to the latter compound as a result of the method used for its preparation.

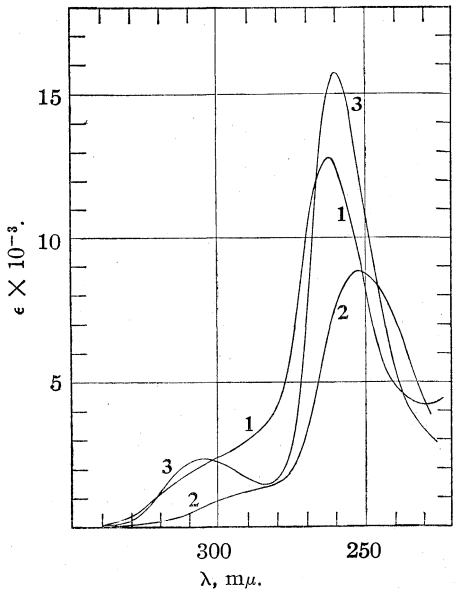

Fig. 3.—Spectra of IV (1), N-phenylpiperidine (2), and di-*n*-butylaniline (3).

The absorption spectrum of the tetrahydropyridine V is entirely different from that of the corresponding piperidine IV. The greater intensity and longer wave lengths at which the absorption of V occurs indicates that the double bond must be conjugated with the nitrogen atom.[5] The spectrum observed for V in conjunction with the hydrogenation of the $C_{18}H_{25}N$ base to form V is evidence against structures Ia and Ib for the dihydropyridine since by 3,6- or 2,5-addition such structures would be expected to lead to Δ^4- and Δ^3-tetrahydropyridines.

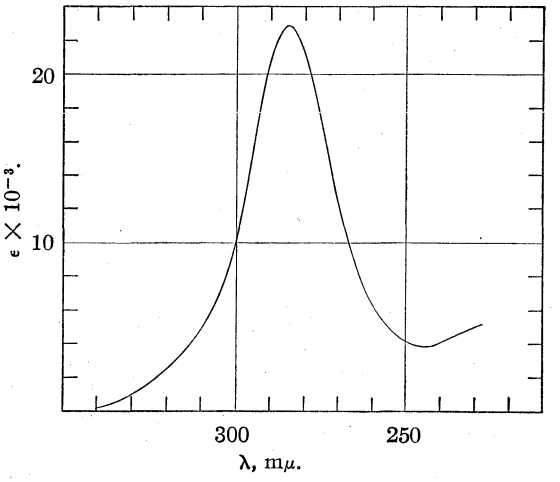

Fig. 4.—Spectrum of V.

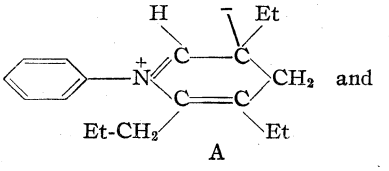
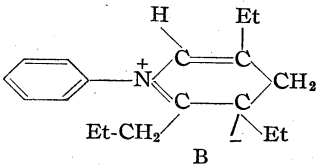
Attachment of two vinyl groups to the nitrogen atom as in structure I makes it possible to write, among others, the nearly equivalent resonance forms, A and B, for the first excited state. This



A



B

leads to considerable stabilization of the first excited electronic level by resonance, and hence, absorption at a longer wave length than would be

(4) Remington, THIS JOURNAL, **67**, 1838 (1945).

(5) Bowden, Brauda, Jones and Weedon, *J. Chem. Soc.*, 45 (1946).

true for structures Ia and Ib for which the forms contributing to the first excited state would have quite different energies. Thus, the 1,4-dihydropyridine reported here has its first maximum at 340 mμ whereas N-phenyl-1,2-dihydropyridine has a maximum at 286 mμ.

Experimental Part

Absorption Spectra.—The spectra were measured in methanol solution except where specified otherwise using a Beckman quartz spectrophotometer, Model DU.

N-Phenyl-3,5-diethyl-2-propyl-1,4-dihydropyridine, Compound I.—One mole (93 g.) of aniline was added dropwise to a mixture of four moles (288 g.) of butyraldehyde containing 8.7 g. of acetic acid and 6 moles (108 g.) of water during thirty minutes. During this period the mixture was stirred and cooled to about 10° with ice water. The mixture was then heated to reflux and maintained at reflux for five hours. The final liquid temperature was 98°. After removal of the water layer, containing most of the acetic acid, butyraldehyde and 2-ethylhexenal were removed by steam distillation during four hours. The remaining oil was dried at reduced pressure. It was a fluid, light brown oil with a characteristic odor and a refractive index of $1.575^{20}D$. The product was distilled to supply a 55% yield of light yellow oil which came over at about 125° at 0.5 mm. pressure. The refractive index of this oil was $1.5725^{20}D$. By redistillation the refractive index was raised to 1.5740. This product was nearly odorless.

Anal. Calcd. for $C_{18}H_{25}N$: C, 84.64; H, 9.87; N, 5.49; mol. wt., 255. Found: C, 84.56; H, 10.26; N, 5.29; mol. wt. in freezing benzene, 241, 242.

Pyrolysis of Compound I.—A mixture of 150 g. of I and 2 g. of anhydrous cobaltous chloride was placed in a 500-ml. distilling flask equipped with a stirrer. The mixture was heated rapidly with stirring to about 275° when decomposition set in. The temperature was raised to 310° during twenty minutes. The distillate amounted to 115 g. and the residue to 35 g. The distillate was extracted with a mixture of 80 ml. of concd. hydrochloric acid and 160 ml. of water. The oil layer was separated, washed with water, dried over potassium carbonate, and distilled. A yield of 15 g. (16%) of colorless oil was obtained which distilled at 210–212°.

Anal. Calcd. for $C_{12}H_{18}$: C, 88.83; H, 11.17. Found: C, 88.99; H, 11.05.

The hydrocarbon was identified by the preparation of the trinitro derivative by the method of Gattermann, *et al.*[6] This derivative melted at 111° alone or when mixed with an authentic specimen of 1,3,5-triethyl-2,4,6-trinitrobenzene.

The acid layer was made basic with strong caustic. The oil which precipitated was dried and distilled. In this way, 14 g. (25%) of aniline and an unidentified oil which distilled at 184–186° at 17 mm. was secured. The aniline was identified by the preparation of the acetyl derivative. The oil analyzed approximately for $C_{18}H_{25}N$. After heating with $CoCl_2$ at 300° it was recovered unchanged.

N-Phenyl-3,5-diethyl-2-propyl-1,4,5,6-tetrahydropyridine.—This compound was formed by shaking 25.5 g. of compound I with 10 g. of Raney nickel and 25 ml. of alcohol under 3 atmospheres of hydrogen for three hours. The pressure drop then corresponded to 1.05 moles of hydrogen per mole of I. The product, isolated in 92% yield, distilled at 115 to 120° at 0.2 mm. and had a refractive index of $1.5518^{20}D$. It required five minutes of shaking for complete solution in six volumes of 6 *N* hydrochloric acid.

Anal. Calcd. for $C_{18}H_{27}N$: C, 83.98; H, 10.58; N, 5.44. Found: C, 83.87, 83.73; H, 10.87, 10.93; N, 5.41, 5.47.

(6) Gattermann, *et al.*, *Ber.*, **32**, 1124 (1899).

N-Phenyl-3,5-diethyl-2-propylpiperidine.—Hydrogenation of compound I over Raney nickel between 30 and 100° and from 3 to 100 atmospheres produced this derivative quite smoothly although the product contained small quantities of the dihydro base and probably the decahydro derivative as well. In a typical run 13.3 g. of I dissolved in 50 ml. of alcohol was shaken with 12 g. of Raney nickel in a copper lined autoclave for ten hours at 70 atmospheres pressure of hydrogen and 50°. The product was distilled at 0.2 mm. Fraction A distilled at 112–115° and Fraction B at 115–120°. These fractions were almost colorless. The combined yield was 93%. The refractive indices $n^{20}D$ of the fractions were 1.5290 and 1.5350, respectively.

Anal. Calcd. for $C_{18}H_{29}N$: C, 83.33; H, 11.27; N, 5.40. Found for A: C, 83.30, 83.40; H, 11.40, 11.32; N, 5.34, 5.40. Found for B: C, 83.46, 83.40; H, 11.24, 11.31; N, 5.42, 5.36.

Although these fractions thus appeared to be analytically pure, their ultraviolet absorption spectra disclosed the presence of the above tetrahydropyridine. It may therefore be inferred that small amounts of some hydrogen rich compound such as the decahydro derivative were present. Extraction with dilute hydrochloric acid removed most of these impurities. The compound thus purified had one absorption maximum (Fig. 3). It had a refractive index of $1.5320^{20}D$.

N-Cyclohexyl-3,5-diethyl-2-propylpiperidine.—This compound was secured by heating 64.5 g. of compound I and 10 g. of Raney nickel at 150° for twenty hours under about 100 atmospheres of hydrogen. The main product, which was isolated in 45% yield, distilled at 103–110° at 0.1 mm. and had a refractive index of $1.4868^{20}D$. Its ultraviolet absorption spectrum had one low peak at 263 mμ probably due to the presence of a trace of the incompletely reduced phenyl derivative. The compound was colorless.

Anal. Calcd. for $C_{18}H_{35}N$: C, 81.42; H, 13.31; N, 5.28. Found: C, 81.37, 81.48; H, 13.15, 13.24; N, 5.29, 5.35.

N-Phenyl-3,5-diethyl-2-propyl-pyridinium Iodide, III.—A turbid mixture containing 2.55 g. (0.01 mole) of compound I, 50 ml. of alcohol, 10 ml. of acetic acid, and 10 ml. of 25% potassium iodide was titrated rapidly with 1 *N* potassium iodate. Only a small amount of the iodate was required to produce a clear solution. An iodine color was apparent when 17.2 ml. had been added. This color deepened during a period of ten minutes and required 0.1 ml. of 0.1 *N* thiosulfate solution to reduce it to the color of the iodine end-point. The sample thus is equivalent to 17.1 ml. of the *N* iodate solution which is 85.5% of the amount (20.0 ml.) required for the reaction

$$C_{18}H_{25}N + I_2 \longrightarrow C_{18}H_{24}NI + HI$$

The conditions of titration were investigated in a preliminary way. The reaction is favored by an excess of iodide ion and can be conducted with alcoholic iodine solution instead of iodate solution. Acetic acid is a satisfactory acid and may be used in considerable excess while hydrochloric acid has a strongly inhibitory action. The solutions from four such titrations were evaporated at reduced pressure until all of the alcohol and most of the acetic acid were removed. Excess 48% sodium hydroxide then was added. This precipitated an oil which crystallized on standing overnight. The crystals were dissolved in a little butanol and the solution filtered. The filtrate after being diluted with one liter of cold ether yielded 12.5 g. of brown solid, m. p. 90–95°. This solid was dissolved again in butanol and precipitated with ether to provide a crop of light brown crystals, m. p. 105–106°. The yield of these amounted to 11.5 g. or 75% of the theoretical amount. Solution in dry alcohol and fractional precipitation with ether gave bright yellow plates, m. p. 107–108°.

Anal. Calcd. for $C_{18}H_{24}NI$: C, 56.66; H, 6.35; N, 3.67; I, 33.33. Found: C, 56.76, 56.71; H, 6.37, 6.38; N, 3.79, 3.73; I, 33.34, 33.26.

The iodide can be produced in good yield by the action of sulfur on compound I in acetic acid solution followed by the addition of sodium or potassium iodide and working up the mixture as described above.

The iodide is very soluble in water, alcohols, ketones, esters and acetic acid. It is insoluble in hydrocarbons such as benzene and hexane. Three liquid phase systems are formed with benzene and water and a solid addition compound is produced with carbon tetrachloride which is sometimes useful in recovering the salt from aqueous solutions.

The iodine content is quantitatively precipitated with aqueous 0.1 *N* silver nitrate. The iodide does not react at moderate temperature with maleic anhydride or with hydrogen over Raney nickel. With sulfur no reaction occurs unless a sulfur "acceptor" is present. Suitable "acceptors" are unsaturated compounds such as styrene or rubber. Reaction also occurs readily with sulfur in the presence of alkali.

N-Phenyl-3,5-diethyl-6 or 4-methyl-2-propyl-1,4-dihydropyridine.—One reaction indicating the quaternary nature of the iodide III is the Freund reaction with excess methylmagnesium iodide in ether solution. The product of this reaction, which was obtained in 82% yield, had a refractive index of $1.5510^{20}D$ and distilled at 105–106° at 0.2 mm. The ultraviolet absorption spectrum of this compound, given in Fig. 1, is similar to that of compound I. The methyl group must be attached to either the 6 or the 4-position of the dihydropyridine ring.

Anal. Calcd. for $C_{19}H_{27}N$: C, 84.69; H, 10.10; N, 5.20. Found: C, 84.44, 84.39; H, 9.83, 9.89; N, 5.54, 5.48.

The reaction of compound I (0.1 mole) with sulfur (0.1 atom) during twenty-four hours on the steam-bath formed hydrogen sulfide and a semicrystalline black mass. Extraction with benzene yielded about 1 g. of nearly colorless crystals which melted at 156–157° after solution in a mixture of acetone and alcohol followed by precipitation with ether.

Anal. Calcd. for $C_{18}H_{25}NSO_4$: C, 61.50; H, 7.18; N, 3.99. Found: C, 61.43, 61.51; H, 7.17, 7.26; N, 4.14, 4.07.

This compound was identified as the acid sulfate corresponding to the quaternary iodide III described above from which it also was prepared by addition of sulfuric acid and distilling off hydroiodic acid at reduced pressure. The product so produced melted at 156–157° alone or when mixed with the analyzed sample. This compound was also secured by shaking I in acetic acid solution with reduced platinum oxide and adding sulfuric acid to the mixture when the evolution of hydrogen had ceased. Most of the acetic acid was evaporated at reduced pressure and the last traces removed by addition of sodium carbonate. The acid sulfate was extracted with warm acetone and precipitated by the addition of ether.

The benzene filtrate from the acid sulfate was evaporated and the resulting solid crystallized twice from alcohol. The yield amounted to 8 g. of bright yellow crystals melting at 127°. The melted product resolidified and then melted again at 132°.

Anal. Calcd. for $C_{18}H_{23}NS$: C, 75.74; H, 8.13; N, 4.91; S, 11.22. Found: C, 75.29, 75.24; H, 8.14, 8.05; N, 5.12, 5.07; S, 11.53, 11.60.

The structure of this compound is believed to be N-phenyl-3,5-diethyl-2-propyl-6-thiopyridone formed by the oxidation of a pseudo form of the pyridinium hydrosulfide.

The Reaction of I with Hydrochloric Acid.—The rate of reaction depends primarily on the concentration of the acid and on the temperature. In the cold and with dilute acid the rate is very slow. A mixture of 12.5 g. of I and 10 g. of 36.5% hydrochloric acid was shaken for twenty minutes at 20°. Gradually solution occurred as might be expected of a vinylamine. The oil precipitated by the addition of caustic to this solution was I. A similar mixture of acid and I was refluxed at 116° for two hours. The product was water soluble. It was neutralized with 6 g. of sodium carbonate. Then 100 ml. of hexane was added and the mixture shaken with small portions of water until free of water soluble substances. The hexane layer was dried over potassium carbonate and distilled. After the hexane 2.5 g. of light yellow oil distilled at 120–125° at 0.7 mm. It had a refractive index, $n^{20}D$ of 1.5523.

Anal. Calcd. for $C_{18}H_{27}N$: C, 83.98; H, 10.58; N, 5.44. Found: C, 83.82, 83.60; H, 10.55, 10.53; N, 5.43, 5.47.

The analysis and refractive index are in agreement with the supposition that this product is identical with the N-phenyl - 3,5 - diethyl - 2 - propyl - 1,4,5,6 - tetrahydropyridine secured by the hydrogenation of compound I. The substantial identity of the two $C_{18}H_{27}N$ samples finally was established by their ultraviolet absorption spectra. The water layer on evaporation at reduced pressure in the presence of 2.5 g. of potassium iodide yielded a mixture of salts which was extracted with butanol. On addition of ether to the butanol extract there was obtained a crop of yellow crystals which after solution and precipitation melted at 105–107° alone or when mixed with N-phenyl-3,5-diethyl-2-propylpyridinium iodide. The yield was 4.5 g.

Reaction with Maleic Anhydride.—A mixture of 5.1 g. of compound I and 1.8 g. of maleic anhydride was stirred with a thermometer. The immediate formation of a red colored product occurred, usually followed by a temperature rise from 30 to 50° during about twenty minutes. In case the temperature did not rise spontaneously the mixture was heated to about 50°. Reaction then became rapid and it was necessary to cool the mixture in order to keep the temperature from rising above about 60°. During about ten minutes longer a solid began to separate and it soon became impossible to stir the mixture. The temperature was allowed to fall and the mixture was allowed to stand overnight. It melted at 112 to 115°. The product was powdered and extracted with 50 ml. of hexane. The residue melted at 115–117° and weighed 4.7 g. This weight represents a yield of 78%. The melting point was raised to 119–120° by recrystallizing from acetone or alcohol and the product was then colorless.

Anal. Calcd. for $C_{22}H_{27}NO_3$: C, 74.75; H, 7.70; N, 3.96. Found: C, 74.64, 74.70; H, 7.71, 7.74; N, 4.02, 4.00.

Occasionally while working up the reaction products of maleic anhydride with impure samples, a second compound was isolated. This was a white solid melting with decomposition at 153° when recrystallized from alcohol.

Anal. Calcd. for $C_{22}H_{29}NO_4$: C, 71.12; H, 7.87; N, 3.77. Found: C, 71.05, 71.01; H, 8.06, 8.00; N, 3.79, 3.38.

This compound, which is the hydrate of the adduct, melts with almost quantitative loss of water to form the original adduct.

Acknowledgment.—The reaction of aldehydes with amines has been examined by many workers in this Laboratory, including Dr. A. W. Sloan. Their results constituted the basis on which the work reported here was initiated. Particular acknowledgment is due Drs. W. L. Semon and H. L. Trumbull for their interest and suggestions.

Summary

1. A main product of the condensation of excess butyraldehyde with aniline in the presence of weak acids has been found to be N-phenyl-3,5-diethyl-2-propyl-1,4-dihydropyridine.

2. The reactions of the dihydropyridine which were investigated include pyrolysis, hydrogenation, dehydrogenation, oxidation, reaction with sulfur, vinylamine type behavior toward acids,

and reaction with maleic anhydride. These reactions led to the isolation of some nine new compounds.

3. Vinylamine behavior may be recognized as an important property of some of the new compounds, especially in connection with their ultraviolet absorption spectra.

