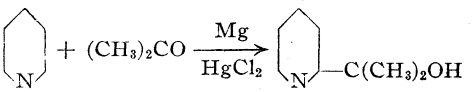
The introduction of halogen atoms seems to increase the rate of copolymerization of the vinyl heterocyclic monomers with butadiene and to soften the resulting rubbers somewhat but the effect is not as great as was hoped for. Our preliminary examination of these rubbers indicates that it would be desirable to introduce at least two halogen atoms per molecule of vinyl compound to obtain greater internal plasticization of the butadiene copolymers. This could probably be achieved more easily in the quinoline series than in the pyridine series since the number of positions available on the pyridine nucleus is limited. Furthermore, halogen atoms in 2, 4 and 6-positions of pyridine are readily hydrolyzed. This leaves only the 3- and 5-positions free for halogen atoms and the 2(6)- or 4-positions for the vinyl groups. It has been shown that alpha-methylvinyl groups in the 2(6)-position do not copolymerize, and the same may very well be true of such groups in the 4-position. Among quinoline compounds only the 2- and 4-positions hold readily hydrolyzable halogens. The 5, 6, 7 and 8 positions of the benzene ring and the 3-position of the pyridine ring offer suitable points of attachment of both halogen atoms and vinyl groups. The preparation of some of these compounds will be described at a later date.

The vinyl compounds studied were prepared by dehydrating corresponding alcohols. The (CH$_3$)$_2$-C(OH)– group in the 3-position of pyridine dehydrated more easily than the same group in the 2-position. Most of the alcohols were prepared from the corresponding acids by well-known methods, but the alcohols corresponding to I[3] and VI[8] were obtained by special methods. Emmert and Asendorf[3] have reported a little known but very interesting reaction for the preparation of 2-(2′-hydroxy-2′-propyl)-pyridine which involves a heterogeneous bimolecular reduction of acetone and pyridine in the presence of magnesium and mercuric chloride.



After improving the published procedure for this reaction we found it to be well suited for the synthesis of I.

Considerable time was spent studying syntheses for 5-chloro- and 5-bromonicotinic acids, intermediates for the preparation of III, IV and V. These acids are both known but the reported syntheses are difficult and give poor yields. We found that nicotinic acid chloride hydrochloride could be brominated directly to give the 5-substituted acid in excellent yields (87%) at 170°.

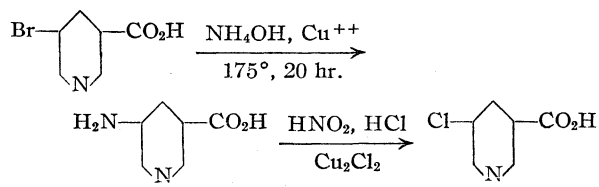
A similar reaction involving picolinic acid gave only tars. Many attempts were made to prepare 5-chloronicotinic acid by direct chlorination, but with only moderate success. On a small scale the desired product was obtained, but on a larger scale rapid sublimation, incomplete fusion of the acid chloride hydrochloride, and failure to form a perchloride complex interfered. Eventually the 5-chloro acid was prepared from the 5-bromo acid *via* the 5-amino acid.



A convenient new synthesis, suitable for laboratory scale preparations, was also developed for ethyl quinaldinate and its 6-chloro analog, intermediates for VIII and IX.

Acknowledgment.—The authors are indebted to the General Tire and Rubber Company for support in the form of a fellowship.

Experimental

2-Isopropenylpyridine

2-(2′-Hydroxy-2′-propyl)-pyridine.—A mixture of 24 g. (0.088 mole) of mercuric chloride, 24.3 g. (1.0 mole) of magnesium turnings and 200 g. (2.53 moles) of pyridine was warmed on the steam-bath until it acquired an opaque gray color. Then 200 g. (3.45 moles) of acetone was added dropwise with stirring during one and one-half hours. After an additional hour the magnesium had disappeared. The mixture was poured over ice and excess potassium carbonate solution, and the brown oil was separated and distilled. The fraction, b. p. 85–95° (12 mm.), was dissolved in dilute hydrochloric acid and steam distilled to remove volatile impurities. The product was recovered by treatment with bases and redistilled; yield 40 g. (29.3% based on the magnesium), b. p. 85–90° (10 mm.), m. p. 49–50° (from chloroform). These properties correspond with those previously reported by Sobecki[9] and by Emmert and Asendorf.[3]

2-Isopropenylpyridine.—The procedure of Emmert and Asendorf[3] gave a 67% yield of an oil b. p. 63–67° (10 mm.), $n^{25}D$ 1.5241, d^{25}_{25} 0.9962 (reported[3] b. p. 172–176°).

3-Isopropenylpyridine

3-(2′-Hydroxy-2′-propyl)-pyridine.—This alcohol was prepared by Graf and Langer,[10] who gave no details of procedure. A solution of 137 g. (1.0 mole) of methyl nicotinate in 1000 ml. of anhydrous ether was added dropwise with stirring to a solution of 540 g. (3.25 mole) of methylmagnesium iodide in 900 ml. of ether. The yellow suspension was stirred and refluxed for three hours and then poured over chopped ice containing acetic acid. The solution was made just alkaline; the product was extracted with ether and distilled; yield 78 g. (57%), b. p. 130° (10 mm.); reported,[10] b. p. 130° (11 mm.), m. p. 53°.

3-Isopropenylpyridine.—Dehydration of the above alcohol with a mixture of sulfuric and acetic acids by the procedure of Oparina[5] gave 3-isopropenylpyridine in 79% yield, b. p. 75° (10 mm.), $n^{25}D$ 1.5381, d^{25}_{25} 0.9775, methiodide, m. p. 103–104° (reported[5] b. p. 187–188°, d^{20}_{20} 0.9771).

Dehydration by heating with half molar quantities of phosphorus pentoxide in benzene for several hours gave a 65% yield but only a 25% conversion to the same compound.

5-Bromo-3-isopropenylpyridine

5-Bromonicotinic Acid.—Nicotinic acid was converted to the acid chloride hydrochloride with thionyl chloride, heated ten hours at 150–170° (oil-bath temperature) with an equimolecular amount of bromine, and then cooled. Ice water was added, the *p*H was adjusted to 3 with base and the precipitated product was filtered and recrystallized (Norit) from ethanol; yield 87%, m. p. 183°.[11] Treatment with thionyl chloride and then dilute base gave the acid chloride, m. p. 75°,[11] in 86% yield.

5-Bromo-3-(2′-hydroxy-2′-propyl)-pyridine.—5-Bromonicotinyl chloride was treated with 3.5 moles of methylmagnesium iodide to obtain the desired tertiary alcohol, a colorless and very viscous oil, b. p. 135–140° (3 mm.), $n^{25}D$ 1.5615, d^{25}_{25} 1.47; methiodide, m. p. 208–210°, dec.

Anal. Calcd. for $C_8H_{10}NOBr$: C, 44.47; H, 4.67. Found: C, 44.80; H, 4.70.

5-Bromo-3-isopropenylpyridine.—Dehydration of the above alcohol by heating with 20% sulfuric acid in acetic acid or by passing the vapors over alumina at 300° (50 mm.) gave 89 and 78% yields, respectively, of product, b. p. 85–87° (3 mm.), $n^{25}D$ 1.5820, d^{25}_{25} 1.4204; methiodide, m. p. 228°, dec.

Anal. Calcd. for C_8H_8NBr: N, 7.07. Found: N, 6.91.

5-Bromo-3-vinylpyridine

Ethyl 5-Bromonicotinate.—A 95% yield of the desired ester, m. p. 38–39°, was obtained by adding excess absolute ethanol to 5-bromonicotinyl chloride, refluxing for thirty minutes, distilling off the excess alcohol, and making the residue alkaline. The crude material was recrystallized from petroleum ether (60–70°).

Anal. Calcd. for $C_8H_8NO_2Br$: N, 6.08. Found: N, 5.86.

3-Acetyl-5-bromopyridine.—This ketone was prepared by three different procedures: (A) from 5-bromonicotinyl chloride and methylmagnesium bromide, yield 18%; (B) from 5-bromonicotinyl chloride and dimethylcadmium. This procedure was more laborious, but gave a slightly better yield (25%). (C) From ethyl 5-bromonicotinate *via* ethyl 5-bromonicotinylacetate: a solution of 0.32 mole of anhydrous sodium ethoxide in 108 ml. of xylene was prepared and added to a mixture of 46 g. (0.2 mole) of ethyl 5-bromonicotinate, 33.4 g. (0.38 mole) of ethyl acetate, and 50 ml. of xylene. After being heated and stirred for six hours and standing overnight, the mixture was poured into 800 ml. of ice water, acidified with 40 ml. of concentrated hydrochloric acid, and hydrolyzed by heating on a steam-bath for five hours. The xylene was removed by distillation, the residue was made basic, and the solid ketone which precipitated was separated by filtration. Recrystallization from petroleum ether (60–70°) gave 30 g. (75% yield) of white plates, m. p. 90°.

Anal. Calcd. for C_7H_6NOBr: C, 42.03; H, 3.04. Found: C, 42.11; H, 3.04.

5-Bromo-3-(1′-hydroxyethyl)-pyridine.—Reduction of 20 g. (0.1 mole) of 5-bromo-3-acetylpyridine with 0.1 mole of aluminum isopropoxide by the standard procedure[12] and isolation by vacuum distillation gave 20 g. (85% yield) of

the desired alcohol as a viscous oil, b. p. 134–136° (3 mm.), $n^{25}D$ 1.5728, d^{25}_{25} 1.5378.

Anal. Calcd. for C_7H_8NOBr: N, 6.93. Found: N, 7.00.

5-Bromo-3-vinylpyridine.—A 103-g. sample of 5-bromo-3-(1′-hydroxyethyl)-pyridine was dehydrated over alumina by the vapor phase method described previously. The 5-bromo-3-vinylpyridine fraction obtained amounted to 63 g. (67% yield), b. p. 74–75° (3 mm.), $n^{25}D$ 1.5810, d^{25}_{25} 1.4823.

Anal. Calcd. for C_7H_6NBr: N, 7.61. Found: N, 7.46.

5-Chloro-3-isopropenylpyridine

5-Aminonicotinic Acid.—One mole, 202 g., of 5-bromonicotinic acid, 400 ml. of ammonium hydroxide solution (sp. gr. 0.9) and 50 g. of copper sulfate pentahydrate were heated to 170–180° for twenty hours in a glass-lined autoclave. The dark-colored solution was removed after cooling and treated with aqueous sodium sulfide to remove copper ions. The filtered solution was adjusted to *p*H 4–5 and the precipitated acid was filtered off, washed with water, and recrystallized from water (Norite). A yield of 96 g. (69%), m. p. 292–294°, was obtained. Graf[11] reports no yield and a m. p. of 288–290° for a product prepared similarly from 5-chloronicotinic acid.

5-Chloronicotinic Acid and Its Chloride.—A sample of 96 g. (0.7 mole) of 5-aminonicotinic acid dissolved in 400 ml. of concd. hydrochloric acid was cooled in an ice–salt-bath to 0° and diazotized with a cold solution of 50.4 g. (0.77 mole) of sodium nitrite in 145 ml. of water. The mixture was poured into a solution of 80 g. (0.7 mole) of cuprous chloride in 400 ml. of concentrated hydrochloric acid. After three hours of stirring the mixture was heated to 60° to complete the reaction, diluted with an equal volume of water, and treated with aqueous sodium sulfide to precipitate the copper ions. The filtered solution deposited the crude chloro acid at *p*H 3. Recrystallization from hot water (Norite) gave 20 g. (18% yield) of 5-chloronicotinic acid, m. p. 169–170°. Graf,[11] who obtained a 25–30% yield of this acid by long heating of nicotinic acid with excess thionyl chloride, eventually in a sealed tube, reports m. p. 170–171°. The acid chloride, m. p. 53°, was prepared in 90% yield with the aid of thionyl chloride by the procedure of Graf and Meyer,[13] who report the same m. p. but give no yield.

5-Chloro-3-(2′-hydroxy-2′-propyl)-pyridine.—Following the procedure for the corresponding 5-bromo compound but starting with 20 g. (0.12 mole) of 5-chloronicotinyl chloride gave 14.2 g. (73% yield) of the desired alcohol, b. p. 115° (3 mm.), $n^{25}D$ 1.5377, d^{25}_{25} 1.199.

Anal. Calcd. for $C_8H_{10}NOCl$: N, 8.17. Found: N, 8.25.

5-Chloro-3-isopropenylpyridine.—Dehydration of 12 g. (0.7 mole) of the above alcohol by the procedure used for the 5-bromo analog gave 8.5 g. (79% yield) of the desired olefin, b. p. 70–73° (3 mm.), $n^{25}D$ 1.5554, d^{25}_{25} 1.1520.

Anal. Calcd. for C_8H_6NCl: N, 9.12. Found: N, 9.15.

2-Vinylquinoline

2-(2′-Hydroxyethyl)-quinoline.—Condensation of quinaldine with formaldehyde by the procedure of Koenigs[8] gave a 30% yield of this alcohol.

2-Vinylquinoline.—A mixture of 10 g. of the above alcohol, 1.5 g. of powdered potassium hydroxide, and 0.1 g. of phenyl-β-naphthylamine was heated in an oil-bath at 140–150° under reduced pressure (5 mm.) until distillation stopped. The oily product was redistilled to obtain 4.2 g. (46.9% yield) of the vinyl compound.

2-Vinylquinoline was also prepared directly from a quinaldine–formaldehyde reaction mixture. Quinaldine, 200 g. (1.4 moles), formalin 180 g. (2.4 moles of formaldehyde), 100 ml. of ethanol and 100 ml. of water were heated twenty-four hours on a steam-bath. The solvents were distilled off, 5 g. of powdered sodium hydroxide and 1 g. of phenyl-β-naphthylamine were added, and the mixture was heated at 7 mm. pressure until distillation ceased. Redistillation gave 103 g. (49% yield) of product, b. p. 120–125° (7 mm.), $n^{20}D$ 1.6439, d^{25}_{25} 1.0692.

Anal. Calcd. for $C_{11}H_9N$: N, 9.04. Found: N, 9.06.

2-Isopropenylquinoline

Ethyl Quinaldinate.—A solution of 111 g. (0.66 mole) of silver nitrate in 660 ml. of water was added carefully with stirring to a solution of 83 g. (0.22 mole) of 2-tribromoquinaldine in 800 ml. of ethanol. The mixture was refluxed for thirty minutes, filtered, acidified with 40 ml. of hydrochloric acid, and concentrated under vacuum to 300 ml. The solution was made strongly basic, the oily product was separated by decantation and ether extraction and was then purified by distillation; yield 25 g. (55%), b. p. 131–136° (1 mm.); reported,[14] b. p. 131–136° (0.3 mm.), $n^{20}D$ 1.5973.

2-(2′-Hydroxy-2′-propyl)-quinoline.—Ethyl quinaldinate was treated with 3.3 moles of methylmagnesium bromide to obtain 16 g. (86%) of the alcohol, m. p. 67°.[15]

2-Isopropenylquinoline.—Dehydration of 17 g. of the above alcohol was accomplished by heating with 50 ml. of concentrated sulfuric acid in an oil-bath at 120–130° for three hours. The mixture was cooled, poured into cold water, made basic, and ether extracted. Distillation gave a pale yellow oil, 7.0 g. (45.5% yield), b. p. 119–120° (3 mm.), $n^{25}D$ 1.6281, d^{25}_{25} 1.0600.

Anal. Calcd. for $C_{12}H_{11}N$: N, 8.28. Found: N, 8.05.

6-Chloro-2-isopropenylquinoline

6-Chloroquinaldine.—The following procedure gives over three times the yield reported previously.[16] A mixture of 80 g. (0.625 mole) of 4-chloroaniline, 500 ml. of absolute ethanol, 53 ml. of concentrated hydrochloric acid, 270 g. of ferric chloride hexahydrate and 10 g. of zinc chloride was heated to 60–65°. Crotonaldehyde, 35 g. (0.5 mole) was added dropwise in two hours. The mixture was refluxed two hours, let stand overnight, distilled under vacuum to remove the alcohol, and then made strongly basic and steam distilled. The distilled solid, after drying, weighed 70 g. (79% yield), m. p. 92–93° (reported,[16] m. p. 91°).

6-Chloro-2-tribromoquinaldine.—A solution of 227 g. (1.44 mole) of bromine in 61 ml. of glacial acetic acid was added in the course of one hour to a mixture of 245 g. (2.98 moles) of anhydrous sodium acetate, 85 g. (0.49 mole) of 6-chloroquinaldine, and 610 ml. of glacial acetic acid at 75–80°. After heating at 90–95° for one hour and standing overnight, the solid product was separated and recrystallized from petroleum ether (60–70°); yield 133 g. (67%), m. p. 59–60°.

Anal. Calcd. for $C_{10}H_5NBr_3Cl$: Br, 57.86; Cl, 8.56. Found: Br, 57.5, 57.6; Cl, 8.5, 8.5.

Ethyl 6-Chloroquinaldinate.—The procedure developed for the preparation of ethyl quinaldinate gave a 44% yield of the 6-chloro analog, m. p. 91–92°.

Anal. Calcd. for $C_{12}H_{10}NO_2Cl$: N, 5.94. Found: N, 5.94.

6-Chloro-2-isopropenylquinoline.—The reaction of 13 g. (0.055 mole) of ethyl 6-chloroquinaldinate with approximately 0.18 mole of methylmagnesium bromide in ether according to the procedure previously described using ethyl quinaldinate gave 7.5 g. of a viscous oil, chiefly 6-chloro-2-(2′-hydroxy-2′-propyl)-quinoline, which was not further characterized but was dehydrated directly with concd. sulfuric acid (20 ml.) at 120° for three hours. The olefin was a pale yellow oil which crystallized from an ethanol–water mixture; yield 4.3 g. (62.5%), m. p. 50°.

Anal. Calcd. for $C_{12}H_{11}NCl$: N, 6.84. Found: N, 6.67.

Polymerization Experiments

Compounds I, VIII and IX gave no polymers alone or copolymers with butadiene, styrene, or methyl methacrylate, in the presence of benzoyl peroxide. Of the remaining compounds II, III, and V gave no polymers alone but copolymerized readily with the above olefins. Compounds IV and VI polymerized readily alone and also copolymerized with the above olefins. Several attempts were made to prepare 6-chloro-2-vinylquinoline (VII) by procedures analogous to those used for 2-vinylquinoline (VI). In every case rapid polymerization interfered with isolation of the monomer. The bulk polymers were prepared by heating the monomers at 70° in stoppered test-tubes with 0.5% benzoyl peroxide catalyst. Equal weights of monomers were used for the copolymers. The emulsion polymers with butadiene were prepared in sealed tubes at 40° (thermostat) using the formula: butadiene 7.5 g., vinyl monomer 2.5 g., water 18 g., soap 0.5 g., potassium persulfate 0.03 g., lauryl mercaptan (OEI) 0.06 g.

Summary

A series of vinylpyridines and vinylquinolines, some containing nuclear halogens, have been prepared and a preliminary study made of their polymerizing and copolymerizing characteristics.

Viscosity–Molecular Weight and Viscosity–Temperature Relationships for Polystyrene and Polyisobutylene[1,2]

BY THOMAS G FOX, JR., AND PAUL J. FLORY

The simple empirical relationship[3]

$$\log \eta = A + C\overline{M}_w^{1/2} \qquad (1)$$

where η is the viscosity, $\overline{M}_w$ the weight average molecular weight and A and C are constants for a specified temperature, has been found to apply with remarkable accuracy to linear polyesters,[3,4] polyamides,[5] and to certain non-linear polymers as well.[5] Extension of this relationship to addition polymers of unsaturated compounds such as polyethylene[6] and polyisobutylene[7] and to polymeric dimethyl silicones[8] has been attempted recently with indications of success. However, either the molecular weights (weight average) were unreliably determined or the range was too limited for positive assurance that equation (1) may be applied to these polymers.

In the present investigation viscosities of two representative hydrocarbon polymers, polystyrene and polyisobutylene, of simple chain structure have been measured over wide ranges of molecular weight, molecular weight distribution and temperature. In addition to providing data with which to test the generality of equation (1), the present results demonstrate the nature of the dependence of the viscosity–temperature coefficient on molecular weight, molecular weight distribution and temperature. Apparent discrepancies which have appeared in the literature on viscosity–temperature coefficients for polystyrene have been accounted for. It is hoped that the results of this investigation will provide a basis for the better understanding of flow mechanisms in high polymers.

Experimental

Preparation and Fractionation.—Seven polymers of styrene varying in viscosity average molecular weight ($\overline{M}_v$) from 7000 to 350,000 were prepared by bulk polymerization at 60°. An average molecular weight in the desired range was obtained in each case by using appropriate concentrations of benzoyl peroxide and dodecyl mercaptan as shown in Table I. The reactions were stopped at conversions of approximately 25%. The polymers were separated by precipitation in an excess of vigorously stirred methanol, and were dried *in vacuo* at 60°.

Four polyisobutylenes with molecular weights as listed in Table I were fractionated.[9] Thus, the polymer known commercially as "Vistanex-LMH" with a viscosity average molecular weight of 69,000, was separated into a series of polymer fractions identified as PB1F1, PB1F2, and so on. The polymer PB5 consisted of a mixture of two large coarse fractions separated from PB2 and PB3.

All polymers were fractionated by single precipitation methods carried out at 30.0°. Solvent–precipitant combinations employed were methyl ethyl ketone–methyl alcohol for polystyrene and benzene–acetone for polyisobutylene. In each case the precipitant was added slowly with stirring to a solution containing 1.3 to 2.5 g. of polymer per 100 ml. of solvent (Table I) until a condition of permanent turbidity was reached. After adding an appropriate excess of the precipitant, the solution was warmed until it became clear, then subjected to gentle stirring while cooling slowly to 30.0°. The insoluble gel which settled out on standing overnight at this temperature was separated from the clear solution by decantation, washed with the non-solvent, and dried first on a steam

(9) The polyisobutylene was supplied by the Standard Oil Co. of New Jersey. We are indebted to Mr. D. W. Young of the Esso Laboratories who made available to us PB7, a laboratory sample of low molecular weight.

TABLE I

THE POLYMERS USED FOR FRACTIONATION

Polystyrene

Polymer	Mole % peroxide	Mole % mercaptan	Extent of reaction	$\overline{M}_v$	Fractionation initial concn., g./100 ml.
14A	0.04	0	26%	349,000	2.0
11A	0.50	0	22	150,000	2.0
8A	1.0	0.010	28	60,000	2.0
6A	1.0	0.024	24	70,000	2.0
3D	1.0	0.055	28	45,000	2.0
4C	1.0	0.22	22	41,000	2.2
16A	4.0	6.5	20	7,060	2.0

Polyisobutylene

Polymer	Commercial designation	$\overline{M}_v$ (approximate)	Fractionation initial concn., g./100 ml.
PB1	Vistanex LMH	69,000	2.00
PB2	100,000 Grade	1,000,000	1.25
PB3	100,000 Grade	1,000,000	1.25
PB4	Vistanex LMS	45,000	2.50
PB5	.....	1,000,000	1.33
PB7	.....	3,100	2.5

bath and then *in vacuo* at 60°. By repeating this procedure a series of fractions was obtained from each polymer, the individual fractions usually representing 5 to 25% of the whole polymer (Table VIII). PB5F1 appears to be a notable exception, as it represents 46% of PB5. However, it represents only 23% of polyisobutylene B-100 since PB5 was obtained by combining fractions representing approximately half of that polymer.

Fractionation of the low molecular weight polystyrene 16A was carried out from acetone solution using as precipitant a mixture containing equal volumes of water and methanol. The acetone-soluble portion of 4C (about two-thirds of the whole) was fractionated in a similar manner.

Inasmuch as the *weight average* molecular weight on which the melt viscosity depends (*cf. seq.*) lies close to the *viscosity average* deduced from intrinsic viscosity measurements, it is evident that efficient fractionation should be unnecessary. Nevertheless, to confirm this expectation experimentally, polystyrene 3D was fractionated by the double precipitation method previously described.[10] The melt viscosity of one of these fractions did not differ significantly from that of a fraction of the same intrinsic viscosity which had been obtained by the single precipitation method. Hence all subsequent fractionations were carried out employing the single precipitation technique.

Molecular Weight Determination.—Molecular weights of the polystyrene fractions have been calculated from their intrinsic viscosities, $[\eta]$, in freshly distilled benzene, using the relationship obtained by Ewart[11]

$$\log \overline{M}_v = (\log[\eta] + 4.013)/0.74 \qquad (2)$$

where $\overline{M}_v$ is the viscosity average molecular weight.[10] Molecular weights of the polyisobutylenes have been obtained from their intrinsic viscosities in carbon tetrachloride, using the equation[12]

$$\log \overline{M}_v = (\log[\eta] + 3.345)/0.64 \qquad (3)$$

The carbon tetrachloride was purified by successive washings with concentrated sulfuric acid, water, 10% sodium carbonate, and water, followed by drying over sodium sulfate and distilling. For the fractionated polymers it is permissible to replace $\overline{M}_v$ with $\overline{M}_w$.

The solution viscosities were measured at 30.08 ± 0.01° using a Ubbelohde no. 1 viscometer the calibration of which included the kinetic energy term.[13]

Relative viscosities, η_r, for solutions of the polystyrene fractions at different concentrations agreed with the relationship reported by Tingey[14]

$$(\ln \eta_r)/c = [\eta] - 0.125\,[\eta]^2 c \qquad (4)$$

where c is expressed in g./100 ml. Consequently it was possible to determine the intrinsic viscosity from the efflux time for a single solution.

The value of $(\ln \eta_r)/c$ for polyisobutylene solutions with relative viscosities between 1.18 and 1.22 was arbitrarily taken to represent $[\eta]$. This value differs by approximately 2% from that obtained by extrapolation to infinite dilution. In some cases, particularly for high molecular weight samples, values of $(\ln \eta_r)/c$ for η_r in the above prescribed range were obtained by extrapolation from measurements in solutions of higher relative viscosities, the error thus introduced being less than 4%.

Molecular weights reported here are generally reproducible to ±3%. For certain of the polymers of higher molecular weight this uncertainty may be ±5%.

Capillary Viscometers.—Melt viscosities in the range of 1 to 10^6 poises were determined according to the procedure previously described.[3] The viscometers consisted of straight capillary tubes, 1.0 to 2.0 mm. in diameter, each marked at four points at appropriate distances from the lower tip. The time required to fill the viscometer capillary from one mark to the next under a predetermined pressure differential was measured. In this way three determinations could be carried out successively. Absolute viscosities in poises were calculated from

$$\eta = ktp \qquad (5)$$

(10) P. J. Flory, THIS JOURNAL, **65**, 372 (1943).

(11) R. H. Ewart, paper presented at the Atlantic City Meeting of the American Chemical Society, April 14, 1947. Recently A. I. Goldberg, W. P. Hohenstein and H. Mark, *J. Polymer Sci.*, **2**, 503 (1947), have proposed yet another intrinsic viscosity–molecular weight relationship for polystyrene. We prefer the Ewart expression for our purposes since it is derived from measurements made over a range similar to that covered in our experiments. Use of the Goldberg, Hohenstein and Mark equation, however, would not affect the general nature of the relationships reported in this paper.

(12) See reference 10. We are indebted to Dr. John Rehner, Jr., of the Esso Laboratories for providing information on the relationship between intrinsic viscosities of polyisobutylene in carbon tetrachloride compared to those in diisobutylene, the solvent originally used[10] in establishing the intrinsic viscosity–molecular weight relationship. According to Rehner, the ratio $[\eta]_{CCl_4}/[\eta]_{diisobutylene}$ is 1.255 ± 0.005 for all molecular weights.

(13) The calibration method outlined in ASTM Designation D445-39T was employed.

(14) H. C. Tingey, unpublished data referred to by R. H. Ewart, "Advances in Colloid Science," Vol. II, Interscience Publishers, New York, N. Y., 1946, p. 210.

where t is the measured time, p the pressure differential (2 to 30 cm. of mercury), and k is a calibration constant computed according to Poiseuille's law from the accurately measured dimensions of the tubes. As a check on the reliability of these calibrations, the constants k for several of the viscometers were independently determined from their tp products for an oil of accurately known viscosity, 493 poises at 30.0°, obtained from the National Bureau of Standards. The two methods agreed within ±1%.

Construction of the Coaxial Viscometer.—To measure viscosities in the range of 10^5 to 10^{11} poises there was constructed a coaxial falling-cylinder viscometer (shown schematically in Fig. 1) of the type described by Segel,[15] systematically studied by Traxler and Schweyer,[16] and used by various other workers.[17] It consists of a steel block 4″ × 3.5″ × 2″ containing a cylindrical cavity of diameter B and length L, the axis of the cavity coinciding with the long axis of the block. A steel rod of smaller diameter, A, is centered coaxially in the cavity, the ends of the rod projecting beyond the respective ends of the viscometer block. The annular space around the steel rod is filled with the sample. With the viscometer suspended with its long axis in a vertical position, the rate of fall, V, of the steel rod under the influence of a suspended weight, W, is observed. The viscosity is calculated from

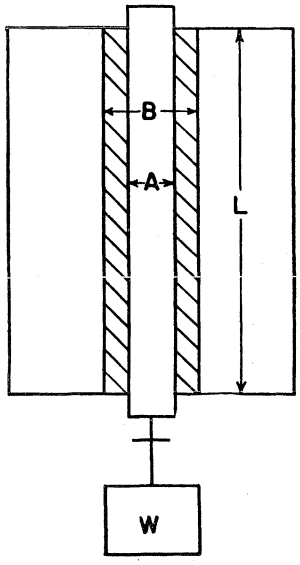

Fig. 1.—Schematic cross-sectional view of the coaxial falling-cylinder viscometer. The values of L, B and A are 10.16 cm., 1.122 cm. and 0.795 cm., respectively.

$$\eta = KW/V \qquad (6)$$

where K is a constant determined from the dimensions of the instrument according to the equation

$$K = (g/2\pi L)\ln(B/A) \qquad (7)$$

where g is the gravitational constant. The instrument was designed with provisions for: (1) molding of the polymer in the annular space about the central rod, (2) obtaining adequate temperature control and (3) the application of a load to, and observation of the rate of fall of, the central cylinder. Important features of the construction are shown schematically in Figs. 2 and 3 (omitting the screws, guide pins, and other details which would make the drawings hopelessly complex).

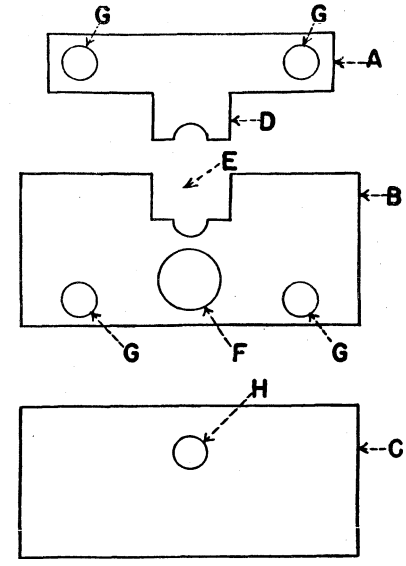

Fig. 2.—End view of the coaxial viscometer. Drawn approximately to scale.

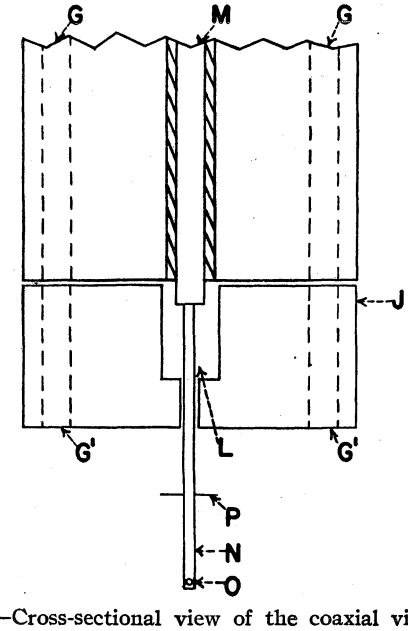

Fig. 3.—Cross-sectional view of the coaxial viscometer; not drawn to scale.

In order to permit molding of the sample within the instrument, the outer block was constructed in two parts, as illustrated by the end view of Fig. 2. As the two sections are brought together the projecting portion (D) of the top member (A) fits snugly into the trough (E) in the bottom section (B), thus providing the necessary compression of the polymer. Positioning of the steel rod in the

cavity during the molding operation is accomplished by two metal plates (C) which can be secured to the ends of the bottom section of the viscometer, each plate being provided with a hole (H) about 0.001″ larger in diameter than the rod.

Four symmetrically placed $^3/_8$″ holes (G) were bored through the length of the block for the insertion of either cartridge-type electrical heaters or copper tubes containing a cooling liquid. A larger hole (F) directly under the cylindrical cavity provides for the insertion of a Fenwal thermoswitch, which in conjunction with an electronic relay provides temperature control. To insure uniform temperature throughout the length of the polymeric cylinder, 1.5″ steel blocks (J in Fig. 3) can be attached at both ends of the viscometer. These blocks are provided with appropriate holes (G′, L) to permit insertion of the heaters and to allow for motion of the inner cylinder and its attachments.

Two thermocouple holes are provided, one being drilled in the core of the steel rod and the other in the side of the viscometer block, the latter reaching within 5 mm. of the annular cavity.

As shown in Fig. 3, a thin steel tube (N) attaches to the end of the steel rod (M) and projects out into the space below the instrument. Weights may be hung from a hole (O) which is drilled at the lower end of this tube. A needle (P) is fastened perpendicular to its length, providing a reference for observing the motion of the falling cylinder. Two rods projecting from the sides of the viscometer provide for its suspension between a pair of iron posts firmly bolted to a cast iron base.

Operation of the Coaxial Viscometer.—In preparation for the molding operation, the end plates (C) are first attached to the lower block (B) of the viscometer and the steel rod is inserted through the holes (H) in the end-plates. The upper and lower blocks are brought to temperature, usually 160°. An amount of polymer slightly in excess of that needed to fill the cavity is distributed evenly in the trough (E) and the upper block is set in place on the lower. The assembly is placed in a press equipped with heated platens and again brought to temperature. A load of 10,000 to 30,000 pounds is applied to close the viscometer assembly, the excess polymer being forced out through three vents drilled in the top of the viscometer. After about ten minutes the viscometer is cooled to room temperature under pressure, the pressure is removed and the two sections of the viscometer are securely fastened together with screws.

In order to make ready for viscosity measurements, the insulating end pieces (J) are substituted for the end plates (C), the heaters and the thermoswitch are inserted in the cavities (G, F) and the necessary electrical connections are made. The steel tube (N) is secured to the steel rod, the thermocouples are set in place, and the assembly is insulated with asbestos board and glass fabric. The instrument is mounted with its axis vertical and brought to the desired temperature. The desired weight is hung on the end of the steel tube and the position of the needle observed at various intervals.

In the experiments reported here, the temperature was controlled within ±2° between −9 and 200°, the readings of the two thermocouples agreeing within ±1°. A traveling microscope accurate to ±0.0005 cm. was used for most of the observations; one of lower accuracy, ±0.003 cm., was used in the initial experiments. Rates of fall varying from 1.5×10^{-7} to 3.5×10^{-3} cm./sec. were observed. Usually ten or more observations were made while the cylinder moved 0.15 to 0.30 cm., after which the viscometer was inverted and the load attached to the other end. Observations were repeated while the cylinder traveled in the opposite direction. The velocity of fall was observed to be independent of the direction of motion of the cylinder.

High Temperature Stability.—Both the melt viscosity and the intrinsic viscosity were observed to decrease on heating polystyrene to 217° in the presence of either air or nitrogen for periods of five minutes to two hours. However, in several instances an insoluble portion appeared and an increase in the intrinsic viscosity of the soluble portion was observed. It appears that degradation and cross-linking reactions occur simultaneously under these conditions. Addition of phenyl β-naphthylamine eliminated all evidence of gelation and reduced degradation to a negligible amount when polysytrene was heated at 217° in a nitrogen atmosphere for up to two hours. Accordingly, approximately 0.5% of this compound was incorporated into all high molecular weight polystyrenes by addition to a benzene solution of the polymer and subsequent evaporation.

No signs of gelation and only a slight decrease in the intrinsic viscosity were observed when polyisobutylene was heated to 217° in the presence of an inert atmosphere for periods of thirty to ninety minutes.

The $\overline{M}_w$ values reported here are derived from intrinsic viscosities measured after the melt viscosity had been determined. In most cases the molecular weights before and after melt viscosity determination agree within 5%.

Results

The Coaxial Viscometer.—The deformation taking place within the coaxial viscometer approaches simple shear; the difference between the outer and inner cylinder diameters being relatively small, the rate of shear is nearly uniform throughout the polymer. If the polymer undergoes Newtonian flow, (1) the motion of the falling cylinder will be linear with time, (2) the observed viscosity will be independent of the applied load and (3) the viscosity values will agree with those obtained by the capillary method.

Results shown in Table II and in Fig. 4 illustrate the constancy of the rate of displacement of the cylinder with polyisobutylenes at viscosities up to 10^{10} poises and loads up to 500 g.

[a] $\eta = 3 \times 10^6$ poises at 160°. [b] d calcd. = Vt, where V is the "best value" for the velocity in cm./sec. [c] $\eta = 2 \times 10^{10}$ poises at 8°.

However, in many cases, particularly at the higher viscosities, there was observed an initial non-linear dependence of displacement on time which later became linear (*i. e.*, the straight lines in Fig. 4 do not go through the origin). It was assumed that the non-linear portion was due to a time-dependent elastic deformation which, however, reached completion in a relatively short time.[18] Since the elastic deformation was of no interest in this work, sufficient time was allowed in most of the experiments for the completion of the elastic deformation prior to observing the fall of the cylinder. Hence, the times recorded in Table II are referred not to the time of application of the load but rather to some arbitrary time thereafter.

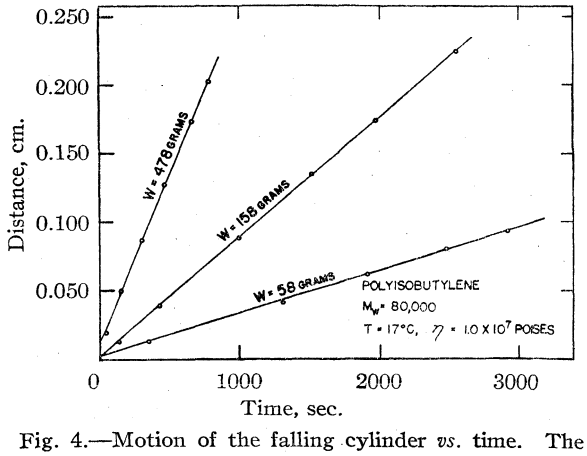

Fig. 4.—Motion of the falling cylinder *vs.* time. The initial observation (distance 0 at zero time) was made as soon as possible after attaching the weight.

Observed viscosity values for polyisobutylenes are independent of the applied load at least up to 500 g., provided the viscosity be less than 10^9 poises. Typical data illustrating this point are given in Table III. The apparent viscosity decreases with increasing load for higher values.

TABLE III

THE APPARENT VISCOSITY AS A FUNCTION OF APPLIED LOAD

In	58	2.85	to zero load	poises
Average (2.95 ± 0.05) × 10^6 poises				

The viscosity at zero load, where the limiting flow characteristics may be assumed to correspond to ideal Newtonian behavior, was obtained in such cases by linear extrapolation (Fig. 5).

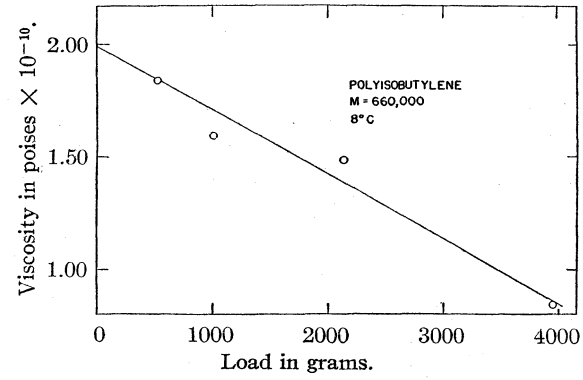

Fig. 5.—The apparent viscosity *vs.* load, employing the coaxial falling-cylinder viscometer.

Measurement of the viscosity of polyisobutylene of molecular weight 80,000 by this method yielded 88,000 poises at 87° which, from the temperature coefficient of flow (*cf. seq.*), corresponds to 79,000 poises at 89°. A similar determination at the latter temperature using a capillary viscometer yielded 80,700 poises. Thus, the two methods are consistent.

Attempts to measure accurately the viscosity of high molecular weight polystyrene in the coaxial viscometer were unsuccessful. Frequently the apparent viscosity was observed to vary with time and/or with the applied load. The results

which appeared most reliable were lower than the corresponding values obtained with capillary viscometers by a factor of at least three. These discrepancies are believed to have been caused by air bubbles trapped in the polystyrene. All efforts to mold high molecular weight polystyrenes in the viscometer so that they were reasonably free of bubbles failed. On the other hand, polyisobutylene could be molded almost bubble-free with no great difficulty.

Viscosity–Temperature Relationships.—The viscosities of fifteen polystyrene fractions ranging in molecular weight from 3700 to 134,000 were measured with capillary viscometers at various temperatures. The maximum temperature range covered was 217 to 53°. Representative data are given in Table IV, and the data for thirteen of the fractions are plotted as log (η_T/η_{217}) *vs.* $1/T$ (°A.$^{-1}$) in Fig. 6. The viscosity ratio is employed in order to facilitate comparison of results for polymers differing in molecular weight. The relationship between log (η_T/η_{217}) and $1/T$ is non-linear. The data for eight fractions with molecular weights from 25,700 to 134,000 may be represented by a single curve (curve 1 of Fig. 6) when plotted in this manner. For fractions of lower molecular weight, a series of curves are obtained, their slopes being lower the lower the molecular weight. This dependence of the viscosity–temperature coefficient on the molecular weight is further illustrated in Fig. 7 where log (η_T/η_{217}) for temperatures of 160, 176 and 190° are plotted *vs.* the molecular weight. (The molecular weights employed here and in Tables IV, V and VI are based on intrinsic viscosity measurements and, hence, to the extent that the particular type of average requires specification when dealing with fractionated samples, they represent viscosity averages. For reasons which will appear later, however, the particular average is not specified.) The temperature-coefficient for polystyrene at a given temperature increases with increasing molecular weight up to approximately

Both types of viscometers were employed for measurements on each of the two highest molecular weight fractions. The capillary method alone was employed for the other polyisobutylenes. The data for the various fractions are represented by a single curve in Fig. 8. The viscosity-temperature coefficient appears to be independent of molecular weight over the range investigated. The corresponding curve for high molecular

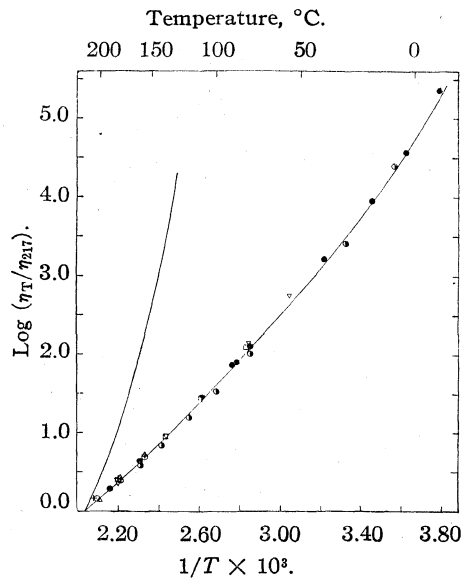

Fig. 8.—Log (η_T/η_{217}) *vs.* $1/T$ (°A.$^{-1}$) for polyisobutylene fractions of various molecular weights: ◑ 660,000, ● 80,000, ○ 81,500, + 56,500, △ 38,200, □ 22,400, ▽ 11,200. The curve to the left, representing high molecular weight polystyrene, is a duplicate of curve 1 of Fig. 6.

weight polystyrene (curve 1 of Fig. 6) has been included for comparison.

The present results are in good agreement with those of Ferry and Parks[19] on the viscosity of an unfractionated polyisobutylene of cryoscopic molecular weight 4900, as obtained from falling sphere and rotating cylinder measurements. As shown in Fig. 9, their data fall on or near the curve for polyisobutylene (from Fig. 8) provided the viscosity of their polymer at 217° (which they did not determine) is assumed to be 7.94 poises.

Both polymers exhibit a non-linear relationship between log η_T and $1/T$. The "apparent" energy of activation, E_T, for viscous flow at temperature T, defined as $2.3R[d(\log \eta)/d(1/T)]$, increases with decreasing temperature for both polystyrene and polyisobutylene. As shown in Table VI (see also Fig. 8), E_T for high molecular weight polystyrene in this temperature range is greater than the corresponding value for polyisobutylene and it increases more rapidly with decreasing temperature. The dependence of the viscosity–temperature coefficient for polystyrene on molecular weight below 25,000 is reflected in the diminished values of E_T in this range.

Viscosity and Molecular Weight.—The viscosities of the lower polyisobutylenes were measured at 217° by capillary viscometers; the coaxial method was used in most cases on the higher polymers. These latter measurements were carried out at several lower temperatures and the corresponding values at 217° were obtained by extrapolation using the viscosity–temperature dependence presented above. The validity of these extrapolations is confirmed by close agreement between values extrapolated from measurements at different temperatures, as shown in Table VII. Viscosities for polystyrene at 217° were obtained by the capillary method.

TABLE VII

EXTRAPOLATION OF COAXIAL VISCOMETER DATA TO 217°

Polymer	T, °C.	log η_T	Extrapolated log η_{217}	Average log η_{217}
PB5F1	160	8.05	7.40	7.40
PB5F2	160	7.69	7.04	7.02 ± 0.03
	115	8.34	6.99	
PB5F3	160	6.74	6.09	6.08 ± 0.01
	112	7.47	6.07	
PB2F4	88	6.38	4.50	4.51 ± 0.01
	38	7.73	4.51	

All of the above data as obtained at 217° or extrapolated to that temperature are summarized in Table VIII and in Figs. 10 and 11 where log η_{217} is plotted against $\overline{M}_w^{1/2}$. Curves drawn through the sets of points for the two polymers are of the same general character. While certain limited portions of the data may be approximated by straight lines, no linear relationship is valid over a wide molecular weight range. For polystyrenes below 25,000 the viscosity–molecular weight relationship is of little significance since for these polymers the viscosity–temperature behavior is dependent on the molecular weight. However, for convenience these data have been included and a dotted line has been drawn through the points.

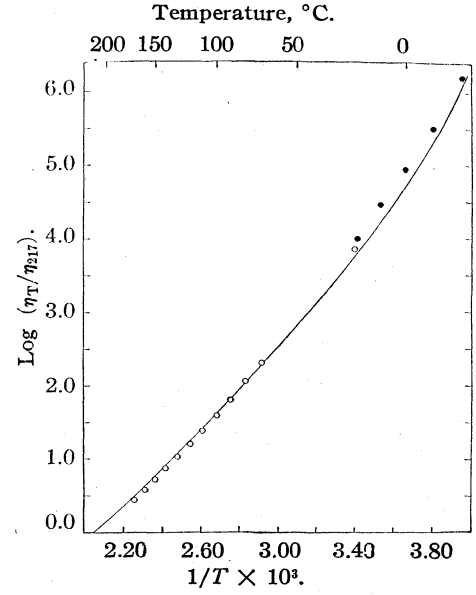

Fig. 9.—Log (η_T/η_{217}) *vs.* $1/T$ (°A.$^{-1}$) for polyisobutylene. The solid line is a reproduction of the curve for polyisobutylene in Fig. 8. The points represent data obtained by Ferry and Parks (ref. 19) on an unfractionated polyisobutylene of cryoscopic molecular weight 4900. The open circles represent falling sphere data; the dark circles represent data obtained with a rotating cylinder viscometer. The value of η_{217}, which they did not measure, was arbitrarily taken as 7.94 poises.

The similarity in behavior of these two polymers is further illustrated if these data are plotted as log η_{217} *vs.* log $\overline{M}_w$. In such plots, the two sets of points may be represented fairly satisfactorily by two straight lines, with identical slopes. However, the approximate linearity of these log–log plots probably is of limited significance, the correct function being of a more complicated nature.

The Viscosities of Mixtures.—Any choice of a particular molecular weight average in Figs. 7, 10, and 11 is necessarily arbitrary so far as the foregoing data are concerned, inasmuch as the various molecular weight averages, $\overline{M}_n$, $\overline{M}_v$, and $\overline{M}_w$ for fractionated samples are similar. In order to establish the particular averages (if any) on which the viscosity and the viscosity–temperature coefficients depend explicitly, seven mixtures of polystyrene fractions and two of polyisobutylene were prepared as detailed in Table IX by evaporating benzene solutions of two fractions of widely separated molecular weights. The melt viscosities of the mixtures were observed at 217° and several lower temperatures (Table IX). In Table X val-

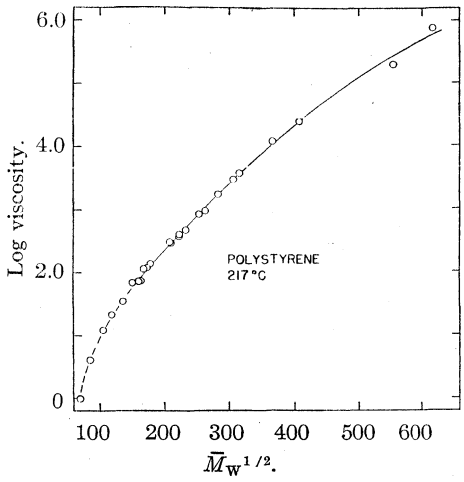

Fig. 10.—Log η_{217} *vs.* $\bar{M}_W^{1/2}$ for polystyrene fractions: measurements were made with capillary viscometers. The viscosity–temperature curves for polystyrenes below 25,000 are not parallel; hence the dotted line through the points for these polymers is for convenience only.

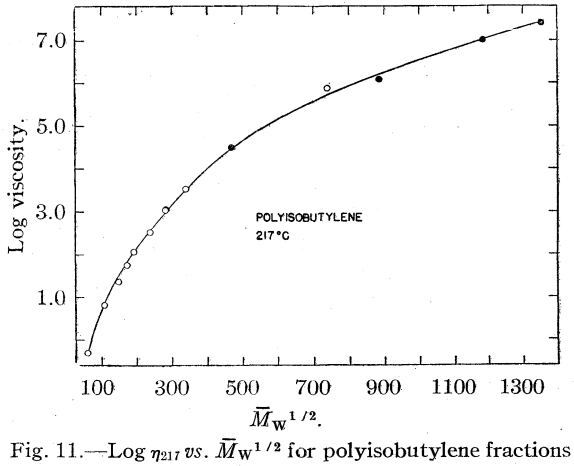

Fig. 11.—Log η_{217} *vs.* $\bar{M}_W^{1/2}$ for polyisobutylene fractions: observations with the coaxial viscometer(extrapolated), ●; with capillary viscometers, ○.

ues of $\bar{M}_n$, $\bar{M}_v$ and $\bar{M}_w$ for these mixtures are given (Columns 6, 2, and 4, respectively) as calculated by the usual equations

$$\bar{M}_n = \sum_i w_i \Big/ \sum_i (w_i/M_i), \qquad (8)$$

$$\bar{M}_v = \left[\sum_i w_i M_i^a \Big/ \sum_i w_i\right]^{1/a} \qquad (9)$$

$$\bar{M}_w = \sum_i w_i M_i \Big/ \sum_i w_i \qquad (10)$$

where w_i is the weight fraction of the species of molecular weight M_i, and a is the exponent in the equation relating the intrinsic viscosity to molecular weight. The experimental values of $\bar{M}_v$ (Column 3), obtained from intrinsic viscosities, agree rather well with the calculated values, although for the higher molecular weight mixtures discrepancies as great as 6% occur.

The quantity designated as "$\overline{M}_{217}$" (Column 5) represents the molecular weight of a homogeneous fraction exhibiting the same viscosity at 217° as the mixture; the $\overline{M}_{217}$ values have been deduced from the measured viscosities of the mixtures at 217° (Table IX) and the previously established curves relating viscosity to molecular weight for the fractions (Fig. 10 or 11). Values of $\overline{M}_{217}$ for both of the polyisobutylene mixtures and for the polystyrene mixtures for which $\overline{M}_n$ is greater than 25,000 are in good agreement with the corresponding *weight average* molecular weights. For each of the polystyrene mixtures for which $\overline{M}_n$ is less than 25,000 (E, F, G), $\overline{M}_{217}$ lies between the number average and viscosity average molecular weights.

The quantity designated as "$\overline{M}_T$" (Column 7) represents the molecular weight of the polystyrene fraction having the same viscosity–temperature relationship as that of the mixture, as deduced from the observed values of (η_T/η_{217}) for the mixture (Table IX) and the curves of Fig. 7. For the two polystyrene mixtures with $\overline{M}_n$ greater than 25,000 (C, D) the viscosity–temperature coefficients are identical with those previously observed to be characteristic of polystyrene fractions having molecular weights in excess of 25,000. For each of the mixtures of lower molecular weight (E, F, G), $\overline{M}_T$ is approximately equal to the *number average* molecular weight of the mixture.

The ratio η_T/η_{217} for polyisobutylene mixture H at $T = 160°$ and 190° (Table IX) was observed to be in agreement with the corresponding value for the polyisobutylene fractions. As with the fractions, no dependence on molecular weight is evident.

Generalizing the above results obtained on simple mixtures of fractions, we conclude that the melt viscosities of polystyrenes for which the *number average* molecular weight is greater than 25,000 and of all polyisobutylenes (above a molecular weight of 11,200 at least) are explicit functions of the *weight average* molecular weight, regardless of the degree of molecular weight heterogeneity. Further, the viscosity–temperature coefficients for these polymers are independent of molecular weight distribution as well as of molecular weight. For polystyrenes of $\overline{M}_n$ less than 25,000, the viscosity–temperature coefficient varies with, and is determined by, the *number average* molecular weight, being otherwise independent of the molecular weight distribution. The melt viscosities of polystyrenes in this molecular weight (number average) range are not uniquely determined by any specific average molecular weight.

Discussion

Failure of equation (1) to accurately represent the dependence of melt viscosities of polystyrene and polyisobutylene on molecular weight is surprising in the face of the number of instances, covering a variety of polymers, in which the square root relationship has been reported to hold. Perusal of these various sets of results reveals, however, either that the molecular weight range covered generally was too limited for a conclusive decision or that the molecular weights were determined by methods which fail to yield an accurate measure of the weight average or something consistently proportional to it. These aspects of previous investigations on the applicability of equation (1) are summarized in Table XI. Only

in the case of the glycol–dibasic acid polyesters has the relationship been demonstrated to apply precisely over a manifold range; it probably applies similarly to the polyamides. The results for polyesters and polyamides are limited to moderate molecular weights, however; it is conceivable that the square root relationship may fail for higher molecular weight polymers of these series.

TABLE XI

Polymer	Mol. wt. range	Mol. wt. determination	Reference
Glycol–dibasic acid polyesters	500–20,000 (40-fold)	End-group titration	3
Polyundecanoates	5,000–22,200 (4-fold)	End-group titration	4
Polyamides	2,880–37,100 (13-fold)	Stoichiometric proportion of reactants	5
Polydimethylsiloxane	2,500–160,000 (64-fold)	Osmotic pressure[a]; end group titration; light scattering	8
Polyisobutylene	134,000–545,000 (4-fold)	Intrinsic viscosity	7
Polyethylene	12,000–36,000 (3-fold)	Staudinger viscosity[b]	6
Paraffin wax–polyethylene mixtures	400–17,000 (42-fold)	Staudinger viscosity[b]	6

[a] Since these three methods were applied to different polymers none of which were fractionated, the results should not be strictly comparable on a weight average basis. [b] Molecular weights by this method are undoubtedly of limited significance.

The difference in the nature of the viscosity–molecular weight relationship for polystyrene and polyisobutylene on the one hand and that for polyesters and polyamides on the other cannot be dismissed as a mere consequence of the displacement of the respective molecular weight ranges covered. Enlarged plots of log η *vs.* $\bar{M}_w^{1/2}$ using the data for polystyrene and polyisobutylene fractions within the molecular weight range covered for the polyesters and polyamides (or, preferably, over the same range of chain lengths) show definite deviations from linearity which considerably exceed the experimental error; the polyester and polyamide plots, on the other hand, are precisely linear.[3] The conclusion cannot be avoided that the square root relationship applies to certain polymers such as the polyesters (at least up to moderate molecular weights), but that it cannot be applied to other polymers such as those investigated here, except, perhaps, as a short range rough approximation.[20] It may be significant that these polyesters and polyamides possess regularly occurring polar groups conducive to crystallization whereas polyisobutylene and polystyrene are nonpolar in character.

It is noteworthy that the melt viscosity appears to be determined explicitly by the weight average molecular weight (except for low molecular weight polystyrenes) in all cases where the effect of molecular weight heterogeneity has been tested.

Recently attempts have been made to interpret the effects of polymer molecular weight and of plasticizer content on softening points[21] and brittle temperatures[22] through the use of relationships based on equation (1). In the light of our results, which refute the general applicability of equation (1), these treatments are of questionable value.

Both polystyrene and polyisobutylene, in common with linear polyesters[3] and many other complex liquids,[23] exhibit non-linear relationships between ln η and $1/T$. If the usual relationship

$$\eta = De^{E/RT} \qquad (11)$$

where E is the activation energy for viscous flow, is to be applied here, either D or E (or both) must be temperature dependent. Hence, to regard the value of $R[\mathrm{d}(\ln \eta)/\mathrm{d}(1/T)]$ as the energy of activation probably is incorrect. The value of E_T considered here is merely a measure of the slope of the log η *vs.* $1/T$ curve at the specified temperature, although for convenience it has been designated as an apparent energy of activation.

There exists in the literature much disagreement concerning the temperature coefficient of viscosity of polystyrene. Spencer and Williams arrived at an estimate for E_T of 8 to 12 kcal. from viscosity measurements between room temperature and 100° on concentrated solutions of polystyrene in several aromatic solvents.[24,25] The linear extrapolation involved in obtaining E_T from the properties of solutions in which the maximum concentration was 50% by weight of polystyrene is of doubtful validity. The viscosity–temperature coefficient as deduced by the same authors[24] from Nason's results[26] on the rates of extrusion at high stresses is of uncertain significance. Observations of Foote[27] on the flow of polystyrene in capillary molds under high pressures indicated a dependence of E_T on temperature, his estimates varying from 40 to 80 kcal. between 200 and 100°. Many of these experiments involved high stresses and the accuracy was admittedly low. Wiley's measurements[28] on the elongation of a strip of polystyrene under a constant load permit a calculation of E_T of 18 kcal. and 79 kcal. at 190 and 150°, respectively, a variation in excess of that reported here. Perhaps, as has been suggested elsewhere,[21] the viscous and elastic effects have not been separated in this case.

Thus, while the confusion concerning the viscosity–temperature coefficient of polystyrene may be due in part to the variation of E_T with tempera-

(20) Investigations now in progress on the viscosities of very low molecular weight polyisobutylene and of polyesters of exceptionally high molecular weight are expected to clarify the difference in the behavior of polymers of these two series.

ture and with molecular weight (for $\overline{M}_n$ less than 25,000), it is chiefly attributable to the low accuracy and unreliability (for this purpose) of much of the data on which previous estimates were based.[29]

Tuckett[21] has suggested that any apparent increase of E_T with decreasing temperature above a value of 20 kcal. is due to the simultaneous occurrence of a slow time-dependent elastic deformation, the activation energy of which he assumes to be greater than that for viscous flow. Elastic effects and other non-Newtonian disturbances were eliminated in the present work by operating at low rates of shear and at relatively large deformations. Results obtained with the capillary viscometers invariably were found to be independent of the pressure employed; the highest viscosities, determined with the coaxial viscometer, were derived from measurements made after elastic deformation appeared to have reached equilibrium. The successful elimination of any complicating elastic effects in our experiments is confirmed by the independence of the viscosity–temperature coefficient of molecular weight (except for polystyrenes for which $\overline{M}_n$ is less than 25,000). This behavior is contrary to that predicted by Tuckett on the basis of the aforementioned assumptions. Tuckett's assumption that E_T for viscous deformation is approximately independent of temperature and that it may not exceed 20 kcal. is not substantiated.

Since the viscosity–temperature coefficient has been observed to depend on the *number average* molecular weight, a commercial polystyrene with a high intrinsic viscosity will not necessarily possess the limiting viscosity–temperature coefficient for high molecular weight polystyrene. The presence of even a small amount of low molecular weight material (*e. g.*, unreacted monomer or an impurity) may cause the number average molecular weight to be less than 25,000, although the weight average molecular weight may be high. This suggests also that the efficiency of low molecular weight compounds as plasticizers for polystyrene is perhaps due to their ability to lower $\overline{M}_n$ (and thus E_T).

Acknowledgment.—The authors wish to acknowledge the assistance of Mr. Robert E. Marshall in carrying out the fractionations and measuring solution viscosities.

(29) Since this manuscript was written, Spencer and Dillon, *J. Colloid Sci.*, **3**, 163 (1948), have reported viscosity–temperature data for high molecular weight polystyrene which are in substantial agreement with the present results. They have also investigated the dependence of viscosity on shearing stress. According to their results, our viscosity values for polystyrenes above 100,000 should in no case be in error by more than about 10% due to failure to extrapolate to zero shearing stress.

Summary

1. The viscosities of polystyrene and polyisobutylene fractions over molecular weight ranges of 4900 to 381,000 and 3,500 to 1,830,000, respectively, have been determined at 217°. The viscosities of polystyrene fractions covering the molecular weight range of 3,700 to 134,000 were measured at several temperatures, the maximum range being 53 to 217°. Similar data were obtained for polyisobutylene fractions in the molecular weight range of 11,200 to 660,000 over a maximum temperature range of −9 to 217°.

2. The viscosity–molecular weight relationships have been expressed in graphical form. Log η_{217} is not a linear function of $\overline{M}_w^{1/2}$ for either of these polymers over the wide range in the molecular weight investigated.

3. Both polymers exhibit non-linear relationships between log η and $1/T$. The viscosity–temperature coefficient is independent of molecular weight except for polystyrene fractions of molecular weight less than 25,000, for which the coefficient at a specified temperature decreases with decreasing molecular weight.

4. From the viscosities of mixtures of fractions of widely separated molecular weights at 217° and at several lower temperatures, the following generalizations have been made: (a) The melt viscosities of these polymers at a specified temperature are determined by the weight average molecular weights, regardless of heterogeneity, except for polystyrenes of number average molecular weight less than 25,000. For the latter the melt viscosity is not uniquely determined by $\overline{M}_n$, $\overline{M}_v$, or $\overline{M}_w$, but appears to be some function of the particular molecular weight distribution. (b) The viscosity–temperature coefficient of these polymers is independent of both molecular weight distribution and molecular weight except for polystyrenes with $\overline{M}_n$ less than 25,000. For the latter the viscosity–temperature coefficient is determined by the number average molecular weight, being otherwise independent of molecular weight distribution.

5. The results of previous investigations on the viscosity–molecular weight and viscosity–temperature relationships of polymeric materials have been discussed.

6. A coaxial falling-cylinder viscometer was designed for determining the viscosity of high molecular weight polyisobutylene. Details have been given concerning its construction and use.

Thiophosphoric Amides: Aminolysis

BY ALLEN C. BUCK[a] AND HERMAN P. LANKELMA

Mixed thiophosphoric triamides of the type $(RNH)_2PS(NHR_1)$ where R is an aromatic radical and R_1 an aliphatic radical have been prepared by Michaelis[1] by the stepwise aminolysis of thiophosphoryl chloride

$$2R_1NH_2 + PSCl_3 \longrightarrow (R_1NH)PSCl_2 + R_1NH_2\cdot HCl \quad (1)$$

$$(R_1NH)PSCl_2 + 4RNH_2 \longrightarrow (R_1NH)\underset{S}{P}(NHR)_2 + 2RNH_2\cdot HCl \quad (2)$$

Michaelis could not use this method to prepare mixed triamides in which both radicals were aromatic since the intermediate, $RNHPSCl_2$, lost hydrogen chloride to give RN=PSCl.

A new approach to the preparation of mixed thiophosphoric triamides was suggested by the addition of aniline to dimeric thiophosphoric anil anilide.[2] The addition of amines to dimeric thiophosphoric anil anilide could yield mixed thiophosphoric triamides

$$(C_6H_5N\text{—}\overset{S}{P}\text{—}NHC_6H_5)_2 + RNH_2 \longrightarrow 2(C_6H_5NH)_2\overset{S}{P}\text{—}NHR \quad (3)$$

When RNH_2 in equation (3) was benzylamine, in excess, the product at temperatures of 30 and 60° was a mixture containing triamides of both benzylamine and aniline. No pure mixed triamide could be isolated. When the reaction temperature was raised to 130° tribenzylthiophosphoric amide was isolated in good yield. This product could have formed only through the addition of benzylamine to dimeric thiophosphoric anil anilide and the replacement of aniline by benzylamine

$$(C_6H_5N\text{—}\overset{S}{P}\text{—}NHC_6H_5)_2 + 6C_6H_5CH_2NH_2 \longrightarrow 2(C_6H_5CH_2NH)_3PS + 4C_6H_5NH_2 \quad (4)$$

A second approach to the preparation of mixed thiophosphoric triamides appeared to be possible through the reaction of dithiophosphoric dianilide with amines according to the equation

$$(C_6H_5NH)_2PSSH + RNH_2 \longrightarrow (C_6H_5NH)_2\overset{S}{P}\text{—}(NHR) + H_2S \quad (5)$$

This reaction has already been carried out with aniline to give thiophosphoric trianilide. When dithiophosphoric dianilide was treated with benzylamine, tribenzyl thiophosphoric amide rather than a mixed triamide was obtained. Tribenzylthiophosphoric amide must have resulted from the concurrent formation of a mixed triamide by loss of hydrogen sulfide between dithiophosphoric dianilide and benzylamine and displacement of aniline by benzylamine

$$(C_6H_5NH)_2PSSH + 3C_6H_5CH_2NH_2 \longrightarrow (C_6H_5CH_2NH)_3PS + 2C_6H_5NH_2 + H_2S \quad (6)$$

The displacement of aniline by benzylamine with the formation of benzylamine triamide in each of these cases suggested the possibility of a similar reaction occurring also with a triamide. The reaction of triamides with primary aliphatic amines and with primary aromatic amines was therefore studied. This reaction could lead to mixed triamides $(RNH)_2\overset{S}{P}(NHR')$ and $(RNH)\overset{S}{P}(NHR')_2$ by partial displacement or to $(RNH)_3PS$ by complete displacement. The results of this study are shown in Table I.

The reaction of thiophosphoric trianilide with tributylamine and with dimethylaniline was tried to determine the effect of tertiary amines, which could not enter into displacement reactions.

When thiophosphoric trianilide was heated at 130° in a large excess of tributylamine, hydrogen sulfide was continuously evolved for twenty hours. Aniline and the phosphate ion were identified as decomposition products. Dimethylaniline promoted a similar decomposition, but required a much longer reaction time. In neither case could any thiophosphoric trianilide be recovered.

It is apparent that this decomposition not only resulted in the rupture of nitrogen–phosphorus bonds, but that the rate at which these bonds were broken was related to the basicity of the tertiary amine used. It would follow that thiophosphoric triamides heated in excess primary aliphatic or aromatic amines would have nitrogen-phosphorus bonds severed in an analogous fashion. In this case, however, a new triamide could form from the excess amine present. Thus is it possible that displacement reactions involving primary amines and thiophosphoric triamides with primary amine residues attached to phosphorus be expressed as a mobile equilibrium

$$(RNH)_3PS + 3R'NH_2 \longleftrightarrow (R'NH)_3PS + 3RNH_2 \quad (7)$$

The position of equilibrium would depend upon the relative stability of the phosphorus–nitrogen bond of the two triamides. The relative rates at which tertiary amines decomposed thiophosphoric acid trianilide indicated that the aliphatic amines would sever nitrogen–phosphorus bonds more rapidly than the less basic aromatic amines. It would follow in equation (7), that the nitrogen–phosphorus bonds of an aliphatic amine would be more stable than that of an aromatic amine. Under the conditions used with the triamides of primary

[a] Piperidyl.

amines, the nitrogen–phosphorus bond of the triamide of a secondary amine, piperidine, was not severed by tertiary amines, either aliphatic or aromatic. Primary amines also would not be expected to sever these bonds under comparable reaction conditions. The establishment of an equilibrium and therefore displacement reactions could not occur. This was verified; Table I, number 5.

This equilibrium could also be shifted by mass action. This is shown by the reaction between thiophosphoric trianilide and benzylamine. Using a large excess of benzylamine, tribenzyl thiophosphoric amide was formed in high yield; Table I, number 3. The reverse displacement could not be accomplished under comparable reaction conditions. Since the boiling points of benzylamine and aniline lie close together, selective removal of the aniline could not be used to displace the equilibrium. However, this was accomplished by using tri-*n*-propylthiophosphoric amide. In this case the triamide with the weaker nitrogen–phosphorus bonds was formed due to the selective removal of the low boiling *n*-propylamine from the equilibrium mixture, Table I, number 9.

The displacement of aniline from thiophosphoric acid trianilide by *p*-chloroaniline, Table I, number 7, was accomplished by the addition of an excess of *p*-chloroaniline to the equilibrium mixture. The displacement of *n*-propylamine from tri-*n*-propylthiophosphoric amide by benzylamine, Table I, number 4, was accomplished with the use of excess benzylamine and the continuous removal of the low boiling *n*-propylamine displaced.

Experimental

Action of Benzylamine on Dimeric Thiophosphoric Anil Anilide.—Six grams of dimeric thiophosphoric acid anil anilide and 15 g. of benzylamine were heated at 180° for three hours. Crystallization of the product from alcohol gave 4 g. of tribenzyl thiophosphoric amide, m. p. 120–123°, a 44% yield. It was identified by a mixed melting point.

At a temperature of 30 and 60° a product melting at 70–80° was obtained. It could not be purified by crystallization from alcohol. It was shown to be a mixture of triamides by cleavage with acetic acid.[2] Acetanilide, benzylamine and phosphoric acid were identified in the cleavage products. At a temperature of 130° a 50% yield of the tribenzyl thiophosphoric amide was obtained.

Action of Benzylamine on Dithiophosphoric Dianilide.—Six grams of benzylamine and 5.6 g. of dithiophosphoric dianilide were heated to 140–150° for four hours. The product was washed with dilute hydrochloric acid and crystallized from alcohol; 1.5 g. of tribenzyl thiophosphoric amide melting at 123–125° was obtained. Aniline was identified in the acid washings by conversion to acetanilide.

Action of Tertiary Amines on Thiophosphoric Trianilide.—Three grams of thiophosphoric trianilide and 20 g. of tributylamine were heated at 130° in an atmosphere of nitrogen. The evolution of hydrogen sulfide was detectable for twenty hours. The mixture was made alkaline with sodium hydroxide solution and steam distilled. The distillate was extracted with ether and the amines recovered by evaporation of the ether. The aniline was separated and identified as the benzenesulfonamide. The aqueous solution from the steam distillation gave a strong test for phosphate ion with ammonium molybdate solution.

Action of Amines on Thiophosphoric Triamides.—The combinations of amine and triamide employed, with the reaction conditions and results, are shown in Table I. The triamides employed were prepared as follows: thiophosphoric acid trianilide from aniline and phosphorus pentasulfide[2]; tribenzyl, tri-*n*-propyl, and tripiperidyl thiophosphoric amides from the amine and thiophosphoryl chloride by the method of Michaelis[1] in yields of 57, 84 and 25%, respectively. The triamide formed in each case was identified by a mixed melting point and the displaced amine was identified as an acyl derivative. In two of the cases where a mixture of triamides was obtained, Table I, numbers 2 and 8, cleavage of the amides with acetic acid yielded a mixture of acetanilide and benzylamine.

Summary

The preparation of mixed thiophosphoric triamides by the addition of amines other than aniline to dimeric thiophosphoric anil anilide was prevented by aminolysis reactions. Similarly, the reaction of amines other than aniline with dithiophosphoric dianilide failed to yield mixed thiophosphoric triamides due to aminolysis reactions.

The primary amine thiophosphoric triamides underwent complete aminolysis reactions upon heating with other primary amines. The thiophosphoric triamide of the secondary amine, piperidine, did not undergo this reaction.

An interpretation of the aminolysis reactions has been presented.

The Reaction of Aniline with Phosphorus Pentoxide: Phosphoric Anilides

BY ALLEN C. BUCK[1] AND HERMAN P. LANKELMA

The reaction of six and four moles of aniline with one mole of phosphorus pentasulfide has been shown to yield thiophosphoric trianilide and dithiophosphoric dianilide, respectively.[1a]

The reaction of six and four moles of aniline with one mole of phosphorus pentoxide under similar conditions gave aniline metaphosphate as the major reaction product along with small amounts of aniline orthophosphate. In addition to aniline metaphosphate, the reaction of four moles of aniline and one mole of phosphorus pentoxide at room temperature in an inert solvent such as toluene gave very low yields of phosphoric dianilide.

The formation of some phosphoric dianilide suggested that the reaction was similar to that with the sulfide, that is, the formation of a dianilide which subsequently reacts with aniline at higher temperatures to form a trianilide. However, the reaction of aniline with phosphorus pentoxide differed in that aniline metaphosphate was formed.

$$2C_6H_5NH_2 + P_2O_5 \longrightarrow (C_6H_5NH)_2POOH + HPO_3 \quad (1)$$

$$C_6H_5NH_2 + HPO_3 \longrightarrow C_6H_5NH_2\cdot HPO_3 \quad (2)$$

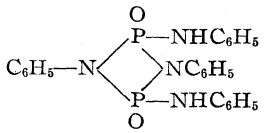
With phosphorus pentasulfide, however, the formation of dithiophosphoric dianilide was not interfered with by the formation of a salt of aniline.

Although phosphoric trianilide was not obtained by the action of aniline on phosphorus pentoxide, it has been prepared by Michaelis and Soden[2] from aniline and phosphorus oxychloride. Phosphoric trianilide, like thiophosphoric trianilide, was stable to prolonged refluxing in water, dilute acids and bases. It was also stable toward glacial acetic acid under conditions which effect a cleavage of thiophosphoric trianilide.[1a]

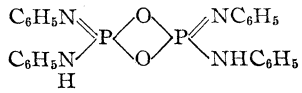
Michaelis and Silberstein[3,4] observed that phosphoric trianilide was thermally unstable when heated under a vacuum, losing aniline to form dimeric phosphoric anil anilide

$$2(C_6H_5NH)_3PO \longrightarrow (C_6H_5N{-}\overset{\overset{O}{\|}}{P}{-}NHC_6H_5)_2 + 2C_6H_5NH_2 \quad (3)$$

They recorded a melting point of 357° for this compound and suggested a cyclic amide structure (A), whereas Oddo[5] reported a melting point of 320–325° and suggested a cyclic isoamide structure (B)



(A)



(B)

Dimeric phosphoric anil anilide, prepared in this laboratory by thermal decomposition of phosphoric trianilide, melted at 357–358° as reported by Michaelis and Silberstein. It has been previously shown that thiophosphoric trianilide exhibited similar thermal instability.[1a]

Since dimeric thiophosphoric anil anilide had reacted with aniline to reform thiophosphoric trianilide,[1a] it appeared that phosphoric anil anilide might undergo a similar reaction. When dimeric phosphoric anil anilide was refluxed in excess aniline, it slowly dissolved with the formation of quantitative yields of phosphoric trianilide.

It has previously been shown that the nitrogen–phosphorus bond in thiophosphoric trianilide was ruptured by tributylamine and that aniline could be displaced from it with primary amines.[6] Phosphoric trianilide was not attacked by tributylamine under similar conditions. This suggested that the aniline might not be displaced by primary amines. Accordingly phosphoric trianilide was treated with excess benzylamine under conditions which had displaced aniline from thiophosphoric trianilide to give eighty per cent. yields of tribenzyl thiophosphoric amide.[6] The phosphoric trianilide was recovered unaltered.

The stability of phosphoric trianilide to displacement reactions suggested that mixed phosphoric triamides might be prepared by the addition of amines other than aniline to dimeric phosphoric anil anilide

$$(C_6H_5N{-}\overset{\overset{O}{\|}}{P}NHC_6H_5)_2 + 2RNH_2 \longrightarrow 2(C_6H_5NH)_2\overset{\overset{O}{\|}}{P}(NHR) \quad (4)$$

This reaction was first tried using *n*-propylamine as the amine. The solid product obtained from the reaction was a mixture which exhibited resistance to hot dilute acids and bases, a property of trianilides, from which phosphoric trianilide was isolated after several crystallizations. When this reaction was repeated with secondary amines, di-*n*-propylamine and piperidine, a mixture of products was again obtained and phosphoric trianilide was isolated after two crystallizations.

Theoretically, amines could react with dimeric phosphoric anil anilide in one or both of the following ways depending upon whether nitrogen–

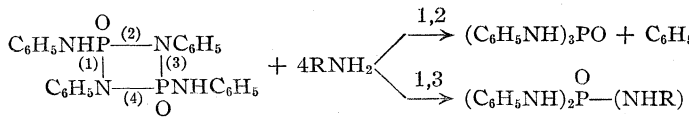
phosphorus bonds 1,2 or 1,3 of the ring were ruptured



Each pair of bonds would have an equal chance to be ruptured and a mixture of products would therefore be expected. The presence of phosphoric trianilide as one of the reaction products regardless of the nature of RNH_2 supported the view that the addition of amines to dimeric phosphoric anil anilide did occur by the rupture of bonds 1,2 above.

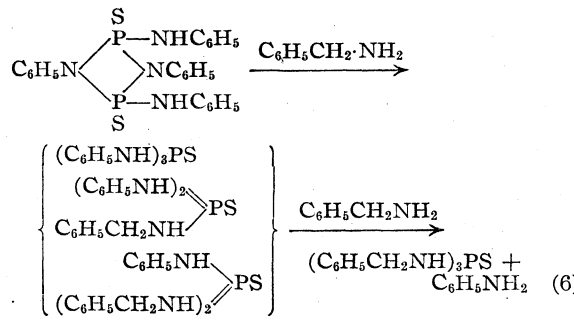
Since mixtures of products were obtained from which phosphoric trianilide was isolated only after repeated crystallization, it appeared quite likely that this mixture contained the two similar mixed phosphoric triamides suggested in equation (5) above. The similar solubilities of these mixed triamides prevented separation into the individual components.

The formation of phosphoric trianilide by the addition of two moles of an amine other than aniline to dimeric phosphoric anil anilide offers proof that the structure proposed by Michaelis[3] for dimeric phosphoric anil anilide is correct. The structure proposed by Oddo would not yield phosphoric trianilide but a mixed triamide.

By analogy with dimeric phosphoric anil anilide, the structure of dimeric thiophosphoric anil anilide previously reported[1a] would contain a four-membered nitrogen–phosphorus ring. This structure was supported by the fact that the addition of aniline gave thiophosphoric trianilide, a reaction comparable to that observed with dimeric phosphoric anil anilide. However, with amines other than aniline there was a difference in the type of triamide obtained. Whereas dimeric phosphoric anil anilide and amines at 180° gave mixtures of phosphoric triamides of which one component was always the trianilide, dimeric thiophosphoric anil anilide and amines such as benzylamine, gave excellent yields of a single triamide, tribenzyl thiophosphoric amide.[6] However, it has been shown previously that the action of excess benzylamine on dimeric thiophosphoric anil anilide at 30 and 60° gave mixtures of thiophosphoric triamides from which no individual triamide could be isolated. Also, displacement of aniline from thiophosphoric trianilide by benzylamine did not occur at 30 and 60° but occurred readily at 180°. It would appear, therefore, that the displacement of aniline in dimeric thiophosphoric anil anilide by benzylamine would not occur at the lower temperatures. The reaction of primary amines, such as benzylamine, with dimeric thiophosphoric anil anilide to form tribenzylthiophosphoric amide would involve severing of the ring to give a mixture of triamides followed by displacement of aniline.

In the case of dimeric phosphoric anil anilide the triamides resulting from the first reaction are stable.

Phosphoric dianilide, $(C_6H_5NH)_2POOH$, obtained in very low yields from aniline and phosphorus pentoxide has previously been prepared by Michaelis and Soden[2] from aniline and phosphorus oxychloride. Phosphoric dianilide was observed by Michaelis to be readily hydrolyzed by hot water and hot dilute acids to give aniline and phosphoric acid. It has previously been shown that thiophosphoric dianilide underwent a similar decomposition with these reagents.[1a]



Experimental

Reactions of Aniline with Phosphorus Pentoxide.—37.2 g. (0.4 mole) of aniline and 14.2 g. (0.1 mole) of phosphorus pentoxide in 100 ml. of toluene were heated at 50° for three hours with stirring. The principal product was aniline phosphate from which the aniline was liberated by treatment with cold 5% sodium hydroxide solution. The aniline was identified as benzene sulfonanilide, the phosphate ion as ammonium phosphomolybdate. In addition 3 g., a 6% yield, of phosphoric dianilide, m. p. 199–200°, was obtained. It was identified by a mixed melting point with a sample of the dianilide prepared by the method of Michaelis and Soden.[2] Using a 6:1 molar ratio of aniline and phosphorus pentoxide and heating at 200° for three hours only aniline phosphate was obtained.

Attempts to Hydrolyze Phosphoric Trianilide.—One gram samples of phosphoric trianilide were refluxed in water, 5% sodium hydroxide, 5% hydrochloric acid and glacial acetic acid for twenty hours without change.

Preparation of Dimeric Phosphoric Anil Anilide and its Reaction with Primary and Secondary Amines.—Nine grams of phosphoric trianilide was heated for thirty minutes at 225° under a vacuum of 30 mm. of mercury; 2.5 g. of aniline distilled over. The residual solid was washed with alcohol and filtered. Six grams of phosphoric anil anilide, m. p. 357–359°, was obtained. This is a yield of 94%.

Three grams of phosphoric anil anilide was heated with 15 g. of aniline at the boiling point for five hours. The excess aniline was removed by steam distillation and the residual solid recrystallized from alcohol and gave 3.9 g. (a 93% yield) of phosphoric trianilide, m. p. 213–215°.

Two grams of phosphoric anil anilide and 15 g. of *n*-propylamine heated at 180–190° in a sealed tube for five hours gave 1.0 g. of product melting at 70–205°. Recrystallizations from alcohol gave 0.2 g. of phosphoric trianilide. No other product could be separated.

Two grams of phosphoric anil anilide with 15 g. of di-*n*-propylamine gave 0.8 g. of phosphoric trianilide, and 7 g. of phosphoric anil anilide with 30 g. of piperidine gave 2 g. of phosphoric trianilide.

Stability of Phosphoric Acid Trianilide to Amines.—Phosphoric trianilide was heated with excess tributylamine for twenty hours at 130° and also with excess benzylamine for four hours at 170°. Unchanged trianilide was recovered in high yield and no reaction products were detected.

Summary

The reaction of aniline with phosphorus pentoxide gave aniline metaphosphate as the principal product.

A comparison of the properties of phosphoric and thiophosphoric anilides has been made.

Proof of structure of the dimeric phosphoric and thiophosphoric anil anilides has been given.

The Preparation of Ethers of Triphenylcarbinol from the Triphenylcarbonium Ion

BY HILTON A. SMITH AND ROBERT J. SMITH

Several years ago Newman[1] reported a new method for the esterification of certain sterically hindered acids. The acids were dissolved in 100% sulfuric acid where they formed carbonium ions. The resulting solutions were poured into alcohols and the esters formed were subsequently recovered. Triphenylacetic acid is a sterically hindered acid which cannot be esterified by heating with an alcohol in the presence of an acid catalyst.[2] When an attempt was made to esterify this acid with methanol by Newman's method, the product was identified as the methyl ether of triphenylcarbinol. This is, perhaps, not surprising since it has already been shown[3] that triphenylacetic acid loses carbon monoxide quantitatively when treated with concentrated sulfuric acid. The mechanism for the formation of the ether is presumably

$$(C_6H_5)_3CCOOH + 2H_2SO_4 \longrightarrow (C_6H_5)_3CCO^+ + H_3O^+ + 2HSO_4^- \quad (1)$$

$$(C_6H_5)_3CCO^+ \longrightarrow (C_6H_5)_3C^+ + CO \quad (2)$$

$$(C_6H_5)_3C^+ + CH_3OH \longrightarrow (C_6H_5)_3COCH_3 + H^+ \quad (3)$$

While this method is a failure as far as the production of esters of triphenylacetic acid is concerned, it does indicate a quick and useful method for the preparation of ethers of triphenylcarbinol. The carbinol is dissolved in 100% sulfuric acid, where it forms the triphenylcarbonium ion according to the equation

$$(C_6H_5)_3COH + 2H_2SO_4 \longrightarrow (C_6H_5)_3C^+ + H_3O^+ + 2HSO_4^- \quad (4)^{4,5}$$

The carbonium ion may then be made to react with various alcohols in the manner indicated by equation (3). The yield of ether is essentially quantitative, and the product may be obtained in very pure form.

A search of the literature indicated that other methods which have been used to prepare ethers of triphenylcarbinol are usually quite long, and give smaller yields of impure products. Such methods include the reaction of triphenylmethyl chloride with an alcohol,[6,7,8] and the reaction of the chloride with sodium alcoholates. This latter method was employed by Norris and Young,[9] who prepared eleven different ethers of triphenylcarbinol in yields ranging from 10 to 60%. In the present research, six such ethers were prepared, the yields of purified products ranging from 86 to 97%. The same method could presumably be used for the formation of ethers of other carbinols which form similar carbonium ions in sulfuric acid (*i. e.*, have *i* factors of 4).

The preparation of pure ethers of triphenylcarbinol is, unfortunately, complicated by their decomposition into triphenylmethane and an aldehyde, as indicated for the ethyl ether by the equation

$$(C_6H_5)_3COC_2H_5 \longrightarrow (C_6H_5)_3CH + CH_3CHO \quad (5)$$

This reaction was extensively studied by Norris and Young[9] who found that the ease of decomposition increased with increasing complexity of the ether. In addition, the reaction is catalyzed by several ions, the most efficient of those studied being the bisulfate ion. The preparation of ethers of triphenylcarbinol from carbonium ions formed in sulfuric acid gives the product in the presence of bisulfate ions, and decomposition will occur for the higher members of the series unless the product is quickly removed.

Conditions were not found which would give the *s*-butyl, *t*-butyl and benzyl ethers. It might also be noted that Newman[1] was unable to prepare the *t*-butyl ester of trimethylbenzoic acid by an analogous method. The failure of such alcohols to give esters or ethers by reaction with the carbonium ions may be due to one of two reasons:

1. The effect of these branched-chain alcohols may be such as to materially decrease the rate of reaction (3).[10]
2. An equilibrium of the type

$$(C_6H_5)_3COR + H_2O \rightleftharpoons (C_6H_5)_3COH + ROH$$

may exist in solution, and the effect of increased complexity of the alkyl group may be of such a nature as to shift the equilibrium toward the formation of the carbinol.

The ethers of triphenylcarbinol also form the triphenylcarbonium ion when dissolved in 100% sulfuric acid, and the triphenylcarbinol may be recovered in essentially quantitative yields if such solutions are poured into water.

In attempting to find the most advantageous procedure for the etherification reactions, a study was first made of the esterification of 2,4,6-trimethylbenzoic acid with methanol and ethanol. It was found that Newman's procedure[1] could be greatly simplified. In fact, the study indicated that, under conditions similar to those employed by Newman, both benzoic acid and 2,4,6-trimethylbenzoic acids may be almost completely esterified, but the benzoates are rapidly hydrolyzed. If the reaction mixture is poured into water rather than having water poured into it, good yields of the benzoates may be obtained. Apparently when water is poured into the sulfuric acid solution, local heating causes hydrolysis of the benzoates. A similar but much slower hydrolysis of the esters of the 2,4,6-trimethylbenzoic acid probably causes a slight reduction in the net yield of these esters. Conditions can be established which show that the fundamental differences between benzoic acid and the sterically hindered benzoic acids discussed by Newman do actually exist. This is shown by the fact that the sterically hindered 2,4,6-trimethylbenzoic acid is almost completely esterified in ten minutes, while the unhindered benzoic acid is not. The *i* factor of 4 for the hindered acid in sulfuric acid indicates a carbonium ion reaction while that of 2 for benzoic acid indicates that the ordinary type of acid-catalyzed esterification is involved.

Experimental

The 100% sulfuric acid was prepared by mixing suitable quantities of 96% sulfuric acid and oleum. It froze at 10° and analyzed 100.3% by dilution and titration with standard base.

Preparation of Ethers from Triphenylcarbinol.—For those ethers which were solids, 2 g. of triphenylcarbinol was dissolved in 6 to 12 g. of 100% sulfuric acid. The resulting yellow solution was added dropwise to 30 ml. of cold alcohol held at −10° by means of a salt–ice-bath. As soon as all of the solution was added, the resulting mixture was poured into 100 g. of a mixture of ice and water. The solid which separated was immediately filtered out, washed, and recrystallized from methanol.

For those ethers which were obtained as liquids, the following modifications were introduced. After pouring the sulfuric acid–alcohol solution into water, the organic layer was extracted with ether. The ether solution was treated with sodium carbonate solution, dried, and all readily volatile matter removed. The triphenylcarbinol ether which remained was fractionated in a small Vigreux column.

Hydrolysis of Ethers.—Several of the above ethers were dissolved in 100% sulfuric acid solution, and the resulting yellow solutions poured into ice water. The solid product which separated was filtered from the liquid, and identified as triphenylcarbinol by its melting point and mixed melting point with known triphenylcarbinol.

TABLE I

ETHERS OF TRIPHENYLCARBINOL

Alcohol used	Yield, %	Melting point or boiling point, °C.[b]
Methyl	97	96 –96.5
Ethyl	94	82.5–83
Propyl[a]	88	54.5–55.5
Isopropyl	86	113 –114
n-Butyl	87	208 at 5.5 mm.
Isoamyl	88	217.5 at 5.5 mm.

[a] It was usually necessary to extract this ether because of difficulty in inducing crystallization. [b] See Norris and Young, ref. 5, for melting or boiling points of the compounds.

Attempted Esterification of Triphenylacetic Acid.—Two grams of triphenylacetic acid was dissolved in 25 g. of 100% sulfuric acid. Some frothing was noted, indicating gas evolution. The resulting yellow solution was poured dropwise into 30 cc. of cooled methanol. This mixture was poured into 100 g. of ice and water. The precipitate was filtered and recrystallized from methanol to give 1.77 g. of white crystals, m. p. 96°.[11]

Anal. Calcd. for $C_{20}H_{18}O$: C, 87.6; H, 6.6. Found: C, 87.5, 87.5; H, 6.8, 6.6.

Esterification of Benzoic and 2,4,6-Trimethylbenzoic Acids.—Benzoic and 2,4,6-trimethylbenzoic acids were esterified in the manner described by Newman[1] (Method I) and by a modification of this method (Method II). The main difference between the two was that in the modified method the reaction mixture was poured into ice and water, while Newman added ice water to the reaction mixture. For each esterification, 2-g. samples of benzoic acid and 1-g. samples of 2,4,6-trimethylbenzoic acids were used.

In two parallel experiments using benzoic acid and ethanol, and allowing the mixture of alcohol, sulfuric acid and benzoic acid to stand for twelve hours, the product worked up by Method I showed 62.5% of acid recovered. Using Method II, no acid was obtained. When methanol and benzoic acid were used, and the mixture allowed to stand for only ten minutes, less than 50% of the acid was recovered by Method II. When the mixture was allowed to stand for one hour, only 10% of the acid was recovered.

In experiments with 2,4,6-trimethylbenzoic acid and methanol, using Method II, 6% of the acid was recovered whether the mixture was allowed to stand for ten minutes or for one hour.

It is much easier to estimate the ester yields from the percentage of acid recovered, than from ester yields. However the esters were isolated in a number of cases, and the amounts obtained were in accord with the results indicated on the basis of recovered acid.

Summary

A method for the formation of ethers of triphenylcarbinol from the triphenylcarbonium ion has been described; the method gives good yields of pure ethers. The esterification of benzoic and 2,4,6-trimethylbenzoic acids by Newman's method has been discussed.

KNOXVILLE, TENN. RECEIVED FEBRUARY 2, 1948

(11) The crystals from some of these preparations first melted at 84°, this being the melting point of a different crystalline form of the methyl ether of triphenylcarbinol. See Hatt, *J. Chem. Soc.*, 483 (1938).

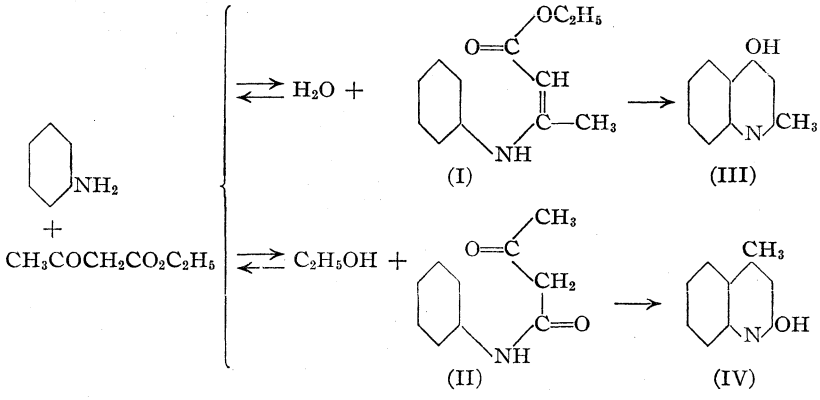
Reactions of β-Keto Esters with Aromatic Amines. Syntheses of 2- and 4-Hydroxyquinoline Derivatives[1]

BY CHARLES R. HAUSER AND GEORGE A. REYNOLDS

Earlier workers have shown that ethyl acetoacetate and aniline react at room temperatures to form ethyl β-anilinocrotonate (I)[2] or the anil, whereas, at 130–140°, acetoacetanilide (II) is produced.[3] On cyclization these products form 2-methyl-4-hydroxyquinoline (III) and 4-methyl-2-hydroxyquinoline (IV), respectively.



We have found that both crotonate and anilide formations are reversible; the crotonate is converted to the anilide by heating with an equivalent of water and a trace of acid[4] at 130–140°, whereas the reverse transformation takes place upon boiling the anilide with ethanol and Drierite. Furthermore, in contrast to ethyl acetoacetate, 2-ethylbutyl and *n*-amyl acetoacetates were found to react with aniline to form mainly the corresponding crotonates even at 130–140°. The crotonates and the anilide were identified by cyclizations to (III) and (IV), respectively.[5] Conceivably differences in the volatility of the by-products govern the course the reaction takes. If at all temperatures considered the equilibrium favors the crotonate, anilide formation in the case of the ethyl ester[6] could be accounted for, because ethanol, the by-product of the anilide formation, is more volatile than water, which would result from crotonate production.[7] On the other hand, one might assume that at 130–140° the equilibrium favors the anilide, and then the results could be understood on the basis of the lower volatility of 2-ethylbutyl and *n*-amyl alcohols as compared to water. The facts at hand do not permit stating which, if any, of these alternatives applies. However, since the products are readily interconvertible, it seems likely that the temperature dependence of the course of reaction is due to displacement of equilibrium rather than to the existence of two competing reaction paths with sufficiently differing temperature coefficients[8] of rate.

In Table I are given the over-all yields of various 2- and 4-hydroxyquinolines obtained from β-keto esters and aromatic amines employing various methods of preparation of the intermediate crotonates and anilides. The crotonates were generally prepared more conveniently by refluxing the reactants with Drierite in ethanol (Method B)[9,10] than by the older procedure (Method A) which requires a much longer time. However, Method B has not been satisfactory with ethyl benzoylacetate with which a modification of Method A was finally adopted (see note *e*, Table

(2) (a) Knorr, *Ber.*, **16**, 2593 (1883); (b) Conrad and Limpach, *Ber.*, **20**, 944 (1887); (c) Cavallito and Haskell, THIS JOURNAL, **66**, 1166 (1944); (d) Coffey, Thomson and Wilson, *J. Chem. Soc.*, 856 (1936).

(3) (a) Knorr, *Ann.*, **236**, 69 (1886); (b) Roos, *Ber.*, **21**, 624 (1888); (c) Knorr and Reuter, *Ber.*, **27**, 1169 (1894); (d) Knorr, *Ann.*, **236**, 74 (1894).

(4) The reaction failed in the absence of a trace of acid. This is not surprising since Coffey, Thomson and Wilson (ref. 2d) have shown that the formation of the crotonate requires a trace of acid, which ordinarily is present in commercial ethyl acetoacetate.

(5) The anilide was also identified (after recrystallization) by its melting point. The crotonates have been distilled at reduced pressures but, since the distillates deposited small amounts of diphenylurea, they were not analyzed. The diphenylurea was formed apparently from anilide, small amounts of which were evidently produced during the heating at 130–140° or during the distillation. Oppenheim and Precht (*Ber.*, **9**, 1098 (1876)) reported that heating the anilide with aniline produced diphenylurea and acetone.

(6) Also isopropyl acetoacetate appears to form the anilide at 130–140°, since a low yield of (IV) has been obtained on cyclizing the crude product. However, in attempts to reproduce this result, the only product isolated was diphenylurea which was formed presumably from the anilide (see note 5).

(7) Knorr (3d) reported that the anilide was obtained from aniline and ethyl acetoacetate when they were heated in a sealed tube at 150° for a long time. An attempt to reproduce this result was unsuccessful.

(8) This is evidently the case, for example, in the reaction of alkali with anti-benzaldoxime acetate which yields mainly the anti-benzaldoxime at 0° but mainly the corresponding nitrile at 30° or above; Hauser and Jordan, THIS JOURNAL, **57**, 2450 (1935).

(9) A little more than the calculated amount of Drierite required to remove the by-product, water, has generally been employed, but one-third of this amount has given, after cyclization of the crotonate, only a slightly lower yield of (III). It was found advisable to add a trace of acetic acid as catalyst.

(10) This procedure has also been satisfactory for the reaction of ethyl ethoxalylpropionate and aniline; cyclization of the resulting intermediate gave 3-methyl-4-hydroxy-2-carbethoxyquinoline, m. p. 177–179°, in 50% yield. However, the procedure using Drierite, as well as the original one, failed with ethyl ethoxalylpropionate and 2-nitro-4-methoxyaniline.

TABLE I

QUINOLINE DERIVATIVES FROM $RCOCH_2CO_2R'$ AND AROMATIC AMINES BY CYCLIZATION OF INTERMEDIATE CROTONATES AND ANILIDES OBTAINED BY VARIOUS METHODS

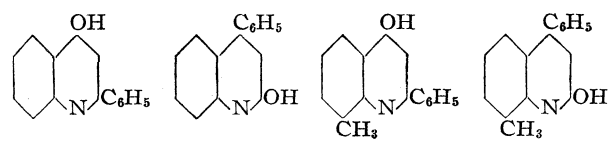
I). Both Method A and B have failed with ethyl acetoacetate and *o*-nitroaniline or 2-nitro-4-methoxyaniline. Method C, which was used only with the higher alkylacetoacetates, is not generally as convenient as Method B. Method D, involving heating the reactant at 130–140°, produces the crotonates only with β-keto esters of sufficiently high boiling alcohols. The anilides were prepared from the ethyl β-keto esters either by Method D or by refluxing the reactants (Methods E and G).

It should be pointed out that, although cyclization of the crude crotonates prepared on a 0.1-mole scale by Method B gave quinolines of satisfactory purity, crude ethyl β-anilinocrotonate, prepared on a 0.5-mole scale, as a rule, gave products which were difficult to purify. When, however, the crotonate was purified by distillation under reduced pressure, the pure quinoline was always obtained.

Knorr reported that, like the crotonate, the anilide from aniline and ethyl benzoylacetate produces 2-phenyl-4-hydroxyquinoline (V) on cyclization.[11] He prepared the anilide by heating the reactants at 150° followed by treatment with dilute acid to hydrolyze ethyl β-phenylamidophenylacrylate, which was formed along with the anilide. However, we have found that heating the reactants at 150°, followed by recrystallization, produces essentially pure anilide, which, on cyclization, forms the expected 4-phenyl-2-hydroxyquinoline (VI). The two isomers, (V) and (VI), melt only a few degrees apart but a mixture of the two melts much lower and over a range. Moreover, treatment of (VI) with phosphorus oxychloride forms a chloro derivative the melting point of which is fifteen degrees higher than that reported for the chloro derivative of (V). Compounds (VII) and (VIII), which have been prepared from *o*-toluidine and ethyl benzoylacetate, melt almost thirty degrees apart. The present method of preparing 4-phenyl-2-hydroxyquinoline appears much more convenient than that described previously employing acetyl-*o*-amidobenzophenone.[12]



(V) (VI) (VII) (VIII)

Experimental[13]

General Procedures.—The crotonates were prepared by one or more of the following procedures using 0.1 mole each of β-keto ester and aromatic amine. Method A: the reactants were allowed to stand at room temperatures (20–30°) either alone for four to five days[2a,b,e] or in the presence of a trace of hydrochloric acid (or aniline hydrochloride) in a vacuum desiccator over concentrated sulfuric acid for one to three days.[2d] Method B: to the reactants was added 30–40 ml. of commercial absolute ethanol, about 35 g. of Drierite, and three or four drops of glacial acetic acid. The resulting mixture was refluxed on the steam-bath for three to four hours. The Drierite was filtered off and the ethanol was distilled at slightly above room temperatures by means of a water aspirator. Method C: the reactants were heated at 95–100° in an oil-bath for three to four hours in the presence of about 10 g. of Drierite and the Drierite then filtered off. Method D (applicable to β-keto esters of higher alcohols): the reactants were heated in an open Erlenmeyer flask or beaker for three or four hours in an oil-bath at 130–140° and then cooled to room temperatures.

The crude crotonate was added as rapidly as possible to 100 ml. of stirred refluxing (250–260°) Dowtherm[14] contained in a 200-ml. three-neck round-bottom flask equipped with a mercury-sealed stirrer and condenser. After fifteen

(13) Analyses by Oakwold Laboratory, Alexandria, Virginia.

(14) This cyclization has been effected previously under other conditions; Cavallito and Haskell (ref. 3c) effected the reaction in mineral oil.

to twenty minutes the stirring was stopped and the mixture allowed to cool, a light yellow solid usually separating. Approximately 200 ml. of Skellysolve "B" was then added. After shaking, the solid 4-hydroxyquinoline derivative was filtered off, washed several times with Skellysolve and recrystallized from water in the case of 2-methyl-4-hydroxyquinoline and from a mixture of water and ethanol in the other cases.

Acetoacetanilides were prepared from 0.1 mole each of ethyl acetoacetate and aromatic amine either by Method D described above or by refluxing the reactants three to four minutes[15] (Method E). The solid, obtained on cooling the mixture, was recrystallized from acetic acid and water and then from ethanol and water yielding acetoacetanilide (m. p. 82–83°)[3a] in 52% yield and acetoaceto-*o*-toluidide (m. p. 107–108°)[15] in 55% yield.

Benzoylacetanilides were prepared from 0.1 mole each of ethyl benzoylacetate and aromatic amine either by heating the reactants at 150° for five hours (Method F) or by refluxing the mixture for fifteen minutes (Method G). After recrystallization as described for acetoacetanilide, benzoylacetanilide (m. p. 107–108°)[11] was obtained in 50% yield, and benzoylaceto-*o*-toluidide (m. p. 130–131°) in a 65% yield.

Anal. Calcd. for $C_{16}H_{15}NO_2$: C, 75.82; H, 5.96. Found: C, 75.51; H, 5.72.

The anilides were cyclized in concentrated sulfuric acid at 80–90° as described in "Organic Syntheses"[16] or by heating on the steam-bath for fifteen minutes. The 2-hydroxyquinoline derivatives were recrystallized from a mixture of water and ethanol. An attempt to cyclize acetoacetanilide (II) in Dowtherm at 250–260° as described above for the crotonate was unsuccessful.

The yields and the melting points of the quinoline derivatives are given in Table I. Admixture of the various samples of the same derivative showed no depression in melting point, but admixture of isomeric 2- and 4-hydroxyquinolines depressed the melting point.

2-Methyl-4-hydroxyquinoline (0.5 mole scale).—A mixture of 46.5 g. (0.5 mole) of aniline, 65 g. (0.5 mole) of ethyl acetoacetate, 100 ml. of commercial absolute ethanol, 135 g. of Drierite, and 1 ml. of glacial acetic acid was refluxed on the steam-bath for four hours. After removing the Drierite and the solvent, the residue was fractionated through a 30-cm. Vigreux column yielding 58 g. (57%) of ethyl β-anilinocrotonate, b. p. 155° at 10 mm.[17] The crotonate was cyclized in 200 ml. of Dowtherm yielding 38 g. (50%) of 2-methyl-4-hydroxyquinoline (m. p. 229–230°).

4-Phenyl-2-chloroquinoline.—A mixture of 10 g. (0.045 mole) of 4-phenyl-2-hydroxyquinoline (m. p. 259°) and 30 ml. of phosphorus oxychloride was heated in an oil-bath at 120° for two hours, the excess oxychloride distilled under reduced pressure and the light brown viscous oily residue poured onto ice. After standing in the refrigerator for one day the solidified oil was recrystallized from absolute ethanol yielding 10 g. (93%) of white crystals of 4-phenyl-2-chloroquinoline, m. p. 87–88°.

Anal. Calcd. for $C_{15}H_{10}NCl$: C, 75.15; H, 4.21; N, 5.86; Cl, 14.8. Found: C, 74.88; H, 4.70; N, 6.12; Cl, 14.68.

Conversion of Crotonate to Anilide.—To 0.1 mole of ethyl β-anilinocrotonate, b. p. 155° at 10 mm., was added 2 g. of water and five drops of concentrated hydrochloric acid and the mixture stirred and heated in an open flask in an oil-bath at 130–140° for three or four hours. The resulting crude anilide was cyclized[16] to form 4-methyl-2-hydroxyquinoline, m. p. 222–223°, in 35% over-all yield.

Conversion of Anilide to Crotonate.—A mixture of 0.1 mole of acetoacetanilide (m. p. 82–83°), 30 ml. of commercial absolute ethanol and 30 g. of Drierite was refluxed four hours and the Drierite then filtered off. After distilling the solvent, the residue was fractionated giving a 50% yield of ethyl β-anilinocrotonate (b. p. 139–143° at 6 mm.) which was cyclized in Dowtherm to 2-methyl-4-hydroxyquinoline, m. p. 229–230°, in 39% over-all yield from the anilide.

Summary

1. The factors governing the formation of crotonates and anilides from β-keto esters and aromatic amines have been considered.

2. Crotonates and anilides, prepared by various methods, have been cyclized to form 4- and 2-hydroxyquinolines, respectively.

3. In contrast to reports in the literature the anilide from ethyl benzoylacetate and aniline was found to form 4-phenyl-2-hydroxyquinoline on cyclization.

(15) Ewins and King, *J. Chem. Soc.*, **103**, 104 (1913), effected the reaction in one and one-half minutes.

(16) Lauer and Kaslow, "Organic Syntheses," Vol. 24, John Wiley and Sons, Inc., New York, N. Y., 1944, p. 68.

(17) Distillation of the residue at a bath temperature of 120° until the forerun was removed and then at 140–160° gave ethyl β-anilinocrotonate, b. p. 128–130° at 2 mm., in 60–70% yield.

The Bacterial Activity of "Racemized Casein," Caseose, and the Four Diastereoisomeric Leucylleucines[1,2]

BY SIDNEY W. FOX, YUTAKA KOBAYASHI,[3] SAMUEL MELVIN[3] AND FREDERICK N. MINARD[4]

Several of the antibiotics, particularly penicillin and gramicidin, are notable for their content of D-amino acid residues. In the case of penicillin, the D-amino acid residue is one of a number of critical structural features, since the L-analog is without activity.[5] D-Amino acids have been shown experimentally to inhibit bacterial growth[6,7] at relatively high concentrations. Recent reports, however, indicate medical utility of some of the simple amino acids, when used in relatively large amounts, in the control of infection.[8] In view of the above observations it is of interest to determine the antibacterial activity of structures re-

lated to the D-amino acids and to the antibiotics in which these simple units are incorporate.[9]

Substances which include the D-amino acid residue repeated within a single large molecule are under investigation in this laboratory; interest in such materials and their behavior has also been expressed elsewhere.[10] The present report describes two types of such material, with some reference to their effects on bacteria.

The simpler type is represented by D-leucyl-D-leucine. For comparative experiments in the present study, all four diastereoisomeric leucylleucines were synthesized by the method of Fischer and Koelker.[11] D-Leucyl-D-leucine was of particular interest because of its relationship to D-valyl-D-valine, which had been isolated from partial hydrolyzates of gramicidin as the benzoyl derivative.[12] In the other type of molecule the D-amino acid residues were linked in the main-chain through both the amino and carboxyl groups. Such material was available through the racemization procedure of Dakin.[13,14] The fractions called by Dakin "racemized casein" and caseose were shown to contain inverted residues of valine, leucine, phenylalanine, proline, tyrosine, aspartic acid, glutamic acid, arginine, lysine and histidine. D-Isomers of the first three amino acids represent all of the D-forms which have been found in gramicidin and tyrocidine.[15–19]

In none of the tests with the described D-amino acid derivatives was antibacterial activity equal to that of D-leucine noted (Table I). The lack of activity of D-leucyl-D-leucine, as an analog of D-valyl-D-valine, is in agreement with the rapid loss of activity of gramicidin under gentle hydrolytic conditions.[20,21] The activity of gramicidin thus seems not to be even partially represented by contiguous D-amino acid residues. The experiments with racemized casein and with caseose indicate that a polypeptide preparation containing a larger proportion of D-amino acid residues than occurs in tyrocidine is without appreciable antibacterial activity.

The results recorded by Dakin and Dudley[22] for the action of pancreatic microbial cultures on racemized casein was in the main confirmed in this work, with *Escherichia coli*. It should be noted that in the present experiments, the effect of *E. coli* on native casein also was tested; no appreciable growth was observed.

The quantitative nature of the behavior of the leucylleucines as sources of L-leucine for *L. arabinosus 17-5* is striking. Table III represents a typical experimental result. The bacterium was capable of utilizing fully, during the experimental incubation period, the L-leucine residues of L-leucyl-L-leucine and of D-leucyl-L-leucine. As might be expected, it could not utilize D-leucyl-D-leucine. *L. arabinosus* was also unable to use L-leucyl-D-leucine. This behavior is in contrast to the utilizability of D-leucyl-L-leucine.[23]

TABLE III

L-LEUCINE ACTIVITY OF LEUCYLLEUCINE ISOMERS FOR GROWTH OF *Lactobacillus arabinosus 17-5* IN LEUCINE-FREE MEDIUM

L-Leucyl-L-leucine	98	102
L-Leucyl-D-leucine	0	0
D-Leucyl-L-leucine	50	50
D-Leucyl-D-leucine	0	0

Experimental

Leucylleucines.—The D–D, D–L, L–D, and L–L leucylleucines were prepared by the same general procedure employed by Fischer and Koelker[11] and by Fischer.[24] The intermediate bromoisocaproylleucines prepared in the present work had the following m. p.'s (cor.): L-α-bromoisocaproyl-D-leucine, 145–7° (F. & K. 149°), L-α-bromoisocaproyl-L-leucine, 126–7°, (F. & K. 128°), D-α-bromoisocaproyl-D-leucine, 125–7°, (F. & K. 128°), and D-α-bromoisocaproyl-L-leucine, 144–6° (F. 149°). Each of the dipeptides was assayed for L-leucine content. Samples of 20 mg. of each dipeptide were dissolved in 5 ml. of 20% hydrochloric acid and autoclaved for three hours at 15 lb. steam pressure. The solutions were then neutralized with sodium hydroxide and each was diluted to 100 ml. The resultant solutions were then assayed against a stand-

(23) Taken in conjunction with the work of Ågren: *Acta. Physiol. Scand.*, **13**, 347 (1947), these results emphasize the importance of position of the amino acid residue.
(24) Fischer, *Ber.*, **39**, 351 (1906).

ard solution of DL-leucine turbidimetrically on a Coleman Model 11 Spectrophotometer at 600 mμ. The organism employed was *Lactobacillus arabinosus 17-5*, which responds only to the L-form of leucine. The medium employed was that of Kuiken, *et al.*[25]

Within the probable limits of error of the assay, the identity of the four leucylleucines was established. The L–L assayed 90–100% L-leucine, the L–D and D–L each 50% L-leucine (±5%), and the D–D hydrolyzate gave 0- < 1% L-leucine.

Partially Racemized Casein Fractions.—Smaco vitamin-free casein was partially racemized by the procedure of Dakin.[12] The $[\alpha]^{27}D$ for the original casein, the acid-precipitable racemized casein and the water-soluble caseose (precipitated by ammonium sulfate) were, respectively: $-104.7° \pm 0.8°$, $-52.0° \pm 0.8°$, and $-37.5° \pm 2.0°$ (0.3 g. in 25 ml. 0.5 *N* sodium hydroxide solution).

Inhibition Experiments.—The leucylleucines and leucines were first tested against *E. coli* in a dilution series. Twenty mg. of each compound was weighed into a small test-tube. Two ml. of nutrient broth[26] was added to each tube and solution was effected by warming. Half of this was mixed with medium in another tube, and this process repeated through a series of a total of six tubes. The tubes were plugged with cotton and autoclaved for ten minutes at 15 lb. steam pressure. The tubes were then inoculated from a fresh subculture of *E. coli*.

After twenty-five hours of incubation at 37°, the turbidities of the cultures were assessed in a Coleman Model 11 spectrophotometer at 650 mμ. The results are presented in Table I. The experiment was repeated with a synthetic medium consisting of 0.5% disodium phosphate, 0.5% dipotassium phosphate, 0.5% ammonium chloride, 0.02% magnesium sulfate and 0.5% glucose, brought to *p*H 7 with phosphoric acid. The visual results were similar to those in nutrient broth; only D-leucine at 10 mg./ml. showed total inhibition. No inhibition was found for any of the peptides tested against *L. arabinosus 17-5* in a yeast extract medium[27] with all other conditions the same as in the *E. coli* experiments. Because of the conceivability of racemization of the D-peptides during autoclaving,[28] the experiment of Table I was repeated with the glucose added aseptically after autoclaving, and again with the glucose replaced by glycerol. In both cases the results were identical with those in synthetic medium.

At concentrations of 10 mg./ml. of added racemized casein and of caseose, *E. coli* grew under the experimental conditions given above. *E. coli* was grown for the other inhibition experiments with nutrient broth as above, except for the added casein or racemized preparations. The racemized casein was dissolved in 2 *N* sodium hydroxide solution, neutralized, and Seitz-filtered for the tests. There was no inhibition of *L. arabinosus 17-5* by racemized casein at a concentration of 3.5 mg./ml. nor by caseose at a concentration of 15 mg./ml. in yeast extract medium at 37° for seventy-two hours.

A corresponding set of experiments with racemized gelatin (not isolated) gave similar results.

Experiments on Support of Growth.—For experiments on support of growth, casein, racemized casein, and caseose were made up in concentrations of 100 mg./ml. of 0.8% sodium carbonate solution containing traces of calcium chloride, magnesium sulfate and trisodium phosphate. No other protein was present. *E. coli* was the organism used. The results are presented in Table II.

Tests of replaceability of L-leucine by the leucylleucines were run in leucine-free synthetic medium[25] inoculated with *L. arabinosus*. The results are presented in Table III.

Summary

Racemized casein and caseose, containing numerous D-amino acid residues per molecule, failed to inhibit the growth of cultures of *Escherichia coli* or *Lactobacillus arabinosus 17-5*. None of the four isomeric leucylleucines showed as much antibacterial activity as D-leucine. The relationship of these experiments to the antibacterial activity of D-amino acids and of the antibiotics which are D-amino acid derivatives has been discussed.

The replaceability of L-leucine by leucylleucine isomers, in the medium for *L. arabinosus 17-5*, has been studied. The L-residues of L-leucyl-L-leucine and D-leucyl-L-leucine were fully utilized. None of the residues of L-leucyl-D-leucine nor of D-leucyl-D-leucine were available to this organism.

Action of Heat on D-Fructose. Isolation of Diheterolevulosan and a New Di-D-fructose Dianhydride

BY M. L. WOLFROM AND MARY GRACE BLAIR[1]

It is probable that the well-established tendency of D-fructose to form bimolecular cyclic anhydrides[2] accounts for some of the molasses formation occurring in cane sugar house processing. Such a view has been expressed by Sattler and Zerban.[3] These authors have investigated the non-fermented products formed on heating a concentrated aqueous solution of D-fructose. They established that the complex mixture obtained closely approximated in composition that required for a mixture of isomeric di-D-fructose dianhydrides. This work has now been repeated in our laboratory and the non-fermented products have been subjected to separation by chromatography on clay, a procedure established by Lew, Wolfrom and Goepp.[4] Two crystalline products were isolated in pure form and characterized. The one was the diheterolevulosan of Pictet and Chavan[5]

and the other, designated diheterolevulosan II, was an isomeric substance (m. p. 250–252°, dec.; $[\alpha]^{25}D$ −39° in water) not identical with any known di-D-fructose dianhydride.

Pictet and Chavan[5] prepared their crystalline diheterolevulosan by treating D-fructose at low temperatures with concentrated hydrochloric acid. This work was repeated in our laboratory in order to obtain material for comparative purposes. The complex reaction product was subjected to chromatographic separation and the diheterolevulosan of Pictet and Chavan[5] was obtained with constants in agreement with those cited by these workers. In addition, diheterolevulosan II was obtained from this source. The crystalline hexaacetate of diheterolevulosan was prepared and was found to have properties in agreement with those described by Schlubach and Behre.[6] The hexaacetate of diheterolevulosan II was likewise obtained in crystalline form.

Pictet and Chavan[5] isolated an amorphous fraction which they termed "heterolevulosan" and which they considered to be a monomolecular anhydride of D-fructose. A material of similar properties was obtained on following their procedure. It was easily demonstrated by chromatographic methods, however, that this fraction was a complex mixture whose main component was the diheterolevulosan II. There thus exists no evidence for a monomolecular anhydride of D-fructose or for its "dimerization"[3,5] to a di-D-fructose dianhydride. Like "glutose,"[3] "heterolevulosan" has no existence in fact and the name should be stricken from the chemical literature.

Schlubach and Behre[6] methylated diheterolevulosan to a crystalline hexamethyl ether from which was obtained on acid hydrolysis a sirupy trimethyl-D-fructose, $[\alpha]^{20}D$ −73.5° in water, which formed an oily phenylosazone without demethylation. McDonald and Jackson[7] noted that diheterolevulosan absorbed four moles of periodate. To this we add that two moles of formic acid and no formaldehyde are produced in this oxidation. Upon these data the structure I (Fig. 1), di-D-fructopyranose 1,2′:2,1′-dianhydride, is evinced for diheterolevulosan. The methylation data do not meet the exacting criteria of crystallinity and are therefore inadequate. Fortunately, the periodate work is definitive and leads uniquely to formula I. The structure of diheterolevulosan is thus established save for the assignment of configurations to the anomeric spirane carbon atoms.

We can presently adduce for the structure of diheterolevulosan II only the results of periodate analysis which are that three moles of oxidant are consumed with the concomitant formation of one mole of formic acid and no formaldehyde. Formulas II and III satisfy these demands and for the sake of simplicity we favor III. Further data are required for an unequivocal proof of structure.

Fig. 1.—Di-D-fructose dianhydrides.

Experimental

Treatment of D-Fructose with Hydrochloric Acid and Recovery of the Crude Reaction Products.—Following Pictet and Chavan,[5] D-fructose (100 g.) was dissolved at 0° in 400 g. of concentrated hydrochloric acid (sp. gr. 1.19 at 15.56°) and the solution was maintained at 0° for seventy-two hours. Neutralization was then effected with basic lead carbonate and the dissolved lead chloride was removed from the filtered solution by ion exchange on Amberlites IR-100 and IR-4.[8] Unchanged D-fructose was removed from the solution (1500 ml.) by fermentation with 20 g. of baker's yeast (Fleischmann) at 30° for three days. Upon the cessation of fermentation, the yeast was removed by centrifugation and filtration through a filter-aid. The filtrate was deionized with Amberlites IR-100 and IR-4[8] and concentrated to a sirup which was dried by the addition of absolute ethanol and its subsequent removal by distillation under reduced pressure. Crystallization was effected from methanol; yield 28 g. in two crops (fraction A). The filtrate (150 ml.) was added dropwise to 1.5 liters of anhydrous ether and the precipitate so formed was removed by filtration; yield 4.7 g. (fraction B), $[\alpha]^{24}D$ −61.0° (*c* 4, water). The material was an amorphous, somewhat hygroscopic, white powder.

Diheterolevulosan from Fraction A.—Fraction A (28 g.) above was recrystallized several times from water to yield pure diheterolevulosan; yield 5.9 g., m. p.[9] 261–263° (dec.), $[\alpha]^{18}D$ −45.8° (*c* 4, water). This material was chromatographically pure; it showed only one zone when chromatographed according to the extrusion procedure described below. Pictet and Chavan[5] cite for

(8) Products of the Resinous Products and Chemical Co., Philadelphia, Pennsylvania.

(9) Unless otherwise noted, all melting points are uncorrected and were taken on a modified Berl–Kullmann block as described by F. W. Bergstrom, *Ind. Eng. Chem., Anal. Ed.*, **9**, 340 (1937). The substances were heated as rapidly as possible from room temperature to near the melting point.

diheterolevulosan the constants: m. p. 266–267°; $[\alpha]^{18}D$ −43.5° (*c* 4, water).

Anal. The substance (1 mole) consumed 4.2 moles of sodium metaperiodate and formed 2.0 moles of formic acid and no formaldehyde.

Acetylation of this material (0.5 g.) with pyridine (7 ml.) and acetic anhydride (4.5 ml.) by shaking mechanically at room temperature for four to five days, yielded hexaacetyldiheterolevulosan (recrystallized from absolute ethanol); yield 0.8 g., m. p. 172.5–173.5° (cor.), $[\alpha]^{28}D$ −59.0° (*c* 1, U. S. P.[10] chloroform). Schlubach and Behre[6] cite for hexaacetyldiheterolevulosan the constants: m. p. 171–173°; $[\alpha]^{20}D$ −59.1° (*c* 1, chloroform).

Diheterolevulosan II from Fraction A.—The aqueous mother liquor from the above-described preparation of diheterolevulosan was concentrated to a sirup; yield 22 g. An amount of 11 g. of this sirup was dissolved in 8 ml. of water, made into a slurry with clay–Celite[11] (5:1 by wt.) and treated with 200 ml. of 95% ethanol. The mixture was added to the top of a 2-liter pharmaceutical percolator packed with 1 kg. of the same clay–Celite mixture and saturated with 95% ethanol. To this mixture was added 95% ethanol until 6.3 liters of effluent was obtained. Evaporation of the filtered effluent yielded a sirup (fraction A-1). Additional development with 95% ethanol removed a negligible amount of material (very weak Molisch test). Changing of the developer to 80% ethanol slowly removed further material. From 5 liters of effluent there was recovered, in the manner described above, crystalline material identified as diheterolevulosan; yield 1.0 g., $[\alpha]^{27}D$ −45.4° (*c* 4, water).

Fraction A-1 was dissolved in water and deionized with Amberlite IR-100 and IR-4.[8] The deionized solution was concentrated under reduced pressure to a thick sirup and crystallized by the addition of methanol; yield 7.2 g., $[\alpha]^{26}D$ −39.5° (*c* 4, water). The material was recrystallized by solution in water, concentration to a thick sirup and addition to this of absolute methanol. This product contained some inorganic material which was removed by solution of the organic crystals in boiling absolute methanol and filtration. The solvent was removed and the procedure was repeated with 90% ethanol. Crystallization was effected by concentration of the dilute ethanol solution; yield 6.4 g., m. p. 250–252° (dec.), m. p. 239–243° on admixture with diheterolevulosan of m. p. 261–263° (dec.), $[\alpha]^{28}D$ −39° (*c* 4, water). The substance reduced Fehling solution after acid hydrolysis with 5% sulfuric acid for thirty minutes at 70°. It was chromatographically pure, showing only one zone when chromatographed on clay according to the procedure detailed below.

Anal. Calcd. for $C_{12}H_{20}O_{10}$: C, 44.44; H, 6.22. Found: C, 44.28; H, 6.18. Periodate analysis: the substance (1 mole) consumed 3.0 moles of sodium metaperiodate and formed 1.0 mole of formic acid and no formaldehyde.

Hexaacetyldiheterolevulosan II.—This substance was prepared according to the procedure described above for hexaacetyldiheterolevulosan except that solution was readily effected in the acetylating mixture and two days standing at room temperature without shaking sufficed. It was obtained crystalline from absolute ethanol; m. p. 123–124°; $[\alpha]^{20}D$ −41.5° (*c* 4, U. S. P.[10] chloroform).

Anal. Calcd. for $C_{12}H_{14}O_{10}(CH_3CO)_6$: C, 49.99; H, 5.60; CH_3CO, 10.4 ml. 0.1 *N* NaOH per 100 mg.; mol. wt., 577. Found: C, 50.11; H, 5.72; CH_3CO, 10.4 ml.; mol. wt. (Rast), 604.

Deacetylation was effected by the procedure of Kunz and Hudson[12] (sodium hydroxide in dilute acetone at −15°). Acetone was removed from the neutralized solution by distillation under reduced pressure and inorganic ions were removed by passage through ion exchange columns (Amberlites IR-100 and IR-4[8]). Concentration to a thick sirup followed by methanol addition yielded the original crystalline diheterolevulosan II; m. p. 250–252°, $[\alpha]^{23}D$ −38.7° (*c* 4, water).

Investigation of Fraction B.—Fraction B above (4.7 g., $[\alpha]^{24}D$ −61° in water) corresponds to the amorphous material described by Pictet and Chavan[5] as "heterolevulosan," $[\alpha]^{24}D$ −66° (*c* 3, water), and considered by them to be a six carbon anhydro-D-fructose. Three grams of this fraction was dissolved in 45 ml. of water and 255 ml. of dioxane (distilled from sodium) was added. The resultant solution was chromatographed in 5-cc. portions on 25 g. of clay–Celite (5:1) in tapered tubes (23 mm. diam. at bottom and 25 mm. diam. at top). Development was effected with 70 ml. of 95% dioxane. Extrusion of the chromatograms and streaking with the alkaline permanganate indicator (1% potassium permanganate in 2 *N* sodium hydroxide) located three zones in each: C, 6–18 mm. from the top; D, 45–70 mm.; E, 95–125 mm. No significant amount of material was present in the effluents. The sectioned fractions were eluted with 80% ethanol. The collected material from the C zones yielded a small amount of crystalline substance that is under further investigation; m. p. 261–263° (dec.), $[\alpha]^{25}D$ −90° (*c* 4, water). Zone E yielded a sirup; yield 0.3 g. Zone D contained diheterolevulosan II; 0.8 g., $[\alpha]^{23}D$ −37° (*c* 4, water). Ash-free material was obtained on recrystallization as described above; m. p. 248–250° (dec.) undepressed on admixture with the material described above, $[\alpha]^{24}D$ −37° (*c* 4, water).

Anal. Calcd. for $C_{12}H_{20}O_{10}$: C, 44.44; H, 6.22. Found: C, 44.08; H, 6.08.

Subjection of an Aqueous Solution of D-Fructose to the Action of Heat and Recovery of the Reaction Products.—Following the heat treatment procedure of Sattler and Zerban,[3] 100 g. of D-fructose was dissolved in 25 ml. of water and the resultant solution was refluxed gently for sixteen hours. The solution was then diluted to 700 ml. with sterile water and fermented and deionized as described previously. The resultant dried sirup was dissolved in 200 ml. of dry methanol and the solution added dropwise to 2 liters of dry acetone. The resultant flaky, cream colored, somewhat hygroscopic, amorphous solid was removed by filtration; yield 26 g., $[\alpha]^{24}D$ −23° (*c* 4, water). The precipitate was redissolved in water, treated with decolorizing charcoal, and the solution again evaporated to dryness under reduced pressure. The dry residue was further purified by two precipitations effected by the dropwise addition of its methanolic solution to acetone; yield 18 g., $[\alpha]^{24}D$ −32.6° (*c* 4, water). An amount of 16.4 g. of this material was crystallized from anhydrous methanol; yield 1.1 g. of crystals (fraction F), $[\alpha]^{22}D$ −37° (*c* 4, water). The mother liquor material will be designated fraction G.

Fraction F (1.1 g.) was dissolved in 15 ml. of water to which was then added 85 ml. of purified dioxane. This solution was chromatographed in 5-cc. portions exactly as described above for fraction B. Two zones were obtained: H, 8–23 mm. from the top; I, 36–72 mm. The collected material from the H zone yielded crystals on concentration of the eluate; yield 0.49 g., $[\alpha]^{30}D$ −48° (*c* 4, water). Pure material was obtained on several recrystallizations effected by solution in a minimum amount of hot water and addition of ethanol. It was identified as diheterolevulosan; m. p. 261–263° (dec.) undepressed on admixture with the above-described material from the acid treatment of D-fructose, $[\alpha]^{24}D$ −45.0° (*c* 4, water).

Anal. Calcd. for $C_{12}H_{20}O_{10}$: C, 44.44; H, 6.22. Found: C, 44.23; H, 5.96.

The hexaacetate was prepared as described above; m. p. 172.5–173.5° (cor.) undepressed on admixture with material from the acid treatment of D-fructose, $[\alpha]^{28}D$ −58.0° (*c* 1, U. S. P.[10] chloroform).

(10) United States Pharmacopoeia.

(11) The clay employed was Florex XXX, a fuller's earth type of clay, produced by the Floridin Co., Warren, Pennsylvania. The Celite (no. 535) was a siliceous filter-aid produced by Johns-Manville Co., New York, N. Y. The mixture was purified by solvent extraction as described by Lew, Wolfrom and Goepp.[4]

(12) A. Kunz and C. S. Hudson, THIS JOURNAL, **48**, 1982 (1926).

The collected material from the above-described zone I was a sirup that crystallized on the addition of anhydrous methanol; yield 0.19 g. (fraction J), $[\alpha]^{20}D$ −37.6° (*c* 4, water). This material was combined below to form fraction K.

An amount of 12 g. of fraction G above was dissolved in 180 ml. of water and to this was added 1020 ml. of purified dioxane. The resultant solution was chromatographed in 5-ml. portions as described above for fraction B. Zones were obtained that were located in the same positions as those found in fraction B. The collected material from the bottom zones yielded a sirup that was not further investigated; yield 1.4 g. The material from the top zones was found to contain diheterolevulosan, identified by optical rotation, which was isolated as described above; yield 0.32 g. The collected material from the middles zones crystallized in part from methanol; yield 1.2 g., $[\alpha]^{28}D$ −39.0° (*c* 4, water). This crystalline material was combined with fraction J above to form fraction K which was further purified from methanol and 90% ethanol and was identified as diheterolevulosan II; m. p. 250–252° (dec.) undepressed on admixture with material obtained by the acid treatment of D-fructose, $[\alpha]^{28}D$ −39.0° (*c* 4, water).

Anal. Calcd. for $C_{12}H_{20}O_{10}$: C, 44.44; H, 6.22. Found: C, 44.31; H, 6.20.

The material was non-reducing toward Fehling solution and yielded the above-described hexaacetate of diheterolevulosan II.

Summary

1. Diheterolevulosan (di-D-fructopyranose 1,-2′:2,1′-dianhydride, I) and a new di-D-fructose dianhydride, designated diheterolevulosan II, have been isolated in crystalline form by chromatographic methods from the products obtained by the action of heat or of hydrogen chloride upon concentrated aqueous solutions of D-fructose.

2. Periodate analysis of diheterolevulosan II (II) favors, but does not prove, a 1,2′:2,1′-dianhydride structure (III) formed between a mole of D-fructopyranose and one of D-fructofuranose.

3. The amorphous "heterolevulosan" of Pictet and Chavan is shown by chromatographic methods to be a complex mixture, the principal constituent of which is diheterolevulosan II.

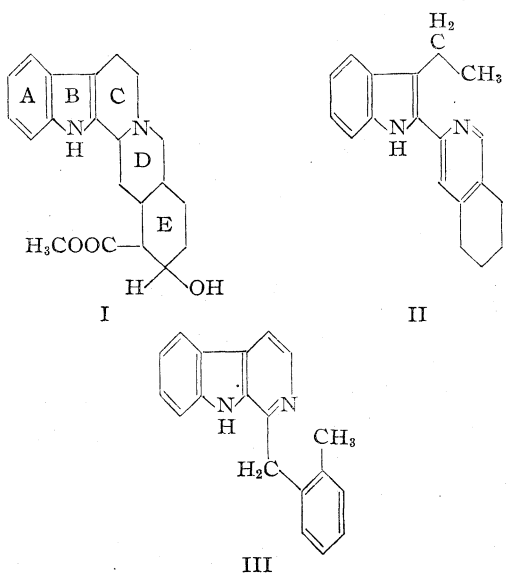
COLUMBUS, OHIO RECEIVED FEBRUARY 16, 1948

[CONTRIBUTION FROM THE CONVERSE MEMORIAL LABORATORY OF HARVARD UNIVERSITY]

The Structure of Ketoyobyrine

BY R. B. WOODWARD AND BERNHARD WITKOP

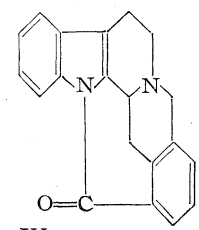
The selenium dehydrogenation of yohimbine (I) gives two bases, tetrahydroisoyobyrine (II), yobyrine (III) and ketoyobyrine, a neutral substance of the formula $C_{20}H_{16}ON_2$. The study of the basic products was of primary importance in deducing the structure of yohimbine, and the structures of the bases have been established beyond question.[1,2] On the other hand, no satisfactory formulation of ketoyobyrine has been forthcoming. Scholz[3] originally put forward the expression (IV); the facts that ketoyobyrine is optically inactive, that it is the product of a drastic dehydrogenation reaction, and in particular that it has no basic properties, are incompatible with that formula. The outstanding phenomenon in the chemistry of ketoyobyrine is the smooth cleavage of the molecule by amyl alcoholic potassium hydroxide to hemellitylic acid and norharmane.[3,4] This behavior has been adduced in support of an alternative formula (V),[2] which, however, still cannot be reconciled with the neutral character of the molecule.



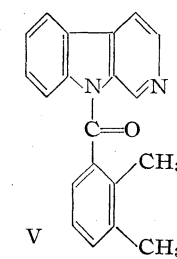
I

II

III



IV



V

In this communication, it is shown that in fact ketoyobyrine[5] has the structure (VI). This formula was deduced from that of yohimbine (I) on the basis of these considerations: (i) when yohimbic acid is heated with selenium, loss of the

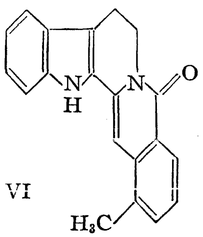
(1) Scholz, *Helv. Chim. Acta*, **18**, 923 (1935).

(2) Witkop, *Ann.*, **554**, 83 (1943); *cf.* Clemo and Swan, *J. Chem. Soc.*, 617 (1946); Julian, *et al.*, THIS JOURNAL, **70**, 180 (1948).

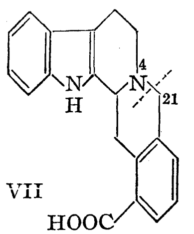
(3) Scholz, Diss. Eidgen. Techn. Hochschule, Zürich, 1934.

(4) Mendlik and Wibaut, *Rec. trav. chim.*, **50**, 91 (1931).

(5) It is clear that the term ketoyobyrine is a misnomer, but in view of long-established usage, we feel that a change is not desirable.

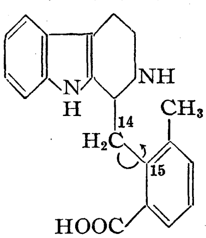


VI

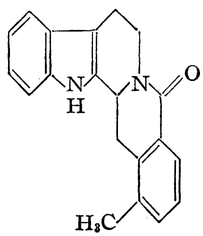


VII

hydroxyl group through dehydration may be followed to some extent by the dehydrogenation of ring E; (ii) the resulting intermediate (VII), as a benzylamine, should be subject to ready reduction cleavage between N.4 and C.21,[6] to give (VIII); (iii) by rotation through 180° about the



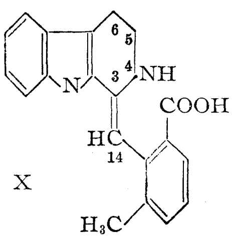
VIII



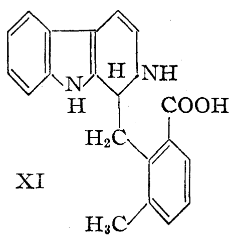
IX

C.14-C.15 bond, (VIII) is in a position to undergo lactamization to (IX); (iv) selenium may effect the further dehydrogenation of the dihydroisoquinolone (IX) to (VI). It is noteworthy that the latter contains a fully aromatic isoquinolone system, and that a compound of that structure should exhibit the high stability characteristic of ketoyobyrine.

The remarkable cleavage of ketoyobyrine by amyl alcoholic potassium hydroxide to norharmane and hemellitylic acid is readily explicable in terms of the structure (VI). Thus, opening of the amide link gives (X). The $\Delta^{3,14}$ double bond of

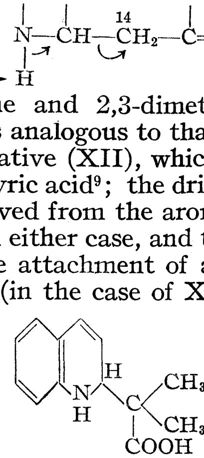


X



XI

(X) migrates to $\Delta^{5,6}$ by three prototropic shifts, for each of which ample analogy is available, *viz.*, enamine (HC=C—NH, 14, 3) → ketimine[7] (CH₂—C=N, 14, 3) ketimine (—C=N—CH₂, 3, 5) → isomeric ketimine[8] (—CH—N=CH, 3, 5), and finally ketimine → enamine[7] (N=CH—CH₂ → NH—CH=CH, 5, 6). The resulting dihydropyridine derivative (XI) then suffers loss of the side chain through the base-catalyzed process N—CH—$\overset{14}{CH_2}$—C=C—COOH, (HO⊖ → H) giving norharmane and 2,3-dimethylbenzoic acid. The cleavage is analogous to that of the dihydroquinoline derivative (XII), which leads to quinoline and isobutyric acid[9]; the driving force for the reaction is derived from the aromatization of the pyridine ring in either case, and the reaction is facilitated by the attachment of a carboxyl group either directly (in the case of XII) or through a



XII

double bond (in the case of XI) to the carbon atom which must accept the electron pair from the broken bond.

The formula (VI) implies that in ketoyobyrine the yohimbine ring system is not fully aromatized. In accordance with that view, we have found that when ketoyobyrine is heated at 280° in the presence of palladium black, exactly one mole of hydrogen is released, and a new substance, $C_{20}H_{14}ON_2$, m. p. 345°, for which we propose the name dehydroketoyobyrine, is formed. The ultraviolet spectrum of the new compound differs considerably from that of its progenitor (*cf.* Fig. 1). It is clear that the structure (XIII) may be assigned to dehydroketoyobyrine.

In marked contrast to ketoyobyrine, dehydroketoyobyrine, when treated with hot amyl alcoholic potassium hydroxide, is converted smoothly to a colorless *amino acid*, $C_{20}H_{16}O_2N_2$, which reverts readily to its precursor on heating, alone, or in a variety of solvents, *e. g.*, even on attempted recrystallization from alcohol. The nature of these changes is clear. Following the cleavage of the

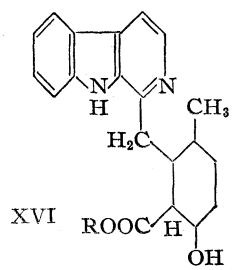
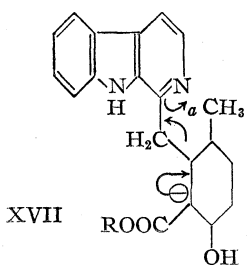
amide link of (XIII) with the formation of (XIV), ring C becomes aromatic through migration of the $\Delta^{3,14}$ double bond to the $\Delta^{3,4}$ position. In this way, we arrive at the conclusion that the amino acid $C_{20}H_{16}O_2N_2$ is carboxyyobyrine (XV). This view is substantiated by the identity of the ultraviolet absorption spectrum of the amino acid in alkaline solution[10] with that of yobyrine[11] (III) (*cf.* Fig. 2). The reconversion of (XV) to (XIII) is readily understandable in the light of the well-known lability of the α-substituted pyridine ⇄ α-pyridone methine equilibrium. When attempts were made to effect the decarboxylation of (XV) to yobyrine itself, the facile reconversion to (XIII) supervened, and dehydroketoyobyrine was the sole isolable product.

The new view of the constitution of ketoyobyrine affords new support for the attachment of the carboxyl group of yohimbine at C.16. Hitherto the acceptance of this position has depended upon the formation of harmane and *m*-toluic acid from



XVI



XVII

(10) The spectrum was determined under alkaline conditions in order to minimize any possible additional contribution to absorption as a result of the conjugation of the carboxyl group of (XV) with the benzenoid ring.

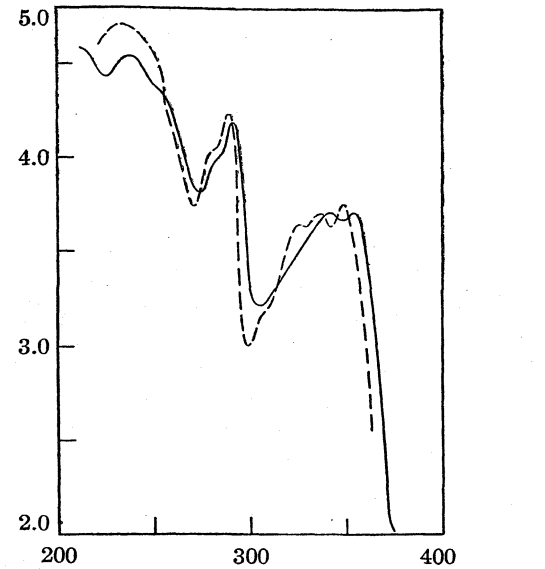

Fig. 2.—Carboxyyobyrine (sodium salt), —; yobyrine, ------.

"tetradehydroyohimbine"[12] (XVI)[2] on boiling with amyl alcoholic potassium hydroxide. The inference from this change is relatively clear, but the structural value of the evidence has been subject to some question in view of the fact that the nature of the cleavage has been obscure, the more so, since, in this reaction, scission of the C.14-C.15 bond occurs, in sharp contrast to the breaking of the C.3-C.14 bond of ketoyobyrine under very similar conditions. We should like to point out that the course of the cleavage of (XVI) is explicable in terms which we have applied elsewhere to the drastic alkaline degradation of alicyclic acids.[13] Thus, removal by base of the hydrogen atom, α to and activated by, the carbomethoxy group of (XVI) gives an anion (XVII), which undergoes a simple electronic shift (XVII, arrows), with cleavage of the C.14-C.15 bond; the acceptance of the liberated electron pair by C.14 is, of course, facilitated by the adjacent pyridine ring (*cf.* XVII, arrow *a*). The addition of a proton to the heterocyclic fragment leads to harmane, and the further changes which lead to *m*-toluic acid from the hydroaromatic fission product are unexceptional. We may point out that the course of this cleavage is in general terms very similar to that of ketoyobyrine, and that the difference in the actual points of cleavage receives a rational explanation in terms of the particular molecular environment present in the one or the other case.

In these circumstances, we consider that the attachment of the carbomethoxy group of yohimbine at C.16 is now entirely free of ambiguity.

Experimental

Ketoyobyrine.—The crude product obtained from the selenium dehydrogenation of yohimbic acid in about 4%

(12) Hahn, Kappes and Ludewig, *Ber.*, **67**, 686 (1934).

(13) Woodward and Brutschy, THIS JOURNAL, in press.

yield was first recrystallized from acetic acid (charcoal) and then extracted from a thimble with alcohol, in which it is moderately soluble; bright yellow rectangular prisms, m. p. 315–320°[14] (dark melt).

Anal. Calcd. for $C_{20}H_{16}ON_2$: C, 79.97; H, 5.37 Found: C, 79.98; H, 5.37.

Dehydroketoyobyrine.—A mixture of 100 mg. of ketoyobyrine and 200 mg. of palladium black was heated to 280° (metal-bath). After about fifteen minutes exactly the equivalent of one mole of hydrogen had been liberated; prolonged heating or higher temperature did not increase the amount of hydrogen (8.5 cc.). From the reaction mixture the dehydroproduct was obtained either by sublimation (280°, 0.001 mm.), or by recrystallization from a thimble with ethyl alcohol (twenty-four hours). The compound is very sparingly soluble in ethanol and forms fans of short needles of a yellowish-green color. The yield is almost quantitative. The crystals when powdered or sublimed have the same yellow color as ketoyobyrine and in solution they exhibit a similar powerful fluorescence; melting point 345–350° (transformation into prisms at 310°, mixed melting point with ketoyobyrine, 305–310°).

Anal. Calcd. for $C_{20}H_{14}ON_2$: C, 80.53; H, 4.69. Found: C, 80.32; H, 4.92.

Carboxyyobyrine.—Dehydroketoyobyrine (0.2 g.) was heated under reflux in 4 cc. of amyl alcohol containing 2 g. of caustic potash. A clear yellow solution was obtained after fifteen minutes, whereas ketoyobyrine requires many hours to go into solution under the same conditions. After ten hours water was added and the mixture was extracted with ether. The ethereal layer contained traces of ketoyobyrine, if that was a contaminant of the starting material, and traces of a fluorescent base yielding a picrate (4 mg.), m. p. 255°, showing no depression on admixture with norharmane picrate. The aqueous alkaline layer contained an acid which on acidification with glacial acetic acid separated as a colorless flocculent precipitate. When the alkaline cleavage was carried out in a glass vessel, silicic acid was precipitated first by adding mineral acid to the alkaline solution to *p*H 8.5. The flocculent amino acid (180 mg.) was obtained crystalline when its solution in dilute ammonia was allowed to stand overnight in a slightly evacuated desiccator. In another run, carboxyyobyrine was obtained in beautiful fine needles when it was reprecipitated from dilute alkaline solution with just the necessary amount of acetic acid and was allowed to stand for two days. The colorless aqueous acidic solution of the acid shows the characteristic pure blue harmane fluorescence. On heating the compound becomes yellow at about 100° and shows then the same melting point as dehydroketoyobyrine. For the analysis the substance has to be dried at room temperature.

Anal. Calcd. for $C_{20}H_{16}O_2N_2 \cdot H_2O$: C, 71.85; H, 5.40. Found: C, 71.46; H, 5.49.

Reconversion to Dehydroketoyobyrine.—When recrystallization of carboxyyobyrine was attempted by extracting it from a thimble with methanol in which the amino acid is sparingly soluble, all the yellow material which had crystallized overnight from the alcoholic solution consisted of dehydroketoyobyrine, m. p. 345°. When 20 mg. of carboxyyobyrine mixed with 40 mg. of soda lime was heated *in vacuo* to 350°, no yobyrine could be isolated from the negligible sublimate. The residue gave some dehydroketoyobyrine.

Acknowledgment.—We are indebted to Miss Adelaide Sutton who, through the courtesy of Dr. Elkan R. Blout (Polaroid Corporation, Cambridge), measured the ultraviolet spectra.

Summary

The structure of ketoyobyrine has been shown to be that of a lactam derived from carboxyyobyrine.

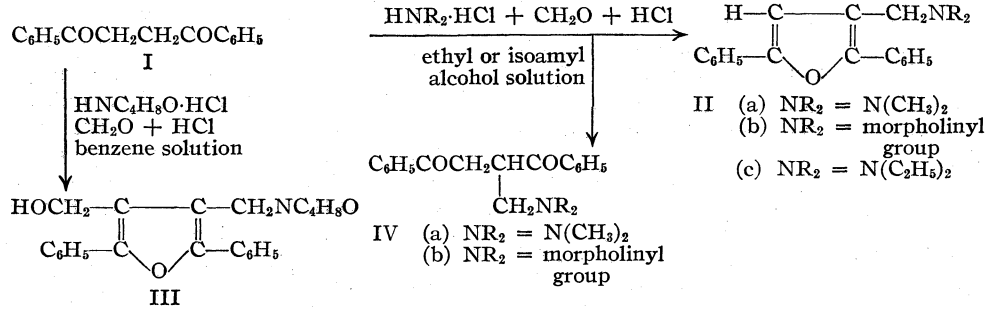
The Mannich Reaction with 1,2-Dibenzoylethane[1,2]

BY PHILIP S. BAILEY[3] AND ROBERT E. LUTZ

The Mannich reaction has been carried out with 1,2-dibenzoylethane, using secondary amine hydrochlorides and paraformaldehyde in ethyl or isoamyl alcohol solution and in benzene solution.[4]



In ethanol solution, using dimethylamine and morpholine hydrochlorides and refluxing for forty-eight hours, the products were the respective substituted furans (IIa and IIb), both of which have previously been made by other methods.[5] When

(1) A portion of the work described in this paper was carried out under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the University of Virginia.

(2) Presented in combination with a paper from The University of Texas at the Chicago meeting of the American Chemical Society, April, 1948.

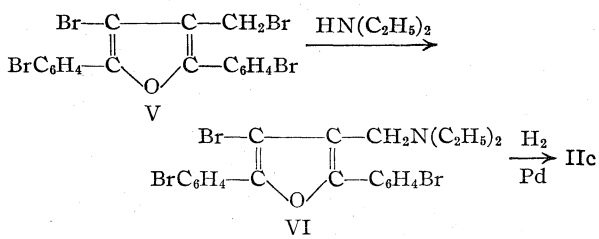
(4) For a discussion of the use of benzene as a solvent in the Mannich reaction see Fry, *J. Org. Chem.*, **10**, 259 (1945).

(5) Lutz and Bailey, THIS JOURNAL, **67**, 2229 (1945).

the reaction was carried out under less acidic conditions, low yields of the respective mono-(aminomethyl)-dibenzoylethanes (IV) were obtained. Never were any di-(aminomethyl)-dibenzoylethanes isolated. When diethylamine hydrochloride was used in ethanol solution, very little reaction occurred. When isoamyl alcohol was used as the solvent, however, a 32% yield of IIc was obtained. The structure of this compound was proved by the same method used in the proof of structure of the other (aminomethyl)-furans,[5] namely, conversions V to IIc.



When the reaction was carried out in benzene solution,[4] using morpholine hydrochloride, the product was a mixture from which was isolated some of the (morpholinylmethyl)-furan (IIb) and the known 3-(hydroxymethyl)-4-(N-morpholinylmethyl)-2,5-diphenylfuran (III).[6,7] The respective yields of these products seem to vary with the acidity of the reaction medium. When 1% by volume of concentrated hydrochloric acid was used in the reaction mixture, compound III was the principal product, but when the amount of hydrochloric acid was cut in half, compound IIb was the principal product.

The basis for the structure assigned to compound III was its synthesis from compound IIb by a bromomethylation reaction followed by a hydrolysis of the resulting bromomethyl compound.[6] Further substantiating this structure was the reaction of the hydroxymethyl compound (III) with acetic anhydride and sulfuric acid or benzoic anhydride and sulfuric acid to yield the acetate or the benzoate, respectively.

Experimental[8]

Preparation of 1,2-Dibenzoylethane (I).—The 1,2-dibenzoylethane used in these reactions was prepared by the reduction of 1,2-dibenzoylethylene by means of stannous chloride and hydrochloric acid. Into a hot suspension of 200 g. of stannous chloride in a solution of 300 ml. of 8 *N* hydrochloric acid and 100 ml. of 95% ethanol, was poured with stirring a hot solution of 200 g. of *trans*-1,2-dibenzoylethylene in 1 liter of 95% ethanol. The mixture was then diluted with 100 ml. of water, cooled and filtered. Recrystallization of the crude dibenzoylethane (190 g., m. p. 125–133°) yielded 156 g. (76% yield) of material which melted at 145–147°.

3-(N-Diethylaminomethyl)-2,5-diphenylfuran Hydrochloride (IIc) (SN-3545)[9] from the Mannich Reaction in Isoamyl Alcohol Solution.—A mixture of 12 g. of 1,2-dibenzoylethane (I), 12 g. of diethylamine hydrochloride, 5 g. of paraformaldehyde, 1 ml. of concentrated hydrochloric acid and 50 ml. of isoamyl alcohol was refluxed for thirty hours, after which the solvent was evaporated under vacuum. An ether suspension of the residue was shaken with dilute hydrochloric acid until everything dissolved in one or the other of the layers, after which the ether layer was evaporated. From the residue was isolated 1.3 g. of 2,5-diphenylfuran which was identified by a mixture melting point with an authentic sample. The hydrochloric acid extract was neutralized with sodium carbonate and extracted with ether. The ether extract was washed with salt solution several times, dried over sodium sulfate and evaporated. An acetone solution of the residual oil was acidified with ethereal hydrogen chloride solution and diluted with dry ether. White crystals were obtained, which weighed 5.4 g. (32% yield) and melted at 168–175°. Several recrystallizations from acetone solution, by the addition of dry ether, raised the melting point to 177–179°.

Anal. Calcd. for $C_{21}H_{23}NO\cdot HCl$: C, 73.77; H, 7.08. Found: C, 73.74; H, 7.16.

The preparation also was attempted using other solvents. In the case of ethanol, reaction was obtained only when excess paraformaldehyde was added daily over a period of fifteen days; yield of IIc, 18%. When the reaction was carried out in benzene solution a mixture of basic products was obtained which was not studied further, due to difficulty in effecting a separation.

4-Bromo-2,5-di-(*p*-bromophenyl)-3-(N-diethylaminomethyl)-furan (VI).—A mixture of 2.8 g. of V[10] and 10 ml. of diethylamine in 25 ml. of isopropyl ether was allowed to react without attention for two days. The diethylamine hydrochloride which precipitated was filtered off and the filtrate was washed several times with salt water and dried over sodium sulfate. Evaporation of the ether solution and crystallization of the residue from 2-propanol gave 2.5 g. (91% yield) of white crystals, m. p. 95–98°; recrystallized from 2-propanol, m. p. 97–98°.

Anal. Calcd. for $C_{21}H_{20}Br_3NO$: C, 46.52; H, 3.72. Found: C, 46.34; H, 3.65.

In a separate experiment it was shown that 4-bromo-3-methyl-2,5-diphenylfuran will not react with amines under the above conditions.

3-(N-Diethylaminomethyl)-2,5-diphenylfuran (IIc) from 4-Bromo-2,5-di-(*p*-bromophenyl)-3-(N-diethylaminomethyl)-furan (VI).—Catalytic hydrogenolysis of 1 g. of VI in 50 ml. of ethanol with 1 g. of palladium-barium sulfate catalyst was carried out until the rate appreciably decreased, at which point 3.5 mole-equivalents of hydrogen had reacted. The reaction mixture was filtered and the filtrate evaporated; the residue was suspended in sodium carbonate solution and the mixture was extracted with ether. The ether extract was washed, dried over sodium sulfate and evaporated. An acetone solution of the residue, acidified with ethereal hydrogen chloride solution and diluted with absolute ether, yielded 0.6 g. of a white crystalline material (m. p. 177–178°), which was shown by a mixture melting point to be the same compound obtained from the Mannich reaction described above.

Oxidation of the furan with nitric acid in acetic acid solution gave an oil which resisted crystallization either as a free amine or as a hydrochloride.

3-(N-Morpholinylmethyl)-2,5-diphenylfuran Hydrochloride (IIb) from the Mannich Reaction in Ethanol Solution.—A mixture of 48 g. of dibenzoylethane (I), 25 g. of paraformaldehyde, 51 g. of morpholine hydrochloride, 200

(6) Lutz and Bailey, THIS JOURNAL, **68**, 2002 (1946).

(7) Due to an erroneous analysis, the fact was not at first apparent that this compound was identical with that reported in ref. 6. Thanks are due to Mr. Gene Nowlin, graduate student of The University of Texas, for subsequent work which led to the identification of III, and which will be reported soon in a paper from The University of Texas.

(8) All melting points reported here are corrected.

(9) The Survey Number, designated SN, identifies a drug in the records of the Survey of Antimalarial Drugs. The antimalarial activities of those compounds to which Survey Numbers have been assigned are tabulated in the monograph, F. Y. Wiselogle, "A Survey of Antimalarial Drugs, 1941–1945," Edwards Brothers, Ann Arbor, Michigan, 1947.

(10) Lutz and McGinn, THIS JOURNAL, **64**, 2583 (1942).

ml. of absolute ethanol and enough ethanolic hydrogen chloride to make the reaction mixture slightly acidic, was refluxed for one hundred and thirty-five hours. During this time an additional 2 g. of paraformaldehyde was added every twelve hours. The reaction mixture was worked up in a manner similar to that of the Mannich reaction using diethylamine hydrochloride. Thus was obtained 21 g. of 2,5-diphenylfuran and 30 g. of 3-(N-morpholinylmethyl)-2,5-diphenylfuran hydrochloride (IIb), both of which were identified by mixture melting points with known samples. The use of isoamyl alcohol as a solvent did not improve the yield.

1,2-Dibenzoyl-1-(N-morpholinylmethyl)-ethane (IVb) from the Mannich Reaction.—When a mixture of 4.7 g. of dibenzoylethane (I), 4.2 g. of morpholine hydrochloride, 1.8 g. of paraformaldehyde and 20 ml. of ethanol (no excess hydrogen chloride present) was refluxed for forty hours (1 g. of excess paraformaldehyde was added every twelve hours) and the reaction mixture was worked up as described above, 0.6 g. of dibenzoylethane was recovered in the non-basic extract and 1.6 g. (24% yield) of IVb (m. p. 80–82°) was found in the basic extract. It was isolated as the free amine and was identified by a mixture melting point with an authentic sample.[5]

3-(N-Dimethylaminomethyl)-2,5-diphenylfuran Hydrochloride (IIa) from the Mannich Reaction in Ethanol Solution.—A mixture of 12 g. of dibenzoylethane (I), 8 g. of dimethylamine hydrochloride, 5 g. of paraformaldehyde, 16 drops of concentrated hydrochloric acid and 50 ml. of absolute ethanol was refluxed for forty-three hours. On cooling, a precipitate formed and was filtered; 2.5 g., m. p. 75–135°; identified as dibenzoylethane after recrystallization. When the filtrate was worked up in the same manner as the Mannich reactions described above, 4.5 g. (31% yield) of white crystals (m. p. 217–220°) was obtained and identified as 3-(N-dimethylaminomethyl)-2,5-diphenylfuran hydrochloride (IIa) by a mixture melting point with an authentic sample.[5]

In another run in which one-half the amount of hydrochloric acid was used, 50% of the product was 1,2-dibenzoyl-1-(N-dimethylaminomethyl)-ethane hydrochloride (IVa); separated from the furan by fractional crystallization and identified by a mixture melting point with an authentic sample.[5]

The Mannich Reaction between 1,2-Dibenzoylethane (I), Paraformaldehyde and Morpholine Hydrochloride in Benzene Solution.—A mixture of 48 g. of dibenzoylethane (I), 51 g. of morpholine hydrochloride, 28 g. of paraformaldehyde, 200 ml. of benzene and 2 ml. of concentrated hydrochloric acid was refluxed for forty-eight hours. Two layers were present during the entire time. The solvent was then evaporated under reduced pressure and the residue was suspended in ether. When the resulting mixture was shaken with approximately 6 *N* hydrochloric acid, some material crystallized (15.3 g., m. p. 145–148°) and was identified as dibenzoylethane by a mixture melting point. The acid layer was separated and was neutralized with sodium carbonate. When this mixture was shaken with ether, some material crystallized and was filtered; 18 g., m. p. 152–165°. The filtrate was thoroughly extracted with ether and the ether extract, upon being washed, dried and evaporated, yielded an oil which was converted to a crystalline hydrochloride and identified as IIb by a mixture melting point; yield 1 g. The 18-g. batch of crystals melted at 176–177° after several recrystallizations from ethanol and was shown to be 3-(hydroxymethyl)-4-(N-morpholinylmethyl)-2,5-diphenylfuran (III) by a mixture melting point with a known sample.[6] A small amount of the compound (III) was converted into a crystalline hydrochloride by acidifying an acetone solution of the material with ethereal hydrogen chloride solution; recrystallized from methyl ethyl ketone, m. p. 178–180° (it gave a large depression in a mixture melting point with the free amine).

Anal. Calcd. for $C_{22}H_{23}NO_3 \cdot HCl$: C, 68.47; H, 6.27. Found: C, 68.32, 68.29; H, 6.26, 6.11.

In another reaction in which only one-half the quantity of hydrochloric acid was used, the yield of III was one-third less, while the yield of IIb was 37%. In yet another experiment where the amount of paraformaldehyde was cut to one-half, the hydrochloric acid to one-fourth and the reaction mixture was refluxed for only one hour, IVb was the product in 8% yield. The recovery of dibenzoylethane was 91%.

3-(Acetoxymethyl)-4-(N-morpholinylmethyl)-2,5-diphenylfuran.—To a suspension of 2 g. of III in 9 ml. of acetic anhydride was added 7 drops of concentrated sulfuric acid. The mixture was allowed to stand for five minutes, after which time it was poured into water. The resulting mixture was neutralized with sodium carbonate and extracted with ether. After the ether extract was washed, dried and evaporated, the residue was converted into a hydrochloride by acidifying an acetone solution of it with ethereal hydrogen chloride solution. Upon cooling and filtering, 1.5 g. of material was obtained (m. p. 183–185°); recrystallized from 2-propanol, m. p. 187–188°.

Anal. Calcd. for $C_{24}H_{25}NO_4 \cdot HCl$: C, 67.36; H, 6.12. Found: C, 67.40, 67.52; H, 6.41, 6.18.

The acetoxy compound was not obtained when acetyl chloride was used in place of acetic anhydride.

The acetoxy compound was converted back to III by treatment with phosphorus pentachloride or methylmagnesium iodide followed by hydrolysis.

3-(Benzoyloxy)-4-(N-morpholinylmethyl)-2,5-diphenylfuran.—A mixture of 1 g. of III and 5 g. of benzoic anhydride was fused at 80°. To the fused mixture was added 4 drops of concentrated sulfuric acid. The reaction mixture was allowed to stand for fifteen minutes at 80°, after which time it was poured into water. The resulting aqueous mixture was extracted with ether and the ether extract was washed four times with dilute sodium hydroxide solution, dried over sodium sulfate, and evaporated. An acetone solution of the residue was acidified with ethereal hydrogen chloride solution, and the resulting crystals were filtered; yield, 1 g.; recrystallized from 2-propanol, m. p. 183–185°.

Anal. Calcd. for $C_{29}H_{27}NO_4 \cdot HCl$: C, 71.08; H, 5.76. Found: C, 71.16; H, 5.73.

The hydroxymethyl compound (III) was not affected by refluxing acetic acid–zinc dust mixture (thirty minutes).

Summary

The Mannich reaction with 1,2-dibenzoylethane has been carried out in benzene and in alcohol solutions. The products isolated were N-substituted 1-(aminomethyl)-1,2-dibenzoylethanes and 3-(aminomethyl)-2,5-diphenylfurans, and in one case 3-(hydroxymethyl)-4-(morpholinylmethyl)-2,5-diphenylfuran. Conditions favoring the formation of each type of product are described.

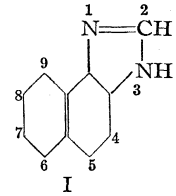
The Synthesis of 2- and 3-Substituted Naphth[1,2]imidazoles

BY EARL W. MALMBERG[1] AND CLIFF S. HAMILTON

Many of the compounds which have been synthesized in this Laboratory because of possible interest as antimalarial agents have included the benzoquinoline nucleus as part of the structure.[2] The syntheses of a number of similar compounds which are based on the naphth[1,2]imidazole nucleus (I) have been studied and are reported in the



I

present investigation. The antimalarial screening of one derivative of the proposed nucleus, 2-aminonaphth[1,2]-imidazole, was reported after the inception of this work; the quinine equivalent was less than 0.08.[3]

The Phillips reaction[4] was used in the preparation of the 2,3-disubstituted naphth[1,2]imidazoles. The parent diamine in the disubstituted series is 1-amino-2-methylaminonaphthalene. The most promising synthesis for this unreported diamine was by reduction of 1-nitroso-2-methylaminonaphthalene. The necessary aminonitroso compound was prepared very simply according to the method of Fischer, Dietrich, and Weiss.[5] Methods usually employed for the reduction of nitroso compounds failed because of the formation of extremely insoluble complexes between the aminonitroso compound and various metallic ions. Reduction with molecular hydrogen and Raney nickel catalyst proceeded very smoothly and in excellent yields.

Literature reports[6] and preliminary experiments with ethyl ϵ-diethylaminocaproate indicated that amino acids do not undergo the Phillips reaction, and so the tertiary amine groups which were desired in the final structure were introduced into the molecule after the ring closure; the secondary hydroxyl group could be present in the molecule of the carboxylic acid. The desired intermediates were therefore prepared from the acids listed below, chloroacetic acid and β-chlorolactic acid. The respective products, 2-chloromethyl-3-methylnaphth[1,2]imidazole and 2-(α-hydroxy-β-choroethyl)-3-methylnapth[1,2]imidazole, were then treated with morpholine and piperidine to give products of the desired structure.

The naphth[1,2]imidazoles which are substituted only in the 2-position can be regarded as derived from 1,2-diaminonaphthalene. However, the Phillips reaction could not be successfully applied to this diamine because of the insolubility of the amine salt in acid of the required strength. Attempts to prepare the desired intermediate by fusion of the diamine and chloro acids were also unsuccessful. Hydroxy compounds have been converted to chloro derivatives in the benzimidazole series quite readily[6,7] and therefore 2-hydroxymethylnaphth[1,2]imidazole was prepared by fusion of the diamine with glycolic acid, the method used by Sachs for the preparation of a perimidine.[8] However, preliminary experiments on the conversion of 2-hydroxymethylnaphth[1,2]imidazole to the desired chloromethyl compound by means of thionyl chloride showed no promise of success because of the insolubility of the hydroxy compound and therefore a third and successful approach was made. 1-Nitro-2-aminonaphthalene was converted to N-(1-nitro-2-naphthyl)-α-chloroacetamide by treatment with chloroacetyl chloride; the halogen on the acetyl group of this compound is active and readily reacted with an amine such as morpholine. The product of this reaction, N-(1-nitro-2-naphthyl)-α-morpholinoacetamide, was converted to the desired compound, 2-morpholinomethylnaphth[1,2]imidazole, by two different methods. Reductive ring closure,[9] refluxing the nitro amide in alcohol with zinc and hydrochloric acid, accomplished the transformation in one step. A somewhat longer but more satisfactory synthesis was through the catalytic reduction of the nitro compound to N-(1-amino-2-naphthyl)-α-morpholinoacetamide; the ring closure was then accomplished by the method of Kelly and Day.[9] In this series the placement of the hydrogen on either nitrogen of the ring is immaterial since the tautomeric nature of the structure has been demonstrated.[9] The compounds of the series with hydrogen on the heterocyclic nitrogen rather than a methyl group were characterized by a very high melting point, very low solubility in organic solvents, and solubility in both aqueous alkali and acid.

Experimental[10]

1-Nitrosonaphthol-2.—This nitroso compound was prepared by the direct nitrosation of naphthol-2.[11] For best results in the subsequent catalytic reduction it was

necessary to recrystallize the crude yield from 88–100° ligroin.

1-Nitroso-2-methylaminonaphthalene (II).—A mixture of 100 ml. of water and 127 ml. of aqueous methylamine (25% methylamine by weight, 0.94 mole) was cooled to 15° and 34.6 g. (0.2 mole) of recrystallized 1-nitroso-naphthol-2 was slowly added. The mixture was warmed to 35° to complete solution of the salt. The mixture was allowed to stand at room temperature for twenty-four hours, during which time the product crystallized out in black platelets. Purification by solution in dilute hydrochloric acid, filtration, and precipitation with dilute ammonium hydroxide was sufficient for excellent results with the subsequent catalytic reduction. The product weighed 33.5 g. (90%). A sample which was recrystallized from methanol melted at 145–146°; literature values vary from 141–142° to 148–149°.[5]

1-Amino-2-methylaminonaphthalene Dihydrochloride (III).—A suspension of 18.6 g. of II in 115 ml. of absolute ethanol was reduced at room temperature with Raney nickel catalyst and molecular hydrogen at 50 lb. pressure. The calculated quantity of hydrogen was absorbed in twenty to twenty-five minutes and the pressure was constant thereafter. After removal of the catalyst, dry hydrogen chloride was passed into the cooled alcoholic solution and the product isolated as the dihydrochloride; yield, 23.3 g. (95%).

This new diamine was found to be an unstable oil with a blue fluorescence; it was always isolated and used as the dihydrochloride. The dihydrochloride salt, after solution in hot water and treatment with charcoal and recrystallization from dilute hydrochloric acid melted with decomposition at 194–196°. The diamine was characterized by the conversion to a known derivative and to three new compounds which are described in the following four procedures; the Phillips reaction with acetic, chloroacetic, lactic and β-chlorolactic acid was used in these conversions. A known compound, 2,3-dimethylnaph[1,2]imidazole,[12] was formed with acetic acid; the identities of the other three products were confirmed by the elementary analysis and by the results of succeeding reactions.

2,3-Dimethylnaphth[1,2]imidazole (IV).—A mixture of 1.0 g. of III, 1.6 ml. of acetic anhydride, and 8 ml. of 4 *N* hydrochloric acid was heated under reflux for one hour. The cooled solution was neutralized with solid sodium bicarbonate, whereupon a quantitative yield of 2,3-dimethylnaphth[1,2]imidazole was obtained in crystalline form. When recrystallized from dilute alcohol and from benzene, the product melted at 142–143°, the same value as reported in the literature.[12]

2-(α-Hydroxyethyl)-3-methylnaphth[1,2]imidazole (V).—A mixture of 1.8 g. (0.02 mole) of lactic acid and 2.45 g. (0.01 mole) of III was refluxed in 24 ml. of 4 *N* hydrochloric acid for six hours. The reaction mixture was cooled in ice and neutralized carefully with solid sodium bicarbonate. The crude yield of crystalline product weighed 2.2 g. (96%). A sample which was recrystallized from benzene and from alcohol melted at 184.1–184.6°.

Anal. Calcd. for $C_{14}H_{14}ON_2$: C, 74.31; H, 6.24. Found: C, 74.22; H, 6.37.

2-Chloromethyl-3-methylnaphth[1,2]imidazole (VI).—Technical chloroacetic acid (5.64 g., 0.06 mole) was dissolved in 72 ml. of 4 *N* hydrochloric acid and the mixture was heated on a steam-bath. Three 1.23-g. portions of III (total of 3.69 g., 0.015 mole) was added at thirty-minute intervals during the first hour of heating. The mixture was heated a total of four hours, after which it was cooled in ice, a layer of ether added, and the mixture carefully neutralized with sodium bicarbonate. The tar which formed during the addition of the first half of the total amount of base was skimmed off before the product began to precipitate. The dried crude yield was extracted with 75 ml. of 2:1 benzene–ligroin, the extract was treated with charcoal, filtered, and the product crystallized from the cooled solution; yield 1.2 g. (34%).

(12) Meldola and Lane, *J. Chem. Soc.*, **85**, 1602 (1904).

VI, similar to an analogous compound in the benzimidazole series,[13] is a powerful skin irritant. The compound was crystallized from benzene–ligroin mixtures and from absolute alcohol. The substance turns yellow at 150–155° and melts with decomposition at 160–162°.

Anal. Calcd. for $C_{13}H_{11}N_2Cl$: C, 67.68; H, 4.81. Found: C, 67.70; H, 4.93.

2-(α-Hydroxy-β-chloroethyl)-3-methylnaphth[1,2]imidazole (VII).—A mixture of β-chlorolactic acid (7.46 g., 0.16 mole) and III (9.8 g., 0.04 mole) in 96 ml. of 3 *N* hydrochloric acid was heated on a steam-bath for seven hours. The subsequent procedure was the same as in the preparation of VI except that 135 ml. of benzene–ligroin was used for the extraction. A yield of 2.96 g. (29%) was obtained from experiments in which two of three separate lots of β-chlorolactic acid were used. With a third lot, identical with the other two as far as physical tests indicated, a yield of only 8–10% could be obtained. The product was recrystallized from benzene and from alcohol; m. p., 168.9–169.0°.

Anal. Calcd. for $C_{14}H_{13}ON_2Cl$: C, 64.49; H, 5.03. Found: C, 64.48; H, 5.11.

β-Chlorolactic Acid.—This acid was prepared by the oxidation of glycerol α-monochlorohydrin.[14] The chlorohydrin was made by the procedure of "Organic Syntheses" and redistilled before use[15]; the fraction which was collected between 117 and 120° at 13 mm. was used in the oxidation. The time required for the oxidation with nitric acid was considerably longer than that reported by Koelsch, but it was also noted that just a few degrees of variation in room temperature had a marked effect on the rate of this exothermic reaction.

A modified method of isolating the desired product was used. The oily crystalline mass of crude product was subjected to prolonged suction on a filter until practically all the oil was removed. The melting point of this product, 77–78°, was excellent, comparable to the values reported for recrystallized material, 77°[14] and 78.5–79.0°.[16]

2-Piperidinomethyl-3-methylnaphth[1,2]imidazole (VIII).—A solution of VI and a three-fold excess of piperidine in benzene was refluxed in benzene for two hours. The piperidine hydrochloride was removed by washing and the product isolated in 97% yield by evaporation of the benzene solution. The product was recrystallized from dilute alcohol and from ligroin; m. p., 134.8–135.0°.

Anal. Calcd. for $C_{18}H_{21}N_3$: C, 77.38; H, 7.58. Found: C, 77.46; H, 7.63.

2-Morpholinomethyl-3-methylnaphth[1,2]imidazole (IX).—The same procedure was used as in the preparation of VIII, with morpholine in place of the piperidine. This very similar product melted at 134.0–134.4°.

Anal. Calcd. for $C_{17}H_{19}ON_3$: C, 72.58; H, 6.81; N, 14.94. Found: C, 72.67; H, 6.82; N, 14.92.

2-(α-Hydroxy-β-piperidinoethyl)-3-methylnaphth[1,2]imidazole (X).—A solution of VII in piperidine was heated on a steam-bath for three hours. The resulting mixture was poured into water and the product allowed to crystallize; the crude yield was 95%. The product was recrystallized from dilute alcohol and from benzene–ligroin. The crystals which were obtained from anhydrous solvents or which were very carefully dried melted at 149.2–149.6°.

Anal. Calcd. for $C_{19}H_{23}ON_3$: C, 73.76; H, 7.49. Found: C, 73.83; H, 7.61.

2-(α-Hydroxy-β-morpholinoethyl)-3-methylnaphth[1,2]imidazole (XI).—This compound was prepared from VII and morpholine by the same procedure as for the preparation of X. The product possessed the same properties as X, with respect to solubility, etc.; the melting point was 168.4–169.0°.

Anal. Calcd. for $C_{18}H_{21}O_2N_3$: C, 69.43; H, 6.80. Found: C, 69.27; H, 6.87.

N-(1-Nitro-2-naphthyl)-α-chloroacetamide (XII).—Seven grams (0.07 mole) of precipitated chalk was suspended in a solution of 12.1 g. (0.064 mole) of 1-nitro-2-aminonaphthalene in 32 ml. of dry dioxane, and to this mixture a solution of 9.6 g. (0.085 mole) of redistilled chloroacetyl chloride in 18.6 ml. of dry dioxane was slowly added. The mixture was stirred and kept between 20 to 25° during the addition and then allowed to stand at room temperature for several days. The product was precipitated by the slow addition of 200 ml. of water, and after acidification the product was collected by filtration. The crude product was purified by crystallization from ligroin. By use of a Soxhlet extractor a yield of 88% of the purified product was obtained. A sample which was crystallized from benzene and from alcohol melted at 119.8–120.6°.

Anal. Calcd. for $C_{12}H_9O_3N_2Cl$: C, 54.33; H, 3.42. Found: C, 54.39; H, 3.50.

N-(1-Nitro-2-naphthyl)-α-morpholinoacetamide (XIII).—A solution of 18.0 g. (0.075 mole) of XII and 16.3 g. (0.1875 mole) of morpholine in 120 ml. of 80% ethanol was refluxed for one hour. The resulting mixture was cooled slowly, finally to −10°, and 19.3 g. (82%) of very pure product crystallized. A sample which was recrystallized from benzene–ligroin and from absolute alcohol melted at 131.9–132.5°.

Anal. Calcd. for $C_{16}H_{17}O_4N_3$: C, 60.94; H, 5.44. Found: C, 61.04; H, 5.50.

N-(1-Amino-2-naphthyl)-α-morpholinoacetamide (XIV).—Fifteen grams of XIII was dissolved in 100 ml. of warm absolute alcohol, Raney nickel catalyst was added, and hydrogen under 50 pounds pressure admitted. The calculated quantity of hydrogen was slowly absorbed and the pressure subsequently remained constant. The final solution was warmed to dissolve the product which crystallized during the reaction, filtered, and upon cooling 8.0 g. of pure product (58%) was obtained. By precipitating the product as the dihydrochloride a yield of 82% was obtained. A sample which was recrystallized from benzene–ligroin, acetone, and absolute ethanol melted at 163.9–164.4°.

Anal. Calcd. for $C_{16}H_{19}O_2N_3$: C, 67.34; H, 6.71. Found: C, 67.36; H, 6.76.

2-Morpholinomethylnaphth[1,2]imidazole Dihydrochloride (XV): Reductive Ring Closure.—One gram of XIII was dissolved in 100 ml. of warm alcohol, 1.0 g. of granulated zinc was placed in the flask, and the solution was refluxed for seven hours. During this time 10 ml. of concentrated hydrochloric acid was added very slowly. The salt of the ring closure product precipitated during the reaction. This salt was freed from inorganic impurities by solution in water and the free base was obtained as an amorphous white solid upon neutralization of the solution with sodium bicarbonate. The dihydrochloride salt was prepared by addition of hydrogen chloride to an ethereal solution of the free base; the characteristics of this salt are described in the following section.

Ring Closure of XIV in Xylene.—One gram of XIV was refluxed in 80 ml. of xylene for one hour. The product was extracted with acid, the solution treated with charcoal, neutralized, and finally the amorphous free base was again isolated as the dihydrochloride salt. The amorphous free base was soluble in dilute acid and alkali and in organic solvents. The dihydrochloride was purified by recrystallization from ethanol which contained 3 to 4% of water; m. p. 241–243°.

Anal. Calcd. for $C_{16}H_{17}ON_3 \cdot 2HCl$: C, 56.47; H, 5.63; Cl, 20.84. Found: C, 56.24; H, 5.73; Cl, 20.74.

N-(1-Nitro-2-naphthyl)-α-anilinoacetamide.—A solution of 1.2 g. (0.0045 mole) of XII and 1.9 g. (0.02 mole) of aniline in 25 ml. of absolute ethanol were heated on a steam-bath for six hours. During this time the volume of solvent was allowed to decrease to 15 ml., and upon cooling the final mixture a precipitate of pure crystalline product was obtained which weighed 1.3 g. (87%). This compound was insoluble in dilute acid, but could be recrystallized from benzene–ligroin and alcohol; m. p. 171–172°.

Anal. Calcd. for $C_{18}H_{15}O_3N_3$: C, 67.28; H, 4.71. Found: C, 67.44; H, 4.84.

1,2-Diaminonaphthalene (XVI).—1-Nitro-2-aminonaphthalene in alcoholic solution was reduced at room temperature with Raney nickel catalyst and molecular hydrogen at 50 lb. pressure. The solvent was evaporated to a small volume and the product precipitated by the careful addition of water; yield, 71%. The crude product melted at 91–92°; literature values vary from 90–96°.[17]

2-Hydroxymethylnaphth[1,2]imidazole (XVII).—A mixture of XVI (3.6 g., 0.023 mole) and glycolic acid (1.8 g., 0.024 mole) was heated slowly up to 150°. The initially fluid mixture became viscous after a considerable amount of water had been lost, and after twenty minutes of heating 10 ml. of glycerol was added. Heating was continued for a total of two hours, and then the mixture was poured into 100 ml. of water. Ten milliliters of 6 *N* hydrochloric acid was added to the mixture, the solution was heated to boiling, treated with charcoal, and filtered while hot. The hydrochloride of XVII crystallized from the filtrate upon cooling; yield, 45%.

The free base is soluble in dilute acid, dilute alkali, and alcohol; it is very sparingly soluble in other organic solvents, but it can be recrystallized from acetone; m. p. 253–255° (dec.).

Anal. Calcd. for $C_{12}H_{10}ON_2$: C, 72.71; H, 5.09. Found: C, 72.78; H, 5.18.

Summary

A new diamine, 1-amino-2-methylaminonaphthalene, was prepared by reduction of 1-nitroso-2-methylaminonaphthalene. Naphth[1,2]imidazoles which are substituted in the 2- and 3-positions were prepared by the Phillips reaction between this diamine and acetic, lactic, chloroacetic, and β-chlorolactic acids. The products from the latter two acids were treated with piperidine and morpholine to give compounds of the desired structures, 2-piperidinomethyl-3-methylnaphth[1,2]-imidazole, 2-morpholinomethyl-3-methylnaphth-[1,2]imidazole, 2-(α-hydroxy-β-piperidinoethyl)-3-methylnaphth[1,2]imidazole, and 2-(α-hydroxy-β-morpholinoethyl)-3-methylnaphth[1,2]imidazole.

Naphth[1,2]imidazoles which are substituted only in the 2-position were prepared by the chloroacetylation of 1-nitro-2-aminonaphthalene, reaction of the chloro compound with morpholine to give N-(1-nitro-2-naphthyl)-α-morpholinoacetamide, and conversion of this compound to 2-morpholinomethylnaphth[1,2]imidazole by two different methods.

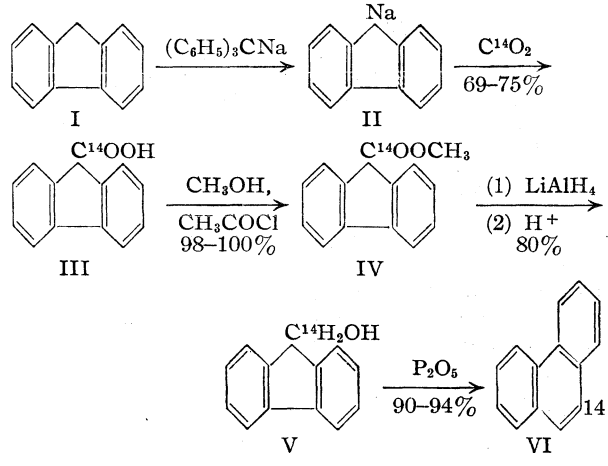
The Synthesis of Phenanthrene-9-C^{14} [1,2]

BY CLAIR J. COLLINS

Due to the widespread interest in cancer producing substances, it appeared that a simple method for introducing carbon-14 in reasonable yields into aromatic polynuclear hydrocarbons should be of value. Accordingly, a synthesis of phenanthrene containing carbon-14 in the 9-position (VI) which the author has designated[3] phenanthrene-9-C^{14} has been effected by means of the Wagner rearrangement[4] of 9-fluorenemethannol-10-C^{14} (V). A new synthesis of the latter compound has been developed. Fluorene (I) was converted to 9-fluorenesodium (II) by interaction with triphenylmethylsodium. Carbonation with carbon dioxide-C^{14} yielded 9-fluorenecarboxylic acid-10-C^{14} (III). Reduction of the methyl ester (IV) with lithium aluminum hydride[5] produced 9-fluorenemethanol-10-C^{14} (V).



The complete synthesis was first worked out with non-radioactive materials, and each compound in the series was purified and characterized. The series was finally effected with purification only at the phenanthrene stage. The generality of this synthetic method is now under investigation.

Acknowledgment.—The author wishes to thank Professor Weldon G. Brown, of the University of Chicago, for the design of the extraction apparatus (Fig. 2) as well as for his many suggestions during the course of this work.

Experimental

Determination of Radioactivity.—Carbon-14 determinations were carried out by measuring the ionization current of carbon dioxide-C^{14} by means of a dynamic condenser electrometer.[6,7] The wet combustion method[8] of Van Slyke, Folch and Plazin was employed to oxidize 9-fluorenecarboxylic acid-10-C^{14} and phenanthrene-9-C^{14} (1–5 mg. samples). The carbon dioxide thus formed was collected in an ionization chamber which had previously been evacuated, using nitrogen to sweep the carbon dioxide into the chamber and to fill it to atmospheric pressure. Barium carbonate-C^{14} samples were similarly analyzed after decomposition with dilute perchloric acid. The conversion of the measured ionization currents to activities in millicuries was made on the basis of data obtained in this laboratory by Dr. W. B. Leslie employing similar chambers and a barium carbonate sample of known isotopic composition.

9-Fluorenecarboxylic Acid (III).[9]—The vacuum line shown in Fig. 1 was used for this preparation. In a typical run, 100 mg. of barium carbonate was weighed into flask A which could be placed directly on the balance pan. The apparatus was then swept with nitrogen. The exhaust nitrogen was passed through Drierite, a barium hydroxide bubbler and soda-lime. Decomposition of the barium carbonate was effected by addition of 5–8 cc. of 5 *M* perchloric acid. Next, nitrogen was passed through the system at a convenient rate for fifteen minutes. The cooling mixture surrounding the Dry Ice trap was kept at −50° to −55° by adjusting the amount of Dry Ice in the $CHCl_3$–CCl_4 mixture. This trap served to collect water vapor; when cooled to Dry Ice temperature, a significant amount of carbon dioxide was retained. Carbon dioxide was frozen in the liquid nitrogen trap. After fifteen minutes the acid decomposition mixture was heated gently with a free flame to liberate the last traces of carbon dioxide. In the reaction flask (B), 3.5 cc. of a stock triphenylmethyl sodium solution, prepared from 2.0 g. of sodium, 5.0 g. of triphenylchloromethane, 40 cc. of dry ether and 40 cc. of dry benzene, by the procedure of Bachmann and Wiselogle[10] was added to 150 mg. of fluorene (m. p. 114.0–114.5°)[11] and the flask was joined to the line. The entire operation was carried out under dry nitrogen. After stirring for three minutes, by means of a magnetic stirring bar, the color changed from deep red to light orange, and the mixture was frozen in liquid nitrogen. The two traps (b, c, Fig. 1) and the reaction flask (B) were evacuated to a pressure of less than 1 mm. of mercury. The carbon dioxide was then distilled from trap c into reaction flask B by cooling the latter with liquid nitrogen, and the flask was isolated from the rest of the line. Upon warming to a

(2) Presented before the Division of Organic Chemistry at the 112th Meeting of the American Chemical Society, New York, N. Y., September 15, 1947.

(3) The carbon-14 labeled compounds described in this paper have been named by analogy to the rules set down in *Chemical Abstracts* (**39**, 5874–5875 (1945)) for deuterium and tritium. Since the prefix "deuterio" is not recommended for compounds containing deuterium, use of the term "radio" to denote the presence of carbon-14 has been avoided. Unlike deuterium nomenclature, however, the present author recommends the use of capital C in preference to lower case *c* for carbon-14 to avoid confusion with the lower case letters denoting bridgehead positions 4a, 4b, 8a, and 10a in phenanthrene. At tracer levels of C^{14} concentrations, "phenanthrene-9-C^{14}" and "phenanthrene-9,10-C^{14}_2" are indistinguishable because of the equivalence of the 9- and 10- positions. Pending the adoption of a formal convention the simpler designation has been used.

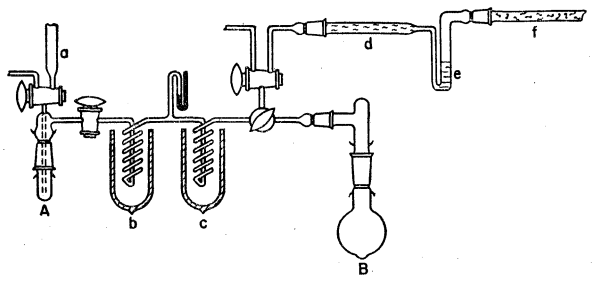

Fig. 1.—Carbonation apparatus: a, perchloric acid funnel; b, Dry Ice trap; c, liquid nitrogen trap; d, drierite; e, barium hydroxide solution; f, soda lime.

point at which the magnetic bar would just turn in the mixture, the reaction was complete, as indicated by a zero pressure in the system when the mixture was cooled to Dry Ice temperature. After admitting nitrogen, flask B was detached and 10 cc. of water was added to it. The layers were separated by means of the extraction apparatus shown in Fig. 2. The ether–benzene layer was washed twice with 5-cc. portions of water, and the combined aqueous layers were washed twice with 3-cc. portions of ether. Next, 10 cc. of 1 *N* hydrochloric acid was added to the aqueous layer, forming a white precipitate which was usually filtered directly when non-radioactive material was used. With radioactive material, however, the mixture was not filtered, but was treated with four 4-cc. portions of ether. The ether layer was washed once with 4 cc. of water, and then treated with three 4-cc. portions of saturated sodium bicarbonate solution. The bicarbonate layer, after one washing with 3 cc. of ether, was decomposed with 10 cc. of 6 *N* hydrochloric acid. Extraction with ether and concentration yielded 73–80 mg. of 9-fluorenecarboxylic acid (III); m. p. 222–226°. Consistent yields of 69–75% were obtained. The best yield was 86%.

Methyl 9-Fluorenecarboxylate (IV).—To 115.5 mg. of 9-fluorenecarboxylic acid (III) was added a chilled mixture of 5.0 cc. of methanol and 0.1 cc. of acetyl chloride. After standing at room temperature for one hour the contents of the flask were taken to dryness, yielding 120 mg. of methyl 9-fluorenecarboxylate (IV), m. p. 63.0–63.5°, 98%.

9-Fluorenemethanol (V).[12]—To 108 mg. of methyl 9-fluorenecarboxylate (IV) in 5.0 cc. of ether was added 10 cc. of 0.15 *M* lithium aluminum hydride solution (in ether). The mixture was stirred for ten minutes and then treated with 10 cc. of moist ether followed by 5.0 cc. of 6 *N* hydrochloric acid. The layers were separated, and the ether layer was washed with 5.0 cc. of water, and taken to dryness, yielding 82.4 mg. of crude alcohol melting at 80–85° (87%). One crystallization gave a product melting at 94–96°. The carbinol (7.7 mg.) was converted to 6.3 mg. (90%) of phenanthrene (VI) by the procedure of Brown and Bluestein.[4]

Phenanthrene-9-C^{14} (VI) Synthesis from Barium Carbonate-C^{14}.—The carbonation reaction was carried out as described elsewhere in this paper using 211.3 mg. of $BaC^{14}O_3$ containing 11.65 millicuries of carbon-14 per mole. Decomposition of this material produced 46.8 mg. of carbon dioxide-C^{14} (47.2 mg. theoretical) determined by direct weight in a gas weighing bulb. This was distilled into 9-fluorenesodium prepared from 300.0 mg. of fluorene and 7–8 cc. of triphenylmethylsodium solution.[10] The yield of 9-fluorenecarboxylic acid-10-C^{14} was 164.5 mg. (73%) whose activity was 11.62 millicuries carbon-14 per mole. To 122.0 mg. of this acid was added 5.0 cc. of methanol and 0.15 cc. of acetyl chloride. After standing for one hour at room temperature, the solution was concentrated in an air stream and desiccated to constant weight of 124.4 mg. over phosphorus pentoxide. This material was dissolved in 7 cc. of ether and to it was added 10 cc. of 0.16 molar lithium aluminum hydride solution. After stirring for fifteen minutes, 5 cc. of moist ether was added, followed by 5 cc. of 6 *N* hydrochloric acid. The layers were separated, the ether layer was washed with 5.0 cc. of water and taken to dryness and desiccated, yielding 114.8 mg. of an oil, which was dissolved in 10 ml. of xylene (doubly distilled over phosphorus pentoxide). To this solution was added 200–400 mg. of phosphorus pentoxide, and the mixture was heated under reflux for thirty minutes. After cooling, 5 cc. of water was added. The layers were separated and the xylene layer was washed twice with 5-cc. portions of water and concentrated and desiccated, yielding 170 mg. of an oil, which was transferred to a centrifuge tube fitted with a 19/38 female joint. This centrifuge tube was so designed that it could replace flask 1 of the extraction apparatus (Fig. 2). To this oil was added 60 mg. of picric acid and then 3.0 cc. of saturated ethanolic picric acid solution. The tube was heated with a free flame until a clear solution resulted; it was then allowed to cool. The phenanthrene picrate was separated by centrifuging, the supernatant liquid being drawn off using the extraction apparatus (Fig. 2). The picrate was decomposed with dilute aqueous sodium hydroxide solution, and extracted with ether, which was washed with water and concentrated. A repetition of this process with the solid so obtained yielded 72.5 mg. of phenanthrene-9-C^{14}, m. p. 94–95°; activity, 10.78 millicuries carbon-14 per mole. The over-all yield from barium carbonate was 51%. One crystallization from ethanol yielded white crystals melting at 96–97°. The picrate of this material melted at 141°. There was no depression of melting point when this material was mixed with an authentic sample of phenanthrene.

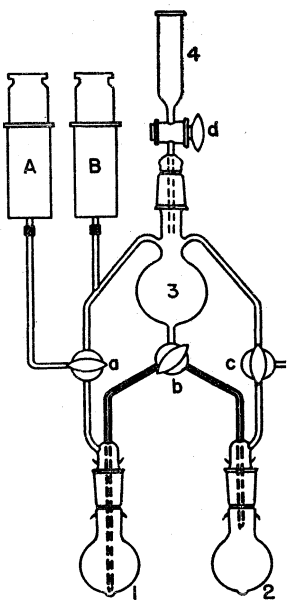

Fig. 2.—Extraction apparatus.

Extraction Procedure.—All extractions were carried out in the apparatus sketched in Fig. 2. The 50-cc. flasks 1 and 2 were interchangeable and were used in the carbonation apparatus (Fig. 1) as the reaction flask B and also in the lithium aluminum hydride reductions as the reactor vessels. This procedure prevented mechanical loss, and kept laboratory contamination with carbon-14 at a minimum. Chromatographic adsorptions were effected by replacing flask 2 (Fig. 2) with a chromatograph tube sealed to a 19/38 female glass joint.

The layers to be separated were placed in flask 1. By proper setting of the stopcocks, downward pressure on the plunger in cylinder A forced both layers into vessel 3 and also moved the plunger in cylinder B upward. Mixing was effected by pressing plunger A downward and forcing air through the two layers in 3. Solvents were added through 4, and by manipulation of stopcock b, liquid could be placed in flasks 1 and 2.

Summary

Fluorene (I) has been converted to 9-fluorenecarboxylic acid-10-C^{14} (III) by carbonation of 9-fluorenesodium (II) with carbon dioxide-C^{14}. Lithium aluminum hydride reduction of the methyl ester (IV) yielded 9-fluorenemethanol-10-

(12) The reduction of the free acid (III) proceeds very slowly, and even after twenty-four hours approximately 10% of the starting material is recovered. Further, prolonged treatment of the acid with lithium aluminum hydride in ether solution decreases the yield of carbinol.

C^{14} (V). Dehydration of V with phosphorus pentoxide was accompanied by a Wagner rearrangement to form the desired phenanthrene-9-C^{14} (VI). The over-all yields of VI, based on barium carbonate, were 50–55%.

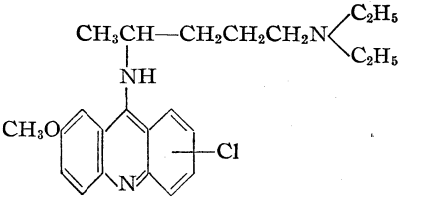
The Synthesis of Nuclear Isomers of Quinacrine

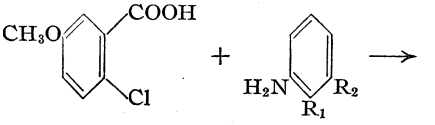
BY WILLIAM G. DAUBEN[1]

During the past few years much work has been done on the synthesis of compounds related to Quinacrine. However, of the four possible isomers of this compound which have the methoxyl

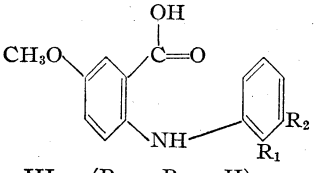


group in position two of the acridine nucleus and the chlorine atom in the opposite, nitrogen-free ring, only two have been reported. They are the 2-methoxy-6-chloro-9-substituted-aminoacridine[2] (Quinacrine) and the related 7-chloro isomer.[3] The present paper is concerned with the synthesis of the 5-chloro and the 8-chloro isomers.[4]

Following the observations of Ullmann and Kipper[5] that 2-chloro-5-methoxybenzoic acid[6] (I) can be used in the Ullmann condensation to prepare substituted N-phenylanthranilic acids (III), this compound (I) was utilized as the precursor of the desired methoxyl-substituted ring of the acridine. When the above acid (I) was allowed to react with *m*-chloroaniline (IIa) in the presence of anhydrous potassium carbonate and copper powder in boiling isoamyl alcohol, N-(3′-chlorophenyl)-5-methoxyanthranilic acid (IIIa) was formed in a yield of 19.9% and the majority of the starting acid (I) was recovered. Likewise, when acid I was allowed to react with *o*-chloroaniline (IIb), N-(2′-chlorophenyl)-5-methoxyanthranilic acid (IIIb) was isolated in a yield of only



I IIa (R_1 = H, R_2 = Cl) IIb (R_1 = Cl, R_2 = H)



III (R_1 = R_2 = H) IIIa (R_1 = H, R_2 = Cl) IIIb (R_1 = Cl, R_2 = H)

11.4% and again the majority of the starting acid was recovered. It was found that the use of solvents with different boiling points, as *n*-butanol, *n*-pentanol, *n*-hexanol and cyclohexanol, gave still lower yields and that when the reaction was conducted in boiling nitrobenzene extensive decomposition occurred.

The small quantity of the desired materials (IIIa and IIIb) was not easily separated from the large amount of starting acid by fractional crystallization. However, this mixture was easily separated by partial acidification of a solution of their potassium salts since a substituted-anthranilic acid is a much weaker acid than a substituted benzoic acid. Crude product was precipitated when the *p*H was adjusted to seven and the starting acid was deposited from solution at a *p*H of five.

In view of the poor yields obtained in the above condensations, it is interesting to note that Ullmann and Kipper[5] have reported that the same acid (I) reacts with aniline to give N-phenyl-5-methoxyanthranilic acid (III) in a yield of 80% and that Lehmstedt and Schrader[7] have reported

(4) Since this paper was submitted for publication, Grigorovskii and Terent'eva (*J. Gen. Chem.* (*U. S. S. R.*), **17**, 517 (1947)) have reported the synthesis of the 5-chloro isomer and the attempted preparation of the 8-chloro isomer. The 2-methoxy-5,9-dichloroacridine (IV), prepared from 2,3-dichlorobenzoic acid and *p*-anisidine through the intermediate N-(4′-methoxyphenyl)-3-chloroanthranilic acid, had identical physical properties with the compound reported in this work. They, likewise, were unable to obtain a crystalline hydrochloride of the Quinacrine analog but they did obtain a solid oxalate. The 5-chloro isomer showed no anti-malarial activity. Their attempted synthesis of the 8-chloro isomer from 2,6-dichlorobenzoic acid and *p*-anisidine failed and the product isolated from the Ullmann reaction was *m*-bis-(*p*-methoxyanilino)-benzene.

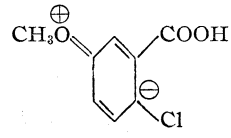
(7) Lehmstedt and Schrader, *Ber.*, **70**, 838 (1937).

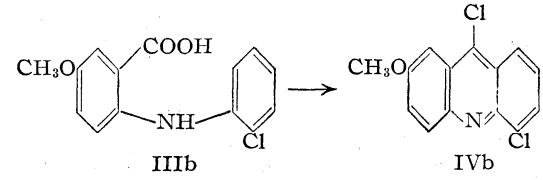
that *m*-chloroaniline (IIa) reacts with *o*-chlorobenzoic acid to give N-(3′-chlorophenyl)-anthranilic acid in 53% yield. If the mechanism of the Ullmann condensation is considered as a nucleophilic displacement of the chlorine atom by the amine, it can be seen that not only is the electrophilic strength of the *o*-chlorobenzoic acid important but also the nucleophilic strength of the reacting amine.[8] For example, Hertel and Luhrmann[9] have shown in a similar type of displacement reaction that the rate of the reaction decreases as the strength of the base decreases. From this work it would appear that the dissociation constant of the amine is a measure of its nucleophilic reactivity. This same correlation is qualitatively observed when the basic strengths[10] of the amines used in the above condensations are

Amine	$K_B \times 10^{10}$	Yield, %
Aniline	126	80
m-Chloroaniline	8.5	20
o-Chloroaniline	1.4	11

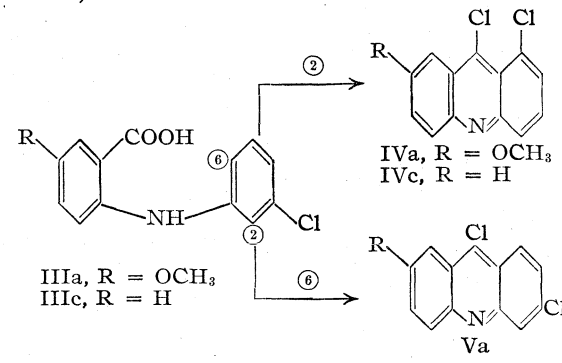
considered. Also, Tuttle[11] has shown that the presence of an electronegative group *para* to the chlorine atom of an *o*-chlorobenzoic acid greatly increases the reactivity of the chlorine toward nucleophilic displacement. In the case of 2-chloro-5-methoxybenzoic acid (I), the presence of an electropositive group, a methoxyl, in the *para* position to the chlorine atom would be expected to lessen the tendency of this chlorine atom to be displaced by a nucleophilic reagent (that is decrease the electrophilic tendency of the carbon atom holding the chlorine).



It is well-known that when a N-phenylanthranilic acid is allowed to react with phosphorus oxychloride a 9-chloroacridine is formed; that is, a ring closure and a subsequent chlorination occur. When the above anthranilic acids (IIIa and IIIb) were allowed to react with boiling phosphorus oxychloride only the corresponding 9-acridones were isolated. However, when chlorobenzene was used as a solvent and the reaction temperature was raised to 140°, good yields of the 9-chloroacridines were isolated. Starting with acid IIIb, 2-methoxy-5,9-dichloroacridine (IVb) was formed in a yield of 83.3%.



In the case of acid IIIa, two possible isomers (IVa and Va) can be formed.



Lehmstedt and Schrader[7] have studied in detail ring closures of this type. They have found in the case of N-(3-chlorophenyl)-anthranilic acid (IIIc) that reaction occurs mainly at the carbon two position to give the 8-chloro isomer (IVc). Linnell[12] also has reported similar results with compounds of this type. When acid IIIa was allowed to react with phosphorus oxychloride, only one pure dichloro compound could be obtained. After eight fractional crystallizations from benzene, 2-methoxy-8,9-dichloroacridine (IVa) was isolated in 24% yield. However, after this work was completed, Nargund and co-workers reported[13] that this same acid (IIIa) upon treatment with phosphorus oxychloride gave 2-methoxy-6,9-dichloroacridine (Va) as the only product of the reaction. These workers have published no experimental detail and no physical properties of their product so it is not possible to fully evaluate their work at this time. The 8-chloro structure was assigned to our compound IVa since it melts at 182° as compared to a melting point of 162° for the 6-chloro compound (Va), and a mixture of the two isomers melts from 145–158°. Also, the Quinacrine analog (VI) differs from Quinacrine in melting point, solubility and biological activity. The structure IVa is likewise in agreement with the results of Lehmstedt and Schrader[7] and of Linnell.[12]

The desired amino-side chain was attached to the acridine nucleus by allowing 2-methoxy-8,9-dichloroacridine (IVa) to react with 1-diethylamino-4-aminopentane in molten phenol. 2-

(8) In view of the specific reactivity of the *o*-halogen in this reaction, the role of the copper powder may be to aid in a simultaneous back and front side attack in the displacement reaction (see Swain, THIS JOURNAL, **70**, 1119 (1948)), by forming a weak, intramolecular coördinate bond between the halogen atom and the carboxylate anion.

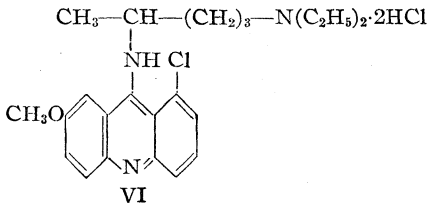
Methoxy-8-chloro-9-[(4-diethylamino-2-amyl)-amino]-acridine (VI) was isolated as the dihydrochloride hydrate in a yield of 58%.



VI

When 2-methoxy-5,9-dichloroacridine (IVb) was treated in a similar manner, no crystalline amino product could be isolated. However, 2-methoxy-5-chloro-9-phenoxyacridine was obtained in 41% yield.

Dr. J. H. Bauer of the Rockefeller Foundation has investigated the antimalarial activity of the 8-chloro-isomer (VI). It was found that when it was used in 50-mg. amounts per day per 65 g. chick, it was non-toxic and had a very definite effect in prolonging the incubation period of the infection. Quinacrine, when assayed under the same conditions, was found to be effective in 8-mg. doses.

The author wishes to express his appreciation to Professor L. F. Fieser for his advice during the course of this investigation.

Experimental[14]

2-Chloro-5-methoxytoluene.[6]—2-Chloro-5-hydroxytoluene (71.5 g., 0.5 mole, m. p. 65°) was methylated in the usual manner with dimethyl sulfate (126 g., 1 mole) and 10% aqueous sodium hydroxide (200 cc.). The methyl ether distils at 77–78° (3 mm.), yield 71.5 g. (91.5%), $n^{23}D$ 1.5348.

2-Chloro-5-methoxybenzoic Acid.[6]—A mixture of 2-chloro-5-methoxytoluene (30 g., 0.192 mole), potassium permanganate (91.2 g., 0.577 mole) and water (9 liters) was refluxed, with stirring, for seven hours. The unreacted toluene compound was removed by steam distillation, the manganese dioxide filtered, and the clear, colorless filtrate acidified. The acid was obtained as white needles, yield 23.0 g. (64.3%), m. p. 172–173°. When the manganese dioxide was dissolved by bubbling-in sulfur dioxide, the same yield of acid was obtained.

N-(3'-Chlorophenyl)-5-methoxyanthranilic Acid (IIIa).—A mixture of 2-chloro-5-methoxybenzoic acid (25 g., 0.134 mole), *m*-chloroaniline (25 g., 0.196 mole), anhydrous potassium carbonate (25 g., 0.181 mole), copper powder (0.6 g.), and isoamyl alcohol (100 cc.) was heated under reflux with stirring for a period of twenty-four hours. The reaction mixture was diluted with water, the isoamyl alcohol and the unreacted amine removed by steam distillation, and the solution decolorized with Norit. The cooled filtrate then was acidified with dilute hydrochloric acid to a *p*H of 7. The yellow precipitate was removed by filtration and the filtrate was acidified to a *p*H of 5. A voluminous white precipitate of the starting acid was deposited. Upon making the latter filtrate acid to congo red, a mixture of the white solid and a brown oil was formed.

Recrystallization of the yellow precipitate from aqueous ethanol yielded N-(3-chlorophenyl)-5-methoxyanthranilic acid as yellow, feather-like needles, yield 7.4 g. (19.9%, 49.7% allowing for recovered acid), m. p. 190–191°.

Anal. Calcd. for $C_{14}H_{12}O_3NCl$: C, 60.54; H, 4.36; N, 5.04; Cl, 12.76. Found: C, 60.44; H, 4.28; N, 5.30; Cl, 12.75.

The white solids upon recrystallization from aqueous ethanol gave 15 g. of starting acid. The brown sirup partially crystallized on standing and the solid which separated was starting acid. The remaining sirup was acidic but its composition was not investigated.

2-Methoxy-8,9-dichloroacridine (IVa).—The ring closure and subsequent chlorination was accomplished by heating a solution of N-(3-chlorophenyl)-5-methoxyanthranilic acid (12.6 g., 0.045 mole), phosphorus oxychloride (100 cc.), and chlorobenzene (250 cc.) at a temperature of 140° for a period of five hours. The reaction mixture was concentrated to dryness in a vacuum at 80°. The brown, sirupy residue upon the addition of dilute aqueous ammonia hardened to a yellow crystalline mass. The solid was filtered, washed with water until the washings were neutral, and then dried. The crude product was dissolved in excess dry benzene, the solution was decolorized with Norit, and the solvent was distilled until crystals began to appear. A small volume of dry benzene then was added and the solution cooled. This procedure was repeated seven times in order to obtain pure 2-methoxy-8,9-dichloroacridine. The product is light-yellow plates melting at 181–182°; the yield was 3.1 g. (24%).

Anal. Calcd. for $C_{14}H_9ONCl_2$: C, 60.45; H, 3.26; N, 5.04; Cl, 25.50. Found: C, 60.45; H, 3.24; N, 5.40; Cl, 25.72.

2-Methoxy-6,9-dichloroacridine melts at 161–162° and a mixture of these two isomers melts from 145–158°.

The mother liquors from the above fractional crystallization on concentration deposited 4.0 g. of a yellow compound which melts over a large range and was entirely melted by 138°. When this solid was treated in the above manner no change in its composition appeared to occur.

2-Methoxy-8-chloro-9-[(4-diethylamino-2-amyl)-amino]-acridine-(VI).—1-Diethylamino-4-aminopentane (2.9 g., 0.018 mole) was added dropwise to a well-stirred mixture of 2-methoxy-8,9-dichloroacridine (3.65 g., 0.0131 mole) and phenol (18.4 g.) over a period of thirty minutes. The entire addition was conducted at steam-bath temperature. The reaction mixture was heated for an additional two hours and then diluted with warm 10% sodium hydroxide (80 cc.). A brown oil separated which floated on the alkaline solution. The entire mixture was cooled and extracted with a 1:1 mixture of benzene–ether. The extract was washed with water, dried over sodium sulfate, and the solvent was removed at reduced pressure at room temperature. The brown sirupy residue which was contaminated with a small amount of the yellow acridone was dissolved in acetone leaving the insoluble acridone. The acetone solution was acidified with dry hydrogen chloride at 0° and a small amount of the solvent was removed by means of a stream of dry air. The cooled solution set to a solid mass which yielded 5.1 g. (82.3%) of the yellow crystalline hydrochloride.

The hydrochloride was dissolved in distilled water (150 cc.) at room temperature, filtered, and the free amine generated by the addition of 50 cc. of one normal sodium hydroxide. The yellow milky solution was extracted twice with 100-cc. portions of ether, the ethereal extract dried, and the solvent removed at reduced pressure at room temperature. The brown residual oil was dissolved in 125 cc. of dry acetone; dry hydrogen chloride was added at 0°. At first, the solution became milky colored and a sirup came out of solution but upon continued addition of the gas, the sirup finally redissolved. The solution was cooled to 0° for twenty-four hours and the precipitate removed by filtration. The air-dried material melts from 135–140°. After drying at 80° at a pressure of 1 mm., the acridine melts at 197.5–199° (dec.), yield 3.75 g. (58%). Quinacrine dihydrochloride melts from 248–250°.

Anal. Calcd. for $C_{23}H_{30}ON_3Cl\cdot 2HCl\cdot H_2O$: C, 56.27; H, 6.98; N, 8.58; Cl, 21.68. Found: C, 56.40; H, 7.16; N, 8.89; Cl, 21.60.

A much less convenient method of crystallization was to dissolve the amine in dilute aqueous hydrochloric acid and

(14) All melting points are corrected. Microcombustions by Miss E. Werble.

allow the solution to stand in a vacuum desiccator over sulfuric acid at 0°. After a few days a yellow solid, identical with the above, appeared.