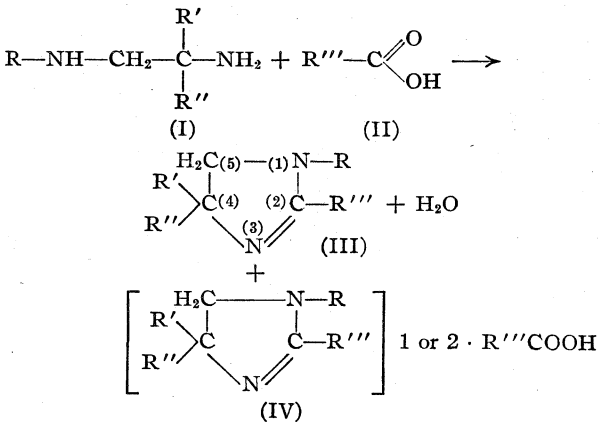
The Synthesis of Imidazolines from 1,2-Diamines and Carboxylic Acids

BY J. L. RIEBSOMER

Chitwood and Reid[2] prepared a series of 2-alkyl-2-imidazolines by distilling or heating the appropriate diacylethylenediamine with sodium, magnesium, zinc, magnesium oxide or sodium hydroxide. Thus 2-methyl-2-imidazoline was produced in 68% yield when diacetylethylenediamine was heated at 270° with magnesium. The yields were less satisfactory with the other inorganic reagents. When ethylenediamine and acetic acid were heated 2-methyl-2-imidazoline was produced in 19% yield and when monoacetylethylenediamine hydrochloride was heated with sodium hydroxide a 26% yield of the imidazoline formed. Hofmann[3] prepared the same imidazoline upon distillation of a sodium acetate and ethylenediamine hydrochloride mixture.

Hill and Aspinall[4] prepared a series of 2-alkyl and 2-aryl substituted imidazolines by heating monoacylethylenediamines.

The technique employed for the preparation of the imidazolines reported here was to add benzene to a mixture of the 1,2-diamine and carboxylic acid and to distil the benzene through a four-foot packed column. As the benzene distilled, water formed from the reaction was carried out as an azeotropic mixture. The column was equipped with a suitable head so that the benzene returned and the water was separated. It might have been anticipated that the imidazoline would be the only product formed by this process. In nearly all instances studied, however, a higher boiling substance was produced along with the imidazoline. Indeed in some instances the higher boiling product was formed almost exclusively. The course of most of these reactions may be formulated as

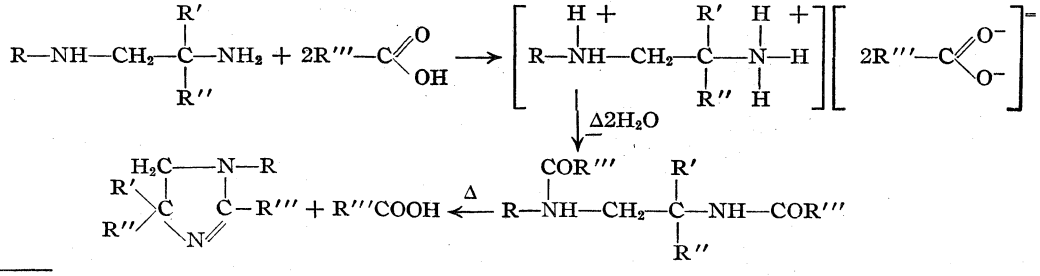


(I) (II) (III) (IV)

R′ and R″′ were H, alkyl, or aryl. R′ and R″ were H or alkyl. The most complete study was made in the case in which R was isopropyl and R′ and R″ were methyl. In this instance R″ was H, alkyl groups from CH_3 to $C_{17}H_{35}$ or aryl.

A few exceptions to the general reaction were noted. When 2,3-dimethyl-2,3-butanediamine reacted with acetic acid none of the expected compounds (III) or (IV) were isolated but a low yield of the diacetate was found. Likewise 1,2-butanediamine and acetic acid reacted to form the diacetyl derivative of the amine along with the imidazoline.

A possible mechanism to account for the formation of the imidazolines by this method may be represented as follows:



The evidence for the existence of the compounds of type (III) seems to be entirely satisfactory. The analyses, neutral equivalents and mode of synthesis all point to the same conclusion.

(1) Most of this work was completed while the author was at DePauw University, Greencastle, Indiana.

(2) Chitwood and Reid, THIS JOURNAL, **57**, 2424 (1935).

(3) Hofmann, *Ber.*, **21**, 2332 (1888).

(4) Hill and Aspinall, THIS JOURNAL, **61**, 822 (1939).

The non-committal formulation of compounds of type (IV) suggests doubt as to their structures. While most of these compounds gave analyses corresponding to one mole of the imidazoline attached to two moles of the acid, there were a few examples studied in which the molar ratio was one of the imidazoline to one of the acid. These exceptions were found mainly in those instances in which R was aryl. It is also of interest to note that the ratio of (IV) to (III) tended to increase as the chain length of R''' increased.

The examination of the nature of compounds of type (IV) was carried out mainly with the products formed from N-(2-aminoisobutyl)-isopropylamine and acetic and stearic acids. When acetic acid was used in this reaction a 26% yield of 2,4,4-trimethyl-1-isopropyl-2-imidazoline and a 32.7% yield of the complex corresponding to (IV) were obtained. The complex in this instance contained two moles of the acid.

This complex was a colorless, viscous oil when freshly distilled. Upon prolonged standing it turned yellow. It was readily soluble in water and insoluble in ether or petroleum ether suggesting salt-like properties. The fact that it distilled at 124–125° at 16 mm. is not characteristic of salts but does not preclude this possibility. It reacted either with strong acids or strong bases with the evolution of considerable heat, which suggested that it was made up of both acidic and basic constituents not firmly combined chemically. Its neutral equivalent was 258 (using 0.1 normal alkali and phenolphthalein). The end-point was not sharp but this figure indicated the acidic constituent to be of greater influence than the basic constituent.

When this complex was treated with cold aqueous sodium hydroxide solution 2,4,4-trimethyl-1-isopropyl-2-imidazoline was formed in good yield. When this imidazoline was mixed with two molar equivalents of acetic acid the complex was formed in high yield. And finally when one mole of N-(2-aminoisobutyl)-isopropylamine reacted with three moles of acetic acid, the complex was produced in 89% yield while no imidazoline was isolated.

The Raman spectrum for 2,4,4-trimethyl-1-isopropyl-2-imidazoline showed lines which would be expected from —C=N— linkage. When a similar experiment was attempted with the corresponding complex a continuous spectrum was obtained from which no definite conclusions could be drawn.[5]

What has been said for the complex produced from acetic acid and N-(2-aminoisobutyl)-isopropylamine can for the most part be repeated for the analogous product formed from the same diamine and stearic acid. In this instance the complex was formed nearly quantitatively and none of the corresponding imidazoline was isolated.

No evidence has been found to establish unequivocally the structure of compounds of type (IV). One might assume simple salt formation with the acid involving the acceptance of a proton by one or both nitrogen atoms. But this assumption of salt formation is open to the objection that imidazolines always form mono-hydrogen halide salts and they titrate potentiometrically as mono-acid bases. This latter observation makes it clear that one of the nitrogen atoms must be very weakly basic. It would be rather unexpected to find this weakly basic nitrogen capable of accepting a proton from acetic or stearic acid and not capable of doing so from hydrochloric acid. It would, therefore, be reasonable to suggest that most of the compounds of type (IV) may be molecular complexes made up of one mole of the acid and one mole of the salt—the latter being formed by the reaction of one mole of acid with one mole of the imidazoline.

(5) The author is indebted to Dr. M. J. Murray for the Raman spectra studies.

Experimental

The experimental procedure for the preparation of all these compounds was substantially the same. One molar equivalent of the diamine and one molar equivalent of the carboxylic acid were mixed with a little benzene and heated from 140 to 220°. The benzene–water mixture was distilled through a 4′ × $^5/_8$″ helix-packed column which was equipped with a decanter still-head filled with benzene, and arranged to drain off the water layer and to return the benzene to the column. Heating was continued until one molar equivalent of water was removed. In some instances one molar equivalent of the diamine and three of the acid were heated until two molar equivalents of water had been removed. The latter procedure generally gave high yields of compounds of type (IV) and none of (III).

After the reaction was complete the product was usually distilled. In some instances the product was a solid and was crystallized from a suitable solvent.

Two specific examples will suffice to illustrate the preparation of most of the compounds.

Preparation of 2,4,4-Trimethyl-1-isopropyl-2-imidazoline and its Molecular Complex.—A mixture of 130.1 g. (1 mole) of N-(2-aminoisobutyl)-isopropylamine and 60 g. (1 mole) of acetic acid was heated at 190–200° for three hours. During this period 21.5 g. of water was removed. The product was distilled and three main fractions were taken. The first came over at 60–63° (38 mm.), and was shown by its refractive index, density and neutral equivalent to be unreacted N-(2-aminoisobutyl)-isopropylamine, 57.4 g., 44% recovery. The second, which boiled at 94–96° (38 mm.), was the imidazoline, 41 g., 26.6% yield. The third fraction, with b. p. 124–125° (16 mm.), was the complex, 29.9 g., 32.7% yield.

In another experiment, 65 g. (0.5 mole) of N-(2-aminoisobutyl)-isopropylamine and 90 g. (1.5 moles) of acetic acid were mixed and heated to 180–220° for three hours until 18 g. (1 mole) of water was removed. The product, which distilled at 128–130° (19 mm.), was the complex; yield, 89%.

Anal. Calcd. for the complex $C_{13}H_{26}N_2O_4$: N, 10.20. Found: N, 9.89.

No imidazoline (VII) was isolated from the product.

[a] A1 = N-(2-aminoisobutyl)—. [b] X = 1. [c] Melting point. [d] X = 2. [e] A2 = -1,3-dimethylbutylamine. [f] N-(2-amino-2-methylbutyl)-1,3-dimethylbutylamine. [g] One R^4 is ethyl. [h] 2,3-Dimethyl-2,3-diaminobutane.

Conversion of the Complex to 2,4,4-Trimethyl-1-isopropyl-2-imidazoline.—To 40 g. of the complex was added 70 ml. of 10% aqueous sodium hydroxide. The alkaline solution was extracted with ether, and the ether solution dried over solid potassium hydroxide. The ether was removed and distillation gave a 15 g. fraction, b. p., 78–80° (15 mm.). There was almost no forerun or residue; yield, 72%.

Anal. Calcd. for the imidazoline, $C_9H_{18}N_2$: N, 18.17; neut. equiv., 154.1. Found: N, 18.10; neut. equiv., 159.2.

Conversion of 2,4,4-Trimethyl-1-isopropyl-2-imidazoline to the Complex.—To 3.08 g. (0.02 mole) of the imidazoline was added 2.4 g. (0.04 mole) of acetic acid. The mixture evolved heat. Upon distillation, the entire product boiled at 122–124° (15 mm.), 4.5 g., 90% yield.

Anal. Calcd. for the complex, $C_{13}H_{26}N_2O_4$: N, 10.20. Found: N, 10.11.

Preparation of 4,4-Dimethyl-1-isopropyl-2-heptadecyl-2-imidazoline Molecular Complex with Stearic Acid.—A mixture of 32.5 g. (0.25 mole) of N-(2-aminoisobutyl)-isopropylamine and 71.1 g. (0.25 mole) of stearic acid was heated to 190–200° for three hours. During the heating process 4.5 g. (0.25 mole) of water was removed. The product was transferred to a distillation flask and 13.3 g. of the original diamine (41%) was recovered. A white, solid, undistilled residue remained. After three crystallizations from acetone, it melted at 54–55°; yield of the complex, 95%.

Conversion of the Stearic Acid Complex to 4,4-Dimethyl-1-isopropyl-2-heptadecyl-2-imidazoline.—To 30 g. of the complex was added 150 ml. of 10% potassium hydroxide and the mixture was extracted with ether. The ether solution was dried over solid potassium hydroxide and the ether removed *in vacuo*. The residue was distilled and a fraction boiled at 204–206° (3 mm.); yield of the imidazoline, 8.3 g. The residue remaining from the ether extraction was acidified with hydrochloric acid. A white solid formed which on the basis of its neut. equiv., its melting point (and mixed melting point) was identified as stearic acid.

Conversion of 4,4-Dimethyl-1-isopropyl-2-heptadecyl-2-imidazoline to the Stearic Acid Complex.—A mixture of 1.135 g. (0.003 mole) of the imidazoline and 1.706 g. (0.006 mole) of stearic acid was warmed over steam just long enough to melt the stearic acid. The product melted at 54–55° after recrystallization from acetone. A mixed m. p. with the complex prepared above (m. p. 54–55°) showed no depression.

Similar experiments to those described above were attempted with N-(2-aminoisobutyl)-aniline and benzoic acid, with N-(2-aminoisobutyl)-isopropylamine and trichloroacetic acid and with N-(2-aminoisobutyl)-isopropylamine and *o*-chlorobenzoic acid, but the expected products did not result from any of these examples.

When 2,3-dimethyl-2,3-butanediamine was allowed to react under the usual conditions with acetic acid, none of the expected imidazoline was isolated but only a 10% yield of the diacetate, m. p. 156–157°.

Anal. Calcd. for 2,3-dimethyl-2,3-butanediamine diacetate, $C_{10}H_{24}N_2O_4$: C, 50.84; H, 10.24; N, 11.96. Found: C, 50.84; H, 10.14; N, 11.98.

A 15% yield of diacetyl-1,2-butanediamine, m. p. 150–151°, was obtained from the reaction of 1,2-butanediamine and acetic acid, in addition to a low yield of the expected imidazoline.

Anal. Calcd. for diacetyl-1,2-butanediamine, $C_8H_{16}N_2O_2$: C, 55.79; H, 9.95; N, 16.26. Found: C, 55.88; H, 9.50; N, 16.26.

Acknowledgment.—The author wishes to express his gratitude to Commercial Solvents Corporation for generous support of this project. Thanks are especially due to Dr. P. F. Tryon of that organization who did considerable preliminary work on this problem.

Summary

1. A series of imidazolines has been prepared by heating 1,2-diamines and organic acids under conditions to remove water during the process.

2. Most of these imidazolines react with the acids from which they are formed to produce molecular complexes involving one or two moles of the acid and one mole of the imidazoline.

3. These complexes can be converted to the imidazolines readily by treatment with dilute alkali.

4. When one amino group of the diamine is secondary, the yields are better than when both amino groups are primary.

5. As the molecular weight of the acids becomes larger the yields of the complexes increase and the yields of the imidazolines decrease.

The Decomposition of 2,5-Dinitrobenzoic Acid by Alkali

BY WILSON D. LANGLEY

In attempts to explain the color given by 2,5-dinitrobenzoic acid in alkaline solution the effect of alkali alone upon the dinitro acid was studied.

Pure 2,5-dinitrobenzoic acid (m. p. 177–178°) in sodium bicarbonate solution is yellow and may be boiled with but slight intensification of color. In strong alkali (0.4 *N* sodium hydroxide), however, even at room temperature, intensification of color to deep red occurs over several weeks. The deep color develops quickly when the solution is heated. After one hour of heating, followed by acidification with hydrochloric acid, 2-hydroxy-5-nitrobenzoic acid, 5-hydroxy-2-nitrobenzoic acid and a non-crystalline brown acid were isolated. Nitrous acid and ammonia also were present in small amounts. Neither unchanged 2,5-dinitrobenzoic acid nor 2,5-dihydroxybenzoic (gentisic) acid could be detected. That the colored acid was probably a mixture of azo and hydrazo compounds was indicated by the composition of the material, and by its close similarity to colored substances which were subsequently prepared by reduction of 2,5-dinitrobenzoic acid with glucose in sodium carbonate solution (not reported herein). At this alkalinity 2,5-dinitrobenzoic acid is not decomposed, and under the conditions used, aromatic nitro compounds in general give rise to azo dyes.

After heating 2-hydroxy-5-nitrobenzoic acid in 0.4 *N* sodium hydroxide for one hour, the unchanged acid was recovered in 60% yield, and no other product could be isolated. No deep color was formed. With similar heating in alkali, 5-hydroxy-2-nitrobenzoic acid was recovered unchanged in 50% yield, a very small amount of unidentifiable red material being formed. Tests with ferric chloride gave no blue color with these alkaline solutions, from which it is concluded that gentisic acid was not present. It is evident from these findings that the hydrolysis of 2,5-dinitrobenzoic acid by strong alkali leads to the ready replacement of either, but not of both, atoms of nitrogen from the dinitrobenzoate.

Experimental

Isolation of the Acids.—For a typical hydrolytic decomposition, 2.0 g. of 2,5-dinitrobenzoic acid was suspended in 50 ml. of water, and 0.8 g. of sodium bicarbonate was added. When the evolution of carbon dioxide had ceased, an equal volume of 0.8 *N* sodium hydroxide was added. This solution was refluxed for one hour, during which time it became deep red. It was cooled, was acidified to congo red with 10% hydrochloric acid and was chilled, whereupon 0.63 g. of brown material separated. The filtrate upon being evaporated to 50 ml. and filtered yielded 0.025 g. more of the brown product.

The 50 ml. was evaporated nearly to dryness, and sodium chloride and a small amount of 2-hydroxy-5-nitrobenzoic acid were filtered off. Addition of ethanol to the filtrate aided in removing more sodium chloride. The sirupy concentrate was extracted repeatedly with about 50 ml. of boiling toluene, the water remaining being distilled off with toluene vapor. Upon cooling the toluene, crystals separated and were filtered off; by several repetitions of the process with the toluene filtrate a total of 0.35 g. of crystalline material was obtained. A negligible amount of dark colored oil insoluble in the toluene but readily soluble in butanol remained, together with a small amount of ammonium chloride. After recrystallization of the product from toluene (0.3 g. dissolved in 90 ml. of boiling toluene, from which 0.235 g. was recovered), it melted at 165–166°, which is the melting point of 5-hydroxy-2-nitrobenzoic acid. Equiv. wt. found, 92.7, 91.5; calculated for hydroxynitrobenzoic acid, 91.5. The *p*-nitrobenzyl ester was prepared and after recrystallization from ethanol melted at 200–202°. The corresponding ester prepared from 2-hydroxy-5-nitrobenzoic acid which was purchased, melted at 115°.

The 0.65 g. of brown precipitate obtained above was extracted three times with about 50-ml. portions of boiling toluene, from which, after cooling, separated 0.22 g. of crystalline material, m. p. 224–225°. Mixed with 2-hydroxy-5-nitrobenzoic acid, the melting point was unchanged. The residue insoluble in toluene was then extracted with boiling water, and was filtered. The slightly soluble brown material separated as an oil, and the filtrate, after chilling, yielded 0.15 g. more of 2-hydroxy-5-nitrobenzoic acid. This process of fractionation was repeated several times when separation of the products seemed to be complete. The air dried brown solid decomposed gradually from about 250 to 300°. It repeatedly came out of 20% ethanol or from dilute 1,4-dioxane as an oil. It was readily soluble in hot butyl or in benzyl alcohol, from which it was precipitated as brown powder by careful addition of toluene. This powder was soluble in sodium bicarbonate with evolution of carbon dioxide. Since it did not give intensification of color upon being heated in 0.4 *N* sodium hydroxide, unchanged 2,5-dinitrobenzoic acid was not present. Attempts were made to obtain crystalline esters, the amide, and copper, barium, and calcium salts, but oils were always obtained. Combustion of the brown acid showed that it contained 47.4% carbon and 2.8% hydrogen. Nitrogen values by the Elek and Sobotka modifications of the Kjeldahl process[1] indicated the substance to be a mixture, as did titration values attempted with the deeply colored solutions, but the analyses established that two atoms of nitrogen per carboxyl group were present. The data, together with the physical properties, suggested strongly that the colored material was a mixture of azo and hydrazo compounds. Extraction with ether removed enough of an oil component so that the residue could be crystallized from hot 50% ethanol. In polarized light three different crystal forms were detected. After filtering off the first crop of obviously impure crystals, a second homogeneous crop melted sharply at 262°, but the crystals were too small for indices of refraction to be determined.

Subsequent experimental work involved the synthesis of 2-nitroso-5-nitrobenzoic acid, and of 2-nitro-5-nitrosobenzoic acid. Both nitroso acids failed to react with the 2,5-aminonitrobenzoic acids even in the presence of rather vigorous dehydrating agents. Therefore synthesis of the desired azo compounds having known structures for comparison with the above colored acid is still to be accomplished.

For the synthesis of 2-nitroso-5-nitrobenzoic acid, 2-amino-5-nitrobenzoic acid was prepared through the following series of reactions described by Hewitt and Mitchell,[2]

(1) Elek and Sobotka, THIS JOURNAL, **48**, 501 (1926).

(2) Hewitt and Mitchell, *J. Chem. Soc.*, **91**, pt. 2, 1258 (1907).

and by Green and Day[3]: 2-acetamido-5-nitrotoluene → 2-acetamido-5-nitrobenzoic acid → 2-amino-5-nitrobenzoic acid.

The 2-amino-5-nitrobenzoic acid was then oxidized with Caro's acid as follows:

2-Nitroso-5-nitrobenzoic Acid.—A solution containing 2.5 ml. of water and 10 ml. of sulfuric acid (sp. gr. 1.85) was cooled to 5°. To it was added 4.1 g. of 2-amino-5-nitrobenzoic acid, the mass being broken up with a glass rod. Then 10 ml. more of cold sulfuric acid was poured in, followed by 25 g. of powdered ammonium persulfate. When a uniform paste was obtained, 20 ml. of ice water was added, whereupon the aminonitrobenzoic acid dissolved. The solution was warmed to 40°, and was held at that temperature. A brown precipitate separated after thirty minutes. After one and one-half hours another 10 g. of ammonium persulfate was added, the solution now being allowed to come to room temperature and to stand overnight. Then 50 g. of cracked ice was added and after fifteen minutes the cold solution was filtered with gentle suction through hardened filter paper. The brown product was washed with ice water and, after being dried in warm air, weighed 3.61 g. No more product could be obtained by further diluting and chilling the filtrate. The unpurified acid was cream colored and melted with decomposition at 202°. For recrystalllization 1 g. was dissolved in 20 ml. of 50% ethanol and was chilled, 0.40 g. being recovered.

Anal. Equiv. wt., 0.2770 g. subs. neutd. 14.73 ml. of 0.0957 *N* sodium hydroxide to phenolphthalein endpoint. Calcd. for $C_7H_4O_5N_2$: equiv. wt., 196. Found: equiv. wt. 196.6.

2-Nitro-5-nitrosobenzoic Acid.—For the synthesis of this acid a series of reactions corresponding to that given above was carried out: 3-aminotoluene → 3-acetamidotoluene → 3-acetamido-6-nitrotoluene → 3-acetamido-6-nitrobenzoic acid → 3-amino-6-nitrobenzoic acid. The 3-amino-6-nitrobenzoic acid was oxidized as has been described under 2-nitroso-5-nitrobenzoic acid. The sulfate was less soluble than that of 2-amino-5-nitrobenzoic acid, and was oxidized in more dilute solution. The crude, light brown product was recrystallized from dilute ethanol as follows: 1 g. was dissolved in 5 ml. of hot 95% ethanol and 12 ml. of hot water was added. After rapid filtration and cooling of the filtrate, 0.88 g. of 2-nitro-5-nitrosobenzoic acid, m. p. 270–270.5°, was filtered off.

Anal. Equiv. wt., 0.1270 g. subs. neutd. 6.11 ml. of 0.1058 *N* NaOH; 0.1737 g. subs. neutd. 8.42 ml. of 0.1058 *N* NaOH. Calcd. for $C_7H_4O_5N_2$: equiv. wt., 196. Found: equiv. wt., 196.6, 194.9.

Evaporation of the filtrates from the recrystallization yielded about 50 mg. of the nitrosonitro acid, and further evaporation to about 25 ml. yielded a light colored oil, which soon crystallized and proved to be 2,5-dinitrobenzoic acid.

(3) Green and Day, THIS JOURNAL, **64**, 1167 (1942).

Summary

By alkaline hydrolysis of 2,5-dinitrobenzoic acid either nitro group may be replaced by hydroxyl, giving rise to 2-hydroxy-5-nitrobenzoic acid, and to 5-hydroxy-2-nitrobenzoic acid. Gentisic acid seemed not to be formed. A brown oil also was isolated. This was a mixture probably of azo and hydrazo compounds, which were not identified.

Synthesis of 2-nitroso-5-nitrobenzoic acid and of 2-nitro-5-nitrosobenzoic acid showed these substances to be practically colorless and unlike the colored product formed by the action of alkali upon 2,5-dinitrobenzoic acid. Both nitroso acids were non-reactive toward the 2,5-aminonitrobenzoic acids.

Ultrasonic Investigation of Molecular Properties of Liquids. II.[1] The Alcohols[1a]

BY ALFRED WEISSLER

Although several investigators[2,3,4,5] have measured the velocity of sound in a variety of liquids, the application of their data to chemical problems has been relatively neglected.[6] Inasmuch as a sound wave is a mechanical impulse transmitted from molecule to molecule, one expects the properties of the molecule to affect the rate of transmission of this impulse.

The use of ultrasonic frequencies permits the apparatus to be of conveniently small size, yet still avoid earlier errors due to wall effect. At one kilocycle the wave length in many liquids is about one meter, while at one megacycle (the frequency employed in this investigation) the wave length is about one millimeter.

For the present work, thirty liquid alcohols were selected as a suitable group of compounds in which correlations could be made between sound velocity and chemical structure. Specifically, sound velocity is of interest in connection with molecular weight, molecular volume, adiabatic compressibility, and the ratio of specific heats.

Experimental

Each alcohol (of the highest purity commercially available from such sources as Eastman Kodak Co., Connecticut Hard Rubber Company, and Carbide and Carbon Chemicals Corporation) was fractionally distilled through a 40-cm. Widmer column shortly before using; the higher boiling compounds were fractionated at a reduced pressure of about 1 mm. A middle fraction of narrow boiling range was selected in each case.

Sound velocity measurements were made by means of

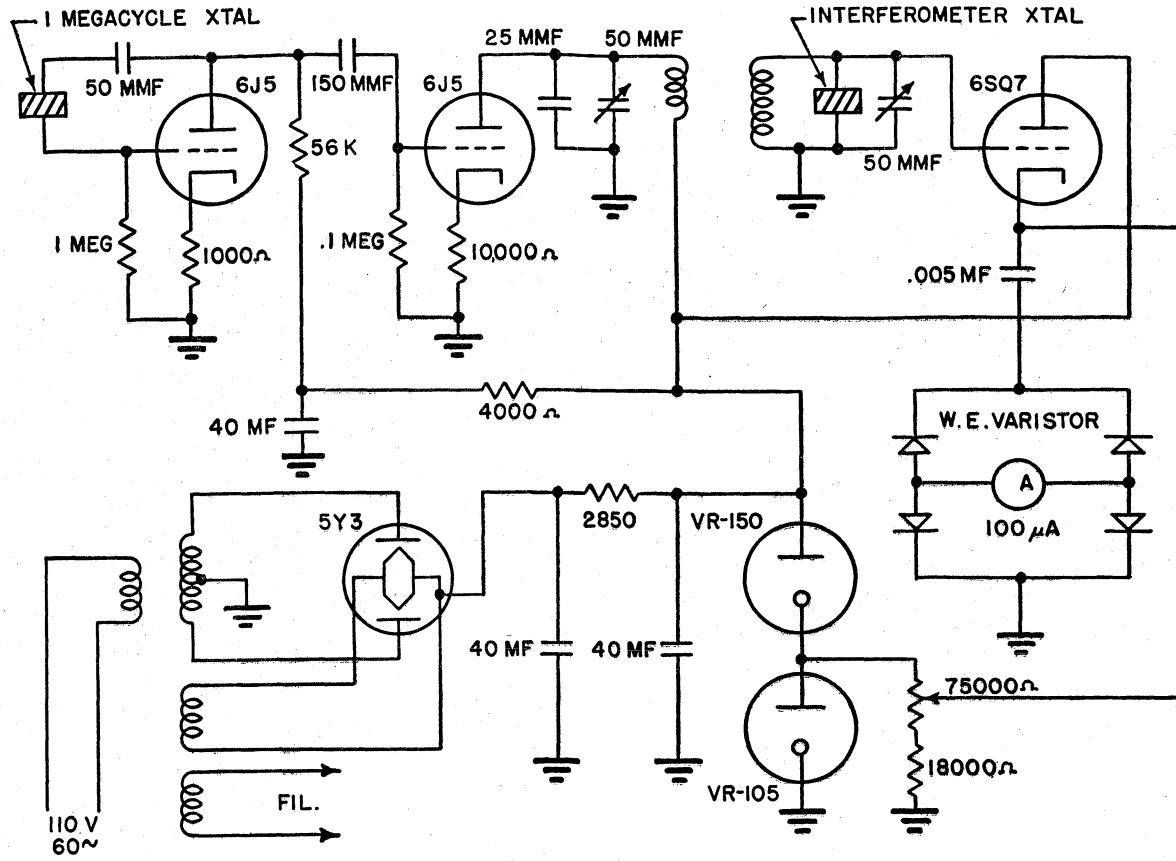

Fig. 1.—Circuit design for interferometer for one megacycle.

an ultrasonic interferometer of conventional type.[6a,7,8] As may be seen in Fig. 1, the circuit includes a power supply, crystal-controlled vacuum-tube oscillator of one megacycle frequency, r. f. amplifier, and microammeter for measuring the current through the interferometer crystal. This latter crystal is the quartz piezoelectric transducer which changes the oscillations from electrical to mechanical.

Figure 2 is a sectional view of the brass interferometer cell, diameter 7 cm. and height 11 cm., immersed in a temperature controlled (±0.05°) oil-bath. The cell contains the liquid to be measured, a sensitive thermometer, a manual stirrer for eliminating temperature gradients, the quartz crystal source of ultrasound, and a movable reflecting plate of nickel-plated brass. As the reflector is moved vertically through the liquid by the micrometer head, cyclical variations in the ultrasonic standing wave pattern recur at distances of integral half-wave lengths: depending on its distance from the source, the reflector will sometimes be at a node of the transmitted wave, sometimes at an anti-node. This causes corresponding cycles in the current through the interferometer crystal, which are observed on a suitable microammeter. The micrometer-head travel required for an interval of two current maxima, then, is equal to the wave length; and the velocity of sound is of course the product of this wave length and the frequency. In practice, one uses an interval of twenty maxima, which makes possible a precision of a few hundredths of one per cent.

Although the instrument described requires about 350 ml. of liquid for a measurement, a new three-megacycle interferometer now in use at this Laboratory requires only 15 ml. of sample.

Results and Discussion

The velocity of sound at 30° in each of these thirty alcohols is listed in Table I, together with the density and refractive index. It is apparent that sound velocity increases (but not linearly) with molecular weight in this series,[9] and that it decreases as the molecule becomes more highly branched. A saturated or unsaturated ring, however, causes a considerable increase in velocity.

Also shown in this table are the molar refraction and molar sound velocity of each alcohol. As expected, the observed refractions agree well with those calculated by summing Denbigh's bond refractions,[10] particularly in the absence of extensive branching. The deviation exceeds 1% only in the case of furfuryl alcohol; such anomalous behavior has previously been reported for the furans.[11]

(9) Rao, *J. Chem. Phys.*, **9**, 682 (1941), reveals greater irregularities in other series.

(10) Denbigh, *Trans. Faraday Soc.*, **36**, 936 (1940).

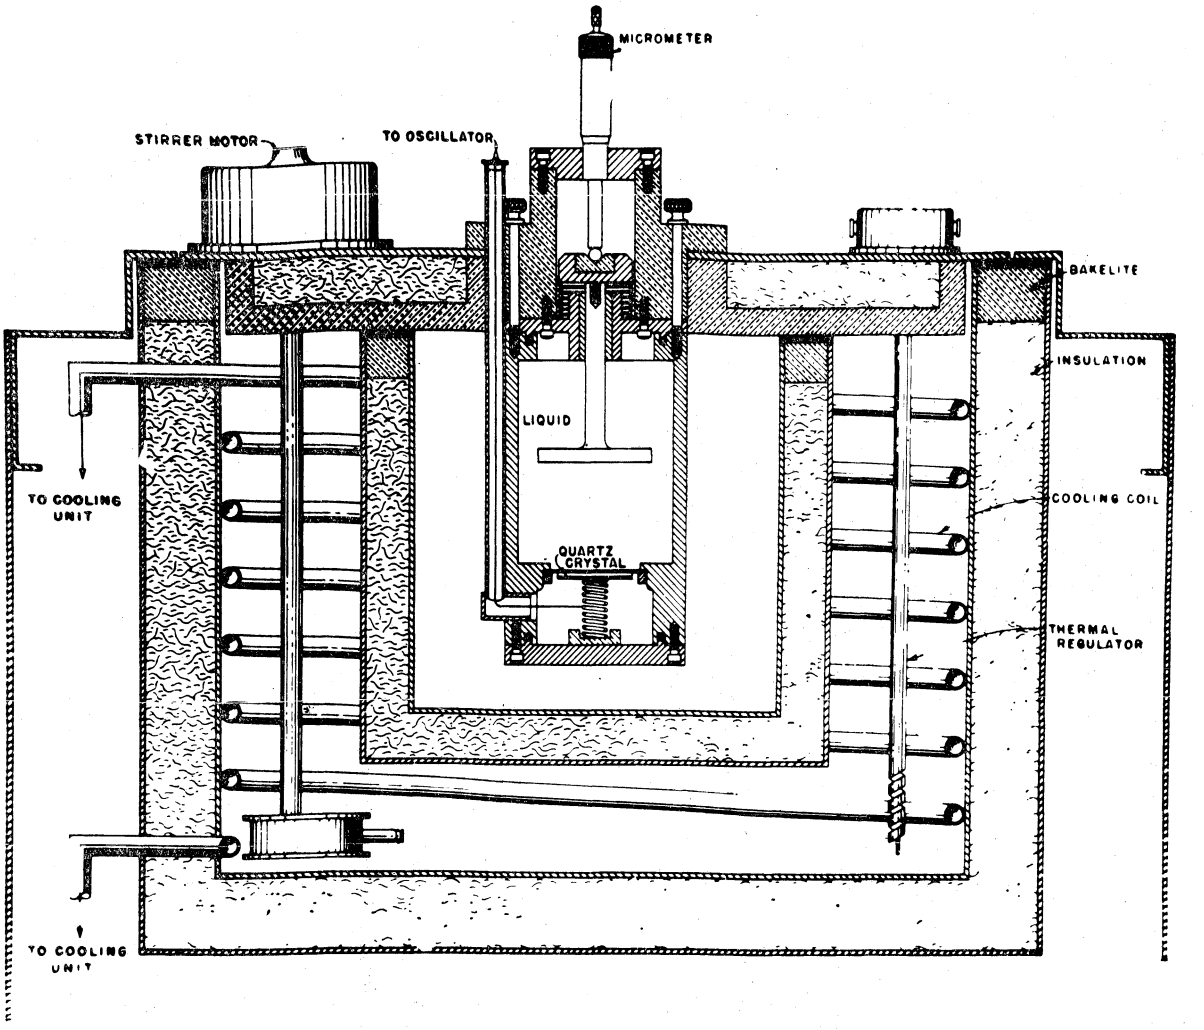

Fig. 2.—Ultrasonic interferometer immersed in thermoregulated oil-bath.

Molar Sound Velocity.—M. R. Rao has proposed[9] the following empirical constant involving sound velocity

$$R = v^{1/3}M/d \qquad (1)$$

where M is the molecular weight, v the sound velocity, d the density, and R may be called the molar sound velocity. For each pure liquid (except a few such as water) R is invariant with respect to temperature. Further, like the other forms of molar volume it is an additive and constitutive property, and is therefore quite analogous to molar refraction except that a theoretical explanation for its constancy has not yet been adduced. An empirical function (the cubic root of sound velocity) which decreases slightly with increasing temperature is used here as a means of correcting the molar volume for thermal expansion. It should be pointed out that R is relatively insensitive to the intermolecular forces which determine the compressibility, since it is inversely proportional to the sixth root of the compressibility.

The observed molar sound velocities computed from equation (1) are compared in Table I with the values calculated by summing Lagemann's bond increments[12] for R. The average deviation is seen to be about 2%, but it is notable that nearly all the errors are in the same direction. This, together with the greater precision of the present measurements, suggests the desirability of a revision of the increment values. For example, changing the R increment for $-CH_2-$ from 195 to 190 would reduce the average deviation to a few tenths of a per cent.

A comparison between the velocity of light (*i. e.*, refractive index) and the velocity of sound is illuminating. Both yield information on the size, shape, and functionality of molecules: the velocity of sound is determined by the distance and elastic forces between them, while the velocity of light depends on their electrical and magnetic characteristics. Both properties can be readily

measured in liquids with an accuracy of five significant figures. In sharp contrast to optical dispersion, sound velocity in liquids does not vary appreciably with frequency, but its relative change with temperature is five to ten times greater than that of refractive index. After thermal equilibrium is established, interferometric determination of the sound velocity requires less than five minutes, but the relatively large sample needed is a disadvantage. For ordinary liquids, the range of sound velocity encountered is 0.8 to 2.0 × 10^5 cm./sec., compared to the refractive index range of 1.3 to 1.8.