N-(2'-Chlorophenyl)-5-methoxyanthranilic Acid (IIIb).—A mixture of 50 g. (0.268 mole) of 2-chloro-5-methoxybenzoic acid, 50 g. (0.392 mole) of *o*-chloroaniline, 50 g. (0.362 mole) of anhydrous potassium carbonate, 1 g. of copper powder,[15] and 250 cc. of isoamyl alcohol was condensed and processed as described above. The yellow precipitate obtained by acidification to a *p*H of 7 was recrystallized twice from aqueous ethanol. The yield was 8.5 g. (11.4%, 28.5% allowing for recovered acid), m. p. 189–190°.

Anal. Calcd. for $C_{14}H_{12}O_3NCl$: C, 60.54; H, 4.36; N, 5.04; Cl, 12.76. Found: C, 60.63; H, 4.32; N, 5.34; Cl, 12.92.

The white precipitate obtained at a *p*H of 5 yielded 30 g. of the starting acid. Further acidification of the mother liquor gave only a brown oil.

2-Methoxy-5,9-dichloroacridine (IVb).—The ring closure was conducted as described above employing 7.4 g. (0.027 mole) of N-(2-chlorophenyl)-5-methoxyanthranilic acid. The yield of pure product was 6.2 g. (83.8%), m. p. 157–158° (benzene).

Anal. Calcd. for $C_{14}H_9ONCl_2$: C, 60.45; H, 3.26; N, 5.04; Cl, 25.50. Found: C, 60.55; H, 3.28; N, 4.77; Cl, 26.01.

2-Methoxy-5-chloro-9-[(4-diethylamino-2-amyl)-amino]-acridine.—The condensation was carried out and worked up as described above using 1.1 g. (0.004 mole) of 2-methoxy-5,9-dichloroacridine. Upon removal of the ether, a mixture of a yellow solid and a brown sirup was obtained. The yellow solid was removed and recrystallized from benzene. The compound was 2-methoxy-5-chloro-9-phenoxyacridine, m. p. 189–190°, yield 0.55 g. (41%).

Anal. Calcd. for $C_{20}H_{14}O_2NCl$: C, 71.53; H, 4.20; N, 4.17. Found: C, 71.42; H, 4.22; N, 4.17.

The brown sirup was processed in a manner analogous to that used for the 8-chloro isomer but no crystalline hydrochloride was obtained. Attempts to distil the product led to decomposition.

(15) When copper bronze was used as the catalyst, it was found necessary to dissolve the coating of wax and stearic acid by heating with ethanol.

Summary

2-Methoxy-8,9-dichloroacridine and 2-methoxy-5,9-dichloroacridine have been prepared. The 8-chloro isomer of Quinacrine has been prepared and its antimalarial activity determined. The 5-chloro isomer has been made but was not obtained in a crystalline form.

Quinazolines. VI. Syntheses of Certain 2-Methyl-4-substituted Quinazolines[1]

BY ARTHUR J. TOMISEK AND BERT E. CHRISTENSEN

The study of the quinazoline compounds provides unusual interest, in view of the many novel[2] reactions and unpredictable[3] reaction products. During the course of nitration studies of 2,4-dimethylquinazoline, another unusual reaction was observed; instead of a nitro-2,4-dimethylquinazoline, the reaction product was 2-methyl-6-nitro-4-quinazolone. Even when equimolar quantities of reagents were used the nitrated quinazolone and unreacted quinazoline were the only compounds isolated from the reaction mixture, which fact indicates that the nitration of the quinazolone must have taken precedence over all other reactions. This reaction again illustrates the marked activity of a univalent substituent in the 4-position of the quinazoline nucleus.[4]

Another unpredictable reaction[5] of the quinazolines is illustrated in the chlorination of 2-methyl-4-quinazolone; in this instance benzenoid chlorination occurs along with the replacement of the 4-hydroxyl group. This makes it impossible to prepare 4-alkylaminoquinazolines with a methyl substituent in the 2-position by the usual procedures, *i. e.*, coupling of the 4-chloro derivative with desired amine. Recently Leonard and Curtin[6] have successfully employed the 4-mercaptoquinazolines in place of the usual chloro derivative as intermediates for synthesis of alkylamino compounds. This procedure has now been used to circumvent the problem of benzenoid chlorination in the preparation of 4-alkylamino-2-methylquinazolines; 2-methyl-4-quinazolone and 6-chloro-2-methyl-4-quinazolone were readily converted to the respective 4-mercaptoquinazolines by means of phos-

phorus pentasulfide in refluxing xylene. 2-Methyl-6-nitro-4-quinazolone on the other hand gave no reaction with phosphorus pentasulfide, even upon twelve hours of heating in boiling *p*-cymene. This was probably due to its solubility characteristics.

The 6-chloro-2-methyl-4-quinazolone was prepared through a series of previously unreported intermediates. For purposes of characterization small amounts of each of these intermediates were purified after each stage of the synthesis. The diagram illustrating this series of reactions is also representative of the synthesis and reaction of 2-methyl-4-quinazolone.

Experimental[7]

6-Chloro-2-methyl-4-quinazolone.—A solution consisting of 25 g. of 5-chloroanthranilic acid[8] and 75 ml. of pure acetic anhydride was refluxed one hour, then cooled to about 0° and filtered. The crystalline product (21.8 g. of crude benzoxazine) was converted to N-acetyl-5-chloroanthranilamide after standing four hours in concentrated ammonia. Ten ml. of 10% sodium hydroxide was added to the unisolated product and the mixture was heated for several minutes; then the quinazolone was brought into solution by addition of an excess of hot 10% sodium hydroxide. The basic solution was decolorized with charcoal, adjusted to *p*H 8 and filtered (5.4 g. of crude N-acetyl-5-chloroanthranilic acid was recovered from the filtrate). The product was recrystallized from alcohol, and residues from the alcoholic liquors were recrystallized (with charcoal treatment) from aqueous acetic acid. The combined quinazolone fractions, 10.45 g., m. p. 283–286°, corresponds to an over-all yield of 37%. An additional recrystallization from the acetic acid raised the m. p. to 287°.

Anal. Calcd. for $C_9H_7N_2OCl$: C, 55.54; H, 3.63; N, 14.40. Found: C, 55.30; H, 3.91; N, 14.55.

6-Chloro-2-methyl-3,1,4-benzoxaz-4-one.—A small amount of the crude benzoxazone[9] was removed at the point indicated above, decolorized and recrystallized from hot acetic anhydride solution. The colorless plates melted at 124–125°.

Anal. Calcd. for $C_9H_6NO_2Cl$: C, 55.26; H, 3.09. Found: C, 55.17; H, 2.84.

N-Acetyl-5-chloroanthranilamide.—A sample of the crude N-acetyl-5-chloroanthranilamide which occurred as an intermediate in the above synthesis of 6-chloro-2-methyl-4-quinazolone was recrystallized from alcohol to yield white crystals of m. p. 183°.

Anal. Calcd. for $C_9H_9N_2O_2Cl$: C, 50.83; H, 4.27. Found: C, 50.88; H, 4.16.

N-Acetyl-5-chloroanthranilic Acid.—The crude N-acetyl-5-chloroanthranilic acid which occurred as a result of incomplete and/or side reaction in the above synthesis of 6-chloro-2-methyl-4-quinazolone was decolorized from hot aqueous alcohol and crystallized. The flat white needles melted at 204°. This compound is not to be confused with 5-chloroanthranilic acid (m. p. 210–212°)[10] the melting point of which in the earlier literature[11] is given as 204°.

Anal. Calcd. for $C_9H_8NO_3Cl$: C, 50.60; H, 3.77. Found: C, 50.71; H, 3.67.

2-Methyl-4-mercaptoquinazoline.—Sixteen grams (0.1 mole) of 2-methyl-4-quinazolone and 21.6 g. (0.1 mole) of phosphorus pentasulfide were mixed dry. One hundred ml. of xylene was added and mixture was refluxed two hours. The heating was interrupted at the end of the first hour to permit repulverizing of the solids in the mixture. The mixture was shaken with 100 ml. of 10% sodium hydroxide and filtered. The solid material from the filtration was thoroughly dried, then extracted with 100 ml. of hot 10% sodium hydroxide. The combined basic solutions after treatment with charcoal were precipitated with acetic acid. The solid material was removed by filtration and reprecipitated from sodium hydroxide solution.

This crude mercaptoquinazoline was recrystallized from aqueous alcohol to yield 8.55 g. (49%) of yellow needles, m. p. 217–219°. The melting point recorded for 2-methyl-4-mercaptoquinazoline as prepared from acetylanthranilic-nitrile is 218–219° (dec.).[12]

6-Chloro-2-methyl-4-mercaptoquinazoline.—The synthesis and isolation were as given for 2-methyl-4-mercaptoquinazoline. The crude 6-chloro-2-methyl-4-mercaptoquinazoline was decolorized and recrystallized from hot aqueous alcohol solution. The yield from 19.5 g. (0.1 mole) of 6-chloro-2-methyl-4-quinazoline was 11.6 g. (55%). An additional recrystallization from aqueous acetic acid gave yellow needles of m. p. (dec.) 276–278°.

Anal. Calcd. for $C_9H_7N_2SCl$: C, 51.30; H, 3.35; Cl, 16.83. Found: C, 51.53; H, 3.21; Cl, 16.78.

4-(β-Hydroxyethylamino)-2-methylquinazoline.—A mixture of 5 ml. of ethanolamine and 1.47 g. of 2-methyl-4-mercaptoquinazoline was heated for seven hours at 80°. The suspension which resulted on cooling was diluted with a small amount of water. This product was recrystallized (preferably by seeding from a previous preparation) yielding rosettes of thick, yellow needles. The product (1.5 g., 88%) was dissolved in hot dioxane, in order to remove a trace of insoluble oil. This solution was then evaporated to dryness, and the residue was recrystallized from the minimum amount of water. The pure 4-(β-hydroxyethylamino)-2-methylquinazoline crystallized from water as yellow prisms and spherulites. When dropped upon a hot melting point block the crystals appeared to melt at 164–166° resolidifying to white needles which melted (with sublimation) at 174.5–176°. Since both forms recrystallized from water to yield a mixture of highly birefringent spherulites and prisms one cannot attribute the behavior to crystal habit or to a monotropic transformation on the basis of the present information.

Anal. Calcd. for $C_{11}H_{13}N_3O$: C, 65.01; H, 6.45; N, 20.68. Found: C, 64.83; H, 6.69; N, 20.69.

6-Chloro-4-(*p*-methoxyanilino)-2-methylquinazoline.—A mixture of 4 g. of *p*-anisidine and 1.75 g. of 6-chloro-2-methyl-4-mercaptoquinazoline was heated for six hours at 190°. The resulting dark yellow solid was triturated first with acid and then with sodium hydroxide. The solid was decolorized and recrystallized from 0.5 *N* hydrochloric acid to yield 0.59 g. of fine, yellow needles of 6-chloro-4-(*p*-methoxyanilino)-2-methylquinazoline hydrochloride. The m. p. in a capillary block preheated to 319° was 321° (dec.).

Anal. Calcd. for $C_{16}H_{15}N_3OCl_2$: C, 57.15; H, 4.50. Found: C, 57.41; H, 4.42.

Nitration of 2,4-Dimethylquinazoline.—Two and one-half grams of 2,4-dimethylquinazoline was dissolved in 20 ml. of concentrated sulfuric acid and 10 ml. of fuming nitric acid (sp. gr. 1.5) was added in one portion. In order to keep the initial temperature below 75°, it was necessary to cool the reaction mixture which was then maintained at 75° for one hour, and then poured on 200 g. of ice; tiny white needles (0.61 g.) separated on standing overnight. The liquors were neutralized to yield more product which was recrystallized from glacial acetic acid; yield 1.84 g. Several recrystallizations from glacial acetic acid and pyridine gave a product with m. p. (dec.) 302–304°, which did not depress the melting point of the 2-methyl-6-nitro-4-quinazolone prepared later by nitration of 2-methyl-4-quinazolone.

Anal. Calcd. for $C_9H_7N_3O_3$: N, 20.48. Found: N, 20.44.

(7) All melting points are corrected.

(8) Eastman Kodak Company, technical grade (blue label).

(10) Magidson and Golovchinskaya, *J. Gen. Chem.* (*USSR*), **8**, 1801 (1938).

(11) Eller and Klemm, *Ber.*, **55**, 222 (1922).

(12) Bogert, Breneman and Hand, THIS JOURNAL, **25**, 377 (1903).

Nitration of 2-Methyl-4-quinazolone.—Two and one-half grams of 2-methyl-4-quinazolone was nitrated according to the directions given for the nitration of 2,4-dimethylquinazoline. The yield of crude product was 2.8 g. The m. p. after several recrystallizations was 298–300° (dec.) Bogert and Geiger reported[13] a melting point of 299° (uncor.) for 2-methyl-6-nitro-4-quinazolone obtained by a similar nitration.

(13) Bogert and Geiger, THIS JOURNAL, **34**, 529 (1912).

Summary

4-Mercapto-2-methylquinazoline can be used as an intermediate for synthesis of 4-(β-hydroxyethylamino)-2-methylquinazoline and 6-chloro-4-(*p*-methoxyanilino)-2-methylquinazoline.

The nitration of 2,4-dimethylquinazoline yields 2-methyl-6-nitro-4-quinazolone.

The Willgerodt Reaction on α-Tetralone

BY W. J. HORTON AND J. VAN DEN BERGHE[1]

The reaction of aliphatic aromatic ketones with aqueous ammonium polysulfide to produce ω-aryl aliphatic amides, first reported by Willgerodt,[2] has been shown to be applicable to olefins, acetylenes, aldehydes, alcohols and mercaptans.[3,4] It is apparent that a rearrangement is not involved.[5] This confirms Willgerodt's experiment[6] in which isovalerophenone was converted to α-methyl-γ-phenylbutyramide rather than the β-methyl-γ-phenylbutyramide expected by rearrangement. This reaction has been successfully repeated in several laboratories.[4,7,8]

The most important suggestions as to the mechanism of the reaction[4,8] have postulated a group which migrates along the chain by reversible steps, the process being terminated by irreversible changes which yield the amide. These ideas have been supported by the fact that the proposed intermediates, olefins, acetylenes, mercaptans, will yield amides if they are submitted to the conditions of the reaction. No intermediates have been isolated from the reaction mixture.

In the hope of interrupting the progression of a functional group along the aliphatic chain, we proposed to terminate the aliphatic chain of the aliphatic aromatic ketone with a second aryl group, or to use α-tetralone in the reaction[9] so that the aryl group of the ketone would also be the terminal group on the chain. We employed for convenience the modification suggested by Schwenk and Bloch[10] which avoids the use of sealed tubes.[11] The principal product of the reaction was a tertiary aromatic amine. When this was hydrolyzed using dilute sulfuric acid in a sealed tube,[12] β-naphthol was obtained and further identified by conversion to β-naphthyl methyl ether. That the amine is 4-(2-naphthyl)-morpholine was fully confirmed by independent syntheses from β-naphthol and morpholine in the presence of aqueous sodium bisulfite, and from β-naphthylamine and β,β′-dichlorodiethyl ether.[13]

The reaction of α-tetralone, morpholine and sulfur gives, in addition to the above amine, small amounts of at least one other product which has not been fully investigated.

When α- or β-naphthol replaced α-tetralone in this reaction, no amines could be found. Thus the conversion of α-tetralone to α-naphthol by means of sulfur cannot be the initial step in the reaction.

We have also investigated the behavior of morpholine and sulfur without the addition of any other material. Several reports in which the Schwenk and Bloch modification of the Willgerodt reaction was used have appeared[14,15] but products of a reaction between morpholine and sulfur have not been noted.[16] At a temperature just above that used to produce 4-(2-naphthyl)-morpholine from α-tetralone, morpholine and sulfur, the latter two components alone gave a high melting compound which resembled that isolated in the reaction of commercial diisobutylene, two styrene homologs, or certain mercaptans with morpholine and sulfur and shown to be dithiooxalodimorpholide.[15] When our product was mixed with known dithioöxalodimorpholide, no depression of the melting point was obtained. Hydrolysis of the high melting material with aqueous hydrobromic acid produced the hydrobromide of β,β′-dibromodiethylamine. It is apparent then that sulfur attacks the morpholine molecule to give hydrogen sulfide and a dithioöxalyl fragment

Experimental[17]

4-(2-Naphthyl)-morpholine.—(a) Morpholine from Commercial Solvents Corp. was redistilled and the colorless fraction, b. p. 121.5–122° at 644 mm., was used. The α-tetralone was prepared by the methods described[18] and had a b. p. 127–137° at 13 mm. α-Tetralone prepared by air oxidation of tetralin gave similar results. A mixture of 4.0 g. (0.027 mole) of α-tetralone, 2.48 g. (0.028 mole) of morpholine and 0.86 g. (0.027 mole) of powdered sulfur was refluxed by heating the flask in an oil-bath at 128–135° for eight hours. Within the first hour, the sulfur dissolved, an odor of hydrogen sulfide was noted and the color of the solution lightened. The reaction mixture was allowed to cool to room temperature and stand overnight, whereupon it solidified. The solid was treated with a warm solution of 5 cc. of concentrated hydrochloric acid in 10 cc. of water and decanted to a filter. This treatment was repeated twice. The oil remaining undissolved was washed with water and the washings added to the acidic filtrate. The cooled filtrate was made basic with ammonia, the suspension of dark precipitate was cooled, filtered and washed with water. The dried crude amine weighed 2.87 g. Steam distillation and three recrystallizations from aqueous ethanol gave thin rods, m. p. 87–90°, reported 90°.[13]

Anal. Calcd. for $C_{14}H_{15}NO$: N, 6.57. Found: N, 6.55.

The amine was dissolved in dilute hydrochloric acid with warming and the acidity was increased to 10% by addition of concentrated hydrochloric acid. On cooling, the hydrochloride of 4-(2-naphthyl)-morpholine appeared as colorless crystals. Recrystallization first from a small volume of water and then from absolute alcohol, produced large granular crystals which melted at 211.5–215° with sudden evolution of gas at 215°.

Anal. Calcd. for $C_{14}H_{16}NOCl$: N, 5.61; neut. equiv., 250. Found: N, 5.64; neut. equiv., 250.

A solution of 0.5 g. of amine and 0.5 g. of picric acid in 25 cc. of warm ethanol gave 0.77 g. of picrate on cooling. Recrystallization from alcohol gave fine, rectangular, canary-yellow rods which melted at 152–155° (dec.).

Anal. Calcd. for $C_{20}H_{18}N_4O_8$: neut. equiv., 442. Found: neut. equiv., 438.

When α-naphthol or β-naphthol (0.027 mole) replaced α-tetralone in the above procedure, no detectable amounts of amines could be obtained from the hydrochloric acid extracts of the reaction mixture.

(b) A sample of 4-(2-naphthyl)-morpholine prepared by the reported procedure[13] melted at 84.5–87° and a mixture with the amine from (a) melted at 87–89°. A picrate was prepared which melted at 152–155° (dec.). No change in m. p. was observed when this was mixed with the picrate obtained in (a).

(c) A sealed glass tube containing 1.0 g. of β-naphthol (0.0069 mole), 1.2 g. of morpholine (0.014 mole), 0.73 g. of sodium bisulfite (0.007 mole) and 1.5 cc. of water was heated for twenty-four hours at 190–200°. Extraction of the tube contents three times with a solution of 1 cc. of alcohol in 9 cc. of 6 *N* hydrochloric acid, filtration and neutralization of the filtrate gave 1.06 g. of crude amine. On solution in dilute hydrochloric acid, filtration and neutralization, 1.03 g. of nearly colorless amine, m. p. 84–87°, was obtained. A mixture with the amine produced in (a) melted at 87–89°. Similarly, a mixture of the picrates melted without depression.

Hydrolysis of 4-(2-Naphthyl)-morpholine.—Two hundred milligrams of the amine from α-tetralone, morpholine and sulfur was sealed in a glass tube with 10 cc. of 15% sulfuric acid.[12] The tube was heated in a metal-bath at 220–240° for three hours. The crystalline contents of the tube were filtered and washed with water. The solid, dissolved in warm benzene, was washed with a solution of 0.5 cc. of hydrochloric acid in 20 cc. of water. The separated benzene solution was washed with water until neutral and the benzene evaporated. The residue partially dissolved in 10% sodium hydroxide. The filtered solution was acidified to yield a gelatinous precipitate which dissolved on warming and reappeared as colorless crystals on cooling. These melted at 114–120° and a mixture with authentic β-naphthol melted at 117–120°. A solution of 10 mg. of the crystals in 0.5 cc. of 10% sodium hydroxide and 2 cc. of water was treated with two 0.1-cc. portions of dimethyl sulfate to yield 5 mg. of β-naphthyl methyl ether, conveniently recovered by steam distillation of the reaction mixture. The β-naphthyl methyl ether was recognized by its distinctive odor, m. p. 71.5–74° alone, and when mixed with known β-naphthyl methyl ether, m. p. 71.5–73.5°.

Reaction of Morpholine and Sulfur.—A mixture of 4.3 g. (0.13 mole) of powdered sulfur and 12.4 g. of redistilled morpholine (0.14 mole) was heated in an oil-bath held at 150–158° for four hours. Use of a Hopkins-type condenser permitted gentle refluxing with only a small portion of the material becoming solid in the condenser. The warm reaction product was mixed with 50 cc. of 95% ethanol and allowed to stand at room temperature overnight. The crystals so obtained were washed with cold alcohol and weighed 1.16 g., m. p. 217–227°. A filtered solution of the compound in hot water deposited 0.45 g. of colorless flat prisms on cooling, m. p. 253.5–255°. The m. p. was not raised by subsequent recrystallization from alcohol.

Anal. Calcd. for $C_{10}H_{16}N_2O_2S_2$: N, 10.76. Found: N, 10.76.

When mixed with dithioöxalodimorpholide prepared by the described method,[15] m. p. 254.5–256°, reported m. p. 252–253°, the mixture melted at 252.5–255°.

Hydrolysis with Hydrobromic Acid.—To 0.28 g. of the compound from morpholine and sulfur was added 10 cc. of 48% hydrobromic acid and the solution was refluxed for twelve hours. Removal of the acid at reduced pressure by warming on the water-bath left a residue which crystallized on cooling. The crystals were dissolved in 10 cc. of warm absolute alcohol, filtered and the solution concentrated. On cooling, crystals appeared which were filtered and washed with ice-cold alcohol. The material weighed 100 mg. and melted at 195–201°. Reported[19] for β,β′-dibromodiethylamine hydrobromide, m. p. 199–200°. A hot water solution of 70 mg. of the hydrobromide and 50 mg. of picric acid deposited 50 mg. of canary-yellow crystals, m. p. 125–134°. Recrystallization from a few cc. of hot water gave crystals, m. p. 132–134° with shrinking at 129°. Reported[19] for the picrate of β,β′-dibromodiethylamine, m. p. 128°.

Oxalodimorpholide.—A solution of 14.4 g. of morpholine in 50 cc. of anhydrous reagent benzene was treated with a solution of 4.2 g. of oxalyl chloride in 50 cc. of benzene. The oxalyl chloride solution was added slowly with swirling and cooling in cold water. After standing at room temperature for thirty minutes, followed by warming on the steam-bath, the cooled mixture was filtered and the filter washed with benzene. After removal of the benzene from the filtrate, the residue and the colorless salt insoluble in benzene were thoroughly extracted with warm acetone. On concentration of the acetone and cooling, 5.32 g. of short, rectangular prisms was obtained, m. p. 173–182.5°, reported 184–185°.[15] By concentration of the filtrate and addition of petroleum ether (b. p. 70–90°), 1.2 g.

(17) Melting points and boiling points are uncorrected.

was obtained, m. p. 138–176°. The first crop material was suitable for the preparation of dithioöxalodimorpholide.[15]

Summary

The reaction of α-tetralone with morpholine and sulfur yields 4-(2-naphthyl)-morpholine.

Dithioöxalodimorpholide has been isolated as a reaction product of sulfur and morpholine.

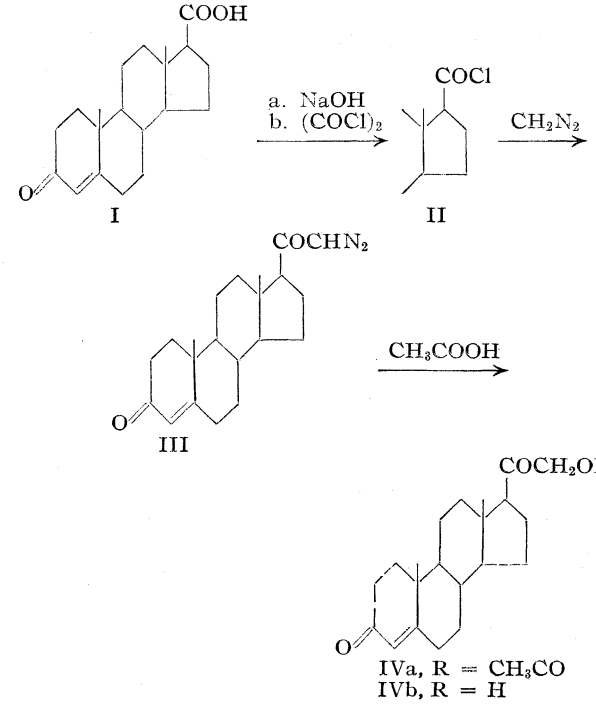
The Preparation of Desoxycorticosterone Acetate from 3-Keto-Δ^4-etiocholenic Acid

BY A. L. WILDS AND CLIFFORD H. SHUNK[1]

Desoxycorticosterone acetate (IVa) has been prepared by Reichstein and co-workers[2] from 3-acetoxy-Δ^5-etiocholenic acid by treating the acid chloride with diazomethane to form the diazoketone, followed by hydrolysis, Oppenauer oxidation of the remarkably stable diazoketone to 21-diazoprogesterone (III) and finally reaction with acetic acid. Attempts to prepare this adrenal cortical hormone from 3-keto-Δ^4-etiocholenic acid (I), thus avoiding the selective hydrolysis and oxidation of the diazoketone, have been unsatisfactory because of difficulties in preparing the acid chloride.[3,4] The α,β-unsaturated ketone grouping seems to be sensitive to reagents, such as thionyl chloride, normally used to prepare the acid chlorides. Apparently because of these difficulties, Reich and Lardon[5] developed a six-step procedure for converting 3-keto-Δ^4-steroids into the 3-acetoxy-Δ^5-derivative. This procedure was employed by von Euw and Reichstein[6] in a partial synthesis of 11-dehydrocorticosterone which necessitated reoxidation to the 3-keto-Δ^4 derivative at a later stage.

In connection with the synthesis of certain analogs of desoxycorticosterone and progesterone lacking ring C, we have developed an improved procedure for converting unsaturated keto acids of this type into the acid chlorides and diazoketones. This procedure has proved to be quite successful with 3-keto-Δ^4-etiocholenic acid (I). The critical step is the formation of the acid chloride at low temperatures (below 15°) by reaction of the sodium salt of the acid with oxalyl chloride.[7,8] After reaction with diazomethane the diazoketone III was obtained in 81% over-all yield from the acid I. By adding the diazoketone to boiling acetic acid,[9] desoxycorticosterone acetate (IVa) was obtained in 73% yield. The over-all yield is considerably higher than those reported for the earlier syntheses.

These procedures should prove of value for similar reactions with the 11-oxygenated derivatives of I.



Experimental[10]

21-Diazoprogesterone (III).—A solution of 506 mg. of 3-keto-Δ^4-etiocholenic acid[11] in 19 ml. of 0.091 *N* sodium hydroxide was frozen and evaporated to dryness (lyophilized) under reduced pressure and the residue dried at 110° (0.1 mm.) for eight hours. After cooling, 10 ml. of dry, thiophene-free benzene and 3 drops of pyridine were added; the salt was scraped from the sides of the flask, mixed thoroughly and cooled in an ice-bath before adding 2 ml. of redistilled oxalyl chloride (b. p. 60–60.5°). There was an immediate evolution of gas which stopped after a few

(9) Dr. Warren R. Biggerstaff has found that this procedure is superior to dissolving in acetic acid before heating.

(10) All melting points are corrected.

(11) We are indebted to the Research Dept. of The Glidden Co., Soya Products Division, for this material.

seconds. The mixture was then allowed to warm to 15° for four minutes and as no further evolution of gas was noticed the solvent was evaporated under reduced pressure. Dry air was then admitted and three 1.5-ml. portions of benzene were added and evaporated, keeping the temperature below 15° at all times. Finally the acid chloride was dissolved in 5 ml. of benzene, filtered through a dry, sintered glass funnel into a cooled receiver and diluted with an equal volume of ether. The acid chloride was added slowly to a cold (−15°) ethereal solution of diazomethane (prepared from 6 g. of nitrosomethylurea[12]), maintained at −15° for one-half hour and at 0° for one-half hour, then the solvent was evaporated under reduced pressure. Trituration of the residual oil with acetone gave a total of 439 mg. (81%) of the light yellow diazoketone which decomposed at 177–178° (reported,[2] 182–184°).

Desoxycorticosterone Acetate (IVa).—To 10 ml. of boiling, purified[13] acetic acid was slowly added 163 mg. of 21-diazoprogesterone; there was immediate evolution of nitrogen and a light yellow solution resulted. After refluxing for three minutes the acetic acid was evaporated under reduced pressure and the residual oil dissolved in acetone. On cooling long needles were obtained which changed to 109 mg. of a powder upon drying at room temperature, m. p. 155–157°. A second crop of 14 mg., m. p. 153–155°, and an additional 8 mg., m. p. 146–154°, after molecular distillation of the filtrate at 160° (0.001 mm.) brought the total yield of desoxycorticosterone acetate to 73%. Recrystallization of a sample from acetone raised the m. p. to 158–159° (reported,[2] 158–159°).

Hydrolysis of the acetate by the method of Reichstein and von Euw[14] gave desoxycorticosterone; after molecular distillation at 150° (0.001 mm.) and two recrystallizations from acetone–ether, this melted at 140–142° and showed no depression when mixed with an authentic sample.

(12) The diazomethane solution was distilled, dried for two hours over potassium hydroxide pellets, and then for one hour over sodium wire before use; see Fieser and Turner, THIS JOURNAL, **69**, 2341 (1947).

(13) The acetic acid was refluxed for six hours with 5% by weight of potassium permanganate, distilled and the distillate fractionated, collecting the last fraction, b.p. 117°.

Summary

A procedure has been developed for preparing acid chlorides from α,β-unsaturated keto acids using the sodium salt and oxalyl chloride in the cold. By means of this reaction it has been possible to convert 3-keto-Δ⁴-etiocholenic acid to 21-diazoprogesterone and desoxycorticosterone acetate in good yields.

Esters of (Carboxymethylmercapto)-succinic Acid

BY JOHN F. MULVANEY,[1a] JAMES G. MURPHY AND RALPH L. EVANS

(Carboxymethylmercapto)-succinic acid has been prepared by Fitger,[1] by Morgan and Friedmann[2] and by Larsson.[3] Larsson gives a procedure for the preparation of the *dl*-acid in excellent yield by the interaction of maleic acid and thioglycolic acid at water-bath temperature.

During an investigation of derivatives of thioglycolic acid, we prepared esters of (carboxymethylmercapto)-succinic acid of the three types indicated in Fig. 1. No attempt was made during this work to isolate any optically active forms of these esters.

Fig. 1

Type I	Type II	Type III
SCH_2COOR	SCH_2COOH	SCH_2COOR
$CHCOOR$	$CHCOOR$	$CHCOOH$
CH_2COOR	CH_2COOR	CH_2COOH

Esters of Type I.—These were prepared in the usual manner with an acid catalyst and with toluene or benzene as water-entraining agents.

The esters were purified by fractional distillation. The octadecyl ester was crystallized from toluene, alcohol and acetone.

The properties of the esters of Type I are listed in Table I. The *n*-propyl (b. p. 125–131° at 0.1 mm.) and isopropyl (b. p. 124–129° at 0.4 mm.) esters were prepared but were not purified for analysis.

Esters of Types II and III.—Preliminary attempts to prepare esters of Type II by the addition of thioglycolic acid to alkyl maleates gave only slow and partial reaction. The isolation of fumaric acid from the reaction mixture indicated hydrolysis and isomerization. When sodium thioglycolate was used, the reaction proceeded almost to completion at room temperatures.

$$NaOOCCH_2SH + ROOCCH{=}CHCOOR \longrightarrow \begin{matrix} SCH_2COONa \\ CHCOOR \\ CH_2COOR \end{matrix} \quad (1)$$

Similarly, it was found that thioglycolic acid esters reacted more completely with sodium maleate than with maleic acid to give esters of Type III.

$$ROOCCH_2SH + NaOOCCH{=}CHCOONa \longrightarrow \begin{matrix} SCH_2COOR \\ CHCOONa \\ CH_2COONa \end{matrix} \quad (2)$$

Experimental

In general, 0.25 mole of the acid was neutralized with 15% sodium hydroxide and an alcoholic solution of the ester (0.25 mole) was added. The mixture was allowed to stand at room temperature until titration with iodine showed that the addition was almost complete.

[a] Purified by dissolving in methanol and precipitating with ether. [b] Purified by dissolving in methanol–water (1:1) and precipitating with acetone. [c] Purified by dissolving in water and precipitating with acetone. [d] White, waxy solids. The octyl and dodecyl compounds have surface-active properties.

The compounds prepared, all as their sodium salts, are listed in Table II.

The (carboctoxymethylmercapto) disodium succinate was converted to the free acid by acidifying an aqueous solution with hydrochloric acid. The oil that separated was dissolved in ether and washed with water. The ether then was evaporated and the oil dried in vacuum. Alkali titration gave an equivalent weight of 165 (theory 160.3) $n^{25}D$ 1.4840, d^{25}_{25} 1.146.

Acknowledgment.—The authors wish to express their appreciation to Miss Lillian Weiss and Mr. J. W. Veale for assistance in the experimental work.

Summary

1. Three tri-esters, two di-esters and three mono-esters of (carboxymethylmercapto)-succinic acid (the latter two types as sodium salts) have been prepared and some of their physical constants determined.

2. An indirect method for the preparation of certain of the mono-esters and di-esters of (carboxymethylmercapto)-succinic acid is reported.

Mechanism for the Reaction of Dioxane Sulfotrioxide with Olefins. II. Sulfonation of Styrene

BY F. G. BORDWELL AND CHRISTIAN S. RONDESTVEDT, JR.[1]

In a continuation of the attempt to elucidate the mechanism[2] of the reaction of dioxane sulfotrioxide with olefins,[3] the sulfonation of styrene has been investigated. Styrene was chosen because of its ready availability in a pure state and because preliminary studies[4] indicated that a variety of products are formed in its sulfonation.

To ensure uniformity in the sulfonating agent and a fixed ratio of dioxane to sulfur trioxide the dioxane sulfotrioxide was prepared by adding an equimolar quantity of dioxane to a solution of sulfur trioxide in ethylene dichloride. In this way a fine suspension of dioxane sulfotrioxide was obtained.

In most of the experiments of the present investigation the sulfonation mixture, prepared at −5 to 0° by dropwise addition of a solution of styrene in ethylene dichloride to the sulfonating agent, was hydrolyzed without allowing the temperature to rise above 5°. When the aqueous layer was neutralized with sodium hydroxide, the water-soluble products were sodium 2-phenylethene-1-sulfonate[4] (I), sodium 2-phenyl-2-hydroxy-1-ethanesulfonate (II) and sodium sulfate. The identity of II was established by separation from I and sodium sulfate by fractional crystallization using alcohol–water mixtures,[5] and comparison of the S-*p*-chlorobenzylthiouronium salt[6] with an authentic sample.[7] From the ethylene dichloride layer 2,4-diphenyl-1,4-butanesultone (III) was obtained.[4,8] At higher reaction temperatures the amount of I increased at the expense of II.

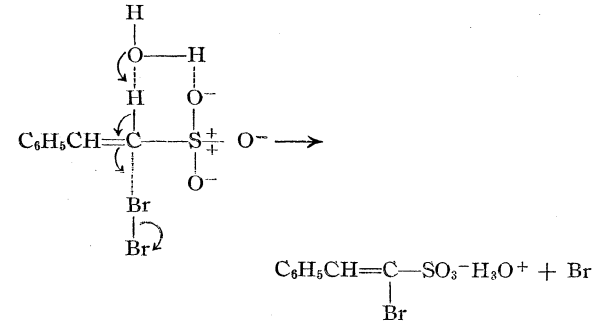
(8) This structure is assigned on the basis of unpublished results.

In order to follow conveniently the variation in the proportions of products with changing experimental conditions it was necessary to devise an analytical method for determining the relative amounts of I and II in the aqueous portions of the hydrolysis mixture. Oxidation of I with potassium permanganate has been reported to be quantitative, but not suitable for the analysis of this mixture since the presence of II interferes with the determination.[5] No reaction occurred when I was treated with hydrogen peroxide and formic acid.[9] However, titration with aqueous bromine using the bromate–bromide method was found to be rapid and quantitative. The presence of II did not affect the analytical results.

The product formed in the reaction of I with bromine water was found to be identical with that obtained in the sulfonation of β-bromostyrene with dioxane sulfotrioxide,[10] as shown by comparison of the corresponding sulfonamides. Truce[10] designated this compound as sodium 2-phenyl-1-bromoethene-1-sulfonate on the basis of its reduction to sodium 2-phenylethene-1-sulfonate under conditions similar to those used by Kohler[11] for the reduction of sodium 1-bromoethene-1-sulfonate to sodium ethene-1-sulfonate. The assigned structure[10] was substantiated in the present investigation by preparation of sodium 1-bromo-2-phenylethene-1-sulfonate from sodium 2-phenylethene-1-sulfonate in a manner comparable to Kohler's preparation of sodium 1-bromoethene-1-sulfonate by bromination of sodium ethene-1-sulfonate, and by the fact that benzaldehyde was obtained on oxidation.

It is of interest to compare the very rapid substitution reaction of sodium 2-phenylethene-1-sulfonate (I) with bromine in aqueous solution to the relatively slow addition of bromine to the double bond of 2-phenylethene-1-sulfonamide and 2-phenylethene-1-sulfonyl chloride. In acetic acid solution 2-phenylethene-1-sulfonamide decolorized an equimolar portion of bromine in about three hours (in the dark about twenty-four hours was required) to give 1,2-dibromo-2-phenyl-1-ethanesulfonamide. In the dark, carbon tetrachloride solutions of 2-phenylethene-1-sulfonyl chloride required about fifteen days for decolorization of an equimolar portion of bromine. The reaction in acetic acid was somewhat faster. When exposed to sunlight and oxygen complete decolorization in carbon tetrachloride solutions occurred in an hour. Hydrogen bromide was not evolved.

The slow rate of electrophilic addition of bromine to 2-phenylethene-1-sulfonamide and 2-phenylethene-1-sulfonyl chloride in acetic acid and carbon tetrachloride solutions is not unexpected in view of the well-known retarding effect of electron-attracting groups on the addition of bromine to olefins. The rapid attack of bromine in aqueous solution on the *alpha* carbon of the ethenesulfonate[11] and 2-phenylethene-1-sulfonate ions is undoubtedly facilitated by the negative charge on the ions. Kohler[11] showed that potassium 1,2-dibromo-1-ethanesulfonate did not undergo dehydrobromination in aqueous solutions, thus ruling out the addition of a molecule of bromine as a preliminary step in the formation of potassium 1-bromoethene-1-sulfonate in this reaction.[12] Further evidence on this point is the observation of Suter and Truce[3] that the 1-methyl-2-phenylethene-1-sulfonate ion which could react by addition but not by comparable substitution, fails to react with bromine under these conditions. A mechanism involving a molecule of water in the transition state is shown for the bromination of I.



Analysis by the isolation technique[5,7] showed that the only water-soluble products present in significant amounts in hydrolysis mixtures from sulfonations carried out below 5° were I, II and

(12) Ingold and Smith, *J. Chem. Soc.*, 2742 (1931), found that iodine chloride reacts with ethenesulfonic acid to give 1-iodoethene-1-sulfonic acid. Apparently they misinterpreted Kohler's work since they suggested that 2-chloro-1-iodo-1-ethanesulfonic acid was an intermediate in this reaction.

sodium sulfate. In subsequent work, therefore, I was determined by bromate–bromide titration, sulfate was determined gravimetrically and the quantity of II was taken as the difference between the total acids present and the amounts of I and sulfate determined. To complete the analysis an approximation of the quantity of III was made by evaporation of the ethylene dichloride layer and isolation of the solid product.

The results of the sulfonations carried out below 5° are summarized in Table I. Table II shows the results obtained when the sulfonation mixture was heated to 54.4° prior to hydrolysis.

[a] Time for which sulfonation mixture was kept at 54.4°. [b] Yield of crude product. One crystallization from acetone–water gave a 60% recovery of reasonably pure material. [c] It seems probable that after a short period of heating the figures in this column also include the percentages of substances other than II (see Discussion). [d] Control taken after completion of the addition of styrene and after the reaction mixture had been allowed to stand for fifteen minutes at 10°.

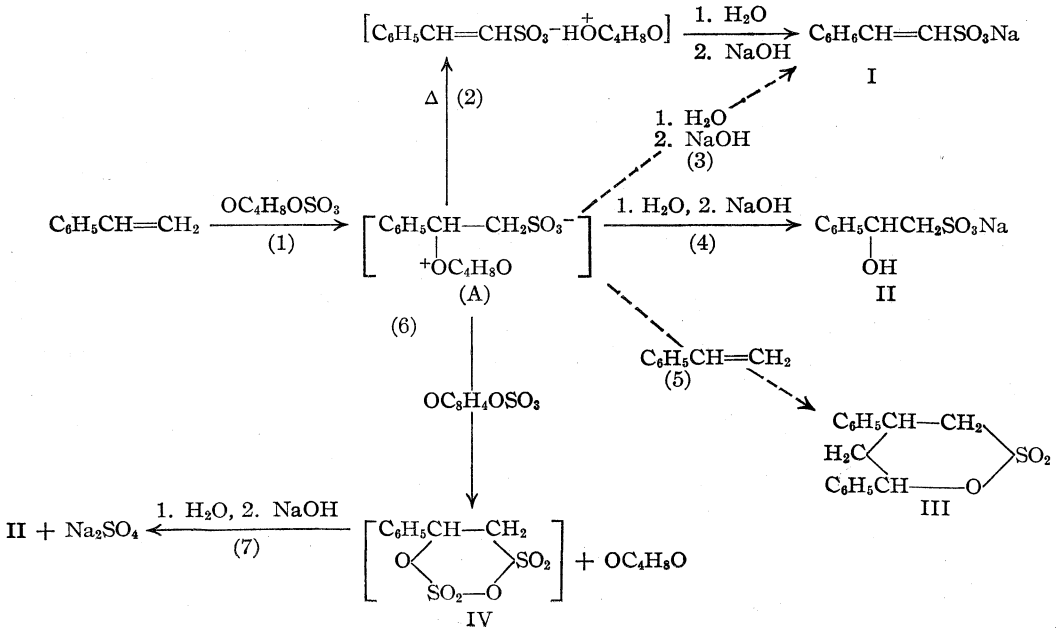
Discussion

The mode of formation previously suggested[2] for the products isolated on hydrolysis and neutralization of sulfonation mixtures obtained from the reaction of dioxane sulfotrioxide and olefins, as applied to the sulfonation of styrene, is represented on the accompanying diagram by solid-shafted arrows (reactions 1, 2, 6, 7). The arrows with broken shafts illustrate new reaction possibilities disclosed by the present investigations (reactions 3, 4, 5). Whether reactions 3, 4 and 5 are peculiar to styrene or applicable to olefins in general is yet to be determined.

At elevated temperatures I is the principal product, and reaction 2 is believed to be the primary route by which it is formed. However, at temperatures below 5° amounts of I varying from 7% to 26% were formed. Since reaction 2 is slow under these conditions (Table I), the formation of as much as 26% of I is surprising. An experiment at 2° utilizing rapid stirring and a slow addition of a more dilute solution of styrene, conditions designed to minimize local heating, resulted in 13% of I. Even at −25° (hydrolysis at 0°) 7% of I was formed. For this reason reaction 3 is tentatively suggested as an additional source of I, but this point requires further investigation.

It has been postulated[2] that the β-hydroxysulfonic acids formed on hydrolysis of these sulfonation mixtures are derived from substituted-ethionic anhydrides (reactions 6 and 7). The fact that equimolar quantities of II and sodium sulfate are not formed in the sulfonation of styrene below 5° eliminates this as the sole source of II. The bulk of II is believed to be formed by reaction 4.

Of the three species (A, III and IV) postulated as being present in the sulfonation mixture at temperatures below 5° only III has been isolated.



Isolation of alkylethionic anhydrides analogous to IV from sulfonation mixtures has been accomplished on a few occasions, but our attempts to isolate such a compound in the present investigation were unsuccessful. The presence of IV is assumed since it appears to be a logical source of the sulfuric acid obtained on hydrolysis.[13]

If (A) is the major source of II, as is suggested, it must possess surprisingly great stability since the amount of II formed on hydrolysis is not changed appreciably when the sulfonation mixture was allowed to stand at 2° for fifty hours (Table I). This stability is probably made possible by solvation with dioxane, since, in the absence of dioxane, styrene is polymerized by sulfur trioxide in ethylene dichloride solution.

If reactions 1, 5 and 6 alone are occurring below 5° prior to hydrolysis, reactions 5 and 6 should be interdependent when equimolar quantities of styrene and sulfur trioxide are used. The molar quantities of III and sulfuric acid should, therefore, be equal. This is only approximately true (Table I), but the amounts are at least of comparable magnitudes. The relatively small quantities of II and sulfuric acid obtained at −5 to 5° indicates that reaction 1 is faster under these conditions than either 5 or 6, since it does not seem likely that either of the latter is reversible. The increased quantity of sulfuric acid obtained at −25° is probably due to incompleteness of reaction 1. The resulting relative increase in the ratio of styrene to (A) leads to an increase in the proportion of III.

Previously[4] a 60% yield of practically pure I was isolated from the first three crops of the hydrolysis and neutralization products of a sulfonation carried out at temperatures above 5°. Using the analytical procedure developed for determination of I the quantity of I present in these crops was found to be 94, 98 and 96%, respectively. The residue was found to contain 56% of I, bringing the total yield of I in this experiment to 75%. A more detailed study of the formation of I at elevated temperatures has now been made (Table II). The increase in the quantity of I is explained by an acceleration of reaction 2. Under these conditions (A) should be converted completely to the dioxane salt corresponding to I, and, in time, the quantity of II should drop to low values. The minimum figure of 22% for II recorded in Table II after extended heating is probably accounted for by the formation of products other than those included in the diagram. Since II was determined only by difference the figures could represent, for example, disulfonation products.

The elimination of the proton in reaction 2 is most likely accomplished with the aid of either an extraneous dioxane molecule or the uncoördinated oxygen of the dioxane molecule incorporated in (A).[14] It was hoped that kinetic data would allow a choice between these two possibilities, but the complexity of the reaction at elevated temperatures discouraged further attempts along these lines.

(13) An alternative representation would be $C_6H_5C^+HCH_2SO_2OSO_3^-$. Other types of anhydrides may also be present.

(14) Models show that this oxygen can approach the α-hydrogen atom closely.

Acknowledgment.—We wish to thank the National Research Council for the Predoctoral Fellowship which supported this work.

Experimental[15]

Dioxane Sulfotrioxide.—The method of Suter and Evans[3] was used in some experiments, but the following method was preferred. Sulfur trioxide was distilled from an all-glass distillation apparatus containing 60% fuming sulfuric acid or "Sulfan B"[16] into dry ethylene dichloride contained in a tared flask cooled by a cold water-bath. The weight of sulfur trioxide was determined by difference to 0.05 g. An equimolar quantity of dioxane, purified by refluxing with sodium and distilling, was then added with rapid stirring. The internal temperature of the flask must be maintained below 5° in this operation to prevent charring. Since the coördination of sulfur trioxide with dioxane is very exothermic, the permissible rate of addition depends on the efficiency of cooling. For large runs it is advantageous to use a cooling bath temperature of about −40°. The reagent was obtained as fine granules.

Hydrolysis of the reagent with cold water gave 99.6% of the theoretical quantity of sulfuric acid, as determined by titration. No unsaturated material was detectable by a bromate–bromide titration.

Sulfonation of Styrene below 5° (Isolation of the Products[7]).—An equimolar quantity of styrene, dissolved in about an equal volume of ethylene dichloride, was added dropwise to dioxane sulfotrioxide suspended in ethylene dichloride. The mixture was stirred and the temperature kept below 5° (usually below 0°) during the addition. Hydrolysis was effected by pouring the reaction mixture into ice water. The ethylene dichloride layer was separated (the use of ether was helpful in overcoming the emulsions sometimes encountered) and washed; after drying, the solvent was removed at room temperature leaving crude 2,4-diphenyl-1,4-butanesultone[8] (III) as the residue. The aqueous portions were combined and neutralized with barium carbonate, and the barium sulfate was collected and determined gravimetrically. The filtrate was evaporated and three successive crops of barium sulfonates collected. A portion of the sulfonates from each crop was converted to the sodium salts by metathesis. Five grams of the sodium sulfonates from the first crop were refluxed with 50 ml. of 90% alcohol for forty-five minutes, the mixture was allowed to cool to room temperature and filtered. This process was repeated with further portions of 90% alcohol until the residue gave a negligible test for unsaturation with cold aqueous potassium permanganate solution. The residue weighed 2.0 g. and gave an 80% yield of S-*p*-chlorobenzylthiouronium 2-phenyl-2-hydroxy-1-ethanesulfonate, m. p. 179–180°, which gave no depression in melting point when mixed with an authentic sample.[6] The salt obtained by evaporating the alcohol filtrates was largely sodium 2-phenylethene-1-sulfonate (I), as shown by converting it to its S-benzylthiouronium salt[4] in 80% yield. The second and third crops were analyzed in a similar fashion. The percentages of crude I isolated from the three crops were 60, 43 and 0%, respectively. Titration of these samples by the bromate–bromide method showed 49, 36 and 2% of I. The mean values are given in Table I.

The analytical method used for subsequent sulfonations, the results of which are summarized in Table I, was similar to that described below for the analysis of the sulfonation run at 54.4°. To make certain that the determination for

(15) The microanalyses were performed by Miss Patricia Craig and Miss Margaret Hines.

(16) The γ-form of sulfur trioxide containing an inhibitor to prevent polymerization. This material was kindly furnished by the General Chemical Company, 40 Rector Street, New York, N. Y.

the experiments carried out over long periods of time was valid, the water-soluble products from a sulfonation mixture kept at 2° for fifty hours prior to hydrolysis were partially separated by the fractional crystallization technique described above. The formation of 2-phenyl-2-hydroxy-1-ethanesulfonic acid and 2-phenylethene-1-sulfonic acid as the principal products was confirmed.

Sodium 1-Bromo-2-phenylethene-1-sulfonate.—A solution of 1.05 g. (0.005 mole) of sodium 2-phenylethene-1-sulfonate was treated with bromine water until a permanent yellow color remained. The solution was evaporated to dryness on a steam-bath with the aid of a current of air. The residue, after crystallization from 90% alcohol, weighed 1.20 g. (87%).

Anal. Calcd. for $C_8H_6O_3SBrNa$: Na, 8.07; Br, 28.03. Found: Na, 8.13; Br, 27.33.

A portion was converted to the sulfonamide (m. p. 130–131°) by the procedure used by Truce,[10] and this showed no depression in melting point when mixed with a sample of his 1-bromo-2-phenylethene-1-sulfonamide, m. p. 130–131°.

1,2-Dibromo-2-phenyl-1-ethanesulfonamide.—A solution of 1.0 g. of 2-phenylethene-1-sulfonamide[4] in about 50 ml. of acetic acid was treated with an equimolar quantity of bromine, and the solution kept in sunlight for three hours. Oxygen appears to catalyze the reaction since decolorization occurs first at the surface. Concentration of the acetic acid at room temperature to about 15 ml. gave 1.0 g. (55%) of crystalline material. After two crystallizations from benzene, colorless needles, m. p. 161–162°, were obtained.

Anal. Calcd. for $C_8H_9O_2Br_2NS$: C, 27.96; H, 2.73. Found: C, 28.00; H, 2.79.

Triethylammonium bromide precipitated immediately when 0.1 g. of 1,2-dibromo-2-phenyl-1-ethanesulfonamide in a warm benzene solution was treated with excess triethylamine. Evaporation of the benzene and crystallization from water gave 1-bromo-2-phenylethene-1-sulfonamide.[10]

Sulfonation of Styrene at 54.4°.—Dioxane sulfotrioxide was prepared from 76.1 g. (0.951 mole) of sulfur trioxide, 83.7 g. (0.951 mole) of dioxane and 150 ml. of dry ethylene dichloride. A solution of 99.0 g. (0.951 mole) of styrene in 30 ml. of ethylene dichloride was added to this reagent in the course of two and one-third hours, the temperature being maintained at 5–7°. After an additional fifteen minutes at 10° two aliquots were withdrawn (by means of a 10-ml. pipet), weighed and hydrolyzed. The remaining solution was heated on the steam-bath to 55° as rapidly as possible, whereupon it was placed in a thermostat at 54.4°. Further aliquots were withdrawn at intervals. The fraction of sulfur trioxide present in each aliquot was determined from the weight of the reaction mixture and the weight of the aliquot. The aliquots were quenched immediately in ice-water, the weight of the aliquot being determined by the increase in weight of the flask holding the ice-water. Ether was added to each aliquot and the layers separated, using sodium chloride to break emulsions where necessary. After washing thoroughly the organic layer was dried and evaporated to dryness at room temperature, the weight of the residue being taken as an approximation of the quantity of 2,4-diphenyl-1,4-butanesultone[3] (III). The water layer was titrated (to phenolphthalein) with standard sodium hydroxide, then acidified and treated with 0.1 mole of barium chloride per mole of sulfur trioxide in the aliquot. The barium sulfate was determined gravimetrically (analysis reproducible to within 1% of the total sulfur trioxide). The filtrate was titrated by the bromate–bromide method to determine the amount of sodium 2-phenylethene-1-sulfonate present. The results are summarized in Table II.

Summary

1. Sulfonation of styrene at temperatures below 5° gave (after hydrolysis and neutralization) sodium 2-hydroxy-2-phenyl-1-ethanesulfonate (II) as the major product. β-Phenylethionic anhydride was ruled out as the principal precursor of II.

2. Titration with aqueous bromine using the bromate–bromide method was used to determine sodium 2-phenylethene-1-sulfonate (I) in the presence of II. A mechanism is given for the rapid reaction of I with bromine in aqueous solution.

3. The olefin–sulfur trioxide intermediate complex previously postulated[2] was useful in accounting for the various products formed in the sulfonation of styrene.

Formation of Ethers in the Preparation of Pentaerythritol

BY STANLEY WAWZONEK AND DONALD A. REES[1,2]

The preparation of pentaerythritol from acetaldehyde and formaldehyde is always accompanied by the formation of dipentaerythrityl ether.[3]

Attempts[3] to arrive at a mechanism by increasing the amount of dipentaerythrityl ether formed in this condensation proved unsuccessful. The only conclusion made was that pentaerythritol was not necessary for the formation of dipentaerythrityl ether.

One possible mechanism for the formation of dipentaerythrityl ether is outlined in the following series of reactions

$$CH_3CHO + HCHO \underset{}{\overset{OH^-}{\rightleftharpoons}} CH_2OHCH_2CHO \quad (1)$$

$$CH_2OHCH_2CHO \rightleftharpoons CH_2{=}CHCHO + H_2O \quad (2)$$

$$CH_2{=}CH{-}CHO + HOCH_2CH_2CHO \rightleftharpoons O(CH_2CH_2CHO)_2 \quad (3)$$

$$O(CH_2CH_2CHO)_2 + 6HCHO + 2OH^- \longrightarrow O(CH_2C(CH_2OH)_3)_2 + 2HCOO^- \quad (4)$$

The existence of an equilibrium between acrolein and β-hydroxypropionaldehyde in aqueous and acid solutions has already been demonstrated by Lucas.[4] Addition of an alcohol to acrolein in

the presence of alkali is the subject of a patent.[5]

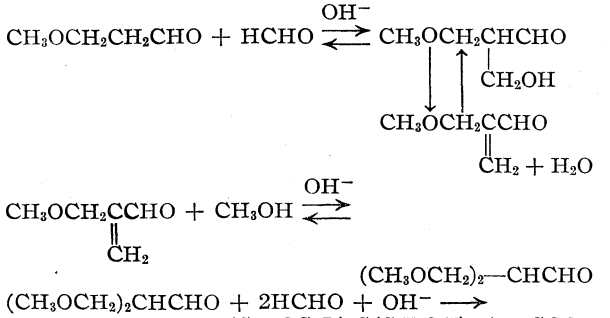
In the present investigation evidence has been obtained for the formation of ethers of pentaerythritol, by the reactions cited above, in the Tollens condensation.

The formation of pentaerythritol under the usual conditions[6] in an aqueous solution containing 50% methanol by volume gave a product which, to aid separation, was propionated. The mixture of propionates obtained was separated by distillation into pentaerythrityl tetrapropionate, the tripropionate of methylpentaerythrityl ether, and the dipropionate of dimethylpentaerythrityl ether. Identification was accomplished by saponification to pentaerythritol, methylpentaerythrityl ether and dimethylpentaerythrityl ether.

Methylpentaerythrityl ether and dimethylpentaerythrityl ether were also separated by chromatographic adsorption of their *p*-phenylazobenzoates.

The formation of methylpentaerythrityl ether indicates that acrolein is an intermediate in the formation of pentaerythritol and that it can add alcohols that may be present to form ethers. The ethers on further reaction with formaldehyde give ethers of pentaerythritol. In the present investigation methyl alcohol gave methylpentaerythrityl ether. Under the usual conditions[6] for preparing pentaerythritol, β-hydroxypropionaldehyde or products resulting from the reaction of β-hydroxypropionaldehyde and formaldehyde or even pentaerythritol can add to acrolein and give rise to dipentaerythrityl ether. The reaction of the last two with more than one molecule of acrolein would give rise to the polypentaerythrityl ethers mentioned in the patent literature.

The formation of dimethylpentaerythrityl ether is entirely consistent with the mechanism proposed. Its formation could proceed from β-methoxypropionaldehyde.



Similar reactions may be involved in the formation of some of the polypentaerythrityl ethers.

Experimental[7]

Preparation of Pentaerythritol in 50% Methanol.—To a suspension of paraformaldehyde (240 g.) in water (750 ml.) and methanol (750 ml.) containing 63 g. of acetaldehyde, there was added 53 g. of powdered quicklime in rather large portions at first in order to bring the temperature to 45° and then at a rate to maintain the temperature between 50–55°. The mixture became slightly yellow in color. After the addition was complete, stirring was continued for an additional three hours. To the resulting mixture, oxalic acid (141 g.) was added; the solid was removed by filtration and washed with two 500-ml. portions of water. The combined filtrates were evaporated under reduced pressure to dryness. The last traces of water were removed by adding 200 ml. of propionic acid and repeating the distillation under reduced pressure. The product obtained was a dark brown sirup.

Separation of the Products.—To a mixture of the sirup and propionic anhydride (780 ml.) at 0°, concentrated sulfuric acid (30 ml.) was added dropwise keeping the temperature below 4°. The resulting solution was stirred overnight at room temperature and then at 100° until solution of the sirup was complete. After two more hours at this temperature, the solution was heated under reduced pressure to remove the excess propionic anhydride, and the propionic acid formed. The liquid obtained was cooled, poured onto ice (1500 g.) and neutralized with sodium bicarbonate. Extraction with ether gave 287 g. of a deep brown colored sirup which was first rapidly distilled at 0.1 mm. from a Claisen flask. A second distillation at 4 mm. through a Vigreux column gave three distinct fractions.

Fraction	Yield, g.	B. p., °C.
I	14.5	135–148
II	52.0	165–172
III	167.4	172–197

Fraction I upon refractionation gave the dipropionate of dimethylpentaerythrityl ether, b. p. 135–138° at 6 mm., $n^{25}D$ 1.4361, d^{20} 1.057.

Anal. Calcd. for $C_{13}H_{24}O_6$: C, 56.50; H, 8.75; OCH_3, 22.46. Found: C, 56.62; H, 8.67; OCH_3, 20.41.

The dipropionate of dimethylpentaerythrityl ether (5.4 g.) was refluxed with a slight excess of sodium methoxide in methanol (20 ml.) for two hours. The resulting solution was neutralized with dilute hydrochloric acid and evaporated to dryness. Extraction with chloroform gave an oil which was recrystallized from (60–70°) petroleum ether; m. p. 34–35°; yield 0.5 g. A mixture with an authentic sample[8] melted at the same temperature.

Fraction II upon refractionation gave the tripropionate of methylpentaerythrityl ether, b. p. 170–172° at 5–6 mm., $n^{25}D$ 1.4410, d^{20} 1.081.

Anal. Calcd. for $C_{15}H_{26}O_7$: C, 56.59; H, 8.23; OCH_3, 9.75. Found: C, 56.79; H, 8.18; OCH_3, 9.03.

The tripropionate of methylpentaerythrityl ether (17 g.) was saponified in a similar manner to that used for the dipropionate of dimethylpentaerythrityl ether. The oil obtained was crystallized from chloroform; m. p. 65–67°; yield 2.3 g. A distillation at reduced pressure (2 mm.) followed by a crystallization from chloroform gave white crystals melting at 71–72°. A mixture with an authentic sample[8] melted at the same temperature.

Fraction III upon refractionation gave pentaerythrityl tetrapropionate, b. p. 184–186° at 3 mm.; m. p. 35–37°. This compound is reported in the patent literature[9] as a liquid.

Anal. Calcd. for $C_{17}H_{28}O_8$: C, 56.65; H, 7.83. Found: C, 56.45; H, 7.81.

Pentaerythrityl tetrapropionate (5.0 g.) was saponified by refluxing with sodium methoxide (0.02 g. of sodium) in dry methanol (50 ml.). Completion of the reaction was indicated by complete solution of a few drops of the reaction mixture in water. Upon cooling pentaerythritol

crystallized from the reaction mixture. One crystallization from water gave a product (1.5 g.) melting at 259°.

Deacylation and Chromatographic Separation of Fraction I.—Fraction I (3 g.) was deacylated in a similar fashion to that used for pentaerythrityl tetrapropionate. Removal of the methanol gave a sirup which was treated in dry pyridine (50 ml.) and *p*-phenylazobenzoyl chloride[10] (3 g.). The mixture was shaken for a short time and then heated at 85° for three days. The resulting solution was shaken with water (2 ml.) for fifteen minutes and then poured onto ice (300 g.) with vigorous stirring. The resulting mixture was neutralized with sodium bicarbonate and extracted repeatedly with chloroform. The combined chloroform extracts were washed once with water and dried. Chromatographic separation was performed on a column of silicic acid 60 cm. long and 3.3 cm. in diameter. Two distinct bands were obtained. Using chloroform as the eluent, the lower band of the tri-*p*-phenylazobenzoate of methylpentaerythrityl ether was run completely through the column in order to separate the di-*p*-phenylazobenzoate of dimethylpentaerythrityl ether from the *p*-phenylazobenzoic acid. The chloroform solution of the tri-*p*-phenylazobenzoate of methylpentaerythrityl ether was concentrated to 55 ml., mixed well with ethanol (100 ml.) and allowed to stand at 0° until no more precipitate formed. The light orange crystals were filtered, washed with ethanol and recrystallized from ligroin, m. p. 190–191°.

Anal. Calcd. for $C_{45}H_{38}N_6O_7$: C, 69.77; H, 4.95; azoyl, 81.0; mol. wt., 774. Found: C, 70.08; H, 4.87; azoyl, 80.4; mol. wt. (Rast), 773, 793.

The di-*p*-phenylazobenzoate of dimethylpentaerythrityl ether was separated mechanically and removed from the silicic acid with a mixture of chloroform and ethanol. Removal of the solvent gave an orange solid which was recrystallized from ligroin, m. p. 93–94°.

Anal. Calcd. for $C_{33}H_{32}O_6N_4$: C, 68.27; H, 5.51; Found: C, 67.50; H, 5.25.

Summary

The Tollens condensation of acetaldehyde with formaldehyde in 50% methanol gives a mixture of pentaerythritol, methylpentaerythrityl ether and dimethylpentaerythrityl ether.

A mechanism for the formation of ethers in the preparation of pentaerythritol is proposed.

Oxidations of Certain Polyacetyl-β-D-thioglycosides to the Corresponding Sulfones

BY WILLIAM A. BONNER AND RICHARD W. DRISKO

A single paper by Wrede and Zimmermann[1] seems to be the only report to date considering the oxidation of carbohydrate derivatives containing divalent sulfur. These investigators prepared di-tetraacetylglucosyl sulfone, di-tetraacetylgalactosyl sulfone, di-heptaacetylcellobiosyl sulfone and methyl 6-sulfo-bis-(6-desoxy-2,3,4-triacetyl-β-D-glucoside) by oxidation of the corresponding sulfides with potassium permanganate in acetic acid. Treatment of the first three of these compounds with ammonia in methanol led to the corresponding deacetylated substances. Since the chemistry of the sulfone derivatives in the sugar series has received little attention, and since no sulfones related to the simple thioglucosides have been prepared, it seemed desirable to prepare and study a few representative members of this class of compounds.

When phenyl tetraacetyl-β-D-thioglucoside was dissolved in acetic acid and treated with a slight excess of aqueous potassium permanganate, phenyl tetraacetyl-β-D-glucosyl sulfone resulted in excellent yield and purity. Phenyl triacetyl-β-D-xylosyl, phenyl triacetyl-D-arabinosyl, and ethyl tetraacetyl-β-D-glucosyl sulfones were similarly prepared. Hydrogen peroxide in acetic acid, after the method of Gilman and Beaber,[2] was also found effective in oxidizing thioglycosides to the corresponding sulfones. Phenyl, benzyl and ethyl tetraacetyl-β-D-glucosyl sulfones were prepared in good yield in this manner. It is noteworthy that when hydrogen peroxide was used as oxidant, the oxidation process was apparently attended by deacetylation of the acetylated thioglucoside despite the acetic acid solvent. This unexpected phenomenon is under further investigation at the present time.

The alkyl and aryl polyacetyl-β-D-glycosyl sulfones prepared in this study were white, nicely crystalline substances. The physical properties of the sulfones prepared in this study are contrasted with those of the corresponding parent polyacetyl-β-D-thioglycosides in Table I. It is seen that oxidation of the divalent sulfur atom in the acetylated thioglycoside to the sulfone state brings about the substantial melting point increase usually observed in converting a thioether to its sulfone.[3] Accurate correlations of the trends in the change of optical activity accompanying oxidation of the thioglycoside to its sulfone cannot be made on the basis of the data at hand, but it is apparent from Table I that such changes in rotatory power probably depend both upon the nature of the thio-aglucone and the configuration of the glycosyl residue.

By use of the calculated quantity of potassium permanganate as oxidant an attempt has been made to convert phenyl tetraacetyl-β-D-thioglucoside into phenyl tetraacetyl-β-D-glucosyl sulfoxide, a typical representative of the class intermediate

TABLE I

COMPARISON OF PROPERTIES OF SEVERAL ACETYLATED THIOGLYCOSIDES WITH THE CORRESPONDING SULFONES

Compound	Acetylated thioglycoside M. p., °C.	$[\alpha]_D$, °	Acetylated sulfone M. p., °C.	$[\alpha]_D$, °
Phenyl β-D-thioglucoside	117[4]	−17.5[4,a]	189.5	−26.9[a]
Phenyl β-D-thioxyloside	78[4]	−58.9[4,a]	154.0	−86.8[a]
Phenyl D-thio-arabinoside	Sirup	+15.7[a]	147.0	+29.4[a]
Benzyl β-D-thioglucoside	98[5]	−93.1[5,b]	199.0	−48.6[b]
Ethyl β-D-thioglucoside	83–84[6]	−27.25[6,b]	154.5	−16.4[b]

[a] In chloroform solution. [b] In ethylene dichloride solution.

in oxidation state between the thioglycosides and their sulfones. Instead of isolating the desired sulfoxide, however, a mixture of the starting thioglucoside and the corresponding sulfone was obtained. It is possible that the sulfoxide, once formed, is more readily oxidized to the sulfone than is the remaining unoxidized thioglucoside oxidized to the sulfoxide.

It was found that by the action of ammoniacal methanol phenyl triacetyl-β-D-xylosyl and phenyl tetraacetyl-β-D-glucosyl sulfones could be readily deacetylated. Both deacetylation products were crystalline solids, the latter forming a hydrate. Both products rapidly reduced Benedict solution. Wrede and Zimmermann[1] similarly report reducing properties for their sulfone derivatives. The deacetylation product of the glucose derivative has been reacetylated to yield its previous acetate, and has been propionylated to give the corresponding tetrapropionate.

An initial attempt has been made to determine the ring structure of the above deacetylation products by their oxidation with periodic acid. The reaction observed, however, seems to be more complex than that usually noted[7] in the periodic acid oxidation of sugar derivatives, since the quantity of periodic acid consumed is not that predicted. Investigations into the cause of this behavior and further ring size studies are currently in progress.

Experimental Part

Phenyl Tetraacetyl-β-D-glucosyl Sulfone.—Phenyl tetraacetyl-β-D-thioglucoside (1.00 g.) was dissolved in glacial acetic acid (25 ml.). To the solution was added slowly with stirring a 5% aqueous solution of potassium permanganate containing 0.53 g. (10% excess) of the oxidant. The mixture was heated on the hot-plate for five minutes at the end of which it had begun to boil. It was cooled and treated with a saturated aqueous solution of sodium bisulfite until clear. On dilution of the clear solution with 125 ml. of water the sulfone precipitated as a white solid; yield 0.93 g. (87%), m. p. 189.5°.[8] On recrystallization from 2-propanol the m. p. was unchanged and the sample had $[\alpha]^{24}D$ −26.9° (chloroform; *c*, 1.895).

In the peroxide oxidation phenyl tetraacetyl-β-D-thioglucoside (10 g.) was dissolved in glacial acetic acid (75 ml.) and treated with 30% hydrogen peroxide (14 g., 173% excess). The mixture was refluxed for two hours, cooled, and poured into an excess of water. No precipitate formed, suggesting that the compound had undergone deacetylation during the course of oxidation. The mixture was distilled to dryness *in vacuo* and the residue treated with acetic anhydride (75 ml.) and sodium acetate (1 g.). After refluxing for one and one-half hours the acetylation mixture was poured into water to give a brown oil which solidified on rapid stirring. The crude material was filtered, dried, and weighed 7.0 g. (65%). After recrystallization from 2-propanol the m. p. was 188° and $[\alpha]^{21}D$ −27.2° (chloroform; *c*, 8.019).

Anal. Calcd. for $C_{20}H_{24}O_{11}S$: C, 50.85; H, 5.12; S, 6.80. Found: C, 50.58, 50.71; H, 5.14, 5.11; S, 6.84.

The failure to observe a precipitate on pouring the reaction mixture from the peroxide oxidation into water was interpreted as indicative of accompanying deacetylation. To test this supposition several test-tube experiments were undertaken.

Four test-tubes were charged with the following mixtures: Tube A, phenyl tetraacetyl-β-D-thioglucoside (0.50 g.) and acetic acid (8 ml.); Tube B, phenyl tetraacetyl-β-D-thioglucoside (0.50 g.), acetic acid (8 ml.) and 30% hydrogen peroxide (1.0 g.); Tube C, phenyl tetraacetyl-β-D-glucosyl sulfone (0.50 g.), acetic acid (8 ml.), and 30% hydrogen peroxide (1.0 g.); Tube D, acetic acid (8 ml.) and 30% hydrogen peroxide (1.0 g.). The tubes were placed in boiling water for two hours and cooled. Then phenyl tetraacetyl-β-D-glucosyl sulfone (0.50 g.) was dissolved in Tube D. The contents of each tube were poured into 125 ml. of water, and the four resulting mixtures placed at 0° overnight. The products were filtered, rinsed with water, and air-dried. Tube A gave unchanged thioglucoside (0.37 g., m. p. 115.5°). Tubes B, C and D gave phenyl tetraacetyl-β-D-glucosyl sulfone as follows: Tube B, (0.19 g., m. p. 180°); Tube C, (0.43 g., m. p. 187.5°); Tube D, (0.46 g., m. p. 188°). The low yield and m. p. of the product from Tube B is interpreted as due to deacetylation accompanying the oxidation of the thioglucoside.

Phenyl Triacetyl-β-D-xylosyl Sulfone.—Phenyl triacetyl-β-D-thioxyloside (1.00 g.) dissolved in acetic acid (15 ml.) was treated with potassium permanganate (0.63 g., 10% excess) dissolved in water (10 ml.). The mixture was heated for thirty minutes on the steam-bath, then cooled, clarified by addition of sufficient solid sodium bisulfite, and diluted with 1–5 ml. of ice water. There resulted 1.09 g. (99%) of crude sulfone, m. p. 151°. After three recrystallizations from 2-propanol the compound had m. p. 154° and $[\alpha]^{22}D$ −86.8° (chloroform; *c*, 1.729).

Anal. Calcd. for $C_{17}H_{20}O_9S$: C, 51.0; H, 5.04. Found: C, 51.0; H, 5.11.

Phenyl Triacetyl-D-thioarabinoside.—Acetyl bromide (27 ml., equiv. amount) was cooled to 0° in a salt–ice mixture. D-Arabinose (10 g.) (α,β-mixture) was added with mechanical stirring over a period of twenty minutes. The cold bath was removed and the mixture allowed to warm slowly. Whenever the reaction became too vigorous as evidenced by excessive evolution of hydrogen bromide the cold bath was momentarily replaced. After twenty minutes of such treatment the reaction mixture was a homogeneous, amber fluid. It was stirred at room temperature for an additional twenty-four hours, then diluted with chloroform (100 ml.). The solution was washed with ice water, cold bicarbonate solution, and ice water, then treated with calcium chloride until clear. Removal of the solvent *in vacuo* at 45–50° resulted in 15.9 g. (70%) of crude acetobromo-D-arabinose, a thick, crystalline paste.

The crude product above (15.9 g.) was dissolved in

(8) All melting points are corrected.

chloroform (75 ml.) and treated with ethanol (75 ml.) containing potassium hydroxide (2.63 g., one equiv.) and thiophenol (5.3 ml., 10% excess) after the manner of Purves.[3] After refluxing forty minutes the mixture was washed twice with water, once with 10% potassium hydroxide solution, again with water, then dried over sodium sulfate and decolorized by filtration through Norit and Celite. Removal of the solvent at 80° *in vacuo* left 7.8 g. (45%) of clear, amber sirup. This showed no tendency to crystallize on standing in 2-propanol, in agreement with the observation of Fletcher and Hudson.[9] The 2-propanol solution was, therefore, poured into water, the mixture extracted with ether, and the extract washed as above. The resulting sirup obtained after drying and distillation of solvent was used without further purification; $[\alpha]^{23}D$ +15.7° (chloroform; *c*, 4.583).

Anal. Calcd. for $C_{11}H_{11}O_6S(OCCH_3)_3$: acetyl, 35.1. Found:[10] acetyl, 34.5.

Phenyl Triacetyl-D-arabinosyl Sulfone.—One gram of the sirupy product above was oxidized exactly as described for the corresponding xylose derivative. The oxidation mixture was poured into water and the milky suspension extracted with ether. The extract was washed with water, bicarbonate solution and water, then dried over anhydrous sodium sulfate. Removal of the solvent left a clear sirup which, on treatment with 2-propanol, gave 0.50 g. (46%) of crude solid product, m. p. 144 to 145°. After four recrystallizations from 2-propanol the substance had m. p. 147° and $[\alpha]^{23}D$ +29.5° (chloroform; *c*, 1.290).

Anal. Calcd. for $C_{17}H_{20}O_9S$: C, 51.0; H, 5.04. Found: C, 51.2; H, 5.02.

Benzyl Tetraacetyl-β-D-glucosyl Sulfone.—Benzyl tetraacetyl-β-D-thioglucoside[4] (2.0 g.) was dissolved in acetic acid (20 ml.), and 30% hydrogen peroxide (5 g.) was added. The mixture was refluxed for two hours, the solvent evaporated under reduced pressure, and the residue acetylated with acetic anhydride (50 ml.) and sodium acetate (2 g.) as before. Isolation of the product in the previous fashion gave 1.6 g. (75%) of crude product, m. p. 196.5°. One recrystallization from 2-propanol gave the pure material, m. p. 199°, $[\alpha]^{23}D$ −44.6° (chloroform; *c*, 1.995), $[\alpha]^{22}D$ −48.6° (ethylene dichloride; *c*, 1.523).

Anal. Calcd. for $C_{13}H_{16}O_7S(OCCH_3)_4$: C, 51.8; H, 5.39; acetyl, 35.4. Found: C, 51.7; H, 5.34; acetyl, 35.7.

Ethyl Tetraacetyl-β-D-glucosyl Sulfone.—Ethyl tetraacetyl-β-D-thioglucoside[4] (5.0 g.) was refluxed for two hours in acetic acid (100 ml.) containing 30% hydrogen peroxide (18 g.). The acetic acid was distilled *in vacuo* with heating below 70°, and the residue acetylated and processed in the previous manner. There resulted 5.6 g. (103%) of crude product, m. p. 154°. After one recrystallization from 2-propanol the pure product had m. p. 154.5°, $[\alpha]^{26}D$ −15.0° (chloroform; *c*, 1.334), $[\alpha]^{22}D$ −16.4° (ethylene dichloride; *c*, 1.095).

Anal. Calcd. for $C_8H_{12}O_7S(OCCH_3)_4$: C, 45.3; H, 5.70; acetyl, 40.7. Found: C, 45.5; H, 5.83; acetyl, 40.9.

Ethyl tetraacetyl-β-D-thioglucoside (0.60 g.) was dissolved in acetic acid (25 ml.) and 5% potassium permanganate solution (8.5 g., 32% excess) added. After heating five minutes the mixture was cooled and processed as in previous permanganate oxidations. The crude product weighed 0.44 g. (68%) and had m. p. 154.5° and $[\alpha]^{23}D$ −15.5° ($CHCl_3$; *c*, 1.611).

Attempted Oxidation of Phenyl Tetraacetyl-β-D-thioglucoside to Sulfoxide.—Phenyl tetraacetyl-β-D-thioglucoside (2.00 g.) was dissolved in acetic acid (25 ml.). To this was slowly added with stirring an aqueous solution (25 ml.) containing 0.49 g. (theoretical amount for oxidation to the sulfoxide) of potassium permanganate. The solution was warmed for five minutes on the hot-plate, cooled, clarified with saturated bisulfite solution, and diluted to 125 ml. with water. The flocculent precipitate was filtered, rinsed and air-dried, m. p. 125° with preliminary softening. This was recrystallized four times from a mixture of acetone and water giving successive melting points of 145, 155, 158–160 and 162–164°. It was then recrystallized six times from 2-propanol to give successive melting points of 172–174°, 176–177°, 176–178°, 183–185°, 187–187.5° and 188°. All melting points but the last two showed preliminary softening. A mixed melting point of the final product with phenyl tetraacetyl-β-D-glucosyl sulfone showed no depression (188°). From the initial filtrate there was obtained an additional 0.18 g. of solid on further standing, m. p. 111°. On recrystallization from 2-propanol this melted at 114° and showed no mixed m. p. depression (114°) with a sample of phenyl tetraacetyl-β-D-thioglucoside of m. p. 115°.

Phenyl β-D-Xylosyl Sulfone.—Phenyl triacetyl-β-D-xylosyl sulfone (0.66 g.) was dissolved in methanol (30 ml.) which had been saturated with ammonia, and the solution permitted to stand for four days in an open beaker. The solvent evaporated to leave a white solid, m. p. 156°, dec. The product, after recrystallization from 2-propanol, readily reduced Benedict solution. The recrystallized product was extracted four times with hot ether. The remaining solid weighed 0.24 g. (53%) and had m. p. 160° dec., unchanged on further recrystallization from 2-propanol; $[\alpha]^{19}D$ was −44.8° (water; *c*, 1.137).

Anal. Calcd. for $C_{11}H_{14}O_6S$: C, 48.2; H, 5.14. Found: C, 48.2; H, 5.09.

Phenyl β-D-Glucosyl Sulfone Hydrate.—Phenyl tetraacetyl-β-D-glucosyl sulfone (2.00 g.) was covered with 100 ml. of methanol saturated with ammonia, and stirred until solution was complete. The solution stood for two days in an open beaker, after which the residual solvent was evaporated in an air stream. The tan residue was extracted four times with hot ether to leave 1.32 g. (102%) of sticky tan solid. This was dissolved in a slight excess of 2-propanol and the solution decolorized with Norit. Ligroin was added to the clear solution until slightly cloudy and on cooling in ice there resulted 0.88 g. (68%) of white crystalline solid, m. p. 90–92°. A second recrystallization raised the m. p. to 91–92°. A combustion analysis and quantitative drying in an Abderhalden pistol showed that this material contained water of hydration. Consequently, the sample was recrystallized from 2-propanol containing 10% water and ligroin, m. p. 92–93°. $[\alpha]^{26}D$ was −15.0° (water; *c*, 1.132).

Anal. Calcd. for $C_{12}H_{16}O_7S \cdot H_2O$: C, 44.7; H, 5.63. Found: C, 44.7; H, 5.73.

On reacetylation of the above sample with acetic anhydride and sodium acetate the acetylated sulfone was obtained in 87% crude yield, m. p. 188.5°, $[\alpha]^{28}D$ −26.8° (chloroform; *c*, 1.047).

An attempt was made to deacetylate phenyl tetraacetyl-β-D-glucosyl sulfone by the procedure of Bonner and Koehler[11] using potassium methylate followed by potentiometric titration with perchloric acid. The product obtained, however, did not crystallize, and proved to contain around 8% of inorganic ash. Apparently the deacetylation product retained a certain amount of potassium perchlorate which could not be separated. The sirup obtained had $[\alpha]^{22}D$ −14.3° (ethyl alcohol; *c*, 2.310), and was shown to be substantially phenyl β-D-glycosyl sulfone by the fact that it could be reacetylated to give the original starting material in 75% yield.

Phenyl Tetrapropionyl-β-D-glycosyl Sulfone.—Impure, sirupy phenyl β-D-glucosyl sulfone (0.14 g.) from the second reaction above was dissolved in pyridine (4 ml.) and treated with propionic anhydride (10 ml.). The mixture stood for two days at 0° and was thrown into ice

(9) Fletcher and Hudson, THIS JOURNAL, **69**, 1673 (1947).

(10) Since the compound in question was a sirup and incapable of further purification by convenient means, and since the sulfone prepared from this sirup gave an acceptable analysis, no attempt was made to obtain further analytical data for this compound.

(11) Bonner and Koehler, THIS JOURNAL, **70**, 314 (1948).

water. After stirring for several hours the oil was extracted into ether and the extract washed with water, 4 *N* hydrochloric acid, water, saturated bicarbonate solution, and water. After drying over sodium sulfate the solvent was distilled to yield 0.17 g. (70%) of amber sirup which could not be crystallized from 2-propanol; $[\alpha]^{19}D$ was −23.9° (chloroform; *c*, 33.3).

Anal. Calcd. for $C_{24}H_{32}O_{11}S$: C, 54.5; H, 6.10. Found: C, 55.3; H, 6.24.

Summary

1. Alkyl and aryl polyacetyl-β-D-thioglycosides have been shown to be readily oxidized to the corresponding alkyl or aryl polyacetyl-β-D-glycosyl sulfones by action of either potassium permanganate or 30% hydrogen peroxide. Partial deacetylation apparently attends the latter oxidation in acetic acid medium. A number of examples of these oxidations are given, and several members of this new class of sulfones are described.

2. Two phenyl polyacetyl-β-D-glycosyl sulfones have been deacetylated using ammoniacal methanol, and the deacetylation products have been described.

5-Alkyl (or 5-Phenyl)-5-propoxymethylhydantoins[1]

BY HENRY R. HENZE, JOE W. MELTON[2] AND EUGENE O. FORMAN

Some time ago, Henze and Rigler[3] prepared 5-ethoxymethyl-5-phenylhydantoin which later was shown to possess considerable anticonvulsant activity.[4] This behavior is in contrast to that of 5-ethyl-5-isoamyoxymethylhydantoin[3] which shows no anticonvulsant activity even in far larger doses,[4] and is, in fact, an unsatisfactory soporific. To obtain additional compounds, suitable for subsequent pharmacological testing for activity, we converted seventeen keto ethers, previously reported,[5] into the corresponding 5-alkyl (or 5-phenyl)-5-propoxymethylhydantoins. The latter have proved to be potent anticonvulsants,[4] the most active being 5-isopropoxymethyl-5-phenylhydantoin which compares favorably with 5,5-diphenylhydantoin in this respect and has merited clinical study.

Experimental

The hydantoins were obtained by warming a mixture of 1 part of keto ether, 1.1 parts of potassium cyanide and 3 parts of ammonium carbonate (U. S. P. cubes) in sufficient 50% alcohol at 58–60° for periods up to twenty-four hours. After the period of interaction, the solutions were evaporated to about half volume, acidified with hydrochloric acid and boiled to remove hydrogen cyanide. Usually, at this point, the hydantoins

separated as white, crystalline solids; some, of lower m.p., separated as liquids which crystallized upon contact with ice. Recrystallization was effected in most cases by use of diluted alcohol or of a mixture of benzene and petroleum ether. The hydantoins can be dissolved in cold 10% solution of alkali and are reprecipitated unchanged upon acidification. Data for melting points and analyses are listed in Table I.

Summary

Seventeen new 5-alkyl (or 5-phenyl)-5-alkoxyalkylhydantoins have been prepared from the corresponding alkyl (or phenyl) *n*- or iso-propoxymethyl ketones. Of these, the 5-isopropoxymethyl-5-phenylhydantoin exhibits outstanding activity as an anticonvulsant.

Organic Thio-antimonials in Schistosomiasis

BY LEROY W. CLEMENCE AND MARLIN T. LEFFLER[1]

Organic antimony compounds have been used for a number of years in the treatment of protozoan diseases, but with certain drawbacks such as toxicity and a high relapse rate. It was felt that oil soluble antimonials would tend to overcome these difficulties because of slower and more prolonged absorption. A series of compounds has been prepared in which each compound is either an oil or a low melting solid and is soluble in vegetable oils. The general structure is $(RS-)_3Sb$ where R is *n*-alkyl (C_8-C_{18}), aralkyl (phenylethyl or naphthylethyl), cycloalkyl (cyclohexylethyl, cyclohexylamyl, tetralylbutyl, decalylbutyl), and heteroalkyl (pyridylethyl).

The compounds were prepared by the action of antimony trichloride on the appropriate mercaptan in chloroform. They were tested in experimental schistosomiasis[2] and preliminary results indicate some promise. Further animal investigation is under way and the results will be published elsewhere.

Experimental

The procedures described below were used for the preparation of the isothiouronium bromides, mercaptans and antimony compounds. Table I gives the physical constants and analytical data of previously undescribed compounds in the two former groups; Table II gives the data on the antimony compounds.

ω-Cyclohexylamyl Bromide.[3]—To 227 g. (1.33 moles) of cyclohexylamyl alcohol[3] (prepared by hydrogenation of ethyl ω-cyclohexylvalerate[3] at 250°, 3600 lb. pressure and copper chromite catalyst; b. p. 106–107° at 3 mm., $n^{25}D$ 1.4634) cooled to −10° in a 500-cc. flask fitted with stirrer, dropping funnel and thermometer, was added dropwise, 144 g. (0.44 mole + 20% excess) of phosphorus tribromide, keeping the temperature below 0°. This

(3) Hiers and Adams, THIS JOURNAL, **48**, 2385 (1926); Katsnelson and Dubinin, *Compt. rend. Acad. Sci. (U. R. S. S.)*, [N. S.], **4**, 405 (1936).

addition required three hours. The reaction mixture was stirred until room temperature was reached, allowed to stand overnight, heated at 100° for several hours, then cooled and poured into 1000 cc. of ice and water with good agitation. The heavy oily layer was dissolved in ether, the ether layer washed several times with water then with sodium carbonate solution, again with water, then dried over magnesium sulfate and evaporated. On distillation in vacuum, the fraction boiling at 89.5–90.5° at 1 mm., $n^{24}D$ 1.4784, was collected; yield 271 g. (87%). *Anal.* Calcd. for $C_{11}H_{21}Br$: C, 56.65; H, 9.01. Found: C, 56.87; H, 9.14.

ω-Cyclohexylamyl Isothiouronium Bromide.—To 23.3 g. (0.1 mole) of the above bromide was added a hot, filtered solution of 7.6 g. (0.1 mole) of thiourea in 125 cc. of absolute alcohol. The mixture was refluxed for thirty-six hours, then cooled and stirred until the whole mass became a crystalline mush. The solid was filtered, washed with a little acetone and dried. The yield was 22.6 g., m. p. 138–141°. After recrystallization of this material from 250 cc. of boiling water using a small amount of norite, the yield was 20.9 g. (68%), m. p. 140–141°. *Anal.* Calcd. for $C_{12}H_{24}N_2S \cdot HBr$: N, 9.06. Found: N, 8.92.

ω-Cyclohexylamyl Mercaptan.—Seventy-eight grams (0.25 mole) of the isothiouronium compound described above was added to a solution of 50 g. (1.25 moles) of sodium hydroxide dissolved in 325 cc. of water. The mixture was heated to boiling and refluxed for ten minutes, then cooled quickly and made acid to congo red by addition of concd. hydrochloric acid. It was extracted with ether and dried over anhydrous sodium sulfate, then evaporated. The residual oil was distilled in vacuum. The main fraction boiled at 93–94.5° at 1.2 mm. It was redistilled, b. p. 89.5–91° at 1 mm., $n^{25}D$ 1.4820, yield 41 g. (87%). *Anal.* Calcd. for $C_{11}H_{22}S$: C, 70.96; H, 11.82. Found: C, 71.06; H, 11.78.

Tri-[ω-cyclohexylamylmercapto]-S-antimonous Acid.—A solution of 7.61 g. (0.033 mole) of antimony trichloride in 50 cc. of warm chloroform was filtered and added to a solution of 18.6 g. (0.1 mole) of ω-cyclohexylamyl mercaptan in 50 cc. of chloroform. The clear solution was evaporated in vacuum to remove the solvent, then placed in a vacuum desiccator over solid sodium hydroxide for forty-eight hours to remove the last traces of hydrochloric acid. A quantitative yield of almost colorless oil was obtained. It was insoluble in water, soluble in chloroform, ether, benzene and vegetable oils. *Anal.* Calcd. for $C_{33}H_{66}S_3Sb$: Sb, 17.99. Found: Sb, 18.33.

The *n*-alkyl mercaptans, except the undecyl, were obtained from the Connecticut Hard Rubber Company. This was prepared by converting undecyl alcohol to the bromide and following the above procedure. β-(*p*-Diisobutylphenoxyethoxy)-ethyl mercaptan was obtained from Rohm & Haas Company; 2-pyridylethyl mercaptan was obtained from Reilly Tar and Chemical Corporation.

The intermediates, for conversion to the remaining mercaptans by the above procedures, were obtained as follows. Phenylethyl bromide was obtained from Columbia Organic Chemicals Company. β-(1-Naphthyl)-ethyl alcohol was prepared by method of Ruzicka.[4] β-Cyclohexylethyl alcohol,[3] b. p. 78–80° at 5 mm., $n^{25}D$ 1.4629, was prepared by catalytic hydrogenation of ethyl cyclohexylacetate.

The following alcohols were previously undescribed. ω-(β-Tetralyl)-butyl alcohol was obtained by hydrogenation of ethyl ω-(β-tetralyl)-butyrate[5] at 250°, 3600 lb. pressure with copper chromite catalyst; b. p. 167° at 5 mm., $n^{25}D$ 1.5391. *Anal.* Calcd. for $C_{14}H_{20}O$: C, 82.32; H, 9.81. Found: C, 82.03; H, 9.98. ω-(β-Decalyl)-butyl alcohol was obtained by further hydrogenation of the above alcohol at 200°, 3500 lb. pressure with Raney nickel catalyst; b. p. 148–149° at 6 mm., $n^{25}D$ 1.4919. *Anal.* Calcd. for $C_{14}H_{26}O$: C, 80.00; H, 12.38. Found: C, 80.64; H, 12.33.

The bromides obtained from the alcohols were slightly impure and were converted to the corresponding isothiouronium bromides without redistillation.

An attempt was made to purify one of the antimony compounds (*n*-dodecyl-) by molecular distillation but decomposition occurred. Tri-[(β-(2-pyridyl)-ethylmercapto]-S-antimonous acid was a resinous material only slightly soluble in olive oil.

Acknowledgment.—The authors wish to thank Mr. E. F. Shelberg for the micro-analyses, Mr. R. Cox for the antimony analyses herein reported, Mr. M. Freifelder for the catalytic hydrogenations and Mr. C. Plummer for assistance in syntheses.

Summary

1. A series of thio-antimony compounds has been prepared, which are either oils or low melting solids soluble in vegetable oils.

2. Several new alcohols, isothiouronium bromides and mercaptans have been prepared.

3. The antimony compounds show some promise in experimental schistosomiasis and further investigation is being carried out.

The Polymorphism of the Mixed Triglycerides of Palmitic and Stearic Acids

BY E. S. LUTTON, F. L. JACKSON AND O. T. QUIMBY

Introduction

The four mixed triglycerides of palmitic and stearic acid are of practical as well as academic interest. Among them are generally to be found important and frequently the predominating components of most of the highly hydrogenated fats and oils of commercial significance. These compounds, as would be expected, show many similarities in polymorphism to the single fatty acid triglycerides, but there are differences more significant than is apparent in the valuable papers of Malkin.[1,2]

The work of Clarkson and Malkin[3] on the simple triglycerides was corrected by other observers.[4,5,6] None of these later authors was in disagreement with Malkin as to number of forms and melting points. The differences from Malkin arose in association of melting points with diffraction patterns and in nomenclature. It is to be emphasized, however, that the nomenclature of the present authors[7] follows the lead of Malkin in designation of X-ray patterns, except in details particularly involving the term "beta prime." Here a form is called "beta prime" on the basis of X-ray pattern type rather than order of melting.

In view of the situation with regard to the simple triglycerides, there has been great need for reëxamination of the four important mixed glycerides of palmitic and stearic acids—namely, the symmetrical glycerides, 2-palmityldistearin (SPS) and 2-stearyldipalmitin (PSP), and the unsymmetrical glycerides, 1-palmityldistearin (PSS) and 1-stearyldipalmitin (SPP). (Theoretically the matter of optical isomerism is to be considered in connection with unsymmetrical glycerides, but it is generally felt that this is a matter of little physical significance for longer acyl groups. In this paper only such "racemic" mixtures as are prepared by ordinary synthesis are discussed.)

Experimental

The four mixed glycerides were made by established methods from the corresponding mono- or diglyceride by reaction with the proper fatty acid chloride. The mono- and diglycerides were prepared by directed rearrangement according to the method of Eckey.[8] Fatty acids were purified by distillation and by crystallization from glacial acetic acid. From the acids the corresponding chlorides were prepared by reaction with thionyl chloride and subsequent distillation. Constants for the starting materials are given in Table I along with those of the final products.

A typical synthesis, that of 1-palmityldistearin, is described in some detail. Twenty grams (0.061 mole) of 1-monopalmitin was dissolved in 50 g. (0.632 mole) of pyridine and 20 ml. of anhydrous chloroform. To this mixture, 41.5 g. (0.137 mole) of stearyl chloride was added slowly while the reaction vessel was cooled in an ice-bath. The mixture was then warmed on a steam-bath for six hours in order to complete the reaction. After this step, the reaction mixture was dissolved in ether and washed consecutively, twice with water, four times with 10% potassium carbonate, three times with dilute sulfuric acid and finally with water until neutral to litmus paper. The ether solution was dried over anhydrous sodium sulfate and filtered. Final purification was accomplished by four crystallizations, one from ether and three from Skellysolve B-ethyl alcohol (1:1) mixtures.

The symmetrical glycerides showed good crystallinity as compared with the chalk-like appearance of unsymmetrical compounds.

The polymorphism of the glycerides was studied by the X-ray and melting point techniques described previously.[5] Briefly flat film patterns were obtained with a regular General Electric XRD unit. The pinhole was 0.025″ and film distances were 2.5 cm. for exploratory patterns, 5.0 cm. for most short spacing determinations and 10.0 cm. for detailed short spacing and for long spacing pat-

terns. In the case of 2-palmityldistearin, it was necessary to take 10 cm. patterns with a 0.005″ slit system for sufficient resolution of certain prominent lines.

For alpha forms three types of capillary thermal points were obtained:

Softening Point.—Sample melted, chilled two seconds at 0°, thrust into bath for observation. Softening point is half-way between the highest point of no increased translucence and the lowest point of definite increase in translucence.

Rapid Complete Melting Point.—Sample melted, cooled rapidly to minimum cloud, thrust into bath. This determination is completed as for the softening point except that complete clarity instead of increased translucence is observed.

Regular Complete Melting Point.—Sample melted, chilled, observed for complete clarity on raising the temperature 0.5° or less per minute.

Beta prime forms were obtained in three ways—from alpha by tempering near the alpha melting point, from melt just above the alpha melting point, and in one case by solvent crystallization. Thermal points were obtained as described for alpha. In the case of "regular complete melting points" samples were stored near the beta prime melting point but not long enough to produce beta.

Beta forms were obtained from beta prime by tempering near the beta prime melting point (or from alpha) and by solvent crystallization (usually Skellysolve B). Melting points were obtained by observing the sample while raising the temperature 0.5° or less per minute.

Detailed melting point and X-ray data are recorded in Tables II and III, respectively. Characterizing data compared with those for tripalmitin and tristearin are to be found in Table IV.

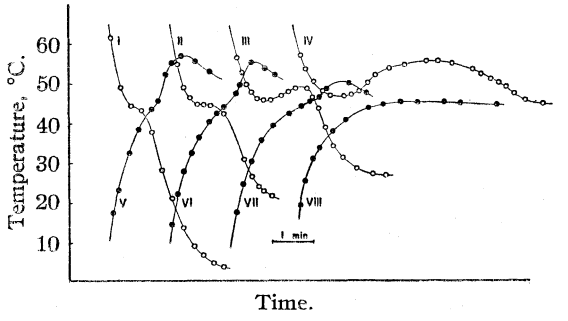

Fig. 1.—Cooling and heating curves indicating the alpha m. p. for PSP. Cooling curves—O, samples melted 100°, placed at temperature without jacket—I, 0°; II, 17°; III, 27°; IV, 44°. Heating curves—●, samples melted, chilled 10°, placed at temperature without jacket—V, 49°; VI, 47°; VII, 45°; VIII, 44°.

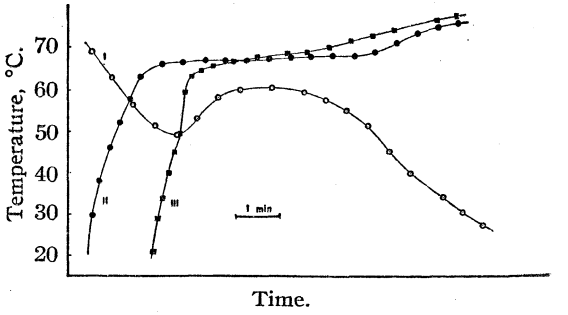

Fig. 2.—Cooling and heating curves involving beta prime for PSP, jacketed samples—I, melted, placed 0°—O; II after I, placed 80°—●; III melted, chilled 10° (no jacket), jacketed at 80°—■.

Thermal curves were run on a 1-g. sample of PSP after the manner of Clarkson and Malkin.[3] The procedure has been described previously in some detail.[12] Examples of the curves are shown in Figs. 1 and 2.

Discussion

These glycerides are more striking in their individuality than in their similarity. Thus one of them is quite unstable as alpha, another is relatively stable. While two are normal in being thermodynamically beta stable, one is beta prime stable and the fourth is apparently equally stable as beta prime or beta.

No vitreous (or gamma) form was found for any of these glycerides. Accordingly no more than three forms, never four, were found for each compound. For a given form of a given glyceride, *actual variation of complete melting point with extent of stabilization is common* and must be the basis for the excess "characteristic" melting points which have been previously reported.[1,2] As much as three degrees variation was observed. It was observed that long spacings were constant with such m. p. variation, while short spacings showed only differences in sharpness.

The two symmetrical glycerides offer a most interesting contrast. It is the alpha form of SPS that is unusually stable while that of PSP is so unstable that no complete melting point for it can be obtained, and the observer must be content with a softening point. Neither glyceride shows more than one form beside alpha. Most startling is the fact that, while beta is the stable form for SPS, as would be expected, beta prime is stable for PSP. The short spacing data of Malkin,[1] by the present nomenclature[7], lead to this same conclusion with regard to PSP, for the form he called beta had no 4.6 Å. spacing but only slightly modified beta prime spacings. The absence of a beta prime form for SPS is a matter of some concern especially since later work has revealed this form for the closely related homolog, 2-myristyldistearin.[13] Moreover, it is known that small amounts of impurity permit beta prime development in SPS. However, there can be no doubt that if the beta prime form exists for pure SPS it is extremely fleet-

(14) Quimby, unpublished.

Cooling and heating curves have been used often by Malkin and by others to study the polymorphism of triglycerides. Properly interpreted they can give valuable information, but there are pitfalls. Complicated relationships existing between

environment, sample and thermocouple and the imperfection of quickly formed crystals are some of the factors which can result in apparently shifting the characteristic level of thermal change. Actually one may obtain halts, bends or nicks in thermal curves at practically any temperature from the minimum to the maximum melting point of a pure triglyceride. It is necessary to confirm the significance of breaks by showing that they occur at approximately the same level with fairly wide variations in surrounding conditions.

Among the mixed glycerides discussed here only PSP has been subjected to thorough examination by thermal curves. It is particularly worthy of investigation since only two forms, instead of the previously reported four,[1] have been found. The curves, Figs. 1 and 2, while they actually support the conclusion that only two forms occur, do show how one may be led astray.

The cooling curves of Fig. 1 plainly show a thermal effect (halt, nick or minimum) at 45 to 47° in spite of large variations in cooling rate. The value is in good agreement with the alpha melting point level for PSP, Table II, and is in line with the general experience of agreement between alpha m. p. and supercooling limit for triglycerides. The heating curves of Fig. 1 also reveal this characteristic thermal point. At the inflections of these latter curves the phenomena are not simple for there are involved (1) melting of alpha, (2) transformation of alpha to beta prime and (3) beta prime crystallization from melt.

The level of beta prime melting is indicated by the heating curves of Fig. 2. Curve I, a cooling curve, shows how one may, from minima and maxima, obtain values between alpha and beta prime m. p. values, but a real significance for these values cannot be confirmed visually, nor by X-ray nor by a series of systematically varied thermal curves. Curve II of Fig. 2, following after I, shows only beta prime melting at the normal level. Curve III, run on a quickly chilled (alpha) sample, shows a slight inflection indicative of alpha melting below 50° but the main feature is beta prime melting in the neighborhood of 68°. Thus only alpha and beta prime forms were confirmed.

The differences between the unsymmetrical glycerides, while not so striking as for the symmetrical glycerides, are of equal interest. Both 1-palmityldistearin (PSS) and 1-stearyldipalmitin (SPP) show the three forms—alpha, beta prime and beta. For PSS, however, beta is obtained only from solvent. The stable form from the melt is beta prime. Accordingly, it is found on stabilization to rise in m. p. almost to the level of the beta m. p. obtained after solvent crystallization.

These four mixed glycerides may be conveniently grouped with regard to the stable form from the melt according to the nature of the acyl residue in the 2-position. This is indicated in Table V.

One must infer from the evidence here presented that many of the homologs of these glycerides which have been discussed by Malkin, *et al.*, must also in many cases have only three, perhaps only two, forms instead of four as reported. For example Malkin's own X-ray data[1] indicate that the glycerides grouped with PSP on the basis of similarity in molecular geometry (namely, 2-palmityldimyristin, 2-myristyldilaurin and 2-lauryldicaprin) must have only two forms, metastable alpha and stable beta prime.

TABLE V

STABLE FORMS FROM THE MELT

	Beta prime stable	Beta stable
Unsymmetrical	PSS	SPP
Symmetrical	PSP	SPS
Acyl in 2- position	S	P

Important differences from the evidence of Malkin, *et al.*, for these four mixed glycerides are here summarized: (1) As in the case of tristearin, no glassy forms were observed, *alpha* actually being the lowest melting form in each case. (2) The number of forms for a given glyceride in no case exceeded three and in two cases was two in contrast to Malkin's recording of four forms. (The variation in melting point here reported for a given form of a given compound seemingly is responsible for Malkin's reporting of superfluous melting points.) (3) The stable form of PSP is called beta prime (instead of beta) according to the modification of Malkin's nomenclature, which has been used in the present work. (4) Also for PSP is reported the impossibility of achieving a complete melting point for the alpha form. The observed softening point is 3° below Malkin's "melting point" value. (5) For SPS no beta prime form is here reported and beta has a characterizing feature; this is the closeness of the two smaller main short spacings so that they are unresolved on an ordinary 5 cm.–0.025″ pinhole pattern (Malkin's values for these spacings are farther apart). (6) Differences in long spacing data are best discussed in relation to Table VI.

TABLE VI

COMPARISON WITH MALKIN'S LONG SPACINGS

(LJQ) are data of Lutton, Jackson and Quimby.
(M) are data of Malkin and co-workers

	SPS			PSP		
	α	β′	β	α	β′	β
(LJQ)	49.2	..	43.1	46.65	42.75	..
(M)	50.5	47.5	44.2	50.2	44.7	43.2

	PSS			SPP		
	α	β′	β	α	β′	β
(LJQ)	48.5	45.1	44.7	47.6	43.8	42.1
(M)	48.8	44.7	46.5	47.8	43.9	42.5

In several cases agreement is within experimental error; in a few instances differences are of the order of 1.0 Å. Serious differences are a 3.55 Å. difference for the alpha form of PSP, a 1.8 Å. difference for the beta form of PSS and difference as to the existence of a beta value for PSP. It is presumed that Malkin's value reported for beta

prime PSP is not correct but that his value for "beta" is the true beta prime long spacing value. Malkin's beta prime value for a pure SPS is tentatively questioned on the basis of the present authors' failure to obtain such a form.

Acknowledgment.—The authors wish to express their appreciation for permission from the Procter & Gamble Co. to publish the portions of this investigation which are of general interest, and to the members of this laboratory who have assisted in the experimental work and have given advice in the preparation of the manuscript.

Summary

As compared with the great similarity in polymorphic behavior of the single fatty acid saturated triglycerides, the mixed palmitic–stearic triglycerides show a remarkable individuality. Many of the conclusions here reached with regard to their behavior are at variance with those of Malkin and co-workers.

The symmetrical isomers show a high degree of crystallinity; the unsymmetrical compounds are microcrystalline. All four compounds exhibit a lowest melting alpha form—unusually stable in the case of 2-palmityldistearin and unusually labile in the case of 2-stearyldipalmitin.

Occurrence of forms other than alpha can be briefly tabulated:

Glyceride	Forms beside *alpha*
2-Palmityldistearin	Only beta
2-Stearyldipalmitin	Only beta prime
1-Palmityldistearin	Only beta prime from melt, beta from solvent (beta prime and beta equally stable)
1-Stearyldipalmitin	Beta prime and beta (beta stable)

A given form of a given glyceride may vary several degrees in melting point depending on its degree of stabilization. This variation may account for the fact that previous workers have reported more characteristic thermal points for a given glyceride than can be substantiated by X-ray diffraction patterns.

The Polymorphism of 1-Monostearin and 1-Monopalmitin

BY E. S. LUTTON AND F. L. JACKSON

Introduction

The polymorphism of the compounds 1-monocaprylin through 1-monostearin has been studied by Rewadikar and Watson[1] by means of capillary melting point methods but without the help of X-ray diffraction data. Malkin and co-workers,[2,3,4] using X-ray diffraction and thermal techniques, have studied the polymorphism of saturated 1-mono-, 1,3-di- and triglycerides. However, further work has led to corrections and new interpretations in the field of triglycerides.[5,6,7] Similarly, re-examination of the 1-monoglycerides, specifically 1-monostearin and 1-monopalmitin, as reported in the present paper has shed new light on the polymorphic behavior of this class of compounds.

As in the case of the triglycerides[6] every effort has been made to maintain the nomenclature introduced by Malkin.[3] However, the discovery of four polymorphic forms (here called subalpha, alpha, beta prime and beta) instead of three for the 1-monoglycerides and the fact that subalpha and beta prime have very similar X-ray patterns required some revision and refinement of Malkin's basis for nomenclature. A particular complication is the subalpha form, a distinct form accounting for the reversible thermal effects reported by Malkin on cooling alpha and subsequent reheating.

The basis for monoglyceride nomenclature may be summarized as follows.

Subalpha has a single strong short spacing line at 4.15 Å., other medium lines at 3.9, 3.75 and 3.55 Å. This form undergoes a reversible transformation to alpha and therefore has no m. p.

Alpha has a single strong short spacing line at 4.15 Å. with other weak short spacing lines. This form has the lowest complete m. p. Triglyceride alpha similarly has a single strong short spacing line at 4.15 Å. and is the lowest melting form.

Beta prime has a strong short spacing line at 4.15 Å., and a 3.65 Å. medium line which is the strongest one between 4.2 and 2.6 Å. This form has an intermediate complete m. p. Triglyceride beta prime has strong spacings at 4.2 and 3.8 Å., and is normally the intermediate melting form.

Beta has a strong short spacing line at 4.55 Å. and is the highest melting form. Triglyceride beta has a strong line at 4.6 Å. and is generally the highest melting form.

It is apparent from the preceding paragraphs that the bases for nomenclature are similar for the mono- and triglycerides.

Experimental

The monoglycerides were prepared according to the

directed rearrangement method of Eckey.[8] Monostearin was prepared from a mix of 35% completely hydrogenated linseed oil and 65% linseed oil, to which was added 15–20% of dry glycerol and 0.5% NaOMe (a catalyst suspended in xylene). The mixture was agitated for forty-eight hours each at 60, 49 and 38°, during which time the crude monostearin precipitated in increasing amounts. An excess of glacial acetic acid was added to kill the catalyst, the mix was water-washed to remove sodium acetate, and the final purification accomplished by six crystallizations from Skelly B–ethyl alcohol mixtures.

Monopalmitin was prepared similarly from cottonseed oil stearine plus 15–20% of glycerol and 0.5% NaOMe catalyst. (The stearine was the precipitate from a partially crystallized oil and contained 30–35% combined palmitic acid.) The temperature cycle used here was 38, 32 and 27°.

The degree of purity of the monoglycerides is indicated by the analyses in Table I.

TABLE I

ANALYSES OF MONOGLYCERIDES

1-Monopalmitin	.0	169.0	101.9	77.0	.0	169.6	100.0	77.0

The samples were examined by X-ray diffraction, thermal methods and by dilatometry. The techniques of X-ray diffraction and thermal examination have been described elsewhere.[6,10]

The X-ray specimens were prepared in three ways: (1) melted samples were drawn into Pyrex glass capillaries and tempered in various ways depending on the polymorphic form desired, (2) powdered crystalline samples were made into 0.5 mm. thick disk-shaped pellets which were X-rayed perpendicularly to the flat side of the disk, and in addition (3) powdered samples were made into 1-cm. rods of 0.5 mm. diameter after the manner of Piper.[3] The rods were mounted vertically in the path of the X-ray beam. They gave excellent long and short spacing X-ray lines on the same film, while the disk-shaped pellets yielded very poor long spacings presumably due to orientation of the hydrocarbon chains perpendicularly to the face of the disk.

Thermal examination was accomplished with samples in capillary tubes. Beta prime and beta melting points were obtained by ordinary complete melting point determination with a rise in bath temperature of 0.5° per minute. Alpha melting points were obtained by thrusting capillaries into a bath of definite temperature. The alpha m. p. was the point halfway between the maximum temperature for remaining solid (indicated by any cloudiness, however faint) and the minimum temperature for complete clarity. These two temperatures were usually less than 0.2° apart.

The dilatometer procedure was without special features. A one-gram sample was placed in a glass bulb and the bulb joined to the dilatometer capillary by an interchangeable joint. The sample was melted, the dilatometer evacuated and the sample then frozen. At this point the dilatometer was completely filled by running mercury into the evacuated space and onto the sample.[11] The mercury content was adjusted by setting the sample at a temperature about 10° above the melting temperature. After the desired sample treatment, dilatometer readings (distance of the mercury meniscus from the top of the dilatometer) were taken at successive temperatures. The dilatometer was particularly helpful in studying the alpha–subalpha relationships.

The alpha form was obtained by rapid cooling of the melt. As in the case of triglycerides, its melting point represents the approximate supercooling limit. Alpha has a low temperature limit of existence at which it transforms reversibly to subalpha, so that at room temperature both monostearin and monopalmitin exist in the subalpha rather than the alpha form.

The beta prime form was obtained by fairly rapid crystallization from dilute (1:300) ether or Skellysolve B solutions. It was not obtained from a melt nor by tempering alpha. By a similar procedure Chen and Daubert[12] obtained metastable forms of triacid triglycerides.

Relatively slow crystallizations from solvents (50–50 mixtures of alcohol and Skellysolve B) gave beta. This form was not obtained by direct crystallization from the melt without seeding, but was obtained by transformation of alpha or beta prime.

Results

The thermal points are recorded in Table II in comparison with the data of Malkin. The two sets of values are in reasonable agreement except that no second transition point was observed below the alpha m. p. as reported by Malkin for monostearin.

[a] Determined by microscope (and approximately by dilatometer).

Detailed X-ray data are shown in Table III with average long spacing values which are compared with those of Malkin[3] and Filer.[7] Long spacing agreement is reasonably good except in the case of the alpha form for monostearin. The present value is 8 Å. short of that reported by Malkin. Characteristic short spacing data are shown in Table IV in comparison with those of Malkin and Filer. For the beta form, agreement is better in certain respects with Filer's data, but some of Filer's strong lines were not confirmed. It is uncertain whether Malkin's so-called beta prime data should properly be regarded as pertaining to beta prime or subalpha. From the reported spacings and description of procedure no decision can be made.

Dilatometer results for the alpha $\rightleftarrows$ subalpha reversible change are shown in Fig. 1.

Discussion

While in most features of behavior the monoglycerides were found to correspond to the beha-

vior described by Malkin, there were departures of considerable significance particularly in the case of alpha and subalpha forms.

Alpha and Subalpha.—Alpha, in the correspondence of its melting point to the supercooling limit and by the value of its one strong short spacing (4.18 Å.), resembles the alpha form

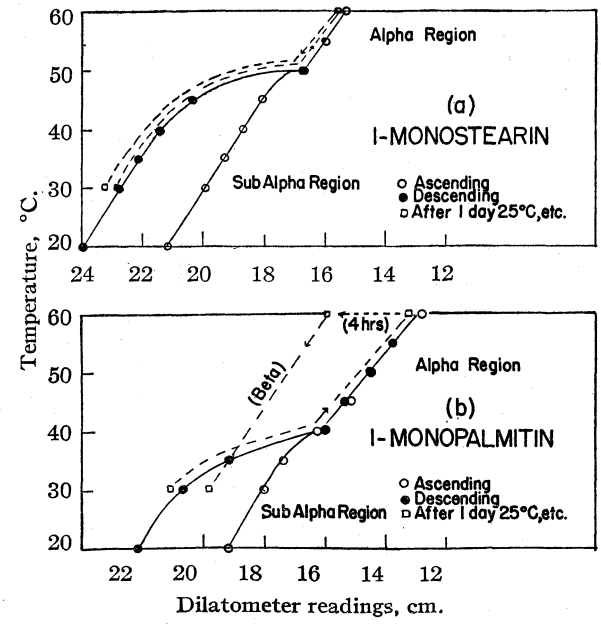

Fig. 1.—Dilatometer curves of reversible alpha to subalpha transformation.

of triglycerides. There are important differences, however. Weak short spacings on both sides of 4.18 Å. evidence certain unidentified complexities of structure not found for triglycerides. Of greater interest are the long spacing values. Double chain length structures are indicated, but the values are 8 Å. short of that to be expected for completely extended untilted molecules, 58 Å. for monostearin. (A value of this magnitude, reported by Malkin, was not confirmed.) Alpha, beta prime and beta values are very nearly equal and the simplest conclusion is that they each indicate titled molecules. A tilted alpha, supposedly of hexagonal cross-sectional type, would be contrary to previous experience and preconceptions.

The alpha form goes reversibly to a form, here called subalpha, at a temperature about 25° below the alpha melting point. The reversibility was completely established, in the present study by successive X-ray exposures above, below and above the transition point to give respectively alpha, subalpha and alpha patterns. This transition point was actually located by Malkin, with the help of thermal curves, but he did not describe a clearcut association of change in diffraction pattern with thermal effect. He said that alpha "is stable only very near its melting point," but it is actually reasonably stable clear down to the transition point. He speaks of the form below the transition point as an "intermediate form" somewhat akin to a "glass" and without "a regular crystalline lattice," but *subalpha* is actually a highly ordered structure, apparently considerably more ordered than *alpha* which is itself of a fair degree of crystallinity.

The alpha $\rightleftarrows$ subalpha change is readily followed also by the dilatometer and microscope.[13]

If a dilatometer sample is melted and chilled quickly to 20°, then heated in steps to 60° and cooled stepwise to 20°, curves such as those shown in Fig. 1 are obtained. The solid ascending curves show a small break at about 49° for 1-monostearin and 39° for 1-monopalmitin. The solid descending curves show greatly accentuated contractions in the same temperature regions indicating that the subalpha form is decidedly more dense than it was initially. The order of contraction in the alpha $\rightarrow$ subalpha change is about 0.04 specific volume units.

After the ascending and descending curves were run the dilatometers stood overnight at room temperature and then were read at 30°, heated directly to 60°, allowed to attain a constant reading, and cooled to 30°. The points obtained are joined by broken lines on Fig. 1 and the time sequence is indicated by arrows. The data show that the descending alpha to subalpha path is essentially duplicated for 1-monostearin. However, 1-monopalmitin transformed to beta in four hours at 60°. Cooling 1-monopalmitin beta to 30° revealed a lower density for this form than for subalpha—a fact which was substantiated for other samples of 1-monopalmitin as well as for 1-monostearin after long stabilization. Preliminary specific volume data for 1-monopalmitin at 30.0 are 0.937 for subalpha, 0.983 for alpha (extrapolated from 0.996 at 60.0°) and 0.949 for beta. Final data will be reported later.

The large density difference between slowly and rapidly chilled subalpha is puzzling, especially in view of the great similarity in X-ray patterns for the two states. The difference may be due to vacuoles or perhaps to a less complete stabilization and less perfect alinement of chains or crystallites in the chilled sample. (Comparable variations in density have been observed, but not yet reported, for triglycerides and in those cases have been found to be associated with observable variations in melting point.)

With the microscope the transformation of alpha to subalpha is revealed quite sharply by the appearance of many little shrinkage cracks as the temperature is lowered to a level just below the point of transformation. These cracks are almost completely "healed" by raising the temperature and holding it just above the transformation point.

It is believed that Malkin was concerned, at least part of the time, with subalpha when he used the term beta prime. Especially in the case of his recent publication[14] containing data on monoelaidin it is apparent that the so-called beta prime form conforms much more closely, in X-ray spacing, to the subalpha values than to the beta prime values here reported for monopalmitin and monostearin. Malkin's beta prime m. ps. are not accounted for by this line of thought, however.

No evidence was obtained by the various techniques employed in this study for the lower of the monostearin transformation points reported by Malkin. It is the higher value that was confirmed and that corresponds to the alpha $\rightarrow$ subalpha change.

Some indication of the stability of the alpha (and subalpha) forms is given by the observation that monopalmitin subalpha persists about thirty days at room temperature as compared with more than one hundred twenty days for monostearin. This is comparable to the room temperature stabilities of the alpha forms of the corresponding triglycerides. A difference in high temperature alpha stability between mono- and triglycerides appears on running complete melting points on alpha (subalpha) forms at a heating rate of 0.5 per minute. Monopalmitin and monostearin give approximately their respective alpha m. p.s but the triglycerides transform during heating to give approximately their beta m. p.s.

Beta Prime.—Despite considerable effort to obtain the beta prime form from the melt or from alpha, it was actually obtained only by rapid crystallization of dilute ether or Skellysolve B so-

(13) Microscopic observations by Dr. Don G. Kolp of this laboratory.

(14) Malkin and Carter, *J. Chem. Soc.*, 554 (1947).

lutions. Crystals, while well defined, were small. As has been indicated, the beta prime X-ray pattern is somewhat similar to that of subalpha. The distinguishing features are indicated in Table IV, a summary table of characteristic values. In brief, the chief difference is that beta prime lacks the two medium strength lines shown by subalpha for the region between 4.15 Å. and 3.65 Å.

Beta.—The beta form is obtained by slow crystallization from solvent or by transformation of alpha and beta prime forms. It was not obtained directly from the melt. The crystals from solvent are relatively large platelets with a beautiful gloss. Beta is the only truly stable crystalline form.

Summary

While largely confirming the work of Malkin, a reëxamination of the polymorphic behavior of 1-monostearin and 1-monopalmitin has resulted in new information which differs in important aspects from earlier findings.

These monoglycerides have four forms—subalpha, alpha, beta prime and beta. The last three have melting points increasing in the order named. Beta alone is thermodynamically stable. Beta prime has been obtained only from solvent. There is a reversible alpha–subalpha transformation about 25° below the alpha m. p. but above room temperature. All forms for a given monoglyceride have very nearly the same long spacing and appear to be tilted double-chain-length structures. The forms are readily distinguished by means of short spacings except for subalpha and beta prime, which, in spite of notable differences in thermal behavior, show only minor differences in diffraction pattern.

Kinetics of the Reaction between Ethylene Chlorohydrin and Hydroxyl or Alkoxyl Ions in Mixed Solvents[1,2]

BY JOHN ED STEVENS,[3] C. LAW MCCABE AND J. C. WARNER

Previous investigations of the reaction between ethylene chlorohydrin and hydroxyl ion have established the following facts concerning the reaction. It is clearly second order,[4,5,6] the rate being proportional to the concentration of chlorohydrin and to the concentration of hydroxyl ion, and the side reaction with water at temperatures in the vicinity of 30° is so slow[7] that it may be neglected. There is no significant back reaction in alkaline solution[8] and the product with water as the solvent is ethylene oxide and not ethylene glycol.[9] There is a very small negative kinetic salt effect in water and in water–ethanol mixtures.[6] More recently, Porret,[10] who apparently was unaware of the work of Winstrom and Warner,[6] has reported the results of an investigation which duplicates their kinetic studies in water as solvent. His velocity constants, activation energy and kinetic salt effects are in excellent agreement with those reported by Winstrom and Warner. Porret[11] has also determined equilibrium constants for the reaction in the temperature range 0 to 50°. These results confirm the view that no correction for the back reaction needs to be made in alkaline solutions.

It was the purpose of the present investigation to study the kinetics of this reaction in a number of water–non-aqueous solvent mixtures down to low dielectric constants for the mixtures, *i. e.*, to high concentrations of the non-aqueous solvents.

Experimental

Materials and Procedure.—Previously described[6] methods for the purification of materials and the preparation of reagents were used with only minor modifications. Temperature variations in thermostats were followed by means of Beckman thermometers and absolute temperatures were established within 0.01° by use of a N.B.S. platinum resistance thermometer. The thermostat operated at 30 ± 0.005° was of the conventional type, and the one operated at 15 ± 0.01° was also of the conventional type, but was placed inside a large insulated container through which air, cooled by ice, was circulated to maintain the environment at 10 to 12°. Experiments at 0 ± 0.005° were carried out in large Dewar flasks filled with washed cracked ice and distilled water.

Standard solutions of sodium ethoxide and sodium methoxide were prepared by treating metallic sodium with the corresponding anhydrous alcohol, determining the concentration by titration and then diluting to the desired strength with the anhydrous alcohol.

Since the reaction proceeds with a decrease in hydroxyl or alkoxyl ion concentration and a corresponding increase in

chloride ion concentration, it is obvious that the reaction may be followed by withdrawing samples at suitable time intervals, delivering them into an excess of standard acid to stop the reaction, and titrating for either excess acid or chloride. In each new solvent mixture, it was always established that these two methods of following the reaction gave results which were in agreement within the experimental error; thereafter the acid–base titration (rosolic acid indicator) was used in a majority of the experiments.

In most experiments, equal starting concentrations of ethylene chlorohydrin and carbonate-free hydroxide (or alkoxide) were used and the velocity constant was obtained from the slope of the best straight line obtained by plotting $1/c$ against time.

Kinetic Results.—Velocity constants were determined in 1,4-dioxane–water, methanol–water, ethanol–water, isopropanol–water and *t*-butanol–water mixtures at 30°. Rates were also determined at 0 and 15° in the first three of the above solvent mixtures.

Velocity constants in ethanol–water mixtures are given in Table I. The rate in 100% ethanol was determined by using sodium ethoxide and ethylene chlorohydrin as reactants in anhydrous alcohol. Table II gives the velocity constants in methanol–water and 1,4-dioxane–water mixtures including the rate constant for the reaction of sodium methoxide with ethylene chlorohydrin in 100% methanol. Table III reports the velocity constants obtained at 30° in isopropanol–water and in *t*-butanol–water mixtures. In Fig. 1, velocity constants as a function of dielectric constant[11a] at 30° are summarized for all of the solvent mixtures.

Reaction Product in Mixed Solvents.—Previous investigators[9] have stated that ethylene oxide is the product of the reaction of ethylene chlorohydrin with hydroxyl ion in aqueous solution. This has been confirmed by our investigations. We considered it necessary, however, to establish the nature of the reaction product in our water-non-aqueous solvent mixtures and in anhydrous ethanol and anhydrous methanol. The possible products would seem to be ethylene glycol, ethylene oxide or (in alcoholic solutions) an hydroxy ether of the Cellosolve type. Any attempt to separate ethylene oxide from the glycol and the hydroxy ether by distillation is complicated by the hydrolysis of the oxide to glycol which is quite rapid at temperatures as high as 80°. Our evidence was obtained by

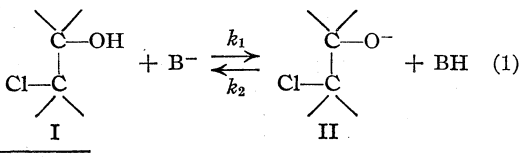
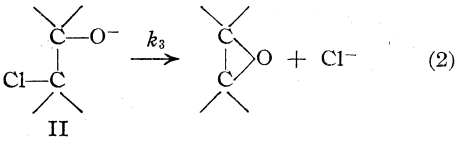
adaptation of Lubatti's method[12] for determining ethylene oxide in gas mixtures: To samples which had reacted to completion, standard solutions of hydrochloric acid and calcium chloride were added in such amounts that a slight excess of acid and 30 g. of chloride ion per 100 ml. were present. Under these conditions ethylene oxide is converted back to ethylene chlorohydrin and an equivalent of acid is consumed. The rate of this reversal in acid solution has been studied.[8] Similar experiments with known solutions of glycol and hydroxy ether showed that no acid was consumed by these substances. That glycol does not react with acid under these conditions is supported by other investigators.[13] Although the method did not yield results of the desired precision and reproducibility, and has since been greatly improved, the acid consumed in various experiments was between 90 and 105% of the amount calculated assuming ethylene oxide was the only product of reaction. It seems safe to say, therefore, that ethylene oxide was the principal product in all of the solvent mixtures used in this investigation as well as in water, in anhydrous methanol and in anhydrous ethanol.

Discussion

The fact that ethylene oxide is the product obtained in all of the experiments performed in this investigation indicates that the second order reaction between ethylene chlorohydrin and hydroxyl ion, alkoxyl ion or mixtures of the two reactants cannot proceed by the usual displacement type of mechanism. Furthermore, the data obtained in methanol–water and in ethanol–water mixtures is unusual and cannot be explained on a basis of the expected influence of the dielectric constant of the solvent upon the reaction rate.

Mechanism.—It seems possible to give a qualitative explanation of all the facts which have been observed by assuming the mechanism suggested by Winstein and Lucas,[14,15] namely



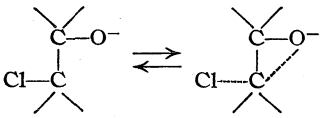


If Step 1 is an equilibrium step for which the equilibrium constant is K and Step 2, in which the anion goes through the activated state to form ethylene oxide with a rate constant k_3, is slow, then

$$\frac{-d[B^-]}{dt} = \frac{d[Cl^-]}{dt} = \frac{k_3K}{[BH]}[CH_2Cl—CH_2OH][B^-]\frac{\gamma_I^0\gamma_{B^-}}{\gamma_{BH}^0\gamma_{II}} \quad (3)$$

where k (observed) $= k_3K/[BH]$, when B^- is the base conjugate to a pure solvent BH. It is obvious that according to this mechanism the rate of reaction should be proportional to the concentration of the chlorohydrin and to the concentration of the anion base (OH^-, CH_3O^- or $C_2H_4O^-$). Furthermore the mechanism accounts for the negligible kinetic salt effect. (As a first approximation,[15a] ionic strength would have little influence on the value of the activity coefficient quotient in Eq. 3).

Influence of Dielectric Constant of Solvent.—One would expect the dielectric constant of the medium to have little effect on the equilibrium (Step 1) because the electrostatic contribution to the free energy of reaction would be small. On the other hand, the conversion of the anion into the activated complex



is quite like the formation of the activated complex in the bimolecular displacement of halide from alkyl halides by hydroxyl ion; there is a distribution of charge and one would expect an increase in rate as the dielectric constant of the medium is decreased.[16] The expected effect is observed in 1,4-dioxane–water mixtures, but it seems obvious that some factor other than dielectric constant has an important influence in the alcohol–water mixtures, especially in methanol–water and ethanol–water.

Influence of Acid–Base Level of Solvent.—If one postulates that ethanol is a stronger acid than water and that methanol is a still stronger acid than ethanol, then hydroxyl ion will be leveled somewhat in these mixed solvents by the reaction $OH^- + ROH \rightleftarrows RO^- + H_2O$. The extent of the reaction, and hence the reduction in the base level of the medium will depend upon the

acid strength of ROH and the ratio [ROH]/[H_2O] in the solvent mixture. The extent to which the carbanion is formed in the equilibrium step of the process (Step 1) undoubtedly depends upon the base level of the system, and a decrease in basicity would, therefore, cause a decrease in rate. It is tentatively suggested that in methanol–water mixtures, the influence of methanol in decreasing the basicity over the entire range of composition is sufficient to more than compensate for the expected increase in rate due to decreasing dielectric constant. It seems logical to assume that ethanol is a weaker acid than methanol and hence has less influence on the basicity. We may assume, at low ethanol concentrations, that the dielectric constant effect is predominant, but that at the higher concentrations the decreased basicity brings about a decrease in rate, thereby accounting for the observed maximum in the rate constants as a function of ethanol composition. The fact that rate constants in the alcohol–water mixtures extrapolate smoothly to the rate constants for reaction with alkoxyl ion in the anhydrous alcohols supports this explanation. Accurate information on acid-base levels in ethanol–water and methanol–water mixtures is sorely needed and is being sought in this laboratory.

Summary

1. The rate of reaction of ethylene chlorohydrin with hydroxyl ion (or with alkoxyl ion) has been measured in 1,4-dioxane–water, methanol–water, ethanol–water, isopropanol–water and *t*-butanol–water mixtures at 30° up to high concentrations of the non-aqueous solvent. Measurements in anhydrous ethanol and methanol are included. For the first three solvent mixtures, rate measurements were also made at 0 and 15°.

2. In methanol–water mixtures, the reaction rate decreased continuously with increase in methanol concentration. With the addition of ethanol to water, the rate at first increased, reached a maximum value at about 38% ethanol (30°), and then decreased at higher ethanol concentrations. In the other solvent mixtures, the rate increased with a decrease in dielectric constant over the entire range of solvent composition.

3. It has been established that ethylene oxide is the principal reaction product in all of the solvents used, including anhydrous ethanol and anhydrous methanol.

4. The Winstein–Lucas mechanism which postulates an initial equilibrium step in which a proton is removed from the chlorohydrin to form an anion, followed by an intramolecular displacement of chloride by the negatively charged oxygen, is consistent with (a) the bimolecular character of the reaction, (b) the absence of an appreciable kinetic salt effect, (c) the formation of ethylene oxide as the principal product, and (d) the increase in rate with decrease in dielectric constant is the principal factor influencing the rate. This mechanism is also capable of giving a qualitative explanation of the unusual results obtained in methanol–water and ethanol–water mixtures by taking into account the possible influence of the acid–base level in these solvents upon the initial equilibrium step.

Measurements on the Absorption of Microwaves. III. Losses of Camphor Dissolved in Cyclohexane

BY D. H. WHIFFEN[1]

The general outline of the type of absorption of electromagnetic radiation of about a centimeter wave length by mobile liquids and solutions has already been established.[2,3] Before investigating some of the details or exceptional systems, it was thought profitable to measure one system carefully; such a system may also be useful for comparing various methods of measurement.

Solutions of camphor in cyclohexane seem to have several advantages for this purpose. Firstly, the use of solutions makes a large range of loss tangents available according to the concentration employed. Secondly, cyclohexane is easily purified so as to give an almost negligible loss; this is in contrast to benzene which is difficult to keep dry. Thirdly, camphor was chosen because of its large dipole moment, its rigidity, its high solubility, the ease of purification by sublimation, and because preliminary experiments had indicated that its solutions in cyclohexane obeyed the Debye loss curve[4] with a relaxation time of 7×10^{-12} sec., which corresponds to a maximum loss at 1.3 cm. wave length.

Experimental

Cavities.—The loss tangents were obtained from the Q of a cavity resonator completely filled with the test liquid. The details of the resonator used at 3.3 cm. are shown in Fig. 1. This is a cylindrical cavity which can be resonant in the $H_{1,1,2}$ mode[5] when filled with a liquid

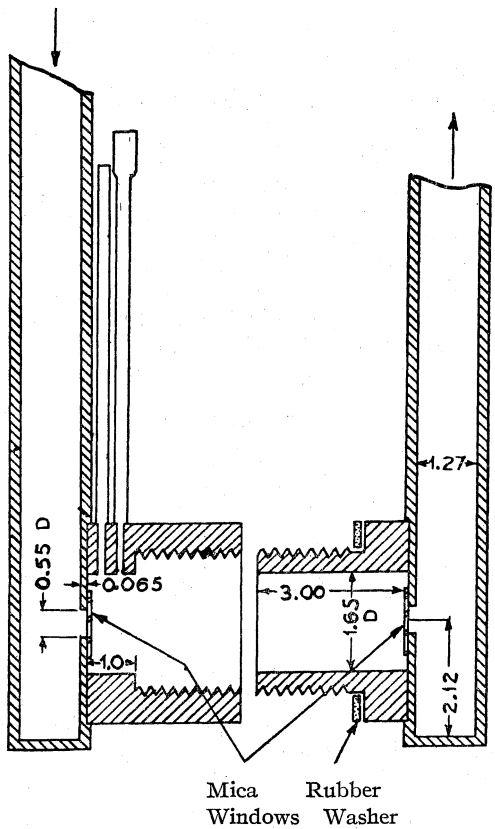

Fig. 1.—3.3-Cm. wave length resonant cavity; dimensions in cm.

of dielectric constant about 2.0 at a frequency near 9,500 Mc./sec. The liquid is contained by two very thin mica windows which are stuck with seccotine over the coupling holes, which are located centrally in each end-plate. The central barrel is in two parts so that the windows could be fixed in position and the cavity can be thoroughly cleaned. When assembled the two parts meet in a butt-joint and this is located one quarter of the way along the barrel, where there is a node in the longitudinal wall currents. The whole is silver-plated and when screwed up the end guides are kept parallel thus ensuring coupling into and out of the same member of the degenerate $H_{1,1,2}$ modes. Since the cavity is not resonant at a convenient wave length when filled with air, the Q due to the wall resistance and the coupling losses must be found with the help of a lossless liquid or by calculation. In this instance the observed Q when filled with the best sample of cyclohexane was 4,050 and the theoretical Q is 7,100, whence the maximum loss tangent of the cyclohexane is 0.00011, which is the difference in the reciprocal Q's; this figure is only a maximum since it has usually been observed[6,7] that the Q's of air filled cavities are lower than the theoretical values calculated from the direct current resistivities of the walls. For work with solutions it is the reciprocal Q of the cavity filled with solvent which must be subtracted from that of the cavity filled with solution to obtain the loss due to the solute molecules, and so the solvent and the resistance losses need not be separated.

The cavity used at 1.3 cm. is essentially a scale model of that already described and has a barrel length of 2.29 cm. and diameter of 0.63 cm. The $H_{1,1,3}$ mode is used and when filled with cyclohexane it has a Q of 2,500; the theoretical Q is 3,800 so that the loss tangent of the cyclohexane is less than 0.00014 at room temperature and 1.3 cm. wave length.

The cavities are immersed in a thermostat whose temperature is held constant to better than 0.1° and the rubber washer indicated in the diagram serves to keep the thermostat liquid from the inside of the cavity.

Q Measurements.—The wave guide bench arrangement is shown in Fig. 2. The signal oscillator is stabilized in frequency by comparison of its output with a cavity resonator, any difference in frequency causing an error voltage to be fed back to the reflector of the oscillator (723A at 3.3 cm.) and also to the thermal tuning grid in the case of the oscillator used at 1.3 cm. (2K50). The error voltage is obtained by a modification of the first Pound[8] circuit or else by a rather different arrangement due to Dr. Townes[9] which involves a very small frequency modulation of the oscillator. The output powers of both the signal and the beat oscillators are monitored with a crystal detector and a microammeter. Superheterodyne detection is employed, the beat oscillator being swept through a small frequency range. The detecting crystal is connected through a calibrated carbon attenuator to a 60 Mc./sec. amplifier and thence to a detecting system whose output meter shows a signal dependent on the peak input during the sweep. The meter is used as a null instrument and the power calibration rests in the attenuator for the 60 Mc./sec. signal.

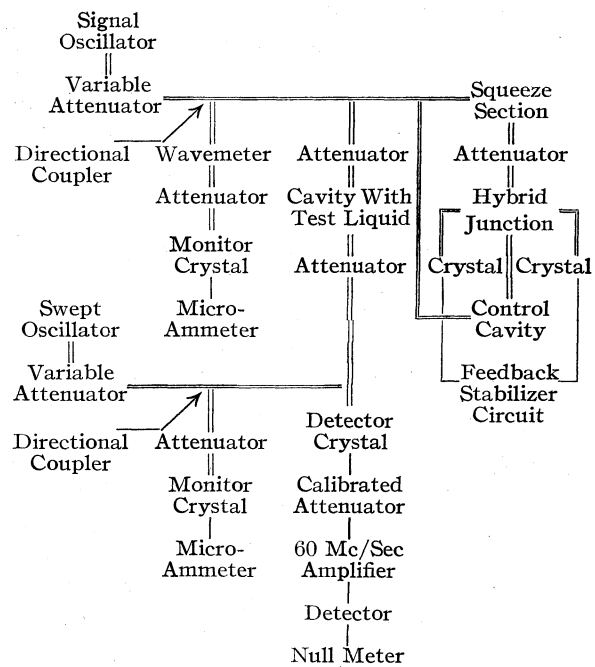

Fig. 2.—Arrangement of the wave-guide bench.

Measurements of the Q are made by observing first the maximum transmission of the cavity and the frequency at which this occurs; then 3 db., or other convenient amount, of attenuation are removed and the frequency of the signal oscillator readjusted so that the output from the cavity is reduced to its former value. From the difference between this frequency and that at the corresponding point on the other side of the maximum the Q can be calculated from the usual formula for a resonance curve

$$Q = f/\delta f(P_{\max.}/P - 1)^{1/2}$$

where f is the frequency, δf the total frequency difference

(9) To be published.

and $P_{max.}$ and P are the power transmissions at the peak and at the points of observation of δf. The frequency meter at 1.3 cm. is an $H_{0,1,n}$ cylindrical resonator which has been calibrated against the ammonia spectrum[10,11] while that used at 3.3 cm. is a coaxial line meter checked against a substandard which derives its calibration from quartz crystals. In the measurement of the Q there is a scatter of experimental values corresponding to a probable error of 3% in each reading; several determinations are made on each Q which reduces this error, but there may also be systematic errors due to the small frequency sensitivity of the directional couplers and the monitor crystals so that the results can only be trusted to 5%.

Measurements at 10 cm.—Measurements at 10 cm. wave length are made using a coaxial line after the method of von Hippel and his co-workers.[12] The test liquid at the end of a short-circuited coaxial line has its surface in contact with a quarter wave length plug of Teflon (polyfluorethylene) of negligible loss; the liquid is introduced from a pipe through the reflecting end of the line. The plug is located so as to leave one quarter wave length of liquid at room temperature. However uncertainty in its expansion leads to some uncertainty in the length of the liquid filling at other temperatures, and the observed losses at the higher temperatures may be too low on this account.

Materials.—The cyclohexane was a commercial product dried and purified by shaking with active silica gel. The *dl*-camphor was a commercial resublimed product.

The solutions for the measurements at 3.3 and 1.3 cm. ranged in concentration up to 2.5 g./liter, whereas the smaller loss and the less sensitive technique at 10 cm. wave length necessitated solutions up to 25 g./liter. The density[13] of pure cyclohexane was used to correct for the change of volume concentration with temperature.

Results and Discussion

The losses due to a solute are best expressed as the molecular loss tangent, that is Loss tangent/C where C is the concentration in g. moles/liter; this name and concentration unit have been chosen to be in keeping with general usage in other fields of chemistry. In no case was there any indication of a departure from a linear dependence of loss with concentration. This is shown for the losses at 3.3 cm. in Fig. 3.

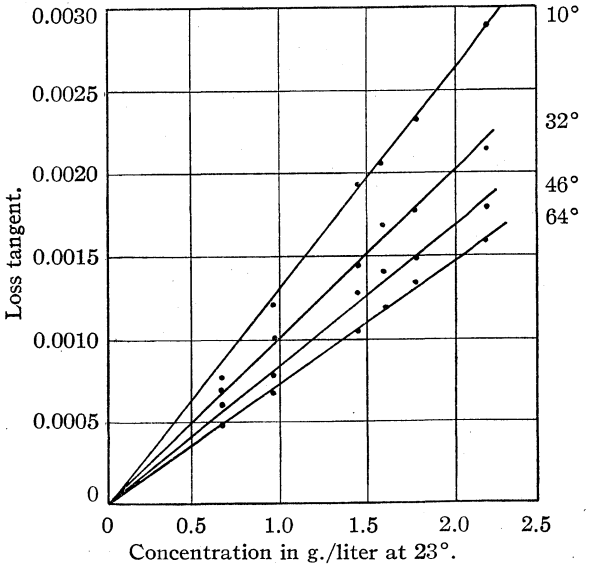

Fig. 3.—Loss of camphor in cyclohexane at 3.3 cm.

The experimental results are summarized in Table I which gives the observed molecular loss tangents; in each case the value is taken from the slope of a graph covering the concentration range. No explanation is offered for the smaller loss at 29° compared to the neighboring temperatures at 1.3 cm. wave length; the reduction is scarcely more than the estimated experimental errors.

For comparison at a common temperature the losses at 10, 30, 50 and 70° were obtained by interpolation and slight extrapolation. These were compared with the Debye loss expression used in the form[2]

$$\text{Loss} = \frac{(\epsilon + 2)^2}{\epsilon} \frac{4\pi N\mu^2}{27kT} \frac{\omega\tau}{1 + \omega^2\tau^2}$$

ϵ, the dielectric constant of the solvent is 2.0 and μ, the dipole moment of camphor, was taken as 3.00 D; Sidgwick's table[14] gives range from 2.94–3.05 D. ω is the angular frequency and τ, the time of relaxation, is the only unknown quantity. The values of this parameter which best fit the results, together with the experimental losses and the calculated losses using these times, are given in Table II. This table shows agreement between

the experimental and calculated losses within 5% except for the higher temperature results at 10 cm. wave length and a special experimental error, which would lead to low experimental values here, has been mentioned above.

Measurements are at too few frequencies for a claim to be made that the Debye expression with one relaxation time is undoubtedly the proper form for describing the loss, but the agreement is such that it can be said that single relaxation times, one for each temperature, do give a reasonable description of the system. In particular the recipro-

cals of these times describe the rate of rotation and the temperature dependance of this rate may be expressed as an activation energy. Figure 4 shows a graph of $\log\tau$ against $1/T$ and the slope of this line is equivalent to an activation energy, E_τ, of 1.7 kcal. if the time of relaxation is expressed by

$$\tau = Ae^{-E_\tau/RT}$$

This value may be compared with that of 1.7 kcal. for the similar activation energy for the rotation of camphor in *n*-heptane,[2] and also with the value of 2.3 kcal. for the corresponding activation energy for the viscosity of cyclohexane[13] over the range 15–30°. Further the interpolated value for the relaxation time at 20° which is 6.8×10^{-12} sec. in cyclohexane is very close to the value 6.5×10^{-12} sec. for camphor in *n*-heptane[2] but these values are by no means proportional to the macroscopic viscosity coefficients which are 0.96 and 0.41 cpoise, respectively.[13]

Acknowledgments.—The author wishes to thank Prof. P. Debye for his interest in the work and Dr. C. H. Townes for many invaluable discussions and suggestions. He also wishes to thank the Commonwealth Fund for the award of a Fellowship and the Bell Telephone Laboratories for granting the use of their facilities so freely during its tenure.

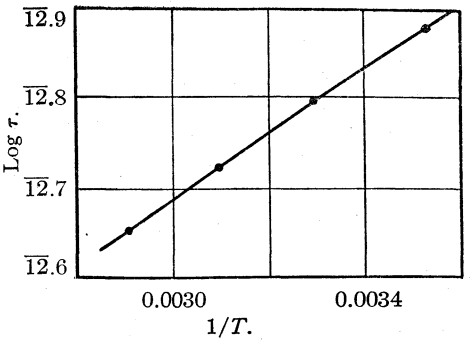

Fig. 4.—Graph of $\log_{10}\tau$ against $1/T$; slope equivalent to 1.7 kcal. energy of activation.

Summary

A description of the measurement of the dielectric loss of liquids at microwave frequencies using a completely filled cavity resonator is given. Solutions of camphor in cyclohexane have been measured over the range 10–70° at three wave lengths, 1.3, 3.3 and 10 cm. The observed losses can be well explained by a single Debye loss curve; the relaxation time is 6.8×10^{-12} sec. at 20° and the temperature coefficient corresponds to an activation energy of 1.7 kcal.

Potentiometric Investigation of Tripyrophosphatomanganic(III) Acid

BY JAMES I. WATTERS AND I. M. KOLTHOFF

Evidence presented in a previous paper[1] indicated that the violet complex ion of manganese (III) and pyrophosphoric acid is a chelate ring complex anion having essentially the formula $Mn(H_2P_2O_7)_3^{-3}$. The ionic weight was estimated by application of Jander's expression[2] to the polarographically determined diffusion coefficients, and the hydrogen content of the complex was deduced from *p*H, ionic charge, and theoretical considerations. An investigation of the oxidation potential of the manganese(II)–manganese(III) couple in acidic pyrophosphate solutions along with the various factors influencing it is described in the present paper.

A new potentiometric procedure for determining manganese by titrating the trivalent complex with standard iron(II) sulfate solution is also described. Volumetric procedures in which the trivalent complex is titrated with iron(II) sulfate and the end-point detected with diphenylamine sulfonate as indicator, as well as amperometrically, will be described in subsequent papers. On the basis of the present studies,[3] Lingane and Karplus[4] have developed a potentiometric method for determining manganese in which manganese(II) is titrated to the violet manganese(III) pyrophosphate complex with standard permanganate solution. Their titration curves substantiate the authors' results.

Theoretical

In the experimental part it is shown that the potential at a platinum electrode of the complex manganic(III)–manganous(II) system is reversible, and that both complexes are mononuclear. It has been mentioned that the trivalent manganese complex contains three pyrophosphate radicals.[1] The hydrogen content of the pyrophosphate ions, either in the form of complex ions or simple ions, is a function of the *p*H of the solution. The number of associated hydrogen ions in the various ions at a particular *p*H, will be indicated by x, y and z. The number of pyrophosphate radicals in the manganese(II) complex will be indicated by m to illustrate the method of its evalua-

tion. The following equation for the electrode reaction can be written

$$Mn(H_xP_2O_7)_m^{-(4m-mx-2)} + (3-m)H_yP_2O_7^{-(4-y)} \rightleftharpoons Mn(H_zP_2O_7)_3^{-(9-3z)} + (mx+3y-my-3z)H^+ + e \quad (1)$$

The equation for the oxidation potential of this system at 25° in terms of activities can be written as

$$E = E_0^c + 0.0591 \log a\mathrm{Mn^{III}C}/a\mathrm{Mn^{II}C} - (3-m)\ 0.0591 \log aH_yP_2O_7^{-(4-y)} + (mx+3y-my-3z)\ 0.0591 \log aH^+ \quad (2)$$

Upon converting hydrogen ion activity to paH and other activities to concentrations, this equation becomes

$$E = E_0^c + 0.0591 \log (f_1/f_2f_3) + 0.0591 \log (\mathrm{Mn^{III}C})/(\mathrm{Mn^{II}C}) - (3-m)\ 0.0591 \log (H_yP_2O_7^{-(4-y)}) - (mx+3y-my-3z)\ 0.0591 pa\mathrm{H} \quad (3)$$

In these equations $Mn^{III}C$ and $Mn^{II}C$ indicate the two complex ions, a denotes molar activity, and f_1 the molar activity coefficient of $Mn^{III}C$, f_2 that of $Mn^{II}C$ and f_3 that of $H_yP_2O_7^{-(4-y)}$ and parentheses indicate molar concentration. E_0^c indicates the standard potential for the reaction.

If only the concentration ratio of the two manganese complexes is varied, the potential change ΔE at 25° at constant p_aH and ionic strength can be expressed as follows

$$\Delta E_{2-1} = 0.0591\ \Delta \log (\mathrm{Mn^{III}C})/(\mathrm{Mn^{II}C})_{2-1} \quad (4)$$

By means of this equation it is possible to establish that the complexes are mononuclear and that a one-electron change occurs.

The effect on the potential resulting from variations of only the total pyrophosphate concentration can be expressed as

$$\Delta E_{2-1} = (m-3)\ 0.0591\ \Delta \log (H_yP_2O_7^{-(4-y)})_{2-1} \quad (5)$$

By simple calculations involving the ionization constants of pyrophosphoric acid it can be shown that, at constant ionic strength and paH, the concentrations of all species of pyrophosphates are proportional to the total pyrophosphate concentration. Accordingly, equation (5) can be converted to the following form

$$\Delta E_{2-1} = (m-3) \times 0.0591\ \Delta \log (C_s)_{2-1} \quad (6)$$

C_s denoting the total pyrophosphate concentration. From this equation, it is possible to determine m, the number of pyrophosphate ions associated with each manganese(II) ion by determining the change in potential, E, as a function of the total pyrophosphate concentration.

The effect of varying the paH is given by the equation

$$\Delta E_{2-1} = (3z+my-3y-mx)\ 0.0591 \Delta pa\mathrm{H}_{2-1} \quad (7)$$

Certain complications enter in the evaluation of x, y and z. Obviously pyrophosphate ions and both complex ions in various degrees of association with hydrogen ion enter the reaction or are in equilibrium with reacting forms. The observed coefficient of paH (eq. 7) will be a weighted average for the several reactions which may occur. An equation for a predominant reaction in a given paH range might be written. In this case, the concentration of the uncomplexed pyrophosphate ion could be evaluated since the ionization constants of pyrophosphoric acid are known. However values of the hydrogen ionization constants of the two complex acids are unknown. Accordingly, the actual concentrations of complex ions of any given degree of dissociation for which the electrode reaction might be written cannot be solved even though the total concentrations of manganese (III) and manganese(II) are known. Recourse to a sufficiently high paH to be certain that one complex contains no associated hydrogen ions is denied because in alkaline solutions the complex manganese(III) ion disproportionates to produce manganese dioxide. Likewise, the complexes are too strongly acidic to assume quantitative association during a variation in paH in fairly strong acidic solutions. The latter behavior is to be anticipated because positive nuclear ions enhance the acidity of acids in the complex. Pyrophosphoric acid complexed with either manganese(II) or manganese(III) is a stronger acid than the simple pyrophosphoric acid, and the manganese (III) should be more acidic than the manganese (II) complex.

The value of z in fairly strong acid solutions has been shown[1] to be close to 2 corresponding to 6 hydrogen ions in the manganese (III) complex. However, the evidence did not preclude the possible association of one or possibly two additional hydrogen ions or the dissociation of several more hydrogen ions depending on the exact pH with a corresponding effect on the potential. It follows that only differences in the acidities of the two complexes can be found on the basis of equation (7).

Experimental

Apparatus.—The potential measurements were made in a 100-ml. tall form lipless beaker with a bright platinum indicator electrode and a saturated calomel reference electrode. The beaker was equipped with a no. 11 rubber stopper with holes to receive electrodes, buret, a stirrer, and a tube for admitting purified nitrogen. Unless otherwise indicated, oxygen-free nitrogen was bubbled through the solution for fifteen minutes to remove oxygen. A temperature of 25 ± 0.1° was maintained by means of a thermostatically controlled water-bath. In a few titration experiments the temperature of the bath was changed to 26°, which was room temperature.

A Leeds and Northrup Student's potentiometer was used on conjunction with a Leeds and Northrup portable enclosed lamp and scale galvanometer. The paH measurements were made by means of a Beckman glass electrode pH meter.

Reagents.—Analytical reagents were employed. A stock solution of 0.1 M manganese(II) sulfate in 0.01 N sulfuric acid was used.[1] Standard 0.1 N iron(II) sulfate solution having a pH of about 1.6 was prepared by dissolving approximately 40 g. of Mohr salt in water, adding 2 ml. of sulfuric acid (1:1) and diluting to one liter. This solution, which was oxidized only slowly by air, was standardized daily just before being used. Standard 0.01 N iron(II) sulfate solution was prepared by dilution

of 0.1 *N* solution with sulfuric acid (1:100). Sodium and potassium pyrophosphate[1] were both used as a source of pyrophosphate. The *p*H of the pyrophosphate solutions was adjusted to the desired value with either sulfuric or nitric acid.

Procedure.—The manganese(III) complex was prepared from the manganese(II) complex, in 0.4 *M* pyrophosphate having a *p*H of about 2, by shaking with lead dioxide and then filtering according to the procedure described in a previous paper.[1] The solution was stirred mechanically during potential measurements.

Results and Discussion

Equations (4) through (7) were tested by means of various experiments designed to permit the observation of potential changes resulting from carefully controlled variations.

Effect of the Manganese(III) to Manganese (II) Ratio.—Experimentally, equation (4) was tested by measuring the potential of solutions prepared by mixing varying proportions of the air-free oxidized and unoxidized portions of a solution, 10 millimolar in manganese ion, 0.4 *M* in sodium pyrophosphate, and 2.40 in *pa*H. The potentials in Table I are plotted as a function of log $(Mn^{III}C)/(Mn^{II}C)$ in line c, Fig. 1. The points fall on a straight line which has a slope of 0.0598 v., in good agreement with the theoretical value of 0.0593 volt for a one-electron transfer at 26°.

TABLE I

−1.39794	.6612
−1.97634	.6323

Another experiment was performed by observing the effect on the potential resulting from changes in total manganese concentration while the ratio of the oxidized to reduced form remained constant. A solution 5 millimolar in both the manganese(III) and the manganese(II) complexes, 0.4 *M* in sodium pyrophosphate and 2.40 in *p*H, was diluted ten times with a solution 10 millimolar in sodium sulfate instead of manganese sulfate, 0.4 *M* in sodium pyrophosphate and 2.40 in *p*H. Upon dilution the potential retained a constant value of 0.7463 v. (S.C.E.). From these experiments it follows that the electrode behaves in a reversible manner for a one-electron transfer with respect to the two manganese complex ions, and that both the oxidized and reduced forms of the complex ions must contain only one manganese atom. This conclusion has further support in the fact that potentiometric titrations discussed later show that the oxidation states differ by unity.

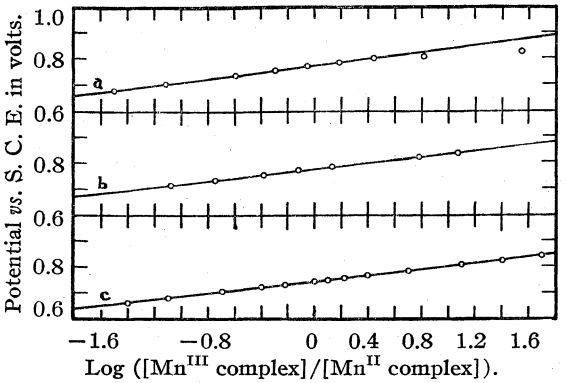

Fig. 1.—Line a, data obtained from the titration curve of 0.001 *M* manganese (III) complex with iron (II); line b, data from titration curve of 0.01 *M* manganese (III) complex; line c, data obtained from Table I.

Effect of the Pyrophosphate Concentration.—Equation (6) was tested experimentally by varying the total concentration of pyrophosphate from 0.4 to 0.04 *M* keeping the ionic strength and the *pa*H constant. In the following experiments the *pa*H was 2.06. The ionic strength of the system which was 0.4 *M* in sodium pyrophosphate was calculated to be 1.83. The solution containing 0.04 *M* pyrophosphate was made 1.83 *M* in potassium nitrate in order to have the same ionic strength as the 0.4 *M* pyrophosphate solution. The various solutions were 0.5 millimolar both in manganese(II) and manganese (III). The average value of the oxidation potential (*vs.* S.C.E.) of the solution 0.04 *M* in pyrophosphate was found to be 0.8278 ± 0.001 v. and of the solution 0.4 *M* in pyrophosphate 0.7670 ± 0.001 v. After correcting for the amount of pyrophosphate combined with manganese, the potential change was found to be 60.8 ± 2.0 mv. for a change in the pyrophosphate concentration from 0.3975 to 0.0375 *M*. Substituting these values in equation (6) yields 2.00 for the value of *m*.

In order to establish that *m* remained constant throughout the dilution, another experiment was performed in which the pyrophosphate concentration was varied continuously. To a solution 5 millimolar in both manganese(II) and manganese (III) and 0.4 *M* in sodium pyrophosphate, was added 1.83 *M* potassium nitrate solution. The *pa*H was kept constant at 1.58 by adding small amounts of nitric acid. The results are given in Table II. They show that in the concentration range of pyrophosphate used a value of $m = 2$ satisfies the experimental data.

From polarographic experiments[1] it was concluded that the manganese(III) complex contains three pyrophosphates. This relation of two to

TABLE II

THE INFLUENCE OF PYROPHOSPHATE CONCENTRATION ON THE POTENTIAL

10.0	884.3	59.6

three in the number of chelate complexing ions has been observed repeatedly in complexes of di- and trivalent elements of the first transition series. An analogous behavior of the iron(III) oxalate–iron(II) oxalate couple was observed by Schaper[5] and verified by Lingane.[6]

Effect of Hydrogen Ion Concentration.—Since the value of m has been found to be two, equation (7) becomes

$$\Delta E_{z-1} = (3z - 2x - y)\, 0.0591\, \Delta paH_{z-1} = -w\, 0.0591\, \Delta paH_{z-1} \quad (8)$$

Experimentally, this equation was tested by measuring the potential as the *pa*H was varied by adding concentrated nitric acid or ammonium hydroxide dropwise to a solution 5 millimolar in both manganese(II) and manganese(III) complexes and 0.4 M in sodium pyrophosphate. The effect of changing the *pa*H in this solution is shown in Table III and Fig. 2. The value of w corresponds to the number of hydrogen ions involved in the reaction if the activity coefficient of the hydrogen ions remains constant with variations in the acidity. Each value given for w is the average obtained with reference to the preceding and succeeding data. In solutions having a *pa*H smaller than 3, the solution was rich violet in color. As the *pa*H approached 7, the color of the complex became increasingly amber. When the *pa*H exceeded 7 appreciably, a precipitate formed due to disproportionation of the amber-colored complex

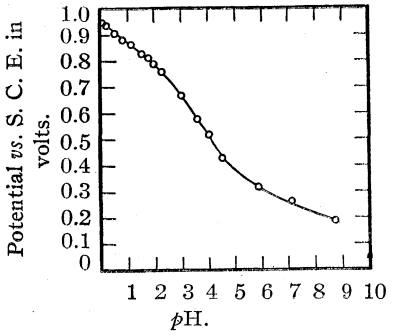

Fig. 2.—Change of potential with *pa*H in mixture 0.005 M in both manganese(II) and manganese(III) complexes and 0.4 M in sodium pyrophosphate.

to form manganese dioxide and manganese (II) ion.

At a *pa*H approaching zero w became approximately 1.5. In the lower limit of this *pa*H range, y can be assigned approximately the value 4 since the pyrophosphoric acid is largely associated. Assigning the value of 2 to z on the basis of polarographic data[1] leads to a calculated value of approximately 2 for x, indicating that both the manganese(II) and the manganese(III) complexes are definitely more acidic than pyrophosphoric acid. The following equation may accordingly be written for the predominant equilibrium in strongly acidic solutions.

$$Mn(H_2P_2O_7)_2^{-2} + H_4P_2O_7 \rightleftharpoons Mn(H_2P_2O_7)_3^{-3}\ (\text{violet}) + 2H^+ + e \quad (9)$$

In the *pa*H range of 0 to 3, there is a large variation in the extent of association of hydrogen ions with pyrophosphoric acid. This factor alone accounts for the major portion of the change of w. Accordingly if there is any decrease in the value of z in this range, there is also a compensating decrease in the value of x.

In the *pa*H range of 3 to 6, pyrophosphoric acid is largely present as $H_2P_2O_7^{-2}$. Furthermore, the degree of association of pyrophosphoric acid does not change rapidly in this range and does not contribute appreciably to the value of w. In the lower half of this range the observed value of w is about 2.5. This value should be zero if both complex ions contained dihydrogen pyrophosphate ions. It is evident that the manganese(III) complex must contain fewer hydrogen ions than the manganese(II) complex. Accordingly z is unity or zero. This decrease in the value of z is accompanied by a change in the color of the manganese (III) complex from violet to amber.

In the *pa*H range of 6.7 to 9.4, the ion $HP_2O_7^{-3}$ preponderates in pyrophosphate solutions. The more acidic complex ions undoubtedly contain

simple pyrophosphate ions. Assigning the value zero to x and z, yields a value of unity for w which is approximately the value observed. The main reaction in this *pa*H range is

$$Mn(P_2O_7)_2^{-6} + HP_2O_7^{-3} \rightleftharpoons Mn(P_2O_7)_3^{-9} + H^+ + e \quad (10)$$

Cartledge and Ericks[7] in a study of the oxalate complexes of manganese(III) observed a red complex, $Mn(C_2O_4)_3^{-3}$, which changed to a brown complex, $Mn(C_2O_4)_2(H_2O)_2^{-1}$, when the concentration of excess oxalate ion was decreased by dilution. The color change in the manganese(III) pyrophosphate complex cannot be due to an analogous displacement of pyrophosphate ions by water molecules because a one-hundred fold dilution of the violet complex with water at a *pa*H of 2 caused no change of color from violet to amber, but a change of the *pa*H to 2.4 caused a definite change in color. Furthermore a large excess of the complex-forming pyrophosphate ions is present in solutions containing the amber-colored complex.

On the basis of these considerations it appears that the manganese(III) complex is rich violet in color when an average of two hydrogen ions are associated with complexed pyrophosphate ion and it is amber in color when one or no hydrogen ion is associated with each pyrophosphate.

Potentiometric Titrations.—Titrations 1 and 2 in which 75 ml. of 1 millimolar manganese(III) complex was titrated with 10.06 millinormal iron (II)sulfate, with air present and with dissolved air removed, yielded curves (a) and (b) in Fig. 3. Titration 3 was performed with a ten-fold increase in the concentration of both the manganese(III) complex and the iron(II) sulfate in the presence of dissolved air. This titration curve was practically identical with curve b in Fig. 3.

In blank determinations performed in the same manner as the titrations, 0.07 ml. of 0.01006 N iron(II) sulfate was added before a potential change was observed. This blank correction due to a trace of oxidizing agent, probably very finely divided lead dioxide, was applied in all calculations. The calculated molarities of the manganic complex in the three titrations, assuming a one electron change, were 1.0013, 1.0010, and 9.972 millimolar corresponding to errors of +0.13, +0.10 and −0.28%, respectively. The large potential break and the accuracy which is better than 0.3% in the presence or absence of dissolved air, indicate the excellence of the potentiometric titration from a practical viewpoint.

Effect of Oxygen.—Although dissolved oxygen had no noticeable effect on the results of the titration, some of the potentials, especially in the more dilute solutions, were influenced by its presence. Before the end-point the corresponding potentials in all three titrations were in good agreement. However, beyond the end-point, the presence of dissolved oxygen influenced the potential in the solutions which were only one millimolar in manganese complex because of air oxidation of the ferrous iron.

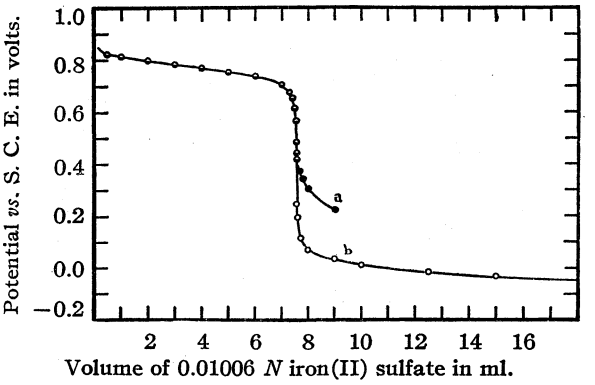

Fig. 3.—Potentiometric titration curve of 0.001 M manganese (III) complex with iron (II); a, dissolved air not removed; b, dissolved air removed.

Since the changes in *pa*H and volume during the titrations were small, the potential change before the end-point was due largely to changes in the ratio of the concentrations of the two complex manganese ions. This permitted a convenient confirmatory test of equation (4). Upon plotting the potential *versus* log $(Mn^{III}C)/(Mn^{II}C)$ for titrations 2 and 3, the lines a and b in Fig. 1 were obtained. Straight lines with slopes of 0.059 v. were found in both cases. Considering the small effect due to dilution and a small *p*H change the average value of the potential of 0.776 v. at the midpoint in the titrations agreed satisfactorily with the formal potential of 0.767 v. of the couple at various concentrations in a solution 0.4 M in sodium pyrophosphate having the same *pa*H, namely, 2.06.

Similar calculations involving the iron(III) and iron(II) pyrophosphate complexes which determine the potential beyond the end-point yielded a slope of 0.059 v. and a potential of 0.033 v. (S.C.E.) for this couple in a solution containing equal concentration of the two complex ions at a *pa*H of 2.06. It follows that both of the manganese and both of the iron complexes are mononuclear and that both undergo one-electron changes.

The potential at the endpoint should be one-half the sum of the above potentials of the two couples at *pa*H of 2.06, namely, 0.405 v. (S.C.E.). The value of 0.410 v. (S.C.E.) calculated by the method of second derivatives from titration b (Fig. 3) is in satisfactory agreement with the theoretical.

The Standard Potential.—The potential of a solution equimolar in the manganese(III) and manganese(II) complexes, in a solution 0.4 M in sodium pyrophosphate and having a *pa*H of 2.06 is +0.767 ± 0.003 v. *versus* the saturated calomel electrode or +1.013 ± 0.003 v. *versus* the

(7) G. H. Cartledge and W. P. Ericks, THIS JOURNAL, **58**, 2065 (1936).

standard hydrogen electrode at 25°. Extrapolating to a *pa*H of zero and a pyrophosphate concentration of unity on the basis of experimental data previously presented yields a value of +1.15 v. as the "formal" oxidation potential for the reaction in equation (9) at 25°. Strictly speaking this potential is not the formal potential, since the hydrogen ion activity and not its concentration was extrapolated to zero. Nor is it the standard potential since the concentrations and not activities of the complex ions and pyrophosphoric acid are used. As the activity coefficients are not known, the standard potential cannot be solved but is probably close to 1.15 v.

Although the data will not permit an accurate evaluation of the instability constants, an approximation may be made of their ratios. On the basis of the standard potential of 1.51 v. for the aqueous manganese(III)/manganese(II) couple determined by Grube and Huberich,[8,9] the following relation between the instability constants K_{III} for tri-dihydrogen pyrophosphatomanganate(III) complex and K_{II} for di-dihydrogen pyrophosphatomanganate(II) is obtained

$$1.15 \text{ v.} = 1.51 + 0.0591 \log \frac{a_{Mn^{+3}}}{a_{Mn^{+2}}} =$$

$$1.51 \text{ v.} + 0.0591 \log \frac{K_{III} a_{Mn^{III}C} \, a_{H_4P_2O_7^{-3}}}{K_{II} a_{Mn^{II}C} \, a_{H_4P_2O_7^{-2}}} \text{ volts} \qquad (11)$$

Since the standard potential is calculated for all substances in the last term at unit activity the following relation is obtained

$$K_{III} = 10^{-6} K_{II} \ (ca.) \qquad (12)$$

Summary

The couple tripyrophosphatomanganic(III) acid/dipyrophosphatomanganic(II) acid was shown to behave reversibly at a platinum electrode. The influence of the total pyrophosphate concentration, ratio of manganese(III)/manganese(II) concentrations, and *pa*H were studied. At a *pa*H near zero, the equilibrium was shown to be essentially

$$Mn(H_2P_2O_7)_2^{-2} + H_4P_2O_7 \rightleftarrows Mn(H_2P_2O_7)_3^{-3} \text{ (violet)} + 2H^+ + e \qquad (9)$$

The potential of a platinum electrode in a solution containing equal concentrations of manganese (II) and manganese(III) in a solution 0.4 *M* in pyrophosphate having a *pa*H of 2.06 is +1.013 ± 0.003 v. *versus* the standard hydrogen electrode. The standard potential for the reaction indicated in equation (9) is E_0 = (*ca.*) −1.15 v. (Lewis and Randall convention).

As the *pa*H approaches 7, the manganese(III) complex becomes increasingly brown amber in color, due to the ionization of additional hydrogen ions from the complex. In an alkaline solution, the manganese(III) complex is unstable disproportionating to form manganese dioxide and manganese(II) ion.

A new method for determining manganese by means of a potentiometric titration of tripyrophosphatomanganic acid with iron(II) sulfate is described.

The Effect of Sodium Silicates on the Absorption Spectra of Some Dyes

BY R. C. MERRILL, R. W. SPENCER AND R. GETTY

That certain dyes change color in the presence of various colloids has long been known. Familiar examples are the variation in color of a biological stain depending on the nature of the stainable substrate, which P. Ehrlich called metachromasy, and the protein error of indicators. Micellar solutions of colloidal electrolytes, such as cetyl pyridinium chloride[1] and long chain sulfonates and sulfates[2,3] change the color of pinacyanol chloride and other dyes.[4,5] This paper reports the effects of another group of colloidal electrolytes, the sodium silicates, on the absorption spectra of the dyes, pinacyanol chloride, toluidine blue O, Rhodamine 6G, and the sodium salt of 2,6-dichlorobenzenone indophenol.

Experimental

All of the sodium silicates used were commercial products of the Philadelphia Quartz Co. Their composition is summarized in Table I. The sodium metasilicate pentahydrate was in the form of pure white free flowing crystals which have a melting point of 72.2°. The "E" and "Star" silicates are clear, transparent, aqueous solutions and the "S" is an opalescent solution. The sodium oxide content is determined by titration with standardized hydrochloric acid to the methyl orange end-point. Silica

is determined gravimetrically. The sodium hydroxide was J. T. Baker analyzed C.P. grade.

The dyes were all commercial products and used without further purification. The pinacyanol chloride and sodium salt of 2,6-dichlorobenzenoneindophenol were purchased from the Eastman Kodak Co. Rhodamine 6G (C.I. No. 752) was obtained from the National Aniline division of the Allied Chemical and Dye Corp. The toludine blue O was the certified dye stain sold by the Coleman and Bell Co. which contained 66% dye. The molar concentrations of the solutions are given on the basis of actual dye content, assuming that the first three dyes were pure. The pH of the dye solution was determined with a Beckman pH meter.

The absorption curves were obtained with a General Electric Co. recording spectrophotometer. From the transmission curves thus obtained the molar extinction coefficients, ϵ_m, were calculated at 10 mμ intervals and at maxima and minima from the equation $\log_{10} I_0/I = \epsilon_m Cd$ where C is the molar concentration of the dye, d the width of the cell (0.50 cm.), and I_0 and I the intensity of the incident and transmitted light. All the absorption curves were obtained at room temperature (around 22–23°).

Results

The absorption spectra of 2×10^{-5} M pinacyanol chloride in water and in 0.02 M solutions of sodium hydroxide, sodium metasilicate and silicates with silica to alkali (Na_2O) ratios of 2.6 and 4.0 are shown in Fig. 1. The effect of four concentrations, including 0.02 M, of the 3.3 ratio silicate on the absorption spectra of 2×10^{-5} M dye is illustrated in Fig. 2. Table II gives the intensities of the band maxima for these solutions. All solutions were diluted fivefold immediately prior to being placed in the spectrophotometer after

having stood about fifteen hours at the higher concentration. Our absorption curve for pinacyanol chloride in water is in excellent agreement with that expected by interpolation from the curves given by Sheppard[6] for different concentrations of dye.

The effect on the dye's absorption spectrum of increasing the silica to alkali ratio of the 0.02 M silicates is to decrease greatly the intensity of the α band at about 595 mμ, and even more that of the β band at 546 mμ. New bands, α' at 630 mμ and γ at about 490 mμ, appear in the metasilicate solution. The intensity of the γ band is about 50% greater in solutions of the higher ratio silicates whereas that of the α' band becomes progressively less with increasing silica to alkali ratio. The effect of increasing the concentration of the 3.3 ratio silicate parallels that of increasing the silica to alkali ratio at a given concentration in that the intensity of the α band is greatly decreased and that of the β band even more. Their effects differ in that the intensities of both the α' band, which becomes apparent in a 2×10^{-3} M silicate solution, and the γ band, first being evident in a 2×10^{-4} M silicate, increase progressively with increase in concentration. Both the α and β bands appear to have a minimum intensity at a silicate concentration about 2×10^{-3} M. The visual color of the dye solutions changes from blue to purple as the silica to alkali ratio or the silicate concentration is increased.

The differences in the absorption spectra of 2×10^{-5} M pinacyanol chloride in 0.020 M sodium metasilicate and 0.006 M 3.3 ratio silicate (Fig. 3) both of which contain the same amount of silica, show clearly that the silica is in a different form in the two solutions.

The differences in the absorption spectra of 2.5×10^{-5} M toluidine blue 0 in 0.01 M sodium metasilicate and varying concentrations of the 3.3 ratio silicate as compared with that in water (Figs. 4 and 5) are similar to those observed in solutions of the polymeric sodium "hexametaphosphate"[7] and agar.[8] Results with this dye suggest that the addition of small amounts of colloidal electrolytes greatly decreases the intensity of the two only partially resolved bands, α at 624 mμ and β (which at this concentration in water occurs at 600 mμ), and gradually decreases the wave length at which the β band maxima occurs. At higher concentrations the intensity of the band at around 540 mμ increases, and in "hexametaphosphate" solutions[7] goes through a maximum. The effects of the silicates on the intensities of the band maxima of 2.5×10^{-5} M toluidine blue 0 solutions are summarized in Table III. The dye

appears blue in water and in the 5.0×10^{-4} *M* 3.3 ratio silicate solution, but is purple at all other silicate concentrations studied.

TABLE III

THE INTENSITIES OF BAND MAXIMA IN 2.5×10^{-5} MOLAR SOLUTIONS OF TOLUIDINE BLUE O

Solvent	*p*H	α Band λ (mμ)	α Band $\epsilon_m \times 10^4$	β Band λ (mμ)	β Band $\epsilon_m \times 10^4$
H_2O	6.53	624	3.69	600	3.59
5.0×10^{-4} *M* $Na_2O{\cdot}3.3SiO_2$	9.49	622	2.57	600	2.54
1.0×10^{-3} *M* $Na_2O{\cdot}3.3SiO_2$	9.91	...	..	546[a]	1.98
5.0×10^{-3} *M* $Na_2O{\cdot}3.3SiO_2$	10.11	...	..	546[a]	2.00
5.0×10^{-2} *M* $Na_2O{\cdot}3.3SiO_2$[b]	11.12	...	..	538[a]	2.27
1.0×10^{-1} *M* Na_2SiO_3	11.96	624	1.31	5.44	1.58

[a] May be new band. [b] There is an indication of a new band at around 640 mμ at this silicate concentration.

Figure 6 shows the absorption spectra of 1×10^{-4} *M* Rhodamine 6G and 1×10^{-4} *M* sodium 2,6-dichlorobenzenone indophenol in water and in 0.010 *M* solutions of $Na_2O{\cdot}3.3SiO_2$. The addition of this concentration of silicate appears to shift by about 6 mμ toward shorter wave lengths, the band (or unresolved bands) of Rhodamine 6G occurring from about 460 to 540 mμ. The water spectrum is probably somewhat complicated by the dye's fluorescence. Rhodamine 6G is orange and fluorescent in water and red and non-fluorescent in micellar solutions of anionic detergents and in solutions of various silicates including the metasilicate.

A 1×10^{-4} *M* solution of sodium 2,6-dichlorobenzenone indophenol has a single band maximum in the visible occurring at 605 mμ with a molar extinction coefficient of 18.2×10^4. The addition of 0.010 *M* $Na_2O{\cdot}3.3SiO_2$ to this dye produces practically no change in the color of the solution but *increases* the intensity maximum 3%. Unlike other dyes used in this investigation, the dye ion in this case has the same charge as the silicate ions and micelles.

Discussion

The reduction in intensity of the α and β bands of solutions of pinacyanol chloride and toluidine blue O of as much as 50% by silicate solutions as dilute as 2×10^{-4} *M* is much larger than that observed for ordinary electrolytes. For example, the height of the main band of methylene blue in water is decreased only 5% when the solution is made 1*M* in potassium chloride and somewhat less with 1*M* potassium nitrate.[9] Lewis, *et al.*,[9] suggest that salts increase the formation in aqueous solution of a colorless form of the dye produced by simultaneous, reversible addition of hydrogen and hydroxyl ions. It appears that this suggestion does not explain the large reductions due to colloidal electrolytes, especially since, as Lewis states, one must also assume polymerization of the colorless substance in order to explain effects

(9) G. N. Lewis, O. Goldschmid, T. T. Magel and J. Bigeleisen, THIS JOURNAL, **65** 1150 (1943).

as large as 5%. A more likely explanation (*cf.* ref. 10) is that the dye and colloidal electrolyte interact in such a manner as to restrict free rotation of some part of the molecule involved in the electronic transitions giving rise to the bands. This decreases the number of fully extended planar ions suitably oriented per unit time to the electric vector of the light rays.

Probably sorption of colloidal particles is involved but the interaction is at least partially electrostatic for effects plainly visible to the eye occur only when the charges on the dye ion and colloidal particles are opposite in sign. Precipitation or flocculation occurs rapidly at dye and silicate concentrations greater than those reported in Tables II and III; the higher concentrations in these tables precipitated after standing a day or two.

The addition of silicates alters the relative intensities of the α and β band maxima of pinacyanol chloride. Thus, the ratio of the maximum molar extinction coefficients of the α to β band is 0.81 in water, 0.85 in 2×10^{-5} M $Na_2O \cdot 3.3SiO_2$ and 1.13 in 2×10^{-4} M $Na_2O \cdot 3.3SiO_2$. Some investigators regard the α band as characteristic of the monomer dye ion, the β band as peculiar to a dimer, and the γ band peculiar to high polymers.[11,12,13,14] Since these bands are generally apparent in organic solvents where there is no evidence of dimerization or polymerization it appears more likely that the β and γ bands are not new bands peculiar to dimers or polymers, but are vibrationally coupled transitions proper to the monomeric ions which are, however, enhanced in the dimer or polymer.[10] Because electrolytes generally increase the extent of formation of associated ions in aqueous systems, it would be expected that, if the first hypothesis is true, the ratio of the intensities of the α to β bands would decrease on the addition of electrolytes. That the opposite effect occurs on the addition of both sodium hydroxide and silicates is evidence that the bands are not peculiar to dimers or polymers. That the relative intensity of the α and β bands of thionine is not affected by the addition of a chloride[14] is a further indication.

Silicates also produce a shift in the wave length at which the band maxima appear and causes new bands to become evident thus producing a visual change in the colors of the solutions. The color change of toluidine blue in agar solutions is attributed to the adsorption of molecular aggregates of dye larger than the dimer by agar.[8] In "hexametaphosphate" solutions the color change has been attributed to a linear complex polymer produced by each dye ion reacting with a phosphate group.[7] The color change of dyes in soap solutions is attributed to preferential solubilization of one form of dye from the equilibrium mixture by the soap micelle.[3] Since silicates do not solubilize water-insoluble dyes and still produce comparable color changes, it is evident that the intimate type of interaction producing solubilization is not necessary to give a change in color. A reasonable explanation is that these color changes are also due to sorption at the surface of the colloidal silica particle and/or chemical combination of the dye cation with the negative ionic groups of the colloid. The change in the wave length at maximum intensity of the various bands with concentration indicates that the complexes responsible for their appearance vary in composition.

Summary

The addition of various sodium silicates to a pinacyanol chloride solution changes the absorption spectra by decreasing the intensity of the α and β bands to different extents, and by forming new α' and γ bands. The visual color change is from blue to purple. Their addition to a solution of toluidine blue 0 reduces the intensity of the absorption band and shifts the band maxima from 620 mμ to about 540 mμ, causing a visual change from blue to purple. Silicates shifted the band maxima of Rhodamine 6G about 6 mμ toward the violet but did not alter the intensity by more than 2%. This dye was orange and fluorescent in water and red and non-fluorescent in silicate solutions. Silicates had little effect on the absorption spectra of the sodium 2,6-dichlorobenzenone indophenol. The silicates used had the molecular formulas Na_2SiO_3, $Na_2O \cdot 2.6SiO_2$, $Na_2O \cdot 3.3SiO_2$ and $Na_2O \cdot 4.0SiO_2$. Their effects are attributed to sorption and electrostatic interaction of the dye ion with the silicate ions and micelles.

Studies of the Fischer–Tropsch Synthesis. IV. Properties of Reduced Cobalt Catalysts[1]

BY ROBERT B. ANDERSON,[2] W. KEITH HALL,[2] AND L. J. E. HOFER[2]

A number of catalysts of easily reducible metals are prepared by precipitation of their oxides or carbonates, followed by reduction in hydrogen to the metal. Since most precipitated oxides or carbonates sinter excessively on reduction, with decreases in both surface area and bulk volume, promoters and carriers are added to minimize these effects. This paper describes such changes for cobalt–thoria–kieselguhr and cobalt–thoria–magnesia–kieselguhr Fischer–Tropsch catalysts and similar preparations with one or more of the components omitted. Also included are carbon monoxide chemisorption and X-ray diffraction studies.

Properties of these catalysts in the unreduced state[3] and of the kieselguhrs used as carriers,[4] and the characteristics of these catalysts in the synthesis[5,6] have been reported previously. It was shown that the surface areas of the cobalt–basic carbonate-promoter complex[7] were only slightly increased by additions of promoters and, or, carriers. However the kieselguhr increased the bulk volume of the catalyst; the bulk volume of granular catalysts containing kieselguhr varied directly with the bulk volume of the kieselguhr. It was also shown that the cobalt basic carbonate was deposited chiefly in the pores of the kieselguhr that were larger than 5 microns in diameter.

Hofer and Peebles[8,9] have reported X-ray diffraction studies of some of this series of catalysts after reduction, carburization and use in the synthesis. McCartney and Anderson[10] have reported electron micrograph and adsorption studies of changes of a pure cobalt oxide powder upon reduction. In a subsequent section of this paper, the results are compared with those of Emmett and Brunauer[11] on reduced iron synthetic ammonia catalysts. Surface–area studies of iron Fischer–Tropsch catalysts, now in progress, will be reported in a later paper.

Experimental

The catalysts studied were cobalt–thoria–kieselguhr (100:18:100) catalyst designated by 108B, a series of cobalt–thoria–magnesia–kieselguhr (100:6:12:200) designated as 89 and preparations similar to the 89-series with one or more components omitted. The methods of preparing these catalysts have been reported in previous papers.[3,5,12] Hofer and Peebles[8] have described the preparation of the cobalt oxide powder used in this work. For reduction, adsorption and density studies, the catalysts were placed in an adsorption vessel with a special four-way stopcock which permitted hydrogen to be flowed over the catalyst during reduction.[13] To facilitate filling and removal of catalysts without change in volume of the vessel, the charge tube as shown previously was extended to the level of the stopcock and closed with a ground-glass joint. After filling of the adsorption vessel a close-fitting glass rod was inserted into the charge tube to minimize the dead space. Adsorption and reduction studies were made in a small vessel which held about one gram of catalyst, and density determinations were made in a larger vessel holding about ten grams. Helium and mercury densities were made on the same reduced sample. In all cases, the reduced catalysts were handled in a manner which precluded exposure to air.

The hydrogen for the reduction was passed over hot copper and through anhydrous magnesium perchlorate to remove traces of oxygen and water vapor. The adsorption vessel was heated in a horizontal position to avoid heating the stopcock and ground joint. The small resistance furnace used to heat the samples was controlled automatically to $\pm 3°$.

Before reduction the samples were evacuated at 100° for one hour to remove adsorbed vapors and to minimize the effect of differences in drying of the samples. The weights of samples after this treatment were used in computing surface areas, and except for the data in Table III the areas of reduced catalysts were expressed per gram of unreduced catalyst. The reduction procedure was to heat the catalyst rapidly to reduction temperature, 360 or 400°, in a slow stream of nitrogen. Since the cobalt was present as a basic carbonate, about 65% of the total weight loss on reduction occurred during this treatment. When the reduction temperature was reached, hydrogen at a space velocity[14] of 6000 was passed over the catalyst for two hours. Then the catalyst was evacuated at the reduction temperature to a vacuum of less than 10^{-3} mm. to remove chemisorbed hydrogen.

Adsorption isotherms were determined by conventional volumetric methods.[15] The gases used were of high purity, containing considerably less than 0.1% of oxygen. Before starting the carbon monoxide isotherms, the samples were

(7) The area of the cobalt-promoter complex was calculated with the following equations which assume the area of kieselguhr to be additive, $A_{complex} = A_{catalyst} - f_{KG}A_{KG}$, where $A_{complex}$, $A_{catalyst}$ and A_{KG} are the area of the complex and catalyst per gram of unreduced catalyst and the area of kieselguhr per gram respectively and f_{KG} is the weight fraction of kieselguhr in the unreduced catalyst. The area of complex per gram of complex in the unreduced catalyst was obtained by dividing $A_{complex}$ by $1 - f_{KG}$. It should be mentioned that the area of the kieselguhr did not change appreciably when subjected to the usual reduction procedures.

Cobalt oxide powder was reduced in hydrogen at a space velocity of 100. [d] Per gram of unreduced catalyst. [e] Per gram of complex in unreduced catalyst. [f] Contains powdered magnesia. [g] Contains precipitated magnesia. [h] A fine powder.

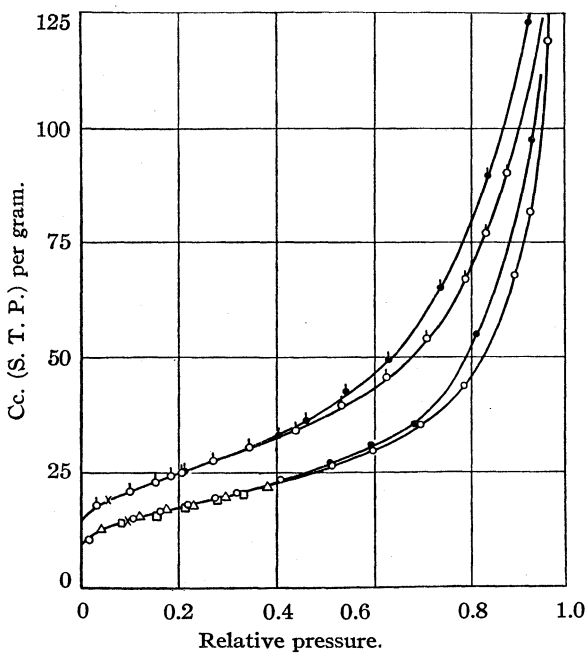

Fig. 1.—Adsorption of nitrogen at −195° on unreduced and reduced cobalt catalyst 89J, where Ó represents the unreduced catalyst and O, □ and △ represent different samples of reduced catalyst. Desorption points are solid, and the volume of gas corresponding to a monolayer is represented by X.

cooled in helium at −195° to ensure temperature equilibration. Surface areas were computed from the simple B. E. T. equation[16] with the cross-sectional area of the nitrogen molecule taken as 16.2 sq. Å. The methods of determining helium and mercury densities have been described previously.[3,4]

The samples used in X-ray diffraction analysis were reduced, using the same conditions as those above. They were opened under petroleum ether and stored for a few days under this liquid. The samples, wet with petroleum ether, were ground to a paste, mixed with collodion and partly extruded from a section of stainless steel tubing. This technique is described by Barrett.[17] The tubing was 19 gage 0.7 mm. inside diameter. The specimens were mounted in a Debye–Scherrer powder camera of 71.62 mm. inside diameter. FeK_α radiation from a sealed-off X-ray tube equipped with beryllium windows with manganese dioxide filters was used. The tube was operated at 30 kv. and 7 ma.

Experimental Results

Surface-area data for unreduced and reduced catalysts and similar preparations are given in Table I. Also included are areas for the cobalt–promoter complex[7] computed by assuming the area of the kieselguhr to be additive. Since part of the surface area of the kieselguhr may be covered or blocked by the cobalt–promoter complex, this area of complex must be considered as the lower limit of its actual value. Nitrogen isotherms at −195° of pelleted catalyst 89J before and after reduction are given in Fig. 1.

Data for changes in surface area during a one-hour treatment with nitrogen at 400° and in a subsequent evacuation at 400° for sixteen hours are presented in Table II. Data for helium and mercury densities (the latter determined at 1 atmosphere), pore volumes,[18] and average pore diameters, $\bar{d}$, computed from the equation for open end cylindrical pores[19] $\bar{d} = 4V/A$, where V is the pore volume and A the surface area, are given in Table III. In Table IV data for the chemisorption of carbon monoxide are presented and compared with the volume of nitrogen required to form a physical monolayer. In Fig. 2 are typical carbon monoxide and nitrogen isotherms at −195° for reduced catalysts. In Table V are given X-ray diffraction data for catalysts and similar preparations.

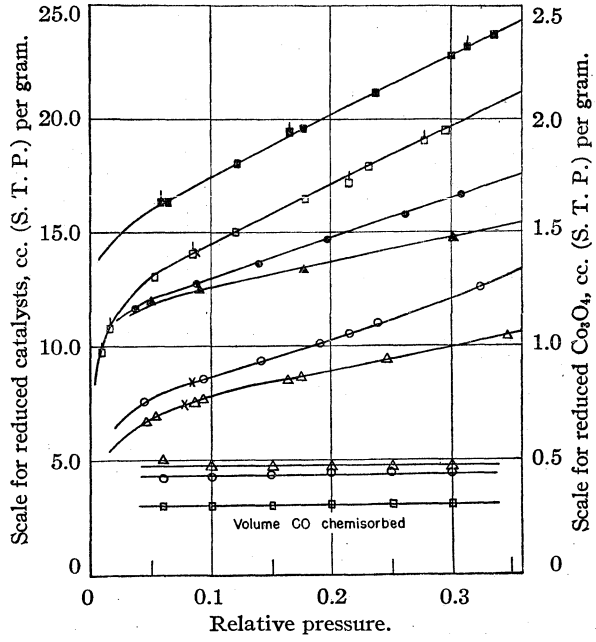

Fig. 2.—Sorption of nitrogen and carbon monoxide at −195° on reduced pelleted catalysts 89H and 89J and reduced cobalt oxide powder where open points represent nitrogen and solid points represent carbon monoxide isotherms. Points of reduced 89H are given by ○, two samples of reduced 89J by □ and ⊡, and the reduced cobalt oxide by △. The volumes of chemisorbed carbon monoxide are given in lower part of the graph.

Changes of Surface Area on Reduction

In Fig. 1 the circles, squares and triangles of the isotherm of the reduced catalyst indicate the reproducibility of isotherms of three different reductions of pelleted catalyst 89J. Isotherms of both unreduced and reduced catalysts showed hysteresis at relative pressures greater than 0.4. The hysteresis loop in the range of relative pressures of 0.4 to 0.7 was considerably smaller for the reduced catalyst than for the unreduced, the hysteresis of the isotherm of the reduced catalyst being only slightly greater than that of the isotherm of the kieselguhr that it contained. This may indicate enlargement or removal of some of the pores of diameters less than 50 Å., since hysteresis in this range is usually related to the presence of small pores.

The data in Table I show that the surface areas of all of the catalysts studied decreased on reduction. The areas of the cobalt-promoter complex[7] of the catalysts containing both promoters and carriers decreased to 37.4 to 75% of the area of the complex of the unreduced catalysts. The area of catalysts with promoter but no kieselguhr decreased to 8.5 to 34.1% of the unreduced areas. The areas of the complex of preparations containing kieselguhr but no promoters decreased to 7.8 to 10.9% of the unreduced areas, and the area of the preparation with neither promoter nor carriers decreased to 2.0% of the unreduced area. Thus it is observed that catalysts of the 89 type were most resistant to sintering upon reduction. Catalysts with calcined and flux-calcined kieselguhrs, 89BB and 89H, respectively, did not sinter any more

(18) The volume of pores with openings smaller than 5 microns in diameter (pores not filled by mercury at atmospheric pressure) computed from the difference of the reciprocals of the mercury and helium densities.

(19) Emmett and DeWitt, THIS JOURNAL, 65, 1253 (1943).

than catalysts prepared from natural kieselguhrs. However, since the areas of these catalysts in the unreduced state were less than those of catalysts with the natural kieselguhrs, the areas of reduced catalysts 89H and BB were less than the rest of the 89 series. Of the individual promoters, magnesia added as a powder appears to be the most effective and thoria the least. However, the data for the preparations with powdered magnesia may be misleading, since the magnesia itself has a high area which is probably not appreciably decreased in the preparation or reduction[20] and thus may increase the total area. Consistent with this, the volume of chemisorbed carbon monoxide per unit surface area (Table IV) was less for preparations with powdered magnesia than for the other samples. Thoria was not very effective in preventing sintering in either the cobalt–thoria preparation or in catalyst 108B. Kieselguhr appears to be nearly as effective as the thoria, the natural kieselguhrs being only slightly more effective than flux-calcined Hyflo Super-Cel.

The surface areas of unreduced catalysts[3] as granules (broken filter cake) was 10 to 15% greater than those of corresponding pelleted catalysts. Here, the explanation was given that the decrease in area on pelleting was due to compression of some of the particles of the cobalt-promoter complex so that nitrogen molecules could not penetrate the spaces between them. After reduction granular catalyst 89K had the same area as reduced pelleted 89K. This is consistent with the previous hypothesis since reduction could cause enlargement of pores so that all of the surface would be accessible.

The data in Table II show the changes in surface area upon heating or evacuations at 400° and during the reduction. The area of the cobalt basic carbonate decreased considerably upon both heating and reduction. The area of the catalyst with kieselguhr but no promoters likewise decreased sizably both on heating and reduction, but not as greatly as the cobalt basic carbonate. The area of the promoted preparation without kieselguhr decreased sizably on heating but only slightly on reduction. The area of the catalysts with both promoters and carriers decreased less in both steps than other preparations, the greatest decrease occurring in the heating step. Thus the kieselguhr appeared to be somewhat effective in preventing sintering of the surface during the heating step and less effective during the reduction. The promoters were about as effective in preventing sintering in the heating step as the kieselguhr, but very effective in inhibiting sintering during reduction. The catalysts containing both promoters and carriers which combine both of the protective actions sinter least in both of the steps.

Changes in Densities and Pore Volumes on Reduction

In Table III the mercury densities determined at 1 atmosphere (under these conditions mercury should penetrate only pores larger than 5 microns in diameter[21]) show that preparations containing kieselguhr did not change in volume as measured by mercury on reduction, whereas the volume of mercury displaced by preparations without kieselguhr decreased considerably. This is shown in the last two columns of Table III. This agrees with the role of the kieselguhr postulated previously[3] —that the kieselguhr acts as a "brush-pile" which defines the volume of the catalyst particle.

It was found that the mercury wet the reduced cobalt basic carbonate (pure cobalt metal) to some extent, which, of course, invalidates the usual interpretation of mercury densities; however, this was the only sample upon which this phenomenon was observed. Presumably, the presence of promoters or kieselguhr prevents such wetting. Should this occur to a slight extent on all of the reduced catalysts, the general picture of the changes in volume on reduction would not be altered, since the changes in volume are easily observed visually.

The helium densities were less accurate than the mercury densities due to the small volume of helium displaced by the reduced catalysts. However, repeated determinations on the same sample usually agreed within 3%. With exception of the low helium density observed with the reduced cobalt–thoria–magnesium oxide preparation, for which we have no explanation except possibly incomplete reduction, the observed densities differed no more than 4% from those computed from the catalyst composition, assuming no solution or compound formation of the catalyst components.

The pore volumes of all the catalysts containing kieselguhr increased on reduction, but those of preparations without this carrier decreased. Average pore diameters were computed by the equation of Emmett and DeWitt[19] for cylindrical open-end pores. Since the decreases in surface area were always greater than decreases in pore volume, the average pore diameters always increased on reduction.

Reduction was accompanied by a decrease in surface area and in some cases by a decrease in bulk volume. With unpromoted and unsupported cobalt, large changes occurred in both. When cobalt atoms are formed by reduction, they must be able to migrate until they find stable sites in the lattice of the already reduced metal. In fact, in the reduction of the cobalt oxide powder (Table I) for twenty-four hours at 250° hexagonal aggregates or possibly crystals of cobalt several microns in diameter were formed.[10]

Kieselguhr provides a framework which prevents the decrease in bulk volume on reduction and at the same time inhibits sintering of the surface. The cobalt–promoter complex probably shrinks about the kieselguhr particles, thus inhibiting the growth of large crystallites of cobalt.

The promoters, which at least in the case of

(20) Zettlemoyer and Walker, *Ind. Eng. Chem.*, **39**, 69 (1947).

(21) Ritter and Drake, *Ind. Eng. Chem., Anal. Ed.*, **17**, 782 (1945).

thoria and precipitated magnesia are thoroughly mixed with the cobalt basic carbonate, have a more intimate role than the kieselguhr. In the change from the basic carbonate to cobalt metal, the volume of the part containing the cobalt decreases several-fold. The cobalt atoms possibly retreat from the surface, leaving a matrix of the relatively unchanged promoter which inhibits migration of atoms and growth of large crystallites.

Chemisorption of Carbon Monoxide on Reduced Catalysts

In the research of Emmett and Brunauer[11,22] the chemisorption of carbon monoxide at −195° was taken as an indication of the extent of iron present on the surface of the iron catalysts. Figure 2 shows typical isotherms of carbon monoxide and nitrogen at −195° on reduced cobalt catalysts and cobalt oxide powder plotted on a relative pressure basis. Since the physical properties of carbon monoxide and nitrogen including molecular size are nearly identical, the nitrogen isotherm was taken equal to the physical carbon monoxide isotherm. The difference of the carbon monoxide (physical plus chemisorption) and nitrogen isotherms at equal relative pressures was taken as the volume of chemisorbed carbon monoxide. The constancy of these differences as shown in Fig. 2 demonstrates the correctness of this assumption. Emmett and Brunauer[11,22] found that the ratio of the amount of chemisorbed carbon monoxide to the physically held monolayer, as determined by the B.E.T. method[16] on pure iron, was 1.10 to 1.18, while on two nickel preparations Emmett and Skau[23] observed ratios of 0.92 and 1.78. Ratios slightly larger than one, such as observed on pure iron catalysts, may be explained by assuming the chemisorbed molecules to be more densely packed in the chemisorbed layer than in the physically held one. On reduced cobalt oxide powder and cobalt basic carbonate the ratios of chemisorbed carbon monoxide to the monolayer of physically held nitrogen were only 0.65. The reasons for these differences of these ratios for pure iron and cobalt are not known. However, Emmett[24] found that with highly sintered iron preparations this ratio was less than 1. The two pure cobalt preparations described in the present paper may be regarded as highly sintered.

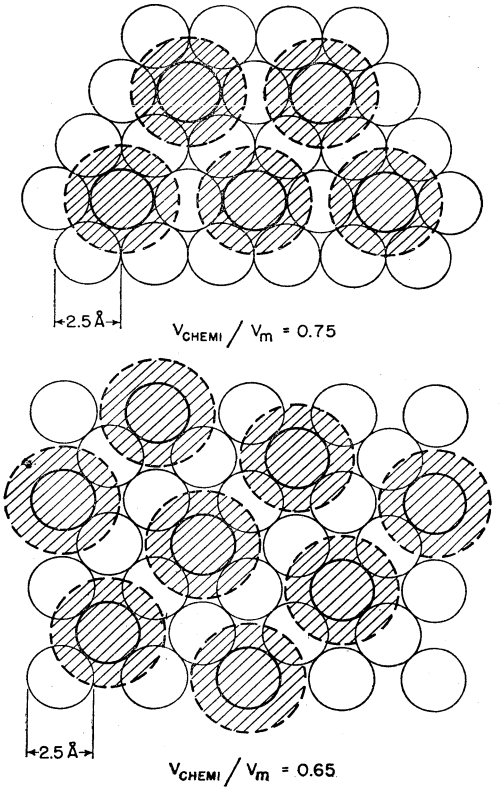

Fig. 3.—A representation of the manner that carbon monoxide may chemisorb on a cobalt surface. The upper drawing represents the closest packed faces of α- or β-cobalt, and the lower drawing the 100 faces of β-cobalt. Chemisorbed carbon monoxide molecules (the sectioned, dotted circles) are assumed to attach to the centers of cobalt atoms. The diameters of these circles give a cross sectional area of 16.2 sq. Å. per molecule in a close packed monolayer.

An explanation which is probably greatly oversimplified may be given from the geometry of possible cobalt surfaces. Two of the possible crystal faces of α- and β-cobalt are shown in Fig. 3. If chemisorbed molecules are assumed to attach to the centers of the cobalt atoms, the size of the molecule will prevent adsorption on adjacent cobalt atoms. The resulting ratios of chemisorbed to physically held molecules will be 0.65 and 0.75 for the faces shown, which are near the ratios observed for cobalt metal in the reduced cobalt oxide powder and cobalt basic carbonate.

For the reduced cobalt–thoria–magnesia kieselguhr catalysts the ratios of chemisorbed carbon monoxide to the V_m value for the complex varied from 0.259 to 0.470, and for the cobalt–thoria–kieselguhr catalyst this ratio was 0.448. The ratios of chemisorbed carbon monoxide to the nitrogen–monolayer for cobalt–promoter and cobalt–kieselguhr preparations varied from 0.461 to 0.586. Cobalt–thoria preparations had higher ratios than those of cobalt–magnesia.

The ratio of chemisorbed to physically held molecules divided by the ratio for pure cobalt metal, 0.65, may not be an accurate indication of the extent of cobalt atoms in the catalyst surface, since, as shown in Fig. 3, all of the atoms adjacent to the cobalt atom adsorbing the carbon monoxide could be replaced by promoters without changing the ratio. In any case, the data of Table IV indicate that the surface of the catalyst with both pro-

moter and carrier must be covered to at least 30% by substances other than cobalt.

X-Ray Diffraction Patterns of Reduced Cobalt Catalysts

The diffraction patterns of this series of preparations in the reduced state show the effect of promoters (thoria and magnesia) and the support (kieselguhr) on crystallite size. The background due to scattering from the amorphous constituents of the catalysts, particularly thoria and kieselguhr, makes exact evaluation of line broadening difficult; nevertheless the trends are unmistakable. Reduced cobalt basic carbonate gave the sharpest diffraction pattern, but some line broadening corresponding to crystallites about 800 Å. diameter was observed. The most diffuse patterns were obtained from 108B, Co:MgO (100:12), Co:ThO_2:MgO (100:6:12), 89J and 89H. The line broadening of this group corresponded roughly to crystallites of 100–300 Å. The preparations Co:ThO_2 (100:6), Co:Filter-Cel (100:200), and Co:MgO (100:8) gave line broadening corresponding to crystallites 300–600 Å. diameter. These results are in general agreement with surface area measurements.

The diffraction patterns of many of these preparations lack expected reflections. This has been previously noted[9] in connection with fully promoted and supported catalysts. The diffraction pattern of the reduced cobalt basic carbonate contained relatively strong 111, 200, 220, and 311 lines of face-centered cubic cobalt as well as faint $10\bar{1}0$ and $10\bar{1}1$ lines of hexagonal close-packed cobalt; such a pattern would normally be expected of a mixture of a relatively large amount of f.c.c. cobalt and a small amount of h.c.p. cobalt. With increasing amounts of promoter and support the 200-f.c.c. line and the $10\bar{1}0$- and $10\bar{1}1$-h.c.p. lines tend to disappear; in a fully promoted and supported catalyst, such as 89J and 108B, the 200-f.c.c. and $10\bar{1}0$- and $10\bar{1}1$-h.c.p. lines cannot even be identified with certainty. It is interesting to note that the persistent lines 111, 220, and 311 of f.c.c. correspond to 0002, $11\bar{2}0$, and $11\bar{2}2$ of h.c.p., respectively, in interplanar spacing. Among the partly promoted or supported preparations, those containing magnesia produced a weak but unmistakable 200-f.c.c. reflection, whereas neither the $10\bar{1}0$- or the $10\bar{1}1$-h.c.p. lines could be positively identified. The converse is true of those partly promoted or supported preparations containing no magnesia. A theoretical discussion of this phenomenon will be published shortly.

Discussion

Promoters may have two functions: first, that of maintaining or increasing the extent of the surface and, second, that of providing a surface of the proper physical or chemical nature. In some cases a single promoter may perform both of these functions and in other cases only one of them. Russell and Taylor[25] showed that thoria as a promoter in nickel catalysts performed both of these functions. The surface area as estimated by the chemisorption of hydrogen and carbon dioxide was increased 20 to 40%, while the activity for hydrogenation of carbon dioxide to methane increased nine fold. Similarly, thoria in cobalt–thoria–kieselguhr catalysts may accomplish both of these functions. Alkali in precipitated- or fused-iron Fischer–Tropsch catalysts appears to alter the distribution of products but does not increase the surface area or activity appreciably. In doubly promoted (alumina–potassium oxide) synthetic ammonia catalysts, alumina is an effective structural promoter and potassium oxide is assumed to alter the chemical nature of the surface to inhibit formation of imide and amide groups on the surface.[11] The studies of Emmett and Brunauer[11] and others demonstrate these effects. The data in the present paper show chiefly the effect of promoters and carriers in maintaining surface area, but the X-ray diffraction and chemisorption data give some information as to the nature of the surface.

The chemisorption studies indicate that a sizable fraction of promoter was present on the catalyst surface. In addition to greater surface areas and surface stability of the promoted catalysts, the relatively isolated metal atoms or groups of atoms at the surface may have greater activity than that of crystallites of unpromoted metals.

The X-ray diffraction data were in qualitative agreement with surface–area measurements, but in addition revealed that the cobalt metal in promoted and supported catalysts had an anomalous crystal structure. The presence of the promoters and the support favored this anomalous structure. It should be noted that X-ray diffraction studies reveal the average structure of the crystallites of cobalt and not just the surface.

It has been suggested that kieselguhr as a carrier in cobalt and nickel catalysts produces the proper degree of dispersion of the active metal and gives the desired porosity.[26] The data in this paper demonstrate the manner in which these effects are accomplished. Kieselguhr provided a framework about which the metal oxide complex shrank when reduced to the metal. Kieselguhr also provided a system of large, accessible pores and appeared to prevent excessive decrease in the area of the metal. It should be noted that in our catalysts the cobalt–promoter complex was deposited chiefly in the pores of the kieselguhr that were larger than 5 microns.[3]

Upon reduction, the bulk volume of the catalyst containing kieselguhr remained unchanged, whereas the bulk volume of the unsupported catalyst decreased several fold. Kieselguhr as a carrier is important if the reaction is highly exothermic, as in the Fischer–Tropsch synthesis, or

if the catalyst is reduced in the reactor. If the reaction is highly exothermic, the heat produced by a dense, unsupported catalyst may exceed the capacity of the reactor to remove the heat of reaction, and the catalyst may overheat. This is possibly the reason for the great improvement in life of cobalt and nickel Fischer–Tropsch catalysts when kieselguhr was used as a carrier.[27] Pichler[28] has stated that industrial development of the synthesis in Germany appeared possible only after the introduction of kieselguhr as a carrier for cobalt catalysts. If the catalyst is to be reduced in the converter, the large decrease in bulk volume on reduction of unsupported catalysts will cause a large amount of reactor space to be wasted.

Ries[29] and Visser and DeLange[30] have shown that unreduced catalysts of cobalt and nickel, respectively, precipitated in the presence of kieselguhr have considerably higher surface areas per gram of active metal than the unsupported catalyst. Visser and DeLange have shown the formation of hydrosilicate bonds between the nickel and kieselguhr. With our catalysts the presence of kieselguhr does not greatly increase the area of the unreduced catalyst, and there is very little evidence to indicate any reaction of cobalt with the kieselguhr. In fact, in the standard methods of preparing the cobalt catalysts these effects are minimized by keeping the time of contact of the reacting solutions with the kieselguhr as short as possible.

Craxford[31] studied the rates of carbiding, hydrogenation of carbide and synthesis on cobalt–thoria–kieselguhr (100:18:100) catalysts and on similar preparations with thoria or kieselguhr or both omitted. The rate of hydrogenation of ethylene was taken as an indication of the surface area, and since these rates were of the same magnitude, it was assumed that the surface areas were about equal. Hence, Craxford concluded that thoria and kieselguhr do not act primarily by increasing the available cobalt area, but as specific promoters for formation and reduction of carbide.

The data presented in the present paper indicate that the differences in both total surface area (Table I) and area of cobalt (Table IV) are quite large. The volume of chemisorbed carbon monoxide per gram of complex varied roughly in the same manner as Craxford's activities for carbide formation and reduction and for the synthesis. The uncertainties of this comparison are large because: (a) in some cases the catalysts compared did not have the same composition, and (b) the methods of catalyst preparation may have been considerably different. However, we believe that this comparison shows the activities of Craxford's catalysts to be strongly a function of surface area.

Acknowledgment.—The authors are pleased to acknowledge the assistance of Norma Golumbic and Harlan Hewlett in catalyst preparation, Raymond Hahn for some of the density measurements, and W. C. Peebles for X-ray diffraction studies.

Summary

1. Reduced cobalt–thoria–magnesia–kieselguhr and cobalt–thoria–kieselguhr catalysts and similar preparations with one or more of the components omitted have been studied by nitrogen surface areas and carbon monoxide chemisorptions at −195°, mercury and helium densities, and X-ray diffraction.

2. The promoters were found to prevent excessive decreases in surface area on reduction.

3. Kieselguhr as a carrier was somewhat effective in preventing the decrease of surface area on reduction, but its most important function was to prevent the decrease in bulk volume of the catalyst on reduction.

4. The carbon monoxide chemisorption studies showed that an appreciable fraction of the surface was occupied by promoter.

5. The X-ray diffraction data were in qualitative agreement with the surface-area determinations, but in addition indicated that the cobalt in supported and promoted catalysts had an anomalous structure.