Determination of Molecular Weight.—Within a homologous series of liquids, linear relationships exist[12] between any two of several molar constants such as molar sound velocity, molar refraction, parachor and molar viscosity.[13] An example of such a relation is the one involving refraction and sound velocity

$$R = AN + B \qquad (2)$$

where A and B are, respectively, the slope and intercept. Upon substitution of the definitions of R and N, this yields an expression for the molecular weight

$$M = \frac{Bd}{v^{1/3} - A\left(\frac{n^2 - 1}{n^2 + 2}\right)} \qquad (3)$$

in terms of the two "series" constants A and B and the observed sound velocity, density and refractive index. One expects the slope A to be nearly the same for all homologous series, because the difference between successive members is always $-CH_2-$.

In Figure 3 the above-mentioned linearity is verified for the normal primary alcohols up to dodecyl, the highest member which is liquid at room temperature. The slope A of this line is 40.92, and the vertical intercept B is 82.50. Even the branched compounds lie very nearly on the same line,[14] while for the ω-phenylalkanols the slope

(13) Souders, THIS JOURNAL, 60, 154 (1938).

(14) Dr. Richard K. Cook of the National Bureau of Standards has pointed out that such a result is not surprising, inasmuch as both variables plotted include the factor M, which changes much more rapidly than v, n or d. For a more sensitive test of the linearity, he suggests rearranging equation (3) to

$$\frac{A}{v^{1/3}}\left(\frac{n^2 - 1}{n^2 + 2}\right) + \frac{Bd}{Mv^{1/3}} = 1$$

the graph of which shows appreciable deviations from a straight line.

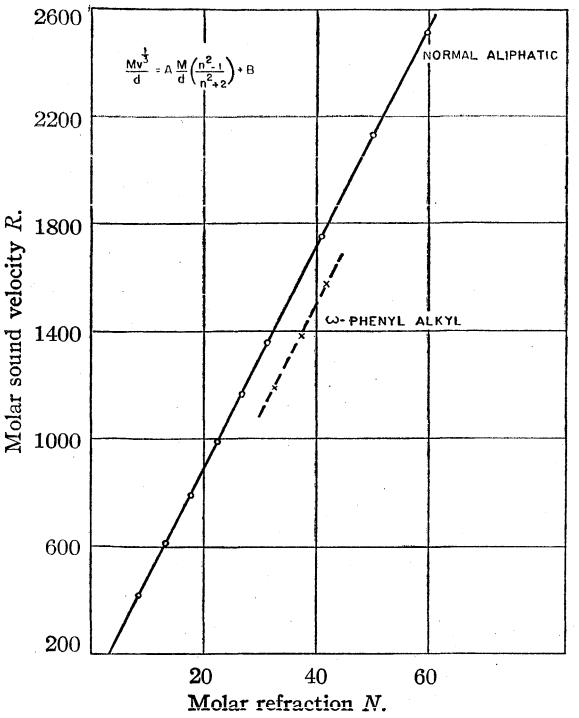

Fig. 3.—Linear relation between molar refraction and molar sound velocity, for primary alcohols.

is exactly the same but the intercept is −136.0.

Using the above values for A and B, the molecular weights of the aliphatic alcohols were computed from equation (3). It is evident from Table II that the average error is only 2% for the primary normal members, but is considerably greater where extensive branching occurs. For the three phenylalkanols, taking B as −136, the average error is only 0.3%.

From one point of view, this method may be considered as a determination of molecular weight through linear interpolation or extrapolation, by means of a suitable combination of physical properties.[15] (The molecular weight is not in general a linear or necessarily even a single-valued function of a single physical property.) Volatility or solubility of the liquid is not required, in contrast with other methods.

Because of the association of alcohols, one might suppose that the molecular weights found should be appreciably higher than the theoretical. However, the constants A and B automatically include any correction of this nature which might be involved.

Estimation of van der Waals b.—Sound velocities in liquids have been used by Schaafs[16] to estimate the size of molecules, through the value of b in the van der Waals equation of state. According to kinetic theory, this quantity represents four times the actual volume of the molecules in one mole of a fluid in thermal motion.

Solving the van der Waals equation for the pressure, and substituting M/d for V, gives

$$P = \frac{RT}{M/d - b} - \frac{d^2 a}{M^2} \qquad (4)$$

If one differentiates this with respect to density, remembers that the square of sound velocity is equal to the derivative of pressure with respect to density, and accepts certain approximations made by Schaafs, the result is:

$$b = \frac{M}{d} - \frac{RT}{v^2 d}\left[(1 + Mv^2/3RT)^{1/2} - 1\right] \qquad (5)$$

This method for obtaining b is much easier than the customary evaluation from the critical data; nevertheless, it is sometimes considered unreliable and caution is required in its use. First, the concept of b is not defined with high precision[17]; it is not constant over a range of temperatures and pressures, and different methods for measuring it give divergent results. Thus, the values obtained from equation (5) and listed in Table III show only fair agreement with such

TABLE II

DETERMINATION OF MOLECULAR WEIGHT BY THE SOUND VELOCITY METHOD

$$M = \frac{82.50d}{v^{1/2} - 40.92\left(\frac{n^2 - 1}{n^2 + 2}\right)}$$

Allyl	61.8	80.27	80.8[b]	1.192
Ethylene glycol	52.9	33.45	34.0[b]	1.130

[a] Values of $b = V_c/3$ for these alcohols are 39.3, 55.7, and 73.4, respectively (I. C. T.). [b] Shiba, *Sci. Pap. Inst. Phys. Chem. Research (Tokyo)*, **16**, 205 (1931). [c] Tyrer, *J. Chem. Soc.*, **105**, 2534 (1914). [d] Fryer, Hubbard and Andrews, THIS JOURNAL, **51**, 759 (1929). [e] Bhagavantam and Rao, *Proc. Ind. Acad. Sci.*, **9A**, 312 (1939).

The additivity of b is demonstrated for the primary normal alcohols in Fig. 4. The values for branched isomers show small changes, but ring compounds of comparable molecular weight exhibit a considerable decrease. Inasmuch as the sound velocity term in equation (5) represents a relatively small correction to the molar volume term, the linearity in Fig. 4 correlates with the familiar additive character of the molar volume.

Determination of Adiabatic Compressibility.— From acoustic theory, the velocity of sound in a medium is

$$v = (1/K_{ad}d)^{1/2} \qquad (6)$$

where K_{ad} is the adiabatic compressibility. The pressure changes which occur during the propagation of a sound wave are so rapid as to prevent heat flow to and from the surroundings.

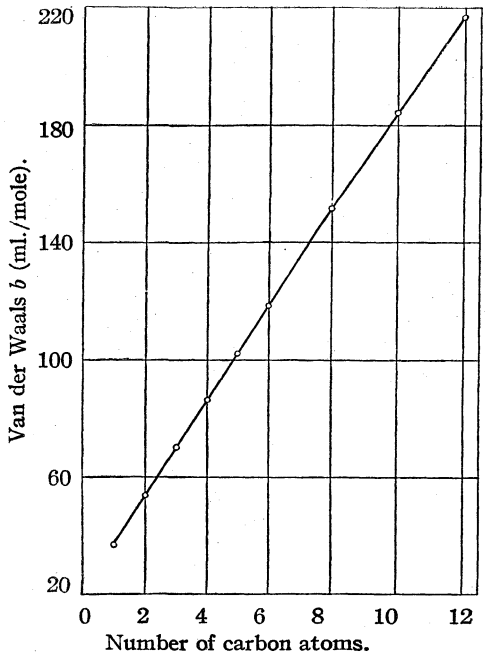

Fig. 4.—Additivity of van der Waals b, for primary normal alcohols.

Table III lists the adiabatic compressibilities of the alcohols, calculated from sound velocity and density as indicated in equation (6). The results agree well with those obtained (mainly from mechanical piezometers) by other investigators. It is apparent that K_{ad} decreases with molecular weight, increases with branching, and is small for ring compounds. The plot of K_{ad} against number of carbon atoms on log–log paper (Fig. 5) reveals more quantitative relations. From the slopes of these lines, adiabatic compressibility is found to be approximately a function of the inverse fourth root of the number of carbons in the molecule, for primary normal alcohols. For iso alcohols, it depends on the inverse 2.6th root; and for tertiary, on the inverse 1.3rd root. The reciprocals of these exponents are in the ratio 3:2:1

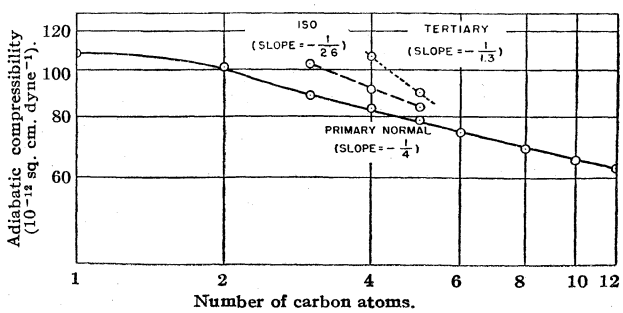

Fig. 5.—Adiabatic compressibility of aliphatic alcohols.

for the cases of no branching, single branching and double branching, respectively, but the precise significance of this result is not apparent.

The compressibility of the methanol molecule estimated from bond force-constants is about 1/1000 as large as the observed compressibility. This indicates that it is the space between the molecules which is compressed, rather than the molecules themselves.

The adiabatic compressibility is of interest in thermodynamics. For example, the ratio of isothermal to adiabatic compressibilities is equal to the ratio of specific heats

$$K_{is}/K_{ad} = c_p/c_v = \gamma \qquad (7)$$

The isothermal compressibility can be obtained either from static measurements or from

$$K_{is} = K_{ad} + T\alpha^2/c_p d \qquad (8)$$

where T is the absolute temperature, α the coefficient of thermal expansion, and c_p the heat capacity at constant pressure.

Sufficient data are available[18] in several cases for calculating[19] the ratio of specific heats from equations (7) and (8). The results in Table III show that γ decreases slightly as the complexity of the molecule increases, as expected because of the larger number of degrees of freedom.

Acknowledgments.—The author is indebted to Dr. G. R. Ringo for many stimulating discussions, to Dr. H. W. Carhart for samples of several of the alcohols, and to The Quaker Oats Company for samples of furfuryl and tetrahydrofurfuryl alcohols.

Summary

The velocity of sound at 30° has been measured in thirty liquid alcohols, using a one-megacycle ultrasonic interferometer. Densities and refractive indices at 30° are also reported.

To illustrate the applicability of sound velocities in chemical studies, these data have been used to calculate molecular weight, van der Waals b, adiabatic compressibility, and the ratio of specific heats. The compressibility has been correlated semi-quantitatively with molecular structure.

The analogy between molar sound velocity and molar refraction has been discussed.

RECEIVED AUGUST 25, 1947

(18) Shiba, *Sci. Pap. Inst. Phys. Chem. Research (Tokyo)*, **16**, 205 (1931).

(19) It is necessary to avoid using the large body of isothermal compressibility data which has been determined for high pressures, because the excess pressure attained in the ultrasonic interferometer is only a very small fraction of an atmosphere.

The Accuracy of Estimation of Hydrogen Peroxide by Potassium Permanganate Titration

BY CHARLES E. HUCKABA[1a] AND FREDERICK G. KEYES[1b]

Introduction

The usual method for analyzing aqueous solutions of hydrogen peroxide is by titration in acid solution with a standard solution of potassium permanganate. However the complete reliability of this method for very accurate determinations has been questioned, because of some doubt as to the optimum conditions for carrying out the titration.

A search of the literature revealed varying recommendations as to the proper sulfuric acid concentration, and some uncertainty as to the rate of addition of the permanganate to the peroxide solution. For example, if the rate of addition is too great, some manganese dioxide may be formed due to a local depletion of acid in the solution and bring about catalytic decomposition of a portion of the peroxide.

There are three possible methods for carrying out the determinations of hydrogen peroxide: titration, colorimetry and decomposition. Titration methods using the following reagents have been described in the literature[2]: potassium permanganate, ceric sulfate, potassium iodide–sodium thiosulfate, sodium arsenite and titanium trichloride. However in each case there has been observed either disagreement regarding the best procedure for performing the titration, or uncertainty as to the reliability of the method. The colorimetric method is applicable only for detecting a few parts per million of peroxide.

The method based on the decomposition of the peroxide with a suitable catalyst followed by measuring the amount of oxygen evolved would appear in principle to combine simplicity and reliability. The reaction occurs as follows

$$2H_2O_2 \xrightarrow{\text{catalyst}} 2H_2O + O_2$$

There are no known side reactions to introduce error as is present in some of the titration procedures.

(1) (a) Results recorded in this article are from a thesis submitted as partial fulfillment of the requirements for the degree of Master of Science in Chemical Engineering at the Massachusetts Institute of Technology; (b) Department of Chemistry, Massachusetts Institute of Technology.

(2) J. S. Reichert, S. A. McNeight and H. W. Rudel, *Ind. Eng. Chem., Anal. Ed.*, **11**, 194 (1939). This paper surveys the titration procedures for peroxide to date.

The inconvenience of the decomposition method in practice would bar it from general use. However there seems to be no doubt that it is an "absolute" method of analysis. Therefore it was concluded that considering the existing confusion concerning other methods, the decomposition procedure was the only completely reliable method with which the titration methods could be compared.

The objective of this investigation involves then the constructing of a suitable apparatus for carrying out the absolute or gasometric analysis by decomposition as a basis for the comparison with the convenient permanganate titration procedure. No record of such a comparison has been found in the literature. The necessity for such a comparison is apparent.

The Gasometric Method

An apparatus was assembled as shown in the drawing for carrying out the analysis by decomposition. It consisted chiefly of a reaction vessel of two sections connected by a ground glass joint, a moisture trap, a Töpler pump, a volumometer, a manometer, a thermometer and a McLeod pressure gage.

The mercury levels in the Töpler pump and the volumometer were controlled by applying either pressure or vacuum to the steel mercury containers. Very accurate control of mercury introduction was attained through the use of steel needle valves. For the volumometer extremely fine adjustment of the mercury levels was afforded by a small piston-type injector.

Small monel metal bellows were placed between the steel tubing from the mercury containers and the glass of both the Töpler pump and the volumometer to absorb any shocks that might occur.

A mixture of Dry Ice and methyl alcohol (t = 78.5°) was used as the refrigerant around the moisture trap, and proved to be adequate. The thermometer was strapped to the outside of the volumometer with asbestos tape. Vacuum for the system was furnished by a mercury diffusion pump capable of producing a high vacuum.

The volumometer was calibrated by weighing the amount of mercury needed to fill the space between the three pointers and the top. The following results were obtained:

Top of volumometer to	Volume, cc.	Precision
Top pointer	34.038	1:3000
Middle pointer	100.341	1:2500
Bottom pointer	202.041	1:3500

The following procedure was used in making a run with the decomposition apparatus:

The manometer, volumometer and Töpler pump were evacuated and closed off from the remainder of the system. The mercury level in the volumometer was adjusted to a point just below the delivery tube from the Töpler pump to seal the manometer off from the volumometer. An 8-10 cc. sample

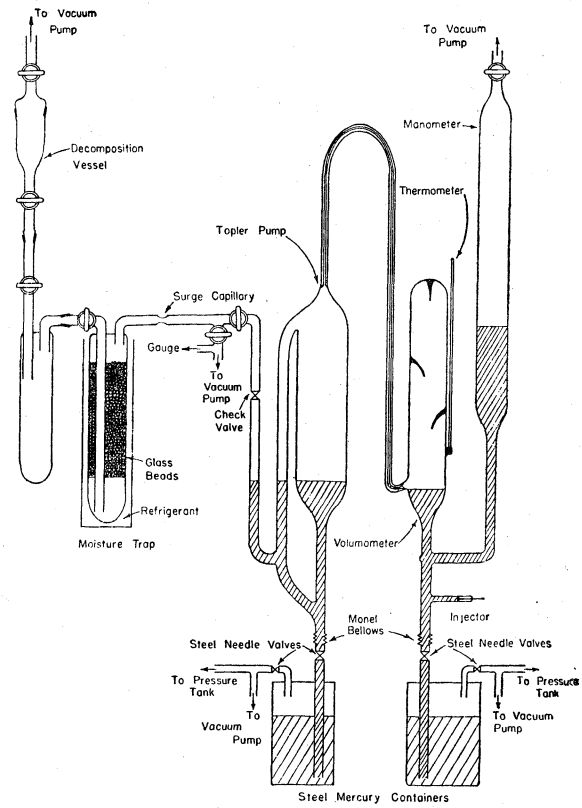

Fig. 1.—Decomposition apparatus.

of 2 to 3% hydrogen peroxide was weighed out in the top part of the reaction vessel, which had previously been cleaned with hot fuming sulfuric acid to prevent premature decomposition of the peroxide. After this part of the reaction vessel had been attached, the remainder of the apparatus was evacuated. With the reaction vessel closed off from the rest of the system, the peroxide was transferred to the cooled (−78°) lower part of the vessel. This was followed by two portions of distilled water of approximately 10 cc. each to rinse all of the peroxide into the lower vessel. Next a great excess of liquid catalyst was introduced in the same manner exercising great precaution not to let air leak into the bottom vessel. The dissolved air in the rinse water and liquid catalyst was removed by applying a vacuum in the top part of the reaction vessel prior to admission of the liquid.

As the peroxide thawed, the decomposition started and it was allowed to go to completion. Tests made by adding huge excesses of several catalysts to the residues proved that the reaction was in truth complete.

The evolved oxygen was transferred to the volumometer by means of the Töpler pump. About eight passes with the Töpler pump which has a volume of about 600 cc. was sufficient to complete the transfer. Completeness of transfer was evidenced by a pressure reading of about 10^{-4} mm. of

mercury in the pump, and by the fact that no appreciable amount of gas was transferred by the last pass with the pump.

The mercury level in the volumometer was adjusted until it was only a few millimeters below the bottom pointer. The temperature of the gas was then allowed to reach equilibrium with that of the surroundings, as evidenced by constancy of the mercury level in the manometer. The mercury level in the volumometer was finally adjusted by means of the injector until it just made contact with the bottom pointer. The mirror nature of the mercury surface made adjustment to a fine point very accurate (±0.001 mm.).