Transference Numbers and Hydration of Some Quaternary Ammonium Salts[1]

BY CECIL H. HALE[2] AND THOMAS DE VRIES

It is a generally accepted fact that ions in aqueous solution are hydrated to some extent. The degree of hydration depends, amongst other factors, upon the nature and size of the ion. Von Hevesy[3] has shown that nearly all univalent organic ions are so large and the strength of the electric field surrounding them so weak that hydration should not occur. If organic ions are not hydrated, the electrolytic transfer of water in solutions of tetraalkylammonium salts should show a transfer of water to the anode equivalent to the amount of water carried by the anions alone or, more probably, the results should show a trend of less hydration for the larger organic cations. In this research, the electrolytic transfer of water in solutions of tetramethyl-, tetraethyl-, tetra-*n*-propyl-, and tetra-*n*-butylammonium iodides was studied. Maltose was used as the non-electrolyte because it has a high optical rotation and its concentration can be measured very accurately by means of a polarimeter. Some experiments were also made in which acetone and ethyl acetate were the reference substances. The well-known Nernst method as developed by Washburn[4] was used in this investigation.

Apparatus and Experimental

The transference apparatus shown in Fig. 1 is a modification of the one described by MacInnes and Dole.[5] It was constructed of Pyrex glass tubing of 19 mm. internal diameter. The stopcocks which separated the anode and cathode compartments were hollow and open at each end to permit the circulation of water through them when the apparatus was in the constant temperature bath. The apparatus consisted of two sections, connected by a spherical joint to allow the anode and cathode compartments to be weighed. The total length of 130 cm. contained 10 bends, spaced to reduce convection and diffusion during electrolysis. For analysis the solution in the apparatus was divided into five portions. The approximate volumes of the different compartments were: cathode, 115 ml.; anode, 150 ml.; cathode middle, 40 ml.; anode middle, 40 ml.; middle, 90 ml. There was never any appreciable variation in the concentrations of the three middle compartments, which proved the effectiveness of the design of the apparatus in the prevention of diffusion and convection.

The electrodes were made of silver and silver iodide, deposited electrolytically on 18-gage platinum wire.

Silver coulometers were used to measure the current. The silver nitrate solutions from the platinum crucibles were filtered through sintered glass crucibles to prevent the loss of deposited silver. One coulometer was connected to each electrode in order to detect any electrical leaks. It was necessary to coat the glass joints with picein wax to prevent such leaks.

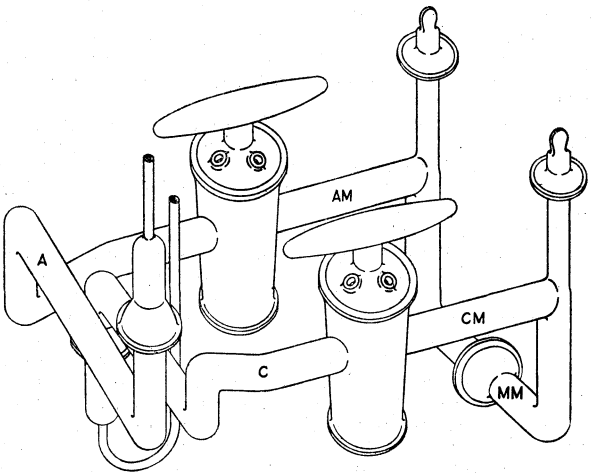

Fig. 1.—Transference apparatus: A, anode compartment; AM, anode middle; MM, middle middle; CM, cathode middle; C, cathode compartment.

The polarimeter was a Schmidt and Haensch instrument which could be read to ±0.01 degree of rotation. Light of wave length 5893 Å. was obtained from a tungsten bulb by means of a monochromator. A four decimeter tube was used.

Electrolysis experiments were carried out in a thermostat maintained at 25 ± 0.02°.

Quaternary ammonium iodides were prepared from alkyl iodides and the corresponding tertiary amines. The compounds were purified by repeated recrystallizations from ethyl acetate to which a small amount of ethanol had been added.

The silver cyanide solution for silver plating the electrodes was prepared by the dissolution of 46 g. of silver nitrate, 70 g. of potassium cyanide, 31.5 g. of sodium carbonate and 0.5 g. of sodium thiosulfate in one liter of distilled water.

The maltose used was Merck, "purified" grade. Electrical conductivity measurements showed it to be free from electrolytes.

In the transference experiments, the electrolysis was allowed to continue for about forty-eight hours. A potential of about 50 volts was necessary to obtain the desired current of about 5 milliamperes. At the end of the electrolysis, the stopcocks were closed and the anode middle, cathode middle and middle solutions were transferred by means of a pipet to weight burets. The apparatus was then removed from the bath and the two sections separated, cleaned and dried, the stopcocks remaining closed. The two sections were first weighed before the solutions were transferred to weight burets.

Analysis.—The quaternary ammonium salt solutions were titrated with 0.05 *M* silver nitrate at about 50°. The end-point was determined potentiometrically using a Garman and Droz[6] titrimeter. Weight burets were used in all the titrations.

The concentration of the maltose in grams per 100 ml. in the solutions were found from the equation $0.1923\alpha - 0.010$, where α is the optical rotation. This relation was established by measuring the rotation of solutions of known concentration. The presence of the quaternary

ammonium iodides was found to have no measurable effect on the optical rotation of the solution.

Acetone determinations were made by a method based on the formation of iodoform.[7] The deviation of triplicate determination was 0.1%.

Ethyl acetate was determined by hydrolysis in alkaline solution. A measured excess of carbonate-free 0.35 *N* sodium hydroxide solution was added to a weighed sample and refluxed for forty-five minutes, and back titrated with 0.1 *N* sulfuric acid. With a correction from blank determinations the deviation of triplicate determinations was 0.05%.

The transference numbers of sodium and potassium iodide were determined to test the apparatus and the techniques. The values obtained at the anode and the cathode agreed well with each other and with the values in the literature to within 0.001.

The quaternary ammonium iodides invariably gave a much larger value for the cation transference number at the anode than at the cathode. A typical set of values are presented in Table I. The deposit on the anode did not have the appearance of pure silver iodide, but was white and somewhat flocculent. Further, the transference numbers calculated from the analysis of the anode solutions did not agree in successive experiments. These facts indicated that formation of solid solutions of the quaternary ammonium iodide with silver iodide. A solution of tetramethylammonium iodide was electrolyzed in a small beaker with no attempt made to separate the solutions at the silver-silver iodide electrodes. The final solution was analyzed for iodide ion concentration and it was found that approximately one mole of tetramethylammonium iodide had disappeared for every four moles of silver iodide deposited at the anode. The transference numbers obtained from measurements of anode solutions were recalculated on the assumption that solid solutions of the quaternary ammonium iodide and silver iodide were formed in the ratio of one to four. The values were in approximate agreement with those obtained at the cathode. In every case, the ratio necessary to give complete agreement was between one to three and one to five.

TABLE I

TRANSFERENCE NUMBER OF TETRAETHYLAMMONIUM IODIDE

Experiment no.	15	16
Initial concn., mole/kg.	0.1013	0.1013
Final concn., anode soln.	0.0888	0.0864
Final concn., cathode soln.	0.1094	0.1113
Final concn., anode middle	0.1010	0.1012
Final concn., cathode middle	0.1011	0.1011
Wt. of anode soln., g.	144.695	144.467
Wt. of cathode soln., g.	115.370	115.107
Wt. of Ag in coulometers, g.	0.4352	0.5477
t_c at anode	0.467	0.437
t_c at cathode	0.236	0.237

The transference numbers of the quaternary ammonium iodides were first measured with no reference substance added and these results are presented in Table II. The concentrations of the salts were about 0.1 *M* except in the case of the tetra-*n*-butylammonium iodide where, because of limited solubility, it was necessary to use about 0.07 *M* solutions. Several attempts to electrolyze solutions of the tetrabutylammonium salt were unsuccessful because of the formation of hydrogen at the cathode. This difficulty was overcome by the use of a silver bromide electrode for the cathode.

Hydration of Ions.—The electrolytic transfer of water in solutions of the quaternary ammonium iodides was measured with maltose as the reference non-electrolyte. The results of a typical experiment with 0.1 *M* solutions of tetraethylammonium iodide are given in detail in Table III. The results with tetramethyl- and tetra-*n*-propylammonium iodides are included in Table IV, which also shows the values found with the other reference substances. Experiments in which tetra-*n*-butylammonium iodide and maltose were used were unsuccessful because of the formation of crystals at the cathode and slight gassing at the anode.

Acetone and ethyl acetate also were used as reference non-electrolytes. Two experiments were made with 0.1 *M* tetramethylammonium iodide which contained 0.1% acetone. The limited accuracy of the analytical method for determining acetone casts some doubt on the values of the actual amount of water transported. However, the results confirmed at least qualitatively those obtained with maltose, and a transfer of water toward the cathode apparently occurred in each case. Acetone could not be used as a reference non-electrolyte with solutions of the other quaternary ammonium iodides because the addition of iodine, involved in the determination, formed precipitates with the higher salts.

(7) M. B. Jacobs, "The Analytical Chemistry of Industrial Poisons, Hazards and Solvents," Interscience Publishers, Inc., New York, N. Y., 1941, p. 535.

Ethyl acetate was used as the reference substance in the electrolysis of tetramethyl-, tetraethyl- and tetrabutylammonium iodide. In each case water was apparently transferred toward the cathode, as was the case with maltose. These results are included in Table IV.

The transfer of water toward the cathode during the hydrolysis indicates that the cation is more highly hydrated than the anion, which is contrary to the prediction that large organic ions should not be hydrated. A plausible explanation of this failure to follow prediction is that the changes in concentration of the reference substance are not only caused by the transfer of water but also by the transfer of the non-electrolyte to the anode. The assumption that the reference substance is carried along with the iodide ion is substantiated by the fact that the anion transference number is decreased by the addition of non-electrolyte. The effects of the non-electrolytes on the cation transference numbers are shown in Table V.

TABLE V

EFFECTS OF NON-ELECTROLYTE ON CATION TRANSFERENCE NUMBERS

Salt	Cation transference number: Nothing added	Maltose added	EtOAc added
$(CH_3)_4NI$	0.322	0.340	0.356
$(C_2H_5)_4NI$	.237	.254	.278
$(C_3H_7)_4NI$	.175	.153	...
$(C_4H_9)_4NI$	.105	...	.110

The association of non-electrolytes with ions in solution has been suggested by Fisher and Koval.[8] They found that sucrose, acetone and urea reduced the transference number of the hydrogen ion in solutions of sulfuric acid and concluded that complex ions of the type, $H_3O^+ \cdot$non-electrolyte, exist. Longsworth[9] recently used the moving boundary method to measure water transport in solutions of alkali chlorides with various reference non-electrolytes. He also concluded that the reference substances were not electrically inert and therefore not stationary during the electrolysis.

If one assumes that neither the iodide ion nor the quaternary ammonium ion is hydrated, that is, that the water molecules are stationary, then the amount of reference non-electrolyte carried along by the iodide can be calculated. The results for such a calculation are presented in Table VI based on the data obtained with maltose, ethyl acetate and acetone. Only about one per cent. of the iodide ions need to be associated with an equivalent amount of maltose to explain the experimental results. One might also assume that the iodide ion but not the quaternary ammonium ion is hydrated and calculate the amount of reference substance associated with the iodide ion. In Table VII are given the results of such a calculation for maltose when the iodide ion is arbitrarily assigned hydration values of five and of ten molecules of water.

TABLE VI

AMOUNT OF REFERENCE SUBSTANCE ASSOCIATED WITH IODIDE IONS ASSUMING WATER STATIONARY

TABLE VII

AMOUNT OF MALTOSE ASSOCIATED WITH IODIDE IONS HYDRATION VALUES OF IODIDE ION ASSUMED

Salt	Mole of maltose per mole of iodide ion: I^-	$I^- \cdot 5H_2O$	$I^- \cdot 10H_2O$
$(CH_3)_4NI$	0.011	0.020	0.028
	.012	.020	.029
$(C_2H_5)_4NI$	.011	.019	.028
	.008	.017	.025
$(C_3H_7)_4NI$	.008	.015	.023
	.006	.016	.024

Summary

The transference numbers of 0.1 *M* solutions of tetramethyl-, tetraethyl-, tetra-*n*-propyl- and tetra-*n*-butylammonium iodide have been measured. The cation transference numbers were found to decrease as the size of the cation increased.

The electrolytic transport of water was measured in solutions of the same quaternary ammonium iodides with maltose, acetone and ethyl acetate as reference non-electrolytes. The results indicated that the reference substances were associated with a small fraction of the iodide ions and could not serve to determine the degree of hydration of the ions.

Quantum Yields of the Photochemical Reduction of Ceric Ions by Water and Evidence for the Dimerization of Ceric Ions

BY LAWRENCE J. HEIDT AND MAYNARD E. SMITH[1]

Water solutions containing ceric perchlorate and perchloric acid evolve oxygen when they absorb ultraviolet light and the ceric is reduced to cerous perchlorate.[2]

Baur[2a] and Weiss and Porret[2b] studied the photochemical reaction in the full light of a quartz mercury arc lamp. Weiss and Porret obtained maximum gross quantum yields of the order of one-tenth in solutions one-tenth molar in ceric perchlorate and one molar in perchloric acid. Their quantum yields decreased as the cerous perchlorate accumulated.

We have measured the quantum yields of the reaction when the solutions are irradiated with monochromatic light of λ 254 mμ. The light intensity, I, and the concentrations of cerous, c_3, and ceric, c_4, perchlorates were varied many fold. The perchloric acid concentration, c_2, was held at 1.03 ± 0.03 M and the ionic strength, μ, at 1.1 ± 0.1, all at 23 ± 3°.

Solutions of ceric perchlorate in perchloric acid are thermally unstable at 25°. The equilibrium ratio c_4/c_3 is about 10^{-8} in molar perchloric acid in equilibrium with the atmosphere (p_{O_2} = 0.2 atm.), but the rate of the thermal reduction of the ceric perchlorate by water is extremely slow. In one of our stock solutions which was 5.3 M in perchloric acid and was kept in the dark at 25 ± 3°, c_4 decreased from 1.36 to 1.20 M in eleven months while c_3 increased from 0.32 M.

Materials.—The chemical reagents were of analytical reagent grade or were prepared from material of this quality. The water was chloride-free distilled water.

Stock solutions of ceric and cerous perchlorates were prepared from a sample of snow white granular ceric oxide, 98.5% pure CeO_2, which was supplied by the Rohm and Haas Chemical Co., Philadelphia, Pa.

The ceric oxide could not be converted directly into ceric perchlorate even when dispersed as a fine hydrous oxide in 72% perchloric acid at room temperature or at 100° for periods of several months.

The ceric perchlorate was finally prepared by reducing the ceric oxide to cerous ions by bromide in perchloric acid. The bromine and excess bromide were removed by boiling. The cerous ions were then oxidized electrolytically to the ceric state. The experimental details follow.

Forty grams of the granular ceric oxide and 80 g. of sodium bromide were added to 275 ml. of 72% perchloric acid. The mixture was simmered for two hours under an appropriate hood. The hot solution was filtered by suction through a sintered glass filter. The filtrate was boiled down to half its initial volume; on cooling a colorless solid separated which was removed by decantation and filtering as above. The colorless filtrate, stock solution C, contained 1.68 moles of cerous perchlorate and 5.3 moles of perchloric acid per liter of solution. It contained no material oxidizable by ceric sulfate.

The stock solution B of ceric perchlorate was made by electrolyzing 63 ml. of solution C in a Pyrex beaker. The cylindrical electrodes were of platinum gauze of the type used for copper determinations. They were placed coaxially in the beaker and the smaller electrode was rotated rapidly to stir the solution. The beaker was surrounded by running tap water. The current density was kept for eleven hours at roughly 0.1 amp. per sq. in. of the anode surface. The solution then contained 1.36 moles of ceric perchlorate, 0.32 mole of cerous perchlorate and 5.3 moles of perchloric acid per liter of solution. The concentration of sodium perchlorate in solutions B and C was less than 10/3 the total cerium concentration. About 9.26 moles of sodium perchlorate dissolve in a liter of water solution at 25° and the density of the solution is 1.678 g. per ml.

Analytical Procedures.—The methods of analysis were entirely volumetric. The primary standard of oxidimetry was U. S. Bureau of Standards Sample 40b of sodium oxalate. The primary standard of acidimetry was potassium acid phthalate.

The cerous, ceric and acid concentrations were determined by essentially the same procedures used by M. S. Sherrill, C. B. King and R. C. Spooner.[3] Several modifications require mention. In determining c_4, 2 ml. of concd. sulfuric acid were added to each 5 ml. sample analyzed and the resulting solution after mixing was either titrated immediately or heated in boiling water for five minutes. Five or ten drops (0.25 or 0.50 ml.) of 0.0043 M orthophenanthroline indicator were used to identify the end-point in each analysis. The titrations were carried out with ferrous sulfate or ferrocyanide solutions. End-points were reproduced at best to $\pm 10^{-7}$ mole of ceric ion. This was accomplished by using similar test-tubes for all the titrations and viewing the solutions end on against a white illuminated background.

The actinometer solutions of uranyl oxalate were titrated at 80° with permanganate solution after adding 2 ml. of 4 N sulfuric acid per 10 ml. of the oxalate sample. End-points were determined to $\pm 10^{-8}$ mole of oxalate by means of the differential electrometric method previously developed.[4] Care was taken to minimize even local excesses of the permanganate until the end-point was reached.

Absorption spectra of the solutions were mapped out by means of a Hilger sector photometer backed by a quartz spectrograph. The cerous solutions were colorless, the ceric solutions ranged from colorless in the case of the most dilute solutions to amber in the case of the most concentrated solutions.

Extinction coefficients, ϵ, were measured in the region of λ, 254 mμ by means of a Beckman ultraviolet spectrophotometer. Values of ϵ were calculated by means of the equation $\epsilon = (1/cd) \log_{10} (I_0/I)$ when c is the concentration of the solute in moles per liter of solution, I_0 and I are the intensities of the light beams after traversing equal depths, d in cm., of the solvent and solution, respectively. Water, perchloric acid and sodium perchlorate absorbed a negligible amount of light of λ, 254 mμ in the cerous and ceric solutions over the range of concentrations and depths

(1) The part of this article concerned with the experimental study of the effect of cerous perchlorate upon the reaction is taken from the thesis submitted by Maynard E. Smith in September, 1946, to the Department of Chemistry of the Massachusetts Institute of Technology in partial fulfillment of the requirements for the degree of Master of Science.

(2) (a) E. Baur, *Z. physik. Chem.*, **63**, 683 (1908), was the first to identify oxygen as the gaseous product of the reaction. This was ater confirmed by (b) J. Weiss and D. Porret, *Nature*, **139**, 1019 (1937).

TABLE I

EXTINCTION COEFFICIENTS, ϵ, OF CEROUS AND CERIC PERCHLORATES IN 1.03 ± 0.03 *M* PERCHLORIC ACID AT 23 ± 3°

c_4	c_3	c_4/c_3	ϵ at λ, 253	254	255 mμ
0	0.00007 to 0.03	0	ϵ_3, 760 ± 70	750 ± 70	740 ± 70
0.0006 to 0.0094		2.5	ϵ_4, 1750 ± 90	1710 ± 95	1670 ± 90
0.0007 to 0.0043		.78	ϵ_4, 1740 ± 110	1680 ± 120	1610 ± 80
0.0024		.42	ϵ_4, 1790 ± 20	1750 ± 20	1660 ± 20
0.0009 to 0.0023		.22	ϵ_4, 1765 ± 85	1700 ± 20	1540 ± 60

The average value of ϵ_4 is 1730 and of ϵ_3 is 750.

employed. The solutions obeyed Beer's law, *i. e.*, $\epsilon c = \epsilon_3 c_3 + \epsilon_4 c_4$ within the limits given in Table I.

Quantum yields were determined for monochromatic light of λ 254 mμ. The apparatus has been described.[5] It has been shown[5] that the light of λ 185 mμ produced by the lamp is completely (more than 99.99%) absorbed between the lamp and the reaction vessel by the two-cm. layer of running tap water and the cylindrical clear fused quartz filter containing a one-cm. layer of chlorine gas at one atm. A one-cm. layer of glacial acetic acid produced the same results.

Two sets of transparent fused quartz cylindrical reaction vessels were employed. In one set the cells had diameters of 1.3 cm and each held 11 ml. when filled to the neck. In the other set the diameters ranged from 2.4 to 2.8 cm. and each held 42 ml. when filled to the neck. The transmission of light of λ 254 mμ by the cell walls of all the reaction vessels was the same within 1%. The stirrers were made of transparent fused quartz ribbon and were rotated on the axes of the cells.

Concentrations of cerous and ceric perchlorates were limited to those that absorbed over 90% of the light of λ 254 mμ incident on the solutions before the light reached the stirrer. Less than 1% of this light emerged from any reaction cell.

Light fluxes incident upon the solutions were measured with the uranyl oxalate actinometer first standardized by W. G. Leighton and G. S. Forbes.[6] The actinometer solution for the 11 ml. cells contained 0.0017 mole of uranyl oxalate and 0.0040 mole of oxalic acid per liter of solution, and for the 42 ml. cells it was half this strength.

Light fluxes were determined at the beginning, middle and end of each day of work or more often if the light flux was believed to be varying more than 5%. The duration of each photolysis was measured to the nearest second. Up to 20% of the oxalate and 16% of the ceric concentrations were destroyed by photolysis.

The photochemical data are given in terms of the quantum yield, ϕ, of the reaction, *i. e.*, the moles of ceric perchlorate reduced to cerous perchlorate per mole of light quanta absorbed only by the ceric perchlorate. The pertinent data are given in Table II. $\phi_{gross} = V\Delta c_4/E$, $\phi = \phi_{gross}(1730\ c_4 + 750\ c_3)/1730\ c_4$, $\phi^* = \phi_{gross}(1730\ c_4 + 750\ c_3)/750\ c_3$. V is the volume in liters of the solution irradiated, Δc_4 is the change in the molar concentration of the ceric perchlorate produced by the irradiation, and E is the fraction of an einstein (6×10^{23} quanta) of light of λ, 254 mμ absorbed by the solution irradiated. The starred values refer to cerous instead of ceric perchlorate.

The values given in Table II for c_3, c_4 and the perchloric acid concentration are the average values during photolysis. The symbol c_4^0 refers to the value of concentration of ceric perchlorate in the unphotolyzed sample. The number in parentheses following the gross quantum yield indicates the number of expts upon which the values in that row are based. The column headed 10^6 E/min. gives the average light flux of λ 254 mμ incident upon the solutions irradiated; in all cases except expt. 1, this value also equals the light flux absorbed by the solution.

In expt. 1, the irradiation of the perchloric acid produced no detectable substances which either oxidized ferrocyanide or reduced permanganate in dilute sulfuric acid.

In two sets of experiments with a solution like that used in expt. 5, ϕ gross remained constant within 4% when the light intensity was changed 1/3.7 by dimming the lamp by means of a variac in the lamp circuit.

Two different methods were employed to change the concentration of cerous perchlorate. In expts. 11 and 14, appropriate amounts of the ceric perchlorate solution in which c_4/c_3 was about three were reduced with hydrogen peroxide free of preservative until c_4 equalled about 0.012. In all the other expts. appropriate amounts of the ceric and cerous stock solutions B and C were mixed. Both methods produced the same results.

The effect of cerous perchlorate upon the reaction is shown in Fig. 1. A decrease in the quantum yield, ϕ, is seen to be produced by an increase in the concentration of cerous perchlorate, *i. e.*, a decrease in the ratio of ceric to cerous perchlorate when other variables are held constant. Cerous perchlorate absorbs ultraviolet light of λ 254 mμ but since ϕ is based upon the light of this wave length absorbed only by the ceric perchlorate, the value of ϕ would have remained unchanged if the cerous perchlorate acted only as an inner filter. The line passing through the data is based on the hypothesis that the cerous perchlorate deactivates the photon activated ceric ions.

The line in Fig. 1 was determined by a plot of $1/\phi$ *vs.* c_3. The data on such a plot fall on a straight line within the limits of error. The line

intercepts the $1/\phi$ axis at 5 ± 0.2 and has a slope, $(1/\phi)/c_3$, of 670 ± 50; hence $1/\phi = 5 + 670\ c_3$ and $\phi = 1/(5 + 670\ c_3)$ for these data.

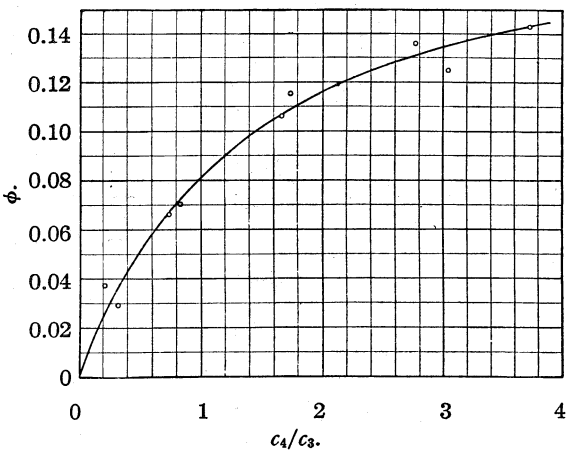

Fig. 1.—c_2 = 1.03 ± 0.003, c_4 = 0.0110 ± 0.00045, μ = 1.2 ± 0.1.

The possibility that the changes in ϕ are produced by changes in the light flux absorbed by the ceric perchlorate is eliminated by the finding noted above that ϕ did not change when the light intensity was changed several-fold while other variables were held constant.

There remains, however, the possibility that the quantum yields, ϕ, are decreased by cerous ions because the light absorbed by them causes them to be oxidized to ceric ions. The data in expts. 15, 16, 17 and 18 show that this reaction does occur and that the quantum yield, ϕ^*, of the reaction is about 0.001 in 0.06 molar cerous perchlorate. This value of ϕ^* is, however, less than 1% of the total decrease of 0.12 produced in ϕ by this concentration of cerous perchlorate in 0.011 molar ceric perchlorate, so the main effect of the cerous ion is to deactivate ceric ions. The decrease of 0.12 in ϕ is obtained from Fig. 1 where ϕ drops from 0.15 to 0.03 when c_4/c_3 decreases from 4 to 0.2 while the concentration of ceric perchlorate remains at 0.011 molar.

The photochemical oxidation of cerous to ceric perchlorate in expts. 15, 16, 17 and 18 was made evident by the orange color of ceric sulfate produced in the photolyzed but not in the unphotolyzed solutions when they were treated with concentrated sulfuric acid in the course of the analysis of them for ceric ions. The intensity of the orange color which developed in the solutions was directly proportional to the amount of ferrous ion required to bleach them. We did not test for hydrogen produced by the photoxidation of the cerous ions, but it is worth noting that when $\epsilon_3 c_3 \phi^* = \epsilon_4 c_4 \phi$, the amounts of cerous and ceric perchlorates in the solution being irradiated would remain unchanged while water was being broken down into oxygen and hydrogen.

Figure 2 shows that an increase in the net quantum yield ϕ accompanies an increase in c_4. The increase occurs in spite of an accompanying increase in c_3 since in the case of these data c_4/c_3 is nearly constant at 2.8. It is not caused by the increase in the concentration of photon activated ceric perchlorate because ϕ was found not to depend upon the light intensity. The line passing through the data is based on the hypothesis that only light absorbed by ceric dimers produces the measured reaction. The dependence of ϕ upon c_4 and c_3 is then given by the equation $\phi = y/(a + bc_3)$ where y is the fraction of the ceric ions dimerized and a and b are constants. $y/(1 - y)^2 = 2K_p c_4$ where K_p is a constant under the prevailing conditions. The last equation for ϕ is repre-

TABLE III

MOLAL POTENTIALS E_1^0 AT 25° FOR THE REACTION $CeOH^{+3} + {}^1/_2H_2 = Ce^{+3} + H_2O$

Calculated from the data of Sherrill, King and Spooner at a perchloric acid concentration of 0.8 M. The values of $^*E_1^0$ have allowed for the dimerization of ceric ions. The symbols are explained in the text.

sented by the line in Fig. 2 when K_p equals 50, and a/y and b/y equal 5 and 670, respectively, from the data in Fig. 1.

The value of K_p was estimated by the method of successive approximations. This involved evaluating c_4 for various values of y and K_p. Next, a and b were evaluated for the values of y at $c_4 = 0.011$. Then ϕ was calculated for the values of c_4 covered by the data. Values of K_p equal to 50 ± 10 fit the data within the limits of error, but when K_p is set equal to 100 or 25 the calculated values of ϕ fall well outside the limits of error especially at the lower values of c_4.

A value of 50 for K_p gives a value of 0.398 for y at c_4 equal to 0.011 and the corresponding values of a and b are 2 and 270, respectively.

The tendency of the observed values of ϕ to fall above the line in Fig. 2 at the highest concentrations of ceric perchlorate suggests that photosensitive trimers and higher polymers of ceric ions are also formed in these solutions.

The nature of ceric monomers in perchloric acid has been postulated by Professor M. S. Sherrill[3] based on e. m. f. data on these solutions. The formulas postulated are $CeOH^{+3}$ and $Ce(OH)_2^{+2}$. The equilibrium constant for the reaction $CeOH^{+3} + H_2O = Ce(OH)_2^{+3} + H^+$ was found to be 0.6. A slight extension of this idea suggests that the formulas of the dimers are Ce–O–Ce^{+6}, HOCe–O–$CeOH^{+4}$ and Ce–O–$CeOH^{+5}$. The formation of the dimers would be expected to take place by splitting out water from the hydroxyls attached to separate ceric monomers. The same kind of reaction would also produce trimers and higher polymers involving the $Ce(OH)_2^{+2}$ ion.

The formation of ceric dimers in ceric perchlorate solutions is also supported by the e. m. f. measurements of M. S. Sherrill, C. B. King and R. C. Spooner.[3] The solutions in their Run III are nearest in composition to our solutions; the main difference is that their perchloric acid concentration, c_2, was 0.8 compared to 1.03 M in our work.

The e. m. f. measurements were made on the cell H_2, $HClO_4$ at c_1/c_2, c_3, c_4 Pt. This cell can be thought of as two cells connected in series, namely, cell I, H_2, c_1/c_2, H_2, and cell II, H_2, c_2/c_9, c_3, c_4 Pt. The first of these cells has a liquid junction potential $E_L = (2T_{H^+} - 1)\ 0.05915 \log (c_1\gamma_1/c_2\gamma_2)$ or very nearly $E_L = (0.6744)\ 0.05915 \log (c_1/c_2) = 0.03989 \log (c_1/c_2)$ as calculated by S. K. S. The observed e. m. f. values, E, were corrected to hydrogen at 1 atm. and 25°. Table III gives the data for their Run III.

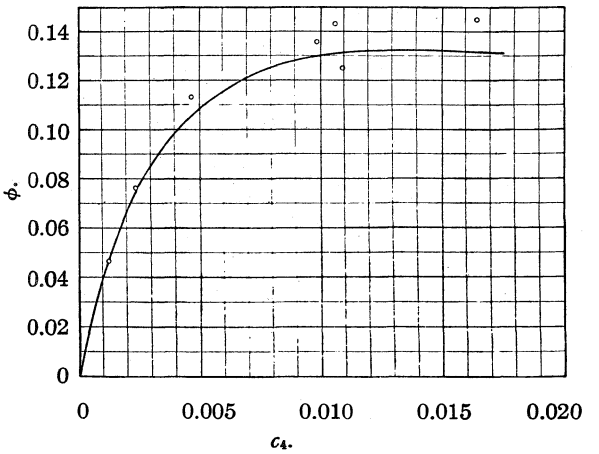

Fig. 2.—$c_2 = 1.03 \pm 0.3$, $c_4/c_3 = 2.80 \pm 0.26$, $\mu = 1.1 \pm 0.1$.

The formal potential E_f^0 ($= E - 0.05915 \log (c_4/c_1c_3) - E_L$) includes the liquid junction potential E_L' produced by c_3 and c_4 in c_2 of Cell II and in addition a term involving the activity coefficients of the various species in the solutions.

Constant values of 1.7134 ± 0.0004 volts were obtained by S. K. S. for the molal potential E_1^0 of the reaction $CeOH^{+3} + {}^1/_2H_2 = Ce^{+3} + H_2O$ when c_2 is between 0.54 and 1.6 M and $c_4 = {}^0c'_m + {}^0c''_m$, ${}^0c''_m/{}^0c'_m = 0.6/c_2$ and $E_1^0 = E_f^0$(extr.) + $0.05915 \log (c_4/c_2{}^0c'_m)$. The symbols ${}^0c'_m$ and ${}^0c''_m$ represent the concentrations of $CeOH^{+3}$ and $Ce(OH)_2^{+2}$, respectively, when there is no dimerization. The symbol E_f^0(extr.) represents the value obtained for E_f^0 when extrapolated to $c_4/(c_3 + c_4)$ equal to zero. The value of E_1^0 calculated from E_f^0 at any actual value of c_4 is always less than the value calculated from E_f^0 (extr.), and it increases as c_4 decreases as shown in Table III. This trend is eliminated when allowance is made for the dimerization of ceric ions. The values of E_1^0 corrected for this effect are the $^*E_1^0$ values in Table III.

$$^*E_1^0 = E_f^0 + 0.05915 \log (c_4/c_2c'_m)$$

TABLE IV

THE VALUES OF $*E_1^0$ FOR THE SEPARATE E. M. F. RUNS MADE BY SHERRILL, KING AND SPOONER. THE AVERAGE VALUE OF $*E_1^0$ IS 1.7174; IT IS 1.7169 WHEN RUN V IS OMITTED

Run	Expts.	c_2	c_4	$*E_1^0$
V	6	0.1973 ± 0.0018	0.0010 to 0.0093	1.72074 ± 0.00085
IV	5	.4787 ± .0016	.0010 to .0086	1.71793 ± .00072
VII	2	.5325 ± .0015	.0032 to .0072	1.71853 ± .00057
VIII	4	.5347 ± .0011	.0009 to .0055	1.71584 ± .00041
III	4	.8036 ± .0007	.0040 to .0084	1.71633 ± .00043
IX	3	1.2977 ± .0007	.0010 to .0045	1.71530 ± .00038
II	2	1.6304 ± .0007	.0032 to .0048	1.71664 ± .00024
I	2	2.3841 ± .0014	.0048 to .0066	1.71751 ± .00026

where

$$c_4 = c'_m + c''_m + 2c_p$$
$$c'_m + c''_m = \sqrt{c_p/50}, \text{ and}$$
$$c'_m/c''_m = 0.6/c_2$$

The values of $*E_1^0$ for the separate runs in the order of increasing acid strength, c_2, are given in Table IV.

The average value of $*E_1^0$ for Run V is significantly higher than the other values and the ionic strength, μ, is the lowest (μ equals 0.26 compared to 0.5 to 2.4 in the other runs). An increase in the value of $*E_1^0$ would be produced if the activity of $CeOH^{+3}$ decreased with μ. This can be seen by comparing the values of E_1^0 and $*E_1^0$ in Table III. The higher values of $*E_1^0$ in Table III are associated with the lower values of the activity of the $CeOH^{+3}$ which resulted from the correction for the dimerization. A decrease in μ favors the hydrolysis of $CeOH^{+3}$ but it also favors a decrease in the dimerization. The two effects thus tend to cancel each other and this is supported by the lack of any trend in the values of $*E_1^0$ in Table IV with changes in μ between 0.5 and 2.4.

Empirically, the values of $*E_1^0$ depend linearly upon the logarithm of $(c_2 + 3c_3 + 4c_4)/c_2$, as is shown in Fig. 3. The equation for the line in the Fig. is $*E_1^0 = (1.71545 \pm 0.00026) + (0.06185 \pm 0.00594) \log [(c_2 + 3c_3 + 4c_4)/c_2]$. The probable deviation of any value of $*E_1^0$ from the line is 0.00082.

The molal oxidation potential E_1^0 of the electrode reaction (1) $CeOH^{+3} + H^+ + E^- = Ce^{+3} + H_2O$ obtained by the above method is 1.7155 instead of 1.7134 volts obtained from E^0_f(extr.).

The molal oxidation potentials of the other

$$E_{1,2p}^0 = (E_1^0 + E_2^0)/2 - 0.05915 \log \sqrt{K_{1,2p}}$$
$$K_{1p} = K_{2p} = K_{1,2p}/2 = 50$$

within the limits of error of either the quantum yield measurements or the e. m. f. data.

The compositions of the ceric perchlorate solutions over the range covered by the quantum yield measurements are given in Table V.

The following reactions in addition to the equilibria given above account for the quantum yields.

K_p $\quad 2c_m = c_p$

k_I $\quad c_p + h\nu = c_p^*$

k_1 $\quad c_p^* + H_2O = 2c_3 + 2H^+ + {}^1/_2O_2$

k_2 $\quad c_p^* + c_3 = c_p + c_3$

k_3 $\quad c_p^* + S = c_p + c_3$

c_m is the concentration of all the ceric monomers
c_p is the concentration of all the ceric dimers
S is any substance except c_3; the solutions do not fluoresce
k_1, k_2, and k_3 are the rate constants for the corresponding reactions

The reactions give a maximum quantum yield of two and the following equation for ϕ

$$\phi = 2yk_1/(k_1 + k_3S + k_2c_3)$$

or

$$\phi = y/(a + bc_3) \text{ at constant ionic strength}$$
$$a = (k_1 + k_3S)/2k_1 = 2.0$$
$$b = k_2/2k_1 = 270$$

Thus the deactivation of the photon-activated ceric dimer by cerous ions is $2 \times 55.5 \times 2.70$ or 30,000 times more efficient at 25° than the reduction of the dimer by water. The remainder of the environment, however, reacts with the photon-activated dimer little more efficiently ($k_3S/k'_1 \cdot (H_2O) = 3$) than the measured photochemical reaction.

Our initial interest in the photochemistry of the ceric perchlorate system was to learn something about the way in which water is photochemically oxidized to oxygen since this oxidation is a fundamental step in the photosynthetic process in living organisms. The work above shows that light absorbed by ceric monomers has a negligible effect upon the reaction. This implies that divalent oxygen is not photochemically oxidized unless the photon activated ceric unit can absorb two electrons from the oxygen. There is no evidence for the intermediate formation of peroxide in the photochemical oxidation of divalent oxygen either in the present research or when the photon activated unit is the persulfate anion,[7] $S_2O_8^=$. In the latter case all tests for the photochemical formation of hydrogen peroxide along with the oxygen were negative although hydrogen peroxide is made thermally from persulfates.

Summary

1. Photolysis of ceric perchlorate in perchloric acid has been measured quantitatively in ultraviolet monochromatic light of λ 254 mμ.

2. Net quantum yields, ϕ, based on the light absorbed by the ceric perchlorate depend on the concentrations of cerous, c_3, and ceric perchlorates. The dependence is given by the equation $\phi = y/(a + bc_3)$ where y is the fraction of ceric ions dimerized and a and b are constants. ϕ does not depend upon the light intensity, and is negligible for ceric monomers.

3. The dimerization of ceric ions is also supported by e. m. f. measurements on solutions of cerous and ceric perchlorates in perchloric acid, but it is not revealed by measurements of the extinction coefficients of the solutions in the region of λ 254 mμ.

4. The molal oxidation potentials of the various cerium species are calculated.

5. Cerous ions were found to be photochemically oxidized to ceric ions.

The Near Ultraviolet Absorption Spectra of Monosubstituted Benzenes: the Effect of Certain Meta Directing Groups[1]

BY W. F. HAMNER AND F. A. MATSEN

The effect of electron donating (*i.e.*, ortho-para directing) groups on the near ultraviolet absorption spectra of monosubstituted benzenes has been extensively investigated[2,3] and the following trends established: the greater the extent of migration into the ring the longer the wave length of the O–O band, the higher the intensity of the spectrum as a whole and of the substitution subspectrum (A, A + C, etc.)[4b] relative to the benzene subspectrum (A + B, A + B + C, etc.).[4a]

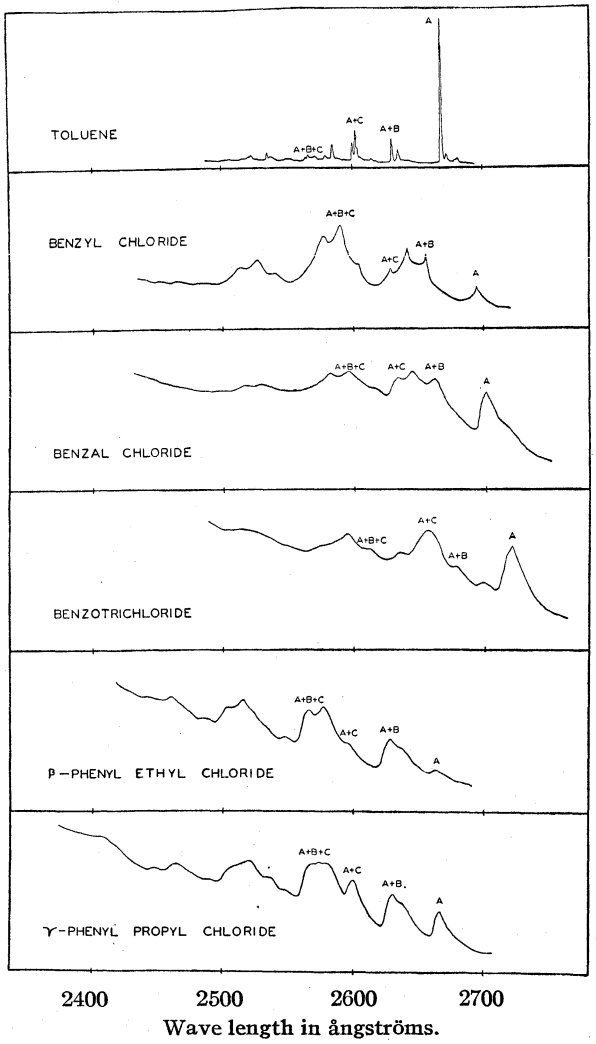

Fig. 1.—Microphotometer tracings of the vapor spectra of chloroalkyl substituted benzenes; intensity scale varies from compound to compound.

It was of interest therefore to investigate the spectra of electron attracting (*i.e.*, meta-directing) groups. According to the data of Flurscheim and Holmes[5] the per cent. meta compound formed upon nitration is as follows: toluene, 4.4; benzyl chloride, 11.6; benzal chloride, 32.8–33.3; benzotrichloride, 48.3–48.6. This is attributed to the increasing migration of electrons out of the ring due to the progressive replacement of the hydrogen atoms by strongly electronegative chlorine atoms. This series presents a gradual transition from ortho-para toward meta direction.

Experimental

The benzyl chloride, benzal chloride and benzotrichloride were donated by the Hooker Electrochemical Company, the β-phenylethyl chloride and γ-phenylpropyl chloride were Eastman Kodak Co. white label grade; the compounds were subjected to vacuum distillation or recrystallization to insure purity. The refractive indices of the fractions used are:

Compound	Temp., °C.	n_D
$C_6H_5CH_2Cl$	17.4	1.5391
$C_6H_5CHCl_2$	19.4, 20.0	1.55155, 1.55121
$C_6H_5—CCl_3$	19.2, 20.0	1.55841, 1.55806
$C_6H_5—CH_2CH_2Cl$	20.0	1.52760
$C_6H_5—CH_2CH_2CH_2Cl$	20.0	1.52237

The spectra of the vapor were photographed in the first order of a three-meter 15,000 line per inch, Eagle mounted grating spectrograph using a 2.5 kva hydrogen discharge tube. The cells were all-quartz connected by a side-arm to a reservoir which contained the sample, the temperature of which controlled the vapor pressure in the cell. The plates were scanned on a Leeds and Northrup microphotometer and the wave lengths determined by comparison with standard iron lines.

The solution spectra were obtained in cyclohexane solution with a Beckman quartz spectrophotometer.

Results

Microphotometer tracings of the vapor spectra are given in Fig. 1 along with that for toluene. The intensities of the spectra are not comparable since conditions were chosen to give maximum contrast. The chloroalkylbenzene spectra are more diffuse than that of toluene which appears to be due to the broadening of the rotational structure and to the interaction of a dissociative electronic level.

From Fig. 1 it will be seen that the substituent subspectrum becomes relatively more important as the number of chlorine atoms on the α atom of

(4) (a) The benzene subspectrum consists of bands containing the 500 cm.$^{-1}$ (B) the mode which makes the benzene spectrum allowed. (b) The substitution subspectrum consists of the additional bands which appear in substituted benzenes: 0 − 0(A), 0 + 900 (A + B) etc.

(5) Flurscheim and Holmes, *J. Chem. Soc.*, 1607 (1928).

the substituent is increased and as the chlorine atom is substituted successively β, γ and α.

The wave lengths, the relative intensities and assignments in terms of excited state fundamentals for the band maxima are given in Table I. These spectra, due to their diffuseness, exhibit only a few of the fundamentals and combination bands exhibited by more discrete spectra.[6] For β-phenylethyl chloride and γ-phenylpropyl chloride the 700 cm.$^{-1}$ fundamental is lost on the shoulder of the stronger 900 cm.$^{-1}$ fundamental but does appear in combinations. The wave numbers of the zero–zero bands lie in the following order: β-phenylethyl chloride > γ-phenylpropyl chloride > toluene > benzyl chloride > benzal chloride > benzotrichloride.

The solution data[7] are given in Fig. 2. The spectra of β-phenylethyl and γ-phenylpropyl chloride lie so close to toluene that they were not included on the graph. The order of the intensities of absorptions are in the order benzotrichloride > benzal chloride > benzyl chloride $\cong$ toluene > γ-phenylpropyl chloride > β-phenylethyl chloride.

Conclusions

The migration of electrons out of the ring has qualitatively the same effect on the spectra as the migration into the ring.

The intensities of absorption and the importance of the substitution subspectrum are functions of the transition probability which is very low for benzene due to the hexagonal symmetry of the electron distribution. It has been proposed by Sklar[2] that the hexagonal symmetry is distorted by migration of electrons into the ring due to the substitution of ortho–para directing groups. This research shows that the distortion is also accom-

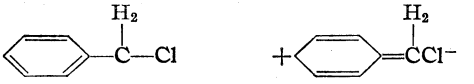
(6) See footnote 3 for particular references.

(7) See also L. J. Anderson and S. L. Linden, THIS JOURNAL, **69**, 2091 (1947).

plished by the migration of electrons out of the ring. Very qualitatively it appears that the migration in for toluene is of the same order as the migration out for benzyl chloride.

The position of the zero–zero bands is a function of the difference of zero point energies in the ground and excited state and the height of the excited state above the ground state. The former is influenced by the mass of the substituent and appears to become smaller as the mass of the substituent increases.[3]

The height of the excited above the ground state may be discussed from the point of view of resonance between valence structures or of molecular orbitals. From the former, there is resonance involving structures like the following



which will lower the excited state relative to the ground state. The substitution of more chlorine atoms produces more ionic structures with a resultant increased lowering of the excited state. From the molecular orbital point of view the withdrawal of electrons by the electronegative chlorine atoms tends to leave vacant a p orbital on the carbon atom. The molecule then possesses seven

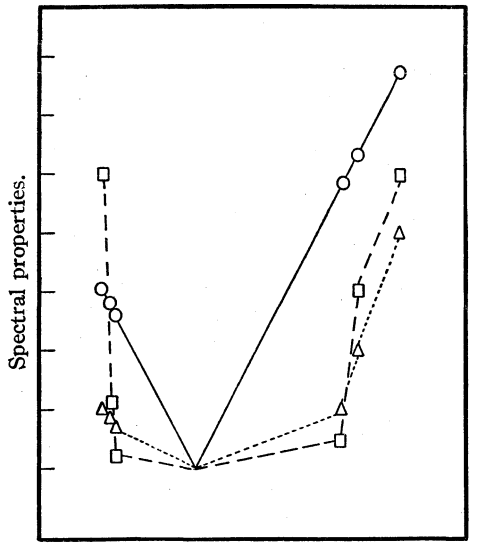


Fig. 3.—Spectral properties and postulated electron migration: The position of the zero–zero bands (O), the estimated intensity of the spectrum compared to that of benzene (△), and the estimated ratio of intensity of the substitution subspectrum to intensity of the benzene subspectrum (□) are plotted as ordinates. From left to right the points correspond to compounds toluene, γ-phenylpropyl chloride, β-phenylethyl chloride, benzyl chloride, benzal chloride and benzotrichloride. The abscissa is a scale of electron migration so chosen as to make the points (O) fall on straight lines.

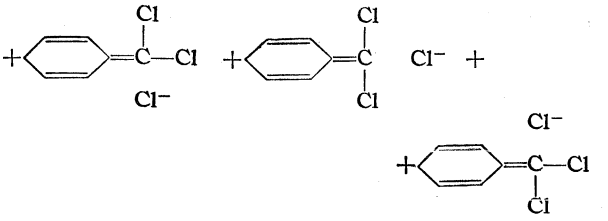

interacting p orbitals in which six π electrons move. This system may be compared to aniline and phenol which also possess seven interacting orbitals; however, eight electrons move in these orbitals. The seven orbital–six electron system may be shown to be more stable and to possess a relatively lower-lying excited state than a six-orbital–six electron system accounting for the observed spectral shifts.

The substitution of chlorine for hydrogen atoms reduces hyperconjugation, the principal mechanism by which the methyl group sends electrons into the ring. The direction of migration is reversed on the replacement of one hydrogen atom by a chlorine as may be seen by Fig. 3.

From left to right along the abscissa of Fig. 3 there is progression from migration into the ring to migration out of the ring. At some point there must be zero migration. Since the right side goes up continuously it seems necessary to locate the zero migration point between toluene and benzyl chloride; that is the direction of migration is reversed by the replacement of one hydrogen atom by a chlorine atom. This is substantiated by the spectrum of β-phenylethyl chloride which has a weaker substitution spectrum, a lower intensity and a zero–zero band which lies farther from the visible than either toluene or benzyl chloride. Thus the shift of the chlorine atom from an α- to a β-carbon atom reduces its effect enough to place β-phenylethyl chloride near the minimum of the curve in Fig. 3. In γ-phenylpropyl chloride the effect of the chloride is so reduced that the hyperconjugation with the ring becomes predominating which places the compound up on the left branch of the curve.

Assuming that in benzyl chloride the migration is out of the ring, the problem is raised as to why the per cent. meta formed is not higher than the 11.6% reported. If the substituent had no effect, 40 per cent. meta should be formed; if the substituent withdrew electrons a still higher per cent. meta should be formed. Several suggestions present themselves: (1) there is a permanent positive inductive (non-resonance) effect associated with carbon which will always be ortho–para directing, (2) there are polarizing effects in the substitution reaction of the kind discussed by Pauling and Wheland[8] which are not detected spectroscopically.

The Relation between the Absorption Spectra and the Chemical Constitution of Dyes. XX. Induced Non-Coplanarity in Symmetrical Benzidine Dyes[1]

BY ROBERT J. MORRIS[2] AND WALLACE R. BRODE[2]

In an earlier paper in this series[3] an investigation was made on the separation of chromophores in disazo dyes by the introduction of insulating methylene, ethenylene and ethylene groups. This study was made on both symmetrical and unsymmetrical disazo dyes and from the data obtained it was shown that when two chromophores were separated by one or two methylene groups, the chromophores function almost as though they were in separate molecules. However, the frequency of each chromophore was slightly diminished by the presence of the other. This was considered due either to the mutual influence of the two chromophores or to added molecular weight. The closer the separated chromophores approached each other when directly connected, the greater their mutual effect. When the azo chromophores were connected by a well-defined conjugate system, each chromophore strongly influenced the electronic excitation of the other.

The observed shift of the principal absorption band to lower frequency caused by an increase in molecular weight of the compound was, however, of a low order of magnitude compared with the shift caused by the conjugation of chromophoric systems.

In azo dye structures, the conditions effecting the coplanarity of the dye molecule would also be expected to have considerable effect on their absorption spectra. As early as 1923, Ley and Rincke[4] made comparisons of the absorption spectra of planar *trans*-stilbene with *trans*-α-methylstilbene. Interpretation of their results indicated that the methyl group in the latter crowds an ortho hydrogen of the more remote benzene ring. Planarity was therefore inhibited, as was, in consequence, the resonance interaction between the two benzene rings. The unsubstituted benzidine nucleus has been shown to exhibit some steric inhibition to complete coplanarity because of the bond angles and distances involved in its structure.[5] Moyer and Adams[6] have shown that the compound 3,3′-diaminodimesityl, because of the steric effects of the methyl groups in the 2,2′,6,6′-positions, was definitely non-coplanar. It was further predicted that the characteristic effect of the conjugation of the biphenyl molecule on the absorption spectra would vanish for compounds possessing this inhibited structure. This hypothesis was supported by observations conducted by Pickett.[7] In this investigation it was shown that the absorption spectra of bimesityl was almost identical with that of mesitylene but differed significantly from biphenyl. Other examples of the effect of 2,2′-substitution on the absorption spectra of the biphenyl molecule have been recorded by Rodebush.[8] Jones[9] has also presented data and a general review on steric hindrance of resonance.

Experimental

The dyes prepared for this study were synthesized from intermediates of known purity by standard procedures for diazotization and coupling. The cresols used were available in grades of acceptable purity. Benzidine, 3,3′-dimethylbenzidine and 3,3′-dimethoxybenzidine obtained from Eastman Kodak Company were analyzed and shown to be of acceptable purity. The 2,2′-dimethyl[10] and 2,2′,6,6′[11]-tetramethyl benzidine derivatives were synthesized and purified before use.

All the dyes prepared were purified by repeated recrystallization from dilute acetic acid until a constant purity resulted. The analysis for the purity of all dye samples was accomplished by the use of a standardized titanium trichloride solution.

Absorption measurements were made by the use of a Beckman quartz spectrophotometer. The properly diluted samples were introduced into 1.00-cm. fused silica cells and their absorption spectra determined using the corresponding solvent as a reference solution. Readings were generally taken at 10 mμ intervals, although in some places determinations were made at closer intervals to increase the accuracy of the measurements. A dilution to 0.000015 *M* served for obtaining the complete absorption spectra of all the dyes measured. In neutral solu-

tion this concentration was attained by the proper dilution of a 0.00006 *M* alcoholic solution (referred to as the stock solution) of the dye by use of additional 95% ethanol. For measurements in basic media, the final concentration of 0.000015 *M* was attained by dilution of the 0.00006 *M* stock with aqueous sodium hydroxide. Determinations in concentrated acid media were made by dilution of the stock solution to 0.000015 *M* with 12 *N* hydrochloric acid (concd. HCl). Absorption data on the dyes, after correction for salt and inert non-absorbing material as indicated by the analytical data, were recorded with molecular extinction as ordinates and frequency (fresnel) as abscissa. (fresnel = vibrations per sec. $\times 10^{-12}$ = wave number per cm. $\times$ speed of light in cm. per second, *i. e.*, $1/\lambda = \nu' = \nu/c$ where λ = wave length, ν' = wave number, ν = frequency and c = speed of light.) Molecular extinction (ϵ) is defined as $k \times$ molecular weight where k is the specific extinction. $k = E/cd$; where E = extinction, c = concn. in g. per l. and d = cell length in cm.

Discussion of Results

The curves obtained for these azo dyes show definite changes in the absorption spectra as a non-coplanar condition becomes established for the benzidine nucleus. This is evident by the shift of the absorption to higher frequencies with the establishment of these conditions. Such a shift is contrary to the expected change with the increasing molecular weight. Although a partial restriction to complete molecular conjugation has been previously reported for the diphenyl molecule because of the interference of the hydrogen atoms in the 2,2′,6,6′-positions, it is believed that the unsubstituted benzidine dyes possessing this structure show considerable conjugation through the 1,1′-bond. This was demonstrated by the distinct change in the absorption bands of these dyes when the relatively large, unreactive methyl groups are introduced in the 2,2′- and 2,2′,6,6′-positions on the benzidine nucleus. Figures 1, 2 and 3 show the definite shift in the absorption band with these molecular changes. The marked change in the absorption observed is undoubtedly

caused by the establishment of more exaggerated non-planar conditions for the half-structures involved. The Fig. 1 shows a typical series of curves using phenol as the coupling constituent; similar types of curves were also obtained when ortho cresol and meta cresol were coupled, except for a very slight displacement to lower frequency due to the additional weight. In Fig. 2, a change in the general absorption curves of the dyes derived from *p*-xylenol was evident in the basic media. This is probably due to the increased difficulty that such dyes would encounter in establishing a quinoid structure due to the interference of the large groups ortho to the azo chromophores. In Fig. 3, the double band formation evident throughout the absorption for these compounds may be ascribed to the two possible chromophoric paths in the quinoid form of phenylazo-*p*-cresol  This would result in a resolvable difference in the absorption for each conjugate system. Figures 3 and 5 illustrate this tendency. These ortho-coupled compounds do not appear at first to bear the simple relationship between the various substituted members as that shown by the para-coupled members. However, when the average of the frequencies of the component parts of the ortho-coupled bands are taken and compared with the frequency changes observed for the para-coupled bands, it will be noted that a similar relationship exists.[12]

Complete insulation of the two chromophores present in these disazo molecules was not accomplished by 2,2′-dimethyl substitution. So pronounced was this insulation for the 2,2′,6,6′-tetramethylbenzidine structure, however, that the absorption spectra exhibited by these dyes not only closely resembled the spectra for a suitable concentration of a corresponding half structure, but also was almost identical with the absorption of a molecule of like structural type in which the insulation at the 1,1′-bond was accomplished by the insertion of a methylene or ethylene link. In Fig. 4 an example of these similarities may be noted. This similarity serves to further indicate the pronounced restriction to complete molecular conjugation through the 1,1′-bond, when a definite non-coplanarity for the two half structures is present.

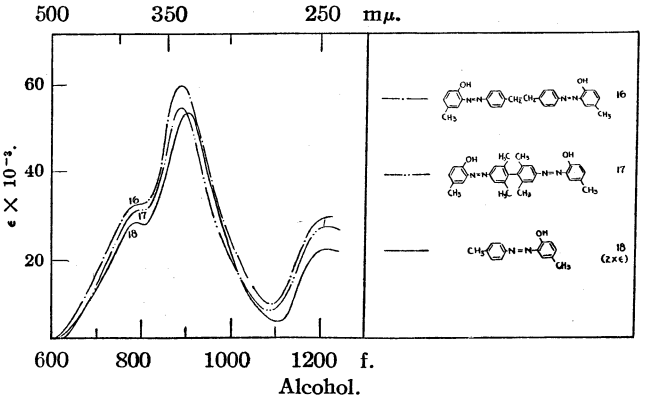

Fig. 4.—Comparison data are presented for the absorption spectra in alcohol solution of two disazo dyes showing restriction to molecular conjugation and a monoazo dye of suitable construction to most nearly represent a half-structure for these molecules.

Absorption spectra taken in acidic and basic media again illustrate the decisive effects of non-coplanarity. With the establishment of more polar conditions for the molecule, either by the use of a solvent that favors the quinoid form for these structures or by introducing the more polar methoxy groups into the 3,3′-position on the benzidine nucleus, even the partial restriction evident for the unsubstituted benzidine nucleus was greatly reduced. This is shown by the marked shift of the

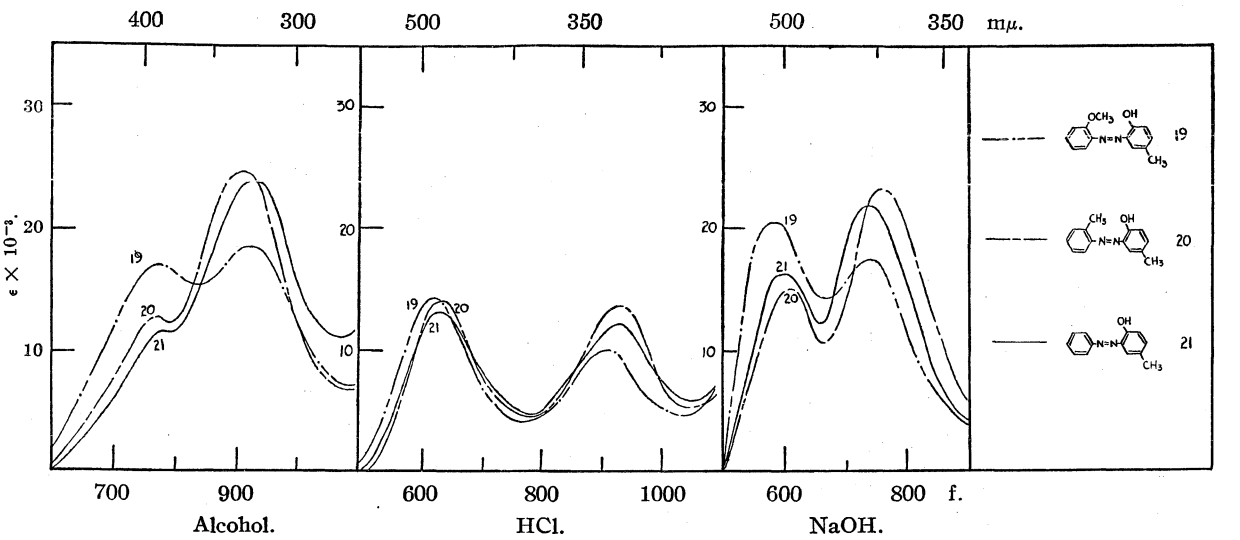

Fig. 5.—The absorption spectra recorded for the monoazo dye phenylazo-*p*-cresol and its derivatives. The absorption spectra from left to right were taken in 95% ethanol, 3% sodium hydroxide and concentrated hydrochloric acid.

absorption to lower frequency attendant with a distinctive increase in the molecular extinction for the molecules altered in the aforementioned ways. The establishment of these more coplanar conditions was most evident in the changes in the absorption spectra recorded for the benzidine dyes as illustrated in Figs. 1, 2 and 3. However, even the more simple monoazo dyes revealed these tendencies as indicated in the Fig. 5. The study of the steric effects in symmetrical dyestuffs as reported in this paper has been extended to unsymmetrical disazo dyes and to trisazo dyes and will be reported in a separate discussion.[13]

Summary

A spectrophotometric study has been made on twenty-five symmetrical benzidine dyes and the absorption spectra for fifteen of these structures have been reproduced as recorded in neutral, acidic and basic media. An absorption study of phenyl-azo-*p*-cresol dye and its methyl and methoxy derivatives was made. The absorption spectra exhibited by the insulated disazo structures caused by non-coplanarity was compared with a corresponding half structure as well as a similar molecule in which the insulation was derived from the insertion of an ethylene link. These data indicate that compounds with restricted rotation differ markedly in their absorption spectra from those capable of free rotation. The partial conjugation present in these dyes is aided by the establishment of a more coplanar configuration for the benzidine nucleus. This molecular conjugation is progressively inhibited by the introduction of the relatively large, unreactive methyl groups in the 2,2′- and 6,6′-positions on the benzidine nucleus. For the dyes prepared from the tetramethyl substituted nucleus, the insulation to molecular conjugation at the 1,1′-bond appears almost complete.

Copolymerization. V. Relative Monomer Addition Rates in Vinyl Copolymerization

BY REID G. FORDYCE, EARL C. CHAPIN AND GEORGE E. HAM

Until the recent publication by Alfrey and Price[1] it has been necessary to refer relative monomer reactivity ratios to the particular two-component system investigated. These authors, however, have indicated that it may be possible by means of two constants, Q and e, to characterize the relative rates of copolymerization of any vinyl monomer with any other vinyl monomer whose Q and e parameters are known. Utilizing the experimental study of Lewis, Mayo and Hulse,[2] Q and e values were assigned to styrene, methyl methacrylate, acrylonitrile and vinylidene chloride which appeared to account satisfactorily for their behavior in copolymerization. Because of the practical and theoretical usefulness of this general approach to the problem of copolymerization, it appeared desirable to test the validity of their relationships[1] for a number of additional systems. It is the purpose of this communication to present additional data on relative monomer addition rates and to examine these results, along with previously published values, in the light of the Alfrey and Price equations.

In this work, the four base monomers cited above were used as reference points to calculate the Q and e values for new monomers. The Q and e values reported for any monomer are based on copolymerization rate data of that monomer with at least two other monomers. To obtain cross checks of this kind, it was necessary to supplement published results with a study of the following systems: vinyl acetate–acrylonitrile, vinyl acetate–methacrylonitrile, α-methylstyrene–acrylonitrile, α-methylstyrene–methacrylonitrile and styrene–methacrylonitrile.

In determining monomer–polymer composition curves for the above systems, polymerizations were allowed to proceed to low conversions (mainly $< 4\%$) and the initial copolymer formed was isolated, purified and analyzed in duplicate by the micro-Dumas method.

The relationships of Alfrey and Price[1] were used to derive simplified forms of the copolymer equations involving n components. Copolymer compositions were calculated by substituting the Q and e values reported in these equations, and a comparison of the predicted composition with the composition determined by analysis was made.

Results and Discussion

The shapes of the monomer–polymer composition curves for the systems vinyl acetate–acrylonitrile, vinyl acetate–methacrylonitrile, α-methylstyrene–acrylonitrile, α-methylstyrene–methacrylonitrile and styrene–methacrylonitrile are shown in Fig. 1. These curves are based on data obtained from mass copolymerizations, interrupted at low conversions. Table I summarizes the polymerization conditions and the analytical results of the experiments.

TABLE I

Monomer, mole % acrylonitrile	Time at polymerization temp., hr.	Wt. % conversion	Nitrogen analyses, % I	Nitrogen analyses, % II	Copolymer, mole % acrylonitrile[a]
Vinyl Acetate–Acrylonitrile copolymerizations

[a] Corrected for incomplete nitrogen evolution. [b] Not corrected.

It was found that the micro-Dumas method of nitrogen analysis gave only 96.8 and 95.5% of the theoretical nitrogen content for polyacrylonitrile or polymethacrylonitrile, respectively. For this reason the nitrogen analyses obtained on the above

(1) Alfrey and Price, *J. Polymer Science*, **2**, 101 (1947).
(2) Lewis, Mayo and Hulse, THIS JOURNAL, **67**, 1701 (1945).

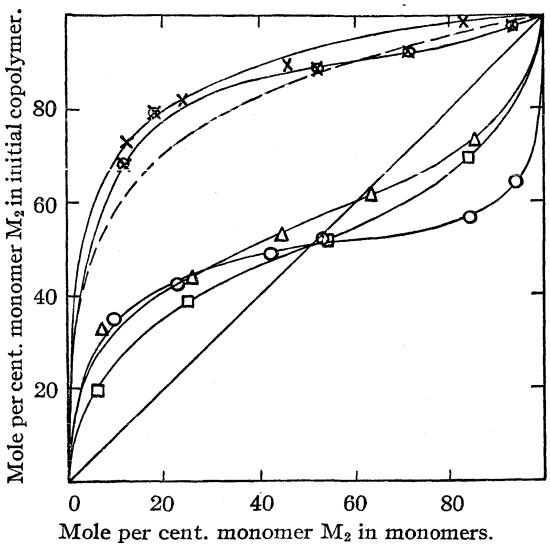

Fig. 1.—Monomer–polymer composition curves: ⊗, vinyl acetate–acrylonitrile (experimental); ---, vinyl acetate–acrylonitrile (theoretical $r_1 = 0.02$, $r_2 = 6$); ⊠, vinyl acetate–methacrylonitrile; O, α-methylstyrene–acrylonitrile; △, α-methylstyrene–methacrylonitrile; □, styrene–methacrylonitrile.

systems were corrected by assuming that any acrylonitrile or methacrylonitrile in a copolymer would evolve a proportionate amount of nitrogen.

Monomer reactivity ratios for these systems were determined by varying their values in the differential copolymer equation[3,4] until a good curve through the experimental points was obtained. This was possible in every case except the vinyl acetate–acrylonitrile system. Here some divergence between the experimental points and the theoretical curve exists as shown in Fig. 1. The relative reactivity ratios[5] for these systems were determined:

	r_1	r_2
Vinyl acetate–acrylonitrile	0.02 ± 0.02	6 ± 2
Vinyl acetate–methacrylonitrile	.01 ± .01	12 ± 2
α-Methylstyrene–acrylonitrile	.1 ± .02	0.06 ± 0.02
α-Methylstyrene–methacrylonitrile	.12 ± .02	.35 ± .02
Styrene–methacrylonitrile	.25 ± .02	.25 ± .02

In connection with the above data it is interesting to note that whereas α-methylstyrene readily forms copolymers containing more than 50 mole per cent. combined α-methylstyrene, we have been unable to polymerize it alone by a free radical mechanism.

The following relationships of Price and Alfrey[1] were employed for assigning Q and e values

$$r_1 = \frac{Q_1}{Q_2} e^{-e_1(e_1-e_2)} \quad (1)$$

$$r_2 = \frac{Q_2}{Q_1} e^{e_2(e_1-e_2)} = \frac{Q_2}{Q_1} e^{-e_2(e_2-e_1)} \quad (2)$$

Owing to the nature of the equations and to the inherent inaccuracies of the values of r_1 and r_2, the Q and e values for a given monomer varied somewhat depending on the system chosen for calculation. Consequently, the values reported represent only a fit to the data available. Undoubtedly, these values will have to be modified as more information becomes available.

The sequence of calculations used for determining Q and e values has a bearing on the results. From published data and data presented here, Q and e values were calculated from the systems indicated.

	Q	e	System
Methyl acrylate	0.34	0.38	Styrene–methyl acrylate[6]
Methacrylonitrile	.77	0.67	Styrene–methacrylonitrile
α-Methylstyrene	.59	−1.26	α-Methylstyrene–acrylonitrile
α-Methylstyrene	.67	−1.11	α-Methylstyrene–methacrylonitrile
Vinyl acetate	.013	−0.45	Vinyl acetate–acrylonitrile
Vinyl acetate	.024	−0.78	Vinyl acetate–methacrylonitrile
Vinyl chloride	.027	−0.22	Vinyl chloride–acrylonitrile[7]
Vinyl chloride	.03	−0.16	Vinyl chloride–methylacrylate[7]

The values of Q and e for methyl acrylate and for methacrylonitrile were not modified. The average of the two values obtained for α-methylstyrene, vinyl acetate and vinyl chloride was taken. The Q and e parameters determined in this manner are summarized, including those previously published[1]

	Q	e
Styrene	1.00	−1.0
Methyl methacrylate	0.64	0
Acrylonitrile	.34	1.0
Vinylidene chloride	.16	0
Vinyl chloride	.028	−0.19
Methyl acrylate	.34	+0.38
Vinyl acetate	.018	−0.61
α-Methylstyrene	.63	−1.18
Methacrylonitrile	.77	+0.67

The degree of agreement between calculated relative rates of polymerization and the values determined experimentally has been fully described by Price and Alfrey for the four reference monomers. A similar comparison for the monomers reported here is

	r_1 Calcd.	r_1 Obsd.	r_2 Calcd.	r_2 Obsd.
Vinyl chloride[a]–acrylonitrile	0.065	0.074[7]	3.7	3.7
Vinyl chloride[a]–methyl acrylate	0.074	0.083[7]	9.8	9.0
Vinyl chloride–styrene	0.046	0.067[7]	16	35
Vinyl chloride–vinyl acetate	1.7	1.8[8]	0.5	0.6

α-Methylstyrene[a]–methacrylonitrile	.09	.12 ± .02		0.35	0.35 ± .02

[a] The data which either were used directly or were used to calculate average Q and e values for the designated monomer. The results of greatest interest, however, are those systems which are not marked, since these data represent the cross checks on the validity of predictions based on the Price–Alfrey relationships.

An examination of the above reveals, first, that in no case has the predicted shape of the monomer–polymer composition curve, with respect to the azeotrope line, been in error. When the curve predicted from the above Q and e values lay above or below the azeotrope line, experimental data have been in agreement with the prediction. Unpublished results on a number of other vinyl copolymer systems studied at these laboratories have not as yet revealed a single exception to this.

Considering the assumptions and uncertainties involved in the derivation of the Alfrey–Price equations, as well as the experimental error involved in many of the rate function parameters, quantitative agreement is surprisingly good. Certain discrepancies shown above are not as significant as they appear. For example, in the system styrene–vinyl chloride the monomer–polymer composition curves drawn from the calculated and from the observed r_1, r_2 values actually lie quite close to each other in spite of the fact that superficial inspection of the figures indicates a serious divergence. It is concluded on the basis of available data that the Alfrey–Price relationship, when regarded as an empirical tool for predicting copolymerization behavior, is of the utmost utility qualitatively, and forecasts good values for the relative rates of copolymerization for comonomers whose Q and e values are known.

The data also verify certain generalizations implicit in the Alfrey–Price relationships. Monomer–polymer curves which cross the azeotrope line occur principally when comonomers with similar Q values but with e values of opposite sign are copolymerized. The above data for the acrylonitriles with the styrenes exemplify this. The copolymerization of comonomers with widely different Q values gives curves which deviate widely from the azeotrope line. The systems styrene–vinyl chloride and vinyl acetate–acrylonitrile show this clearly.

$$\frac{d[M_1]}{d[M_2]} = \frac{[M_1]^2Q_1^2e^{-e_1^2} + [M_1][M_2]Q_1Q_2e^{-e_1e_2} + \cdots + [M_1][M_n]Q_1Q_ne^{-e_1e_n}}{[M_2]^2Q_2^2e^{-e_2^2} + [M_1][M_2]Q_1Q_2e^{-e_1e_2} + \cdots + [M_2][M]_nQ_2Q_ne^{-e_2e_n}}$$

$$\frac{d[M_1]}{d[M_n]} = \frac{[M_1]^2Q_1^2e^{-e_1^2} + [M_1][M_2]Q_1Q_2e^{-e_1e_2} \cdots + [M_1][M_n]Q_1Q_ne^{-e_1e_n}}{[M_n]^2Q^2{}_ne^{-e_n^2} + [M_1][M_n]Q_1Q_ne^{-e_1e_2} \cdots + [M_n][M_{n-1}]Q_nQ_{n-1}e^{-e_ne_{n-1}}}$$

The concepts of Price and Alfrey can be used to transform the equations for relative monomer addition rates into simpler forms requiring much less time for calculations. The simplification is particularly useful for systems containing three or more monomers. For the general case of n monomers substitution in the derivation of Walling and Briggs[9] gives $n - 1$ simultaneous equations.

It is of interest that these copolymer equations exist in a form which clearly shows the individual steps involved in the propagation reaction, *i.e.*, the sum of all the terms in the numerator or denominator represent the sum of all possible propagation reactions resulting in addition of the given monomer to the growing chain.

The Q and e values given above have been substituted in these equations to predict interpolymer compositions for systems containing more than two monomers. These values were then compared with the results obtained. The following is typical of the agreement obtained between calculated and analytical values

	Initial[a] monomer composition	Predicted[a] polymer composition	Polymer[a] composition by analysis
Styrene	32.0	65.7	67.1[7]
Acrylonitrile	48.8	33.7	32.5
Vinyl chloride	19.2	0.6	0.4
Styrene	30.2	70.5	70.4[7]
Acrylonitrile	15.4	26.4	26.2
Vinyl chloride	54.4	3.1	3.4
Styrene	60	75.5	76.1[7]
Methyl acrylate	20	23.4	22.8
Vinyl chloride	20	1.1	1.1
Styrene	25.21	41.5	40.7[10]
Methyl methacrylate	25.48	27.4	25.5
Acrylonitrile	25.40	24.7	25.8
Vinylidene chloride	23.91	6.4	8.0

[a] Data for the three-component systems are expressed as weight per cent., those for the four-component system are expressed as mole per cent.

Agreement between calculated and observed values, as shown above, is further support for the general validity of the Alfrey–Price relationships. The agreement obtained also lends weight to the approximate correctness of the Q and e values reported.

Experimental

Vinyl Acetate Monomer.—Redistilled Niacet Chemical Co. material was taken for all experiments.

Styrene monomer was the redistilled product of Monsanto Chemical Co.

Acrylonitrile was the redistilled product of American Cyanamid Chemical Co.

Methacrylonitrile was redistilled Shell Development Co. product.

α-Methylstyrene.—Redistilled Dow Chemical Co. product was used.

Benzoyl Peroxide.—The product of the Lucidol Corp. was used as received.

(9) Walling and Briggs, THIS JOURNAL **67**, 1774 (1945).

Mass Copolymerization.—The method for determining monomer–polymer composition curves for the five systems reported was essentially the same in each case. Solutions comprising 100 g. of total monomers were prepared by adding appropriate amounts of monomer, comonomer and benzoyl peroxide to 4-oz. French square bottles. The concentrations employed are given in Table I. Air above the monomers was swept out with nitrogen and a metal cap screwed tightly on the bottle mouth. Copolymerizations were carried out in an air oven regulated to ±1° within the polymerization temperature given in Table I. Polymerization at that temperature was continued until a slight increase in viscosity was observed or, in the case of copolymer samples high in combined nitrile, until a small amount of insoluble copolymer had precipitated from the comonomer solution. The reaction was then poured into 3000 ml. of stirred denatured ethanol (2B) at room temperature and the bottle rinsed with ethanol. In the case of vinyl acetate copolymers, hexane was used in place of ethanol throughout. The mixture was boiled to complete the coagulation and filtered. Final purification was effected by similar treatment with two fresh 1500-ml. portions of denatured ethanol. After drying in an evaporating dish for forty-eight hours in a circulating air oven at 60°, the copolymer was analyzed in duplicate for nitrogen by the micro-Dumas method. Analytical data and conversion values are summarized in Table I.

Summary

Monomer–polymer composition curves for the systems vinyl acetate–acrylonitrile, vinyl acetate–methacrylonitrile, α-methylstyrene–acrylonitrile, α-methylstyrene–methacrylonitrile and styrene–methacrylonitrile are reported. These data, along with previously published copolymerization rates, were used to check the validity of predictions based on the Price–Alfrey relationships. Excellent qualitative and good quantitative agreement was found for the systems studied.

Values for the Q and e parameters for five additional monomers are suggested, and simplified forms for copolymer equations involving any number of components are presented.

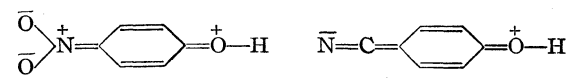
The Steric Inhibition of Resonance. III.[1] Acid Strengths of Some Nitro- and Cyanophenols

BY G. W. WHELAND, R. M. BROWNELL[2] AND E. C. MAYO

The acid strength of a phenol is greatly increased by the introduction of a nitro group para to the hydroxyl group. In most instances, in fact, the ionization constant of a *p*-nitrophenol is approximately a thousand times as large as is that of the corresponding unnitrated phenol; in other words, a para nitro group usually decreases the pK_a of a phenol by about 3 units. This greater acidity of the nitrophenol has been attributed[3,4] in part to an electrostatic interaction between the ionizable proton and the dipole moment of the nitro group; and in part also to resonance with a relatively unstable quinoid structure (such as I). Moreover, the effect produced by a para *cyano* group upon the acid strength of a phenol is qualitatively the same as (but usually rather smaller than) that produced by a para nitro group. Again, the observed increase in acid strength can be attributed[3] in part to an electrostatic interaction, since the dipole moment of the para cyano group (like that of the para nitro group) is directed so that its positive end points toward the aromatic ring, and hence toward the ionizable proton; and in part also to resonance with an unstable quinoid structure (such as II).



I II

Although both the electrostatic and the resonance effects should therefore increase the acid strengths of the nitro- and cyanophenols, there is no *a priori* way for the estimation of either their absolute or their relative magnitudes. Data now in the literature suggest, however, that the two effects are fairly large and of comparable magnitude. Thus, calculations by Westheimer[3] have led to the conclusion that the electrostatic effect alone should decrease the pK_a of *p*-nitrophenol (with respect to that of phenol itself) by approximately 1.25 units; hence, it may be inferred that the resonance effect must be responsible for the observed further decrease of approximately 1.6 units (*cf.* Table I, below). Similarly, Westheimer's calculations show that, with *p*-cyanophenol, the electrostatic effect alone should decrease the pK_a by approximately 1.30 units; hence, it can likewise be inferred that the resonance effect must here be responsible for the observed further decrease of approximately 0.75 unit (*cf.* Table I, below).

The experiments reported in this paper were performed in order to obtain additional evidence either for or against the belief that the electrostatic and the resonance effects are about equally responsible for the relatively great acid strengths

TABLE I

VALUES OF pK_a AT 25°

Compound	I (E. C. M.)[a]	II (R. M. B.)[a]
Phenol[b]	9.99[c]	...
3,5-Dimethylphenol	10.18	10.09[c]
2,6-Dimethylphenol	10.58	10.60[d]
p-Nitrophenol[b]	7.16	7.21[d]
3,5-Dimethyl-4-nitrophenol	8.25[f]	8.24[e]
2,6-Dimethyl-4-nitrophenol	7.22[d,e,f]	7.16[d,e,g]
p-Cyanophenol[b]	7.95[c]	...
3,5-Dimethyl-4-cyanophenol	8.21[f]	...
2,6-Dimethyl-4-cyanophenol	8.27[f]	...

[a] Since these two sets of data were obtained at quite different times, by different investigators, and hence, possibly, under somewhat different circumstances, both sets are merely recorded separately, without any attempt to average corresponding values. [b] *Cf.* Landolt–Börnstein, "Physikalisch-chemische Tabellen"; "International Critical Tables." [c] Average of four determinations. [d] Average of three determinations. [e] Average deviation, 0.02. [f] Mixtures warmed to effect solution. [g] Samples dissolved by complete neutralization with calcium hydroxide and resulting solutions back-titrated, to approximately two-thirds neutralization, with standard hydrochloric acid.

of *p*-nitro- and *p*-cyanophenols. If the resonance with the quinoid structure (such as I or II) is prevented from occurring, only the electrostatic interaction remains; hence, from the observed acid strength of the compound in question, the magnitude of the electrostatic effect alone can be directly estimated. If the resonance effect is important, such an "inhibition" of the resonance should, therefore, lead to a significant decrease in acid strength, and so to a significant increase in the value of pK_a. Now, with a *nitro*phenol, the quinoid resonance (of the type stated) is largely, if not entirely, inhibited[5] when there is a methyl group in each of the two positions ortho to the nitro group; for, under such circumstances, the nitro group cannot lie in the plane defined by the benzene ring, but must instead be twisted out of that plane by a rotation about the carbon–nitrogen bond. With a *cyano*phenol, on the other hand, the quinoid resonance can*not* be thus inhibited[1]; for, since the cyano group is linear, it cannot be twisted out of the plane of the ring by any sort of rotation.

The foregoing considerations lead to the conclusion that, if resonance is an important factor in increasing the acid strengths of the *p*-nitro- and *p*-cyanophenols, the pK_a of a *p*-nitrophenol should be appreciably increased by the introduction of two methyl groups in the positions *ortho* to the nitro group; but that that of a *p*-cyanophenol should not be greatly affected by a corresponding substitution. Since, however, methyl substituents *directly* influence the acid strengths of phenols, even in the absence of nitro or cyano groups, a complete analysis of the problem requires that the pK_a's of several phenols besides the ones mentioned be also measured.

The data obtained in this investigation are listed in Table I. As expected, methyl groups ortho to the nitro group markedly decrease the acid strength of the phenol, whereas methyl groups ortho to the cyano group have comparatively little effect. The prediction, based on the assumption that the quinoid resonance increases the acid strengths of the *p*-nitro- and *p*-cyanophenols, is therefore confirmed. Methyl groups ortho to the *hydroxyl* group slightly decrease the acid strength, presumably because of either a direct electrostatic effect or a direct resonance (hyperconjugation) effect, or of both.

From a comparison of the data given in Table I for 3,5-dimethylphenol and for 3,5-dimethyl-4-nitrophenol, it appears that the electrostatic effect of the nitro group decreases the pK_a of the latter compound by about 1.9 units. The discrepancy between this value and the one calculated by Westheimer (1.25 units) may be explained by the assumption either that the quinoid resonance in 3,5-dimethyl-4-nitrophenol is only partially inhibited, or that the methyl groups increase the electrostatic interaction between the nitro group and the proton by decreasing the effective dielectric constant of the medium.[3] That the second of these two factors (just mentioned) really exists, and is important, is suggested by the fact that the decrease in acid strength produced by methyl groups ortho to the hydroxyl group is much smaller in 2,6-dimethyl-4-nitrophenol and in 2,6-dimethyl-4-cyanophenol than it is in 2,6-dimethylphenol, even though, in neither of the first two compounds, could the methyl groups in any way affect the resonance.

Experimental

Method and Apparatus

The pK_a values reported were measured potentiometrically. A typical cell contained an aqueous solution of the desired phenol, which had been partially neutralized by standard calcium hydroxide; a Corning 015 glass electrode with an inner reference electrode[6]; and a saturated calomel electrode. The design of the calomel electrode assembly (Leeds and Northrup Company, Cat. No. 7724) was such that the liquid junction was formed through a ground glass joint at the end of the salt bridge. The cell was immersed in an oil thermostat maintained at 25 ± 0.5°. The values of the e. m. f. were measured to the nearest 0.2 mv. by means of a Leeds and Northrup vacuum tube electrometer.

The phenol concentrations in the solutions measured ranged from 0.0015 to 0.0088 *M* and were determined by the solubilities of the respective phenols, by the degrees of neutralization intended, and by the normalities of the calcium hydroxide solutions to be used. In general, the concentration of phenol was such that not less than 9 or 10 ml. of calcium hydroxide solution would be required per 100 ml. of final solution. Calcium hydroxide was

(5) (a) Birtles and Hampson, *J. Chem. Soc.*, 10 (1937); (b) Ingham and Hampson, *ibid.*, 981 (1939); (c) Wheland and Danish, THIS JOURNAL, **62**, 1125 (1940); (d) Spitzer and Whelan, *ibid.*, **62**, 2995 (1940); (e) Westheimer and Metcalf, *ibid.*, **63**, 1339 (1941).

(6) The glass electrodes used in obtaining one set of data (II (R. M. B.), Table I) were made by Mr. John D. Farr and contained silver–silver chloride inner reference electrodes. The one used for the other set of measurements (I (E. C. M.), Table I) was a commercial product, purchased from the Central Scientific Company; the inner reference electrode was unspecified and unobservable.

chosen as the base because of the low error attending the positive ion of this substance in measurements with glass electrodes.[7] The concentrations of the calcium hydroxide solutions used varied between 0.00770 and 0.01940 *N*. The ionic strength of the final solution was always well under 0.01.

The glass electrode was standardized daily by measuring the e. m. f. of a cell containing a Sörensen borate–hydrochloric acid buffer with a *p*H of 8.25 (interpolated) at 25°.[8] The *p*H of each phenol solution was calculated in the usual way[9] from the corresponding e. m. f. and the appropriate value of the e. m. f. given by the buffer solution. From the *p*H value thus obtained, the pK_a of the phenol was computed.[10] The pK_a's were corrected for the ionic strength effect by means of the Debye–Hückel limiting law,[11] and for the hydrolysis of the salt with use of the assumption that the concentrations of hydrogen and hydroxide ion were equal to the respective activities, as determined by the measured *p*H.

Unless otherwise noted in Table I, each pK_a value reported is the average of at least five independent determinations, with an average deviation of not more than 0.01 *pK* unit. The measurements of column II (R. M. B.) were made on phenol solutions, each of which was approximately half neutralized with calcium hydroxide; those of column I (E. C. M.), on the other hand, were made on solutions which varied in degree of neutralization as widely as was permitted by the solubilities of the particular phenols concerned. If, in a measurement, there was any question whether an error had been made, the value obtained was not included in the average even if it were reasonable. Three values were rejected on statistical grounds.[12]

With the cyanophenols, it was necessary to consider the possibility that the cyano groups might be hydrolyzed during the preparation of the solutions studied. The belief that no significant hydrolysis occurred is supported by the following evidence: (1) Nitriles of comparable molecular weight are, in general, not appreciably hydrolyzed under the conditions here employed. More specifically, Thiele and Eichwede[13] have stated that 2,6-dimethyl-4-cyanophenol is not hydrolyzed when it is boiled with dilute aqueous acids or bases; and, although the hydrolysis of 3,5-dimethyl-4-cyanophenol, itself, is not mentioned in the literature, a number of comparable compounds,[14] such as 2,6-dimethylbenzonitrile[15] and 2,4,6-trimethylbenzonitrile[16] in particular, have been reported to be stable toward alkalies. Moreover, 3,5-dimethyl-4-cyanophenol was found in this present study to be apparently unaffected when it was warmed with alkaline aqueous hydrogen peroxide. (2) Calculations indicate that appreciable hydrolysis of a cyanophenol to a product of significantly different acid strength would probably be evidenced by a systematic variation, exceeding experimental deviations, in the pK_a values calculated for that compound over the range of degrees of neutralization concerned. No such systematic variations were observed. (3) The excellent agreement between individual results, which was obtained for each of the cyanophenols studied, was independent, not only of the degree of neutralization, but also of the age of a solution and of the length of time during which it was warmed. (4) The three cyanophenols investigated, when recovered from representative solutions by acidification and extraction with ethyl acetate, showed no marked change in melting point. (5) With the use of Nessler reagent, the amount of ammonia produced was shown, in typical instances, to be less than 0.5% of that corresponding to complete hydrolysis.

Materials

The temperatures reported below are uncorrected. They were taken, unless otherwise indicated, on a thermometer calibrated against one standardized by the Bureau of Standards, or on the latter itself.

Phenol.—Mallinckrodt Analytical Reagent grade was distilled; a portion of the large amount that boiled, according to a non-standardized thermometer, constantly at 177.0° was reserved for use and stored in a vacuum desiccator in the presence of phosphorus pentoxide.

3,5-Dimethylphenol.—Eastman Kodak Co. best grade was recrystallized from light petroleum ether; m. p. (R. M. B.) 62.8–63.3°, m. p. (E. C. M.) 62.5–63.0°.[17]

2,6-Dimethylphenol.—2,6-Dimethylphenol, prepared from Eastman Kodak Co. *m*-2-xylidine through the diazonium salt, was recrystallized from light petroleum ether; m. p. (R. M. B.), on non-standardized thermometer, 48°, m. p. (E. C. M.) 44.7–45.6°.

***p*-Nitrophenol.**—Eastman best grade was recrystallized from carbon tetrachloride; m. p. (R. M. B.) 112.6–113.0°, m. p. (E. C. M.) 113.2–113.7° and 113.0–113.5°.

3,5-Dimethyl-4-nitrophenol.—3,5-Dimethyl-4-nitrophenol, prepared by the nitration of 3,5-dimethylphenol, was isolated by the codistillation procedure used by Rassow and Schultzky[18] for *p*-nitrophenol. This procedure employs a high-boiling petroleum fraction; an "ink oil" obtained from the Martin Driscoll Company, Chicago, was found to have approximately the correct boiling range, *viz.*, 265–280° (760 mm.). This method was found to give much more satisfactory yields than the usual procedures for isolating the *para* isomer; m. p. (R. M. B.) 107.1–107.6°, m. p. (E. C. M.), after recrystallization from carbon tetrachloride, 107.6–108.3°.

2,6-Dimethyl-4-nitrophenol.—2,6-Dimethyl-4-nitrophenol, obtained by condensation of the sodium salt of nitromalonaldehyde with diethyl ketone, as described by Jones and Kenner,[19] was purified by several decolorizations with Norite or Nuchar and recrystallizations from various solvents, of which the most efficacious was carbon tetrachloride. Because of the evident instability of this compound at temperatures near its melting point, the melting point of any sample varied markedly with the duration of heating; the best melting points obtained for the two portions used for measurement were, respectively: m. p. (R. M. B.) 170.5–170.6°, m. p. (E. C. M.), on non-standardized thermometer, 169.6–169.7°.

***p*-Cyanophenol.**—*p*-Cyanophenol, prepared from *p*-aminophenol by a Sandmeyer reaction, was decolorized with Norite and recrystallized from carbon tetrachloride; m. p. 112.0–112.4°.

3,5-Dimethyl-4-cyanophenol.—3,5-Dimethyl-4-cyanophenol was prepared by a stepwise procedure from 3,5-dimethylphenol. The 3,5-dimethylphenol was converted, by means of a Gattermann reaction, to 2,6-dimethyl-4-hydroxybenzaldehyde and the oxime of this aldehyde was dehydrated with acetic anhydride, as described by v. Auwers and co-workers,[20] to the desired cyano-xylenol. It was found that the yield of 2,6-dimethyl-4-acetoxybenzonitrile, the intermediate involved in the dehydration

(17) Kester (*Ind. Eng. Chem.*, **24**, 770 (1932)) states that although melting points of 64, 64.5 and 68° have been reported, 63.2° was the highest melting point obtained in his laboratory.

(18) Rassow and Schultzky, *Angew. Chem.*, **44**, 669 (1931).

(19) Jones and Kenner, *J. Chem. Soc.*, 1842 (1931).

(20) v. Auwers, Mürbe, Saurwein, Deines and Schornstein, *Fortschr. Chem. Physik physik. Chem.*, **18**, no. 2, 5 (1924).

process, could be greatly improved through purification of this compound by vacuum distillation rather than by recrystallization from water. The crude 3,5-dimethyl-4-cyanophenol was recrystallized from benzene; it formed glistening, white scales; m. p., on non-standardized thermometer, 177.5–177.7°.

Because of reports[19,21] that 3,5-dimethyl-4-cyanophenol crystallizes from benzene in small needles and melts at about 175°, the identity of this compound was confirmed by analysis.[22]

Anal. Calcd. for C_9H_9ON: C, 73.38; H, 6.16; N, 9.52. Found: C, 73.55; H, 6.38; N, 9.46.

2,6-Dimethyl-4-cyanophenol.—2,6-Dimethyl-4-cyanophenol was prepared from mesitol by the method of Thiele and Eichwede[13] and recrystallized from medium-boiling petroleum ether; m. p. 124.0–124.4°.

(21) Houben and Fischer, *Ber.*, **66**, 339 (1933).

(22) The carbon–hydrogen analysis was made by Mr. James G. Burt.

Summary

1. The pK_a's of the following compounds have been determined at 25°: 3,5-dimethylphenol, 2,6-dimethylphenol, 3,5-dimethyl-4-nitrophenol, 2,6-dimethyl-4-nitrophenol, 3,5-dimethyl-4-cyanophenol, 2,6-dimethyl-4-cyanophenol.
2. The pK_a's at 25° have been redetermined for the following compounds: phenol, *p*-nitrophenol, *p*-cyanophenol.
3. The results provide evidence that the total effect produced by a para nitro or para cyano group on the acid strength of phenol is due about equally to an electrostatic interaction and to resonance.

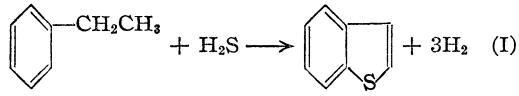
Catalytic Synthesis of Thianaphthene from Ethylbenzene

BY CORWIN HANSCH AND FRED HAWTHORNE

In a recent paper, Moore and Greensfelder[1] published the procedure for a new synthesis of thianaphthene from styrene and hydrogen sulfide. While this procedure is an excellent one for the preparation of thianaphthene itself, it would not be as convenient for the preparation of substituted thianaphthenes because of the lack of availability of the proper styrenes as starting materials. Thus, it seemed that the dehydrogenation of an alkylbenzene in the presence of hydrogen sulfide might be accomplished over a single catalyst with formation of the thianaphthene in one step according to Equation I.



(I)

The present paper reports the results of such an attempt.

Experimental

All experiments were carried out in a Pyrex catalyst tube in a continuous flow system. The apparatus used was similar to that described by Hoog, Verheus and Zuiderweg.[2]

The hydrogen sulfide used in this work was commercial grade used directly from the cylinder. Eastman Kodak Co. white label ethylbenzene was distilled before using.

Catalyst Preparations. I. Chromium on Aluminum Oxide.—To a boiling solution of 36.4 g. of chromic anhydride in 400 ml. of distilled water was added 200 g. of ALORCO alumina,[3] Grade H40, Type R2200, 8–14 mesh. The mixture was dried at 100°.

II. Chromium and Nickel on Aluminum Oxide.—Chromic anhydride (7.6 g.) and 12.5 g. of $Ni(NO_3)_2 \cdot 6H_2O$ were dissolved in 50 cc. of water and the solution brought to boiling. To this solution was added 50 g. of activated alumina with vigorous stirring. The mixture was then dried in an oven at 100°.

For the preparation of thianaphthene, the straight chromium catalyst[4] was reduced *in situ* with a slow stream of hydrogen, for one hour at the temperature at which dehydrogenation was to be made, then a stream of hydrogen sulfide passed over the catalyst for fifteen to twenty minutes at the same temperature. Ethylbenzene was then introduced at a uniform rate. A space velocity ratio of about 9:1 of hydrogen sulfide and ethylbenzene was found to give the highest conversion. Most of the liquid products were separated in a Liebig condenser. A small amount of liquid entrained in the large volume of hydrogen sulfide and hydrogen was separated by passing the gases through a U-tube filled with glass wool and cooled in an ice-bath. Using this technique, it was possible to obtain excellent material balances in all runs. The thianaphthene was isolated by distillation and identified by a comparison of it and its picrate with that of a sample prepared by a known procedure.[5]

Discussion

Table I shows the effect of temperature and space velocity on the conversion of ethylbenzene to thianaphthene.

TABLE I

The space velocity of hydrogen sulfide in all runs was 1400 cc./cc./hr.

Catalyst	Temp., °C.	Space velocity,[a] ethylbenzene cc./cc./hr.	% Conversion to thianaphthene
I	550	160	9.3
I	575	160	18.5
I	575	260	13.2
II	575	160	17.0
II	610	245	13.2
II	625	160	18.5

[a] Calculated as cc. of vapor at S.T.P.

The above runs were made for periods of four hours. It was observed that, although the rate of dehydrogenation (as estimated by hydrogen evolution) was more rapid

(2) Hoog, Verheus and Zuiderweg, *Trans. Faraday Soc.*, **35**, 995 (1939).

(3) This type of alumina was used exclusively in the research and was supplied through the courtesy of the Aluminum Ore Company.

(4) The nickel–chromium catalysts were reduced for two hours.

(5) Hansch and Lindwall, *J. Org. Chem.*, **10**, 381 (1945).

at temperatures of 600° and above, the activity of the catalyst decreased much more rapidly than at the optimum temperature 575°. Very little difference in activity or life of the two catalysts reported in this paper was noted. Several other catalysts of different ratios of chromium and nickel were prepared; they also showed very little difference in activity. With space velocity ratio of 4:1 of hydrogen sulfide to ethylbenzene, only low yields (~5%) of thianaphthene were obtained.

Preliminary results with other alkylbenzenes indicate that the reaction may be general, however, the yields do not appear to be as good as in the case of ethylbenzene.

Acknowledgment.—The authors are very much indebted to the Research Corporation for a Frederick Gardner Cottrell grant-in-aid which supported this research.

Summary

Thianaphthene has been prepared in 18.5% conversion from hydrogen sulfide and ethylbenzene using a chromia on alumina catalyst at 575°.

The Purification and Properties of Antibody against *p*-Azophenylarsonic Acid and Molecular Weight Studies from Light Scattering Data

BY DAN H. CAMBPELL, ROBERT H. BLAKER AND ARTHUR B. PARDEE[1a]

It is becoming increasingly evident that many fundamental problems dealing with the structure and behavior of antibody molecules must be studied with purified antibody preparations in solution of known composition rather than in complex solutions such as serum. Methods which are devised for the isolation and purification of antibodies on a practical scale are hence of considerable interest and importance. The following report describes a method for the isolation and purification of antibody against *p*-azophenylarsonic acid in which the antibody is removed from the antiserum by specific precipitation with a polyhaptenic dye and recovered from a solution of the dissociated antigen–antibody complex.

The recovery of antibodies from specific antigen–antibody complexes has been accomplished by a variety of methods.[1b] Perhaps the best known is the one described by Heidelberger and Kendall[2] and Heidelberger and Kabat,[3] in which 15% sodium chloride solutions were used to produce a shift in the antigen–antibody ratio of specific precipitates of SSS or of intact Pneumococcus and antipneumococcus serums favoring the liberation of antibody. Liu and Wu[4] were able to obtain as good if not better yields of antibody preparations by acid dissociation of similar antigen–antibody complexes at about *p*H 4.0 with subsequent isolation of antibody by salt precipitation or removal of antigen by centrifugation if bacterial cells were used. Recently, a report has been made by Haurowitz, *et al.*,[5] which describes the isolation and purification of antibody against *p*-aminobenzylamine, anthranilic, arsanilic, and sulfanilic acids by the use of methods somewhat similar to those used by us in the present investigation. The principal difference was their use of an acid-insoluble conjugated protein for a precipitating antigen. Our own investigations of a number of antigen–antibody systems have indicated that, in general, acid dissociation is the method of choice, at least for the systems involving ovalbumin, polysaccharide, and arsanilic acid antigens. The last of these is a particularly good system since simple polyhaptenic dye antigens can be used for specific precipitating agents. The physical properties of such antigens are so different from those of the antibody proteins that the dissociated complexes can usually be separated into the antigen and antibody components without difficulty. Certain dye antigens have the added advantage that they have a low solubility under acid conditions and hence upon dissociation of the antigen–antibody precipitate the antibody dissolves and the antigen remains behind as an insoluble acid.

Purification of Antibody.—Several methods were studied for the dissociation of antibody from antigen–antibody complexes and its subsequent recovery from the dissociated mixture. For example, treatment of precipitates by alkali at *p*H 9.0–10.0 resulted in considerable dissociation, as evidenced by solution of the precipitates, but the yields of antigen-free protein were low because of the high solubility of the antigen and its tendency to remain attached to the protein. Furthermore, some denaturation of antibody protein always occurred and the purity of antibody as based on the ratio of specifically precipitable protein to total protein usually gave values of only 10 to 20%. Another method which was used with some success was dissociation of dye–antigen complexes with a simple hapten such as arsanilic acid and subsequent dialysis against the hapten until the solution was free of the dye antigen. This

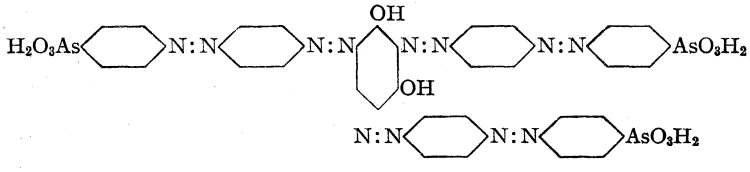
method was limited to precipitating antigens of sufficiently small molecular size to permit diffusion through the dialysis membrane. Such antigens are rather inefficient precipitating agents, and considerable time was required to dialyze away first the dye antigen and then the arsanilic acid. The method of choice in most instances and the one used for the antibody preparation in the present study was (1) the use of a good precipitating dye antigen, (2) dissociation of the antigen–antibody complex with arsanilic acid and then acidification to about *p*H 3.5, and (3) precipitation of the dissociated antibody with salt. The purified antibody used in study of physical properties was a pool obtained by mixing several purified preparations, but all were made by essentially the same method.

Serums from a number of rabbits which had been immunized over a period of many months with sheep serum-*p*-azophenylarsonic acid were pooled and a preliminary precipitation titration was made in order to determine the antigen–antibody ratio for optimum precipitation as well as to obtain an approximate idea of the antibody concentration. The antigen used for all preparations was a trisubstituted resorcinol dye having the following structure



The antigen solutions was adjusted to *p*H 8.0 and dilutions were made which varied by a factor of 2 from 1:1000 to 1:256,000, and these were added in 0.5 ml. volumes to tubes containing 0.5 ml. of a 1:4 or 1:5 dilution of the pooled antiserum at *p*H 8.0. The mixtures were allowed to react for about two hours at room temperature and forty-eight hours at 4°. The precipitates were then washed with 1.0% sodium chloride solution and analyzed for protein by the Folin–Ciocalteu method as modified by Pressman.[6] Most of the pooled sera gave maximum precipitation in slight antigen excess with antigen dilutions around 1:40,000 under the above conditions, and antibody protein values of from about 6 mg./ml. of serum to as high as 15 mg./ml. For precipitation of antibody from an 850-ml. batch of pooled serum which showed a preliminary titration maximum for antibody precipitation of 1:10,000 (1:40,000/1:4) was adjusted to *p*H 8.0 with 0.5 *M* sodium hydroxide, diluted with one volume of saline, and mixed with an equal volume of 1:20,000 antigen solution. After several hours at room temperature and about seventy-two hours at 4° about half of the supernatant was siphoned off and the remainder centrifuged and the precipitate washed free of soluble dye and protein with 1.0% sodium chloride at room temperature. The insoluble antigen–antibody complex was usually dissociated first with sodium arsanilate and was then acidified. Although acid dissociation alone was fairly successful it was found that hapten dissociation facilitated separation and gave higher yields. Thus the precipitate was first suspended in 25 to 50 ml. of 10% sodium arsanilate at *p*H 8.0–8.5 and the mixture carefully stirred until no further solution was evident. This required from two to four hours and usually resulted in a solution with only faint turbidity. When precipitates were allowed to develop over a period of longer than seventy-two hours the dissociation with haptens required much longer time and in a few extreme instances were not complete at twelve hours. The antigen–antibody–hapten solution was then quickly adjusted to *p*H 3.2 and again carefully stirred for about one hour at room temperature. At this *p*H most of the dye antigen became insoluble and the antibody protein remained in solution. A small amount of antibody usually remained with the insoluble dye and arsanilic acid but practically all was recovered in one washing with saline and was added to the original acid extract. The small amount of antibody which remained with the insoluble dye was easily recovered by washing. The antibody was precipitated by addition of a saturated sodium chloride solution in a final concentration of 4.0 *M*. Traces of dye which remained soluble in the acid solution were removed by the careful fractional precipitation with salt solution. The dye being relatively insoluble precipitated with much less salt than was required for antibody globulin. In such instances, 10–20% of the antibody would precipitate with the dye but could be recovered by further fractional precipitation with salt at *p*H 3.2. The final salt precipitated antibody was then re-

TABLE I

[a] The trisubstituted resorcinol dye described in text. [b] A chromotropic acid derivative containing two azophenyl-azo-arsonic acid groups. These antibody preparations were not used in the present study. [c] Subsequent experiments with the purified antibody indicated that less precipitate was obtained in the presence of serum proteins, hence these values may represent only relative amounts of antibody. [d] Protein based on microkjeldahl analysis. [e] Purity = specific precipitable protein/total protein in solution.