The difference in mercury levels in the volumometer and manometer were read with a Geneva cathetometer. The cathetometer, of special construction, consists of two telescopes which are mounted on a vertical invar metal bar and each telescope eyepiece is equipped with a micrometer cross-hair arrangement which allows the mercury levels to be read to 0.002 mm. The brass scale used with this cathetometer was calibrated by the Bureau of Standards and found to be accurate to about three parts in 100,000.

The space above the mercury in the manometer was evacuated, and therefore the difference in mercury levels corrected for capillarity was the absolute pressure of the gas in the volumometer. The temperature was read from the thermometer attached to the volumometer.

The gas in the volumometer was the oxygen produced from the decomposed peroxide plus the dissolved air in the sample of peroxide.

It was first attempted to remove this dissolved air by alternate freezing, and pumping away the air. However, it was discovered that the peroxide decomposed during the thawing operation.

Since the removal of air from the peroxide was impractical, it was decided to apply a correction for the dissolved air. To determine the value of the correction, several blank runs were made using a sample of water which had been stored under similar conditions to the peroxide. It was assumed that the amount of air dissolved in 3% hydrogen peroxide is the same as that in water.

The procedure used in the blank runs was exactly the same as that employed in the runs with peroxide. The average value obtained was 0.022 cc.[3] of air at standard temperature and pressure per gram of water at 25°. The value given is somewhat higher than will be found in the literature and this is due to the fact that the number corresponds to a measurement made using the exact procedure where two quantities of pumped rinse water were used. This value was used to correct the observed volumes of gas evolved from the decomposition.

Calculation of the weight of oxygen was carried out by using a simplified approximation of the Beattie–Bridgeman equation of state for oxygen as follows[4]

$$v = (2.5644T/P) + B_0$$

$$B_0 = \left(1.445 - \frac{1447}{2.5644T} - \frac{1.5 \times 10^6}{T^3}\right)$$

where

v is the specific volume of oxygen in cc. per gram,
P = pressure in normal atmospheres
T = 273.16 + t (°C.)

The total volume of oxygen was divided by the specific volume to obtain the weight of oxygen, from which the percentage by weight of hydrogen peroxide in the original solution was calculated.

The Titration with Potassium Permanganate

A survey of the literature was conducted to obtain the available information pertaining to all phases of the titration of hydrogen peroxide with permanganate. General agreement was found concerning procedures for the preparation and storage of the permanganate solution. The following procedure was actually used.

Permanganate of potassium of high purity was dissolved in hot distilled water which had been boiled for about fifteen minutes and the solution allowed to stand in a stoppered bottle for a week. The precipitated manganese dioxide was removed by filtering the solution through the sintered glass plate of a funnel. The solution was then stored in a pyrex bottle which had been covered with a coat of black paint. The bottle was fitted with a siphon having a stopcock in the line for convenient withdrawal of the solution. During withdrawal of the solution air entered the bottle through a fiber glass filter to remove air-borne dust.

If proper care is taken in its preparation and storage, a solution of potassium permanganate is quite stable. The results of several studies reported by Bruhns,[5] Halverson and Bergeim,[6] Kato[7] and others substantiated this fact, and show that no great deterioration occurs in as much as one to three years. However for very accurate work the solution should be standardized about once a month. The solution prepared for this investigation dropped in concentration about one part in a thousand in approximately six weeks.

The standardization of the permanganate solution can be carried out by using sodium oxalate, arsenious acid, iron, potassium dichromate and other primary standards. Of these, sodium oxalate is probably the most convenient and thus the most widely used. The confusion concerning the best procedure for carrying out the standardization with sodium oxalate was cleared up by the work of Fowler and Bright[8] at the National Bureau

(3) The reproducibility of the blank measurements was such that the maximum error in the corrected volume of oxygen was not greater than a part in 4000.

of Standards. Their investigation showed that McBride's procedure[9] gave results that are about 0.4% too high compared with the results obtained by using arsenious acid, pure iron, and potassium dichromate. Fowler and Bright worked out a procedure that gave results within 0.03%, or within the experimental error of the results obtained by the other methods. The recommended method using sodium oxalate was used in this investigation.

The oxalate used had a purity of about 99.98%. A precision of approximately one part in 3500 was realized in the standardization. The titer of the permanganate was 0.4899% by weight corresponding to a normality of about 0.16.

As stated above, considerable disagreement is expressed in the literature regarding the optimum conditions for carrying out the titration of an aqueous solution of hydrogen peroxide with potassium permanganate. The situation was also confused by the fact that in most cases no reasons for the given procedure were stated.

The various recommendations for the weight ratio of sulfuric acid to hydrogen peroxide ranged from 50/1 to 300/1. No specific recommendations were given as to the correct rate of addition of the permanganate to the peroxide solution. Kolthoff and Stenger[10] state that the results are influenced by this rate of addition, and while the error is almost negligible at slow rates, it is more serious at fast rates. L. J. Heidt[11] also reports the influence of rate of addition on the results.

The following procedure for the titration was used in this investigation: A 10-g. sample of 2–3% peroxide was weighed out in a glass-stoppered flask,[12] and rinsed with approximately 50 cc. of distilled water into a beaker containing 150 cc. of distilled water and 7 cc. of 95% sulfuric acid. The distilled water (conductivity water) had been boiled for fifteen minutes to destroy any organic matter, and then cooled to room temperature before use. The rate of addition of the permanganate solution was approximately 35–40 cc. per minute. The titration was carried out at room temperature and with moderate stirring.

The weight ratio of acid to peroxide in this procedure was about 65/1, which corresponds closely to that recommended in Scott's "Standard Methods of Analysis."[13] However the procedure described, while corresponding in some respects to that given by Scott and others, was used as a point of departure with the thought of introducing alterations as shown by experience to be necessary under comparison with the absolute method by oxygen measurement.

As an aid in achieving accuracy, a weight buret (capacity 500 cc.) instead of the usual volumetric type was used in both the standardization of the permanganate and in the titrations. The permanganate was standardized in terms of per cent. by weight of permanganate in the solution instead of normality. By touching the tip of the buret to the stirring rod, the end-point can be determined within about a third of a drop or about 0.017 g. If it is desired to obtain the end point closer than one-third of a drop, a correction for the amount of permanganate needed to color the solution can be estimated by determining what fraction of a drop of permanganate added to a volume of water equal to that of the solution produces a coloration of equal intensity to that at the end point of the titration. Approximately 100 cc. of 0.4899 weight per cent. permanganate were required in the procedure outlined.

The permanganate titration cannot be used if any organic matter is present in the peroxide solution. Some commercial peroxide contains small amounts of organic compounds added as stabilizers against decomposition. In this case the ceric sulfate titration has been recommended by various authors[2,14,15] since ceric sulfate will not react with organic matter.

Experimental Results

Using the procedures outlined above, runs were made to compare the permanganate titration with the gasometric method for analyzing hydrogen peroxide solutions. Seven runs were made using osmic acid as the decomposition catalyst, and three were made using lead oxide as the catalyst. Since varying amounts of two different catalysts left the same results unaltered, it was concluded that the catalyst is effective in causing complete decomposition into oxygen and water. The osmic oxide was used in basic solution and the lead oxide in a water suspension.

Table I shows the results of the runs made. The values reported for the gasometric method represent only one trial because the time required for carrying out the procedure was about five hours, and approximately four hours were required to prepare the apparatus for another run as the trap system had to be pumped free of moisture after each run. After this time had elapsed, the peroxide would have changed in concentration sufficiently (about one part in 500) to have made the data therefrom unreliable for comparison with the previous run. The values reported for the titration represent the average of three titrations, with the greatest deviation from the average about one part in 3000 to 4000.

(12) The inside of glass ware can be made anti-catalytic by treating with hot fuming sulfuric acid. If this procedure fails, the surface of the glass probably has catalytic dust particles fused into its surface. We have preferred to construct glass ware from tubing scrupulously cleaned with fuming sulfuric acid, rinsed with the purest distilled water and using air in the glass blowing filtered through fresh medical cotton.

TABLE I

Run no.[a]	Wt. % H_2O_2 by absolute method	Wt. % H_2O_2 by titration	Average	Deviation from average
1	2.3105	2.3032	2.3069	1:625
2	1.9628	1.9638	1.9633	1:4000
3	1.9196	1.9262	1.9228	1:625
4	1.9066	1.9091	1.9079	1:1450
5	1.8378	1.8380	1.8379	1:18,000
6	1.7652	1.8035	1.7844	1:95
7	2.8004	2.7992	2.7998	1:4700
8	2.8002	2.8029	2.8015	1:2200
9	2.8068	2.8076	2.8072	1:7000
10	2.8095	2.8102	2.8099	1:8000

[a] Osmic acid was used as the catalyst in runs 1–7; lead oxide was used as the catalyst in runs 8–10.

The results show a favorable comparison of the permanganate titration with the gasometric method. The average deviation from the average of the two methods is about one part in 5000. It is to be noted that the runs using the osmic acid catalyst and those using the lead oxide catalyst in varying amounts led to the same result. Therefore it is assumed the catalyst ran the reaction to completion.

Run 6 in which there was a part in 95 deviation from the average cannot be explained except by some undetected error in carrying out the procedure.

While it was not the purpose of this investigation to determine the effect of varying all conditions under which the titration may be performed, a few variations were made. The results of these tests indicate that variation in the titration procedure, as outlined above, had little effect on the results. Thus, doubling the acid concentration produced a difference of about one part in 10,000 which is within the experimental error. Tests made at rates of addition of 10 cc. per minute and at 50 cc. per minute differed by about the same amount, which may be taken to indicate that some flexibility can be tolerated in the titration procedure.

Conclusions

The experimental results show that, even where accurate results are required, the permanganate titration, using the procedure given above, can be used for determining the concentration of aqueous solutions of hydrogen peroxide. The procedure can be modified somewhat as indicated and still give sufficiently accurate results, but just how far modifications can be carried without causing decreased accuracy remains to be determined.

In applying the proposed procedure to more concentrated solutions, it is suggested that a sample containing an equivalent amount of hydrogen peroxide to that contained in 10 g. of 3% solution be used. For instance in analyzing a solution near 90%, 0.33 g. of the solution would contain approximately 0.3 g. of hydrogen peroxide, which in turn is approximately the amount contained in 10 g. of 3% solution. If the size of the sample is varied from that stated, precaution should be exercised that the weight ratio of sulfuric acid to hydrogen peroxide is at least 60–70 to 1. There is no reason to believe that higher ratios are harmful, but they are unnecessary. With lower ratios the chance of manganese dioxide formation increases, and for that reason should be avoided.

The rate of addition of the permanganate should be about 35–40 cc. per minute or slower. Excessively fast rates of addition increase the probability of the formation of manganese dioxide, which as previously stated is highly catalytic toward the decomposition of hydrogen peroxide. The titration should of course be carried out at room temperature, since higher temperatures cause loss by vaporization of the peroxide.

The results also indirectly substantiate the procedure recommended by Fowler and Bright[8] for standardization of potassium permanganate solutions. If the standardization procedure had given erroneous results, the good agreement of the titration values with those of the gasometric method would not have been possible.

The authors express their acknowledgment to the Naval Bureau of Ordnance for the support and release of this work.

Summary

An apparatus and procedure has been described for carrying out the "gasometric" method by decomposition for determining the concentration of aqueous solutions of hydrogen peroxide. The results obtained by this method were compared with those obtained by titration with potassium permanganate. On the basis of the good agreement between the two methods, a procedure for performing the titration was recommended. Also, the method recommended by Fowler and Bright[6] for the standardization of the potassium permanganate solution against sodium oxalate has been substantiated.

Metalation Studies in the Thiophene Series. II. Transmetalation of the Alkylthiophenes

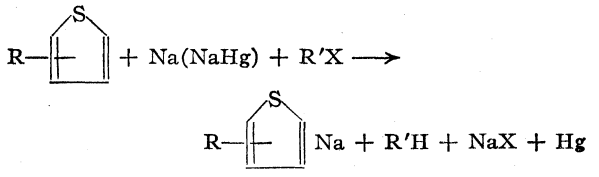
BY JOHN W. SCHICK AND HOWARD D. HARTOUGH

The authors previously reported the metalation of the thiophene and 2-halothiophenes to yield 2-thienylsodium and 5-halo-2-thienylsodium. Subsequent carbonation and acidulation yielded the 2-thiophenecarboxylic acid and 5-halo-2-thiophenecarboxylic acids,[1] respectively.

An extension of these studies to the alkylthiophenes, namely, 2-methyl-, 3-methyl-, 2-*t*-butyl-, 2-*t*-amyl-, 2-(1,1,3,3-tetramethylbutyl)- and 2-(1-phenylethyl)thiophene, has produced a convenient method for preparing alkyl-substituted 2-thiophenecarboxylic acids.

5-Methyl-2-thiophenecarboxylic acid was prepared in low yield by Gilman and Breuer[2] from 2-methylthiophene, dibenzylmercury and sodium. Hartough and Conley[3] have prepared the substituted acids by the sodium hypochlorite oxidation of the acetylalkylthiophenes.

It was found that the alkylthiophenes do not metalate directly with sodium. Metalation, however, was accomplished via the transmetalation reaction by interaction of an alkylthiophene, metallic sodium, and an alkyl or aryl halide in a neutral solvent.



Substitution of a 70–90% sodium amalgam for metallic sodium gave increased yields in some cases.

Table I records the substituted alkyl-2-thiophenecarboxylic acids that were prepared by the described general procedure.

Experimental

General Procedure.—A cold mixture of 16 g. (0.25 mole) of ethyl chloride, in 200 ml. of anhydrous ether, was cooled dropwise over a one hour period to a stirred, externally cooled mixture of 12 g. (0.5 gram atom) of freshly prepared sodium sand, 49 g. (0.5 mole) of 2-methylthiophene and 100 ml. of anhydrous ether. The reaction was carried out under nitrogen. After the addition of the ethyl chloride was completed, the reaction mixture was stirred for an additional two hours at room temperature. Carbonation of the organo-metallic compound was accomplished with pieces of Dry Ice. The temperature was kept below 30° with ice. Two hundred milliliters of distilled water was added cautiously to destroy the small amount of unreacted sodium. The aqueous layer was separated and acidified with 70 ml. of hydrochloric acid. The crystalline product was filtered and recrystallized.

Bromobenzene and *n*-butyl bromide were also substituted for ethyl chloride with good results.

TABLE I

ALKYL-2-THIOPHENECARBOXYLIC ACIDS FROM THE CORRESPONDING ALKYLTHIOPHENES

Alkyl-2-thiophenecarboxylic acid	Yield, %	Recrystallized from	Melting point, °C.	Neutral equivalent Calcd.	Obs.

[a] Ref. 3, m. p. 137–138°. [b] Ref. 3, m. p. 120–121°. [c] 3-Methylthiophene metalated exclusively in the 5-position. No trace of the normal substitution product, 3-methyl-2-thiophenecarboxylic acid, could be detected.

Acknowledgment.—The authors wish to express their appreciation to Dr. D. E. Badertscher for his advice and interest and to Mrs. Josephine Sindoni Piel who carried out some of the experiments.

Summary

The alkylthiophenes, namely, 2-methyl-, 3-methyl-, 2-*t*-butyl-, 2-*t*-amyl-, 2-(1,1,3,3-tetramethylbutyl)-, and 2-(1-phenylethyl)-thiophene were metalated with metallic sodium or sodium amalgam to yield the corresponding 2-thiophenecarboxylic acid upon carbonation and acidulation.

Metalation Studies in the Thiophene Series. III. Condensation of Thienyl- and Substituted Thienyl-sodium Compounds with Ethylene Oxide

BY JOHN W. SCHICK AND HOWARD D. HARTOUGH

The preparation of the carboxylic acids of thiophene,[1] halothiophenes[1] and the alkylthiophenes[2] has been previously described. Although organometallic compounds are reported to react similarly to Grignard reagents, the only literature references that can be found deal with their reactions with carbon dioxide and formaldehyde or its polymers. Amylsodium, phenylsodium and benzylsodium have been condensed only with trioxymethylene[3] to yield hexyl alcohol (28%), benzyl alcohol (17%) and phenylethyl alcohol (17%), respectively.

The study of the reaction of ethylene oxide with thienyl-, halothienyl- and alkylthienylsodium compounds was undertaken in order to obtain the corresponding ethanols and vinyl compounds. Previously, the simple alcohols such as 2-thienylcarbinol[4] and 2-(2-thienyl)-ethanol[5] were prepared from 2-thienylmagnesium bromide or iodide and monomeric formaldehyde and ethylene oxide, respectively.

2-Thienylsodium and substituted 2-thienylsodiums, namely, 4-methyl-, 5-methyl-, 5-*t*-butyl- and 5-chlorothienylsodium, were condensed with ethylene oxide to yield the corresponding thienylethanols. Dehydration of the thienylethanols by conventional means yielded vinyl and substituted vinyl-thiophenes which may be useful in the plastics and rubber industries. Table I records several vinylthiophenes thus obtained with their observed properties. The vinylthiophenes polymerized at room temperature, and more rapidly at elevated temperatures in the presence of a catalyst, benzoyl peroxide, to yield very pale yellow to orange colored, clear polymers.

Experimental

2-(2-Thienyl)-ethanol.—A mixture of 118 g. (1.0 mole) of 2-chlorothiophene in 500 ml. of benzene was added to a freshly prepared sodium amalgam sand[1] containing 50 g. (2.17 gram atoms) of sodium and 20 g. (0.10 gram atom) of mercury and the reaction mixture was stirred and refluxed for three hours in a nitrogen atmosphere. The mixture was cooled to 0–10° in an ice-bath and 44 g. (1.0 mole) of ethylene oxide in 100 ml. of benzene was added over a twenty-minute period. The temperature rose rapidly to about 50° and then slowly fell. The ice-bath was removed and the stirring was continued until the temperature dropped to 25°. A solution containing 125 ml. of concentrated hydrochloric acid in 325 ml. of distilled water was cautiously added with stirring and the whole solution was filtered to remove salt and sludge. The benzene layer was separated, dried over anhydrous sodium sulfate and the benzene removed by distillation. The residue was distilled under reduced pressure. Sixty grams (47%) of 2-(2-thienyl)-ethanol, a white oily fluid having the odor of roses, was obtained; b. p. 99–100° (7 mm.); $n^{20}D$ 1.5478.

The phenylurethan was recrystallized from petroleum ether, m. p. 52–53°.

Anal. Calcd. for $C_{13}H_{13}O_2NS$: S, 12.96; N, 5.67. Found: S, 12.95; N, 5.79.

2-(5-Chloro-2-thienyl)-ethanol.—One mole (118 g.) of 2-chlorothiophene was converted to the corresponding 5-chloro-2-thienylsodium by a method described earlier.[1] To the ice-cooled reaction mixture was added 66 g. (1.5 moles) of ethylene oxide in 200 ml. of ether over a period of one hour. The mixture was then stirred at room temperature for thirty minutes and then warmed to reflux for two hours. Unreacted sodium was decomposed with 150 ml. of alcohol and a solution of 170 ml. of concd. hydrochloric acid in 500 ml. of water added cautiously over a period of thirty minutes. The resultant emulsion was broken with sodium chloride. The ether layer was separated, dried and the ether distilled. Thirty-five grams (22%) of 2-(5-chloro-2-thienyl)-ethanol, a white, oily fluid having the odor of roses was obtained; b. p. 98.5–100° (1–2 mm.); $n^{20}D$ 1.5576. The phenylurethan derivative was recrystallized from petroleum ether, m. p. 57–58°.

Anal. Calcd. for $C_{13}H_{12}ClNO_2S$: N, 4.97. Found: N, 4.81.

2-(4-Methyl-2-thienyl)-ethanol.—A cold mixture of 64 g. (1.0 mole) of ethyl chloride in 300 ml. of diethyl ether was added dropwise over one hour (in a nitrogen atmosphere) to a stirred mixture of sodium amalgam sand containing 46 g. (2.0 gram atoms) of sodium and 12 g. (0.06 gram atom) of mercury and 147 g. (1.5 mole) of 3-methylthiophene in 200 ml. of diethyl ether which was cooled to 0–5°. After the addition was completed, the ice-bath was removed and the temperature kept below the reflux temperature of ether for one hour, after which it was warmed to the reflux temperature for fifteen minutes. The reaction was cooled below 10° and a cold solution of 44 g. (1.0 mole) of ethylene oxide in 100 ml. of ether was added with stirring over a period of one hour. The temperature was permitted to rise to room temperature. The reaction mixture was worked up as described in the preparation of 2-(5-chloro-2-thienyl)-ethanol. Seventy-one grams (51%) of 2-(4-methyl-2-thienyl)-ethanol was obtained; b. p. 87–89° (2 mm.); $n^{20}D$ 1.5397. The phenylurethan derivative was recrystallized from petroleum ether, m. p. 68–69°.

TABLE I

VINYLTHIOPHENES

	B. p., °C.	Mm. Hg pressure	$n^{20}D$	Yield, %	Formula	Sulfur, % Calcd.	Sulfur, % Found
2-Vinylthiophene	65.5–66.5	48	1.5720	80	C_6H_6S	29.1	28.9
4-Methyl-2-vinylthiophene	86.5–87.5	45	1.5590[a]	95	C_7H_8S	25.8	25.7

Anal. Calcd. for $C_{14}H_{15}O_2NS$: S, 12.26; N, 5.35. Found: S, 12.15; N, 5.43.

2-(5-*t*-Butyl-2-thienyl)-ethanol.—To two moles of sodium amalgam sand was added 32 g. (0.5 mole) of ethyl chloride and 70 g. (0.5 mole) of 2-*t*-butylthiophene in 200 ml. of ether in a similar manner to that described directly above. After cooling below 10°, 22 g. (0.5 mole) of ethylene oxide in 100 ml. of ether was added during a one-hour period. The temperature rose rapidly but was controlled at about 30° by means of an ice-bath. After this addition the mixture was stirred for ninety minutes at ambient temperatures and then treated as described in the preparation of 2-(5-chloro-2-thienyl)-ethanol. Sixty-three grams (68%) of 2-(5-*t*-butyl-2-thienyl)-ethanol, a white, viscous fluid, was obtained; b. p. 115–116° at 3 mm.; $n^{20}D$ 1.5198. The phenylurethan derivative was recrystallized from petroleum ether, m. p. 73–74°.

Anal. Calcd. for $C_{17}H_{21}O_2NS$: S, 10.56; N, 4.62. Found: S, 10.71; N, 4.71.

General Procedure for Preparing the Vinylthiophenes.—The thienylethanol was dehydrated to the corresponding vinylthiophene by heating the ethanol with a large excess (1:4) of molten potassium hydroxide at a reduced pressure (45–50 mm.). The vinylthiophene distilled along with water and the distillate was extracted with ether. After drying the ether solution with anhydrous sodium sulfate, the ether was removed on a steam-bath and the residue was distilled under reduced pressure.

The 2-(5-chloro-2-thienyl)-ethanol did not dehydrate well by this method and the low yield of a vinyl compound did not contain the theoretical amount of chlorine.

Acknowledgment.—The authors wish to thank Dr. D. E. Badertscher for his advice and interest, and Mrs. Josephine Sindoni Piel, who carried out some of the experiments.

Summary

2-(2-Thienyl)-, 2-(5-*t*-butyl-2-thienyl)-, 2-(4-methyl-2-thienyl)- and 2-(5-chloro-2-thienyl)-ethanol have been prepared from the corresponding thienylsodium compound and ethylene oxide in yields of 47, 68, 51 and 22%, respectively.

Dehydration of several of the thienylethanols, namely, 2-(2-thienyl)-, 2-(4-methyl-2-thienyl)- and 2-(5-*t*-butyl-2-thienyl)-ethanol with molten potassium hydroxide at reduced pressure yielded the corresponding vinylthiophenes in yields of 80, 95 and 94%.

Acylation of Benzene Compounds with Iodine as a Catalyst

BY SAUL CHODROFF AND HOWARD C. KLEIN

Iodine has been used successfully as a catalyst in acylations of furan and thiophene.[1] It was of interest to extend this reaction to benzenoid compounds. Acylations were successful with the more active members of the benzene series, such as anisole[2] and acetanilide, whereas the alkylated benzenes, toluene and cumene, failed to react. As previously noted,[1] the aroyl halides gave higher yields than aliphatic anhydrides. Dibasic aliphatic anhydrides, such as succinic anhydride, failed to react with anisole. As might be expected from the reduced aromaticity of the benzenoid compounds compared to furan and thiophene, the reactions were not exothermic, required longer periods of time and higher temperatures, and generally required higher catalyst concentrations for optimum yields, the range of $2\text{–}7 \times 10^{-2}$ mole of iodine per mole of reactant being quite effective.

The influence of catalyst concentration on yield in the reaction between naphthalene and benzoyl chloride was marked; the yield of ketone rose from 15 to 52% as the molar ratio of iodine to reactants was increased from 2.1×10^{-2} to 7.6×10^{-2}. The reaction favors the formation of the α-isomer predominantly, for, the ratio of the α to β isomers in the mixture of the crude benzoylnaphthalenes was 95 to 5, as determined by the precipitation of the picrate of the β isomer from a benzene solution,[3] after standing for two weeks at 5°.

Acknowledgment.—The authors are grateful to Dr. Roland Kapp of this Laboratory for encouragement and interest in the promotion of this work.

Experimental

***p*-Acetylanisole.**—Two hundred and fourteen grams (2.0 moles) of anisole and 102 g. (1.0 mole) of acetic anhydride were refluxed for two hours in the presence of 2 g. of iodine. After cooling, the dark brown solution was taken up in 300 ml. of ethylene dichloride and washed successively with dilute potassium carbonate, sodium bisulfite, and water. Drying over sodium sulfate, removal of the solvent, and distillation of the residue gave 98.6 g. (66%) of *p*-acetylanisole, b. p. 120–125° (5 mm.), as a colorless oil. Crystallization from aqueous methanol yielded crystals, m. p. 38°. The product formed a semicarbazone, m. p. 198–198.5°.[4]

***p*-Benzoylanisole.**—To a mixture of 37.8 g. (0.35 mole) of anisole and 22.4 g. (0.18 mole) of benzoyl chloride, was added 1 g. of iodine. The solution was refluxed gently for eight hours, until the evolution of hydrogen chloride had subsided. After cooling, the solution was diluted with 100 ml. of benzene, washed with potassium carbonate, sodium bisulfite, and water. The dried solvent was removed on the steam-bath and the residue distilled, yielding 33.8 g. (88.6%) of *p*-benzoylanisole, b. p. 175–179° (1 mm.), as a yellow liquid which solidified,

(1) Hartough and Kosak, THIS JOURNAL, **68**, 2639 (1946).

(2) NOTE ADDED IN PROOF.—After this manuscript had been submitted, Kosak and Hartough, *ibid.*, **69**, 3144 (1947), reported the acetylation of ansole in 45% yield, using phosphoric acid as a catalyst. They also indicated that iodine and other acid catalysts may be employed in this reaction without reporting the yield.

(3) Rousset, *Bull. soc. chim. France*, [3] **15**, 71 (1896).

(4) Wahl and Silberzweig, *Bull. soc. chim.*, [4] **11**, 69 (1912), list m. p. of 197°.

m. p. 53–55°. Crystallization from 90% methanol raised the m. p. to 61–62.5°. A 2,4-dinitrophenylhydrazone was obtained, m. p. 180°.[5]

p-**Acetylaniline.**—Fifty-four grams (0.4 mole) of acetanilide and 50 ml. of acetic anhydride were refluxed with 4 g. of iodine, distilling the acetic acid formed through a 38-cm. Vigreux column. In fifteen minutes, 30 ml. of distillate was collected, b. p. 110–120°. An additional 25 ml. of acetic anhydride was added to the reaction mixture and 25 ml. of distillate collected, the final vapor temperature rising to 132°. The reaction mass was poured into 250 ml. of water, the oil extracted twice with 75-ml. portions of ethylene dichloride and the excess iodine washed out with bisulfite. Removal of the solvent left a tarry residue which was hydrolyzed by refluxing for one hour with 50 ml. of concentrated hydrochloric acid. After being made strongly alkaline, the unreacted aniline was steam distilled and the residual black tar extracted twice with 75-ml. portions of ethylene dichloride, washed until neutral and dried over sodium sulfate. The solvent was removed and the residue distilled, yielding 10.5 g. (19.4%) of a golden yellow oil, b. p. 165–168° (6 mm.), which solidified, m. p. 67–68°. Crystallization from hot water gave white crystalline *p*-acetylaniline, m. p. 105–106°; acetyl derivative, m. p. 165–166°.[6]

Refluxing the reactants for two hours without removal of the acetic acid formed reduced the yield of *p*-acetylaniline to 7%.

α-**Phenyl Naphthyl Ketone.**—Twenty-five and six-tenths g. (0.2 mole) of naphthalene was refluxed gently with 28 g. (0.2 mole) of benzoyl chloride in the presence of 4 g. of iodine. A vigorous evolution of hydrogen chloride began immediately and ceased within two hours. The reaction mass was taken up in 150 ml. of ethylene dichloride, washed with dilute sodium hydroxide and bisulfite and the solvent and unreacted naphthalene removed by steam distillation. The black, tarry mass was extracted with benzene, washed with water and dried over sodium sulfate. The solvent was removed and the residue distilled, yielding 23.9 g. (51.7%) of a golden yellow, viscous liquid, b. p. 165–169° (1 mm.) which slowly solidified, m. p. 73–74°. The product was crystallized from ethanol, m. p. 74–75°, and gave an oxime, m. p. 161°.[7] One gram of the crude ketone dissolved in 20 ml. of benzene containing 1 g. of picric acid deposited, after fourteen days at 5°, 100 mg. of the picrate of the *β*-isomer, m. p. 112–113°, equivalent to 5% of *β*-benzoylnaphthalene.[3]

Summary

Acylations have been carried out successfully on the more active members of the benzene series, using iodine as a catalyst.

The Volatility and Vapor Pressure of Ten Substituted 2-Chloroethylamines[1]

BY C. ERNST REDEMANN,[2] SAUL W. CHAIKIN AND RALPH B. FEARING[3]

In a study of the toxicity and vesicancy of the so-called nitrogen mustards it soon became apparent that neither the necessary volatility nor vapor pressure data for assessing these agents were available. The first member of this group of 2-chloroethylamines to be prepared, and its potent vesicant action described, was tris-(2-chloroethyl)-amine.[4] However, no vapor pressure data were given nor were any subsequently reported. It was, therefore, necessary to measure the volatility before any quantitative evaluation of these compounds could be made. In the course of this study the volatility and vapor pressure were determined for ten substituted 2-chloroethylamines at temperatures between 0 and 60°. Their numerical values are reported here.

The method employed for measuring the volatility and the equations by which the vapor pressure was calculated from the volatility have been described in two earlier reports.[5] The equations derived for these compounds should not be used at temperatures much outside the specified range without recognizing that the values so computed may have errors considerably larger than the probable error over the 0 to 60° interval.

Experimental

The details of the measurements and the apparatus have been given in earlier reports.[5]

All the compounds employed in this study were prepared in laboratories other than that of the authors. The source of each compound is given in Table I. All but one of the 2-chloroethylamines were received as the hydrochlorides, well crystallized compounds of definite, reproducible melting point, which could be readily purified by crystallization from suitable solvents. These hydrochlorides were usually received in an analytically pure form and were stored in a cool, dry place until they were used. Each hydrochloride was converted into the free base by treatment with a cold 50% aqueous solution of potassium hydroxide. Where practical the base was separated from the aqueous solution without use of any solvent; when the amine phase would not separate cleanly from the aqueous phase the former was diluted with ethyl ether before separation. The amines were dried over anhydrous potassium carbonate before distillation. The dry amine was distilled under reduced pressure, the pressure being so chosen that the amine boiled below 100° in all but two cases (see Table I). For eight of the ten amines the boiling point was constant; for *t*-butyl-bis-(2-chloroethyl)-amine a one degree boiling range was tolerated, and for 4-(2-chloroethyl)-morpholine the sample submitted was too small to purify before use and was therefore run as received.

Since these amines slowly give self-condensation products, especially when not completely dry, they were placed in the vaporizer immediately after distillation and

were run as promptly as feasible. When there was evidence of self-condensation having occurred during a determination, as shown by the separation of a solid quaternary ammonium salt (see Discussion), the vaporizer unit was cleaned and filled with freshly distilled amine before continuing the measurements.

Dry nitrogen was used as the entrainment gas to avoid possible oxidation of the compounds. The values for the boiling point, refractive index and density of the samples of the compounds studied are given in Table I.

Discussion

This series of compounds presented certain difficulties which were not encountered in our previous studies.[5b,6] The chlorine atom in the β-position to the amino group, while not highly reactive, still shows sufficient activity to react slowly at room temperature with the amino group in an adjacent molecule. Since the amines studied in this series are all tertiary amines, reaction with the β-halogen of an adjacent molecule leads to the production of a quaternary ammonium compound. In these cases the quaternary ammonium chlorides are very sparingly soluble and were observed to crystallize from the reaction mixture. The insolubility of the salts was helpful for two reasons, first, it served as an index of the amount of polymerization which had taken place and, second, the solubility proved to be so low that it did not alter the vapor pressure measurably, as shown by the fact that volatilities measured for samples free from polymer agreed within experimental error with volatilities measured upon samples with some crystalline polymer. Nevertheless, a vigorous effort was made to make measurements only upon samples free from any solid polymer.

It was also observed that much longer time of contact was necessary in order to produce equilibrium between the liquid and its vapor with this group of compounds than was found for any other group of compounds studied. Consequently, for most of these runs the rate of flow of the nitrogen through the saturator was reduced 50 to 75% over the values used for other compounds of similar boiling point.

In Table I are recorded, in addition to the previously mentioned properties, the three constants A, A', and B for the equations

$$\log p = A - B/T \quad (1)$$

$$\log WT = A' - B/T \quad (2)$$

computed by the method of least squares from the experimental points and also the percentage deviation from the smoothed curve of the points calculated from the least squares equation. The constants apply when the pressure, p, is expressed in millimeters of mercury, the temperature, T, is the centigrade temperature plus 273.2 and the volatility, W, is expressed in milligrams of agent per liter of air (or nitrogen). An average value for the molar heat of evaporation, L_{ev}, in calories per mole over the temperature range 0 to 60° is also given for each compound. These values were calculated from equation (1).

The mean percentage deviation of the *experimental* points from the smoothed curve is under 2% for all compounds except cyclohexyl-*bis*-(2-chloroethyl)-amine which has a mean deviation of 5.4%. This arises from the very small volatility of this compound, since the amine collected for weighing was only about 5 mg. at the lowest temperature.

Acknowledgment.—Thanks are due to Miss Dora Benedict for her helpful work in making some of these measurements.

(6) Redemann, Chaikin, Fearing and Benedict, THIS JOURNAL, 70, 637 (1948).

Summary

1. The volatility of ten substituted 2-chloroethylamines has been measured between 0 and 60° by an air saturation method.

2. From the measured volatilities vapor pressures have been calculated. Logarithmic equations have been developed for both the vapor pressure and the volatility as a function of the temperature.

3. The mean molar latent heat of evaporation over the temperature range 0 to 60° has been computed from the vapor pressure equation for each compound.

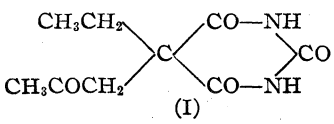
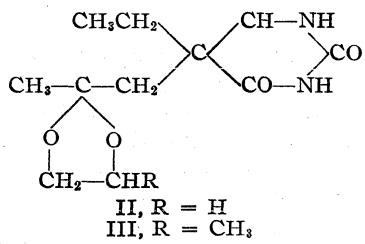
Cyclic Acetals Related to Ethylacetonylbarbituric Acid

BY CHARLES D. HURD AND MARGARET L. MCAULEY

This investigation deals with the synthesis and reactions of certain new derivatives of ethylacetonylbarbituric acid (I). This acid was synthesized from sodium ethylbarbiturate and chloroacetone, instead of the previously used[1] bromoacetone. To use chloroacetone, it was found that sodium iodide was an effective catalyst.[2] Yields of 75% of I were obtained with this catalyst as contrasted with 10–32% yields without it. Butylacetonylbarbituric acid was similarly prepared and with the same high yield. In view of this, it is of interest to note that no significant reaction product could be obtained when solutions of sodium ethylbarbiturate, 2-chloromethyl-2-methyldioxolane (made from chloroacetone and ethylene glycol), and sodium iodide were mixed and treated similarly. Ethyl *sodio*-butylmalonate also failed to give a reaction product with 2-chloromethyl-2-methyldioxolane at refluxing temperature in alcohol solution.



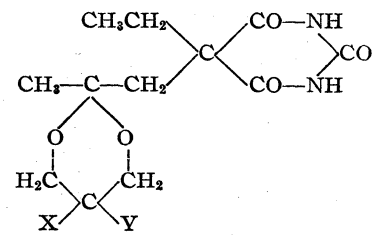
(I)



II, R = H
III, R = CH_3

Dioxolanes of the structure II or III were synthesized by reaction of ethylacetonylbarbituric acid with ethylene glycol or propylene glycol in the presence of *p*-toluenesulfonic acid. The water formed in the reaction was removed as formed by slowly distilling benzene or toluene from the reaction mixture. The compounds formed were high melting, crystalline solids.