(6) David Pressman, *Ind. Eng. Chem., Anal. Ed.*, **15**, 357 (1943).

suspended in 0.9% saline and dialyzed against saline until the *p*H became practically neutral.

Representative values for several batches of pooled serum are given in Table I. It will be seen that the preparations obtained by use of the trisubstituted dye antigen were better than those obtained by use of a chromotropic acid derivative. This was due largely to the fact that the latter antigen showed an appreciable solubility at *p*H 3.5 and hence tended to complex with the soluble protein. Serums with lower titers always gave smaller yields.

Electrophoretic Pattern.—Electrophoretic studies of the purified preparations in the Tiselius apparatus indicated a very high degree of homogeneity. The experiments were made with approximately 1.0% protein solutions in 0.15 *M* sodium chloride plus 0.04 *M* phosphate buffer at *p*H 7.2. The current used was approximately 15 ma. and the pattern allowed to develop for two to three hours. The electrophoretic mobility was very similar to that of the gamma globulin fraction of serum.

Molecular Weight Determination. (a) From Osmotic Pressure.—The molecular weight determinations by osmotic pressure were made with simple osmometers of the static rise type with a Visking cellophane bag used for the membrane. The protein concentration was 2.0% in 0.15 *M* sodium chloride and 0.04 *M* phosphate buffer at *p*H 7.3. The values obtained varied from 136,000 to 144,000, as compared to the currently accepted values of 158,000. The slightly lower values were probably a reflection of the *p*H at which the determinations were made.

(b) From Light Scattering Data.—Measurements of the turbidity, refractive index, and depolarization of a protein solution can, under certain conditions, be used to calculate the molecular weight of the dissolved protein. The theoretical bases of these calculations are due principally to Rayleigh,[7] Von Smoluchowski,[8] Einstein,[9] Raman,[10] and Debye.[11]

If the dissolved particles are small compared with the wave length of light the following equation gives a relation between the turbidity of the solution, its concentration, refractive index, depolarization, and the molecular weight of the solute.

$$h = \left\{ \frac{32\pi^3 n^2 \left(\frac{\partial n}{\partial c}\right)^2 c}{\lambda^4 N_0 \left(1/M + \frac{2Bc}{RT}\right)} \right\} \left(\frac{6 + 3\rho}{6 - 7\rho}\right) \qquad (1)$$

where

h is the extinction coefficient due to scattering
n is the refractive index of the solution
c is the concentration
$\partial n/\partial c$ is the refractive index increment of the solute
λ is the wave length of the incident light
N_0 is Avogadro's number
M is the molecular weight of the solute
B is a constant which describes the deviation of the system from van't Hoff's law
R is the gas constant
T is the absolute temperature
ρ is the depolarization of the scattered light.

In practice it is difficult to measure h accurately so instead the amount of light which is scattered at an angle of 90° to the incident beam is measured. For solutions of particles which are small compared with the wave length of light the angular distribution of intensity of scattered light obeys a $(1 + \cos^2\theta)$ relation where θ is the angle between the direction of the incident beam and the scattered beam. The relation between h, I_0, the intensity of the original beam and i, the intensity of the light scattered at 90° to the incident beam, is

$$h = \frac{16\pi}{3} i/I_0 \qquad (2)$$

The direct measurement of the quantity, i/I_0, is a time consuming task so that routine measurements in this Laboratory are made by comparing the light scattered from a solution with that scattered from a sealed tube of purified carbon disulfide. Various investigators have reported values of i/I_0 for carbon disulfide and in addition the value has been redetermined in this Laboratory.[12] The value of i/I_0 for carbon disulfide which has been used in this investigation is $4.4 \cdot 10^{-5}$ for light of the wave length of 5461 Å.

The instrument which was used for the measurement of the scattered light is one which was designed and built in this Laboratory. A slightly convergent beam of monochromatic light from a mercury arc (GE-AH-4) is passed up through the bottom of a cylindrical glass cell. The light which is scattered in directions near 90° to the incident beam is focused on a 931-A electron multiplier phototube. A small fraction of the incident beam is reflected to another phototube and the outputs of the two tubes are balanced against one another by means of a potentiometer arrangement. A constant voltage transformer reduces fluctuations in the mercury arc and in the supply of a voltage regulator and rectifier which provides a source of high potential for the plates of the phototubes.

A diaphragm arrangement is installed in the path of the scattered beam which permits sections of polaroid film with known orientations to be switched in and out of the light path. This device gives a convenient way of measuring the depolarization of the scattered light.

The refractive index increment is measured with a differential refractometer similar in design to one which has been described in the literature.[13,14]

(12) A more complete description of the light scattering apparatus and technique which have been developed in this Laboratory will soon be published.
(13) D. Rau and W. Roseveare, *Ind. Eng. Chem., Anal. Ed.*, **8**, 72 (1936).
(14) P. Debye, *J. Applied Phys.*, **17**, 392 (1946).

Four solutions of the protein were made with a dilute salt solution (0.15 *M* sodium chloride) and were dialyzed against the same solution for two weeks at 4°. The *p*H of the protein solution at the end of the dialysis was 7.5. The solutions were then centrifuged for twenty minutes in a field 32,000 times that of gravity to remove any suspended dust, placed in a scattering cell, and the intensity of the scattered light compared with that scattered from carbon disulfide for a wave length of 5461 Å. Depolarization measurements were made. The refractive index increment was computed from the difference between the refractive indices of the solution and the solvent. Two of the solutions were slightly colored. Optical density measurements were made on these solutions with a spectrophotometer at the wave length used so that the magnitude of the scattering could be corrected for the true absorption. Concentrations were determined as described in the previous section.

The molecular weight of the dissolved protein is given by

$$M = \frac{\lambda^4 N_0}{2\pi^2 n^2 \left(\frac{\partial n}{\partial c}\right)^2 (c/i/ics_2)_{c\to 0}(I_0/ics_2)} \qquad (3)$$

which follows from (1) and (2)

$c/i/ics_2$ is the concentration of the solution divided by the ratio of the intensity of the light scattered from the solution to that scattered from carbon disulfide. This quantity is corrected for the depolarization of the scattered light and is extrapolated to zero concentration.

A plot of $c/i/ics_2$ *vs.* c is given in Fig. 1. The refractive index increment of this protein is 0.171. The depolarization of the solution is 0.032 and apparently is independent of concentration.

The value of the molecular weight which is calculated from light scattering measurements, 158,000 ± 10,000 compares favorably with previously published data from sedimentation and osmotic pressure studies.

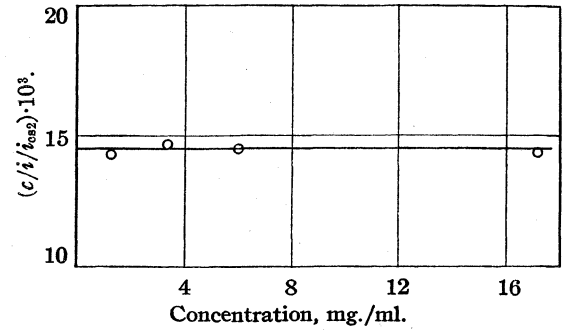

Fig. 1.—Light scattering data for purified rabbit antibody.

There is evidence, however, that the turbidity, depolarization, and refractive index of a protein solution change somewhat with *p*H and perhaps with salt content.[15,16] Not enough work has yet been done to understand how these changes should be taken into account when a value of the molecular weight is to be calculated.

We wish to express our thanks to Professor R. M. Badger and Dr. Stanley Swingle for their suggestions and assistance.

This work was supported in part by a Grant from the Rockefeller Foundation.

Summary

Methods are described for the isolation and purification of rabbit antibody against *p*-azophenylarsonic acid. The purified preparations were electrophoretically homogeneous and similar to gamma globulin.

Molecular weight studies from osmotic pressure and light scattering data gave values of approximately 140,000 and 158,000, respectively.

The Inhibition of Microbiological Growth by Allylglycine, Methallylglycine and Crotylglycine[1,2]

BY KARL DITTMER, HARLAN L. GOERING,[3] IRVING GOODMAN AND STANLEY J. CRISTOL

The interchange of an aromatic sulfide for a vinylene group in thiamin,[4] nicotinic acid[5] and phenylalanine[6] has led to the formation of specific metabolite antagonists. Because of these effects and because of the theoretical basis for the similarity of the vinylene group (—CH=CH—) and a divalent sulfur atom (—S—),[7] it has been possible to assume that substituting a sulfur for a vinylene group or *vice versa* may be the basis for the preparation of one type of specific metabolite antagonist.[8,9,10]

Since all of these examples are of aromatic com-

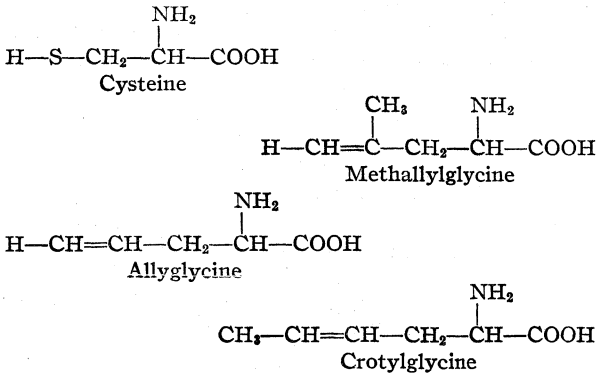
pounds, it seemed desirable to determine whether similar changes in aliphatic compounds containing sulfur or vinylene groups would likewise result in the formation of antagonists. To test this we chose to make the vinylene analogs of the sulfur-containing amino acids. In this paper we wish to report on the growth-inhibitory properties of the vinylene analogs of cysteine, allylglycine and the two closely related unsaturated amino acids methallylglycine and crotylglycine. The structural relationships of these unsaturated amino acids to cysteine are illustrated by the following chemical formulas. The position of the double bond in these compounds is inferred from their syntheses.



We have determined the amounts of these unsaturated amino acids required to inhibit the growth of three strains of *Escherichia coli* and strain 139 of *Saccharomyces cerevisiae*. The effects of various amino acids and vitamins on the toxicity of these unsaturated amino acids are now being investigated.

Experimental

Preparation of Unsaturated Amino Acids.—The syntheses of the unsaturated amino acids by procedures similar to those reported by Albertson[11] will be described in a separate paper.[12] The starting materials were allyl chloride, methallyl chloride and crotyl chloride from which were obtained *dl*-allylglycine, *dl*-methallylglycine and *dl*-crotylglycine, respectively.

Inhibition of Growth of *Escherichia coli*.—Three strains of *E. coli* were used in this study; one was an unidentified strain[13] which will be referred to as strain N; the second is listed by the American Type Culture Collection as number 9723; and the third was kindly supplied by Dr. William Shive; it will be referred to as strain T. For these tests the organisms were grown for sixteen hours in the synthetic medium described by MacLeod.[14] Best results were obtained when the medium was prepared daily and the *p*H carefully adjusted to 7.3. Six and five-tenths milliliters of medium was added to the various addenda dissolved in a volume of 1.0 ml. in the assay tubes (20 × 150-mm.). The tubes were capped by aluminum caps and autoclaved for five minutes at 15 pounds pressure and then inoculated with 1 drop of a pure *E. coli* suspension. The inoculum was prepared and handled as described previously,[6] except that during these experiments each culture was washed once with sterile saline before it was diluted for the inoculum.

The effects of increasing amounts of *dl*-allylglycine, *dl*-methallylglycine and *dl*-crotylglycine on the growth of three strains of *E. coli* are illustrated by the curves plotted in Figs. 1, 2 and 3, respectively. The amounts of each

inhibitor required to reduce the growth of each strain to 50% of normal and to complete inhibition are tabulated in Table I. The data of Table I represent the averages obtained from a large number of determinations. From these data and the curves of Figs. 1, 2 and 3, it can be seen that allylglycine and methallylglycine have very similar inhibitory activity, but crotylglycine is less active for all three strains of *E. coli*.

TABLE I

DATA ILLUSTRATING THE RELATIVE EFFECTIVENESS OF THREE UNSATURATED AMINO ACIDS AS MICROBIAL GROWTH INHIBITORS

Microörganism	Amounts of unsaturated amino acid required[a] per 7.5 ml. of medium: *dl*-Allylglycine γ	*dl*-Methallylglycine γ	*dl*-Crotylglycine γ
E. coli, strain N			
for 50% Inhibition[a]	16[b]	22	50
for 100% Inhibition[a]	20–40	25–40	50–80
E. coli, strain 9723			
for 50% Inhibition	27	20	50
for 100% Inhibition	30–50	25–40	50–70
E. coli, strain T			
for 50% Inhibition	17	10	23
for 100% Inhibition	20–30	15–25	30–40
S. cerevisiae, strain 139			
for 50% Inhibition	6	55–100	700–1000
for 100% Inhibition	50	>1 mg.	>4 mg.

[a] The amounts required for complete inhibition vary much more than the amounts required for 50% inhibition. The values for 50% inhibition are averages while the range of amounts required for 100% inhibition are given. [b] For a short period of time during these tests, between 30 and 50γ were required for 50% inhibition of normal growth.

Allyl chloride, allyl alcohol and allylurea were tested at a concentration of 1 mg. per 7.5 ml. of medium and were found to be either completely inactive or only slightly inhibitory.

Inhibition of the Growth of *Saccharomyces cerevisiae*.—The technique followed in the yeast growth experiments was similar to that described previously.[6] The medium employed was that used by Snell, Eakin and Williams[15] except for the level of aspartic acid, which was increased to 2 g. per 10 liters of medium.

The effects of increasing amounts of *dl*-allylglycine, *dl*-methallylglycine and *dl*-crotylglycine on the growth of *S. cerevisiae* are shown in Fig. 4. The amounts of the inhibitors required to produce 50 and 100% inhibition of normal growth are also listed in Table I. From the curves of Fig. 4 and the data of Table I it is evident that of the three unsaturated amino acids, allylglycine is by far the best yeast growth inhibitor and crotylglycine is the poorest.

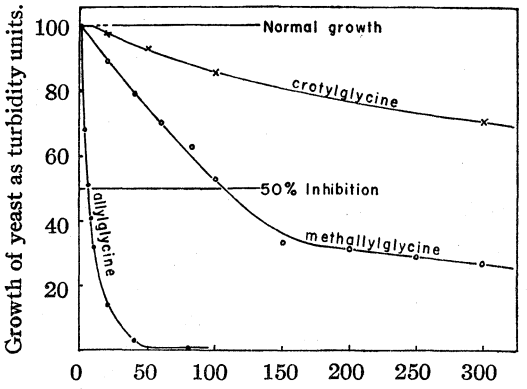

Fig. 4.—The inhibition of the growth of *S. cerevisiae*, strain 139, by *dl*-allylglycine, *dl*-methallylglycine and *dl*-crotylglycine.

Acknowledgment.—The authors are greatly indebted for the very excellent assistance received from Mrs. Charmion McMillan, Mrs. Hester P. McNulty and Mrs. Virginia Janda. The authors also wish to thank Mr. V. C. Irvine and Mr. W. S. Thornhill of the Shell Chemical Corporation for generous supplies of allyl chloride and methallyl chloride.

Summary

As possible antagonists for cysteine three unsaturated alpha amino acids, allylglycine, methallylglycine and crotylglycine, were tested for their growth inhibition of three strains of *Escherichia coli* and strain 139 of *Saccharomyces cerevisiae*. Allylglycine and methallylglycine were almost equally effective inhibitors of *E. coli*, producing complete inhibition of growth for sixteen hours in very small concentrations. Crotylglycine was less active on the growth of all three strains of *E. coli*. For *S. cerevisiae*, allylglycine was the most effective inhibitor of the three unsaturated amino acids and crotylglycine showed only low inhibitory action.

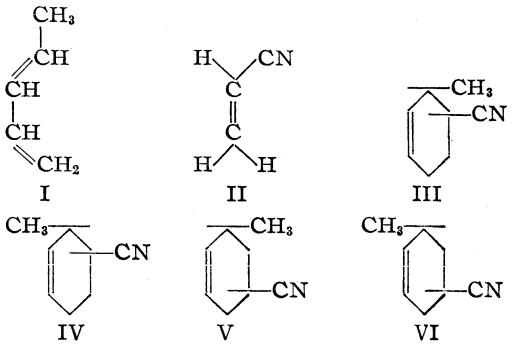
The Condensation of Piperylene with Acrylonitrile and Methyl Acrylate

BY JOHN S. MEEK AND JAMES W. RAGSDALE

When a diene such as piperylene (I) which possesses only one plane of symmetry undergoes the Diels–Alder reaction with an unsymmetrically substituted dienophile such as acrylonitrile (II) then possibly four different racemic nitriles might be formed. In this case these are *cis*- (III) and *trans*-1,2,5,6-tetrahydro-*ortho*-tolunitrile (IV) and *cis*- (V) and *trans*-1,2,3,6-tetrahydro-*meta*-tolunitrile (VI). The possibility of the formation of

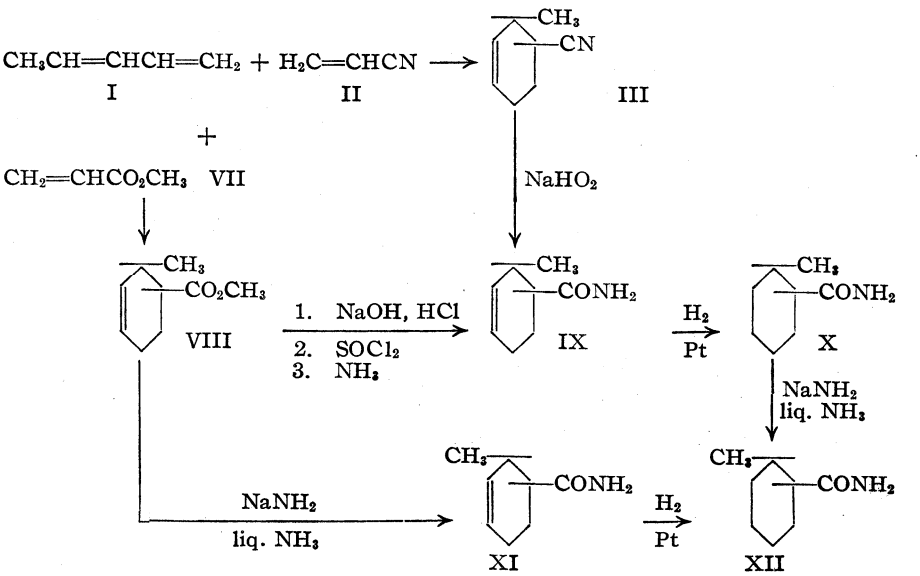


such isomers was recognized by Lehmann and Paasche.[1] However, in only a few cases have the adducts been identified as ortho or meta isomers and in no case has it been definitely proven whether these were *cis* or *trans* in nature. Lehmann and Paasche condensed acrolein with 4-*p*-xylyl-1,3-pentadiene and assigned to the resulting adduct the structure of an ortho isomer in which the aldehyde group and the *p*-xylyl group were *trans* to each other.[1] Their proof of structure was inconclusive and their adduct was not converted to any known compound.

Recently it was found that the adduct of acrylonitrile and piperylene was a mixture of an ortho and a meta isomer and that the ortho isomer was roughly seven times as abundant as the meta isomer in the mixture.[2] Therefore, this reaction was chosen in an effort to learn if these isomers were *cis* or *trans* in nature, and at the same time it was planned to study the previously unreported condensation of piperylene and methyl acrylate (VII).

Methyl acrylate was found to condense readily with piperylene to give a 65% yield of an adduct (VIII). Dehydrogenation of VIII and subsequent hydrolysis produced *o*-toluic acid. No *m*-toluic acid was isolated. Saponification of VIII, conversion to the acid chloride, and treatment with ammonia gave a solid amide (IX). This upon hydrogenation gave the known *cis*-hexahydro-*o*-toluamide (X).[3] The over-all yield from the crude adduct to IX was 57%, showing that the majority of the adduct was the *cis*–ortho isomer VIII.

In an attempt to get a better conversion of VIII to IX, ammonolysis was tried. None appeared to take place with alcoholic ammonia solutions. The use of liquid ammonia with ammonium chloride was next tried,[4] but no identifiable product could be obtained. The use of sodium amide in liquid ammonia gave a small yield of a compound (XI) which was identified as *trans*-1,2,5,6-tetrahydro-*o*-toluamide by hydrogenation to the known *trans*-hexahydro-*o*-toluamide (XII).[3] A subsequent experiment showed that under similar conditions the *cis* amide was converted to the *trans* isomer.



The crude adduct of piperylene and acrylonitrile was treated with sodium hydroxide and hydrogen peroxide in alcohol. An 85% yield of IX was obtained and thus the majority of the adduct was shown to be III. Attempts to isolate an amide

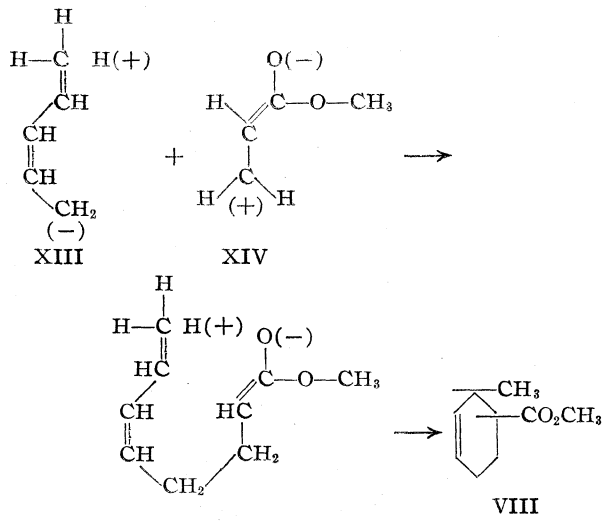
derived from either IV, V or VI have failed so far although it has been shown that V or VI if not both must be present in the reaction mixture.[2]

From these two examples it appears that piperylene condenses with a negatively substituted unsymmetrical ethylene to give chiefly the *cis*-ortho isomer. This is what one would expect on the basis of resonance and inductive effects in the compounds studied. For in piperylene it has been shown that the inductive and hyperconjugative effect of the methyl group causes a negative charge to reside on the terminal carbon atom[5] (XIII). In methyl acrylate, as well as many other negatively substituted ethylenes, the β-carbon atom is positive when compared to the α-carbon atom due to mesomeric effects (XIV). Thus the molecules may line up as pictured below to form the ortho isomer, the negative end of one being attracted by the positive end of the other. In the piperylene molecule (XIII) hyperconjugation of the methyl group results in its having a positive charge. This charge attracts it to the negative charge on the carbonyl group resulting from resonance, and thus a *cis* configuration results.



XIII XIV

VIII

The formation of the meta isomer in the case above would require the positive end of the dienophile to join with the positive end of the diene which would need a higher energy of activation than that required for the formation of the ortho isomer.

Experimental

The piperylene, methyl acrylate and acrylonitrile used in these experiments were Eastman Kodak Company practical grade, and they were used without further purification. About 70% of the piperylene was the *trans* isomer.

Adduct of Piperylene with Methyl Acrylate (VIII).—A mixture of 57 g. (0.67 mole) of methyl acrylate, 45.5 g. (0.67 mole) of piperylene and 0.1 g. of hydroquinone were placed in a Parr hydrogenation bomb under 1200 pounds of hydrogen pressure and heated for six hours at 200°. The hydrogen was used to test for leaks in the apparatus, and also in the hope that it would cut down peroxide formation and the diffusion of the piperylene which might result in polymerization taking place around the valves of the bomb head. No such polymerization was encountered and the use of the bomb avoided the dangers of sealed glass tubes and permitted the use of larger amounts of materials. The product was distilled through a short Vigreux column and 67.4 g. (65%) of adduct was obtained, b. p. 180–205° (627 mm.). A small portion was redistilled and the fraction boiling at 181–183° (622 mm.), $n^{20}D$ 1.432 was taken for analysis.

Anal. Calcd. for $C_9H_{14}O_2$: C, 70.13; H, 9.15. Found: C, 70.28; H, 8.98.

The adduct was dehydrogenated by heating under reflux with a 25% palladium on charcoal catalyst. Saponification of the resulting oil and acidification gave *o*-toluic acid. This was identified by means of a mixed melting point with an authentic sample and by preparing the *p*-bromophenacyl ester derivative.

Adduct of Piperylene with Acrylonitrile (III).—A mixture of 38.5 g. (0.72 mole) of acrylonitrile, 58 g. (0.85 mole) of piperylene and a trace of hydroquinone and iodine were placed in the bomb as in the above procedure and were heated at 130° for eight hours. Distillation of the resulting product gave 18.7 g. of crude piperylene, 18.4 g. of acrylonitrile, and 47.6 g. (54%) of crude adduct. Frank, Emmick and Johnson[2] have reported a 56% yield when equivalent amounts of *trans*-piperylene and acrylonitrile were heated for twenty-four hours on a steam-bath. Fractionation of our adduct through a column possessing 12 theoretical plates failed to separate the position isomers shown to be present but not isolated by those authors. The adduct boiled at 190–191° (620 mm.), $n^{20}D$ 1.4710.[6]

***cis*-1,2,5,6-Tetrahydro-*o*-toluamide (IX).**—To a solution of 2.1 g. of VIII in 15 ml. of methanol was added a solution of 1.6 g. of potassium hydroxide in 3 ml. of water. The mixture was allowed to stand in the cold for forty hours. This was then acidified with hydrochloric acid and extracted with ether. This extract was then warmed to remove the ether and any methanol present, and the residual oil was heated with 6 g. of thionyl chloride for thirty minutes. The acid chloride was poured into ice-cold concentrated ammonium hydroxide and the resulting solid was isolated by means of filtration and washed with water. Recrystallization from hot water gave 1.1 g. (58%) of amide, m. p. 143°.

This same amide was prepared from the adduct of acrylonitrile and piperylene by the action of alkaline hydrogen peroxide using the procedure given for converting *o*-tolunitrile to the amide[7] with 18.1 g. (0.15 mole) of the adduct being used. A yield of 16.1 g. (85%) of the amide was obtained, m. p. 140–142°. Recrystallization from 10% methanol gave crystals melting at 143° as before and a mixed melting point of the two was not depressed.

Anal. Calcd. for $C_8H_{13}NO$: C, 69.02; H, 9.41; N, 10.06. Found: C, 69.1; H, 9.20; N, 10.13.

Methyl *cis*-Hexahydro-*o*-toluate.—Hydrogenation of a small quantity of VIII showed that about 2% more than the theoretical amount of hydrogen was absorbed at room conditions with Adams catalyst being used. Hydrogenation of 20 g. (0.13 mole) of VIII in 40 ml. of methanol with 50 mg. of platinum oxide was carried out. The platinum was removed by means of filtration and the filtrate was distilled through a short Vigreux column. The main fraction boiled at 181–183° (623 mm.) and weighed 15.2 g. (75%); $n^{20}D$ 1.432; d^{24} 0.956.

Anal. Calcd. for $C_9H_{16}O_2$: C, 69.19; H, 10.32. Found: C, 69.15; H, 10.46.

***cis*-Hexahydro-*o*-toluamide (X).**—The 15.2 g. of hydrogenated ester prepared above were allowed to stand

(5) Hannay and Smyth, *ibid.*, **65**, 1931 (1943).

(6) We are indebted to Mr. Robert C. Ronald for this fractionation.

(7) Noller, "Organic Syntheses," Col. Vol. II, John Wiley & Sons, Inc., New York, N. Y., 1943, p. 586.

almost two days with 6 g. of sodium hydroxide in aqueous ethanol. The mixture was acidified with hydrochloric acid and then ether extracted. Fractional distillation gave 10 g. (72%) of *cis*-hexahydro-*o*-toluic acid, b. p. 119–121° (9 mm.), $n^{20}D$ 1.4572; reported,[8] b. p. 122–123° (10 mm.), $n^{20}D$ 1.458. A small amount of the acid was heated with thionyl chloride, the excess reagent was removed by distillation and the acid chloride was poured into ice-cold ammonium hydroxide. The amide obtained was recrystallized twice from a methanol–water mixture and melted sharply at 149.5°; reported[8] m. p. 151–153°.

Twelve grams of IX prepared from the adduct of acrylonitrile was placed in 135 ml. of methanol with 50 mg. of Adams catalyst and hydrogenated at room conditions. The platinum was removed by filtration and the filtrate was evaporated to dryness and gave 11.3 g. (93%) of crude amide, m. p. 149°. Treatment with charcoal in a 10% methanol solution gave a product melting sharply at 150°. A mixed melting point with the hexahydroamide prepared from VIII as reported previously showed no depression.

Attempted Ammonolyses of VIII.—All attempts to prepare IX by the action of ammonia on VIII failed. Treatment of VIII with aqueous ammonia or anhydrous ammonia in absolute ethanol with heating failed to give any solid product. Finally the procedure of Fellinger and Audrieth[4] was tried. A solution of 4.8 g. of VIII and 2 g. of ammonium chloride in 120 ml. of liquid ammonia was placed in a 500 ml. Parr bomb and heated at 80–100° for twenty-four hours. The ammonia was allowed to evaporate and the residue was dissolved in 10% methanol and treated with charcoal. After removing the charcoal by filtration and the methanol by evaporation, chilling the solution resulted in the formation of white crystals, 0.1 g. (5%), m. p. 120–122°. Hydrogenation of 52.6 mg. of the substance with 10 mg. of Adams catalyst absorbed slightly more than the theoretical amount of hydrogen which would have been taken up by a tetrahydrotoluamide. Recrystallization of the hydrogenated product gave a white solid, m. p. 141.5°. This does not correspond to the melting point of 155–156° reported for the only known form of hexahydro-*m*-toluamide,[9] and save for an analysis of the hydrogenated material these compounds were not investigated further.

Anal. Calcd. for $C_8H_{15}NO$: N, 9.91. Found: N, 9.70.

***trans*-1,2,5,6-Tetrahydro-*o*-toluamide (X).**—To 120 ml. of liquid ammonia were added 2 g. of sodium hydride and 4.8 g. of VIII. The mixture was heated as before in a Parr bomb, and then the ammonia was allowed to evaporate. The resulting powder was dissolved in water, neutralized with hydrochloric acid, and then ether extracted. Evaporation of the ether gave a gum which was dried on a porous plate and then treated with charcoal and recrystallized from 10% methanol; yield, 0.1 g. (5%), m. p. 166°.

Anal. Calcd. for $C_8H_{13}NO$: N, 10.06. Found: N, 9.75.

***trans*-Hexahydro-*o*-toluamide (XII).**—Twenty-six milligrams of XI was hydrogenated with Adams catalyst in methanol. Slightly more than the theoretical amount of hydrogen was absorbed. Evaporation of the methanol following removal of the catalyst gave a product melting at 178°. Recrystallization from hot water raised the melting point to 180°, reported m. p. for *trans*-hexahydro-*o*-toluamide is 180–181°.[3-8]

Two grams of *cis*-hexahydro-*o*-toluamide, 2 g. of sodium hydride and 100 ml. of liquid ammonia were heated under pressure at 90° for two hours. The material was worked up as in the preparation of XI and 0.3 g. (15%) of amide, m. p. 180°, was obtained. A mixed melting point with the product obtained by hydrogenating XI was not depressed. When 2 g. of X, 2 g. of sodium hydride and 100 ml. of liquid ammonia were allowed to stand together for several hours while the ammonia gradually evaporated, no *trans* amide was obtained.

Acknowledgment.—This work has been supported in part by a grant-in-aid from the Council of Research and Creative Work of the University of Colorado. The sodium hydride used in this work was a gift of the Electrochemical Division of E. I. du Pont de Nemours, Inc., and the thionyl chloride was a gift of the Hooker Electrochemical Company.

Summary

The condensation of piperylene with two negatively unsymmetrically substituted ethylenes, acrylonitrile and methyl acrylate, in the Diels–Alder reaction has been found to give in both cases chiefly the *cis*-ortho isomer. This is in agreement with predictions based upon electronic theories.

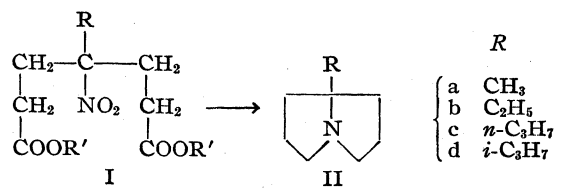
The Synthesis of Pyrrolizidines. II. Basicities of 8-Alkylpyrrolizidines[1]

BY NELSON J. LEONARD AND KARL M. BECK[2]

The 8-alkylpyrrolizidines (II) offer an excellent opportunity for the detection of F-strain[3] in a bicyclic amine system, and the method of synthesis of 8-methylpyrrolizidine (IIa) reported from this Laboratory[1] shows promise of general application. Therefore, the preparation of homologous 8-alkylpyrrolizidines has been investigated so that the relative basicities of the products could be determined.

A favorable yield of 8-methylpyrrolizidine (IIa) had previously been realized in the hydrogenation of diethyl γ-methyl-γ-nitropimelate (Ia) in ethanol over copper chromite at 250–350 atm. and 275°.[1] In extending the method to 8-*n*-propyl-



(1) For the first article in the series, see Leonard, Hruda and Long, THIS JOURNAL, **69**, 690 (1947).

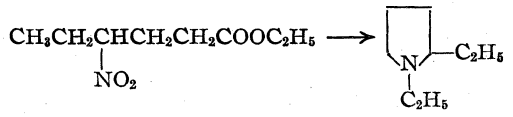
(3) Brown, THIS JOURNAL, **67**, 374 (1945).

pyrrolizidine (IIc) and 8-isopropylpyrrolizidine (IId), it was found advantageous to employ dioxane as the solvent.[4] The reaction time in dioxane was one-third that required in ethanol. Yields between 60 and 65% were realized. 8-Ethylpyrrolizidine (IIb) was obtained in comparable yield by the one-step catalytic reduction of the condensation product of 1-nitropropane with two moles of ethyl acrylate (Ib). When the condensation product of 1-nitropropane with one mole of ethyl acrylate (III) was hydrogenated in ethanol over copper chromite at 200–300 atm. and 250°, 1,2-diethylpyrrolidine (IV) was obtained in 50% yield. Catalytic hydrogenation gave about the



III IV

same yield of IV whether the reduction was carried out in one step or by the two-step process with platinum oxide at low pressure followed by copper chromite at high pressure.[1] That N-alkylation occurred is not surprising, since Adkins[5] has cited the N-ethylation of primary and secondary amines with ethanol solvent above 150°, and Barr and Cook[6] have observed N-alkylation in the preparation of certain piperidines by catalytic hydrogenation over copper chromite in methyl, ethyl and butyl alcohols. N-Methylation did not proceed readily in the pyrrolidine series, for when III was hydrogenated in methanol over copper chromite at 200–300 atm. and 250°, none of the expected 1-methyl-2-ethylpyrrolidine could be isolated.

The precursors (Ic,d) of 8-*n*-propyl-and 8-isopropyl-pyrrolizidine were prepared conveniently by the general method of Bruson,[7] through the condensation of methyl acrylate with 1-nitrobutane and 1-nitro-2-methylpropane in the presence of benzyltrimethylammonium hydroxide. Seventy to eighty per cent. of the nitroparaffins was accounted for in the form of condensation products when about 0.07 mole of benzyltrimethylammonium hydroxide was employed per mole of nitroparaffin. From 1-nitrobutane were obtained dimethyl γ-*n*-propyl-γ-nitropimelate (Ic) and methyl γ-nitroheptanoate; from 1-nitro-2-methylpropane, dimethyl γ-isopropyl-γ-nitropimelate (Id) and methyl γ-nitroisoheptanoate. The condensation of nitroisobutane with methyl acrylate gave a predominant yield of the isoheptanoate and only 10% of the pimelate derivative. In further reaction of the methyl γ-nitroisoheptanoate with another mole of methyl acrylate to give dimethyl γ-isopropyl-γ-nitropimelate, diethylamine[8] was found to be superior to benzyltrimethylammonium hydroxide as the condensing agent.

The reduction of the γ-nitropimelate esters furnished a series of alkylpyrrolizidines, for which it was desired to determine the basicity values. The high pK_H value (11.48) for heliotridane, or optically active 1-methylpyrrolizidine, as measured by Adams, Carmack and Mahan,[9] suggested that the fusion of two five-membered rings through a common C–N bond placed the electron pair of the nitrogen in an exposed or sterically freed position. Determination of the *p*H at half neutralization for other alkylpyrrolizidines would indicate whether the unusually high figure for heliotridane was inherent in the pyrrolizidine nucleus. None of our observed pK_H values for alkylpyrrolizidines (see Table I) was in the range of the figure for heliotridane; all exhibited basicity of a much lower order, yet higher than that for analogous acyclic tertiary amines. The higher basicity of cyclic, as compared with acyclic ethers and amines has been ascribed by Brown to B-strain[3] in the acyclic molecules.[10] F-strain[3,11] in the pyrrolizidines should increase with increasing size of the 8-alkyl group attached to the pyrrolizidine nucleus, because the apparent *cis* fusion of the two rings necessitates the protrusion of the 8-alkyl group toward the face of the nitrogen atom. This may be seen by comparing the accompanying photographs of models of the 8-methyl (Fig. 1), 8-ethyl (Fig. 2), 8-isopropyl (Fig. 4), and 8-*n*-propyl (Fig. 3) compounds. The pK_H values determined

TABLE I

BASICITY OF 8-ALKYLPYRROLIZIDINES AND RELATED COMPOUNDS

Compound	Formula	pK_H	BF_3 adduct	Picrate m. p., °C.
2-Methylpyrrolizidine[12]		10.49	....	169–170
8-Methylpyrrolizidine[1]	IIa	10.69	Solid	281
8-Ethylpyrrolizidine[1]	IIb	10.67	Solid	238
8-Isopropylpyrrolizidine	IId	10.70	Solid	228–229
8-*n*-Propylpyrrolizidine	IIc	10.61	None	156–157
1,2-Diethylpyrrolidine	IV	10.02	Liquid	120–121

(4) An amide is the probable last intermediate[1] in the over-all reduction process, and Adkins ("Reactions of Hydrogen," University of Wisconsin Press, Madison, Wisconsin, 1937, pp. 95, 112) has recommended the use of dioxane as a solvent for the catalytic reduction of amides.

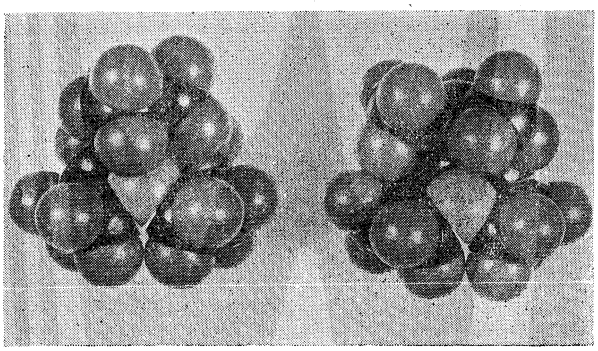

Fig. 2.

Fig. 3.

Fig. 4.

in 50% aqueous methanol for the series of 8-alkylpyrrolizidines are indicated in Table I, as corrected to 25° and accurate within ±0.01 *p*H unit. In the homologous series of 8-alkylpyrrolizidines, the pK_H values decrease in the order: 8-methyl > 8-ethyl > 8-*n*-propyl, corresponding to the increase in steric hindrance of the 8-alkyl group. The steric effect outweighs the positive inductive effect (+I) of the alkyl group introduced since, in consideration of the polar effect alone, the order of basicities would be the reverse of the observed order. The proximate pK_H values for 8-isopropyl- and 8-methylpyrrolizidine indicate that in IId the increased positive inductive effect of the isopropyl group and the increased steric effect (similar to that in IIb) are about equal in their counteracting influences. The basicity value for 8-methylpyrrolizidine is greater by 0.20 *p*H unit than that for 2-methylpyrrolizidine. This is probably due to the inductive effect of the methyl group, which is only one carbon removed from the nitrogen in the 8-methylpyrrolizidine. A comparison of the effect on basicity of the introduction of a methyl group into the 2- and 8-positions of pyrrolizidine with that of the introduction of a methyl group into the corresponding positions of 1-ethylpiperidine[13] indicates close analogy between the two systems. Thus, the basicity value for 1-ethyl-2-methylpiperidine is greater by 0.22 *p*H unit than that for 1-*n*-propylpiperidine. The basicity value for 1,2-diethylpyrrolidine (IV, Table I) is much lower than that for the pyrrolizidines, a fact which illustrates that the bicyclic bases (five-membered rings) are stronger than analogous monocyclic bases (five-membered ring) with the same number of carbon atoms and the same mode of attachment.

The acid in these determinations of basicity was the proton, since the pK_H values were determined by half-neutralization of the amine with dilute hydrochloric acid. It is apparent from Brown's work[3,10,11] that a bulkier acid, such as boron trifluoride or trimethylboron, would amplify the steric effect of the 8-alkyl substituent on the basicity of the pyrrolizidine nucleus. The results of passing boron trifluoride through the liquid amines are summarized in Table I. Solid adducts of boron trifluoride were formed immediately with IIa, b and d, and a distillable liquid adduct, b.p. 253° (755 mm.), was obtained with IV. No solid product was obtained with IIc, and if any adduct was formed, it was highly unstable since IIc could be distilled from the reaction mixture. Thus the greater F-strain in 8-*n*-propylpyrrolizidine revealed in the reaction with a protonic acid is indicated more strikingly in the reaction with boron trifluoride. An interesting but possibly fortuitous correlation between pK_H values and picrate melting points has also been included in Table I.

Experimental[14]

Methyl γ-Nitroheptanoate and Dimethyl γ-*n*-Propyl-γ-nitropimelate (Ic).—The esters were made from 1-nitrobutane[15] essentially by the procedure described by Bruson[7] for the condensation of 1-nitropropane with methyl acrylate, with the exception that three times the recommended amount of Triton B was employed. The methyl γ-nitroheptanoate was obtained in 51% yield as a colorless liquid, b. p. 102° (2 mm.); $n^{20}D$ 1.4388.

Anal. Calcd. for $C_8H_{15}NO_4$: C, 50.78; H, 7.99; N, 7.40. Found: C, 51.18; H, 7.97; N, 7.64.

The dimethyl γ-*n*-propyl-γ-nitropimelate was obtained in 36% yield as a yellow-green oil, b. p. 157° (1 mm.); $n^{20}D$ 1.4612; d^{20}_4 1.133.

Anal. Calcd. for $C_{12}H_{21}NO_6$: C, 52.35; H, 7.69; N, 5.09; *MR*D, 66.57. Found: C, 53.07; H, 7.74; N, 5.29; *MR*D, 66.63.

Methyl γ-Nitroisoheptanoate and Dimethyl γ-Isopropyl-γ-nitropimelate (Id).—Using the same procedure, 75.7 g. (0.734 mole) of 1-nitro-2-methylpropane (nitroisobutane)[16] was caused to condense with 130 g. (1.5 moles) of methyl acrylate in the presence of 30 g. of Triton B. The methyl γ-nitroisoheptanoate was obtained as a colorless liquid, b. p. 102° (2 mm.); $n^{20}D$ 1.4397; d^{20}_4 1.115; yield, 82.5 g. (59.3%).

Anal. Calcd. for $C_8H_{15}NO_4$: C, 50.78; H, 7.99; N, 7.40. Found: C, 51.08; H, 7.92; N, 7.48.

The dimethyl γ-isopropyl-γ-nitropimelate was obtained as a green oil, b. p. 168° (2 mm.); d^{20}_4 1.138; yield, 19.1 g. (9.5%).

Anal. Calcd. for $C_{12}H_{21}NO_6$: C, 52.35; H, 7.69; N, 5.09. Found: C, 54.09; H, 7.68; N, 4.58.

(14) Melting points and boiling points have not been corrected for stem immersion. We gratefully acknowledge the assistance of Donald L. Felley and Gradus L. Shoemaker.

(15) We are indebted to Dr. Robert F. Taylor, Commercial Solvents Corporation, for this material.

(16) Made by the method of Shaw, *Bull. roy. acad. Belg.*, [3] **34**, 1019 (1897), modified by the use of ether solvent in the reaction mixture.

The condensation of 79 g. of methyl γ-nitroisoheptanoate with 40 g. of methyl acrylate in the presence of 30 ml. of *t*-butyl alcohol and 25 g. of Triton B produced 23 g. (20%) of Id, and 69% of the isoheptanoate was recovered. The condensation of 54.2 g. of methyl γ-nitroisoheptanoate with 40 g. of methyl acrylate in the presence of 30 ml. of *t*-butyl alcohol and 30 g. of diethylamine produced 32.5 g. (41%) of dimethyl γ-isopropyl-γ-nitropimelate, and again most of the unreacted monobasic ester was recovered.

1,2-Diethylpyrrolidine (IV)

One-Step Reduction.—A solution of 38 g. (0.2 mole) of ethyl γ-nitrocaproate[7] (b. p. 93° (1 mm.), $n^{20}D$ 1.4358) in 100 ml. of ethanol was reduced with hydrogen in the presence of 20 g. of copper chromite at 250° and 300–350 atm. An exothermic reaction began when the temperature reached 125°, and the theoretical amount of hydrogen was absorbed after five hours at 250°. The catalyst was removed by filtration, 200 ml. of benzene was added, and the benzene–ethanol–water azeotrope was removed at 63–65° followed by solvent at 78–80°. The 1,2-diethylpyrrolidine was collected at 140–141° (750 mm.); $n^{20}D$ 1.4372; d^{20}_4 0.8098; yield 11.2 g. (44%). The analysis and physical properties of the tertiary amine and the analysis of its picrate were consistent with the structure assigned to this product.

Anal. Calcd. for $C_8H_{17}N$: C, 75.52; H, 13.47; N, 11.01; MR_D, 41.06. Found: C, 75.79; H, 13.72; N, 10.96; MR_D 41.18.

When the same procedure was followed using methanol as the solvent, a high-boiling liquid was obtained, b. p. 230–233° (750 mm.); $n^{20}D$ 1.4535; d^{20}_4 0.9804, the identity of which has not been established.

Anal. Found: C, 62.63; H, 11.25.

Two-Step Reduction.—A solution of 56 g. (0.31 mole) of ethyl γ-nitrocaproate in 125 ml. of ethanol was reduced with hydrogen in the presence of 1 g. of platinum oxide catalyst at 2–4 atm. and 25°. After seven days the theoretical amount of hydrogen for reduction of the nitro group had been absorbed, and the catalyst was removed by filtration. The filtrate was reduced further at 250° and 300 atm. with hydrogen in the presence of 20 g. of copper chromite. After five hours the theoretical amount of hydrogen had been absorbed. Twenty grams (50%) of 1,2-diethylpyrrolidine was isolated in the same manner as in the more convenient one-step hydrogenation of ethyl γ-nitrocaproate in ethanol.

1,2-Diethylpyrrolidine Picrate.—Prepared in and recrystallized from ethanol, the picrate formed yellow needles, m. p. 120–121°. The melting point of a mixture with picric acid was depressed.

Anal. Calcd. for $C_{14}H_{20}N_4O_7$: N, 15.72. Found: N, 15.86.

8-*n*-Propylpyrrolizidine (IIc) and 8-Isopropylpyrrolizidine (IId).—Method and yield are similar for these compounds and for IIb, starting with the appropriate γ-alkyl-γ-nitropimelic ester. The synthesis of IId serves as an example. A solution of 46 g. (0.167 mole) of dimethyl γ-isopropyl-γ-nitropimelate (Id) in 90 ml. of purified dioxane was hydrogenated at 250–260° and 200–350 atm. in a high-pressure bomb. Rocking was begun when the temperature in the bomb reached 100°. After fifteen minutes at 125° sufficient hydrogen had been absorbed to reduce the nitro group, and rocking was discontinued until the temperature reached 260°. After seven hours, the theoretical amount of hydrogen had been absorbed. The catalyst was removed by filtration, and the filtrate was fractionated at atmospheric pressure. The colorless, basic fraction distilling at 187–193° (745 mm.) was collected and purified by redistillation; yield, 16.5 g. (64.4%).

8-*n*-Propylpyrrolizidine: b. p. 192° (745 mm.); $n^{20}D$ 1.4632; d^{20}_4 0.8918.

8-Isopropylpyrrolizidine: b. p. 191° (745 mm.); $n^{20}D$ 1.4692; d^{20}_4 0.8899.

Anal. Calcd. for $C_{10}H_{19}N$: C, 78.36; H, 12.45; N, 9.14; MR_D, 48.10. Found (IIc): C, 77.99; H, 12.66; N, 8.57; MR_D, 47.35. Found (IId): C, 77.73; H, 12.40; N, 8.52; MR_D, 47.98.

8-*n*-Propylpyrrolizidine Picrate.—Prepared in and recrystallized from ethanol, the picrate formed brilliant yellow needles, m. p. 156–157°.

Anal. Calcd. for $C_{16}H_{22}N_4O_7$: C, 50.26; H, 5.80; N, 14.65. Found: C, 50.54; H, 5.75; N, 14.73.

8-Isopropylpyrrolizidine Picrate.—Prepared in and recrystallized from ethanol, the picrate formed brilliant yellow needles which melted, with decomposition, at 228–229°.

Anal. Calcd. for $C_{16}H_{22}N_4O_7$: C, 50.26; H, 5.80; N, 14.65. Found: C, 50.10; H, 5.80; N, 14.57.

Determination of Basicity Constants.—The pK_H values were determined by dissolving a weighed portion of freshly distilled amine, calculated to require 15–20 ml. of 0.12 *N* hydrochloric acid, in 90 ml. of aqueous methanol calculated to be about 50% methanol at the end of the neutralization. The amount of 0.1200 *N* hydrochloric acid necessary to react with exactly half of the amine present was then added, and the solution was allowed to stand for twenty minutes. The *p*H of the solution was then measured using a Beckmann model G (laboratory model) *p*H meter with a high *p*H glass electrode (designed for *p*H measurements from 9 to 14). Duplicate or triplicate measurements were made in each case, and the pK_H values were corrected to 25°.[17] The method was checked to determine its accuracy. The pK_H value for one of the amines was determined at one-half the amine concentration used in the series. The identical value observed indicated that activities were not an influential factor in the determination. Also, the *p*H values at one-third and two-thirds neutralization of one of the amines were measured, and the pK_H was calculated by use of the equation $pK_H = pH \pm \log 2$. The identity of the values thus obtained with the *p*H at one-half neutralization was substantial proof that the half-neutralization point was actually being determined by the general procedure employed. The pK_H values are considered accurate within ±0.01 *p*H unit.

Summary

1. The preparation of pyrrolizidines by the one-step catalytic reduction of γ-nitropimelic esters has been extended to the synthesis of 8-*n*-propyl- and 8-isopropyl-pyrrolizidine.

2. Comparison of the pK_H values of 2-methyl-, 8-methyl-, 8-ethyl-, 8-*n*-propyl- and 8-isopropyl-pyrrolizidine have shown that the basicity of the pyrrolizidine is decreased as the length of the 8-alkyl group is increased.

The Action of Alkali on Chloral-quinaldine

BY R. B. WOODWARD AND EDMUND C. KORNFELD

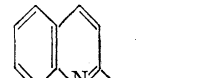
By treatment of chloral-quinaldine (I) with alcoholic sodium hydroxide, Einhorn[1] obtained β-(2-quinolyl)-acrylic acid (II), and a *bright orange* sodium salt, $C_{12}H_{10}O_2NNa\cdot 3H_2O$, which was formulated as a derivative of the hydroxyacid (III).

I

II

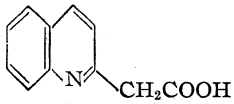
The salt was supposed to have been transformed by oxidation in turn to quinoline-2-acetaldehyde (IV) and quinoline-2-acetic acid (V). Borsche[2]

III

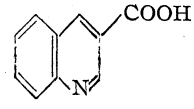


IV

noted that the properties of the acid obtained by oxidation were inconsistent with the formulation as (V), and was able to demonstrate that the substance was quinoline-3-carboxylic acid (VI), but did not challenge the expressions for the anterior substances.

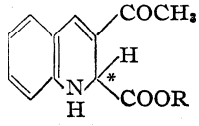


V

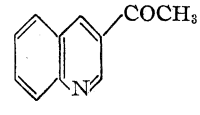


VI

In this communication it is shown that the orange sodium derivative is in fact a salt of 3-acetyl-1,2-dihydroquinoline-2-carboxylic acid (VII, R = H).

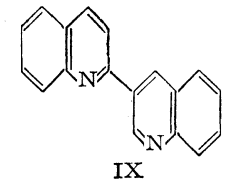


VII

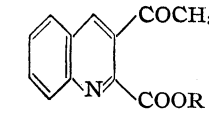


VIII

We were able to demonstrate first, by direct comparison, that the carbonyl derivative obtained on oxidation, and formulated by Einhorn as (IV), is 3-acetyl-quinoline[3] (VIII). The (erroneous) proof of the structure (IV) rested on the conversion of the substance, by condensation with *o*-aminobenzaldehyde, to 3-(2-quinolyl)-quinoline (IX); it is interesting to note that 3-acetylquinoline gives the same product (IX) in that reaction.[4] The orange salt, and the ethyl ester (VII, R = Et), m. p. 110.5–111.5°, obtained from it, were



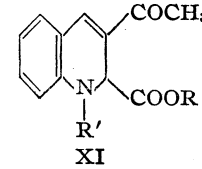
IX



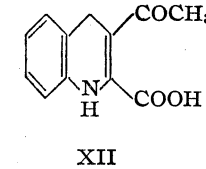
X

oxidized by potassium permanganate in aqueous pyridine to 3-acetylquinoline-2-carboxylic acid[3] (X, R = H) and the corresponding ester[3] (X, R = Et), respectively.

Further, the methyl ester (VII, R = Me) was transformed by benzoyl chloride in pyridine to an N-benzoyl derivative (XI, R = Me, R′ = C_6H_4-CO—), m. p. 140–141°, while the ethyl ester (VII, R = Et) gave with acetic anhydride the N-acetyl derivative (XI, R = Et, R′ = CH_3CO—), m. p. 130–131°. These facts necessitate the formulation of the original acid as (VII, R = H) or XII. An unequivocal decision in favor of (VII,



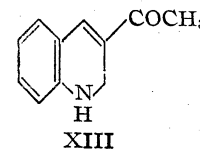
XI



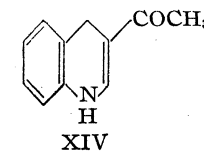
XII

R = H) was made possible through the isolation, through resolution by brucine, of an optically active sodium salt, $[\alpha]^{28}D$ −430°. Of the two possibilities, only VII possesses an asymmetric carbon atom (starred).

We turn now to a consideration of certain remarkable properties of the orange acid (VII, R = H). When this substance is pyrolyzed, 3-acetylquinoline and a *product*, $C_{11}H_{11}ON$, are formed. The latter was isolated by previous investigators,[1,2] but was not identified. We have found that the substance is oxidized by aqueous permanganate to 3-acetylquinoline, and that in turn, it may be resynthesized by the hydrogenation of the latter substance in the presence of Raney nickel. Since the compound is colorless, the expression (XIII) is excluded, and it seems probable that the structure (XIV) represents the



XIII



XIV

compound correctly. This conclusion is supported by the close similarity of the ultraviolet absorption spectrum of the substance (Fig. 1) to that of acetylacetone anil (XIVa) which contains the

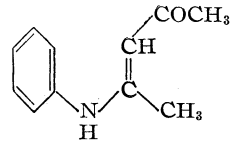
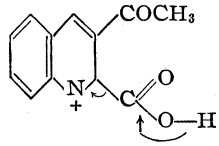
(4) Koller and Ruppersberg, *ibid.*, **58**, 238 (1931).



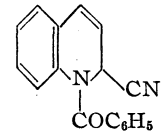
XIVa

same chromophore as XIV. The failure of the hydrogenation to proceed beyond the dihydro-stage, as well as the lack of carbonyl reactivity in (XIV) may be attributed to the interaction, through the double bond, between the imino and the carbonyl groups. The formation of (XIV) from (VII, R = H) takes place by decarboxylation, with simultaneous wandering of a double bond; it is worthy of note that not infrequently the decarboxylation of β,γ-unsaturated acids takes place with movement of the double bond to the α,β-position.[5]

Another interesting transformation of the orange acid is its spontaneous air oxidation. When the acid is exposed to air, the color gradually fades, and changes from orange to buff. The conversion is remarkably accelerated by light, and the sole product is 3-acetylquinoline. No 3-acetylquinoline-2-carboxylic acid (X, R = H) can be isolated and, further, the latter acid is stable under the conditions of the experiment. It is clear that (X, R = H) cannot be an intermediate in the change and that another intermediate, more subsceptible to decarboxylation, must be involved. We suggest that the withdrawal of two electrons and a proton (probably in stages) from (VII, R = H) gives an intermediate (XV) in which the environment of the carboxyl group is favorable to the ready loss of carbon dioxide, with the electronic shift shown (XV, arrows); the



XV



XVI

change thus becomes fully analogous to the decarboxylation of β-keto-acids, β-bromo-acids, and other acids containing properly situated electron-accepting centers. A similar mechanism must be operative in the aqueous permanganate oxidation of (VII) since, again, 3-acetylquinoline is the sole product, and (X, R = H) is stable under the conditions of the experiment (presence of permanganate *and* manganese dioxide).

The behavior of the N-benzoyl derivative (XI, R = Me, R′ = C_6H_5CO—) on acid hydrolysis presents an interesting contrast to that of N-benzoyl-2-cyano-1,2-dihydroquinoline (XVI).[6] While the latter undergoes a remarkable cleavage to benzaldehyde and quinoline-2-carboxylic acid

(5) *Cf.* Wallach, *Ann.*, **365**, 258 (1909). The change is also formally similar to that which accompanies the decarboxylation of β-keto-acids.

(6) Reissert, *Ber.*, **38**, 1610 (1905).

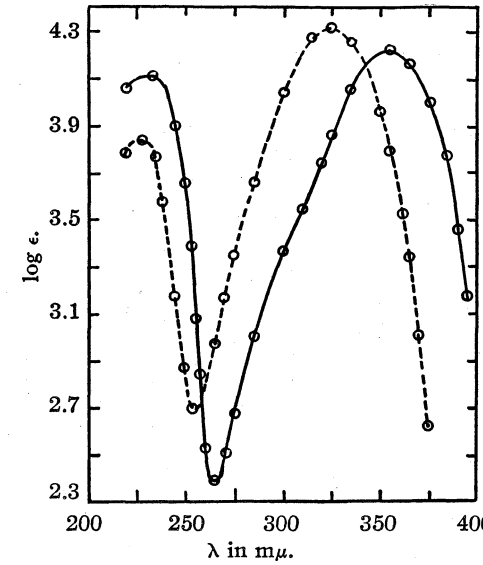


Fig. 1.— ----, Acetylacetone anil; —, 3-acetyl-1,4-dihydroquinoline.

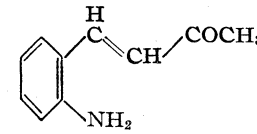
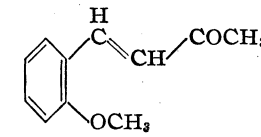
(the reaction forms the basis of a general method for the preparation of aldehydes from acids), (XI, R = Me, R′ = C_6H_5CO—), under the same conditions, gave only the corresponding *acid* (XI, R = H, R′ = C_6H_5CO—), m. p. 198° (dec.) on more vigorous treatment, benzoic acid was split off, but in no instance could benzaldehyde be detected.

The color of the compound (VII) and its derivatives is consonant with the structure now assigned to it. It was, in fact, this property which revealed at once that the previous structure (III) could not be correct, since from the point of view of light absorption III is simply a 2-alkylquinoline, and consequently colorless. On the other hand (VII) possesses the absorbing system of *o*-aminobenzalacetone (XVII); unfortunately, the

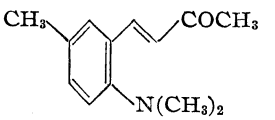


XVII

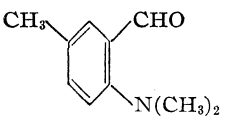


XVIII

latter substance does not appear to be capable of existence, in consequence of its ready conversion to quinaldine. However, there can be no doubt that it (and VII) should be colored. The corresponding methoxy compound (XVIII), for example, is bright orange. We have obtained absorption data which provide further support for these views. In view of the non-existence of (XVII), we had hoped to examine the spectrum of 2 - dimethylamino - 5 - methylbenzalacetone (XIX); the methyl group is (to a good approximation) irrelevant to the spectral discussion, and its presence offers preparative advantages (*vide infra*). It might be doubted that the spectrum of (XIX) and that of (VII) would be directly com-



XIX



XX

parable, in view of the considerable bulk of the N-methyl groups, which might force the dimethylamino group, or the adjacent side chain out of the plane, with consequent resonance damping; in any case, remarkably, and possibly for steric reasons, we were unable under any conditions to bring about the condensation of 2-dimethylamino-4-methylbenzaldehyde (XX) with acetone. On the other hand, we did determine the ultraviolet absorption spectrum of the aldehyde (XX) (Fig. 2), of *p*-dimethylaminobenzaldehyde (XXI) (Fig. 2)

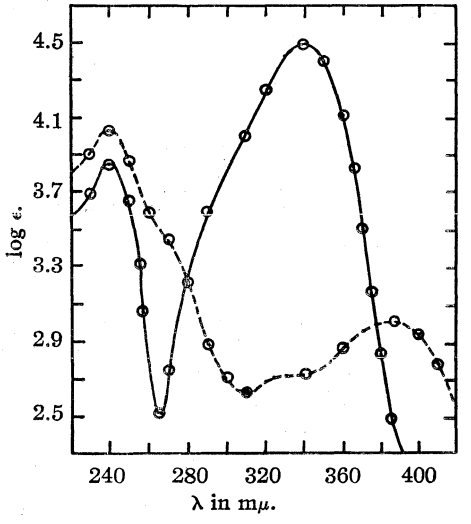


Fig. 2.— —*p*-Dimethylaminobenzaldehyde; ---, 2-dimethylamino-5-methylbenzaldehyde.

and *p*-dimethylaminobenzalacetone (XXII) (Fig. 3). It may be expected that the differences between the spectra of the *p*-substituted aldehyde and its condensation product will be reflected in the comparison of the spectrum of (XX) with that (Fig. 4) of the orange compound and its derivatives. The fact that this is the case provides confirmation of our view of the constitution of these substances; in the change XXI → XXII, a short wave length band (240 mμ) is displaced to 250 mμ (Δ = 10 mμ) and a long wave length band (338 mμ) moves to 385 mμ (Δ = 47 mμ). Correspondingly, in comparing (XX) with (VII), a shift of a short wave length band (240 mμ) to 250 mμ (Δ = 10 mμ), and of a long wave length band (370 mμ) to 415 mμ (Δ = 45 mμ) is observed. In the latter case, a third band, discernible only as a shoulder (~270 mμ) in the spectrum of (XX) appears as a well-defined maximum at 320 mμ in that of (VII). Furthermore, the relative intensities of the various bands, which differ markedly in the *ortho* as compared with the *para* series, are in each case comparable within the series. The greater complexity

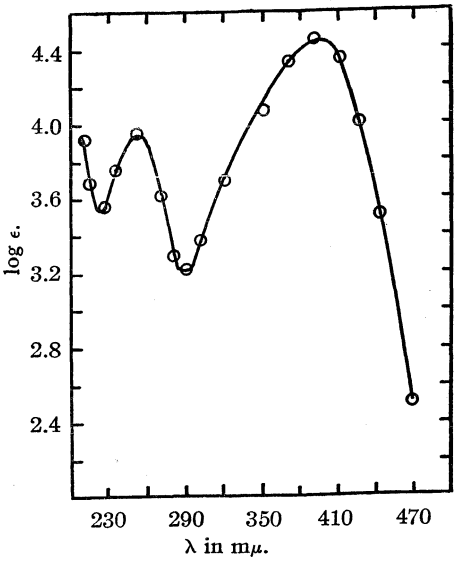

Fig. 3.—*p*-Dimethylaminobenzalacetone.

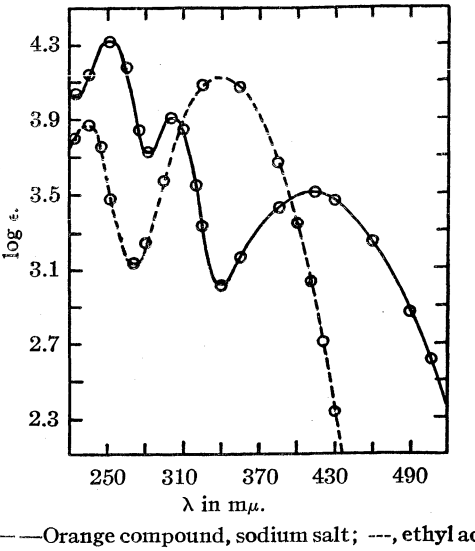

Fig. 4.— —Orange compound, sodium salt; ---, ethyl acetopyruvate-anil.

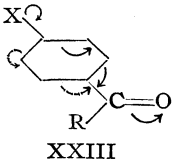
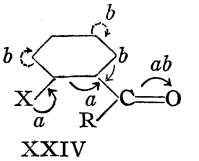
of the spectra of the *ortho* as compared with the *para* compounds is another example of a general effect[7] which probably has its origin in the greater symmetry of the latter; thus, while the available oscillatory paths in (XXIII) are indistinguishable, in (XXIV), two distinct oscillations of different



XXIII

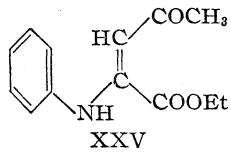


XXIV

length (*a* or *b*) may be envisaged, whose excitations should involve different energies and, corre-

(7) *Cf.* Dede and Rosenberg, *Ber.*, **67**, 147 (1934); Morton and Stubbs, *J. Chem. Soc.*, 1347 (1940); Blout and Gofstein, THIS JOURNAL, **67**, 15 (1945).

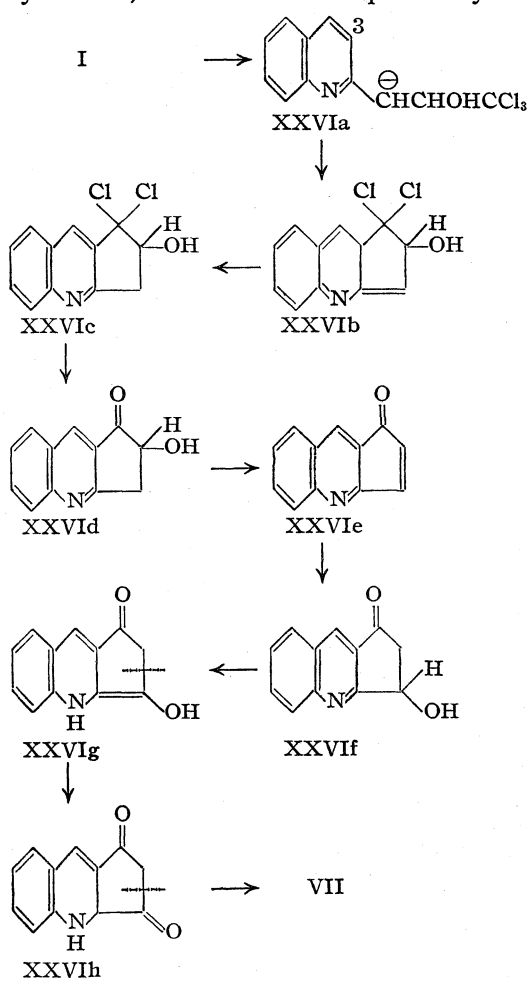
spondingly, different absorption bands. A final spectrographic check on our structural conclusions is provided by the absorption spectrum (Fig. 4) of (XXV), which contains the absorbing system



XXV

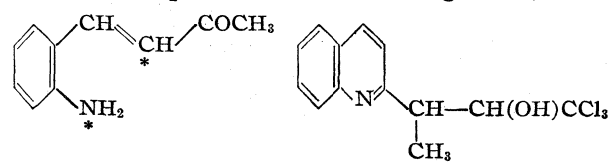
of (XII). It is clear that this spectrum bears no resemblance to those of the orange acid and its esters, and that consequently the expression (XII) is excluded for these substances.

There remains only a consideration of the mechanism of the remarkable change, I → VII. The following mechanistic scheme is a reasonable one; it is intended as an outline only, and in particular, the sequence of steps, and the exact nature of the various intermediates may be varied considerably. Thus, the removal of a proton by base



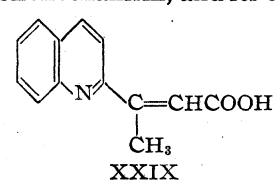
XXVIa XXVIc XXVIb XXVId XXVIe XXVIg XXVIf XXVIh VII

gives XXVIa, in which the availability of electrons at C.3 permits attack on the trichloromethyl group, with loss of halide ion and cyclization. The α,γ shift (XXVIb → XXVIc) with aromatization, and the hydrolysis of the remaining chlorine atoms are unexceptional. The loss of water (XXVId → XXVIc) is permissible in view of the β-position of the hydroxyl group with respect to the quinoline nucleus and its subsequent readdition in the opposite sense (XXVIe → XXVIf) is characteristic of α,β-unsaturated carbonyl compounds. The change XXVIf → XXVIg is reminiscent of the familiar α-methylpyridine–α-pyridone methide equilibrium, which in this case is rendered irreversible by the ketonization, XXVIg → XXVIh. Normal cleavage of the β-diketone (XXVIh) then leads to VII. Complicated as the suggested sequence is, it is difficult to conceive of a simpler series to account for so deep-seated a change. We have considered one other possibility, namely, that in effect the chloral-quinaldine (I) breaks down to give *o*-aminobenzalacetone (XXVII) and chloral, or equivalents of these fragments; sub-



XXVII XXVIII

sequent re-condensation of the aldehyde group of chloral at the starred positions, followed by hydrolysis could lead to (VII). It will be noted that a prerequisite for the mechanism outlined above is the presence of *two* hydrogen atoms on the carbon α to the quinoline nucleus. On the other hand, the second mechanism possesses no such feature. Consequently, the chloral-α-ethylquinoline condensation product (XXVIII) should undergo an analogous rearrangement to 3-propionyl-1,2-dihydroquinoline-2-carboxylic acid, if the second mechanism is operative, but no such change is possible in the event that the alternative sequence is correct. We have prepared XXVIII and observed that it is smoothly converted by alcoholic sodium hydroxide to β-(α-quinolyl)-crotonic acid (XXIX); no evidence of the formation of a rearrangement product analogous to (VII) could be obtained. Consequently, we reject the cleavage–recondensation mechanism, and its equivalents.



XXIX

In conclusion, we may point out that we have prepared the chloral condensation products XXX,[8] XXXI,[9] XXXII[10] and XXXIII[11] and subjected them to the conditions which bring about the change I → VII. In none of these cases

Experimental

Chloralquinaldine (I).—The method of Bachman[12] was used. It was found to be essential that the initial exothermic reaction be moderated so that the temperature did not exceed 100°. Dark-colored by-products were formed if the mixture was allowed to overheat; yield, 71%, m. p. 145–146°.

Sodium Salt of 2-Carboxy-3-acetyl-1,2-dihydroquinoline (VII, R = Na).—This product was obtained in 35–45% yield by the method of Einhorn.[1] The free acid, m. p. 123–125° (dec.), was obtained by neutralizing a concentrated aqueous solution of the sodium salt with hydrochloric acid.

The acid was resolved in the following way: the orange sodium salt (32.8 g., 0.112 mole) and brucine sulfate (56 g.) were dissolved together in 500 ml. of hot water. The product which separated slowly from the cooled solution was collected and recrystallized twice from water, with considerable loss. The salt was then decomposed by taking up in 50 ml. of water and adding a solution containing 1.8 g. of sodium hydroxide. Brucine was removed by three extractions with chloroform. The aqueous layer was cooled, and the *l*-sodium salt which separated was recrystallized from dilute ethanol, m. p. 187–191°; $[\alpha]^{28}D$ −430° (l = 2 dcm, C = 0.5 g./100 ml. H_2O). A sample for analysis was dried at 125°.

Anal. Calcd. for $C_{12}H_{10}O_3NNa$: C, 60.25; H, 4.21; N, 5.86. Found: C, 60.33; H, 4.51; N, 5.61.

2-Carbethoxy-3-acetyl-1,2-dihydroquinoline (VII, R = Et).—The sodium salt trihydrate of 3-acetyl-1,2-dihydroquinoline-2-carboxylic acid (4.0 g.) was suspended in 40 ml. of absolute ethanol, the solution was immersed in ice, and saturated with dry hydrogen chloride. After twelve hours the solvent was removed *in vacuo*, the residue was stirred with ice and water and neutralized with sodium bicarbonate. After addition of cold 10% sodium hydroxide (25 ml.) the product was removed, washed with water and dried; yield, 2.16 g. (65%). Recrystallized from dilute ethanol, it formed bright-yellow needles, m. p. 110.5–111.5°. *Anal.* Calcd. for $C_{14}H_{15}O_3N$: C, 68.55; H, 6.16. Found: C, 68.63; H, 5.75.

The ester was obtained in like yield by direct esterification of the free acid (VII, R = H). The corresponding **methyl ester (VII, R = Me)** was obtained in a similar manner. After repeated recrystallization from dilute methanol, it formed golden-yellow prisms, m. p. 140–141°. It is undoubtedly identical with the ester, m. p. 145°, obtained by Borsche[2] from the acid and diazomethane. *Anal.* Calcd. for $C_{13}H_{13}O_3N$: C, 67.52; H, 5.67. Found: C, 67.22; H, 5.21.

N-Benzoyl-2-carbomethoxy-3-acetyl-1,2-dihydroquinoline (XI, R = Me, R′ = C_6H_5CO—).—The above methyl ester (VII, R = Me, 0.95 g.) and benzoyl chloride (0.62 g.) were dissolved in 10 ml. of dry pyridine. After standing several days the solvent was removed *in vacuo* and the residue was made alkaline with dilute sodium bicarbonate solution. The product which oiled out was washed by decantation with water and recrystallized from methanol; yield, 0.4 g., pale yellow crystals, m. p. 140–141°. *Anal.* Calcd. for $C_{20}H_{17}O_4N$: C, 71.63; H, 5.11. Found: C, 71.84; H, 4.87.

When this benzoyl derivative (0.1 g.) was allowed to stand for two days with 1 ml. of concentrated hydrochloric acid, addition of water gave the crystalline free *acid* (XI, R = H; R′ = C_6H_5CO—) which was recrystallized from dioxane; m. p. 198–199° (dec.). *Anal.* Calcd. for $C_{19}H_{15}O_4N$: C, 71.02; H, 4.71. Found: C, 70.33; H, 4.89.

More drastic hydrolysis of the N-benzoyl ester (XI, R = Me, R′ = C_6H_5CO—) with concentrated hydrochloric acid at 100° gave benzoic acid in 55% yield and an unidentified oil. No benzaldehyde could be detected.

2-Carbethoxy-1,3-diacetyl-1,2-dihydroquinoline (XI, R = Et, R′ = CH_3CO—).—2-Carbethoxy-3-acetyl-1,2-dihydroquinoline (VII, R = Et, 0.6 g.) was dissolved in 2 ml. of pyridine and 3 ml. of acetic anhydride; the solution was warmed on the steam-bath for three hours. The excess solvents were removed *in vacuo* and ice-water was added to the residue. The oil soon solidified and was collected, washed and recrystallized from ethanol; yield of pale-yellow prisms, 50%; m. p. 131–132°. *Anal.* Calcd. for $C_{16}H_{12}O_4N$: C, 66.88; H, 5.96. Found: C, 67.32; H, 5.69.

3-Acetylquinoline (VIII).—This ketone was prepared by permanganate oxidation of the sodium salt (VII, R = Na) according to Borsche and Manteuffel[2] (yield, 85%), by chromic acid oxidation (A) of the salt or by the action of light and air on the free acid (VII, R = H) (B).

(A) The sodium salt (VII, R = Na, 5 g.) was dissolved in a mixture of 150 ml. of glacial acetic acid and 100 ml. of water. Concentrated sulfuric acid (2 ml.) was added followed by a solution of 1.85 g. of potassium dichromate in 30 ml. of water. The solution which turned green was concentrated *in vacuo* and the residue was made alkaline with ammonium hydroxide. The solution of the residue in ethanol was filtered and evaporated *in vacuo*. The residue was crystallized twice from water. It then had m. p. 96–98° and mixed with a sample from the permanganate oxidation of (VII, R = Na) or with an authentic sample of 3-acetylquinoline (see below) melted at 96–99°.

(B) A sample of the orange acid (VII, R = H) was allowed to stand in air for eleven days with frequent stirring of the crystals. The bright orange color gradually faded and finally a buff-colored crystalline solid remained. The decomposition was markedly favored by sunlight; exposure in thin layers was best. The product was stirred with 10% sodium bicarbonate solution, removed by filtration and washed with water. Recrystallization from water gave 3-acetylquinoline, m. p. 96–98°. From the sodium bicarbonate solution a small further quantity of 3-acetylquinoline, but no 3-acetylquinoline-2-carboxylic acid was obtained.

For comparison authentic samples of 3-acetylquinoline (VIII), m. p. 97–99°, 3-acetylquinoline-2-carboxylic acid (X, R = H), m. p. 142–143° (dec.), and the corresponding ethyl ester (X, R = Et), m. p. 93–94.5°, were prepared by the condensation of *o*-aminobenzaldehyde (Raney nickel reduction of *o*-nitrobenzaldehyde[13]) with ethyl acetopyruvate followed by hydrolysis and decarboxylation, according to Koller.[3]

Oxidation of (VII, R = Na) and (VII, R = Et) with Permanganate in Aqueous Pyridine.—While permanganate oxidation of (VII, R = Na) according to Borsche's procedure gives only 3-acetylquinoline, careful oxidation in aqueous pyridine gives some 3-acetylquinoline-2-carboxylic acid:

One hundredth of a mole (2.96 g.) of the sodium salt was suspended in 140 ml. of pyridine. A solution of 1.2 g. in potassium permanganate in 140 ml. of warm pyridine was then added. Little evidence of reaction was noted until 50 ml. of water was added. After a few minutes the pre-

(12) Alberts and Bachman, THIS JOURNAL, 57, 1284 (1935).

(13) Ruggli and Schmid, *Helv. Chim. Acta*, 18, 1235 (1935).

cipitated manganese dioxide was removed and the filtrate was concentrated to a very small volume. Addition of a little sodium acetate caused the crude acid to separate (m. p. 120° (dec.)). The product was stirred with 2 ml. of 10% sodium bicarbonate and the mixture was filtered to remove 3-acetylquinoline. The filtrate was first acidified with hydrochloric acid and further concentrated *in vacuo*. The pure acid, m. p. 141–142° (dec.), separated as white needles from the cooled solution. The mixed melting point with authentic 3-acetylquinoline-2-carboxylic acid, m. p. 142–143° (dec.) (see above), was likewise 141–142° (dec.).

The ethyl ester (VII, R = Et) (2.0 g.) was dissolved in 200 ml. of pyridine and 200 ml. of water. The solution was cooled in ice to 2°. Potassium permanganate (1.4 g.) in 80 ml. of pyridine and 80 ml. of water was added dropwise, with stirring and cooling in ice. After the addition which took about twenty minutes the solution was warmed to room temperature and the manganese dioxide was removed. The filtrate was treated with 0.75 ml. of concd. hydrochloric acid and concentrated *in vacuo* to a very small volume. The residue which crystallized was suspended in a little ice water and was filtered and washed with water; yield, 50%. Recrystallization from ethanol gave white needles, m. p. 93–94°, mixed with an authentic sample (see above) of (X, R = Et), m. m. p. 93–94.5°.

Stability of (X, R = H) under Conditions of Aqueous Permanganate Oxidation.—A solution containing 5 ml. of 1% potassium permanganate, 0.5 ml. of 10% sodium bicarbonate and 4 ml. of water was cooled in ice and 5 ml. of 1% sodium bisulfite was added. 3-Acetylquinoline-2-carboxylic acid (0.1 g.) was added and the solution was heated to boiling. Manganese dioxide was removed and the filtrate was concentrated *in vacuo*. Acidification with one drop of concd. hydrochloric acid yielded the unchanged acid, m. p. 142–143° (dec.).

3-Acetyl-1,4-dihydroquinoline (XIV). (a) **By Pyrolysis of (VII, R = H).**—3-Acetyl-1,2-dihydroquinoline-2-carboxylic acid (8.1 g.) was placed in a 200-ml. round-bottom flask and heated in a metal-bath for twenty minutes at 180–190°. (Nitrogen was bubbled through the flask during the pyrolysis.) The resultant red oil was cooled and taken up in ethanol. From the cooled solution colorless plates separated which after recrystallization from dilute ethanol melted at 177–181°.

(b) **By Catalytic Hydrogenation of 3-Acetylquinoline.**—One gram of the ketone was hydrogenated at atmospheric pressure in 100 ml. of absolute ethanol using about 2 g. of Raney nickel catalyst. The theoretical volume of hydrogen was absorbed in two hours. The catalyst was removed and the filtrate concentrated *in vacuo* to *ca.* 15 ml. From the cooled solution the product (XIV) separated in 40% yield, m. p. 174–180°.

Permanganate Oxidation of 3-Acetyl-1,4-dihydroquinoline (XIV).—A sample of the dihydro-compound (XIV) (200 mg.) was dissolved in a hot mixture of 50 ml. of water and 10 ml. of acetone. A solution of 122 mg. of potassium permanganate in 10 ml. of water was then added dropwise and with shaking in the course of ten minutes. The resulting mixture was reheated to boiling, filtered and the filtrate concentrated *in vacuo* to about 10 ml. The product crystallized on cooling and was recrystallized from water; yield, 50%; m. p. 97–98°; mixed with authentic 3-acetylquinoline, m. m. p. 98–99°.

α-Anilinoacetopyruvic Ester (XXV).—One tenth of a mole each of aniline and ethyl acetopyruvate were mixed with 40 ml. of ether. After three days the ether was evaporated and the product distilled twice *in vacuo;* yield, 65%; b. p. 170–171° (8 mm.). *Anal.* Calcd. for $C_{13}H_{15}O_3N$: C, 66.93; H, 6.48. Found: C, 67.22; H, 6.38. The corresponding *o*-toluidino ester was prepared similarly from *o*-toluidine and ethyl acetopyruvate; yield, 57%, b. p. 154–155° (3 mm.). *Anal.* Calcd. for $C_{14}H_{17}O_3N$: C, 67.99; H, 6.93. Found: C, 68.07; H, 6.40.

2-Dimethylamino-5-methylbenzaldehyde (XX).—2-Dimethylamino-5-methylbenzyl alcohol was prepared by the method of von Braun and Kruber[14] in 45% yield, b. p. 125–127° (8 mm.). Oxidation to the aldehyde was carried out by the modified Oppenauer procedure of Woodward, Wendler and Brutschy.[15]

Potassium (20 g.) was dissolved in 400 ml. of *t*-butanol and the excess alcohol was removed completely *in vacuo*. To the dry potassium *t*-butoxide was added 33 g. of 2-dimethylamino-5-methylbenzyl alcohol, 2 liters of dry benzene and 260 g. of dry benzophenone. The mixture was refluxed in an atmosphere of nitrogen for twenty-three hours, after which it was extracted with dilute hydrochloric acid (150 ml. concd. acid and 500 ml. of water). The acid extract was made alkaline with sodium hydroxide and the product was extracted with 300 ml. of ether in three portions. The ether was removed and the residue was fractionated through a 30-cm. Podbielniak column. About 35% of dimethyl-*p*-toluidine (b. p. 90–97° (12–15 mm.)) and 40% of the bright-yellow desired aldehyde, b. p. 138–142° (16 mm.), were obtained.

The *p*-nitrophenylhydrazone, prepared in hot ethanol containing a few drops of glacial acetic acid, crystallized from ethanol in deep red-orange prisms, m. p. 185–186°. *Anal.* Calcd. for $C_{16}H_{18}O_2N_4$: C, 64.41; H, 6.08. Found: C, 64.50; H, 5.69.

The azine was prepared by allowing a solution of 0.7 g. of the aldehyde, 2.5 ml. of ethanol, 2.0 ml. of water and 0.1 g. of hydrazine hydrate to stand at room temperature for twenty-four hours. It crystallized from ethanol in lemon-yellow elongated plates, m. p. 147–148°. *Anal.* Calcd. for $C_{20}H_{26}N_4$: C, 74.49; H, 8.13. Found: C, 74.83; H, 7.92. In several attempts to effect condensation of the aldehyde with acetone, the starting material was recovered unchanged.

2-Ethylquinoline.—This compound was prepared by a method similar to that used by Ziegler[16] in the preparation of 2-butylquinoline.

Lithium metal (28 g.) was pounded into a thin sheet and the sheet was cut with scissors into small pieces, which were added quickly to 1200 ml. of dry ether. The mixture was stirred and cooled in ice while 200 g. of ethyl bromide was added dropwise during thirty minutes. The addition was conducted at such a rate that a steady reflux of the ether was maintained. Quinoline (200 ml.) was then added dropwise during fifteen minutes with stirring and cooling in ice. Unreacted lithium was then skimmed off and water was added cautiously with stirring to the mixture. The ether layer was separated, washed with water and dried over sodium sulfate. After the solvent was evaporated the residue of crude 1,2-dihydro-2-ethylquinoline was dissolved in 500 ml. of nitrobenzene. The mixture was heated slowly to 200° and was kept at that temperature five minutes. The solution was cooled, diluted with ether and the bases were extracted with dilute hydrochloric acid containing 175 ml. of the concd. acid. The acid extract was made alkaline with sodium hydroxide, and the product was taken up in ether. The ether extract was dried over potassium hydroxide after which the solvent was distilled. The residue was fractionated carefully *in vacuo*, and the 2-ethylquinoline was obtained as a yellow oil, b. p. 125–130° (15 mm.); yield 30%. The picrate was prepared, m. p. 147–149°. Doebner[17] reports a melting point of 148°.

Chloral-2-ethylquinoline (XXVIII).—To 58 g. of ethylquinoline was added 40 ml. of pyridine and 54.5 g. of chloral. The mixture was heated on a steam-bath for one and one-half hours. During the early part of the heating period, the reaction was exothermic, and the temperature was kept below 105° by periodic cooling. The product was then poured into water and was washed several times with water by decantation. Addition of a little ethanol caused the product to crystallize slowly. The adduct was filtered and washed with cold alcohol to remove dark-colored impurities, yield, 57%. A sample was recrystallized for analysis from methanol; m. p. 117–118°. *Anal.*

Calcd. for $C_{13}H_{12}ONCl_3$: C, 51.26; H, 3.97. Found: C, 51.02; H, 4.11.

Hydrolysis of Chloral-2-ethylquinoline.—This hydrolysis was conducted using the same molar proportions and conditions as those used for chloral-quinaldine.

Five hundredths of a mole of the adduct was warmed with 67 ml. of ethanol, and 56 ml. of water was added slowly. The mixture was heated to boiling, and to it was added, as quickly as the vigorous ebullition would permit, a solution of 11.7 g. of sodium hydroxide in 37 ml. of water. After the reaction had subsided the solution was kept hot for five minutes and 100 ml. of hot ethanol was added. After the mixture had cooled overnight, no crystalline product had separated, so the solvents were removed *in vacuo*, and the residue was dissolved in water. The product was precipitated with 11 ml. of concd. hydrochloric acid and 5 ml. of acetic acid: yield, 79%, m. p. 190–195° (dec.). Recrystallization from dilute dioxane gave the colorless β-2-quinolylcrotonic acid, m. p. 204–206° (dec.).

Anal. Calcd. for $C_{13}H_{11}O_2N$: C, 73.22; H, 5.20. Found: C, 72.85; H, 5.18.

Summary

The action of alcoholic sodium hydroxide on chloral-quinaldine gives 3-acetyl-1,2-dihydroquinoline-2-carboxylic acid.

The Reaction of Benzophenone β-Naphthil with Phenylmagnesium Bromide and with Phenyllithium

BY HENRY GILMAN AND JOHN MORTON

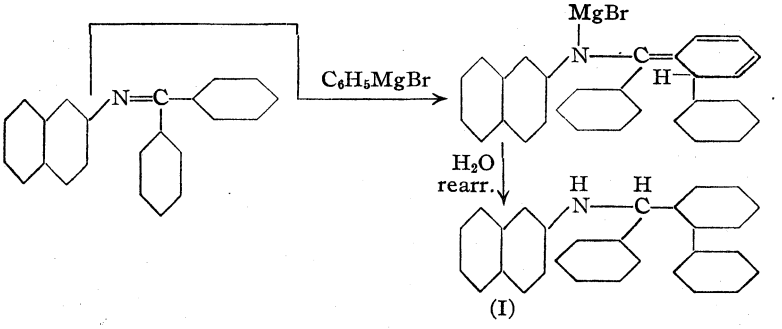
The forced reaction of phenylmagnesium bromide with benzophenone anil was reported earlier from this Laboratory.[1] It was found that the Grignard reagent undergoes a lateral-nuclear 1,4 addition to the conjugated system consisting of the anil linkage and an unsaturated linkage of one benzohydrylidene phenyl group to produce, after hydrolysis and a hydrogen shift, *o*-phenylbenzohydrylaniline. Similar lateral-nuclear additions, in which Grignard reagents add 1,4 to ketones whose carbonyl groups are conjugated with unsaturated linkages in aromatic nuclei, have since been described[2]; also, it has been demonstrated that benzalquinaldine adds phenylmagnesium bromide in a lateral-nuclear sense.[3]

Further work in this Laboratory[4] established that phenyllithium adds to benzophenone anil at the anil linkage only, yielding triphenylmethylaniline. This reaction proceeds at the temperature of refluxing ether, whereas phenylmagnesium bromide has no detectable effect upon the anil at this temperature.

The present study of the reaction of benzophenone β-naphthil with phenylmagnesium bromide and with phenyllithium, has been carried out to discover whether the substitution of an N-β-naphthyl group for the N-phenyl group of benzophenone anil could affect the course of reaction with either of the organometallic compounds, and particularly whether any addition involving the naphthyl group itself could be observed.

We find that the naphthil behaves quite similarly to the anil with respect to both organometallic compounds. With phenylmagnesium bromide at the temperature of refluxing ether, no reaction occurs; when ether–toluene is used and the temperature is raised to 90–100°, a compound melting at 185–186° and having a nitrogen content corresponding to that of *o*-phenylbenzohydryl-β-naphthylamine (I) is obtained in pure yields as high as 71%. Like the similarly substituted aniline described earlier,[1] this substance yields 9-phenylfluorene when refluxed with alcoholic hydrochloric acid.

The compound melting at 185–186° has been shown to be identical with the product of the forced reaction between *o*-biphenylylmagnesium iodide and benzal-β-naphthylamine, and was thus identified as (I). The reaction leading to the formation of compound (I) from the naphthil is shown.



(I)

We find that phenyllithium, on the other hand, reacts with the naphthil at the temperature of refluxing ether to produce a compound which melts at 185° but which gives a large depression of melting point when mixed with (I). The product from the RLi reaction proved to be identical with the product of the condensation of triphenylcarbinol with β-naphthylamine in glacial acetic acid. The

product, then, must be triphenylmethyl-β-naphthylamine (II), and its formation from the naphthil must proceed as follows

$$\beta\text{-}(C_{10}H_7)N{=}C(C_6H_5)_2 \xrightarrow{C_6H_5Li} \beta\text{-}(C_{10}H_7)NLi{-}C(C_6H_5)_3 \xrightarrow{H_2O} \beta\text{-}(C_{10}H_7)NH{-}C(C_6H_5)_3 \quad (II)$$

The pure yield is 72.5%.

Experimental

Preparation of Benzophenone β-Naphthil.—The preparation of this compound given by Reddelien[5] was modified as follows: 143 g. (0.56 mole) of benzophenone anil was heated with 148 g. (1.03 mole) β-naphthylamine in a flask equipped with a downward condenser and evacuated to 20 mm. Heat was applied with a strong, direct Bunsen flame. After a considerable quantity of aniline had distilled over, solid β-naphthylamine began to appear in the receiver, whereupon the heating was stopped. The reaction mixture solidified on cooling. Two recrystallizations of this solid from absolute ethanol gave 110 g. (64%) of greenish crystals melting at 96–97°.

Reaction of Phenylmagnesium Bromide with Benzophenone β-Naphthil.—Two-tenths mole of phenylmagnesium bromide in ether was added to 15.5 g. (0.05 mole) of benzophenone β-naphthil in toluene. There was no observable reaction during the addition. The solution was partly freed of ether by raising the temperature to 90–100°, and was stirred for ten hours at the elevated temperature. The mixture was then cooled and hydrolyzed with iced ammoniacal ammonium chloride, and the ether–toluene layer was separated and steam-distilled. The light-colored residue weighed 14–16 g. (71–82%) and generally melted between 175 and 180°. Solution of this material in boiling ethanol–toluene and subsequent extended cooling yielded 10.5–14 g. (51–71%) of pure white powder melting at 185–186°. In one case, there appeared a small amount (approx. 0.5 g.) of a resinous material which separated from the alcohol–toluene some weeks after all the amine had crystallized. The composition of this substance has not as yet been determined.

Anal. Calcd. for $C_{29}H_{23}N$: N, 3.62. Found: N, 3.45, 3.87.

Cleavage of o-Phenylbenzohydryl-β-naphthylamine and of Triphenylmethyl-β-naphthylamine.—One gram of (I) was refluxed for seventeen hours in a mixture of 10 cc. of concentrated hydrochloric acid and 30 cc. of 95% ethanol. The solution was evaporated and the solid residue treated with dilute hydrochloric acid to remove amines. The remaining solid was recrystallized from 95% ethanol to give 0.21 g. (34%) of 9-phenylfluorene, and β-naphthylamine. Triphenylmethyl-β-naphthylamine (1 g.) cleaved under the same conditions to give 0.33 g. (53%) of triphenylmethane, and β-naphthylamine. The identities of the cleavage products were established by comparison with authentic specimens.

Reaction of o-Biphenylylmagnesium Iodide with Benzal-β-naphthylamine.—Thirty grams (0.1 mole) of *o*-iodobiphenyl[1] in dry ether was added to 5 g. (0.2 atom) of magnesium turnings. Activated copper–magnesium alloy[6] was used to start the reaction, which proceeded smoothly with the formation of 0.074 mole (74%) of Grignard reagent. The resulting solution was added to a solution of 17.1 g. (0.074 mole) of benzal-β-naphthylamine[7] in toluene. Ether was distilled off until the temperature reached 90°, and the solution was stirred at this temperature for eight hours. The mixture was hydrolyzed with dilute hydrochloric acid, and the toluene layer was separated and steam-distilled. The tarry residue from this process was dissolved in hot ethanol–toluene, and this solution, after lengthy cooling, deposited 2.5 g. (8.8%) of salmon-colored crystals melting at 182–184°. Another recrystallization from the same solvent yielded 2.0 g. (7%) of almost colorless crystals melting at 185–186°. This melting point is not depressed by mixture with the compound obtained from benzophenone β-naphthil and phenylmagnesium bromide.

Reaction of Benzophenone β-Naphthil with Phenyllithium.—Twenty-three grams (0.075 mole) of the naphthil in ether was treated with 0.08 mole of phenyllithium in ether. Gentle spontaneous refluxing occurred as the solutions were mixed. After being stirred for six hours at reflux, the solution was hydrolyzed with water. Just prior to hydrolysis, the solution gave a positive Color Test I.[8] The ethereal layer was separated, washed with water, and steam-distilled. Twenty-four grams (84%) of greenish-white residue melting at 176–178° was obtained. This was recrystallized from ethanol–toluene to give 21 g. (72.5%) of white crystals melting at 185–186° but giving a large depression of this melting point when mixed with (I).

Anal. Calcd. for $C_{29}H_{23}N$: N, 3.62. Found: N, 3.50.

Condensation of β-Naphthylamine with Triphenylcarbinol.—In this reaction, modeled after the synthesis of the similarly substituted aniline given by Baeyer and Villiger,[9] 5 g. of triphenylcarbinol and 10 g. of β-naphthylamine were refluxed for one-half hour in glacial acetic acid. The solution was cooled and diluted with water, whereupon a white precipitate appeared. This was filtered off and washed with 95% ethanol, leaving a powdery residue which, when recrystallized from watered acetone, weighed 0.1 g. (1.3%) and melted at 185–186°. A mixed melting point with the material from the phenyllithium reaction showed no depression.

Summary

Benzophenone β-naphthil undergoes a lateral-nuclear 1,4 addition with phenylmagnesium bromide under forced conditions, yielding *o*-phenylbenzohydryl-β-naphthylamine. The same naphthil undergoes 1,2 addition with phenyllithium under mild conditions, to yield triphenylmethyl-β-naphthylamine.

The Reaction of α,β-Dichloropropionaldehyde with a Number of Grignard Reagents

BY VAUGHN W. FLOUTZ

The research project here reported was undertaken to determine the behavior of representative Grignard reagents with α,β-dichloropropionaldehyde. Studies have shown that chloral and α,α,β-trichlorobutyraldehyde, commonly called butyl chloral, react normally with arylmagnesium halides, but abnormally with certain other Grignard reagents to give a primary alcohol by reduction of the aldehyde and an unsaturated hydrocarbon by oxidation of the Grignard reagent.[1,2] Unlike chloral and butyl chloral, α,β-dichloropropionaldehyde carries one chlorine atom on the alpha carbon rather than a maximum number. It was found that the reaction proceeds normally with phenylmagnesium bromide and gives a good yield of secondary alcohol. α,β-Dichloropropionaldehyde reacts with *n*-hexylmagnesium bromide, cyclohexylmagnesium bromide and β-phenylethylmagnesium bromide to give the secondary alcohols of normal addition in a smaller yield. In each case there is formed in addition to the secondary alcohol 2,3-dichloropropanol-1 (glycerol 2,3-dichlorohydrin) by the reduction of some of the aldehyde, and an unsaturated hydrocarbon by oxidation of some of the Grignard reagent. In the case of benzylmagnesium chloride no secondary alcohol was detected; the only reaction product identified was dibenzyl. It has been found that both chloral and butyl chloral exhibit this same behavior with benzylmagnesium chloride.[2]

Experimental[3]

α,β-Dichloropropionaldehyde and Phenylmagnesium Bromide.—In the preparation of this Grignard reagent, and also those subsequently considered, a 1-liter, three-necked flask, fitted with a mercury-seal stirrer, dropping funnel and condenser was employed. A 0.25 gram-atom portion of magnesium turnings was placed in the flask and covered with 250 ml. of anhydrous ether, and the reagent was formed by adding 0.25 mole of the halide dissolved in an equal volume of dry ether. The reagent was cooled and the aldehyde, dissolved in a like volume of dry ether, was added at a rate such that there was no refluxing of the ether. The product was poured slowly into a mixture of ice and water, and the resulting mixture was cleared by the addition of 5% aqueous acetic acid. The ether layer was removed, washed in turn with sodium bicarbonate solution, saturated sodium bisulfite solution, and water, and then dried over anhydrous sodium sulfate.

The ether solution from the reaction of α,β-dichloropropionaldehyde and phenylmagnesium bromide was subjected to distillation to remove the ether. The distillation was then continued under reduced pressure in an atmosphere of nitrogen to obtain the secondary alcohol 2,3-dichloro-1-phenylpropanol-1.

α,β-Dichloropropionaldehyde and *n*-Hexylmagnesium Bromide, Cyclohexylmagnesium Bromide and β-Phenylethylmagnesium Bromide.—The ether solution of the products from the reaction of the aldehyde with *n*-hexylmagnesium bromide was subjected to distillation to remove the ether and the hexene-1 formed in the reaction. The ether and larger portion of the hexene-1 were distilled by use of a hot water-bath; following this the residue was heated in an oil-bath to a bath temperature of 120°, and this additional distillate was added to the first portion. To determine more accurately the amount of hexene-1 produced, the hydrocarbon was converted into 1,2-dibromohexane; this was accomplished by treating the distillate in subdued light with a slight excess of bromine. The residue from the removal of ether and hexene-1 was distilled under diminished pressure to obtain the primary alcohol 2,3-dichloropropanol-1, and the secondary alcohol 1,2-dichlorononanol-3. The primary alcohol was further identified through its oxidation with fuming nitric acid to produce α,β-dichloropropionic acid.[4]

The reaction mixture from the cyclohexylmagnesium bromide, treated in a similar way, gave cyclohexene, determined as the dibromide, the primary alcohol and 2,3-dichloro-1-cyclohexylpropanol-1. That from β-phenylethylmagnesium bromide yielded styrene, determined as the dibromide, the primary alcohol and 1,2-dichloro-5-phenylpentanol-3.

α,β-Dichloropropionaldehyde and Benzylmagnesium Chloride.—The ether solution of the reaction products was distilled to remove the ether. The residual liquid on standing overnight deposited a considerable amount of non-crystalline solid. This substance had the characteristics of a polymerized material or a condensation product from the aldehyde, and was not identified. The liquid remaining from the removal of this solid was distilled under reduced pressure in an atmosphere of nitrogen. The only product isolated from the distillate was dibenzyl.

TABLE I

REACTION PRODUCTS

	Secondary alcohol											Dibromo addition product		Primary alcohol $CH_2ClCHCl-CH_2OH$	
						Analyses, %									
		Yield,		B. p.,		Calculated			Found						
RMgBr	Formula	G.	%	°C.	Mm.	C	H	Cl	C	H	Cl	G.	%	G.	%
C_6H_5MgBr[a]	$C_9H_{10}OCl_2$	35	68.3	150–151	10	52.71	4.92	34.58	52.39	4.89	34.36	..	..	...	..
$C_6H_{13}MgBr$[b]	$C_9H_{18}OCl_2$	19.5	36.6	139–141	12	50.71	8.51	33.27	50.41	8.61	33.32	10	16.4	6.5	20.2
$C_6H_{11}MgBr$[c]	$C_9H_{16}OCl_2$	13.5	25.6	144–146	12	51.20	7.64	33.59	51.30	7.66	33.50	14	23.1	8	24.8

(2) Floutz, *ibid.*, **68**, 2490 (1946).

(3) A portion of the α,β-dichloropropionaldehyde was furnished through the courtesy of the Shell Development Company. That used in the initial studies was synthesized by the low temperature addition of chlorine to acrolein, according to the literature.

(4) Yarnell and Wallis, *J. Org. Chem.*, **4**, 270–283 (1939).

No secondary alcohol was detected; the larger part of the liquid began to decompose and carbonize at a bath temperature of 180° and pressure of 4 mm. An average of results from two runs gave amorphous solid, 12.5 g.; dibenzyl, 6.3 g.; tarry, carbonaceous residue, 14.5 g.

Table I provides essential data. Yields in each case are averages from two runs.

Summary

1. The reaction of α,β-dichloropropionaldehyde with phenylmagnesium bromide, *n*-hexylmagnesium bromide, cyclohexylmagnesium bromide, β-phenylethylmagnesium bromide and benzylmagnesium chloride has been studied.

2. The new secondary alcohols 2,3-dichloro-1-phenylpropanol-1, 1,2-dichlorononanol-3, 2,3-dichloro-1-cyclohexylpropanol-1 and 1,2-dichloro-5-phenylpentanol-3 have been prepared via the Grignard reaction.

Cyclobutane Derivatives. IV. Ziegler Bromination[1a] of Methylenecyclobutane[1b,2]

BY EDWIN R. BUCHMAN AND DAVID R. HOWTON

In connection with another investigation,[3] we have studied the reaction,[1a] under a variety of conditions, between N-bromosuccinimide (NBS) and methylenecyclobutane (I). It was found that, although NBS reacted with I faster in the usually employed carbon tetrachloride[1a] than in benzene,[4] higher yields of allylic bromides, C_5H_7Br, were obtained in the latter solvent; in both cases the addition of small amounts of dibenzoyl peroxide[5] proved advantageous. A typical experiment carried out in benzene and with added peroxide gave the following products[6]: a C_5H_7Br fraction (14%), methylenecyclobutane dibromide[7] (56%), N-phenylsuccinimide[9] (15%) and succinimide (66%). In carbon tetrachloride and without added peroxide another minor product was encountered, apparently formed by direct 1:1 addition[8] of NBS to I.

The C_5H_7Br mixture (II + III) was investigated as indicated on the diagram. II and III were separated by virtue of the great difference in the rates at which they react with trimethylamine in benzene at room temperature. III reacted in a few minutes to precipitate the corresponding[10] allylic quaternary ammonium bromide (V) while the complete conversion of II to IV required several weeks; the relative amounts of IV and V isolated indicate a II:III ratio in the C_5H_7Br fraction of about 15:1.

The structure[11] of V (and indirectly that of IV) was established by relating it to the known[13] saturated quaternary bromide (IX). In this connection the applicability of a recently described[12] two-step reduction method was investigated. The addition of bromine to V yielded a single dibromo bromide to which structure VII must be assigned since on catalytic hydrogenation it was converted to a bromide identified (by comparison with an authentic sample[13]) as IX. However, the bromination of IV gave not only compound VI isomeric with VII (and yielding on reduction VIII isomeric with IX) but also, by a novel rearrangement, a nearly equal amount of bromide VII identical with the material originating from V.

A structure proof based on reactions not accompanied by possible rearrangements was achieved

(6) Yields based on NBS.

(7) Földi[8] obtained saturated dibromides from reactions of N-bromo-N-methylbenzenesulfonamide with certain olefins. In this Laboratory it has been found that I and cyclobutene,[3] which react slowly with NBS, give dibromides as major products (yield apparently independent of added peroxide but dependent on nature of solvent, see Experimental), while cyclohexene,[9] which reacts rapidly, gives only a small amount of dibromide.

The mechanism of formation of the dibromides remains obscure. Földi's unsubstantiated explanation that substituted derivatives of ethylenediamine and substituted dibromides are formed in equivalent amount obviously cannot apply in the present case. The possibility that hydrogen bromide (which would combine with NBS to make free bromine available, *cf.* Meystre, Ehmann, Neher and Miescher, *Helv. Chim. Acta*, **28**, 1252 (1945); Wieland and Miescher, *ibid.*, **30**, 1876 (1947); Barnes, THIS JOURNAL, **70**, 145 (1948)) is formed during the slow reaction is unsupported by experimental evidence; brominated reaction products from I appear to be stable and no loss of hydrogen bromide was noted during the Ziegler reaction or during the working-up procedure.