1,3-Dioxanes represented by formula IV, V were synthesized similarly from I by reaction with trimethylene glycol or tris-(hydroxymethyl)-nitromethane. These compounds all melt above 200°. Conditions were not found for satisfactory interaction of (I) and 2-nitro-2-methyl-1,3-propanediol.



IV (X = Y = H)
V (X = NO_2, Y = CH_2OH)
VI (X = NH_2, Y = CH_2OH)
VII (X = NHAc, Y = CH_2OH)

The nitro group in 5-ethyl-5-(1-methyl-4-nitro-4 - hydroxymethyl - 2,6 - dioxacyclohexyl)-methylbarbituric acid (V) was readily reduced at 100° to an amino group under a hydrogen pressure of 1600 lb./sq. in., using Raney nickel catalyst The amine (VI) is moderately soluble in water. In accordance with its dipolar ion character, it is insoluble in non-polar solvents. Conditions were not found for the acetylation of this amine by acetic anhydride, but acetylation to VII was achieved readily by the use of ketene.

We are indebted to Edgar B. Carter, Lucy Johnson and G. M. Everett of Abbott Laboratories for pharmacological tests made on the above compounds. These compounds were tested: II, III, IV, butylacetonylbarbituric acid (VIII), and acetonylbarbituric acid (IX). The compounds were non-toxic toward mice by intravenous injection in doses of 50 to 200 mg./kg., but such doses produced no hypnotic effect. To test anticonvulsant activity, mice were given 400 mg./kg. orally and after various periods of time were tested with 100 mg./kg. of metrazol with results shown in Table I.

It is seen that all except IX show some anticonvulsant action. Compound III was tested further with oral doses of 500 mg./kg. After periods of 10, 30, 60, 120 minutes, 100 mg./kg. of metrazol was given. All mice showed jerks and approximately half showed convulsions after all

IX	Conv. F	Jerks, conv. F	Jerks, conv. F

time intervals. The protection against the minimum convulsant dose (75 mg./kg. of metrazol) was also unsatisfactory. All test animals had jerks and three out of six had convulsions.

Experimental

Ethylacetonylbarbituric Acid.—For this synthesis, ethylbarbituric acid of m. p. 193–194° was prepared in accordance with the method of Fischer and Dilthey[3] except for the modification of not separating the sodium ethylbarbiturate. Instead, water was added to dissolve it, then the free acid was precipitated by adding concentrated hydrochloric acid and chilling. The yield was 83%, in contrast to the reported yield of 45%.

A solution of 72.2 g. of ethylbarbituric acid, 40 ml. of alcohol and 900 ml. of 0.5 *N* sodium hydroxide was adjusted to neutrality to litmus. It was stirred vigorously while a mixture of 91 ml. of chloroacetone, 10 g. of sodium iodide and 300 ml. of alcohol was added rapidly. After a half hour of refluxing, the solvents were removed at 40 mm. pressure, thereby causing separation of a solid which was collected, washed with a little water, and dried; yield, 81.6 g., or 74.6%. The m. p. was 237–238°, agreeing with 238–239° listed in the literature.[1]

When 2.5 g. of sodium iodide was used instead of 10 g. the yield was about the same, but when longer or shorter reaction times were taken, the yield dropped. The yield was about 50% with either ten minutes or one hour of refluxing, and the yield dropped to 39% with two hours of refluxing.

If no sodium iodide was present, the yield changed progressively from 10 to 32% with a refluxing change from thirty minutes to two hours. The yield was no better using the method of Dox and Houston.[1b]

Butylacetonylbarbituric Acid.—Substitution of butylbarbituric acid for ethylbarbituric acid in the above preferred procedure (use of sodium iodide and thirty minutes of refluxing) gave rise to a 75% yield of butylacetonylbarbituric acid. Kirsanov and Ivashchenko[1] used bromoacetone (no sodium iodide) and reported yields of 50–70%.

Ethyl Acetonylmalonate.—This compound has been made previously from bromoacetone.[4] The present synthesis uses chloroacetone.

To a suspension of 15 g. of finely divided sodium in 500 ml. of dry ether was added 33 ml. of absolute alcohol. After twelve hours, when hydrogen was no longer evolved, 99 ml. of ethyl malonate was added, followed by slow addition of a solution of 52 ml. of chloroacetone in 90 ml. of dry ether. Three hours later the mixture was filtered and the filtrate distilled, thereby recovering 59 g. of ethyl malonate and obtaining 32.5 g. of ethyl acetonylmalonate, b. p. 110–111° (2 to 4 mm.). This is a 61% yield, based on unrecovered malonic ester.

Black tarry materials resulted from the interaction of ethyl acetonylmalonate with ethyl iodide in the presence either of anhydrous potassium carbonate, or dimethylaniline, or sodium ethoxide solutions at refluxing temperatures. About half of the ethyl acetonylmalonate was recovered. Likewise, no ethyl butylacetonylmalonate was obtained starting with ethyl butylmalonate, chloroacetone, and refluxing sodium ethoxide solution.

Reaction of Ethylacetonylbarbituric Acid (I) with Glycols.—This general procedure was followed. Five to fifteen grams of (I) was taken for each run. For each mole of (I) there was added 1.3 moles of the glycol and 0.1 g. of *p*-toluenesulfonic acid. Then 120–250 ml. of benzene or toluene was added. The apparatus was set for distillation with an automatic separator for the hydrocarbon and water in the distillate, the hydrocarbon layer being continuously returned to the flask. Reaction proceeded for about fifty hours. The products were then separated and purified by crystallization. Usually a little of the (I) was recovered. Yields were in the range of 61–69%, based on unrecovered (I). 2-Nitro-2-methyl-1,3-propanediol was the only glycol tested which failed to react, and 83% of I was recovered.

5-Ethyl-5-(1-methyl-2,5-dioxacyclopentyl)-methylbarbituric acid (II), 5-ethyl-5-(1,3-dimethyl-2,5-dioxacyclopentyl)-methylbarbituric acid (III), and 5-ethyl-5-(1-methyl-2,6-dioxacyclohexyl)-methylbarbituric acid (IV) were made, respectively, using ethylene glycol, propylene glycol, and trimethylene glycol. These compounds were purified by crystallization from benzene, then from water. Analytical data and properties are listed in Table II. Analyses were by the micro Dumas method, by T. S. Ma.

TABLE II

Compound	M. p., °C.	Formula	Nitrogen, % Calcd.	Found
II	216–217	$C_{11}H_{16}N_2O_5$	10.94	10.37
III	202–204	$C_{12}H_{18}N_2O_5$	10.37	10.27
IV	264–265	$C_{12}H_{18}N_2O_5$	10.37	10.24
V	239–240, dec.	$C_{13}H_{19}N_3O_8$	12.17	12.23
VI	236–237, dec.	$C_{13}H_{21}N_3O_6$	13.33	12.78
VII	231–232, dec.	$C_{15}H_{23}N_3O_7$	11.80	11.25

That compounds II and I form a eutectic, m. p. 191–192°, may be demonstrated simply by crystallization of a mixture of equal amounts of the pure ingredients from water.

Tris-(hydroxymethyl)-nitromethane was the glycol used in the synthesis of 5-ethyl-5-(1-methyl-4-nitro-4-hydroxymethyl-2,6-dioxacyclohexyl)-methylbarbituric acid (V). The crude reaction product was washed thoroughly with water and then crystallized from water. A mixture of I (m. p. 237–238°) and V melts at 213–216°. Since I melts without decomposition whereas V blackens and evolves gas on fusion, it is easy to distinguish one from the other in spite of the close melting points. The solubility in water is another difference, since 0.2 g. of I or V require 5.5 and 14.6 cc., respectively, of boiling water for solution.

5-Ethyl-5-(1-methyl-4-amino-4-hydroxymethyl-2,6-dioxacyclohexyl)-methylbarbituric Acid (VI), by Reduction of V.—Two catalytic reductions of V (3.5, 6.4 g.) in purified dioxane (20 ml.) at 1600 lb./sq. in. of hydrogen pressure with Raney nickel catalyst (0.2, 1.0 g.) at 100–125° gave rise to 55–58% of amine (VI). Thirty minutes was required for the calculated drop in pressure. The product was crystallized from dioxane or from equal parts of dioxane and ethyl acetate. To dissolve 0.2 g. of VI in boiling water, 14.6 ml. is required, thus showing the same solubility as V.

Reaction with Ketene.—A stream of ketene was bubbled at the rate of 0.47 mole per hour for five minutes into a warm solution of 1.4 g. of VI in 100 ml. of water. On cooling, 0.64 g. of 5-ethyl-5-(1-methyl-4-acetamido-4-hydroxymethyl-2,6-dioxacyclohexyl)-methylbarbituric acid (VII) separated. From the filtrate, 0.56 g. of VI was recovered. The amide was crystallized from water. This material depressed the m. p. of I and VI. It dissolved readily in dilute sodium hydroxide. Hydrolysis by boiling dilute hydrochloric acid (ten minutes) gives rise to I, m. p. and mixed m. p. 239–240°.

(3) Fischer and Dilthey, *Ann.*, **355**, 334 (1908).

(4) Gault and Salomon, *Compt. rend.*, **174**, 754 (1922); *Ann. chim.*, **2**, 133 (1924).

No evidence for the acetylation of VI was obtainable, using acetic anhydride in pyridine or in glacial acetic acid. Also V was unacetylated by treatment with acetic anhydride and sodium acetate at 100°.

Summary

Ethylacetonylbarbituric acid may be made in good yields from sodium ethylbarbiturate and chloroacetone in the presence of a little sodium iodide. Several cyclic acetals were prepared by reaction of ethylacetonylbarbituric acid with glycols, including a nitro glycol. The nitro acetal was hydrogenated to an amino acetal, and the latter was acetylated with ketene to an acetamido acetal. Pharmacological toxicity data and anticonvulsant tests are included.

EVANSTON, ILLINOIS RECEIVED DECEMBER 8, 1947

NOTES

Amide Vinylogs

BY ROBERT H. BAKER AND ARTHUR H. SCHLESINGER[1]

In a survey of the behavior of ethoxymethylenediketones and esters as alkylating agents toward amines, amides, the Grignard reagent and in Friedel–Crafts and other type reactions some new compounds have been encountered and are described below.[2]

Ethoxymethyleneacetoacetic ester reacts readily with aminoacetic ester and with progressive difficulty with *p*-aminobenzoic ester and urethan to produce open chain amide vinylogs which are cleaved by hydrogen (PtO_2, 2 atm., 25°) as are derivatives of typical amines.[3] Thiourea reacts to form the mercaptopyrimidine similar to the cyclization product of the urea derivatives.[3]

Experimental[4]

Ethyl α-(N-Carbethoxyaminomethylene)-acetoacetate.—Equimolar quantities of ethyl ethoxymethyleneacetoacetate and ethyl carbamate were heated at 143–165° for 1.7 hours and then cooled at 0° for three hours to induce crystallization. Three crystallizations from cyclohexane, employing activated alumina as decolorizing agent, produced yellow needles, m. p. 40.5–41.0°; 13% yield.

Anal. Calcd. for $C_{10}H_{15}NO_5$: C, 52.3; H, 6.55; N, 6.11. Found: C, 52.4; H, 6.90; N, 6.10.

Ethyl α-(*p*-Carbethoxyanilinomethylene)-acetoacetate.—This was produced similar to the above from ethyl *p*-aminobenzoate at 110–135° for one hour. It was decolorized in hot ethanol solution by alumina. Five crystallizations from ethanol, then from cyclohexane and finally ethanol gave colorless crystals, m. p. 105°, 70% yield.

Anal. Calcd. for $C_{16}H_{19}NO_5$: C, 63.0; H, 6.26; N, 4.60. Found: C, 63.2; H, 6.50; N, 4.50.

Ethyl α-(N-Carbethoxymethylaminomethylene)-acetoacetate.—Slow addition of freshly distilled glycine ethyl ester to an equivalent of the ethoxymethylene compound at 0° produced a vigorous reaction, and the contents of the reaction flask were solid within thirty minutes. Two crystallizations from 70% ethanol gave matted colorless needles, m. p. 71.0–71.5°; 66% yield.

Anal. Calcd. for $C_{11}H_{17}NO_5$: C, 54.4; H, 7.00; N, 5.76. Found: C, 55.2; H, 7.15; N, 5.58.

Ethyl 2-Mercapto-4-methylpyrimidine-5-carboxylate.—Thiourea and an equivalent of the ester vinylog were heated at 150° for thirty minutes. The mixture frothed vigorously and a hard, red solid was obtained which was purified by digestion on the steam-bath with ethanol. The liquors upon chilling gave a red powder which was treated three more times in a similar manner. The red product, 52% yield, failed to melt but sintered at 160° and decomposed. Sublimation *in vacuo* failed to improve its appearance. It is soluble in 10% sodium hydroxide solution and decolorizes iodine.

Anal. Calcd. for $C_8H_{10}N_2O_2S$: N, 14.10. Found: N, 13.94.

Some Quaternary Ammonium Salts of Substituted Thiazoles

BY CARL T. BAHNER, DONALD PICKENS[1] AND DOROTHY BETTIS BALES[2]

The biological results obtained by Shear and associates[3] at the National Cancer Institute using quaternary salts derived from pyridine and its homologs and benzologs have led us to prepare similar quaternary salts containing the thiazole ring. Particular interest attaches to this series in view of the fact that thiamin chloride is a quaternary salt containing this ring. The substituted thiazoles which we have used are 4-methyl-2-β-hydroxyethylthiazole, 2,4-dimethylthiazole, 2-ethyl-4-methylthiazole, 4-methylthiazole, benzothiazole, and 2-methylbenzothiazole. These have been caused to react with phenacyl and substituted phenacyl bromides and with phenylethyl and cyclohexylethyl halides. Most of these bases reacted with the phenacyl bromides readily upon

[a] Melting points below 200° are corrected. Others are uncorrected. [b] Also analyzed for C and H by Dr. Carl Tiedcke. Calcd.: C, 53.89; H, 3.59. Found: C, 53.78; H, 3.72. [c] Made by treating phenacylbenzothiazolium bromide with hydroxylamine hydrochloride, a method which gave a very small yield, and also in better yield by mixing benzothiazole with phenacyl bromide oxime prepared by the method given by Korten and Seboll for obtaining the *syn*-form; *Ber.*, **34**, 1907 (1901). On account of difficulty in carrying out a Volhard analysis on this particular compound a Kjeldahl nitrogen analysis was made by Marvel Fielden. Calcd.: N, 8.02. Found: N, 7.91. [d] A melting point of 216° was reported for this compound, crystallized from a different solvent by Kondo and Nagasawa, *J. Pharm. Soc. Japan*, **57**, Abstracts, 308–310 (1937).

heating to 100° for about five minutes, using a small amount of chloroform or ethanol as solvent in those cases where the starting materials alone did not form a homogeneous liquid at 100°, but the benzothiazole and 4-methyl-2-β-hydroxyethylthiazole reacted somewhat more slowly. The phenylethyl and cyclohexylethyl halides were much less reactive and were usually heated with the base three or four days at 100° in a sealed tube. Some substituted benzothiazoles, such as 2-chlorobenzothiazole, 2-methylmercaptobenzothiazole, and 2-phenylbenzothiazole gave little or no crystalline quaternary salt on heating with phenacyl bromide.

The quaternary salts obtained were purified by recrystallization from ethanol and the ionic halogen content determined by Volhard analysis. (Hartwell and Kornberg[4] had found that some compounds which gave satisfactory combustion analyses held the halogen in non-ionic form and appeared not to be the expected quaternary salts.)

(4) Hartwell and Kornberg, THIS JOURNAL, **68**, 868 (1946).

Samples of the salts listed in Table I have been submitted to the National Cancer Institute for testing. Results of the screening tests will be taken into account in planning further syntheses in this series.

Intermediates.—Phenacyl bromide, *p*-bromophenacyl bromide, *p*-phenylphenacyl bromide, β-cyclohexylethyl bromide, benzothiazole, 2-methylmercaptobenzothiazole, 2-phenylbenzothiazole, 2-chlorobenzothiazole, and 2-methylbenzothiazole were purchased from Eastman Kodak Company and phenylethyl iodide from Edcan Laboratories. The 4-methyl-2-β-hydroxyethylthiazole was furnished by Merck and Company. The other halides used were prepared in the usual way by halogenation of the corresponding methylaryl ketones or by the Friedel–Crafts reaction of bromoacetyl bromide with the proper substituted aromatic hydrocarbon. The other substituted thiazoles were made by the method of Schwarz.[5]

Density Data for Two Methylchlorosilanes

BY E. W. BALIS, W. F. GILLIAM, E. M. HADSELL, H. A. LIEBHAFSKY AND E. H. WINSLOW

Density data for dimethyldichlorosilane (DDS) and for methyltrichlorosilane (MTS), which were used several years ago to lay the foundation for a successful routine method to aid in controlling chlorosilane distillation, are given below. There appear to be no comparable earlier published data.

Pure Compounds.—As a by-product of painstaking distillation work done in 1943, the details of which are to be published later, the following densities (g./ml. at 25°) were obtained on chlorosilanes among the purest ever prepared here: for DDS, 1.0663; for MTS, 1.2691. The corresponding weight percentages of chlorine by hydrolysis were: DDS, 54.93 *vs.* 54.95 (theor.); MTS, 71.19 *vs.* 71.17 (theor.), the deviations from the theoretical being comparable with the possible uncertainty in the atomic weight of silicon.[1]

Temperature Coefficients.—For the interval 25–30°, dilatometric measurements on the best materials available from the pilot plant in 1944[2] yielded the following values for the change in density with temperature (g./ml./°C.): DDS, 0.00145; MTS, 0.00173. These precise results are in good agreement with older data (0.0015 and 0.0018, respectively) obtained on a Westphal balance.

The 50-ml. dilatometer was designed and manipulated to give a precision better than 0.005% in a density determination. Special techniques were required to mitigate the difficulty of handling the methylchlorosilanes, and the dilatometer itself did not change weight by more than a few tenths milligram—if at all—during the measurements.

Volume Additivity.—In order to establish whether any volume change on mixing DDS and MTS is negligible for purposes of routine control, the routine density-balance (to be described elsewhere) was used on DDS[2] and MTS[2], and on six solutions carefully prepared by weight therefrom. The measured densities are given in Table I alongside densities calculated for the solutions on the assumption of volume additivity.