(10) The precipitated fractions are quite pure; we assume that III is the precursor of V and II of IV.

(11) As a possible aid in assigning structures to such compounds, it may be noted that there appears to be a degree of correspondence in m. p.'s between allylic quaternary picrates and the related saturated picrates, *e. g.*, picrates corresponding to V and IX melt at 127 and 117°, respectively, while for the IV–VIII pair the values are 215 and 245°; Howton[12] gives: 2-cyclohexenyltrimethylammonium picrate, m. p. 130°, and cyclohexyltrimethylammonium picrate, m. p. 125°; allyltrimethylammonium picrate, m. p. 220°, and *n*-propyltrimethylammonium picrate, m. p. 200°.

(12) Howton, THIS JOURNAL, **69**, 2555 (1947).

by the direct catalytic reduction of IV and of V. From V, IX was obtained, while IV gave a relatively good yield[14] of VIII identical with the reduction product from VI; this synthesis of VIII incidentally confirms the formulas assigned to both VI and VIII.

This research was aided by a grant from the Research Corporation; the authors wish also to express their thanks to Dr. Saul Winstein and to Dr. Martin G. Ettlinger for helpful discussions.

Experimental[15]

Ziegler Bromination of I.—A two-liter three-necked flask was charged with 178 g. (1.0 mole) of NBS,[1a] 2.42 g. (0.01 mole) of dibenzoyl peroxide, 71.0 g. (1.044 mole) of I[16] and 740 ml. of thiophene-free benzene (dried over sodium); the flask was equipped with a mercury-sealed Hershberg stirrer, a water-cooled reflux condenser topped by another containing Dry Ice, and a thermometer dipping into the reaction mixture. The stirred mixture was maintained at 75–80° (gentle reflux) by means of a heating mantle. From time to time the reaction mixture was cooled to about 40° and a drop of liquid was removed and tested with aqueous potassium iodide for the presence of NBS; after six and one-half hours the test was negative. After standing overnight at room temperature, 57.9 g. of crystalline solid (A) was filtered from the brown mixture; 11.6 g. of I was recovered from the filtrate by distillation at atmospheric pressure, using a 30-cm. helix-packed column. Most of the benzene was then removed through the same column at 200 mm. On standing overnight, 19.7 g. of solid (B) crystallized from the residue. The filtrate from B was then distilled rather rapidly through a 9-cm. helix-packed column with efficient condensation (Dry-Ice trap) of the distillate, first at 70 mm. and then at 30 mm. until all of the allylic bromides had been removed. The resulting distillate was refractionated through the same column giving 21.6 g. (14.6%[6]) of a mixture of II and III, b. p. 55.2–56.7° at 70 mm. This material rapidly decolorized potassium permanganate in acetone solution, slowly decolorized bromine in carbon tetrachloride, gave an immediate precipitate with alcoholic silver nitrate and slowly darkened on standing at room temperature exposed to light.

Anal.[17] Calcd. for C_5H_7Br: C, 40.84; H, 4.80; Br, 54.36. Found: C, 40.83; H, 5.11; Br, 54.78.

The residual oil from the rapid initial distillation of the C_5H_7Br fraction deposited 12.1 g. of crystalline material (C) on standing; this was filtered off and the filtrate combined with a small amount of oil left from the final fractionation of the C_5H_7Br distillate and distilled at 3 mm., giving 65.1 g. (56.2%[6]) of I dibromide, pale yellow subtly lachrymatory oil, b. p. 43–50°, $n^{25}D$ 1.532,[17] d^{25}_4 1.801[17]; this material[18] decolorized permanganate in acetone rapidly and formed a precipitate soon after mixing with a benzene solution of dimethylamine.

Removal of I dibromide from the reaction mixture left 43.8 g. of dark brown, very viscous oil which deposited 1.8 g. of crystalline material (D) after standing several months. Careful examination of the four crops of crystalline material showed A to be substantially pure succinimide, B and D to be N-phenylsuccinimide[9] and C to be a mixture of these two substances; total yield[6] of the first 66%, of the latter 15%. A fractional distillation *in vacuo* was carried out on the 42 g. of residual oil; small additional amounts of succinimide and of N-phenylsuccinimide were obtained but no other homogeneous product was isolated.

Reactions of this type gave consistently approximately the yields of bromination products indicated above; a bromination in benzene but without added peroxide required eleven and one-half hours and yielded[6] 9.1% of allylic bromides and 57.1% of the dibromide. In carbon tetrachloride the results were less consistent; figures[6] are given for two representative runs; 8.8% of allylic bromides and 52.8% of dibromide (two and one-half hours, 1.6 mole % peroxide), 5.6% of bromides and 34.1% of dibromide (three and one-half hours, no peroxide added). In *n*-heptane with 1.6 mole % peroxide the reaction appeared complete after two hours; 6.0% of monobromides and 24.3%[6] of dibromide were isolated from the gummy reaction mixture. Using excess of I as solvent and with added peroxide, no appreciable bromination took place even after twenty hours of refluxing.

From an experiment carried out in carbon tetrachloride (no added peroxide), it was found possible to isolate a small amount of a slightly colored, very viscous oil, b. p. 79° at 0.25 mm., which gave analytical figures close to those calculated for the adduct of I and NBS; it was difficult to completely free this oil from succinimide by distillation.

Anal. Calcd. for $C_9H_{12}BrNO_2$: C, 43.92; H, 4.92; N, 5.69. Found: C, 44.46; H, 5.31; N, 6.16.

(2-Methylenecyclobutyl)-trimethylammonium Bromide (IV) and (1-Cyclobutenylmethyl)-trimethylammonium Bromide (V).—The above mixture of II and III (21.6 g.) was treated in a centrifuge bottle with 63 g. (slight excess) of an 18% solution of trimethylamine in C. P. benzene. A voluminous crystalline precipitate (V) formed immediately; after standing for fifteen minutes at room temperature, this product was separated by centrifugation, washed with benzene and dried *in vacuo*, yield 1.4 g. (4.6%). Crude V, m. p. 162.5° (prior sintering), was found to be extremely hygroscopic (in other experiments V was obtained as an oil); it decolorized permanganate[19] rapidly and was characterized by conversion

(14) Whereas V behaved normally[12] on reduction, giving trimethylamine as a major reaction product, IV yielded somewhat better than 50% of VIII. Seemingly IV does not possess a fully effective allylic double bond.

(15) All melting points are corrected. Microanalyses by Dr. G. Oppenheimer and G. A. Swinehart of this Institute.

(16) B. p. 40.0–42.3°; preparation, see Shand, Schomaker and Fischer, THIS JOURNAL, 66, 636 (1944); a portion of the material used in this research was prepared by Mr. J. R. Fischer.

(17) These figures were obtained from a sample prepared in a similar fashion from a Ziegler bromination carried out in carbon tetrachloride.

(18) An authentic sample of I dibromide, b. p. 41–45° at 2.2 mm., $n^{24}D$ 1.537, decolorized permanganate and gave with dimethylamine the same series of reaction products (to be described in another connection).

(19) The behavior of quaternary bromides and picrates toward potassium permanganate in acetone or acetone–water solution was investigated. The unsaturated bromides IV and V as well as the corre-

to the quaternary picrate,[19,20] large dark yellow striated blades from ethanol–acetonitrile, m. p. 126.6–127.1° (analysis see below).

A small amount of material (0.4 g.) which deposited in the next seventy-five minutes was shown (by conversion to the picrate[20]) to be predominantly IV. After the benzene solution had stood tightly stoppered for two weeks longer, a dense network of colorless needles had formed which was centrifuged off (16.2 g. of IV); two months later another crop (4.6 g.) was collected; total yield of crystalline IV, 70%. A small amount of oily material (crude IV) subsequently separated from the benzene solution and there remained a certain amount of bromine-containing benzene-soluble material which apparently did not react with trimethylamine.

Fractional crystallization of the IV obtained above and examination of the mother liquors (by conversion to the picrate[20]) failed to disclose the presence of any appreciable amount of V. IV[19] formed hygroscopic sparse clusters of colorless rods from acetone–ethanol, m. p. 229° dec.

Anal. Calcd. for $C_8H_{16}BrN$: C, 46.61; H, 7.82; N, 6.80. Found: C, 47.17; H, 8.07; N, 6.60.

The picrate[19,20] corresponding to IV crystallized from ethanol in long yellow feathers, m. p. 215–217° dec.

Anal. Calcd. for $C_{14}H_{18}N_4O_7$: C, 47.46; H, 5.12; N, 15.81. Found (IV picrate): C, 47.51; H, 5.41; N, 15.85. Found (V picrate): C, 47.47; H, 5.36; N, 15.59.

Bromination of IV.—A solution of 1.41 g. of IV (as obtained from the benzene–trimethylamine solution) in 5 ml. of chloroform was treated with 1.10 g. (one molecular equivalent) of bromine; the resulting two-liquid-phase mixture was tightly stoppered and allowed to stand at room temperature for ten days. The crop of clustered jagged crystals (VI) which had emerged from the pale orange solution was freed of mother liquors by rinsing with chloroform and dried, m. p. 203.5° dec., yield 1.02 g. (41%). A sample was recrystallized from ethanol–water, colorless truncated dog-tooth-like crystals, some arranged in rows to form long, irregular blades, m. p. 195.5° dec.[21] (analysis below).

The mother liquors and washings from this crop of VI were freed of solvent and rapidly diluted with acetone, giving a voluminous white crystalline precipitate of crude VII weighing 0.93 g. (37%), m. p. *ca.* 168°. This was recrystallized by dissolving in a small amount of warm methanol and rapidly diluting with acetone, broad colorless plates with bluntly pointed terminations, m. p. 163–164° dec.[21]

Anal. Calcd. for $C_8H_{16}Br_2N$: C, 26.25; H, 4.41; N, 3.83. Found (VI): C, 26.19; H, 4.85; N, 3.74. Found (VII): C, 26.77; H, 4.64; N, 3.77.

Another bromination of IV (procedure similar to that used for bromination of V, see below) gave a 33% yield of VI and a 27% yield of VII (isolated as the picrate). VII obtained in this manner and the corresponding picrate were compared (mixed m. p.'s gave no depression) with material from bromination of V. VII from bromination of IV was also converted (see below) to IX and its picrate (mixed m. p.'s).

The quaternary picrate corresponding to VI was recrystallized from ethanol–water, yellow rhombic plates, some with striations parallel to all four edges of the rhombs, others growing to a point in such a way as to form stubby triangular prisms, m. p. 173°.[21] The picrate corresponding to VII, orange-yellow bars or granules from ethanol–water, melted at 172°.[21] A mixture of the two isomeric picrates gave a difficultly-detectable depression of the melting point.

Anal. Calcd. for $C_{14}H_{18}Br_2N_4O_7$: C, 32.70; H, 3.53. Found (VI picrate): C, 32.80; H, 3.55. Found (VII picrate): C, 32.99; H, 3.60.

Bromination of V.—A solution of 1.09 g. of crude crystalline V in 4 ml. of chloroform was treated dropwise with bromine until a heavy oil separated out; the mixture was then diluted with benzene and treated with more bromine until the color of the latter persisted in the benzene epiphase. The heavy oil was then thoroughly washed with benzene, taken up in 25 ml. of ethanol and slowly freed of solvent on the steam-bath; the residual clear tan sirup was taken up in 10 ml. of acetone and placed in an ice-box overnight, giving rise to 0.65 g. of VII, compact rosettes, crude m. p. 170° dec. Mother liquors yielded an additional 0.24 g. of VII, crude m. p. 169° dec. and 0.57 g. of crude VII picrate[22] (total yield of VII, 66.5%).

(2-Methylcyclobutyl)-trimethylammonium Bromide (VIII).—Recrystallized IV (0.90 g.) was added to a suspension of pre-reduced palladium-on-barium-sulfate catalyst[12] (2.25 g.) in 25 ml. of water and the mixture was shaken with hydrogen at room temperature and atmospheric pressure. After nineteen hours the absorption rate was negligible and 155.8 ml. of hydrogen had been absorbed (theory for one mole-equivalent, 112 ml.). The catalyst was centrifuged off, the solution was treated with sodium hydroxide in slight excess and the liberated trimethylamine was removed on the steam-bath *in vacuo*. Then, after neutralization with hydrobromic acid, the solution was evaporated to dryness. The residue was extracted with chloroform and the extracts were freed of solvent and treated with acetone; in this way three crops of crude VIII were obtained totaling 0.41 g. (45%) and from the mother liquors 0.11 g. of VIII picrate (total yield of VIII, 52%). VIII picrate made from this crude VIII did not depress the m. p. of a like picrate obtained from VI (see below).

Catalytic reduction[12] of VI gave a theoretical yield of crude VIII; after recrystallization from acetone–methanol, it formed colorless plates of various rectangular shapes, m. p. 270° dec.

Anal. Calcd. for $C_8H_{18}BrN$: C, 46.16; H, 8.71; N, 6.73. Found: C, 46.04; H, 8.97; N, 6.10.

The corresponding picrate formed bundles of yellow needles from ethanol, m. p. 244.6–244.8°.

Anal. Calcd. for $C_{14}H_{20}N_4O_7$: C, 47.19; H, 5.66. Found: C, 47.24; H, 5.81.

(Cyclobutylmethyl)-trimethylammonium Bromide (IX).—Reduction[23] of cyclobutyl cyanide[24] in ethanol–12 *N* hydrochloric acid using a palladium-on-Norit catalyst gave cyclobutylmethylamine hydrochloride, characteristic colorless flakes from acetone–ethanol, m. p. 235.5°. This hydrochloride (1.54 g.) was methylated in the usual way[13b] with methyl iodide and potassium hydroxide in methanol. After removal of solvent the product was separated by continuous extraction with chloroform, yield of crude (cyclobutylmethyl)-trimethylammonium iodide nearly quantitative (3.18 g.); recrystallization from acetone–ethanol gave glistening colorless needles, m. p. 205.6–206.5°.

Anal. Calcd. for $C_8H_{18}IN$: C, 37.66; H, 7.11; N, 5.49. Found: C, 37.80; H, 6.96; N, 5.48.

The iodide was converted to the base with silver oxide and this after neutralization with hydrobromic acid gave

sponding picrates decolorized permanganate rapidly while VI, VII, VIII and IX and their picrates did not. The stability of VI is of interest since I dibromide reacts readily with permanganate under these conditions, see ref. 18.

(20) See ref. 12, footnote 5.

(21) Melting point bath heated slowly; m. p. varies considerably with rate of heating.

(22) Mother liquors from this picrate gave 0.45 g. of material m. p. below 95°, from which, after several recrystallizations, a homogeneous substance was obtained, sparsely-clustered thin rectangular slats from ethanol–acetonitrile, m. p. 142.5–143.2°, halogen-free, unsaturated to permanganate. This may be (2-methyl-2-butenyl)-trimethylammonium picrate derived from 2-methylbutene-1 originally present (see footnote 8 of ref. 16) as an impurity in I.

Anal. Calcd. for $C_{14}H_{20}N_4O_7$: C, 47.19; H, 5.66; N, 15.72. Found: C, 47.25; H, 5.73; N, 15.75.

(23) *Cf.* Hartung, THIS JOURNAL, **50**, 3370 (1928).

(24) B. p. 147–148° (747 mm.), prepared in 62% yield according to Freund and Gudeman, *Ber.*, **21**, 2697 (1888).

IX, beautiful sparse clusters of colorless triangular prisms from acetone–methanol, m. p. 220–221° (lit.[13a] m. p. 214°). Another sample of IX (from reduction of VII) exhibited dimorphism; on seeding a supercooled solution of the material in acetone–methanol, colorless needles were rapidly deposited which changed into massive granules, the interconversion being complete in about three hours at 0°. These granules melted at 219.6–220.2°, resolidified on withdrawing from the bath, then melted at 226°; a sample mixed with authentic IX showed the same behavior.

Anal. Calcd. for $C_8H_{18}BrN$: C, 46.16; H, 8.71; N, 6.73. Found: C, 45.75; H, 8.77; N, 6.39.

The above salts gave the corresponding picrate, bright yellow-orange dendrites from ethanol, m. p. 116.5–117.1°.

Anal. Calcd. for $C_{14}H_{20}N_4O_7$: C, 47.19; H, 5.66; N, 15.72. Found: C, 47.40; H, 5.75; N, 15.50.

The halides with excess of aqueous sodium picrate gave a picrate–sodium picrate double salt,[20] fine yellow needles from ethanol, m. p. 164.4–164.7° (prior sintering).

Anal. Calcd. for $C_{14}H_{20}N_4O_7 \cdot C_6H_2N_3NaO_7 \cdot 0.5H_2O$: C, 38.97; H, 3.76; N, 15.91; Na, 3.73. Found: C, 38.83; H, 4.04; N, 16.26; Na, 3.39.

Catalytic reduction[12] of VII gave in good yield IX (mixed m. p. with authentic IX) which was converted to the picrate (mixed m. p.). A very small yield of IX (isolated as the picrate–sodium picrate double salt, mixed m. p. and analysis) resulted from the reduction[12] of crude V using a palladium-on-Norit catalyst; trimethylamine hydrobromide constituted the major reaction product.

Summary

The Ziegler bromination of methylenecyclobutane has been studied. The major bromination product is the olefin dibromide and under the best conditions found (in benzene and with added peroxide) the yield of allylic bromides is 14%.

The allylic bromides were investigated by conversion to the allylic trimethylammonium bromides, the structures of which were established.

Analysis of the Vibrations of Benzene Derivatives. I. The Class A_1 Carbon Vibrations of Toluene

BY A. R. CHOPPIN AND C. H. SMITH[1,2]

The assignment of experimentally observed vibrational frequencies of aromatic molecules to definite modes of vibration has encountered difficulties, chief of which has been the large number of vibrations belonging to each symmetry class. Only for the highly symmetrical benzene molecule has it been possible to make assignments with confidence.

For toluene, the assignments have been more speculative. The polarization measurements in the Raman spectrum made by Cabannes and Rousset[3] and by Cleveland[4] have been of importance in identifying the totally symmetric vibrational frequencies. However, the number of observed polarized lines is less than the theoretical number of totally symmetric vibrations, even if toluene is assigned C_{2v} symmetry. Teets and Andrews[5] constructed a mechanical model of toluene, and found certain correlations between its vibrational frequencies and those observed in the Raman spectrum of toluene. Pitzer and Scott,[6] reasoning by analogy with benzene, assigned a frequency and vibrational form to each of the fundamental vibrations of the toluene molecule. However, except for the 1003 cm.$^{-1}$ frequency, they did not analyze the changes that occur in the vibrational forms on going from benzene to toluene. Ginsburg, Robertson and Matsen[7] have analyzed the near-ultraviolet absorption spectrum of toluene vapor and made a considerable number of frequency assignments.

Recently, the authors[8] have developed an interpretation of the ultraviolet absorption spectrum of toluene which differs from that of Ginsburg, Robertson and Matsen in that the 623 cm.$^{-1}$ frequency (in the ground state) is assigned to Class A_1 instead of Class B_1. Furthermore, the authors have proposed certain approximate vibrational forms for the Class A_1 carbon vibrations of toluene. These forms were based upon analogies with benzene and upon frequency changes taking place upon the substitution of deuterium for the various hydrogens of toluene. They differ in some cases from the forms assigned by Pitzer and Scott,[6] and from the forms observed in the mechanical model.[5]

In an attempt to settle these differences in the assignment of the frequencies and modes of vibration of toluene, the mathematical analysis presented in this article was made.

Calculations

In order to simplify the mathematical analysis, the carbon and hydrogen vibrations are treated as distinct uncoupled sets. This follows a previous qualitative treatment of the benzene vibrations.[9] For the purpose of the calculation of the carbon vibrations, it is assumed that each hydrogen is

condensed into the nucleus of the carbon atom to which it is attached, forming a "molecule" containing seven mass-points. The methyl group has a relative mass of 15, the carbon in position one a mass of 12, and each of the other carbons a mass of 13. The "molecule" belongs to point-group C_{2v}. It has 15 normal vibrations, six belonging to Class A_1 (totally symmetric), one belonging to Class A_2 (symmetric only with respect to the two-fold axis), five belonging to Class B_1 (symmetric only with respect to the molecular plane), and three belonging to Class B_2 (symmetric only with respect to the plane of symmetry perpendicular to the molecular plane). When the secular equation is expressed in terms of symmetry coördinates,[10] it can be factored into four separate equations, one for each symmetry class. The Class A_1 vibrations may be set up in a sixth-order determinant. The calculations of this article use a valence-force potential system with the following force constants: 4.50×10^5 dynes per cm.,[11] valence-stretching constant for the single bond; 7.58×10^5 dynes per cm.,[12] valence-stretching constant for the aromatic bonds; 0.65×10^5 dynes per cm.,[12] force constant for the bending of the aromatic –C–C–C– angle in the plane of the ring. The single bond force constant was calculated by Stitt from an analysis of the ethane molecule. This particular value does not include interaction between the hydrogens of ethane. It was used since Pitzer and Scott[6] found that the methyl group of toluene has essentially free rotation. The aromatic bond force constants were calculated by Lord and Andrews from the benzene molecule. The aromatic bond distances in toluene were assumed to be the same as in benzene; it is not necessary to use any actual values.

The six roots of the Class A_1 factor of the secular equation are as follows: 497, 779, 965, 1156, 1380 and 1704 cm.$^{-1}$. The normal coördinates are given in Table I and in Fig. 1.

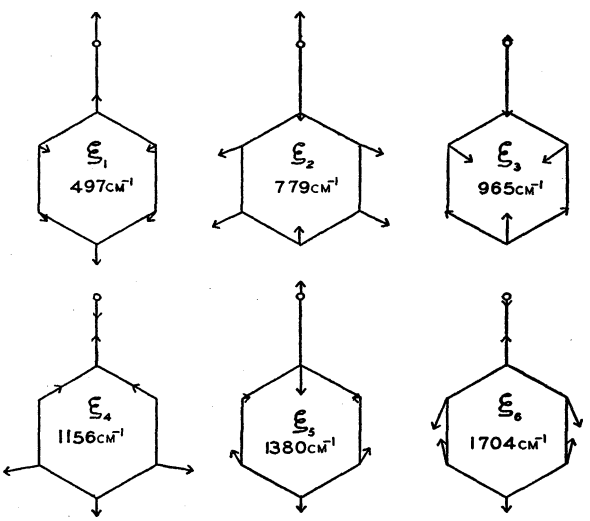

Fig. 1.—Calculated frequencies and normal coördinates for the Class A_1 carbon vibrations of toluene.

Discussion

Comparison with Spectral Frequencies.—Theoretically, all of the Class A_1 carbon vibrations should be active in the Raman spectrum (giving polarized lines) and in infrared and ultraviolet absorption. Possible correlations between calculated and observed frequencies of toluene are shown in Table II.

The frequency changes taking place when deuterium is placed on the toluene molecule[8] are of value in checking the vibrational forms. If deuterium is placed upon a carbon atom which is vibrating with a large amplitude, there will be a greater decrease in frequency than would be the

case if the deuterium were placed upon a carbon atom vibrating with a small amplitude.

The calculated 497 cm.$^{-1}$ frequency correlates with the polarized 520 cm.$^{-1}$ Raman line. The frequency changes upon deuteration check with the calculated normal coördinate, ξ_1, except for the meta carbon atom.

No calculated frequency lies near the observed 623 cm.$^{-1}$ line. It must be concluded that this frequency *does not* correspond to a Class A_1 carbon vibration. This is in agreement with the observation that this line is depolarized in the Raman spectrum. It disagrees with the authors' previous assignment.[8]

The calculated 779 cm.$^{-1}$ frequency correlates with the polarized 786 cm.$^{-1}$ Raman line. The frequency changes upon deuteration check with the calculated form, ξ_2, except for toluene-2-*d* in the ground state.

From Raman data alone, the calculated 965 cm.$^{-1}$ frequency could belong to either the 1003 or the 1029 cm.$^{-1}$ Raman line. However, the 1029 cm.$^{-1}$ frequency was not observed in ultraviolet absorption. This gives rise to the assumption that the 1029 cm.$^{-1}$ Raman line belongs to a Class A_1 hydrogen-bending vibration. This idea is supported by the observation of a line, which has been assigned to a Class A_1 hydrogen-bending vibration, at 1031.0 cm.$^{-1}$ in the Raman spectrum of benzene-*d*.[16] The observed 1003 cm.$^{-1}$ line must correspond with the 965 cm.$^{-1}$ calculated frequency (ξ_3). In the ground state, frequency changes upon deuteration check, with form ξ_3 in every case. This coördinate, where the motion is chiefly confined to the 2, 4 and 6 positions, strikingly confirms the form deduced by Pitzer and Scott[6] from a consideration of the spectra of benzene and the methyl benzenes. In ultraviolet absorption, two strong frequencies were observed in the excited state in this spectral region (933 and 966 cm.$^{-1}$ for toluene). One possible explanation is that the hydrogen-bending vibration, observed at 1029 cm.$^{-1}$ in the Raman spectrum, is coupled in with the carbon vibrations in the excited state, even though it does not appear in the ultraviolet absorption for the ground state. A more probable explanation lies in assigning one of these excited state lines to a carbon vibration of another symmetry class. It is to be noted that, for the excited state, the group of frequencies in the deuterated toluenes, beginning with 966 cm.$^{-1}$ for toluene itself, check with the form of the normal coördinate ξ_3.

The calculated 1156 cm.$^{-1}$ frequency corresponds with the observed 1209 cm.$^{-1}$ polarized Raman line. The observed frequencies of the deuterated toluenes are not in particularly good agreement with the form ξ_4.

The calculated 1380 cm.$^{-1}$ frequency is near the 1379 cm.$^{-1}$ polarized Raman line. However, this frequency was not observed in ultraviolet absorption; it differs from other correlated frequencies in that the calculated value is not lower than the observed value. This makes its correlation questionable, especially since Pitzer and Scott[6] correlated the 1379 cm.$^{-1}$ Raman line with the symmetric hydrogen-bending motion within the methyl group. Cabannes and Rousset[3] observed a polarized Raman line at 1483 cm.$^{-1}$ and Pitzer and Scott[6] assigned this line to a Class A_1 vibration. However, neither Howlett[13] nor Kohlrausch and Wittek[14] observed a Raman line at 1483 cm.$^{-1}$, raising doubt as to its actual existence. Several infrared bands have been observed in the region[15]; possibly one of them may correspond to the calculated form ξ_5. Apparently, ξ_5 is not active in either the Raman spectrum or near-ultraviolet absorption.

The calculated 1704 cm.$^{-1}$ frequency is far removed from the 1603 cm.$^{-1}$ line which Pitzer and Scott[6] assigned to a Class A_1 vibration, and no Raman lines have been observed near the calculated value. Possibly, one of the frequencies observed in the infrared may correspond to form ξ_6. Apparently, ξ_6 is inactive in both the Raman and ultraviolet spectra.

Comparison with the Vibrations of Mechanical Models.—Teets and Andrews[5] constructed a mechanical model of the toluene molecule and observed its vibrational forms and frequencies. Unfortunately for comparison with the calculated frequencies, they used the centric formula of benzene as the basis for their model. This resulted in relatively high frequencies for those vibrations involving bending of the ring.

Trenkler[17] constructed mechanical models for mono-substituted benzene, using the resonating benzene formula as the basis for his model. One of the models had a mass distribution somewhat similar to that found in toluene. The actual form

of the vibrations of these models has been given by Kohlrausch.[18] The agreement between the calculated forms and frequencies and those observed in the model is not bad, except that Trenkler's form ω_3 has more motion in the meta carbon atoms than does form ξ_3, and its frequency is completely out of line with both calculated and observed values.

Summary

The approximate vibrational forms and frequencies of the Class A_1 carbon vibrations of toluene have been calculated, using a simplified valence-force potential system and force constants from benzene and ethane. The calculated vibrations have been compared with spectral frequencies and with the vibrations of mechanical models. The results have been interpreted so as to *indicate* the following:

1. The observed 623 cm.$^{-1}$ frequency of toluene *does not* belong to a Class A_1 carbon vibration.
2. The 520, 786, 1003 and 1210 cm.$^{-1}$ observed frequencies of toluene belong to Class A_1 carbon vibrations.
3. The 1029 and 1379 cm.$^{-1}$ frequencies of toluene belong to symmetric hydrogen-bending vibrations.
4. Two of the Class A_1 carbon vibrations of toluene are not active in either the Raman or the near-ultraviolet absorption spectra.

Fluorination of Thiophosphorylethoxydichloride[1]

BY HAROLD SIMMONS BOOTH, DONALD RAY MARTIN[2] AND FRED E. KENDALL[3]

Inasmuch as thiophosphoryl trichloride has been stepwise fluorinated in this Laboratory[4] to give thiophosphoryl chlorofluorides and trifluoride, it was of interest to study the effect of substituting an ethoxy group for a chlorine atom upon the fluorination reaction. Therefore, the fluorination of thiophosphorylethoxydichloride by the Swarts reaction was undertaken.

Experimental

Preparation and Purification of Thiophosphorylethoxydichloride.—The thiophosphorylethoxydichloride was prepared by a modification of the directions given by Pishchimuka[5] from thiophosphoryl trichloride and dried, redistilled absolute ethyl alcohol. The thiophosphoryl trichloride was a C. P. (chemically pure) grade obtained from the Victor Chemical Company which was then fractionally distilled.

Two hundred grams of thiophosphoryl trichloride was placed in a three-necked flask fitted with a stirrer, drying tube and a separatory funnel containing 100 g. of absolute ethyl alcohol. The alcohol was added dropwise over a period of two to three hours, care being exercised that the temperature of the reactor did not exceed 10°[6] thus reducing the yield. The crude thiophosphorylethoxydichloride was fractionated once under a pressure of 70 mm. and 4 times under a pressure of 25 mm. in a Raschig ring-packed electrically heated column to give a 70% yield of the purified product.

Fluorination of Thiophosphorylethoxydichloride.—The method and apparatus used for the stepwise fluorination, using the Swarts reaction,[7] was the same as that described elsewhere,[8,9] except that, owing to the high boiling points of the products, an air-cooled condenser was substituted for the usual water-cooled condenser. In order to obtain the chlorofluoride, the fluorination products were removed with an automatic stopcock set to maintain a pressure of 20–30 mm. in the generator. The temperature of the generator must be at, or below, 50° to prevent decomposition of thiophosphorylethoxydichloride and thiophosphorylethoxychlorofluoride. In exploratory fluorination reactions, it was observed that simple addition of antimony trifluoride to thiophosphorylethoxydichloride in a flask, open to the atmosphere through a drying tube, produced about the same results providing the temperature of the reactor was kept below 50°. Little or no reaction was observed when the fluorination was attempted without antimony pentachloride as the catalyst.

Purification of Thiophosphorylethoxydifluoride.—The fluorination products were fractionally distilled in a modified Dufton column as described by Booth and Bozarth.[10] The best coolant for the column head was water, cooled by ice and salt. Samples, from separate generations, were collected by distillation at two different operating pressures, namely, 60 and 100 mm., and found to be identical. The tailings in the still pot had such a low vapor pressure that their distillation in this type of fractionating column was not possible.

Purification of this compound was first attempted with the heated column used to purify the starting material. The distillation was attempted at atmospheric pressure with the receiver open to the atmosphere through a drying tube. However, a reaction of a volatile product with the atmosphere outside the drying tube was observed so this method of purification was abandoned.

Purification of Thiophosphorylethoxychlorofluoride.—The tailings of the above distillations were placed in the heated column used for the purification of thiophosphorylethoxydichloride and were fractionally distilled at pressures of 25 and 70 mm. These samples were found to be

identical. After the removal of the thiophosphorylethoxychlorofluoride, there remained in the still pot a heavy, viscous residue which did not lend itself to subsequent distillation inasmuch as it apparently polymerized at the temperature required to cause vaporization. This material was seemingly resistant to water and organic solvents, but was readily attacked by nitric acid. A similar product forms in the preparation of thiophosphorylethoxydichloride as first observed by Pishchimuka.[5]

Analyses.—The samples weighed in approximately 1-ml. sealed glass ampoules[11] were hydrolyzed in a calculated excess of a 0.5 *N* solution of sodium hydroxide. The hydrolyses were rapid for thiophosphorylethoxydifluoride and thiophosphorylethoxychlorofluoride, but slower for thiophosphorylethoxydichloride. Usually the hydrolytic reactions were allowed to proceed overnight before the samples were treated with hydrogen peroxide to oxidize the sulfide to sulfate. After insurance of the complete removal of excess peroxide, the chlorine was determined by the Volhard method,[11] the sulfur as sulfate gravimetrically[12,13] and the phosphorus volumetrically by precipitating it as ammonium phosphomolybdate which was then dissolved in an excess of 0.25 *N* sodium hydroxide and back-titrated with standardized nitric acid to the phenolphthalein end-point.[12,14,15] Separate samples were hydrolyzed, as described above, and the alcohol fractionally distilled into a tared receiver. The weight of distillate and its density at 25° were used to determine the percentage of ethoxy group present.[16] Fluorine was obtained by difference. A summary of the analyses is contained in Table I.

[a] Constants in the equation $\log p$ (mm.) $= (A/T) + B$. [b] Variation in vapor pressure in mm. [c] Corrosion $= C = 43.9W/ASt$. [d] At 760 mm. pressure.

Determination of Physical Constants (see Table I).—The freezing points of separately generated and fractionally distilled samples of these compounds were determined as described by Booth and Martin.[17] In the determination of the freezing points of the dichloride and the difluoride, supercooling was observed to the extent of 12.6 and 10.5°, respectively. The freezing point of thiophosphorylethoxychlorofluoride was difficult to obtain due to a tendency toward glass formation. Further cooling of the glass produced a crystalline product which gave a very short, but reproducible, break in the cooling curve. The transformation from the glass to the crystalline solid was accompanied by a crackling noise and frequently the freezing point cell was broken. Attempts to obtain a melting point were unsuccessful.

Liquid densities were determined at 0° using the method of Booth and Hermann.[18] Qualitative solubility tests were made by adding each compound dropwise to comparable volumes of solvents and allowing the components to stand in contact with each other without stirring for thirty minutes. Except for water, complete miscibility with the solvent was observed immediately upon contact.

The vapor pressures were determined by the static method of Booth, Elsey and Burchfield.[19] The equations in Table I are derived from the original vapor pressure data.

Discussion

Thiophosphorylethoxydichloride was described by Pischimuka[5] as being an oily, clear liquid, possessing a peculiar odor. The liquid density and the boiling point reported by Pischimuka[5] are in poor agreement with the values reported in this study which may be due to impurities in the product obtained by Pischimuka due to reactions described by Cloez[20] and Chevrier.[21] The determination of the vapor pressure of this compound was not possible above 90° because it decomposes into a more volatile constituent. In air and in water, thiophosphorylethoxydichloride shows no tendency to hydrolyze. Small amounts of the liquid have no vesicant action upon the hands. No corrosion was observed when the vapors were in contact with mercury and only slight corrosion was measured[22] when steel was kept in contact with the liquid for eighty-four hours at 0° (see Table I).

Thiophosphorylethoxychlorofluoride is a clear liquid with an odor similar to, but sharper than, thiophosphorylethoxydichloride. Upon exposure to air, dense grayish-white clouds of smoke appear which are attributed to oxidation rather than hydrolysis, inasmuch as no reaction was observed when the liquid was placed in water although it did react readily with a 0.5 *N* solution of sodium hydroxide. A similar reaction occurs to a greater extent when the difluoride is exposed to the atmosphere. The chlorofluoride in the gaseous state apparently does not attack mercury and its corrosion of steel, as would be expected, is less than that of the dichloride which is very slight as shown in Table I.

Thiophosphorylethoxydifluoride is a clear, highly refractive liquid, having an odor similar to that of the dichloride and chlorofluoride. Voluminous clouds of a grayish-white reaction product are liberated when the difluoride is allowed to mix with the atmosphere. As with the chlorofluoride,

the reaction is believed to be one of oxidation inasmuch as the liquid does not appear to react with water. The fumes have an odor similar to that of ozone. As with the other compounds, little or no reaction with mercury or steel was observed (see Table I).

As expected, the substitution of fluorine for chlorine increases the stability of the compounds in this series. In the determination of the vapor pressures it was observed that the dichloride decomposes around 90°, and the chlorofluoride around 100° whereas the difluoride was observed to be stable up to its normal boiling point, 78.4°.

Although the equations for the vapor pressure of the dichloride and chlorofluoride are reliable only up to around 100°, calculation of the boiling points of these compounds under 760 mm. pressure gives values of 157 and 120°, respectively. Once again the Swarts rule for regular lowering of the boiling point of a compound by substitution of a fluorine atom is valid. One fluorine atom lowers the boiling point from 157 to 120° (Δ = 37°) and the second fluorine substitution cause the boiling point to drop to 78.4° (Δ = 42°).

Acknowledgment.—This investigation was carried out under the sponsorship of the Naval Research Laboratory. We are deeply indebted to members of the staff of the Chemical Division for valuable suggestions and encouragement during its progress.

Summary

Thiophosphorylethoxydichloride was prepared from thiophosphoryltrichloride and ethanol, purified and certain of its physical and chemical properties observed. Upon fluorination, by means of the Swarts reaction with antimony pentachloride as catalyst, thiophosphorylethoxychlorofluoride and thiophosphorylethoxydifluoride were obtained. These new compounds were purified and some of their physical and chemical properties studied.

The properties determined for the above compounds include freezing point, vapor pressure, boiling point, heat of vaporization, Trouton constant, liquid density, solubilities, corrosion tests, and hydrolysis.

Polarographic Characteristics of +2 and +3 Vanadium. I. Polarography in Non-complexing Solutions[1]

BY JAMES J. LINGANE AND LOUIS MEITES[2]

Previous papers[3,4] from this Laboratory have discussed the polarography of the +2 and +3 states of vanadium in solutions of dilute acids and of oxalates. In these media the V(II)–V(III) couple is thermodynamically reversible at the dropping electrode. The investigation described in this and a following paper was undertaken to extend the information concerning solutions of these ions and of their complexes. The polarographic characteristics of +2 and +3 vanadium have been studied in a wide variety of media, including dilute acids and alkalies, phosphate, acetate, pyridine, and carbonate buffers, and solutions of the halides, thiocyanate, cyanide, thiosulfate, pyrophosphate, borate, benzoate, phthalate, salicylate, tartrate and citrate. This paper discusses only the cases in which no complex ions are formed. The experimental technique was essentially the same as that used in previous studies.[3,4]

Data and Discussion

We have found the half-wave potential for the reduction of vanadic to vanadous ion in 1 *N* sulfuric, hydrochloric, or perchloric acid to be -0.508 ± 0.002 v. *vs.* the saturated calomel electrode, which agrees very well with the standard potential of the couple reported by Jones and Colvin.[5] Zeltzer's determination of this constant[6] actually corresponds to the half-wave potential of +4 vanadium[3]; his solutions appear to have been quantitatively air-oxidized.

As the concentration of free acid is decreased, the wave becomes somewhat irreversible and shifts to more negative potentials. In 0.002 *N* acid the half-wave potential is −0.59 v. A second small wave at about −0.95 v. develops as the acid concentration is decreased. This wave is due to reduction of the hydrolysis product $V(OH)^{++}$, whose polarographic characteristics are discussed below.

We previously found the anodic half-wave potential of vanadous ion in 1 *N* sulfuric acid to be −0.50 v.,[3] and the corresponding (anodic) diffusion current constant to be -1.74 ± 0.01.[4] Since this constant is much larger than that found for vanadic ion, 1.41 ± 0.01, it follows that aquovanadous ion must be much smaller than aquovanadic ion. The half-wave potential of this anodic wave is not measurably affected by replacing the sulfuric acid with hydrochloric or perchloric acid.

Vanadic ion in 1 *N* acid solutions shows no anodic wave, nor is vanadous ion oxidized beyond the +3 state in these solutions.

Polarograms of +3 vanadium in unbuffered potassium chloride solutions consist of several very irreversible waves, whose total height decreases as hydrous vanadic oxide precipitates. Since several species are clearly involved, the over-all half-wave potentials are meaningless.

Polarograms of +3 vanadium in acetic acid–sodium acetate buffers (1 *M* total acetate) are presented in Fig. 1. These polarograms consist of two cathodic waves whose relative heights are a function of *p*H. Thus, at *p*H 4.1 the over-all diffusion current constant is 2.21 times that of the first wave alone, at *p*H 5.4 the ratio is 2.44, and at *p*H 6.3 it is 2.72. The individual diffusion current constants have been determined only in the buffer of *p*H 5.4, where they are, respectively, 0.57 ± 0.01 and 1.39 ± 0.01. The total diffusion current constant is so close to that found for a one-electron reduction of +3 vanadium in 1 *N* sulfuric acid that the reduction in these acetate media must proceed only to the +2 state and the doublet waves must be attributed to two different molecular species of +3 vanadium in sluggish equilibrium.

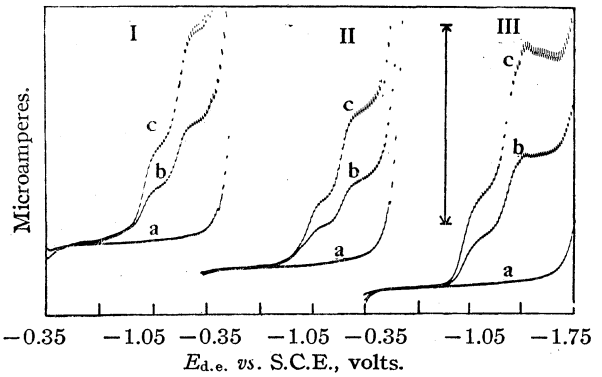

Fig. 1.—Polarograms of (a) 0, (b) 1.83, and (c) 3.44 millimolar +3 vanadium in acetic acid–sodium acetate buffers (1 *M* total acetate) of *p*H (I) 4.10, (II) 5.40, and (III) 6.30. The height of the arrow corresponds to six microamperes.

These species are most probably $V(OH)^{++}$ and VO^{+} formed by hydrolytic dissociation of the aquovanadic ion

$$V^{+++} + H_2O = V(OH)^{++} + H^{+} \quad (1)$$
$$V(OH)^{++} = VO^{+} + H^{+} \quad (2)$$

Since the relative height of the first wave decreases with increasing *p*H, this wave corresponds to reduction of $V(OH)^{+}$ and the second wave results from reduction of the more hydrolyzed species VO^{+}. It is not possible to compute the exact relative concentrations of the two species in the body of the solution from the relative wave heights. At potentials on the first wave the equilibrium in reaction 2 *tends* to shift to the left as $V(OH)^{++}$ is removed by the electrode reaction, and consequently the relative height of the first wave *tends* to be larger than corresponds to the true relative concentration of $V(OH)^{++}$ in the body of the solution. In an acetate buffer of *p*H 5.4 the ratio of the second to first wave heights is 1.44, from which we conclude that the $(VO^{+})/V(OH)^{+}$ ratio in the body of the solution is equal to or greater than 1.44. This is consistent with the data for the hydrolysis of vanadic ion given by Jones and Ray.[7]

The half-wave potential of the first wave in acetate buffers is −0.970 v. at *p*H 4.1, −0.978 v. at *p*H 5.4, and −1.008 v. at *p*H 6.3. Corresponding values for the second wave are, *seriatim*, −1.232, −1.245 and −1.300 v. Since both waves are somewhat irreversible, little thermodynamic significance can be attached to the magnitude of either rate of shift. However, the fact that a given *p*H change causes approximately twice as great a shift of the half-wave potential of the second wave as the first is in agreement with the expected relative effect of hydrogen ion if the electrode reactions are, respectively

$$V(OH)^{++} + H^{+} + e = V^{++} + H_2O \text{ and}$$
$$VO^{+} + 2H^{+} + e = V^{++} + H_2O$$

In an acetic acid–sodium acetate buffer of *p*H 5.4, +2 vanadium yields a double anodic wave as shown in Fig. 2. The first wave has a half-wave potential of −0.886 v. and a diffusion current constant of −1.090 ± 0.007. The half-wave potential of the second wave is −0.106 v. and its diffusion current constant is −3.36 ± 0.06. The

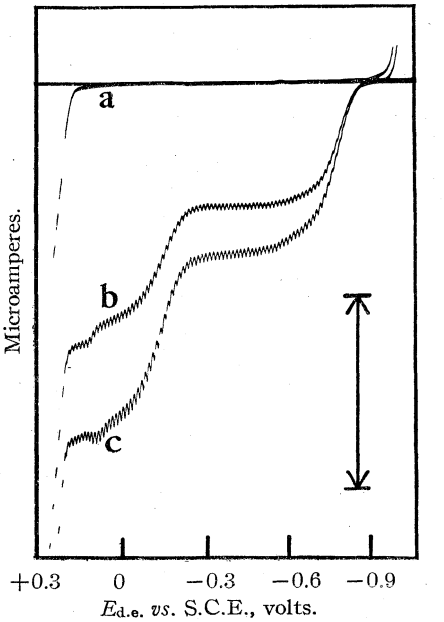

Fig. 2.—Polarograms of (a) 0, (b) 2.83, and (c) 3.96 millimolar +2 vanadium in an acetic acid–sodium acetate buffer (1 *M* total acetate) of *p*H 5.40. The height of the arrow corresponds to ten microamperes.

(7) G. Jones and W. A. Ray, THIS JOURNAL, **66**, 1571 (1944).

ratio of the diffusion current constants, 3.08, indicates that the waves are due to successive 1- and 3-electron oxidations of the +2 vanadium to the +3 and + 5 states. Plots of $-E_{d.e.}$ against log $(i/i_d - i)$ have slopes of −73 and −54 mv. (according to the common sign convention, this slope is negative for an anodic wave) instead of the −59.1 and −29.6 expected[4] for reversible −1 and −2 electron oxidations. Therefore neither stage of the oxidation proceeds strictly reversibly, and the $V^{+3} \rightarrow V^{+5}$ stage is less reversible than the $V^{+2} \rightarrow V^{+3}$ step.

Hydrous vanadic oxide is quantitatively precipitated on addition of solutions of +3 vanadium to a supporting electrolyte containing 1 *M* sodium hydroxide and 0.08 *M* sodium sulfite, and polarograms made immediately after the solutions are composited show no anodic or cathodic wave. However, even though the solutions are protected against air-oxidation by both hydrogen and sulfite, a double anodic wave at about −0.46 and −0.38 v. soon develops and rapidly increases in height as the solution ages. We have succeeded in keeping solutions of very powerful reducing agents (*e. g.*, vanadous oxalate[4]) for hours without measurable air-oxidation, and hence it appears that alkaline suspensions of vanadic hydroxide are actually thermodynamically metastable. Since +5 vanadium gives no anodic wave whatever, and +4 vanadium in this medium gives only a single anodic wave at −0.432 v.,[3,8] the reaction which takes place probably produces two hypovanadite ions at approximately equal concentrations and in slow equilibrium with each other.

Curves I in Fig. 3 are polarograms of +3 vanadium in weakly acid (*p*H about 3) 1 *M* potassium fluoride. No wave due to reduction of the vanadium is observed; the wave which appears in the residual current curve is probably due to an impurity in the potassium fluoride used. A colorless precipitate, possibly of $K_2VF_5 \cdot H_2O$,[9] is formed in these mixtures. This is the most insoluble salt of + 3 vanadium encountered in the whole of the present work.

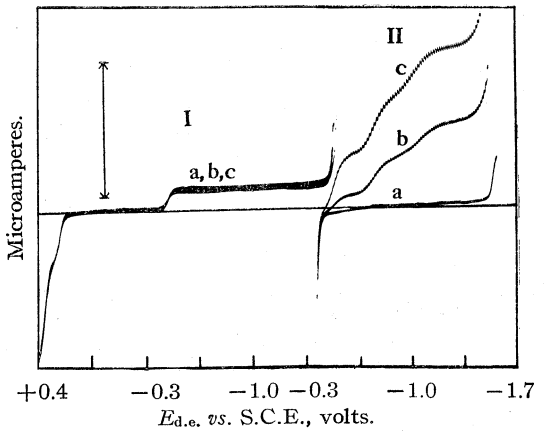

Fig. 3.—Polarograms of (a) 0, (b) 1.83, and (c) 3.44 millimolar +3 vanadium in (I) 1 *M* potassium fluoride and (II) 1 *M* potassium iodide. The height of the arrow corresponds to ten microamperes.

Solutions of +2 vanadium in the same medium (Curves I, Fig. 4) give three approximately equal anodic waves, with half-wave potentials of −0.701, −0.15, and +0.21 v. The first wave, which has a diffusion current constant of −1.96 ± 0.01, corresponds to oxidation to the +3 state. The other waves, which are too ill-defined for accurate measurement, must therefore represent oxidation to the +4 and +5 states. The vanadous–vanadic fluoride couple in this medium is very irreversible: the slope of the plot of $-E_{d.e.}$ against log $(i/i_d - i)$ is −166 mv., instead of the −59.1 mv. expected[4] for a reversible one-electron oxidation.

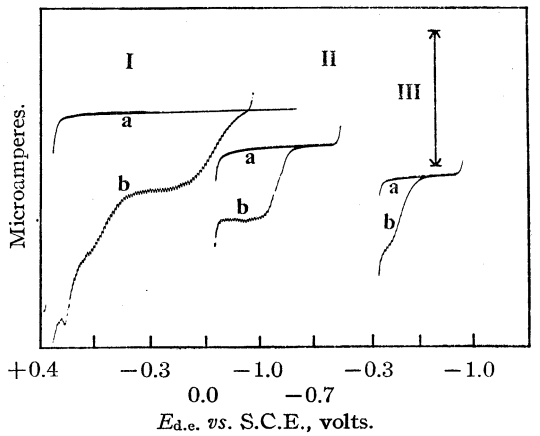

Fig. 4.—Polarograms of (I) (a) 0 and (b) 2.03 millimolar +2 vanadium in 1 *M* potassium fluoride, (II) (a) 0 and (b) 1.55 millimolar +2 vanadium in 1 *M* potassium bromide, and (III) (a) 0 and (b) 1.47 millimolar +2 vanadium in 1 *M* potassium iodide. The height of the arrow corresponds to ten microamperes.

In a 1 *M* potassium bromide solution (Curves II, Fig. 4), +2 vanadium gives a single well-defined anodic wave whose half-wave potential is −0.495 v. The magnitude of the corresponding diffusion current constant, −2.03 ± 0.03, indicates that the oxidation proceeds only to the +3 state. Plots of $-E_{d.e.}$ against log $(i/i_d - i)$ have slopes of −74 mv., and this small irreversibility appears to be the cause of the deviation from the reversible half-wave potential of the vanadous–vanadic couple.

Solutions of +3 vanadium in 1 *M* potassium bromide give a double cathodic wave (Fig. 5) with half-wave potentials at −0.43 and −0.87 v. Both waves are well-defined, but the ratio of their diffusion current constants varies with the *p*H: at *p*H 6 the diffusion current constant for the total second wave is 3.3 times that of the first wave alone, at *p*H 4.7 the ratio is 1.75, and at *p*H 4 it is 1.46. Below *p*H 4 the over-all diffusion current

(8) J. J. Lingane and L. Meites, *Anal. Chem.*, **19**, 159 (1947).

(9) E. Petersen, *J. prakt. Chem.*, [2] **40**, 48 (1889).

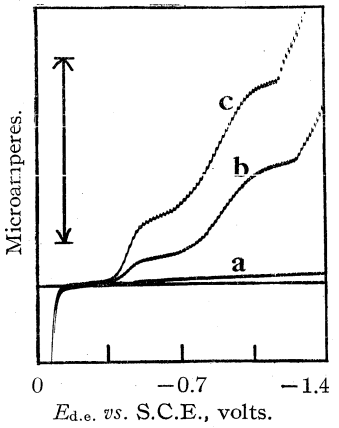

Fig. 5.—Polarograms of (a) 0, (b) 1.83, and (c) 3.44 millimolar +3 vanadium in 1 *M* potassium bromide, *p*H 2.5. The height of the arrow corresponds to ten microamperes.

constant is 1.940 ± 0.009, while that of the first wave alone is 1.419 ± 0.005, and the ratio is 1.37 ± 0.01. Since the over-all constant is close to that which corresponds to a one-electron oxidation of +2 vanadium in the same medium, it follows that the reduction of +3 vanadium must also involve only one electron, and consequently that the waves are due to the reduction of two species in sluggish equilibrium. Since both waves are irreversible (the slopes of plots of $E_{d.e.}$ against log $(i/i_d - i)$ are 74 and 170 mv., respectively), polarographic identifications of these species are impossible.

Only one ill-defined anodic wave is observed with solutions of +2 vanadium in 1 *M* potassium iodide (Curves III, Fig. 4). This wave has a half-wave potential of −0.49 v. and a diffusion current constant of −2.275 ± 0.03; it represents oxidation to the +3 state.

Solutions of +3 vanadium in 1 *M* potassium iodide show a triple cathodic wave (Curves II, Fig. 3) at a *p*H of about 2.5. The half-wave potentials of these waves are −0.46, −0.71 and −0.98 v. At *p*H values between 2 and 3 the total diffusion current constants of the second and third waves are 0.792 ± 0.003 and 2.75 ± 0.02, and the fact that the latter figure is fairly close to the value found for a one-electron oxidation of +2 vanadium leads to the conclusion that the sum of all three waves represents reduction only to the +2 state.

Table I contains data on the variation of the half-wave potentials of +3 vanadium with *p*H and potassium iodide concentration. These data were assembled from polarograms of which Fig. 6 is representative.

The half-wave potentials of the two waves given by +3 vanadium in an iodide-free acetate buffer of *p*H 5.0, calculated by interpolation in the data quoted previously, are −0.98 and −1.24 v. These figures are in good agreement with those observed in the presence of 1 *M* iodide; the small

differences are probably not significant. Therefore, according to our earlier interpretation of this same double wave, the wave at −1.0 v. must be due to reduction of $V(OH)^{++}$ and the wave at −1.2 v. to the reduction of VO^+. As would be predicted from this, the relative height of the first wave decreases with increasing *p*H and increasing hydrolysis, and the effect of *p*H on the half-wave potential of the second wave is about twice as great as on that of the first wave. Then the second wave at *p*H 1.8 must also be due to reduction of $V(OH)^{++}$, while the first, since it is at the same potential as the wave given by +3 vanadium in 1 *N* acid solutions, must be due to reduction of the simple vanadic ion. The wave at −0.71 v., which appears only when the *p*H is close to 2.5, is difficult to explain. It may be due either to a hydroxy-iodo complex of vanadic ion or to a compound such as $HV(SO_4)_2$,[10] but there is no definite evidence to confirm either supposition.

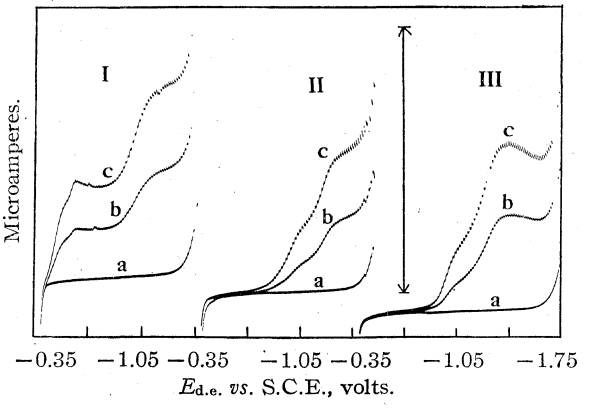

Fig. 6.—Polarograms of (a) 0, (b) 1.83, and (c) 3.44 millimolar +3 vanadium in 1 *M* potassium iodide, *p*H (I) 1.8 (0.02 *N* sulfuric acid), (II) 4.0, and (III) 5.5. The solutions of (II) and (III) contained acetic acid–sodium acetate buffers (1 *M* total acetate). The height of the arrow corresponds to twenty microamperes.

Summary

1. Acidic solutions of +3 vanadium are shown to contain, in addition to simple vanadic ion,

(10) H. T. S. Britton and G. Welford, *J. Chem. Soc.*, 761 (1940).

V^{+++}, its hydrolysis products $V(OH)^{++}$ and VO^{+}.

2. Data are presented on the ionic states and polarographic characteristics of +2 and +3 vanadium in solutions of dilute acids and alkalies, acetate buffers, and of the various halide ions.

CAMBRIDGE, MASS. RECEIVED JANUARY 23, 1948

Free Radical-initiated Reaction of Ethylene with Carbon Tetrachloride

BY R. M. JOYCE, W. E. HANFORD[1] AND J. HARMON

This paper describes the free radical-initiated polymerization of ethylene in the presence of the chain transfer agent, carbon tetrachloride. Because of the simplicity of the products formed from ethylene as a polymerizing monomer, and because carbon tetrachloride is a very efficient chain transfer agent for ethylene, it has been possible to isolate and establish the structures of the products of this chain transfer polymerization reaction. In addition, a qualitative study of the variation of chain length of the products with reaction conditions has been made.

The presence of chlorine in polystyrene prepared in carbon tetrachloride has been observed by several investigators,[2] and Price[3] has advanced the hypothesis that these polymers contained Cl and CCl_3 end-groups. Kharasch[4] has reported the addition of carbon tetrachloride to octene-1 to produce 1,1,1,3-tetrachlorononane, initiated by free radicals from diacyl peroxides. More recently, Kharasch[5] has described the addition of carbon tetrachloride to ethylene at low pressures to obtain a compound believed to be 1,1,1,3-tetrachloropropane. Evidence presented in this paper establishes that this structure is correct.

We have investigated the benzoyl peroxide-initiated reaction of ethylene with carbon tetrachloride over the pressure range 50–15000 lb./sq. in., and have shown that the reaction gives a series of compounds of the formula $Cl(CH_2CH_2)_nCCl_3$. When this reaction is carried out at an ethylene pressure of 1500 lb./sq. in., the major portion of the product comprises the first four members of this series. These compounds have been separated by fractional distillation, and their properties are given in Table I.

TABLE I

PROPERTIES OF $Cl(CH_2CH_2)_nCCl_3$

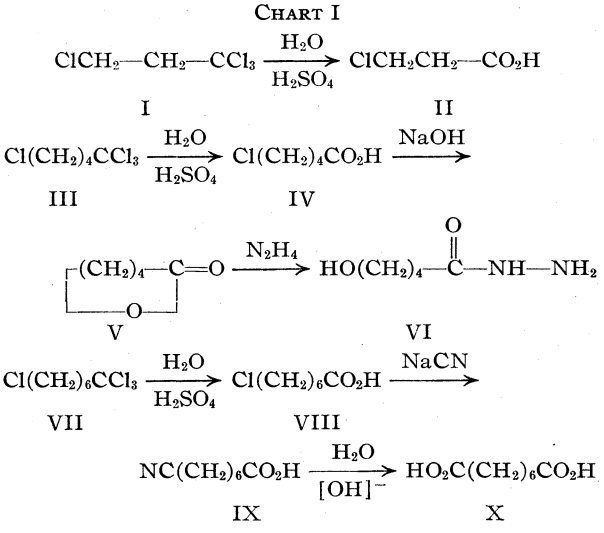
[a] Kharasch[5] reported b. p. 155°, $n^{20}D$ 1.4825.

The structures of the first three compounds were established by the reactions shown in Chart I, beginning with the hydrolysis of the CCl_3 group to a carboxylic acid with sulfuric acid and water.[6]

CHART I



Under these conditions the tetrachloropropane (I) gave β-chloropropionic acid (II) melting at 40–42°. The tetrachloropentane (III) gave 5-chlorovaleric acid (IV). This was readily converted to δ-valerolactone (V), b. p. 124° (30 mm.), by treatment with aqueous or alcoholic alkali. Reaction of the lactone with hydrazine gave the known hydrazide of 5-hydroxyvaleric acid (VI) melting at 105–107°. The tetrachloroheptane (VII) gave 7-chloroheptanoic acid (VIII). The structure of this acid was proved by reaction with sodium cyanide followed by hydrolysis to suberic acid (X). Similar hydrolysis of the tetrachlorononane gave a chlorononanoic acid which is believed to be the 9-chloro compound. The properties of these chloro acids are shown in Table II.

The reaction of ethylene with carbon tetrachloride has been run at pressures ranging from 50 to 15000 lb./sq. in. The reaction rate increases

markedly with pressure and, unless careful control is maintained, particularly with respect to dissipation of the heat of reaction, violently explosive reactions may occur.[7]

In this connection it is important to provide efficient agitation. The use of a diluent is desirable if the reaction is to be carried out on a scale greater than 500–1000 ml. reactor volume, except at pressures below about 150 lb./sq. in. A diluent is definitely advisable on any scale when the reaction is run above about 1000 lb./sq. in. The most effective diluent for moderating the reaction is water, presumably because of its inertness under reaction conditions and its high specific heat. We have carried out the reaction with a charge comprising 100 g. each of water and carbon tetrachloride and 0.23 g. of benzoyl peroxide in a 400-ml. reactor at 12000 lb./sq. in. It should not be inferred, however, that these conditions are necessarily safe, particularly if the agitation is inefficient. An explosion is a definite possibility should this reaction be attempted on a larger scale, or with a higher ratio of benzoyl peroxide to carbon tetrachloride.

When benzoyl peroxide is employed as initiator, the reaction proceeds smoothly in the temperature range 90–120°. A small amount of benzoyl peroxide suffices to initiate the reaction and it has been our practice not to employ more than 0.003 molecular equivalent of this peroxide based on carbon tetrachloride. As little as 0.0007 molecular equivalent has been used successfully. Within these ranges of benzoyl peroxide concentration, and employing a charge comprising 210 g. of carbon tetrachloride and 35 g. of water at 1400 lb./sq. in. ethylene pressure, we have obtained yields of 300–370 g. of reaction product per gram of benzoyl peroxide. The yields are somewhat lower at lower pressures. The exclusion of oxygen from the reaction mixture is desirable.

The proportions of the individual tetrachloroalkanes in the reaction product depend on the concentration of ethylene relative to that of carbon tetrachloride. This concentration can be changed by varying the ethylene pressure. Moreover, at a given pressure, dilution of the carbon tetrachloride with a solvent for ethylene which is relatively inert as a chain transfer agent, such as an aliphatic hydrocarbon, also serves to increase the concentration of ethylene relative to carbon tetrachloride. The variations in chain length of the products formed under various reaction conditions are shown in Table III.

TABLE III

VARIATION IN CHAIN LENGTH OF $Cl(CH_2CH_2)_nCCl_3$ WITH REACTION CONDITIONS

Ethylene pressure, lb./sq. in.	$Cl(CH_2CH_2)_nCCl_3$ Wt. per cent. of total product $n = 1$	$n = 2$	$n = 3$	$n = 4$	$n > 5$
50	77	23	..	..	..
80– 150	62.6	32.0	5.4	..	..
1200–1400	9.5	59.4	22.6	6.5	2.0
1500–1700	3.7	46.7	28.1	13.1	8.4
4000	1.0	24.1	24.5	21.8	28.6
1200–1400[a]	5.7	46.4	28.1	15.3	4.5
1200–1400[b]	1.8	24.0	25.9	21.7	26.6

[a] Organic phase comprised 96 g. of carbon tetrachloride and 59.5 g. of 2,2,4-trimethylpentane. [b] Organic phase comprised 54 g. of carbon tetrachloride and 87.5 g. of 2,2,4-trimethylpentane.

The concept of chain transfer in a free radical polymerization was first proposed by Flory.[8] The following mechanism, by which the tetrachloroalkanes are believed to be formed from ethylene and carbon tetrachloride, has been proposed by others[3,5] for this type of reaction. The establishment of the structures of these tetrachloroalkanes and our failure to isolate compounds of other structures from this reaction support this mechanism.

$$R\cdot + CCl_4 \longrightarrow RCl + \cdot CCl_3 \quad (1)$$

$$\cdot CCl_3 + C_2H_4 \longrightarrow Cl_3CCH_2CH_2\cdot \quad (2)$$

$$Cl_3CCH_2CH_2\cdot + nC_2H_4 \longrightarrow Cl_3C(CH_2CH_2)\cdot_{n+1} \quad (3)$$

$$Cl_3C(CH_2CH_2)\cdot_{n+1} + CCl_4 \longrightarrow Cl_3C(CH_2CH_2)_{n+1}Cl + \cdot CCl_3 \quad (4)$$

$$2\cdot CCl_3 \longrightarrow Cl_3CCCl_3 \quad (5)$$

The initiating radical R· is derived from benzoyl peroxide. It would be expected to be the phenyl radical, since the decomposition of benzoyl peroxide in carbon tetrachloride has been shown to produce chlorobenzene in considerable quantity.[9] However, chlorobenzene has not been isolated as a by-product in this reaction, benzoic acid being the only aromatic compound obtained.

Definite evidence that the $\cdot CCl_3$ radical propagates the chain cycle is provided by the isolation of hexachloroethane from the reaction mixture. During the fractional distillation of the product from a run involving 5.5 kg. of carbon tetrachloride, several grams of hexachloroethane distilled between the C_3 and C_5 cuts.

The above mechanism appears to be the only one operating in this reaction. Careful fractional distillation of the products has failed to reveal the presence of any other types of compounds, such as $Cl(CH_2CH_2)_nCl$ or $Cl_3C(CH_2CH_2)_nCCl_3$. The formation of the former type would require a mechanism in which an initiating free radical reacted with carbon tetrachloride as follows

$$R\cdot + CCl_4 \longrightarrow RCCl_3 + \cdot Cl \quad (6)$$

This type of free radical reaction is much less probable than reaction 1.[10] Compounds of the type

(8) Flory, THIS JOURNAL, **59**, 241 (1937).

(10) Waters, "Chemistry of Free Radicals," Clarendon Press, Oxford, 1946, p. 130.

$Cl_3C(CH_2CH_2)_nCCl_3$ could be formed by a chain termination reaction involving the combination of two growing radicals such as those produced in equations (2) and (3). However, the termination reaction (4) evidently predominates so that these compounds are not formed to any significant extent.

Experimental

Small-Scale Reaction of Ethylene with Carbon Tetrachloride.—A stainless steel-lined tubular pressure reactor having an internal volume of about 350 ml. and equipped with a thermocouple well and gas inlet was charged with 210 g. (1.36 moles) of freshly distilled carbon tetrachloride, 35 g. of water, and 0.47 g. (0.00194 mole) of benzoyl peroxide ("Lucidol"). The reactor was evacuated, pressured to 500 lb./sq. in. with ethylene, and placed horizontally in a shaking box equipped with a heater. When the temperature of the reaction mixture had been raised to 70°, the pressure was increased to 1400 lb./sq. in. by injection of ethylene, and the heating was continued. The reaction mixture was maintained at 95°, and the pressure in the range 1200–1400 lb./sq. in. by injection of additional ethylene as required, for five hours. The reaction product was then removed from the cooled reactor, separated from the water, and dried over anhydrous magnesium sulfate. After removal of the unreacted carbon tetrachloride by distillation, a preliminary fractional distillation gave the following results

Cut	B. p., °C.	Mm.	Weight, g.	Weight per cent.
C_3	<90	12	11.7	7.2
C_5	90–115	11	97.0	59.7
C_7	115–145	11	36.0	22.2
C_9	145–175	11	12.5	7.7
$>C_9$	Residue		5.0	3.2

The pure compounds can be obtained from these cuts by redistillation (*cf.* Table I).

Large-Scale Reaction of Ethylene with Carbon Tetrachloride.—A horizontal stainless steel autoclave having a capacity of 12.5 l., equipped with a horizontal agitator, a thermocouple well, gas inlet, and rupture disc assembly, was charged with 4420 g. of carbon tetrachloride (28.7 moles), 4420 g. of water, and 10 g. (0.0414 mole) of benzoyl peroxide. The reactor was purged twice by pressuring with ethylene to 300 lb./sq. in. and venting. The reactor was then pressured to 510 lb./sq. in. with ethylene and heated with stirring. When the temperature reached 85° the pressure was increased to 1500 lb./sq. in. by injection of additional ethylene from a storage vessel. A rapid reaction set in when the temperature reached 95° and the temperature rose to 139° in about five minutes, the pressure remaining constant at 1600 lb./sq. in. during this period. The reactor was cooled slowly to 100°, maintaining the pressure in the range 1500–1700 lb./sq. in. by injection of additional ethylene as required. The lack of further pressure drop when the temperature was maintained at 100° indicated that the reaction had ceased and the mixture was cooled and discharged.

The water was separated from the organic phase and the latter was washed with 10% sodium carbonate solution and twice with water. It was then dried over anhydrous magnesium sulfate. The carbon tetrachloride was removed from the product in a stripping still and careful fractional distillation of the residue gave the following results:

Cut	Weight, g.[a]	Weight % of total	Molecular equivalents of carbon tetrachloride
C_3	126	3.7	0.69
C_5	1580	46.6	7.53
C_7	951	28.1	4.00
C_9	444	13.1	1.67
$>C_9$	285	8.5	0.95[b]
Total	3386	100.0	14.84

[a] These figures do not include small amounts of intermediate cuts and a few grams of hexachloroethane distilling between the C_3 and C_5 cuts. [b] Analysis of the residue indicated the composition $Cl(CH_2)_{10.5}CCl_3$.

Of the carbon tetrachloride charged, 1565 g. was recovered, leaving 2855 g., 18.54 moles, to account for. The yield of isolated compounds based on carbon tetrachloride was (14.84/18.54) × 100 = 80.0 per cent.

Structure of 1,1,1,3-Tetrachloropropane.—A mixture of 25 g. of 1,1,1,3-tetrachloropropane, 100 g. of 96% sulfuric acid, and 1 g. of water was stirred vigorously while heating on a steam-bath for one and one-half hours. At the end of this time, the evolution of hydrogen chloride had ceased and a dark, homogeneous solution resulted. The solution was cooled, poured onto 300 g. of ice, and extracted continuously with ether overnight. The ether solution was dried over magnesium sulfate, filtered, and distilled to obtain 9 g. (55% of the theoretical) of *beta*-chloropropionic acid boiling at 110° (20 mm.) and melting at 40–42°.

Structure of 1,1,1,5-Tetrachloropentane.—A mixture of 1260 g. of 1,1,1,5-tetrachloropentane and 1500 g. of 96% sulfuric acid was stirred vigorously and heated to 90–95° on a steam-bath. A vigorous evolution of hydrogen chloride set in. A solution of 180 g. of water and 330 g. of concentrated sulfuric acid was then added under the surface of the reaction mixture over a period of one hour. After maintaining the heating and stirring for an additional hour, the reaction mixture was cooled and poured onto 2500 g. of cracked ice. The crude separated acid was extracted with three 500-cc. portions of carbon tetrachloride. The combined carbon tetrachloride solutions were washed well with water and the carbon tetrachloride was then removed in a stripping still. The resulting product was purified by distillation through a precision still, and there was obtained 639 g. (78% of theoretical) of 5-chlorovaleric acid boiling at 128–131° (11 mm.).

A solution of sodium hydroxide in methanol (406 ml., 2.0 *N*) was placed in a 1-liter 3-necked flask equipped with a stirrer, thermometer and dropping funnel. The solution was cooled to 10–15° and a solution of 111 g. of 5-chlorovaleric acid in 150 ml. of methanol was added, maintaining the temperature below 15°. The resulting solution was made neutral to phenolphthalein by adding methanolic sodium hydroxide solution, and was refluxed with stirring for two hours. It was then cooled and filtered. The methanol was removed from the filtrate in a stripping still and the residue distilled through a precision column, yielding 63 g. (77.5% of the theoretical) of δ-valerolactone boiling at 92° (8 mm.), $n^{26}D$ 1.4550.

One-half gram of the lactone was heated on a steam-bath with 2 ml. of 85% aqueous hydrazine for one hour and then evaporated under reduced pressure. The resulting hydrazide of 5-hydroxyvaleric acid solidified and was recrystallized from ethanol, melting point 105–107°.

Structure of 1,1,1,7-Tetrachloroheptane.—One gram of 1,1,1,7-tetrachloroheptane was stirred vigorously with 10 ml. of concentrated sulfuric acid on a steam-bath for one and one-half hours. The mixture was cooled, poured on ice, extracted with ether, and the ether solution dried over magnesium sulfate. Half of the solution was evaporated, the residue neutralized with sodium hydroxide and treated with *p*-phenylphenacyl bromide. There was obtained the *p*-phenylphenacyl ester of 7-chloroheptanoic acid, melting at 73–75°.

Anal. Calcd. for $C_{20}H_{23}O_2Cl$: Cl, 10.72. Found: Cl, 10.83.

The second portion of the ether solution was evaporated and the residue neutralized with *N*/3 sodium hydroxide. Two-tenths gram of sodium cyanide was added to the solution and the mixture was refluxed for five hours. One and one-half grams of potassium hydroxide was then

added and the solution refluxed for six hours; ammonia was evolved during this operation. The resulting solution was cooled and acidified to congo red with hydrochloric acid. The precipitated suberic acid was collected on a filter and recrystallized from water, m. p. 138–140°; neut. eq., 86.4. There was no depression of the melting point when mixed with an authentic sample of suberic acid.

Hydrolysis of 1,1,1,9-Tetrachlorononane.—A mixture of 500 g. of concentrated sulfuric acid and 15 g. of water was heated to 95° with stirring on a steam-bath, and 133 g. (0.5 mole) of 1,1,1,9-tetrachlorononane was dropped in over a period of one hour. Stirring and heating were continued for three hours. The solution was then cooled, poured on 1200 g. of cracked ice, and extracted with two 100-ml. portions of carbon tetrachloride. The extract was dried over magnesium sulfate and distilled to obtain 55 g. (57% of the theoretical) of a chloro acid, presumably 9-chlorononanoic acid, boiling at 163.5–167° (7.5 mm.); $n^{36}D$ 1.4540; calcd. for $C_9H_{17}O_2Cl$: neut. eq., 192.5; found: neut. eq., 192.8.

Summary

The benzoyl peroxide-initiated reaction of ethylene with carbon tetrachloride gives a series of compounds having the general formula $Cl(CH_2CH_2)_nCCl_3$. When the reaction is carried out at 1500 lb./sq. in. the product is comprised principally of these compounds in which n has the values 1–4. The effect of reaction conditions on the proportions of individual members of this series in the reaction product is described.

I. The Peroxide-Catalyzed Chlorination of Trimethylchlorosilane and *t*-Butyl Chloride[1]

By J. J. McBride, Jr., and H. C. Beachell

Trimethylchlorosilane has been chlorinated directly by Krieble and Elliot, a mixture of chlorination products being obtained.[2] Chlorination by sulfuryl chloride in the presence of benzoyl peroxide has been applied to various aliphatic hydrocarbons[3] and to certain organosilicon compounds.[4,5] This method of chlorination, however, has not been applied to trimethylchlorosilane, nor to its carbon analog, *t*-butyl chloride, previous to this work. The results are of interest in furnishing further information on the deactivation effect of the $-SiCl$ group on an alpha methyl group. (Sommer and Whitmore report that, like methylchloroform, methyltrichlorosilane cannot be chlorinated in this way.[4]) The chlorination of *t*-butyl chloride by the same method affords a means of comparing the relative effect of a silicon atom and a carbon atom in this reaction

Trimethylchlorosilane.—Refluxing an equimolar mixture of trimethylchlorosilane and sulfuryl chloride in the presence of benzoyl peroxide for several hours gave no detectable amount of chlorination product. When the experiment was repeated, however, using chlorobenzene as an inert diluent to increase the reflux temperature, a 38% yield of chloromethyldimethylchlorosilane was obtained after four hours. The yield of product was increased to 52% by adding the sulfuryl chloride dropwise to the refluxing mixture of trimethylchlorosilane and chlorobenzene. Density and refractive index have been determined for chloromethyldimethylchlorosilane. These are new physical constants for this compound.

In the majority of cases of fractionation of the reaction mixture, it was found that when almost all the chloromethyldimethylchlorosilane had been distilled off and there was a high concentration of higher boiling material left, *i. e.*, chlorobenzene and residue, the temperature dropped abruptly from 116° to about 71° where equilibrium was attained. The boiling point of dimethyldichlorosilane is given as 70°.[6] The identity of the material was established by determination of density, which is given in the literature[6] and by analysis for hydrolyzable chlorine. The presence of dimethyldichlorosilane may be due to disproportionation of chloromethyldimethylchlorosilane at a temperature above its boiling point or to the pyrolysis of unidentified polymeric by-products. No evidence for the presence of higher chlorinated products has been found, and other experimental evidence indicates that the reaction is limited to the introduction of a single chlorine under the conditions of the experiments.

The molar refraction for chloromethyldimethylchlorosilane was calculated by the Lorentz and Lorenz formula using the values obtained for density and refractive index. A value of 34.41 was obtained. This is in excellent agreement with the value of 34.70 obtained by addition of the atomic refraction equivalents. (The value used for silicon is that given by Whitmore for silicon in trimethylchlorosilane.[7])

***t*-Butyl Chloride.**—The chlorination of *t*-butyl chloride was carried out under the same conditions as that of trimethylchlorosilane. When an

equimolar mixture of *t*-butyl chloride and sulfuryl chloride in the presence of benzoyl peroxide was refluxed with chlorobenzene, a 46% yield of 1,2-dichloro-2-methylpropane (b. p. 107–108°) was obtained after three hours. When the sulfuryl chloride was added dropwise to the refluxing mixture, a 59% yield of the chlorination product was obtained after three and one-quarter hours.

Experimental

Trimethylchlorosilane.—The trimethylchlorosilane used in this work was purchased from the Dow–Corning Corporation and redistilled, taking the fraction boiling at 57–58° at 760 mm. The boiling point is given as 57.6°.[5]

Chloromethyldimethylchlorosilane.—(a) 100 g. (0.92 mole) of trimethylchlorosilane, 124.2 g. (0.92 mole) of sulfuryl chloride, 0.5 g. of benzoyl peroxide and 200 ml. (220 g.) of chlorobenzene were placed in a 500-ml. round-bottomed flask fitted with a 30-inch reflux condenser surmounted with a cold finger, the inside dimensions of which were 3.5 × 25 cm. This was filled with a salt–ice mixture. Ground glass joints were used throughout. The evolved gases were passed through a drying tube of indicating Drierite into two 1-liter Florence flasks, the first a trap, and the second containing water so that the flow of gas could be observed. The flask was heated with a Glas-Col mantle. The mixture was refluxed vigorously. Gas was evolved at a fairly rapid rate and a gentle reflux was maintained from the cold finger. After three hours the evolution of gas had nearly stopped. The reaction mixture was fractionated in a Whitmore–Fenske total condensation, partial take-off column of about twenty theoretical plates. Twenty-eight grams of unreacted trimethylchlorosilane was recovered and 36 g. of chloromethyldimethylchlorosilane (b. p. 115–117°) obtained before the temperature dropped to 70°. Four grams was obtained between 70 and 131°. Two hundred and seventeen grams of chlorobenzene was recovered and 34 g. of a dark viscous liquid remained in the still pot. The yield based on unrecovered starting material was 38%.

(b) A 500-ml. 3-necked flask was fitted with a 250-ml. dropping funnel, a mercury-sealed stirrer and the reflux system described above. Fifty-four grams (0.5 mole) of trimethylchlorosilane, 0.5 g. of benzoyl peroxide and 108 ml. (119 g.) of chlorobenzene were placed in the reaction flask. The flask was heated as before. When the mixture was refluxing vigorously, sulfuryl chloride was added slowly with stirring over a period of four hours. The mixture was refluxed for two hours more until gas was no longer evolved. Fractionation of the product gave 22 g. of unreacted trimethylchlorosilane, 22 g. of chloromethyldimethylchlorosilane and 107 g. of chlorobenzene. Seventeen grams of tarry residue remained. The yield in this case was 52%.

(c) The chloromethyldimethylchlorosilane obtained in these experiments was redistilled and the middle cut, b. p. 115.2–116° at 762 mm. taken for analysis and determination of physical constants; $n^{20}D$ 1.4360; d^{20}_4 1.0865; M_D calcd. 34.70; M_D obs. 34.41. *Anal.* Calcd. for $(CH_3)_2Si(Cl)CH_2Cl$: hydrolyzable Cl, 24.79. Found: Cl, 24.42.

Dimethyldichlorosilane.—A 2.5-g. 71–73° fraction collected in one of the distillations was examined. The following constants were found: d^{20}_4 1.0637; $n^{28}D$ 1.4002; M_D calcd. 29.42; M_D obs. 30.09. Rochow gives the density as 1.062 at 20°.[6]

1,2-Dichloro-2-methyl-propane.—Fifty grams (0.39 mole) of *t*-butyl chloride (b. p. 51.0–51.5°), 53.1 g. (0.39 mole) of sulfuryl chloride, 0.5 g. of benzoyl peroxide, and 100 ml. (110 g.) of chlorobenzene were refluxed as in (a). Reaction was practically complete in three hours. The product was fractionated in a Whitmore–Fenske column of about twenty theoretical plates. There was obtained 10.3 g. of unreacted *t*-butyl chloride, 25.2 g. of 1,2-dichloro-2-methylpropane (b. p. 107.1–108.0°, $n^{28}D$ 1.4316), 101 g. of chlorobenzene and 13 g. of dark, oily residue. This is a yield of 46.3%.

The reaction was repeated as in (b) using 100 g. (0.79 mole) of *t*-butyl chloride, 106.2 g. (0.79 mole) of sulfuryl chloride, 0.5 g. of benzoyl peroxide and 200 ml. (220 g.) of chlorobenzene. Evolution of gas was rapid from the start. Reaction was complete in three hours. Fractionation of the product gave 28.5 g. of unreacted *t*-butyl chloride and 58.5 g. of 1,2-dichloro-2-methylpropane, b. p. 107–108°, $n^{25}D$ 1.4323. This is a yield of 59%.

Discussion

It appears that *t*-butyl chloride is chlorinated more readily by sulfuryl chloride than is trimethylchlorosilane. This is in accord with the action of the silicon atom as an electron sink.[8]

The deactivating effect on an α-methyl group of a chlorine attached to carbon is evident since the yields of monochlorinated product from *t*-butyl chloride are not nearly so high as those obtained with other types of hydrocarbons and chlorinated hydrocarbons.[3,9]

Summary

Trimethylchlorosilane has been chlorinated by the use of sulfuryl chloride and benzoyl peroxide in the presence of chlorobenzene (as an inert diluent to increase the reaction temperature), to give chloromethyldimethylchlorosilane.

Two new physical constants, density and refractive index, have been determined for chloromethyldimethylchlorosilane. These are: d^{20}_4 1.0865; $n^{20}D$ 1.4360.

t-Butyl chloride has been chlorinated under the same conditions to give 1,2-dichloro-2-methylpropane.

Further Studies of the Action of Pancreatic Amylase: Extent of Hydrolysis of Starch[1]

BY ROSLYN B. ALFIN[2] AND M. L. CALDWELL

Although pancreatic amylase has been known and studied for many years, remarkably little quantitative information is available concerning its action. A survey of the literature shows contradictory statements about the extent of the hydrolysis of starches by this amylase[3-10] and uncertainty about the products formed or the order of their appearance.[3,4,10-16]

The present report is a summary of part of a detailed study of the action of highly purified pancreatic amylase[17] carried out under conditions which have been found to favor its activity and to protect it from inactivation.[18] Information of this kind is important to a better understanding both of the amylase and of the chemical nature of starch.

Experimental

Preparations of highly purified pancreatic amylase were obtained from pancreatin[19] by a modification of the method of Sherman, Caldwell and Adams.[17] They showed no evidence of maltase activity in the concentrations used in this work.

The hydrolyses of starch were carried out at 40° and the reaction mixtures were adjusted to *p*H 7.2 in the presence of 0.01 *M* phosphate (sodium) and 0.02 *M* chloride (sodium), conditions which had been shown to protect this amylase from inactivation and to favor its activity.[16] The amylase preparations, also, were dissolved in 0.01 *M* phosphate, 0.02 *M* chloride at *p*H 7.2 at 0° and used as promptly as possible.[18]

The substrates included whole potato starch, a straight chain component of corn starch[20] and Lintner's soluble potato starch. The latter was included for comparative purposes as it has been the most widely used substrate for the laboratory study of amylase action. The starches were washed repeatedly with distilled and with redistilled water and air dried.

In experiments designed to study the extent of the hydrolysis of starch, concentrations of the amylase were chosen so that the reactions would proceed rapidly and be practically complete before contamination by yeasts and bacteria might be expected appreciably to influence the results. Phemerol[23] and toluene were added to hydrolysis mixtures which were allowed to react for more than five hours. Neither of these reagents was found to influence the activity of the amylase nor the reducing values of the reaction mixtures in the concentrations used.

The reducing values of the reaction mixtures were converted to their equivalents of maltose and usually are given in terms of the percentage yield of the maltose which could be obtained theoretically from the substrate. Usually, the reducing values were determined by iodometric titration[24] although a ferricyanide ceric sulfate method[25] also was used.

Results

Extent of Hydrolysis of Starch.—The average data given in Fig. 1 are typical of the results obtained when different concentrations of pancreatic amylase reacted with soluble potato starch, whole potato starch or with the linear fraction from corn starch.[26,27] They show that the extent of the hydrolysis of these substrates by pancreatic amylase depends in each case within wide limits upon the concentration of amylase used. Similar results have since been obtained with corn starch[28] and with waxy maize starch.[29] With each substrate the hydrolysis curves show a change from a rapid to a slow phase of the reaction, typical of many other enzyme reactions but, here, the reaction curves tend to flatten at higher values as the concentration of amylase is increased. With different concentrations of pancreatic amylase, there was no evidence of a common limit in the extent of the hydrolysis of any of these substrates such as has been reported for this amylase[6,7,8,10] or as is observed when different concentrations of beta amylase act on starch or on its branched-chain components.[30] These results illustrate an important difference between the action of pancreatic amylase and that of beta-amylase. They also cast doubt upon the rather common practice[6,7,8] of assuming a limit in the hydrolysis of starch by

pancreatic amylase at 75% theoretical maltose when solutions of unknown amylase concentrations are being compared and evaluated.

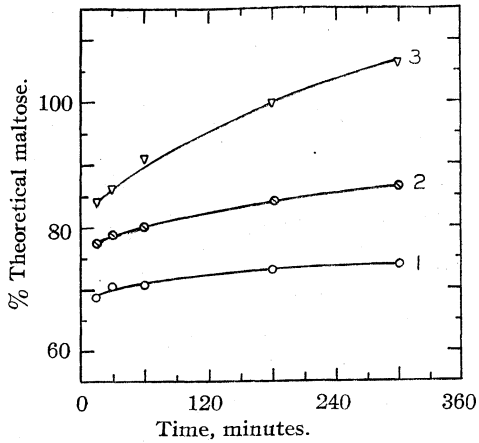

Fig. 1.—Influence of amylase concentration upon the extent of the hydrolysis of Lintner soluble potato starch by purified maltase-free pancreatic amylase: amylase preparation, mg. per 1000 mg. starch: Curve 1, 1 mg.; Curve 2, 8 mg.; Curve 3, 32 mg.; optimal conditions.[18]

Study of Hydrolysis Mixtures at Stages of Very Slow Action.—It was found repeatedly that the introduction of additional amylase into reaction mixtures which had reached stages of very slow rates of change resulted in further increases in their reducing values and, as would be expected, that larger increases in reducing value followed the use of larger additions of amylase. It is evident that products capable of further hydrolysis by the enzyme remained in reaction mixtures which had reached stages of very slow rates of change.

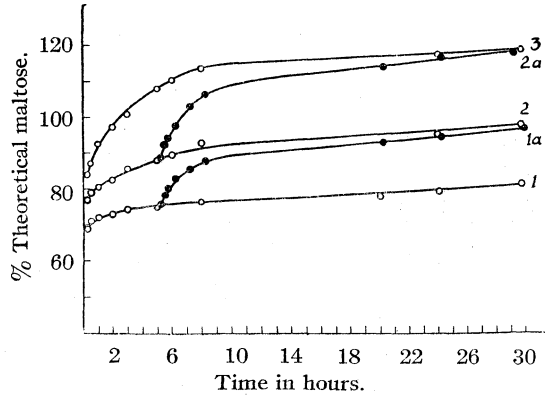

Fig. 2.—Extent of hydrolysis by additional pancreatic amylase of hydrolysis mixtures which had reached stages of very slow rates of change: Curve 1, 1 mg. amylase preparation per 1000 mg. starch; Curve 2, 8 mg.; Curve 3, 32 mg.; Curve 1a, addition of amylase to reaction 1 to bring amylase concentration equal to that in reaction 2; Curve 2a, addition of amylase to reaction 2 to bring amylase concentration equal to that in reaction mixture, 3; optimal conditions.[18]

Moreover, the data summarized in Fig. 2 show that the extent of hydrolysis attained was practically the same, as judged by the theoretical maltose calculated from the reducing values, whether a given concentration of amylase was added at the start of the reaction or in part after the reaction had reached the stage of slow action. The data given in Fig. 2 are strictly comparable as the reaction mixtures which had reached stages of very slow action were divided and one portion was treated with additional amylase while the other was continued at 40° as before.

Similarly, the data summarized in Fig. 3 show that the amylase had not been inactivated irreversibly to any appreciable extent in reaction mixtures which had reached stages of very slow rates of change. Additional substrate, introduced into such reaction mixtures, was hydrolyzed to an extent which was very similar to that attained in comparable reaction mixtures which had contained initially an equivalent concentration of amylase and ratio of amylase to substrate. It should be pointed out that the conditions of these experiments were chosen to protect the amylase from inactivation.[18]

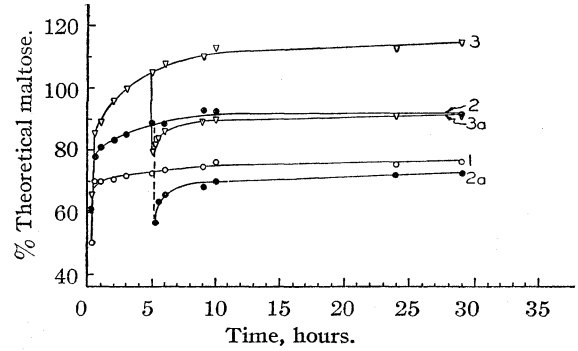

Fig. 3.—Hydrolysis of additional substrate by pancreatic amylase in starch hydrolyzates which had reached stages of very slow rates of change: Curve 1, 1 mg. amylase preparation per 1000 mg. starch; Curve 2, 8 mg.; Curve 3, 32 mg.; Curve 2a, part of reaction mixture of Curve 2 diluted with substrate to give amylase concentration equal to that in reaction mixture of Curve 1; Curve 3a, part of reaction mixture of Curve 3 diluted with substrate to bring amylase concentration equal to that in reaction mixture of Curve 2; optimal conditions.[18]

These findings, that the per cent. of theoretical maltose, calculated from the reducing values of the reaction mixtures, is practically the same under a number of different conditions, does not mean necessarily that the same products are formed from the starch in these different reaction mixtures. This point will be considered more fully elsewhere.[31]

Removal of Products by Dialysis.—The results so far reported suggested the possibility that under favorable conditions the hydrolysis of starch by pancreatic amylase continues until

(31) Alfin and Caldwell, unpublished.

equilibrium is established and that this equilibrium is upset by the addition either of more amylase or of more substrate. The slowing down of enzyme reactions has often been attributed to reaction with or equilibrium between the enzyme and its substrate or between the enzyme and the products of its action.

These possibilities were studied by the use of efficient dialysis to remove the readily dialyzable products during the hydrolyses. Starch–amylase mixtures were prepared and divided into two portions. One of these was allowed to react as usual in a flask held at 40° and was examined at intervals for reducing value. The other portion was placed in small dialyzing bags[32] and dialyzed at 40° against a buffer solution of the same electrolyte concentration and *p*H value as the substrate. The bags held approximately 5-ml. portions. They were kept in rapid motion during the dialysis and the outside solution, which was used in portions equal to four times the total volume of the hydrolysis mixture being dialyzed, was replaced ten to twenty times during a five-hour dialysis. At intervals during the reaction, one or two of the dialysis bags were removed and the contents measured for volume and examined for reducing value and for total solids. At intervals, the outside solution, also, was concentrated and examined for reducing value. Typical data for comparable hydrolyses conducted with and without dialysis are summarized in Tables I and II.

[a] Lintner's Soluble Potato Starch: 1%; 0.01 *M* phosphate; 0.02 *M* chloride; *p*H 7.2. Hydrolyses at 40°; amylase preparation, 1 mg. per 1000 mg. starch. [b] Dialyzed during the hydrolysis against 0.01 *M* phosphate; 0.02 *M* chloride at *p*H 7.2.

The data summarized in Table I show remarkably good agreement between the per cent. of theoretical maltose calculated from the reducing values of comparable dialyzed and undialyzed hydrolysis mixtures of soluble potato starch and pancreatic amylase. These data lead to the conclusion that the slowing down of the reaction in the hydrolysis of starch by pancreatic amylase cannot be explained by assuming reaction with or equilibrium between the amylase and maltose or glucose or other readily dialyzable products of the reaction. If this were the case, the removal of such products would be expected to increase the extent of the hydrolysis of the dialyzed reaction mixtures.

(32) Cellophane tubing purchased from the Visking Corporation was used to make the bags.

[a] Potato starch, 1%; 0.01 *M* phosphate; 0.02 *M* chloride; *p*H 7.2; hydrolyses at 40°. Amylase preparation, 1 mg. per 1000 mg. of starch. [b] Dialyzed during hydrolysis against 0.01 *M* phosphate; 0.02 *M* chloride at *p*H 7.2.

When whole potato starch was used as the substrate (Table II) instead of Lintner soluble starch (Table I), there was not such good agreement in the per cent. of theoretical maltose calculated from the reducing values of comparable dialyzed and undialyzed hydrolysis mixtures. However, as the values for the undialyzed hydrolysis mixtures were consistently higher than those for the dialyzed hydrolysis mixtures, these data, also, lead to the conclusion that inter-reaction with or equilibrium between readily dialyzable products and amylase does not explain the slowing down of the reaction between pancreatic amylase and starch.

The reducing products formed from Lintner soluble potato starch hydrolyzed with and without dialysis were differentiated into fermentable sugars (maltose and glucose) and non-fermentable reducing products by a modification of the method of Somogyi.[33] The data summarized in Table III show that when the hydrolysis was accompanied by dialysis, reducing products capable of further hydrolysis by the amylase escaped hydrolysis, presumably by being dialyzed away. In this comparison again, the total reducing values of dialyzed and of undialyzed hydrolysis mixtures were very similar even though the products responsible for that total reducing action were quite different.

When the initial concentrations of amylase were not too large, the addition of amylase to dialyzed hydrolysis mixtures which had reached stages of very slow rates of change resulted in small but measurable increases in their reducing values. These results showed the presence in the dialyzed

hydrolysis mixtures of products capable of further hydrolysis by the amylase.

Similarly, the addition of substrate to dialyzed hydrolysis mixtures which had reached stages of very slow action resulted in extensive hydrolysis of the added substrate. The typical data given in Table IV show that a second portion of substrate was hydrolyzed in five hours to a similar extent (66.2% theoretical maltose) as the original portion of the substrate (69.7% theoretical maltose). It is evident that there had been no significant irreversible loss or inactivation of pancreatic amylase in the dialyzing hydrolysis mixtures under the conditions of these experiments.

TABLE IV

[a] Lintner Soluble Potato Starch: 1%; 0.01 *M* phosphate; 0.02 *M* chloride; *p*H 7.2; 40°. Amylase preparation, 1 mg. per 1000 mg. starch.

On the other hand, marked inactivation of the amylase (86 to 87%) occurred when portions of the same solutions of purified pancreatic amylase were dialyzed for five hours at 40° under the same conditions, but in the absence of substrate, against a buffer solution of the same electrolyte concentration and *p*H value. These results give experimental evidence for the suggestion often advanced that the amylase unites with its substrate, in this case with the larger less readily dialyzable products of the hydrolysis of starch, and thus is protected from appreciable irreversible inactivation or from appreciable loss due to dialysis.

The loss of pancreatic amylase activity which occurs during dialysis of its aqueous solutions has not yet been reversed[17,34] by uniting the dialyzed solution with its dialyzate as has been possible under suitable conditions with certain enzymes which contain dialyzable prosthetic groups.

The data reported here indicate that the slowing down of the reaction in the hydrolysis of starch by pancreatic amylase is due to the replacement of the original substrate by products for which the amylase has less affinity. These dextrins are hydrolyzed only slowly by pancreatic amylase and are present in relatively low concentrations. Under the conditions of these experiments, the slowing down of the reactions is not due to irreversible inactivation of the amylase nor, as is often reported,[10] to action with or equilibrium between the more readily dialyzable products of the hydrolysis and the amylase. However, there is evidence of union between the amylase and the less readily dialyzable products of the hydrolysis of starch. These products are being investigated.

Examination of Preparations of Purified Pancreatic Amylase for Traces of Maltase, Phosphorylase and Phosphatase Activities.—No evidence of *maltase* activity was found in composite samples of the preparations of purified pancreatic amylase even when the highest concentrations used in this work were held for twenty-four hours with 1% maltose under the conditions used for the hydrolysis of starch. This failure to find maltase activity furnishes conclusive evidence that the results reported here were not influenced to any significant extent by traces of maltase activity.

Similarly, no evidence of *phosphorylase*[35,36] or of *phosphatase*[37] activity was found in relatively high concentrations of the preparations of purified pancreatic amylase.

Examination of Preparations of Purified Pancreatic Amylase for Traces of Other Carbohydrases.—The preparations of purified pancreatic amylase were also examined for traces of carbohydrases other than amylase by attempts to cause the selective inactivation of amylase activity, on the one hand, and of other carbohydrase (glucosidase, or dextrinase) activities on the other. Amylase activity refers here to the increase in the reducing value (mg. maltose) per unit weight of amylase preparation in the early stages of hydrolysis of 1% starch or to the

disappearance of starch[38] per unit weight of amylase preparation when these measurements were made in thirty minutes at 40° under specified conditions.[18] "Glucosidase" activity refers to the increase in the reducing value (calculated as mg. maltose) per unit weight of amylase preparation in two hours when the substrates were hydrolysis mixtures of starch and pancreatic amylase which had reached stages of very slow change but which still contained products capable of further hydrolysis by additional amylase preparation.

TABLE V

A SUMMARY OF ATTEMPTS TO CAUSE THE SELECTIVE INACTIVATION OF AMYLASE AND OF "GLUCOSIDASE" ACTIVITIES OF PURIFIED PANCREATIC AMYLASE PREPARATIONS

[a] Saccharogenic activity: mg. of "maltose" formed in thirty minutes at 40° per mg. amylase preparation acting on 1% soluble potato starch under specified conditions.[18] [b] Amyloclastic activity: mg. of soluble potato starch hydrolyzed per mg. amylase preparation in thirty minutes at 40° under specified conditions to products which give a clear red color with iodine. [c] "Glucosidase" activity: increase in mg. "maltose" per mg. added amylase preparation when amylase is added at stage of very slow rate of action to a potato starch-amylase reaction mixture and allowed to react for two hours. [d] Amylase solution: 25 mg. of amylase preparation in 100 ml. solution (0.02 *M* sodium chloride, 0.01 *M* phosphate, at *p*H 7.2). Held at 0° until examined for activity. [e] A portion of amylase solution of *d* held at 50° for five minutes before being examined for activity. [f] and *g* Same as *d* and *e* but the dry purified amylase preparation had been stored in the refrigerator for several weeks. [h] Same as *d* but held at *p*H 4.5 or at *p*H 4.6 or at *p*H 5.0 at 0° for five, ten or fifteen minutes before being adjusted to *p*H 7.2 and measured for amylase activity (average values). [i] Amylase solution: 25 mg. of amylase preparation in 100 ml. solution (0.02 *M* sodium chloride, 0.02 *M* calcium chloride, at *p*H 7.2) held at 50° for five minutes. [j] Same as *i* but without calcium chloride. [k] Amylase solution: 25 mg. of amylase preparation in 100 ml. solution (0.02 *M* sodium chloride, 0.02 *M* calcium chloride), held at 0° at *p*H 4.0, *p*H 4.5, or at *p*H 5.0 for five or ten minutes before being adjusted to *p*H 7.2 and measured for amylase activity. [l] The same as *k* but containing no calcium chloride. [m] Amylase preparation dissolved in 0.25 *M* sodium acetate, 0.01 *M* sodium phosphate and 0.02 *M* sodium chloride at *p*H 4.8 held at 0° for fifteen minutes before being adjusted to *p*H 7.2 and measured for amylase activity. [n] Same as *m* but with addition of 1.0 *M* sodium nitrite. All data are averages of several determinations.

(38) Hydrolysis of starch to products which give a clear red color with iodine.

All determinations of amylase and of "glucosidase" activities in any given series of measurements were kept strictly comparable. Amylase solutions were prepared and divided into two portions. After one had been treated to cause partial inactivation of the amylase, both portions were examined side by side, with portions of each of the two substrates, for amylase and for "glucosidase" activities.

The conditions chosen for the partial inactivation of the amylase were based upon the results of much previous work in this laboratory with similar purified preparations[17,39,40] and on preliminary experiments.

The data summarized in Table V (A and B) show that there was appreciable loss of "glucosidase" as well as of amylase activity when aqueous solutions of purified pancreatic amylase were partially inactivated at 50° or at unfavorably high hydrogen-ion activities.

Kneen[41] has shown that calcium ions protect malt α-amylase from inactivation when its aqueous solutions are held at unfavorable temperatures or at unfavorably high hydrogen-ion activities. The data summarized in Table V (C and D) show that both the amylase and the "glucosidase" activities of purified pancreatic amylase were protected by calcium ions from inactivation in aqueous solutions held at 50° or at unfavorably high hydrogen-ion activities.

In 1942, Little and Caldwell[39,40] showed that the amylase activity of pancreatic amylase depends upon the presence of free primary amino groups in the protein molecule. Any treatment which caused the loss of primary amino nitrogen caused a corresponding loss of amylase activity. The data summarized in Table V (E) show that "glucosidase" as well as amylase activity was decreased when solutions of purified pancreatic amylase were treated with nitrous acid under conditions which caused the rapid loss of primary amino groups. In these experiments the influence of the unfavorably high hydrogen-ion activities was taken into consideration. Aliquots of the amylase solution adjusted to *p*H 4.8, and 0.25 *M* acetate, 0.01 *M* phosphate and 0.02 *M* chloride were held at 0° for the specified length of time in the absence of and in the presence of 1.0 *M* nitrite. The solutions were then adjusted to *p*H 7.2 with phosphate and compared with an untreated control solution for amylase and for "glucosidase" ac-

tivities. The excess nitrite was removed by treatment with sulfamic acid before reducing values were determined.

The data summarized in Table V fail to give any evidence by selective inactivation for the presence of a second carbohydrase in addition to amylase in the preparations of purified pancreatic amylase used here. The differences obtained in the inactivation studies of "glucosidase" activities were small and undue emphasis cannot be placed on comparisons of inactivation percentages when different activities, obtained by different types of measurements, are involved. However, the results as a whole give the same trend for the inactivation of "glucosidase" and of amylase activities and appear to justify the conclusion that the properties of pancreatic amylase observed in this investigation are not influenced to any important extent by the presence of contaminating carbohydrases.

Summary and Conclusions

A study of the action of highly purified pancreatic amylase shows that the extent of the hydrolysis of unfractionated potato starch, Lintner soluble starch and of the linear fraction from corn starch depends in each case upon the concentration of amylase. Relatively very high concentrations of the amylase gave no evidence of a limit in the hydrolysis of starch by pancreatic amylase such as is observed with β-amylase.

The reaction curves showed a rapid phase of reaction followed by a phase of very slow rate of change but the extent of the hydrolysis attained was dependent within wide limits upon the concentration of amylase. Under the conditions of these experiments the slowing down of the reactions was not due to any appreciable inactivation of the amylase nor to inter-reaction with or equilibrium between amylase and maltose, glucose or other readily dialyzable products of hydrolysis.

Evidence is presented which shows that the slowing down of the hydrolysis is due to relatively low concentrations of products which the amylase hydrolyzes slowly, for which it has low affinity.

Data are presented which show that the results obtained here are not influenced to any appreciable extent by the presence of maltase or of other carbohydrases.

Butylation of Benzene during Propylation in the Presence of Isobutane. Ratio of Reactivities of Benzene and Isobutane

BY FRANCIS E. CONDON AND MARYAN P. MATUSZAK

In an experiment originally designed to determine the ratio of the rates of alkylation of benzene and isobutane, a mixture of these two hydrocarbons was subjected to alkylation with propylene in the presence of hydrofluoric acid as catalyst. It was found that, besides isopropylation of benzene, considerable *t*-butylation occurred. The formation of *t*-butylbenzene may be taken as an indication of the intermediate formation of *t*-butyl carbonium ions, which must have been derived from isobutane in accordance with the following considerations.

According to the ionic mechanism of catalytic alkylation of a hydrocarbon, the initial step is formation of a carbonium ion[1]; for example

$$H^+ + C_3H_6 \longrightarrow i\text{-}C_3H_7^+ \qquad (1)$$

When the alkylatable hydrocarbon is an isoparaffin like isobutane, the various subsequent steps may be generalized as reactions in which a carbonium ion, however formed, produces another carbonium ion, either by acquiring hydrogen with its bonding electrons from isobutane, thereby producing also a paraffin

$$i\text{-}C_3H_7^+ + i\text{-}C_4H_{10} \xrightarrow{k} t\text{-}C_4H_9^+ + C_3H_8 \qquad (2)$$

or by uniting with an olefin, which may have been introduced as such, or may have been formed by the reverse of a reaction like 1

$$i\text{-}C_3H_7^+ + i\text{-}C_4H_8 \longrightarrow C_7H_{15}^+ \qquad (3)$$

The new carbonium ions formed by such reactions undergo similar reactions; in addition, some of them undergo preliminary rearrangement, thereby accounting for the multiplicity of products from isoparaffin alkylation.[2]

In the aforementioned experiment, substantially no alkylation of isobutane occurred, in spite of a 50-fold molecular excess of isobutane over benzene. Consequently, it was not possible to deduce, from the composition of the alkylation product, a numerical value for the ratio of the rate of alkylation of benzene to the rate of alkylation of isobutane. There was deduced, however, an approximate numerical value for the ratio of the reactivity of benzene with isopropyl carbonium ion to the reactivity of isobutane with this ion. This deduction was possible because the isopropylation of benzene

$$i\text{-}C_3H_7^+ + C_6H_6 \xrightarrow{k'} i\text{-}C_3H_7C_6H_5 + H^+ \qquad (4)$$

(1) Price and Ciskowski, THIS JOURNAL, **60**, 2499 (1938).

was competitive with reaction 2, which must have been substantially the only precursor to the *t*-butylation of benzene, inasmuch as the benzene was reacting with all carbonium ions so rapidly that reaction 3 was negligible. On the assumption that all *t*-butyl carbonium ions reacted with benzene immediately after formation by reaction 2, the ratio of the rate of reaction 4 to the rate of reaction 2 must have equalled the ratio of the number of isopropyl groups, *a*, to the number of *t*-butyl groups, *b*; that is

$$\text{Rate 4/Rate 2} = k'(i\text{-}C_3H_7^+)(C_6H_6)/k(i\text{-}C_3H_7^+)(i\text{-}C_4H_{10}) = a/b$$

Consequently

$$k'/k = a(i\text{-}C_4H_{10})/b(C_6H_6)$$

The value of a/b, obtained from the composition of the product, was 7.1. The value of $(i\text{-}C_4H_{10})/(C_6H_6)$ was taken as 49, the mol ratio of isobutane to benzene in the feed, on the approximation that alkylated benzene is alkylated at the same rate as benzene. These values gave $k'/k = 350$. That is, benzene was approximately 350 times as reactive as isobutane.