TABLE I

VOLUME ADDITIVITY OF DDS AND MTS AT 27°

Weight fraction DDS	Measured densities, g./ml.	Calculated densities, g./ml.
MTS	1.2593	....
DDS	1.0618	....
0.81450	1.0939	1.0936
.66014	1.1217	1.1216
.42930	1.1665	1.1662
.42930	1.1659	1.1662
.29397	1.1940	1.1940
.14036	1.2275	1.2273

The measured densities tend to exceed those calculated by an amount comparable with the experimental error; consequently, volume additivity could permissibly be assumed in the control work. The data in Table I indicate that this pair of methylchlorosilanes belongs among those for which volume additivity comes closest to being realized, which suggests that a thorough investigation of these and other chlorosilanes along lines laid down by Young[3] would be welcome.

(1) Baxter, Guichard and Whytlaw-Gray, THIS JOURNAL, **69**, 731 (1947). The chlorine titrations were not of atomic weight precision. Correction of the final average chlorine contents for all conceivable sources of error would lower the percentages by 0.02; taking 28.10 as the atomic weight of silicon would produce the same change in the theoretical values. The density data have been corrected for all conceivable sources of error.

(2) The methylchlorosilanes used in the work on temperature coefficients and volume additivity were sufficiently pure for these purposes as the following data show. DDS, density at 25°, 1.065 g./ml.; wt. % Cl by hydrolysis, 54.72, 54.64. MTS, density at 25°, 1.263 g./ml.; wt. % Cl by hydrolysis, 70.64, 70.69.

p-Bromobenzyl Bromide in the Identification of Some Aromatic Carboxylic Acids

BY B. A. FIEKERS AND E. M. DI GERONIMO

As part of a study of suitable derivatives for the identification of organic acids, *p*-bromobenzyl esters of benzoic acid, some of its derivatives and similar acids have been prepared and characterized in this Laboratory. The general preparation of these esters is given by the equation.

$$p\text{-BrC}_6\text{H}_4\text{CH}_2\text{Br} + \text{NaOCOR} \longrightarrow \text{NaBr} + p\text{-BrC}_6\text{H}_4\text{CH}_2\text{OCOR}$$

Experimental

***p*-Bromobenzyl Bromide.**—This was prepared from *p*-bromotoluene by bromination of the side-chain, using ultraviolet light, quartzware and heat.[1] The solid product was purified by recrystallization from alcohol until a constant melting point (61.5°) was obtained.

Preparation of the Esters.—The sodium salt of the acid was formed by dissolving a slight excess of the acid in 5 ml. of 0.5 *M* sodium carbonate solution. The mixture was refluxed on a steam-bath and water was added sparingly, when necessary, until solution was complete. 1.25 g.

(1) Weizmann and Patai, THIS JOURNAL, **68**, 150 (1946).

(0.005 mole) of *p*-bromobenzyl bromede and 10 ml. of 95% ethyl alcohol were then added and the mixture was refluxed. The refluxing was continued for an hour after the solution had again cleared. When necessary, more alcohol was added in order to bring the reagent into solution. The solution was then cooled rapidly in a stream of cold water and finally in an ice mixture. The esters were filtered and recrystallized from alcohol until constant melting points were obtained. Departures from this general procedure are noted in Table I. All given temperatures are uncorrected.

Analysis.—The Parr bomb was used in conjunction with the Volhard titration method.

TABLE I

p-BROMOBENZYL ESTERS OF SOME AROMATIC CARBOXYLIC ACIDS

Acid	Obs., m. p., °C. Acid	Ester	Halogen, % Calcd. Ester	Found Ester

cis and *trans* Forms of β-(*p*-Chlorophenyl)-cinnamic Acid

BY REYNOLD C. FUSON AND HAROLD L. JACKSON

In view of results communicated to us privately by Dr. F. Bergmann,[1] we have modified the procedure of Alexander, Jacoby and Fuson[2] for the preparation of β-(*p*-chlorophenyl)-cinnamic acid by the Reformatsky method and have been able to isolate the acid in *cis* and *trans* modifications.

In the revised procedure 5 g. of crude ethyl β-phenyl-β-(*p*-chlorophenyl)-β-hydroxypropionate, made by the method of Alexander, Jacoby and Fuson,[2] was heated under reflux for two hours with 50 ml. of glacial acetic acid and 25 ml. of acetic anhydride. The acetic acid and acetic anhydride were removed by distillation at the aspirator. The residue was distilled under 1–2 mm. pressure, and the product that distilled between 65 and 69° was collected.

This distillate was treated with 10 g. of sodium hydroxide dissolved in 20 ml. of water and 10 ml. of ethanol. The alkaline hydrolysis mixture was heated under reflux for twenty hours. When the cooled solution was poured into 100 ml. of cold water, a white crystalline solid precipitated. The mixture was made acid with dilute hydrochloric acid. The product melted over a range of 140 to 157°; yield, 3.4 g. Fractional crystallization of this product from dilute ethanol yielded two isomers; one melted at 164.8–165.7° and the other at 173.0–173.8°. Mixed melting point determinations with samples, kindly supplied by Dr. Bergmann, showed these acids to be identical with his low-melting and high melting compounds.

Infrared absorption spectra[3] indicated that the two forms were *cis* and *trans* isomers. The presumption that the low-melting isomer was the *cis* modification was supported by the observation that it was more soluble in diethyl ether than the high-melting isomer.

From these results it appears that the compound described by Alexander, Jacoby and Fuson[2] and melting at 168° must have been an impure sample of the *trans* acid, the contaminant being presumably the *cis* isomer.

2-Benzofuryllithium and 3-Benzofuryllithium

BY HENRY GILMAN AND DONALD S. MELSTROM

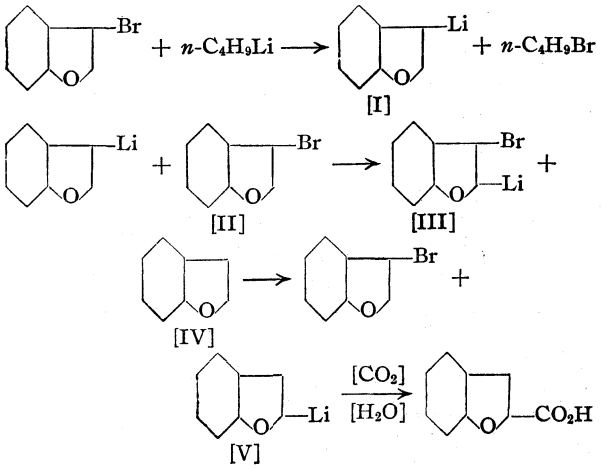
2-Bromobenzofuran does not react with magnesium, under conventional conditions, to give a Grignard reagent.[1] However, Reichstein and Baud[2] showed that the activated magnesium–copper alloy[3] react with 3-bromobenzofuran to give, subsequent to carbonation, about 1% of 3-benzofurancarboxylic acid in addition to 28% of *o*-hydroxyphenylacetylene.

By means of the recently developed halogen–metal interconversion reaction, we have shown that 2-bromobenzofuran reacts with *n*-butyllithium to give, on carbonation, a 62% yield of pure 2-benzofurancarboxylic acid.

The yield of 3-benzofurancarboxylic acid, from 3-bromobenzofuran and *n*-butyllithium, was 12%. However, this reaction was particularly interesting because of the formation of appreciable quantities of the isomeric 2-benzofurancarboxylic acid. It is probable that the 2-acid was formed from the 3-bromo compound in essential accordance with

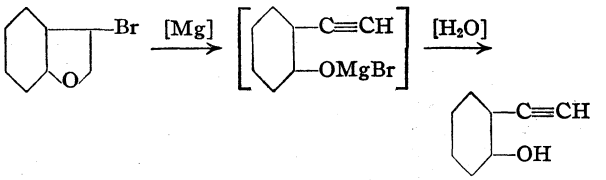
(1) E. W. Smith, unpublished studies.
(2) Reichstein and Baud, *Helv. Chim. Acta*, **20**, 892 (1937).
(3) Gilman, Peterson and Schulze, *Rec. trav. chim.*, **47**, 19 (1928).

the following transformations. That is, the initially formed 3-benzofuryllithium [I] metalated [II] in the highly reactive *ortho*- or 2-position to give 3-bromo-2-benzofuryllithium [III] which then metalated the unsubstituted benzofuran [IV] in the expected 2-position to give 2-benzofuryllithium [V]. Another possible explanation in-



volves intramolecular metalation, or essentially rearrangement of the 3-lithium compound to the 2-lithium compound. A related transformation occurs when 3-bromodibenzofuran is treated with *n*-butyllithium and the acids obtained were 3-dibenzofurancarboxylic acid and 4-dibenzofurancarboxylic acid.[4] It is highly probable that a related so-called rearrangement will be observed with other systems in which there is available a hydrogen which is quite sensitive to metalation.[5]

From a room temperature reaction between 3-bromobenzofuran and three equivalents of *n*-butyllithium we obtained a 67% yield of *o*-hydroxyphenylacetylene. It has been suggested[2] that this compound, isolated from the reaction between magnesium and 3-bromobenzofuran, owes its formation to an intramolecular cleavage. In



support of this postulate is the difficulty of forming Grignard reagents from β-halogen ethers like β-bromoethyl phenyl ether (which gives phenol and ethylene),[6a] and 2-bromomethyltetrahydrofuran (which gives γ-vinylpropyl alcohol).[6b]

(4) Gilman, Willis and Swislowsky, THIS JOURNAL, **61**, 1371 (1939).

(5) A case in point is the simple monocyclic furan type. The phenyl alkyl ethers may not show the reaction under usual conditions because the metalation proceeds generally with more difficulty than the halogen-metal interconversion reaction. See, Gilman, Moore and Baine, *ibid.*, **63**, 2479 (1941), for some factors influencing the rates of these reactions.

(6) (a) Grignard, *Compt. rend.*, **138**, 1048 (1904); (b) Robinson and Smith, *J. Chem. Soc.*, 195 (1936).

However, substituents may have a marked effect because 2,4,5-triphenyl-3-furyllithium is formed in yields of at least 66% from 2,4,5-triphenyl-3-bromofuran and *n*-butyllithium[7]; and 3-furylsodium and -potassium are formed by the direct action of 3-iodofuran with sodium–potassium alloy.[8] Also, there is a possibility that the cleavage reaction is not confined to β-halogen ethers because the reaction mixture of 2-bromobenzofuran and *n*-butyllithium appeared to contain some of the *o*-hydroxyphenylacetylene as evidenced by the unusually characteristic odor of this compound.

Experimental

2-Bromobenzofuran and *n*-Butyllithium.—First, the 2-bromobenzofuran was prepared from benzofuran dibromide[9] in accordance with the following directions of E. W. Smith.[1] One-tenth mole of crude, dry benzofuran dibromide was distilled at atmospheric pressure. A vigorous evolution of hydrogen bromide occurred, and the oily fraction distilling at 200–235° was collected. This distillate was dissolved in ether, and then washed successively with water, 10% sodium carbonate solution, and again with water. After drying over sodium sulfate, the ether was removed and the 2-bromobenzofuran was obtained (55% yield) by fractional distillation.

Then, a solution of 2 g. (0.01 mole) of 2-bromobenzofuran in a few cc. of ether was added all at once to a solution of 0.014 mole of *n*-butyllithium in 50 cc. of ether, cooled to −70° in a Dry Ice–acetone bath. The reaction mixture was stirred for two minutes and then carbonated. The yield of crude 2-benzofurancarboxylic acid, melting at 187–189°, was 1.4 g. (86%). Crystallization from dilute ethanol yielded 1.04 g. (62%) of pure acid melting at 192.5–193°. The compound was identified by a mixed m. p. determination with an authentic specimen.[9] In experiments carried out at room temperature, the yield of crude 2-benzofurancarboxylic acid after a reaction period of twenty minutes was 62%, and after forty minutes the yield was 28%. The aqueous filtrates from the acid had the characteristic odor of *o*-hydroxyphenylacetylene, indicating that some cleavage of the benzofuran ring had taken place.

3-Bromobenzofuran and *n*-Butyllithium.—The 3-bromobenzofuran was prepared by the following sequence of reactions: coumarin dibromide → 2-benzofurancarboxylic acid → benzofuran[2] → benzofuran dibromide → 3-bromobenzofuran.[1,2,10] The compound, which melted at 35.5–36° after crystallization from petroleum ether (b. p. 28–38°) at −20°, appeared to be unstable and discolored on standing.

A solution of 2 g. (0.01 mole) of 3-bromobenzofuran in a few cc. of ether was added quickly to a solution of 0.014 mole of *n*-butyllithium in 50 cc. of ether at −70°. The reaction was then stirred for two minutes, and after carbonation there was obtained 0.23 g. (14%) of acid melting at 154–159°. Crystallization from a mixture of benzene and petroleum ether (b. p. 60–68°) gave 0.19 g. (12%) of acid melting at 160–161°, with no change in melting point subsequent to another crystallization from dilute ethanol. The reported melting point is 162° (cor.).[11] A mixed melting point with the 2-isomer showed a depression.

Anal. Calcd. for $C_9H_6O_3$: neut. equiv., 162. Found: neut. equiv., 164 and 161.

Then a series of experiments was carried out varying the time of the reaction and the temperature, and in each case

(7) Gilman and Melstrom, THIS JOURNAL, **68**, 103 (1946).

the only acid isolated was 2-benzofurancarboxylic acid in the following crude yields: 13, 10, 23.5, 13 and 16%. From an experiment carried out in petroleum ether (b. p. 28–38°) with 3 g. (0.025 mole) of 3-bromobenzofuran and a slight excess of *n*-butyllithium, there was obtained, after carbonation and hydrolysis, 0.15 g. of crude *o*-hydroxyphenylacetylene and a trace of unidentified acid melting at 127–129° (possibly *o*-hydroxyphenylpropiolic acid).

o-Hydroxyphenylacetylene from 3-Bromobenzofuran.—A solution of 10 g. (0.051 mole) of 3-bromobenzofuran in 30 cc. of ether was added during five minutes to a solution of 0.154 mole of *n*-butyllithium in 220 cc. of ether at room temperature. The solution was stirred for one hour and then hydrolyzed by pouring on iced dilute hydrochloric acid. The yield of *o*-hydroxyphenylacetylene, distilling at 95–98° under 10 mm., was 4 g. (67%). A part of the phenol was converted to the *p*-nitrobenzoate by treatment with *p*-nitrobenzoyl chloride in pyridine. The melting point was 108–109°, and the reported melting point is 107–108° (cor.).[2]

Syntheses in the Pyrazene Series: The Preparation and Properties of Pyrazine Sulfonic Acid

BY EUGENE HORT AND PAUL E. SPOERRI

Although recent electron diffraction studies have shown that benzene and pyrazine have very similar structures,[1] direct substitution with the usual electrophilic reagents, which proceeds so well with benzene operates only with great difficulty or not at all with pyrazine. This deactivation seems to be due to the electron-withdrawing inductive and resonance effects of the nitrogen atoms.[2] Even under such severe conditions as those used in the cleavage of lumazine,[3] *i. e.*, treatment with 100% sulfuric acid at 240°, sulfonation has not been observed. In fact, no direct sulfonation of the pyrazine nucleus has ever been reported. It seemed, therefore, of interest to attempt the synthesis of pyrazine sulfonic acid by means of indirect methods.

Methods based on the oxidation of pyrazine thiol were considered impractical because of the susceptibility of pyrazine to strong oxidizing agents. The reaction of chloropyrazine with sodium sulfite solutions was therefore investigated. Since chloropyrazine had previously been found to possess a chlorine atom intermediate in activity between an alkyl and aryl halide,[4] this method was adopted for the preparation.

Chloropyrazine was obtained by the following sequence of operations. Lumazine prepared according to Cain, Mallette and Taylor,[5] was cleaved to 2-hydroxy-3-pyrazinoic acid and then to hydroxypyrazine according to Weijlard, Tishler and Erickson.[3] Chloropyrazine was then prepared by the method of Erickson and Spoerri[4] with the notable exception that phosphorus oxychloride (in a ratio of five moles to one of hydroxypyrazine) was used as sole chlorinating agent.[6]

Experimental[7]

Chloropyrazine was heated in a sealed tube for twelve hours at 150° with a solution of sodium sulfite. The resulting solution was evaporated and the product crystallized from alcohol as bundles of white needles. Analysis after drying at room temperature *in vacuo* showed that the product was sodium pyrazine sulfonate monohydrate. It was extremely soluble in water, slightly soluble in alcohol, insoluble in ether and petroleum ether, and melted at 295°. Neither silver nitrtae nor barium chloride precipitated an insoluble salt.

The free pyrazine sulfonic acid was prepared by treatment of the sodium salt suspended in dry ether with dry hydrogen chloride gas followed by filtration and evaporation of the ether. It was found to be extremely hygroscopic and unsuitable for an analysis even after extensive drying at 50° *in vacuo*. Its aqueous solution gave a strong acid reaction with hydrion paper.

Three grams (0.026 mole) of 2-chloropyrazine, 4.0 g. (0.032 mole) of anhydrous sodium sulfite, and 25 ml. of water were sealed in a Carius tube and thoroughly mixed. The 2-chloropyrazine remained as a separate layer and some of the sodium sulfite remained undissolved. After keeping the tube at 150° for twelve hours and then allowing to cool, it was opened and the homogeneous yellow solution was evaporated to dryness *in vacuo*. The yellow solid residue was extracted with three 50-ml. portions of boiling 95% ethanol. On cooling the solution, masses of white needle clusters separated and were filtered. The filtrate was evaporated to dryness and extracted with two 8-ml. portions of boiling 95% ethanol. The combined extracts were allowed to stand (crystallization is slow), filtered, and the crystals added to the previously obtained portion; yield, 0.75 g. (15%) of colorless needles, m. p. 295°.

The analytical sample was recrystallized twice from 95% ethanol and dried at room temperature for sixty hours *in vacuo* over phosphorus pentoxide. *Anal.* Calcd. for $(C_4H_3N_2)SO_3Na\cdot H_2O$: C, 24.00; H, 2.52; S, 16.02; Na, 11.49. Found: C, 24.08; H, 2.79; S, 16.02; Na, 11.50.

3,4,5-Triiodobenzoyl Chloride as a Reagent for Alcohols

BY DAVID C. O'DONNELL, JOHN K. KELLEY, JR.,[1] ROBERT F. O'MALLEY[1] AND ROY H. UPHAM[1]

The use of 3,4,5-triiodobenzoyl chloride for the identification of cellosolves and carbitols has been reported previously.[2] Since the compound is relatively stable to water, it was applied to the monohydric alcohols. The alcohols were used as obtained from the manufacturer without further purification. The acid chloride of the 3,4,5-triiodobenzoic acid was prepared by the method of Klemme and Hunter.[3]

(1) Taken from theses submitted in partial fulfilment for the M.S. degree.