[a] By titration of 1 g. with 1 *N* potassium hydroxide (phenolphthalein). [b] Including unreacted benzene. [c] In view of recently reported findings of Melpolder, Woodbridge and Headington, THIS JOURNAL, **70**, 935 (1948), the *m*-diisopropylbenzene (b. p. 203.18°) may have included some *o*- (b. p. 203.75°). [d] B. p. above 270°.

Experimental Part

Materials.—The isobutane and the propylene were products of Phillips Petroleum Company. They were analyzed by fractionation in a Podbielniak Heligrid low-temperature column. C. P. benzene was used.

Anhydrous hydrofluoric acid from the Harshaw Chemical Company was used.

Equipment and Procedure.—The experiment was of the continuous type, with recycling of the acid. The hydrocarbon feed was blended in a 94-liter (25-gal.) steel cylinder, from which it was displaced by pumping water in through a tube which led to the bottom. From the cylinder the feed passed through a silica-gel drier into the reactor. Surging of the feed was minimized by an electrically heated surge tank attached to the feed line after the drier. The reactor[3] was a 1470-ml. steel vessel having a 6.3-cm. (2.5-in.) turbo-mixer, turning about 1725 r. p. m. The reactor was surrounded by a stirred water-bath. Temperature in the reactor was measured by a thermocouple. Acid-to-hydrocarbon volume ratio in the reactor was maintained near unity by occasional additions of fresh acid. This ratio was determined by withdrawing several ml. of the mixture through an eduction tube into a graduated test-tube immersed in a Dry Ice-bath and measuring the volumes of the hydrocarbon and acid layers. From the reactor the mixture passed to a 1440-ml. inclined separator, from which the acid layer was recycled to the reactor by gravity through a U-shaped trap which prevented passage of the reaction mixture into the acid-return line. The pressure in the system was maintained at 10 atm. by a Hanlon-Waters air-operated motor valve, controlled by a Taylor "Fulscope" controller, located on the effluent line from the settler. The hydrocarbon effluent was collected in tared 57-liter (15-gal.) steel cylinders.

The data for the experiment are in Table I. In part 1, half of an isobutane–benzene mixture was used, without propylene, to equilibrate the silica-gel drier and the catalyst and to test the isobutane for any possible presence

(3) See "Hydrofluoric Acid Alkylation," Phillips Petroleum Co., Bartlesville, Oklahoma, 1946, p. 2, Fig. 1.

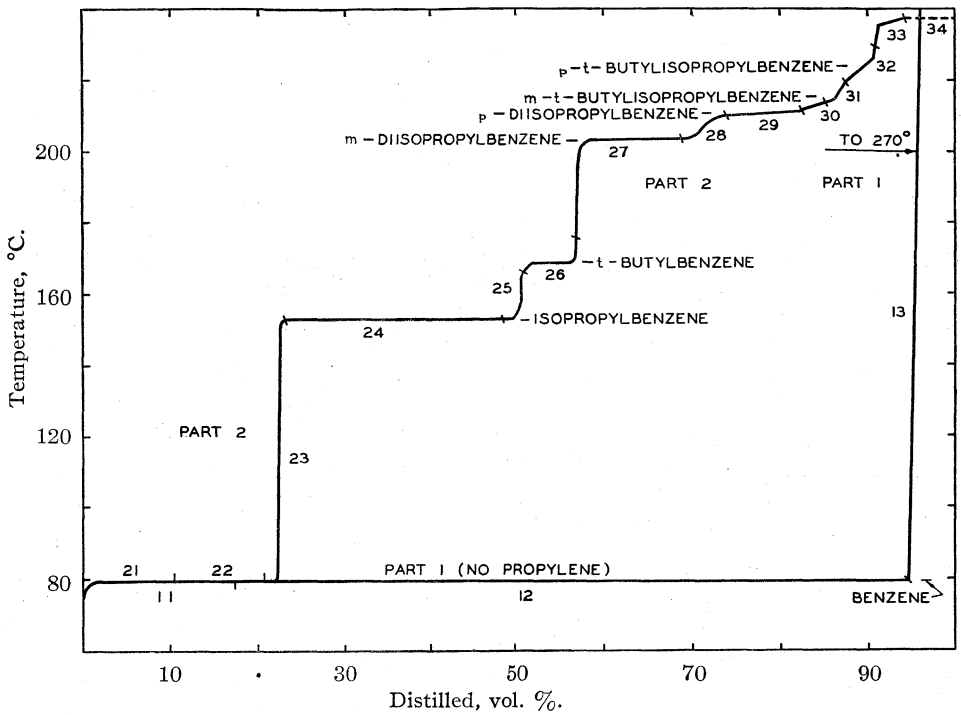

Fig. 1.—Fractionation of product from HF alkylation of 2 mole % benzene in isobutane with propylene (numbers designate fractions).

of isobutylene as an impurity. In part 2, the other half of the isobutane-benzene mixture, after being mixed with the propylene, was used; the first 0.5 kg. of hydrocarbon effluent was discarded, inasmuch as it represented flushing of the system.

The hydrocarbon effluent was partly debutanized in a 3-m. (10-ft.) Monel column, 3.17 cm. (1.25 in.) in diameter, packed with 6.35-mm. (0.25-in.) carbon Raschig rings. The debutanization was completed in a 1.5-m. (5-ft.) vacuum-jacketed glass column, 12.7 mm. (0.5 in.) in diameter, packed with 2.4-mm. ($^3/_{32}$-in.) wire helices. All overhead material was combined and was analyzed by low-temperature Podbielniak fractionation.

Product boiling above 25° was fractionated in a Podbielniak Heligrid vacuum-jacketed column. To a 20-g. residue from fractionation of the product from part 1, 18 g. of cetane (b. p. 290°) was added as a "chaser," and distillation was continued from an ordinary distilling flask.

From the fractionation curves shown in Fig. 1, from the properties of the fractions in Table II, and from the results of preparation of solid derivatives described in Table III, the product compositions reported in Table I were computed.

Preparation of Derivatives (Table III).—*p-t*-Butylacetanilide was prepared according to Ipatieff and Schmerling.[4] Benzoic acid and *m*- and *p-t*-butylbenzoic acids were obtained by oxidizing 1-cc. (0.85-g.) samples with 8.5 g. of chromium trioxide in 30 cc. of boiling glacial acetic acid for one hour. Iso- and terephthalic acids were obtained from fractions 27 and 29 by oxidizing 3-cc. (2.5-g.) samples with 200 cc. of boiling dilute nitric acid (1:3). They were esterified with methanol, in the presence of a little sulfuric acid.

Acknowledgments.—Mr. G. T. Leatherman assisted with the experiment; Miss Alicia Perez determined molecular weights; and Phillips Petroleum Company kindly granted permission to publish the data.

Summary

A 2 mole per cent. mixture of benzene in isobutane was subjected to hydrofluoric acid-catalyzed alkylation with propylene. The principal

(4) Ipatieff and Schmerling, THIS JOURNAL, **59**, 1056 (1937).

reaction was isopropylation of benzene. Substantially no alkylation of isobutane occurred; however, isobutane reacted, yielding *t*-butylbenzene and *m*- and *p*-*t*-butylisopropylbenzenes. The composition of the product showed that benzene reacted approximately 350 times as readily as isobutane.

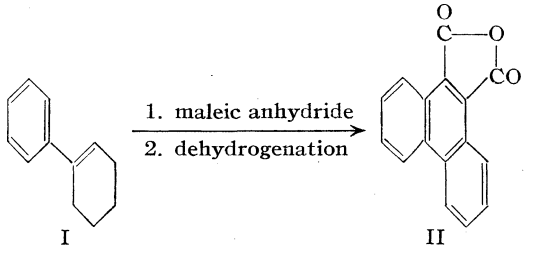
Condensation of Phenylcycloalkenes with Maleic Anhydride. I. Synthesis of 7-Methoxy-3,4-benzphenanthrene

BY JACOB SZMUSZKOVICZ[1] AND EDWARD J. MODEST

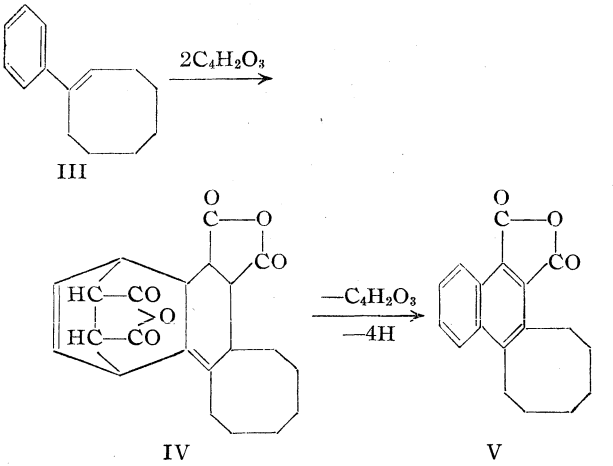
Additions to diene systems in which one double bond is in a benzene ring and the second in an alicyclic ring have not hitherto been reported.[2] The 1,2-double bond in naphthalene in conjugation with the double bond of an olefinic system,[3] with that in cyclopentene[4] or in cyclohexene,[5] is sufficiently reactive to participate in the Diels–Alder condensation. Styrene itself forms copolymers with dienophiles, but some derivatives of styrene form normal adducts.[6,7]

We now have found that 1-phenylcyclohexene-1 (I) adds maleic anhydride at 220° with formation of an amorphous adduct, which can be dehydrogenated to phenanthrene-9,10-dicarboxylic acid anhydride (II); the over-all yield is 25%. Other investigators have prepared this aromatic anhydride from bicyclohexenyl (17% yield)[8]; from phenanthrene, sodium, and carbon dioxide (25.7% yield)[9]; and from diphenyl-2-carboxylic acid (42% yield).[10]



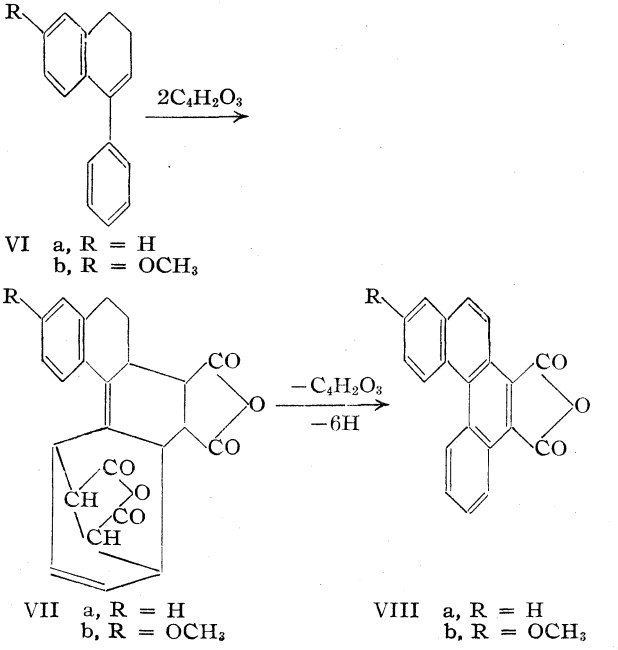
I II

1-Phenylcycloöctene-1 (III) reacts with maleic anhydride at steam-bath temperature. The product, obtained in quantitative yield, is the bis-adduct (IV), which upon dehydrogenation with sulfur yields 1,2-cycloöctanonaphthalene-3,4-dicarboxylic acid anhydride (V).



III IV V

1-Phenyl-3,4-dihydronaphthalene (VIa) and 1-phenyl-6-methoxy-3,4-dihydronaphthalene (VIb) react with maleic anhydride; the bis-adducts VIIa and VIIb are formed. The yields vary with the reaction temperature employed, from moderate at 95° to quantitative at 160°.



VI a, R = H
b, R = OCH_3

VII a, R = H
b, R = OCH_3

Upon treatment with sulfur VIIa and VIIb are aromatized to the anhydrides VIIIa and VIIIb in 100 and 68.5% yields, respectively.

Decarboxylation of VIIIa with barium hydroxide and copper bronze affords 3,4-benzphenanthrene in 70% yield (compare ref. 5). Decarboxylation of VIIIb gives the hitherto unknown 7-methoxy-3,4-benzphenanthrene (63.7% yield).

These reactions thus constitute an efficient synthesis of 3,4-benzphenanthrene in three steps and provide a route to various substituted benzphenanthrenes. Comparable additions to systems containing the thiophene ring will be reported shortly.

Acknowledgment.—The authors wish to express their thanks to Prof. L. F. Fieser for his generous support of this investigation and to Mrs. Mary Fieser for her advice and assistance in preparing the manuscript.

Experimental[11]

Phenanthrene-9,10-dicarboxylic Acid Anhydride, II.—1-Phenylcyclohexene-1[12] (1 g.) was heated with maleic anhydride (2 g.) at 220° for three hours. The brown viscous mass was cooled, dissolved in warm acetic acid, and precipitated with water. The light brown substance, obtained in quantitative yield, softens at 105° and melts completely at 160°. This crude material (1.7 g.) was heated with 850 mg. of sulfur for twenty minutes at 230–250°. The anhydride II was sublimed at 240–270° (0.005 mm.), 390 mg., 25%. On crystallization from acetic anhydride it forms yellow rods melting at 316–317°.

Anal. Calcd. for $C_{16}H_8O_3$: C, 77.42; H, 3.25. Found: C, 77.00; H, 3.25.

1,2-Cycloöctanonaphthalene-3,4-dicarboxylic Acid Anhydride, V.—1-Phenylcycloöctene-1[13] (1 g.) was heated with maleic anhydride (2 g.) on the steam-bath for twenty-four hours. The brown oil was decanted from the well-formed prisms, which were washed with acetic acid and methanol; m. p. 249–250°.

Anal. Calcd. for $C_{22}H_{22}O_6$: C, 69.09; H, 5.80. Found: C, 68.74; H, 5.43.

The oil was dissolved in acetic acid and precipitated with water. This crude material could be purified by crystallization from dilute dioxane. The over-all yield was quantitative.

Dehydrogenation of the adduct (284 mg.) was carried out with sulfur (70 mg.) at 220–240° for fifteen minutes. The crude product sublimed at 220–240° (0.001 mm.); the yellow sublimate (150 mg., 53.5%), after crystallization from acetic acid, was obtained as yellow plates, m. p. 175–176°.

Anal. Calcd. for $C_{18}H_{16}O_3$: C, 77.12; H, 5.75. Found: C, 77.08; H, 5.63.

3,4-Benzphenanthrene.—A mixture of 1-phenyl-3,4-dihydronaphthalene[14] (1 g.) and maleic anhydride (2.5 g.) was heated on the steam-bath for twenty hours. The brown oil was dissolved in acetic acid; scratching induced crystallization. The white precipitate was filtered and washed with methanol (300 mg., 14.8%), m. p. 315–316°. Crystallized from acetic acid, it forms clusters of leaflets, m. p. 315–316° (dec.). The analysis conforms to that of the tetracarboxylic acid monoanhydride of VIIa.

Anal. Calcd. for $C_{24}H_{20}O_7$: C, 68.56; H, 4.80. Found: C, 68.43; H, 5.05.

If the mixture of starting materials was heated for twenty hours at 150–160°, 1.5 g. of the bis-adduct was obtained, m. p. 315–316°. An additional 500 mg. of white material melting at 160–170° (probably the tetracarboxylic acid) resulted from addition of water to the filtrate. The yield was quantitative.

Dehydrogenation of the adduct (200 mg.) was conducted with large excess of sulfur (75 mg.) at 270–290° for nine minutes. The excess sulfur is necessary in this case to lower the initial temperature and to prevent carbonization; The product (VIIIa) sublimed at 230–245° (0.001 mm.). m. p. 249–251°. It crystallized from acetic anhydride in the form of elongated yellow needles melting at 257–258°.[5] The yield was quantitative.

Anal. Calcd. for $C_{20}H_{10}O_3$: C, 80.53; H, 3.38. Found: C, 80.53; H, 3.38.

The same aromatic anhydride resulted from the dehydrogenation of the tetracarboxylic acid mentioned above.

The aromatic anhydride (VIIIa) (0.7 g.) was finely ground with 4 g. of crystalline barium hydroxide and 1.4 g. of copper bronze and the mixture was heated in a tube. The reaction started at 300°; water-pump suction was applied and heating was continued to 350°. The oily distillate solidified on treatment with methanol (375 mg., 70%). This material, crystallized from ethanol, m. p. 68°, was identical with 3,4-benzphenanthrene (mixed m. p. determination).

7-Methoxy-3,4-benzphenanthrene.—The addition of maleic anhydride to 1-phenyl-6-methoxy-3,4-dihydronaphthalene[15] was carried out as in the preceding case. The bis-adduct (VIIb) was obtained in 49% yield at 95° and in quantitative yield at 150–160°. It crystallized from the reaction mixture in the form of white prisms, m. p. 348–349° (dec.).

Anal. Calcd. for $C_{25}H_{20}O_7$: C, 69.44; H, 4.66. Found: C, 69.39; H, 4.81.

A mixture of VIIb (1.75 g.) and sulfur (0.49 g.) was heated to 307°. A violent reaction ensued and heating was continued at 270–280° for twenty minutes. Sublimation at 230–300° (0.001 mm.) yielded 0.91 g. (68.5%) of yellow material VIIIb, m. p. 220–225°, which crystallized from acetic anhydride as yellow needles, m. p. 233–234°.

Anal. Calcd. for $C_{21}H_{12}O_4$: C, 76.82; H, 3.69. Found: C, 76.90; H, 3.50.

Decarboxylation, carried out as before, led to a yellow oil (63.7% yield), which solidified on treatment with methanol and which crystallized from the same solvent in the form of colorless plates, m. p. 90–91°. The analysis conforms to that of 7-methoxy-3,4-benzphenanthrene.

Anal. Calcd. for $C_{19}H_{14}O$: C, 88.34; H, 5.46. Found: C, 88.28; H, 5.59.

The picrate formed in ethanol and crystallized from the same solvent as elongated red needles, m. p. 120–121°.

Anal. Calcd. for $C_{25}H_{17}O_8N_3$: C, 61.60; H, 3.52. Found: C, 61.39; H, 3.27.

Summary

1. Four compounds of the phenylcycloalkene series have been successfully condensed with maleic anhydride.

2. An efficient synthesis of 3,4-benzphenanthrene has been developed.

3. Preparation of 7-methoxy-3,4-benzphenanthrene is described.

Anomalous Oxidation of Some Secondary Alcohols Containing an α-Neo Carbon[1]

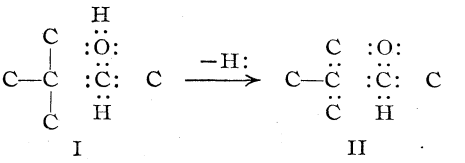
BY WILLIAM A. MOSHER AND FRANK C. WHITMORE

The oxidation of secondary alcohols with such reagents as chromic anhydride in acetic acid solution generally gives good yields of the corresponding ketones. In connection with the preparation of methyl *t*-amyl ketone for use in the synthesis of 2,3,4-trimethylhexane[2] an unexpected product was isolated. The oxidation of methyl-*t*-amylcarbinol with chromic anhydride in acetic acid, containing about 20% water, gave 7% *t*-amyl alcohol in addition to the desired ketone. The same reaction with methyl-*t*-butylcarbinol gave 6% *t*-butyl alcohol, and isopropyl-*t*-amylcarbinol gave 7% *t*-amyl alcohol.

Although this preliminary work is not sufficiently comprehensive to permit any generalization as to this type of reaction, the indications are that complete substitution on the carbon *alpha* to the hydroxyl-bearing carbon leads to unusual behavior on oxidation with chromic anhydride. Probably other alcohols with a lower degree of substitution behave in a similar manner, but greater susceptibility of the alcohols which might be formed to oxidative attack prevents their isolation. It is believed that the complete elucidation of the formation of the tertiary alcohols in this unexpected oxidation may well be the key to all oxidative carbon-to-carbon single bond ruptures in oxygenated organic compounds in polar solvents. Related studies are now under way.

From the standpoint of mechanism, the first question is whether the tertiary alcohols are formed from the carbinol or from the ketone formed in the oxidation. The oxidation of pinacolone with dichromate and acid has been studied by Friedel and Silva[3] and by Butlerow[4] who found that trimethylacetic acid was formed. We have repeated this oxidation using chromic anhydride as employed in the above alcohol oxidations. While the oxidation of the alcohols is rapid at 30° no oxidation of the pinacolone is apparent until temperatures close to 100° are reached. Only trimethylacetic acid could be isolated although any *t*-butyl alcohol which might have been formed would probably have been further oxidized. The great difference in ease of oxidation of ketones and carbinols, which is well known, points to a different mechanism and favors the belief that the fission to the tertiary alcohols occurs in the carbinol rather than in the ketone.

The following tentative mechanism for the cleavage exemplified with pinacolone, is suggested. The oxidizing agent abstracts a hydrogen with an electron pair (a hydride ion) from the hydroxyl group. Certainly the hydrogen of the hydroxyl is the most polar hydrogen in the molecule so that the energetics would favor approach of the oxidizing agent. The great difficulty with which ethers are oxidized by reagents, other than oxygen, is also in harmony.



I II

The intermediate ion II, which would be expected to show many carbonium ion type reactions, can be stabilized intramolecularly in two ways. First, a proton may be expelled followed by rearrangement of an electron pair to create a carbonyl group. This process is apparently the chief one because of the high yields of ketone obtained. The second possibility depends on the fact that the electronically deficient oxygen atom exerts a powerful attraction for the electron pair joining the *t*-butyl group to the oxygenated carbon atom, while the *t*-butyl has a low attraction for these same electrons.[5] The configuration here, R_3C-C-O^+, is analogous to that found by Whitmore and Stahly to be critical for the acid catalyzed depolymerization of branched olefins,[6] R_3C-C-C^+. If this electron pair is appropriated by the oxygen, rupture of the molecule occurs to form a tertiary carbonium ion and a molecule of aldehyde. Both stabilization processes are summarized in Fig. 1. We have made the assumption that the normal product of the reaction, the ketone, and the abnormal product, the tertiary alcohol, have come from a common intermediate. There is no direct evidence for this, and later work may possibly show that two independent mechanisms are involved.

The carbonium ion formed in the cleavage may react with water: $(CH_3)_3C^+ + HOH \rightleftarrows (CH_3)_3COH + H^+$. Reaction with acetic acid to give *t*-butyl acetate might also take place, but such esters are hydrolyzed very readily in acidic solutions.[7] At higher temperatures olefin would be expected through the expulsion of a proton from the tertiary carbonium ion and this has been found to be the case.[8] The experimental conditions used in

this work would oxidize any aldehyde which might be formed. Aldehydes have been isolated under modified conditions, however, and the description of that work will be published later.

This work has been supported in part by a Frederick Gardner Cottrell grant from the Research Corporation, which is gratefully acknowledged.

Experimental

Materials.—Methyl-*t*-amylcarbinol was prepared from *t*-amylmagnesium chloride and acetaldehyde, methyl-*t*-butylcarbinol from *t*-butylmagnesium chloride and acetaldehyde and isopropyl-*t*-amylcarbinol from isopropylmagnesium bromide and dimethylethylacetyl chloride, employing the usual procedures. All products were fractionated through columns of 12–15 theoretical plates. One sample of methyl-*t*-butylcarbinol was prepared by the catalytic reduction of pinacolone prepared from acetone. Further details will be published with the original investigation.[2]

Oxidation of Alcohols.—All oxidations were carried out in the following manner, exemplified with methyl-*t*-amylcarbinol. In a 3-necked 3-liter flask 336 g. of methyl-*t*-amylcarbinol (2.9 moles, $n^{20}D$ 1.4300) was dissolved in 150 ml. of glacial acetic acid. The flask was equipped with a stirrer, dropping funnel, and thermometer. Two moles (200 g.) of chromic anhydride was dissolved in 100 ml. of water and 250 ml. of glacial acetic added when solution in the water was complete. The chromic anhydride solution was added dropwise to the carbinol over a period of eight hours with the temperature below 30° at all times. The product was diluted with 2 liters of water and the ketone layer separated and washed with bicarbonate solution and then water. The water layer from the reaction was steam-distilled after the addition of 20 ml. of ethyl alcohol to react with any unused oxidant. The oil layer from the steam distillate was combined with the main portion after washing as before. The crude ketone was dried over potassium carbonate which also served to remove any acids present. The dry product was fractionated through a column equivalent to 15 theoretical plates.

Identification of Products.—From each oxidation early distillation cuts were obtained with physical properties corresponding to *t*-amyl or *t*-butyl alcohol. It was the characteristic odor of these cuts which prompted further study. These suspected cuts were treated with concentrated hydrochloric acid and the chlorides obtained, after checking density and index of refraction, were converted to the Grignard reagents, and these reacted with phenyl isocyanate to give, respectively, *t*-amylacetanilide, m. p. and mixed m. p. 105–106°, and *t*-butylacetanilide, m. p. and mixed m. p. 132°. The tertiary alcohol cuts from methyl-*t*-butyl-, methyl-*t*-amyl-, and isopropyl-*t*-amylcarbinols were, respectively, 6, 7 and 7%. The yields of ketone obtained were 70–75%. Three separate oxidations

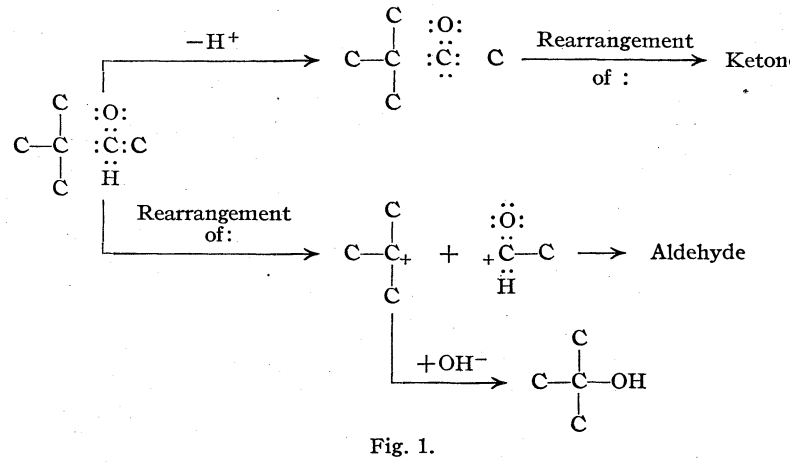

Fig. 1.

were made with methyl-*t*-amylcarbinol and two with methyl-*t*-butylcarbinol; the results were identical. The yield of *t*-butyl alcohol from methyl-*t*-butylcarbinol prepared from pinacolone was the same as the yield from the product made through the Grignard reaction.

Oxidation of Pinacolone.—Pinacolone was prepared according to "Organic Syntheses."[9] Oxidation was carried out as in the case of methyl-*t*-amylcarbinol above. Oxidation did not take place at 50 or 80°, but did proceed at 100°. After five hours the reaction mixture was diluted and steam distilled. Basic reagents were avoided. Fractionation gave 75% trimethylacetic acid (b. p. 164° (760 mm.), anilide m. p. and mixed m. p. 129°) and 18% unreacted ketone. No tertiary butyl alcohol was detected.

Summary

1. Oxidation of methyl-*t*-amylcarbinol and isopropyl-*t*-amylcarbinol with chromic anhydride in acetic acid gives in both cases 7% *t*-amyl alcohol. Similarly methyl-*t*-butylcarbinol gives 6% *t*-butyl alcohol.

2. These tertiary alcohols are formed from the carbinols as the oxidation of pinacolone does not take place under similar conditions and under more drastic conditions yields trimethylacetic acid.

3. A mechanism involving the removal of a hydride ion from the hydroxyl group to give an intermediate ion with an electronically deficient oxygen is proposed. The tertiary alcohols are obtained by rearrangement of an electron pair without the attached group, while ketones, the principal products, are obtained by expulsion of proton from the intermediate.

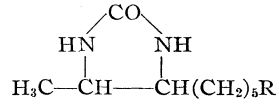
The Synthesis and Biological Activity of 4-Methyl-5-(ε-sulfoamyl)-2-imidazolidone, a Sulfonic Acid Analog of Desthiobiotin

BY ROBERT DUSCHINSKY AND SAUL H. RUBIN

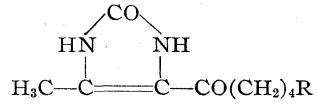
Replacement of carbonyl by sulfonyl groups in metabolites sometimes results in substances of antagonistic biological behavior.[1] In this respect the study of a sulfonic acid analog (I, R = SO_3H)



I

of desthiobiotin (I, R = CO_2H) appeared of interest. The substance was therefore synthesized and tested microbiologically.[2]

The general methods involved in the synthesis have been described previously.[3] 4-Methyl-2-imidazolone and δ-bromovaleryl chloride were submitted to a Friedel-Crafts condensation. The bromoketone obtained (II, R = Br) was converted



II

into the sodium sulfonate (II, R = SO_3Na) which was reduced catalytically to give the sodium salt of 4-methyl-5-(δ-sulfoamyl)-2-imidazolidone (I, R = SO_3Na). As in the completely analogous step in the synthesis of desthiobiotin,[3] two moles of hydrogen corresponding to the reduction of the keto group were absorbed rapidly, while the third mole corresponding to the hydrogenation of the double bond was taken up much more slowly. In view of the similarities of method and behavior, it is assumed that, as in the desthiobiotin synthesis, *cis*-addition at the double bond takes place.

The growth-promoting or growth-inhibiting properties of the compound for *Saccharomyces cerevisiae* 139 and *Lactobacillus casei* were tested by methods which have been previously reported.[4]

The sulfo compound did not support growth in biotin-free media. For *S. cerevisiae* it proved to be an antibiotin at a molar inhibition ratio of about 300,000. When *d,l*-O-heterobiotin was substituted for biotin in the medium, the ratio was found to be 17,000. This result presents additional evidence for the reported greater resistance of biotin toward inhibitors as compared to its oxygen analog.[5] When *d,l*-desthiobiotin was substituted for biotin, the growth of *S. cerevisiae* was inhibited at a molar ratio of 40,000. With *L. casei* no inhibition of growth was noticed at a molar ratio of more than 5,000,000 in media supplemented with *d*-biotin or *d,l*-O-heterobiotin.

Experimental[6]

4-Methyl-5-(δ-bromovaleryl)-2-imidazolone (II, R = Br).—δ-Bromovaleric acid was prepared in good yield by the procedure of Hunsdiecker and Hunsdiecker[7] by the reaction of methyl silver adipate with bromine and saponification of the resulting ester with a mixture of acetic and hydrobromic acids. The product was converted into the acid chloride[8] by means of thionyl chloride. The δ-bromovaleryl chloride (26.7 g.) was added to a suspension of 13.1 g. of 4-methyl-2-imidazolone[3] in 130 cc. of nitrobenzene. Aluminum chloride(44 g.) was added gradually with continuous stirring and occasional cooling. After heating the mixture for four and one-half hours in a bath at 60°, the evolved hydrochloric gas being driven off with a slow stream of nitrogen, it was poured on 200 g. of ice. Stirring and addition of 200 cc. of ether produced crystals, which were washed well with water and ether. The yield was 16.2 g. (43%), m. p. 199–201° (dec.). Recrystallization from 95% ethanol gave rectangular plates melting at 206–207° (dec.).

Anal. Calcd. for $C_9H_{13}O_2N_2Br$: C, 41.39; H, 5.02; Br, 30.61. Found: C, 41.92; H, 5.20; Br, 30.33.

Sodium Salt of 4-Methyl-5-(δ-sulfovaleryl)-2-imidazolone (II, R = SO_3Na).—A mixture of 2.61 g. of the bromoketone, 1.38 g. (1.1 moles) of sodium sulfite and 8.5 cc. of water was refluxed for two hours. The solution was evaporated to dryness and the residue boiled with 22 cc. of water and 140 cc. of ethanol; some insoluble material was separated by filtration. Upon cooling, crystals deposited which were washed bromine-free with ethanol. The yield was 2.1 g. (74%) of prismatic needles which, after recrystallization from aqueous 80% ethanol, melted in an evacuated capillary tube at 332–334° (dec.).

Anal. Calcd. for $C_9H_{13}O_5N_2SNa$: C, 38.02; H, 4.61; Na, 8.09. Found: C, 38.17; H, 4.45; Na, 8.29.

Sodium Salt of 4-Methyl-5-(ε-sulfoamyl)-2-imidazolidone (I, R = SO_3Na).—The foregoing imidazolone (1.68 g.) was hydrogenated at room temperature and atmospheric pressure with 1 g. of prehydrogenated Adams platinum catalyst in 15 cc. of acetic acid. Two moles of hydrogen were taken up in one hour, a third mole overnight, whereby the material, initially in suspension, passed into solution. After separation of the catalyst, the solution was evaporated to a sirup, which was rendered free of acetic acid by evaporation with methanol. The final residue was dissolved in 25 cc. of hot methanol. Addition of 25 cc. of dry ether and cooling produced 1.09 g. of crystals (68%). The substance was recrystallized for analysis by dissolving in methanol and adding ether. It did not show a distinct melting point.

Summary

A sulfonic acid analog of desthiobiotin was synthesized. The compound showed inhibitory activity toward *S. cerevisiae*, which was more pronounced against *d,l*-O-heterobiotin and *d,l*-desthiobiotin than *d*-biotin. The compound had no effect on *L. casei*.

The Reaction of Some Radioactive Mustard-type Vesicants with Purified Proteins[1]

BY JOHN L. WOOD,[2] JULIAN R. RACHELE, CARL M. STEVENS,[3] FREDERICK H. CARPENTER AND VINCENT DU VIGNEAUD

In a collaborative attack on the problem of the mechanism of action of mustard-type vesicants, we had undertaken to study the reaction of vesicants with proteins. A study of the reactions of a large number of amino acids with vesicants has already been described.[4] The second phase of our work was the study of the interaction of vesicants with certain well characterized, highly purified proteins. Preliminary experiments indicated that treatment of certain proteins with relatively large amounts of vesicant resulted in a chemical reaction. The reaction products differed from the original proteins in physical properties and had a higher sulfur content. These observations supplemented earlier evidence[5] of chemical reactions between vesicants and proteins and indicated the desirability of a detailed study.

Kistiakowsky, Moritz, Henriques and co-workers[6] had already demonstrated that an extremely small amount of mustard gas (H) is bound in the tissue at the site of a burn produced by a minimum amount of H. At the same time, all indications were that the vesicants were capable of reacting with a large number of different types of groups presumably present in proteins. Reactions at the site of the burn must involve only a small percentage of these groups and possibly only certain types. It was, therefore, of particular interest to study the reaction of H-type vesicants with proteins *in vitro* at correspondingly low ratios of vesicant to protein in an effort to determine the most reactive groups under these conditions. It was decided to utilize the radioactive tracer technique in approaching this question.

Benzyl β-chloroethyl sulfide (benzyl-H*) and *n*-butyl β-chloroethyl sulfide (butyl-H*), containing S^{35} of 87-day half-life,[7] were synthesized from benzyl mercaptan* and butyl mercaptan*, respectively. The general scheme for the synthesis of the vesicants is shown

$$RMgX \xrightarrow{S^*} RS^*MgX \xrightarrow[H^+]{HOH} RS^*H \xrightarrow[ClCH_2CH_2OH]{NaOH}$$

$$RS^*CH_2CH_2OH \xrightarrow{HCl} RS^*CH_2CH_2Cl$$

A number of syntheses of these compounds containing isotopic sulfur have already been described.[8] The procedure employed by us in this investigation contains technical features which facilitated the handling of the small amounts of materials involved, and is, therefore, presented in some of its details.

The estimations of radioactivity were carried out essentially by the method of Henriques and coworkers.[9] The radioactivity of the sulfur in the vesicants used to treat the proteins was sufficient to allow the detection of as little as 5×10^{-6} mg. of benzyl-H* or butyl-H* residues per milligram of protein sulfur in the protein derivative or its hydrolysis products.

The proteins utilized were crystalline insulin, crystalline pepsin and crystalline tobacco mosaic virus.

Insulin.—Insulin was selected for study particularly because of its unique physiological activity, and because a large amount of chemical data on the molecule is available. Furthermore, it has no known organic constituents other than amino acids.

Insulin was treated with benzyl-H* or butyl-H* in amounts ranging from 0.25 to 4.0 mg. of vesicant per 100 mg. of protein. This resulted in insulin-vesicant* preparations containing from 0.3 to

(7) An asterisk (*) is used to indicate the presence of radiosulfur in a compound.

5.3 vesicant residues[10] per molecule of insulin, as shown by the data of Table I (Preparations 1–9). It may be pointed out that the amount of vesicant which combined with the protein depended upon the amount of vesicant applied. In fact, despite the sixteenfold variation in the amount of vesicant applied, the per cent. of the applied vesicant which combined with the insulin was approximately constant (*ca.* 50%).

Using a method which is essentially that employed by Scott[11] for the crystallization of insulin, it was possible to obtain from an insulin-benzyl-H* preparation crystals of the alkylated protein. After recrystallization, this product contained an average of 1.1 vesicant residues per molecule of protein. It is of interest that the product, when tested in rabbits, displayed considerable hypoglycemic activity.

Pepsin.—Crystalline pepsin was dissolved in 0.05 *M* borate buffer (*p*H 7.4) at a concentration of 20 mg./cc. and treated with benzyl-H*. From the data of Table I (Preparation 10), it can be seen that pepsin combined with approximately 35% of the vesicant.

Tobacco Mosaic Virus Protein.—The early reports of Berenblum[5b] on the susceptibility of nucleoproteins to precipitation by mustard gas indicated the desirability of studying the nature of the reaction of vesicants with nucleoproteins.[12] As a protein for study, we selected tobacco mosaic virus (TMV). This material contains 6% of nucleic acid. The protein has a unique amino acid composition, being devoid of histidine as well as methionine, and possessing a small content of cysteine, which, however, is not detectable chemically except after denaturation.[13] Furthermore, the intact protein has a unique and readily measurable biological activity which might be of help in characterizing the changes brought about by vesicant treatment.

Treatment of TMV with various amounts of benzyl-H* or butyl-H* (Table I, Preparations 11–14) resulted in the attachment of 25–40% of the applied vesicant to the TMV. Because of the enormous molecular weight of the virus, even the lowest level of vesicant applied (0.25 mg./100 mg. of TMV) resulted in the substitution of approximately 260 vesicant residues per virus molecule.

Through the kindness of Dr. W. M. Stanley and Dr. L. O. Kunkel, we were able to obtain tests of the biological activity of Preparations 11 and 13.

The determination of the virus activity was carried out on 34 half-leaves of *N. glutinosa*, and the samples were inoculated at a concentration of 10^{-5} g./cc. As a control, buffered solutions of a sample of virus and a sample of benzyl-H* were stirred separately and then combined and dialyzed. This control sample was found to be as active as the original virus and was used as the standard. Preparation 11 possessed 93% of the activity of the control sample, while Preparation 13 showed 52% of the activity of the control.

From these results, it may be concluded that Preparation 11 was not appreciably inactivated, while Preparation 13 had only about half of the activity of the control. These samples contained, respectively, 1500 and 3200 vesicant residues per virus molecule. Apparently, then, treatment leading to the addition of approximately 1500 vesicant residues to reactive groups of the protein caused no appreciable inactivation, while treatment resulting in the substitution of an additional 1700 groups caused 50% inactivation.

Preparation 11 was also tested for the production of mutants. Each of 225 plants was inoculated with material from a different lesion produced in *N. glutinosa* by the control sample of virus, and each of 225 more plants with material from a different lesion produced by benzyl-H*-treated virus. Of the plants inoculated with the control virus, 196 became diseased, and 4 of these were atypical, resulting apparently from mutants. Of the plants inoculated with the vesicant-treated virus, 174 became diseased, and 5 of these appeared atypical. Thus, the vesicant treatment which resulted in the substitution of approximately 1500 vesicant residues caused neither inactivation nor mutation of the virus to an extent detectable by the tests employed.

Experimental

Benzyl β-Chloroethyl Sulfide (Benzyl-H*) Containing Radiosulfur.—Barium sulfate*[14] was reduced to barium sulfide* by a procedure similar to those which have already been described.[15] Dried barium sulfate* (116 mg.) was spread in a thin layer on a platinum boat and placed in a Vycor tube. The air was expelled by a stream of hydrogen and the Vycor tube was heated at 900–1000° for two hours and then allowed to cool, a slow stream of hydrogen being maintained throughout the reduction. The issuing gases were bubbled through an absorption train consisting of 6 cc. of 0.5 *N* sodium hydroxide in a small test-tube and 1 cc. in a second tube.

The boat containing the barium sulfide* was placed along with 5 mg. of zinc dust in a 125-cc. ₹ 24/40 Erlenmeyer flask equipped with a separatory funnel and a delivery tube. The delivery tube was attached to the sodium hydroxide absorption train used with the reduction of the barium sulfate* and the apparatus was swept with oxygen-free nitrogen. Twenty cubic centimeters of 6 *N* phosphoric acid, which had been boiled with about 5 mg. of zinc dust to expel air and cooled somewhat, was placed in the separatory funnel. This acid was dropped onto the barium sulfide* at such a rate as to produce a slow evolution of hydrogen sulfide*, which was absorbed in the

(10) These values represent a statistical average of the number of vesicant residues per molecule in the particular preparation, and are not intended to indicate that every molecule contains this number of residues.

(15) Cooley, Yost and McMillan, THIS JOURNAL, **61**, 2970 (1939); Boursnell, Francis and Wormall, *Biochem. J.*, **40**, 743 (1946); Henriques and Margnetti, *Ind. Eng. Chem., Anal. Ed.*, **18**, 476 (1946).

sodium hydroxide scrubbers. When all the acid had been added, the reaction mixture was warmed slowly to its boiling point, allowed to cool in a stream of nitrogen and swept with nitrogen for one hour.

Fifteen cubic centimeters of 0.1 *N* iodine in potassium iodide and 1 cc. of concentrated hydrochloric acid were placed in a 50-cc. centrifuge cone. The 6 cc. of sodium sulfide* solution from the first scrubber was introduced at the bottom of the solution by means of a long slender pipet. The 1 cc. of solution from the second scrubber was used to wash the first and the washings were added to the iodine solution. The scrubbers were washed further with small portions of water until a nitroprusside or lead acetate test for the sulfhydryl group on the washings was negative. The portion of the transfer pipet coated with sulfur* was then broken off and placed in the iodine solution. After fifteen minutes the excess iodine was destroyed with a few drops of a freshly prepared solution of stannous chloride in 5 *N* hydrochloric acid. When the resulting suspension was allowed to stand overnight, the free sulfur* coagulated and was then collected by centrifugation. The precipitate was washed with water by centrifugation and decantation.

Ten cubic centimeters of purified *m*-xylene was added and the sulfur* was dissolved by boiling the mixture cautiously. The xylene solution was transferred to a 15-cc. centrifuge cone, washed first with a few cc. of the acid stannous chloride solution to remove traces of iodine and then with water. The traces of water in the xylene solution were removed by azeotropic distillation. The xylene solution was transferred to a 50-cc. centrifuge cone with xylene, evaporated to a volume of 5 cc. and cooled to room temperature under nitrogen. Five cubic centimeters of a 0.4 *N* solution of benzylmagnesium bromide in benzene was added. The tube was stoppered and allowed to stand overnight at room temperature.

The resulting suspension of benzylmercaptomagnesium bromide* was centrifuged and the excess Grignard solution was decanted. The solid was washed 3 times with 5-cc. portions of petroleum ether (b. p. 35°) by centrifugation and decantation. It was then suspended in petroleum ether (5 cc.) and cooled in an ice-bath under nitrogen. (A nitrogen atmosphere was maintained as long as benzyl mercaptan* was present.) One cubic centimeter of 5 *N* hydrochloric acid was added and the mixture was shaken until free of solids. The acid layer was separated by means of a pipet. The petroleum ether layer containing the benzyl mercaptan* was washed with two 1-cc. portions of water and the washings were added to the acid layer. The combined aqueous layers were extracted with 1-cc. portions of peroxide-free ether until the nitroprusside test for the sulfhydryl group was negative. The combined ether extracts were added to the petroleum ether layer. Then 1 cc. of an ether solution containing 36 mg. of ethylene chlorohydrin and 1 cc. of 1 *N* sodium hydroxide were added. The two layers were thoroughly mixed by bubbling the alkali through the organic layer with the aid of a pipet. The mixture was heated gently in a hot water-bath until the organic solvents had evaporated. If the aqueous solution was not alkaline or not free of mercaptan, additional alkali or additional ethylene chlorohydrin or both were added and warming was continued until all the mercaptan had reacted.

The benzyl β-hydroxyethyl sulfide* was extracted with one 5-cc., one 3-cc. and three 1-cc. portions of ether. In a 15-cc. centrifuge tube, the combined ether extracts were washed with 1 cc. of water. The ether solution was transferred to a Carius tube which was heated on a water-bath to remove the ether. The last traces of ether were removed by attachment to a water pump. Two cubic centimeters of petroleum ether and 3 cc. of concentrated hydrochloric acid were added to the residue. The tube was cooled, sealed and shaken at 65–70° for twenty-four hours; 2 cc. of petroleum ether was added and the petroleum ether layer was separated. The acid layer was extracted with three 2-cc. portions of petroleum ether. The combined petroleum ether solutions were concentrated at −40° and 10^{-3} mm. Toward the end of the concentration, crystals generally appeared. The last traces of petroleum ether were removed at 0° (10^{-3} mm.). If the product on melting was not perfectly colorless, it was distilled at 10^{-3} mm. and 40° onto a cold finger which was cooled to *ca.* −70° with a Dry Ice–cellosolve mixture. The apparatus was so arranged that after completion of the distillation the colorless product dropped into a cup. The product adhering to the cold finger was rinsed into a cup with 2 cc. of petroleum ether and this solution was transferred to a small weighing tube. The tube was connected to a distilling apparatus and cooled to −70°. The benzyl β-chloroethyl sulfide* crystallized and the petroleum ether was removed *in vacuo* at gradually rising temperatures up to 10°. The yield was 70–72 mg. (75–77%).

Anal. Calcd. for $C_9H_{11}ClS$: Cl, 19.0. Found: Cl, 18.9.

Butyl β-Chloroethyl Sulfide (Butyl-H*) Containing Radiosulfur.—Barium sulfate* (116 mg.) was converted to sulfur* and the sulfur* was dissolved in xylene in the manner described previously. To the dried, cooled solution in a 50-cc. centrifuge cone was added 40 cc. of a 0.6 *N* solution of *n*-butylmagnesium bromide in benzene. After three to four hours the tube was filled with petroleum ether (b. p. 50–60°) and the mixture was centrifuged. The supernatant liquid was decanted into a 100-cc. centrifuge tube. The residue of butylmercaptomagnesium bromide* was stirred with 25 cc. of petroleum ether and centrifuged. This supernatant liquid was added to the solution in the 100-cc. centrifuge tube and the volume was increased to 100 cc. with petroleum ether, whereupon an additional amount of precipitate was obtained. This was collected and added to the main residue. The combined precipitates were washed with 25 cc. of petroleum ether by centrifugation.

The butylmercaptomagnesium bromide* was suspended in a few cc. of petroleum ether, cooled in an ice-bath under nitrogen and treated with 2 cc. of 5 *N* hydrochloric acid. The mixture was transferred to a 30-cc. glass-stoppered flask with a little petroleum ether. The flask was shaken violently until the magnesium salts had dissolved. The hydrochloric acid was separated and the petroleum ether layer was washed with 2 cc. of water. The combined aqueous solutions were extracted with small portions of petroleum ether until a test for the sulfhydryl group was negative. To the combined petroleum ether layers in the 30-cc. flask were added 1 cc. of water containing 40 mg. of ethylene chlorohydrin and 1 cc. of 1 *N* sodium hydroxide.

The flask was shaken at room temperature for three to four hours until all the mercaptan had reacted. The aqueous layer was separated and the organic layer was washed with 2 cc. of water. The combined aqueous layers were extracted repeatedly with 1-cc. portions of petroleum ether. The combined petroleum ether layers were centrifuged and then were passed through an 8 × 50 mm. column of Permutit (Permutit according to Prof. Otto Folin, Eimer and Amend No. 901194). The product was then eluted with 25 cc. of dry benzene. The benzene solution was concentrated at room temperature under reduced pressure (water pump). The residue was distilled at 0° and 10^{-3} mm. onto a cold finger at −70°. The butyl β-hydroxyethyl sulfide* was transferred to a Carius tube with 2 cc. of petroleum ether, and 3 cc. of concentrated hydrochloric acid was added. The tube was sealed and shaken for twenty-four hours at 65°. The butyl β-chloroethyl sulfide* was then isolated in the manner described for the benzyl analog except that in this case the temperature was not raised above −40° (10^{-3} mm.) for removal of the last traces of petroleum ether. The product was usually analytically pure without distillation. The yield of butyl β-chloroethyl sulfide* was 33–46 mg. (44–62%).

Anal. Calcd. for $C_6H_{13}ClS$: Cl, 23.2. Found: Cl, 23.1.

Treatment of Insulin with Vesicants*.—Crystalline zinc insulin (500 mg.) was dissolved in 10 cc. of water by the slow addition of 4.5 cc. of 0.1 *N* hydrochloric acid. Five

cubic centimeters of 0.25 *M* borate buffer (*p*H 7.4) was added, followed by the dropwise addition with stirring of 5.5 cc. of 0.1 *N* sodium hydroxide. The final solution had a *p*H of 7.4.

Procedure A.—Samples (0.25–4.0 mg.) of benzyl-H* or butyl-H* were added to 5-cc. aliquots of the protein solution and the mixtures were stirred gently for twelve to twenty-four hours. The stirring was carried out in such a way as to disperse the vesicant in fine droplets throughout the protein solutions with minimal disturbance of the surface of the solutions. The reaction mixtures were then extracted with peroxide-free ether or were dialyzed against running water. Either treatment was found to remove practically all of the radiosulfur-containing material not precipitated by trichloroacetic acid. This procedure was used for Preparations 1–7 (Table I).

TABLE I

VESICANT*-TREATED PROTEINS

Prepn.	Protein	Vesicant*	Mg. ves. applied / 100 mg. protein	% Applied vesicant attached to protein	*M* Vesicant / *M* Protein[a]
1	Insulin	Benzyl-H*	0.25	55	0.3
2	Insulin	Benzyl-H*	2.0	55	2.4
3	Insulin	Benzyl-H*	4.0	50	4.3
4	Insulin	Benzyl-H*	4.0	50	4.3
5	Insulin	Benzyl-H*	2.0	55	2.4
6	Insulin	Butyl-H*	4.0	50	5.3
7	Insulin	Butyl-H*	0.25	55	0.4
8	Insulin	Butyl-H*	2.1	40	2.2
9	Insulin	Butyl-H*	1.6	50	2.1
10	Pepsin	Benzyl-H*	2.0	35	1.3
11	TMV	Benzyl-H*	2.0	35	1500
12	TMV	Butyl-H*	0.25[b]	40	260
13	TMV	Benzyl-H*	6.0	25	3200
14	TMV	Benzyl-H*	2.0	40	1700

[a] These ratios are calculated on the basis of the following molecular weights: insulin, 40,000; pepsin, 35,000; tobacco mosaic virus, 40,000,000. [b] In this experiment, the concentration of the protein solution was 40 mg./cc.; in all other experiments it was approximately 20 mg./cc.

Procedure B.—In this procedure, dilute, ethanolic solutions of the vesicant* (1.6–2.1 mg.) were added portionwise with stirring over a period of several hours to 5-cc. aliquots of the protein solution. The solutions were then dialyzed. Preparations 8 and 9 (Table I) were obtained in this manner.

Crystallization of Benzyl-H*-treated Insulin.—Preparation 5, after dialysis against running water for twenty-four hours, was transferred to a 25-cc. volumetric flask; 1 cc. of 0.1 *N* hydrochloric acid was added and the volume was adjusted to 25 cc. by addition of water. A 6-cc. aliquot of this solution (containing 24 mg. of vesicant*-treated insulin) was added to a solution consisting of 10.5 cc. of 0.67 *M* phosphate buffer (*p*H 7.15), 5 cc. of water and 0.84 cc. of 1 *N* hydrochloric acid. One cubic centimeter of zinc acetate solution (2.5 mg. of zinc), 2.1 cc. of acetone and 0.6 cc. of 1 *N* ammonium hydroxide were added. The *p*H of the solution was then adjusted to 6.2 with 0.1 *N* hydrochloric acid, and it was allowed to stand at 5° for twelve hours and at room temperature for twenty-four hours. The yield of crystalline material was 12 mg.; from a control experiment with untreated insulin, 16 mg. of crystals was obtained. The recoveries were thus 50 and 66%, respectively, of the total protein. The radioactivity of the vesicant*-treated protein indicated that it contained 1.5 benzyl-H* residues per molecule of insulin.

For recrystallization, 9 mg. of the crystals was dissolved in 1 cc. of 0.05 *N* hydrochloric acid. A small residue was removed by centrifugation. To the solution was added a slightly warmed mixture of 7.5 cc. of water, 7.5 cc. of phosphate buffer (*p*H 7.15) and 1.5 cc. of acetone. The mixture was centrifuged and the supernatant liquid was decanted. The *p*H of the supernatant was lowered from 7.1 to 6.1 by addition of 1 *N* hydrochloric acid and the solution was allowed to stand overnight at room temperature. A small amount of crystalline precipitate formed. This was collected, washed with water and then with absolute alcohol, and dried. The yield was approximately 2 mg. The radioactivity of this recrystallized sample indicated the presence of 1.1 benzyl-H* residues per molecule of insulin. The specific activity was thus 73% of that of the once-recrystallized material.

Treatment of Tobacco Mosaic Virus (TMV) with Vesicants*.—Preparations 11, 13 and 14 (Table I) were obtained by treatment of solutions of TMV (20 mg./cc.) in 0.05 *M* borate buffer (*p*H 7.5) with benzyl-H* (0.4–1.2 mg./cc. of protein solution) under conditions similar to Procedure A for insulin.

For Preparation 12, 1 g. of TMV was dissolved in 25 cc. of 0.25 *M* borate buffer (*p*H 7.5). To this solution, 1 cc. of an ethanolic solution of butyl-H* (2.5 mg.) was added in ten portions over a period of six hours with continuous stirring. The solution was then dialyzed against running water for twenty-four hours.

Acknowledgment.—The authors wish to thank Dr. G. H. A. Clowes for crystalline insulin, Dr. R. M. Herriott for crystalline pepsin, and Dr. W. M. Stanley for crystalline tobacco mosaic virus. They also wish to thank Mr. Roscoe C. Funk, Jr., for the microanalyses and for assistance with the radioactivity measurements. The authors would also like to take this opportunity to express their appreciation to Dr. Mary Elizabeth Wright for invaluable aid in the preparation of this manuscript.

Summary

A method is described for the synthesis of the mustard-type vesicants, benzyl β-chloroethyl sulfide (benzyl-H) and *n*-butyl β-chloroethyl sulfide (butyl-H), containing radiosulfur. Studies were made of the reaction of these radioactive vesicants with three highly purified proteins: insulin, pepsin and tobacco mosaic virus.

Chemical Studies on Vesicant-treated Proteins[1]

BY FREDERICK H. CARPENTER, JOHN L. WOOD,[2] CARL M. STEVENS[3] AND VINCENT DU VIGNEAUD

In a preceding paper[4] we have described the treatment of certain crystalline proteins (insulin, pepsin and tobacco mosaic virus (TMV)) with benzyl β-chloroethyl sulfide (benzyl-H*) and *n*-butyl β-chloroethyl sulfide (butyl-H*) containing radiosulfur.[5] The present report describes studies made on these vesicant*-treated proteins with the object of determining the nature of the attachment of some of the substituting groups.

The work of other investigators[6] on the nature of the linkages formed by the action *in vivo* of mustard gas on tissues had shown that a large percentage of the vesicant residues could be split from these tissues by alkali or heat. There was also evidence from the work of another Laboratory[7] that a large proportion of the vesicant residues bound to certain proteins by vesicant treatment *in vitro* could be removed by the action of alkali.

It was of interest to study in more detail the alkali lability of the linkages formed by the treatment of proteins with vesicant. For this purpose we used the vesicant*-treated protein preparations described previously,[4] which contained relatively minute amounts of vesicant* residues and were in this respect comparable to the tissue preparations.

A study was made of the effect of *p*H and temperature upon the rate of liberation of vesicant residues from two preparations of butyl-H*-treated insulin. These preparations contained 2.2 and 2.1 vesicant* residues[8] per mole of protein. The results are summarized in Table I and Fig. 1. Treatment with relatively strong alkali (Table I) liberated in a few minutes about 65% of the radiosulfur-containing residues in a form soluble in trichloroacetic acid; continued treatment up to fifty-two hours liberated very little more radiosulfur-containing material. Treatment with alkali under milder conditions (Fig. 1) demonstrated that the rate of liberation of radiosulfur-containing residues from butyl-H*-treated insulin was a function of both the *p*H and the temperature. At *p*H 9.5 (30°) and 11 (0°, 30°), the radioactive material was liberated initially at a rapid rate which decreased to a fairly constant value.

TABLE I

EFFECT OF ALKALI ON BUTYL-H*-TREATED INSULIN

Time, hr.	Radiosulfur liberated, % 1.2 *N* NaOH at 0°	0.1 *N* NaOH at 27°
0.25	65	57
0.75	64	67
3.00	67	71
5.00	68	71
52.00	75	75

The nature of the radiosulfur-containing residues split from vesicant*-treated insulin by alkali was also investigated. When the trichloroacetic acid solutions of the alkali-labile vesicant* residues from the above experiments were extracted with petroleum ether, the major portion of the radiosulfur-containing material was found to be in the organic solvent. These experiments were not carried further, but in similar experiments on benzyl-H*-treated insulin it was shown that, after treatment of the protein preparation with alkali, the portion of the radioactive material which could be extracted into ether consisted almost entirely of benzyl β-hydroxyethyl sulfide*. Identification of the compound* was accomplished through application of the "washing-out" technique. A known amount of non-radioactive benzyl β-hydroxyethyl sulfide was added to the ether extract as a carrier and the solution was treated with α-naphthyl isocyanate. The resulting urethan derivative was purified by successive recrystallizations to constant radioactivity. From the amount of radioactivity in this purified derivative, the amount of benzyl β-hydroxyethyl sulfide* present in the ether extract could be calculated.

A considerable proportion (30–50%) of the radiosulfur-containing residues could be split in an ether-extractable form from vesicant*-treated insulin by heating at 150° in neutral solution. Here again evidence was obtained that the residues consisted almost entirely of the hydroxy compounds ($RS^*CH_2CH_2OH$, R = C_4H_9— or $C_6H_5CH_2$—).

With benzyl-H*-treated pepsin (Preparation 10[4]), 95% of the radiosulfur-containing material could be extracted into ether after autoclaving the pepsin preparation at 150° for five hours, while

(8) These values represent a statistical average of the number of vesicant residues per molecule in the particular preparation, and are not intended to indicate that every molecule contains this number of residues.

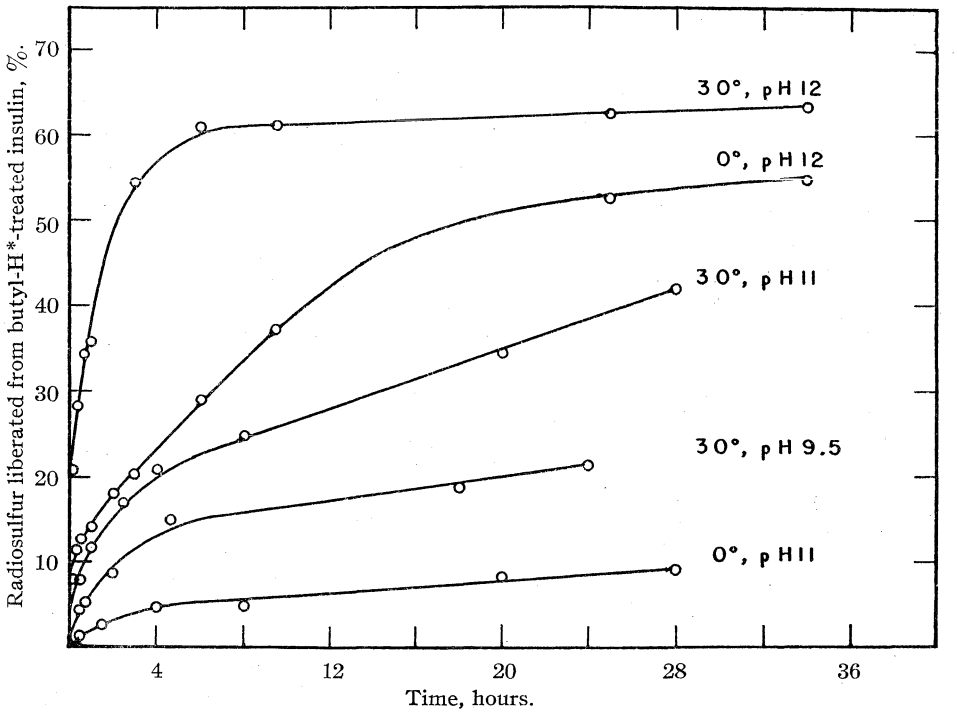

Fig. 1.—The liberation of radiosulfur-containing material, in a form not precipitated by trichloroacetic acid, from butyl-H*-treated insulin at various temperatures and *p*H levels.

70% of the vesicant* residues was liberated by treatment at *p*H 11 for three days.

We were interested in investigating vesicant*-treated TMV to determine what proportion, if any, of the vesicant residues was attached to the nucleic acid moiety. The nucleic acid which was separated from butyl-H*-treated TMV (Preparation 12[4]) was found to contain 5% of the radioactivity of the original TMV preparation. When it is recalled that TMV contains only 6% nucleic acid, it can be seen that the nucleic acid has "competed" quite effectively with the protein for the vesicant. In addition, it was noted that in the case of the nucleic acid moiety a smaller proportion of the vesicant* residues was attached through alkali-labile linkages than in the case of the protein moiety. Alkali treatment of the nucleic acid moiety liberated about 33% of the vesicant* residues, while similar treatment of the protein moiety resulted in the liberation of 86% of the vesicant* residues.

Experimental

Cleavage of Vesicant* Residues from Butyl-H*-treated Insulin Preparations by Treatment with Alkali.—In the general procedure employed, 1 volume of the appropriate buffer was mixed with 1 or in some cases 2 volumes of a dialyzed solution of a butyl-H*-treated insulin preparation.[4] The final concentration of insulin varied from 4 to 12 mg. per cc. The buffer and insulin solutions were brought to the same temperature before being mixed, and this temperature was maintained throughout the reaction. At noted time intervals after mixing, 1 cc. of the reaction mixture was withdrawn and delivered into 1 cc. of a 10% solution of trichloroacetic acid in 0.06 *N* hydrochloric acid. This served to stop the reaction and to precipitate the protein. (Control experiments had shown that treatment with trichloroacetic acid precipitated all the radiosulfur-containing material from the original vesicant*-treated insulin preparations.) The major portion of the protein precipitate was removed by centrifugation and the remainder by passing the supernatant liquid through a gravity micro filter. Analyses for radiosulfur[9] were carried out on the filtrate.

The rate of liberation of radiosulfur-containing material from Preparation 8[4] by treatment with alkali was determined under the following conditions: 1.2 *N* sodium hydroxide at 0° (Table I); 0.1 *N* sodium hydroxide at 27° (Table I); and 0.1 *M* borate buffer (*p*H 9.5) at 30° (Fig. 1). Similar studies were made on Preparation 9[4] in 0.1 *M* phosphate buffer (*p*H 12) at 0° and 30°, and in 0.1 *M* borate buffer (*p*H 11) at 0° and 30° (Fig. 1). The final *p*H of the reaction mixture was slightly lower than that of the buffer in some cases. The greatest decrease noted was that of 0.4 *p*H unit in the case of the *p*H 11 buffer.

Identification of Vesicant* Residues Liberated from Vesicant*-treated Insulin.—A solution of benzyl-H*-treated insulin (Preparation 4[4]; 18 mg.) in 1.8 cc. of 0.1 *N* sodium hydroxide was allowed to stand for seventy-two hours and was then extracted with ether. The ether layer contained 57% of the total radioactivity of the original benzyl-H*-treated insulin. To the ether extract were added 370 mg. of non-radioactive benzyl β-hydroxyethyl sulfide and 0.2 cc. of α-naphthyl isocyanate. The solution was evaporated to dryness and the residue was heated on a water-bath for five minutes. The resulting urethan derivative (β-(benzylmercapto)-ethyl 1-naphthalenecarbamate*) was recrystallized from hexane to constant radioactivity and melting point (86°).[10]

Anal. Calcd. for $C_{20}H_{19}NO_2S$: S, 9.50. Found: S, 9.96.

(9) The radioactivity estimations were carried out essentially by the method described by Henriques, Kistiakowsky, Margnetti and Schneider [*Ind. Eng. Chem., Anal. Ed.*, **18**, 349 (1946)].

(10) All melting points are corrected capillary melting points.

Radioactivity determinations on the purified derivative indicated that at least 90% of the ether-extractable radioactive material split from benzyl-H*-treated insulin by alkali was benzyl β-hydroxyethyl sulfide*.

Preparation 4[4] of benzyl-H*-treated insulin was treated with alkali under milder conditions (borate buffer; *p*H 9) for twenty-four hours. After extraction with ether, 17% of the initial radioactivity was found in the ether layer, and 95% of the radioactivity in the ether layer was shown to be due to the presence of benzyl β-hydroxyethyl sulfide*.

An aqueous solution of butyl-H*-treated insulin (Preparation 6[4]; 10 mg.) was heated at *p*H 6.5 in a sealed tube at 150° for five hours. The resulting solution was extracted with ether. The ether extract contained 30% of the radioactivity of the original protein solution. Nonradioactive *n*-butyl β-hydroxyethyl sulfide (92 mg.) and α-naphthyl isocyanate (0.1 cc.) were added to the ether solution. The mixture was evaporated to a sirup, heated on a steam-bath for a few minutes and extracted with hot hexane. When the hexane solution was cooled, the β-(*n*-butylmercapto)-ethyl 1-naphthalenecarbamate* crystallized. It was recrystallized to constant radioactivity. The product had a melting point of 74.5–75.5°; there was no depression in melting point upon admixture with a sample of the urethan prepared from authentic *n*-butyl β-hydroxyethyl sulfide.

Anal. Calcd. for $C_{17}H_{21}NO_2S$: S, 10.57. Found: S, 11.05.

The results of the radioactivity determinations indicated that 85% of the ether-extractable radioactive material split from butyl-H*-treated insulin by heat was *n*-butyl β-hydroxyethyl sulfide*.

Heating of benzyl-H*-treated insulin (Preparation 4[4]) under the same conditions resulted in the liberation of 53% of the radiosulfur-containing material in an ether-extractable form. In this case, 70% of the radioactivity in the ether extract could be accounted for as benzyl β-hydroxyethyl sulfide*.

Separation of Protein and Nucleic Acid Moieties from Vesicant*-treated Tobacco Mosaic Virus.—The procedure of Cohen and Stanley[11] was used to cleave the virus into nucleic acid and protein. An aliquot of a solution of benzyl-H*-treated TMV (Preparation 11[4]), which contained 1.25 mg. of virus per cc., was adjusted to *p*H 5.5 and made 0.1 *M* with respect to sodium chloride by the addition of salt. The solution was boiled for two minutes and cooled overnight. The precipitate of protein was collected, washed and analyzed for radiosulfur. It contained 84% of the radioactivity of the original benzyl-H*-treated TMV preparation. Control experiments indicated that protein separated in this manner contained less than 0.25% nucleic acid.

A cleavage experiment was also carried out using butyl-H*-treated TMV (Preparation 12[4]). The protein moiety was separated as a precipitate by the heat treatment described above. The supernatant liquid was made acid to congo red paper and the nucleic acid was precipitated by the addition of an equal volume of ethanol. The protein precipitate contained approximately 75% of the radioactivity originally present in the butyl-H*-treated TMV preparation, while the nucleic acid contained approximately 5% of the radioactivity of the original TMV preparation. The nucleic acid was dissolved as the ammonium salt, the solution was acidified, and the nucleic acid was reprecipitated with ethanol. The specific radioactivity of the nucleic acid was unchanged by this process.

The reprecipitated nucleic acid was treated with 5% sodium hydroxide for two hours at 0°, the solution was acidified and the nucleic acid was again precipitated with ethanol. The alkali-treated nucleic acid had a specific radioactivity equivalent to two-thirds that of the original nucleic acid, thus indicating that 33% of the vesicant* residues was attached to the nucleic acid moiety through alkali-labile linkages. The protein moiety was treated with 5% sodium hydroxide for two hours at 0° and then precipitated with trichloroacetic acid. Analyses for radiosulfur on the precipitate and the supernatant liquid indicated that 86% of the vesicant* residues attached to the protein moiety had been liberated by the action of alkali.

Acknowledgment.—The authors wish to thank Dr. Julian R. Rachele who supervised the radioactivity measurements and Mr. Roscoe C. Funk, Jr., who carried out the microanalytical procedures. They would also like to take this opportunity to express their appreciation to Dr. Mary Elizabeth Wright for invaluable aid in the preparation of this manuscript.

Summary

A study was made of the cleavage by alkali of the linkages between protein and vesicant residues in preparations obtained by the treatment of insulin, pepsin and tobacco mosaic virus with benzyl β-chloroethyl sulfide (benzyl-H) or *n*-butyl β-chloroethyl sulfide (butyl-H) containing radiosulfur. The extent of liberation of vesicant residues varied with the different proteins; in all cases, a certain fraction of the vesicant residues was not cleaved by the alkali under the conditions studied.

A more detailed investigation of the action of alkali on vesicant-treated insulin showed that the rate of liberation of vesicant residues was dependent upon the temperature and *p*H of treatment. Heating of vesicant-treated insulin at 150° in neutral solution also resulted in the liberation of vesicant residues.

By application of the "washing-out" technique to the radiosulfur-containing material cleaved from butyl-H- or benzyl-H-treated insulin, the cleavage product was demonstrated to consist mainly of the corresponding alkyl β-hydroxyethyl sulfide.

Studies on vesicant-treated tobacco mosaic virus indicated that vesicant residues were attached to both the nucleic acid and protein moieties of the virus.

Studies on Acid Hydrolysates of Vesicant-treated Insulin[1]

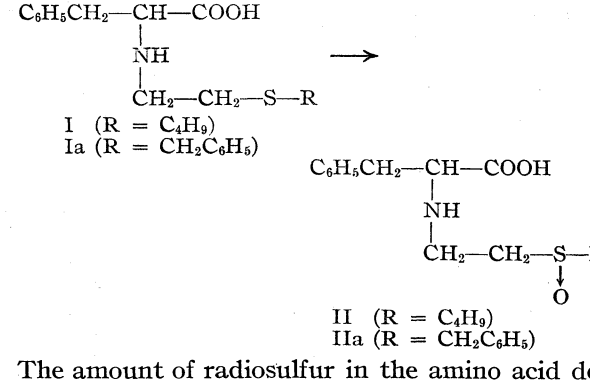
BY CARL M. STEVENS,[2] JOHN L. WOOD,[3] JULIAN R. RACHELE AND VINCENT DU VIGNEAUD

The treatment of insulin with benzyl β-chloroethyl sulfide (benzyl-H*) and *n*-butyl β-chloroethyl sulfide (butyl-H*) containing radiosulfur[4] has already been described.[5] Studies on these vesicant*-treated insulin preparations, containing an amount of vesicant* residues comparable to that found in tissues at the site of a burn, have shown that approximately 30% of the vesicant* residues was bound to the protein through linkages that were relatively stable to alkali.[6]

The experiments discussed in the present communication were designed to determine whether the vesicant* had reacted with the free amino groups in the insulin molecule. If such a reaction had occurred, the resultant linkages would be expected to be not only relatively stable to alkali but also stable to acid. The presence of such linkages in the protein might then be detected by the isolation of N-substituted vesicant* derivatives of amino acids from the acid hydrolysates of vesicant*-treated insulin.

A preparation of butyl-H*-treated insulin which contained approximately 5 vesicant* residues[7] per molecule of insulin was hydrolyzed with acid under various conditions. The "washing-out" technique was used to test for the presence of vesicant* derivatives of amino acids in the hydrolysates. The non-radioactive vesicant derivative of a given amino acid[8] was added to the hydrolysate to serve as a "carrier." The reference compound was then isolated from the mixture and examined for radiosulfur. The absence of radiosulfur in the isolated material indicated that the compound in question was not present in detectable amounts in the original hydrolysate. The presence of radiosulfur in the isolated material was not in itself regarded as sufficient evidence for the existence of the radioactive form of the reference compound in the hydrolysate. However, if the specific radioactivity of the isolated derivative reached a value which remained constant through successive recrystallizations and through chemical conversion of the compound to a suitable derivative, it was concluded that the hydrolysate contained the vesicant* derivative of the amino acid in question.

Since Jensen and Evans[9] had obtained evidence that the amino group of some of the phenylalanine moieties in insulin was chemically reactive,[10] we examined a sulfuric acid hydrolysate of butyl-H*-treated insulin for the presence of N-(β-butylmercapto)-ethyl-phenylalanine* (I). The non-radioactive form of I was dissolved in the hydrolysate and the N-(β-butylmercapto)-ethylphenylalanine was isolated from the mixture and recrystallized. It was found to contain radiosulfur; the content of radiosulfur did not change through several additional recrystallizations or through conversion to the sulfoxide (II).



The amount of radiosulfur in the amino acid derivative was equivalent to 5% of the total radiosulfur of the original butyl-H*-treated insulin. When the same preparation of butyl-H*-treated insulin was hydrolyzed with a mixture of hydrochloric and formic acids, the radiosulfur content of the isolated and purified compound I was equivalent to 3% of the total radiosulfur of the original protein preparation. This observed discrepancy in values from the two types of hydrolyses casts doubt upon the quantitative aspects of the results. Accordingly they are interpreted only in a qualitative manner to indicate the presence of N-(β-butylmercapto)-ethyl-phenylalanine* (I) in the acid hydrolysate of butyl-H*-treated insulin.

It is conceivable that the phenylalanine derivative I was formed during the hydrolysis procedure and was not actually present in the original vesicant*-treated insulin. If this were the case, one would expect to be able to detect in these insulin hydrolysates vesicant* derivatives of other amino acids known to be present in insulin. Accordingly,

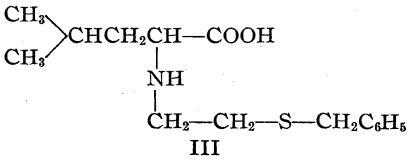
a hydrolysate of benzyl-H*-treated insulin was tested for the presence of N-(β-benzylmercapto)-ethyl-leucine* (III) by the "washing-out" technique. Despite the fact that insulin contains approximately 30% leucine, none of the leucine derivative III could be detected in the hydrolysate.



III

The possibility of the formation of new vesicant* molecules and their reaction with released amino acids or protein fragments during the hydrolysis of the insulin preparation was also investigated. When mixtures of benzyl-H* and phenylalanine or N-benzoyl-phenylalanine were treated with acid under conditions used for protein hydrolysis, no detectable amount of N-(β-benzylmercapto)-ethyl-phenylalanine* (Ia) was formed. Moreover, after a mixture of insulin and butyl-H* had been hydrolyzed together, the radioactive phenylalanine derivative I could not be detected in the hydrolysate.

It was also conceivable that there might be some transfer of the radiosulfur onto the "carrier" compound from vesicant* decomposition products in the hydrolysate of vesicant*-treated insulin. A mixture of non-radioactive N-(β-benzylmercapto)-ethyl-DL-phenylalanine (Ia) and benzyl-H* was treated with acid under the conditions of protein hydrolysis. The phenylalanine derivative Ia was isolated from the mixture and was found to contain radiosulfur. However, the radiosulfur was lost upon conversion to the sulfoxide (IIa).

Because of the interruption of this work by more pressing wartime studies, the investigations were not carried further. However, the data obtained strongly indicate that when a vesicant* derivative of an amino acid is found in a hydrolysate of vesicant*-treated insulin, the derivative was originally present in the protein preparation before hydrolysis and was not formed by subsequent reactions during the hydrolysis procedure. On this basis it may be concluded that when insulin was treated with a minute amount of vesicant at *p*H 7.4, a fraction of the vesicant became attached to the amino group of phenylalanine.

Experimental

Detection of N-(β-Butylmercapto)-ethyl-phenylalanine* (I) in Hydrolysates of Butyl-H*-treated Insulin.—One hundred milligrams of crystalline insulin was dissolved in 5 cc. of *p*H 7.4 borate buffer and the solution was stirred gently for twenty-four hours with approximately 4 mg. of butyl-H*.[5] The solution was extracted three times with ether, and the protein was precipitated by the addition of 2 volumes of 0.3 *N* trichloroacetic acid, ground with several portions of dry ether and dried *in vacuo*. A determination of radiosulfur[11] on this material showed it to contain 5.3 vesicant* residues per molecule of insulin (on the basis of a molecular weight of 40,000 for insulin).

In one experiment, 9.5 mg. of the butyl-H*-treated insulin was hydrolyzed by heating it in a sealed tube with 1 cc. of concentrated sulfuric acid and 4 cc. of water at 95–105° for four days. The hydrolysate was diluted to 5.3 cc. To 2 cc. of the hydrolysate was added 54 mg. of N-(β-butylmercapto)-ethyl-DL-phenylalanine[8] (I) and enough acetic acid to give a clear solution. Addition of 50 cc. of water caused the derivative to separate from the solution. The material was recrystallized and then analysed for radiosulfur. On successive recrystallizations of the material the radiosulfur content remained constant and was equivalent to 5% of the total radiosulfur originally attached to the insulin. Repetition of the experiment using 3 cc. of the hydrolysate and 96 mg. of the phenylalanine derivative I gave a similar result. A sample of the isolated radiosulfur-containing derivative I was then converted to the sulfoxide II by the procedure described below. The radiosulfur content of the sulfoxide was equivalent to that of the starting derivative I.

A second sample of the same butyl-H-treated insulin preparation (5 mg.) was heated with 1 cc. of a 1:1 mixture of hydrochloric and formic acids at 100° for six days. The solution was evaporated to dryness to remove the acids. The residue was dissolved in 5 cc. of water and 100 mg. of the phenylalanine derivative I was added. The solution was made 30% in acetic acid and was heated to boiling. After centrifugation to remove a small amount of insoluble material, the supernatant liquid was diluted with water. The derivative was recovered and recrystallized from dilute acetic acid. The radiosulfur content of the derivative was equivalent to 3% of the original radiosulfur in the protein preparation. The value did not change after four recrystallizations.

Test for N-(β-Benzylmercapto)-ethyl-leucine* (III) in a Hydrolysate of Benzyl-H*-treated Insulin.—One hundred milligrams of crystalline insulin was treated with 4 mg. of benzyl-H*[5] and then precipitated with trichloroacetic acid under conditions similar to those described above for the preparation of butyl-H*-treated insulin. Analysis for radiosulfur showed that 4.1 vesicant* molecules had combined with 1 molecule of insulin.

A portion of this preparation (20.4 mg.) was allowed to stand in 2 cc. of 0.1 *N* sodium hydroxide for thirty-six hours. The vesicant* residues that had been cleaved by the alkali were extracted into ether. Analyses for radiosulfur on the aqueous layer indicated that 1.4 vesicant* residues were attached to 1 molecule of insulin through linkages stable to this alkali treatment. Ten cubic centimeters of a 1:1 mixture of hydrochloric and formic acids was added to the aqueous layer and the resulting solution was heated at 100–110° for fifty hours. Aliquots of this hydrolysate were used for the experiments below.

To 1 cc. of the hydrolysate were added 79.5 mg. of N-(β-benzylmercapto)-ethyl-DL-leucine[8] (III), 1 cc. of glacial acetic acid, 1 cc. of hydrochloric acid and 3 cc. of water. The resulting solution was heated on the steam-bath for one and one-half hours, and then concentrated to dryness. The residue was recrystallized twice from 33% aqueous acetic acid. The resulting product did not contain a detectable amount of radiosulfur. From the sensitivity of the measurement, it was calculated that the hydrolysate contained less than 0.5% of its radiosulfur in the form of the leucine derivative III.

On the other hand, when 82 mg. of the N-(β-benzylmercapto)-ethyl-DL-phenylalanine[8] (Ia) was added in place of the leucine derivative III and the mixture was treated in exactly the same manner as that described above for the leucine derivative III, the purified phenylalanine derivative Ia contained an amount of radiosulfur equivalent to approximately 5% of that originally present in the hydrolysate.

Preparation of Sulfoxides.—N-(β-Butylmercapto)-ethyl-DL-phenylalanine (I) (100 mg.) was dissolved in 5 cc. of glacial acetic acid. Then 0.4 cc. of a 3% solution of hydrogen peroxide in acetic acid was added and the flask was warmed on the water-bath for one hour. The

(11) The analyses for radiosulfur were carried out essentially by the method of Henriques, Kistiakowsky, Margnetti and Schneider [*Ind. Eng. Chem., Anal. Ed.*, **18**, 349 (1946)].

solution was then concentrated to dryness. The resulting solid crystallized from 10 cc. of hot water in the form of needles, m. p. 208–210°.[12]

Anal. Calcd. for $C_{15}H_{23}NO_3S$: C, 60.6; H, 7.80. Found: C, 61.3; H, 7.97.

The sulfoxide of N-(β-benzylmercapto)-ethyl-DL-phenylalanine was prepared in exactly the same way except that the recrystallization in this case was from a large volume of aqueous acetone. The product melted at 219–220°.

Anal. Calcd. for $C_{18}H_{21}NO_3S$: C, 65.2; H, 6.39. Found: C, 64.9; H, 6.45.

Control Experiments. A.—In a series of experiments, DL-phenylalanine (68 mg.) was dissolved in 15 cc. of either 5 *N* hydrochloric acid, 30% (by weight) sulfuric acid, or a 1:1 mixture of 5 *N* hydrochloric acid and glacial acetic acid. Benzyl-H* (0.2–0.5 mg.) was added and the mixtures were heated at 100–110° for twelve to fifty-four hours. To each reaction mixture was added non-radioactive N-(β-benzylmercapto)-ethyl-DL-phenylalanine (Ia). The derivative Ia was isolated from the mixture, recrystallized, and analysed for radiosulfur. In no case did the isolated compound contain as much as 0.1% of the radiosulfur added as benzyl-H*.

B.—A mixture of N-benzoyl-DL-phenylalanine and benzyl-H* was heated in a 1:1 mixture of 5 *N* hydrochloric acid and glacial acetic acid. The phenylalanine derivative Ia was added, isolated from the mixture, and then analysed for radiosulfur. It contained less than 0.1% of the radiosulfur added as benzyl-H*.

C.—A mixture of 50 mg. of crystalline insulin and 1 mg. of butyl-H* was heated at 100° in 10 cc. of 5 *N* hydrochloric acid for forty-four hours. The mixture was diluted to 25 cc., and to an aliquot (2.5 cc.) were added 100 mg. of the phenylalanine derivative I and 2 cc. of 50% aqueous acetic acid. The derivative I was isolated from the mixture, purified, and analysed for radiosulfur. It contained no measurable amount of radiosulfur.

D.—The phenylalanine derivative Ia (0.53 g.) and benzyl-H* (0.38 g.) were heated under reflux for nineteen hours in 5 cc. of 5 *N* hydrochloric acid and 10 cc. of glacial acetic acid. When the reaction mixture was diluted with water to a volume of 100 cc. and cooled, the product separated. It was recrystallized from 45 cc. of 30% aqueous acetic acid to give 0.36 g. of product which contained 7.1% of the radiosulfur added to the reaction mixture as benzyl-H*.

A portion of this product (105 mg.) was converted to the sulfoxide by the procedure described above. After the sulfoxide had been recrystallized twice from hot water and once from 50% acetone, it had a melting point of 218–220°, and did not contain a detectable amount of radiosulfur.

(12) All melting points are corrected micro melting points.

Acknowledgment.—The authors wish to thank Mr. Roscoe C. Funk, Jr., for performing the microanalyses and for aid in the radioactivity measurements. They also wish to thank Dr. G. H. A. Clowes for supplying the crystalline insulin. They would also like to express their appreciation to Dr. Mary Elizabeth Wright for invaluable aid in the preparation of this manuscript.

Summary

Insulin which had been treated with a minute amount of *n*-butyl β-chloroethyl sulfide (butyl-H) containing radiosulfur was subjected to acid hydrolysis. By application of the "washing-out" technique, evidence was obtained for the presence of radiosulfur-containing N-(β-butylmercapto)-ethyl-phenylalanine in the hydrolysate. Various control experiments provided no evidence for the attachment of vesicant residues to the amino group of phenylalanine during the hydrolysis procedure. Therefore it was concluded that in the vesicant-treated insulin, a fraction of the vesicant had been attached to the free amino group of some of the phenylalanine moieties in the intact protein molecule.

Studies of the Effect of Mustard-type Vesicants on the Phenol Color Reaction of Proteins[1]

BY CARL M. STEVENS,[2] HERBERT MCKENNIS, JR.,[3] AND VINCENT DU VIGNEAUD

In the course of the wartime studies on the reaction of H (bis-(β-chloroethyl) sulfide) and H-type vesicants ($RSCH_2CH_2Cl$) with proteins, the action of Folin's phenol reagent[4] on vesicant-treated proteins was investigated. Herriott, Anson and Northrop[5] found that proteins which had been treated with vesicant at *p*H 6 gave less color with the phenol reagent at *p*H 8 than the corresponding untreated proteins. These investigators also noted that in most instances the chromogenic power of the vesicant-treated proteins toward the phenol reagent returned to normal after treatment with alkali for various lengths of time.

One possible interpretation of this phenomenon was that a chemical reaction had occurred between the vesicant and the tyrosine or tryptophan groups in the intact proteins, the subsequent action of the alkali being to cleave the linkages thus formed and to free the phenolic or indolyl groups for reaction with the phenol reagent.

(1) The work described in this paper was carried out under Contract OEMsr-144 between the Office of Scientific Research and Development and Cornell University Medical College and is described in Progress Reports to the National Defense Research Committee, December, 1942, to September, 1943.

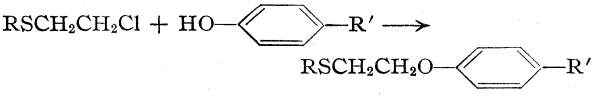
(5) Northrop, *et al.*, Informal Progress Reports to NDRC Section B4C (1942); for the published results of this work, see Herriott, Anson and Northrop, *J. Gen. Physiol.*, **30**, 185 (1946).

During the course of our wartime researches on the reaction of H-type vesicants with proteins,[6] we had prepared numerous derivatives of amino acids by their reaction with the one-handed vesicants, *n*-butyl β-chloroethyl sulfide (butyl-H) and benzyl β-chloroethyl sulfide (benzyl-H).[6b] In these studies we had found no evidence for a reaction of the vesicants with the indolyl group of tryptophan or with the phenolic group of tyrosine when the *p*H of the reaction mixture was in the range 6–8. However, in strongly basic solution the vesicants did react appreciably with the phenolic group of tyrosine to yield phenolic ethers of the type



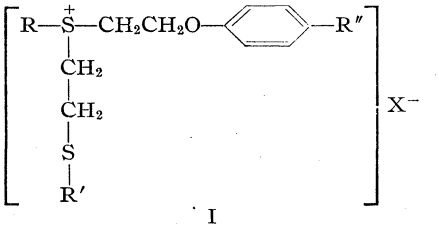
Phenolic ethers are in general very stable.[7] The stability of the O,N-disubstituted benzyl-H derivative of tyrosine to alkali was tested. After this tyrosine derivative was boiled for ten minutes in 0.5 *N* sodium hydroxide, the reaction mixture produced no color upon treatment with the phenol reagent. This result indicated that the linkage between the vesicant and the phenolic group of tyrosine was stable to alkali. In view of this stability, it was difficult to attribute the recovery of chromogenic power which followed alkali treatment of vesicant-treated proteins to cleavage of phenol-vesicant linkages.

In exploring other possible explanations for the behavior of the vesicant-treated proteins toward the phenol reagent, it occurred to us that the methods used by Miller[8] in studying the loss of chromogenic power toward the phenol reagent of tobacco mosaic virus upon treatment with various acylating agents might be applied to the study of the vesicant-treated proteins. Miller found that following treatment of the virus derivatives with sodium dodecyl sulfate in acid solution there was partial recovery of the chromogenic power toward the phenol reagent at *p*H 8 without any significant cleavage of acyl groups from the protein. He concluded that the amount of color produced by tobacco mosaic virus or its derivatives on treatment with the phenol reagent at *p*H 8 depended to a large extent on the degree of denaturation of the virus protein.

In the present publication, experiments are described which applied this concept to the vesicant-treated proteins. Pepsin and tobacco mosaic virus which had been treated with butyl-H gave a much smaller amount of color with the phenol reagent at *p*H 8 than did the untreated proteins. However, if the vesicant-treated or untreated proteins were first submitted to the action of Duponol C (sodium dodecyl sulfate) in acid solution and then subjected to the phenol reagent at *p*H 8, the same amount of color was produced from both the vesicant-treated and untreated proteins. Furthermore, it was possible to show that no significant amount of vesicant residues was liberated from vesicant-treated proteins by the action of Duponol C. These results demonstrate that the increase in the amount of phenol color from vesicant-treated proteins after the action of Duponol C is in all probability not due to the cleavage of vesicant residues from the tyrosine or tryptophan groups of the proteins. Thus it appears that the decreased chromogenic power of vesicant-treated proteins toward the phenol reagent at *p*H 8 is not due to the reaction of the vesicant with tyrosine or tryptophan groups in the protein molecule.[9]

This conclusion is in harmony with the results of the studies of Herriott, Anson and Northrop[5] on the nature of the alkali-labile linkages between vesicants and proteins. They were able to show that the number of free carboxyl groups lost from the protein upon treatment with H equalled, in several cases, the number of alkali-labile H residues bound to the vesicant-treated protein. Thus, not enough alkali-labile H residues were attached to the vesicant-treated protein to have combined both with the free carboxyl groups and the tyrosine phenolic groups of the protein.

Rydon,[10] in considering the decreased determinable phenolic groups of a vesicant-treated protein and the reversibility of this effect by alkali, suggested the possibility of the formation of sulfonium compounds[11] of the type I and their subsequent cleavage with release of tyrosine phenolic groups.



I

We have prepared such a compound (I, R = CH_3, R′ = C_4H_9, R″ = H) by the reaction of butyl-H with methyl β-phenoxyethyl sulfide and isolated it as the dilituarate. This compound gave almost no color with the phenol reagent at *p*H 8 either before or after treatment with Duponol C.

TABLE I

PHENOL COLOR VALUES[a]

Sample	Method A (Duponol + acid)	Method B (no treatment)	Method C (Duponol)	Method D (acid)	Method E (alkali-20°)	Method F (alkali-50°)
Tobacco mosaic virus	132	70	78	70	125[p]	135[p]
Butyl-H-treated tobacco mosaic virus	132	30[p]	52[p]	30[p]	38[p]	113[p]
Pepsin	191	190	195		200	204
Butyl-H-treated pepsin	188	106	179		199	102[p]
Dimethyl β-phenoxyethyl sulfonium iodide[b]	24	20[p]			335	
Methyl β-phenoxyethyl β-butylmercaptoethyl sulfonium diliturate[b]	21	20[p]			293	

[a] The figures given are the actual colorimeter readings. Under these conditions, a sample containing 0.02 mg. of tyrosine gave a reading of 75. [b] One cubic centimeter of an 0.001 *M* aqueous solution was used. [p] Samples thus marked indicate that a precipitate formed. In order that colorimetric determinations could be made, the precipitates were removed as completely as possible by centrifugation. It seems possible that precipitation may in some cases involve loss of reactive groups.

Experimental

Stability of the Benzyl-H Derivative of Tyrosine.—O,N-Di-(β-benzylmercaptoethyl)-L-tyrosine[6b] gave a negative test with Folin's phenol reagent[12] in alkaline solution. After the derivative had been allowed to stand in 0.5 *N* sodium hydroxide for one week at room temperature, or had been heated in the alkali for ten minutes at 100°, it still gave no color with the phenol reagent.

Reaction of Tobacco Mosaic Virus with Butyl-H.—A dialyzed solution of tobacco mosaic virus[13] (7.5 cc.) containing 300 mg. of virus was added to 7.5 cc. of 0.5 *M* sodium bicarbonate. To this solution was added 0.4 cc. of butyl-H and the mixture was stirred gently for seven hours. The resulting solution was shaken with ether and the aqueous layer was dialyzed against running water. This solution was diluted with 3 volumes of water; 0.2-cc. aliquots were removed and diluted to 1 cc. for use in the phenol color determinations.

Reaction of Pepsin with Butyl-H.—To 10 cc. of an aqueous solution of pepsin (1.2 mg. N/cc.)[14] was added 0.2 cc. of butyl-H. The mixture was stirred for one and one-half hours, the *p*H being kept at approximately 7 by the dropwise addition of 1 cc. of 0.5 *M* sodium bicarbonate. The aqueous layer was decanted and stirred gently with an equal volume of ether. The aqueous layer was then dialyzed, diluted to 20 cc., and 0.2-cc. aliquots were removed and diluted to 1 cc. for use in the phenol color determinations.

Determination of "Phenol Color Values."—The modified procedures utilized for the phenol color determinations were developed from the methods of Miller,[8] who used sodium dodecyl sulfate as a denaturing agent.

Method A.—One cubic centimeter of the unknown (containing a suitable amount of the protein or other material) was placed in a test-tube containing 0.2 cc. of a 10% solution of Duponol C.[15] One-tenth cubic centimeter of 0.2 *N* hydrochloric acid was added and the mixture was allowed to stand for fifteen minutes. Then 0.1 cc. of 0.2 *N* sodium hydroxide was added, followed by 0.6 cc. of water, 1 cc. of diluted phenol reagent and 2 cc. of phosphate buffer. The buffer was prepared by adding 10 cc. of 10% sodium hydroxide to 90 cc. of 0.5 *M* disodium hydrogen phosphate. The phenol reagent[12] was diluted so that 1 cc. mixed with 2 cc. of phosphate buffer and 1 cc. of water had a *p*H of 7.7 at the end of thirty minutes.

Method B.—The same as Method A except that 0.2 cc. of water was added in place of the Duponol C solution, and 0.2 cc. of 0.1 *M* sodium chloride was added in place of the acid and alkali.

Method C.—The same as Method A except that 0.2 cc. of 0.1 *M* sodium chloride replaced the acid and alkali.

Method D.—The same as Method A except that 0.2 cc. of distilled water was used in place of the Duponol C solution.

Method E.—One cubic centimeter of the unknown was added to 0.1 cc. of 0.2 *N* sodium hydroxide, and the mixture was allowed to stand for fifteen minutes at 20°. Then 0.1 cc. of 0.2 *N* hydrochloric acid, 0.8 cc. of water, 1 cc. of diluted phenol reagent, and 2 cc. of phosphate buffer were added in this order.

Method F.—Identical with Method E except that the treatment with alkali was at 50° rather than 20°.

In all cases the color was allowed to develop for thirty minutes at room temperature and then was estimated in a Klett–Summerson photoelectric colorimeter using the No. 54 (green) filter. The data are recorded in Table I.

Stability of Protein-Vesicant Linkages to Sodium Dodecyl Sulfate.—If vesicant residues were split from butyl-H-treated proteins by the action of Duponol C, the expected hydrolysis product[5d] would be *n*-butyl β-hydroxyethyl sulfide ($C_4H_9SCH_2CH_2OH$) (IV). Preliminary experiments showed that this compound could be extracted almost quantitatively from water by an equal volume of ether; after removal of the ether the amount of IV could be determined by Northrop's procedure[16] for the determination of mustard gas and related compounds. Since, in the case of the vesicant-treated proteins, no other ether-soluble compounds were likely to be present in the system, this method was considered to be quite specific for vesicant residues.

Samples (2 cc.) of the solutions of the vesicant-treated and untreated pepsin were added to 0.4 cc. of 10% Duponol C and 0.2 cc. of 0.2 *N* hydrochloric acid, and the resulting solutions were allowed to stand for twenty minutes. At the end of this period the liberated butyl-H residues were determined. The solutions were shaken for one minute with 2 volumes of peroxide-free ether; 1-cc. aliquots of the ether solutions were added to 2 cc. of water, and the ether was evaporated *in vacuo* at room temperature. One cubic centimeter of 2 *M* sulfuric acid and 2 cc. of water were added, and the solution was titrated by the procedure described by Northrop.[16] The untreated pepsin gave a titration value which was equivalent to approximately 0.01 mg. of butyl-H residues per 7 mg. of protein; this value was used as a blank. The vesicant-treated pepsin gave a corrected titration value equivalent to less than 0.02 mg. of vesicant residues per 7 mg. of vesicant-treated pepsin. If the increase in the phenol color value of the vesicant-treated pepsin after treatment with Duponol C were due to cleavage of the linkages between tyrosine and vesicant residues, it would require the liberation of approximately 0.2 mg. of butyl-H residues per 7 mg. of protein, a value ten times that actually found.

(12) Folin and Ciocalteu, *J. Biol. Chem.*, **73**, 627 (1927).

(13) This sample of virus was kindly supplied by Dr. W. M. Stanley.

(14) The pepsin was kindly supplied by Dr. R. M. Herriott.

(15) This Duponol C (du Pont) was stated to be 92% sodium dodecyl sulfate and 8% sodium sulfate. The suspension obtained upon dissolving the Duponol C in water was allowed to settle, and the clear liquid was decanted for use.

(16) Northrop, Informal Progress Report to NDRC Section B4C, July 23, 1942; for published method, see Ref. 5.

Identical experiments with solutions of vesicant-treated and untreated tobacco mosaic virus gave similar results. After the action of Duponol C on the vesicant-treated virus, a value of 0.01 mg. of vesicant residues per 7 mg. of virus was obtained.

These results demonstrate that the restoration of phenol color value in vesicant-treated pepsin and tobacco mosaic virus by the action of Duponol C is not accompanied by any appreciable degree of cleavage of vesicant residues from the proteins.

Dimethyl β-Phenoxyethyl Sulfonium Iodide.—This salt was prepared by treatment of methyl β-phenoxyethyl sulfide with methyl iodide under the conditions described by Crane and Rydon.[10,17]

Methyl β-Phenoxyethyl β-Butylmercaptoethyl Sulfonium Dilituratе.—Methyl β-phenoxyethyl sulfide (1.68 g.) and butyl-H (3.0 g.) were dissolved in 20 cc. of 95% ethanol. After four days, the mixture was diluted with 3 volumes of water and centrifuged. The upper layer was removed and treated with 3 volumes of a saturated aqueous solution of dilituric acid (5-nitrobarbituric acid). The light yellow prisms which separated were collected and washed with cold methanol and cold acetone. The product (1.5 g.) was purified by one recrystallization from acetone and two recrystallizations from methanol. The recrystallizations were carried out at a maximum temperature of 25° on account of the instability of the compound. The purified sulfonium salt melted on the hot stage with decomposition and evolution of gas at 120–130°.

Anal. Calcd. for $C_{15}H_{25}OS_2 \cdot C_4H_2O_5N_3$: N, 9.18; S, 14.01. Found: N, 9.18; S, 13.85.

Phenol Color Reactions of the Sulfonium Compounds.—The phenol color reactions of the sulfonium compounds are summarized in Table I. A very small amount of color was produced by the action of the phenol reagent at *p*H 8 on the sulfonium compounds; the amount of color produced remained unchanged after preliminary treatment with Duponol C. However, considerable color was produced with the phenol reagent after the compounds had been treated with alkali.

Acknowledgment.—The authors would like to take this opportunity to express their appreciation to Dr. Mary Elizabeth Wright for invaluable aid in the preparation of this manuscript.

Summary

A study has been made of the decreased chromogenic power toward Folin's phenol reagent at *p*H 8 displayed by pepsin and tobacco mosaic virus which had been treated with *n*-butyl β-chloroethyl sulfide (butyl-H). After treatment with sodium dodecyl sulfate (Duponol C), the vesicant-treated and untreated proteins give the same amount of color with the phenol reagent. Moreover, no significant amount of vesicant residues is liberated by the action of Duponol C on the vesicant-treated proteins.

It is concluded that the increase in the amount of phenol color from these vesicant-treated proteins after the action of Duponol C is not due to the cleavage of vesicant residues from the tyrosine or tryptophan groups of the proteins. It is further concluded that the decreased chromogenic power of vesicant-treated proteins toward the phenol reagent at *p*H 8 is not due to reaction of the vesicant with the tyrosine or tryptophan groups in the proteins.

The Reaction of α-Methylstyrenes with Thioglycolic Acid

BY CHEVES WALLING, DEXTER SEYMOUR AND KATHERINE P. WOLFSTIRN

Studies of the relative reactivities of meta- and para-substituted styrenes[1] and α-methylstyrenes[2] with free radicals derived from copolymerizing monomers have been useful in determining the nature of the "alternating effect" in copolymerization. An entirely similar approach may be made to the study of the nature of the attack of solvent radical on monomer in the chain transfer reaction.[3] This paper presents an investigation of the relative reactivities of six meta and para substituted α-methylstyrenes toward the radical $\cdot SCH_2COOH$ derived from thioglycolic acid.

Since the transfer constant for an α-methylstyrene with thioglycolic acid is very large,[4] when two α-methylstyrenes are heated with thioglycolic acid in the presence of a free-radical catalyst, virtually the only reaction by which styrenes will be consumed will be by reaction with the $\cdot SCH_2COOH$ radical (to give, eventually, β-phenylpropylmercaptoacetic acid), and the kinetic equations will be identical with those for the system of two α-methylstyrenes and maleic anhydride.[2] *I.e.*, $d[M_1]/d[M_2] = k_1[M_1]/k_2[M_2]$ where M_1 and M_2 represent the two styrenes and k_1 and k_2 the rate constants for their reaction with the mercaptide radical.[5] Calculations of relative reactivities including the determination of experimental errors were, accordingly, carried out as described previously.[2]

Experimental

Materials.—Thioglycolic acid was obtained by fractionating commercial material. Its physical constants were b. p. 79–80 (1 mm.), m. p. −17.5 to −15.5°. The α-

(3) Mayo, *ibid.*, **65**, 2324 (1943).

(4) The styrene radical reacts with ethyl thioglycolate 58 times as readily as with styrene. *Cf.* Gregg, Alderman and Mayo, *ibid.*, in press. Since α-methylstyrene shows relatively little tendency to polymerize with itself, its transfer constant with thioglycolic acid is presumably even larger.

(5) It is of interest that the equation describing chain transfer, in general, is a special case of the copolymerization equation in which the "monomer reactivity ratio" for the solvent is zero and the "transfer constant" is the reciprocal of the "monomer reactivity ratio" for the monomer considered.

methylstyrenes were portions of the same samples used in the maleic anhydride work.[2,6]

Technique.—Experiments were carried out using 0.1 mole of mixed styrenes, 0.05–0.1 mole of thioglycolic acid, and 0.14–0.18 millimole of benzoyl peroxide. Techniques of polymerization, isolation of unreacted monomers, and analysis were identical with those used with the maleic anhydride systems.[2] Results are listed in Table I.

Discussion

Relative reactivities of the six α-methylstyrenes toward the mercaptide radical from thioglycolic acid are listed in Table II, together with relative reactivities toward the maleic anhydride type radical, included for comparison. In each case, reactivities have been referred to α-methylstyrene as unity even though the actual comparison was with α,p-dimethylstyrene. Experimental errors have been taken as the standard deviation of separate experiments and are somewhat greater than those reported for the maleic anhydride study.[2] While they could doubtless be reduced by further refinement of technique, accuracy is ample for the discussion which follows.

TABLE II

RELATIVE REACTIVITIES OF α-METHYLSTYRENE TOWARD THIOGLYCOLIC ACID AND MALEIC ANHYDRIDE-TYPE RADICALS

Substituent	Reactivities toward Thioglycolic acid radical	Maleic anhydride radical[2]
p-OCH_3	215 ± 100	18.5
p-CH_3	2.28 ± 0.54	1.72

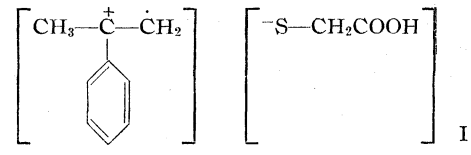
p-F	0.51 ± 0.13	0.72
p-Br	0.90 ± 0.56	0.73
m-Br	0.96 ± 0.56	0.96

(6) Seymour and Wolfstirn, *ibid.*, **70**, 1177 (1948).

Copolymerization studies[1,2] have shown that the reactivity of styrene toward carbonyl conjugated radicals is increased by substituents in the order p-CH_3 < p-OCH_3 < $N(CH_3)_2$, and that the effect of each substituent increases with the tendency of the monomer from which the attacking radical was derived to alternate in copolymerization with styrene. Table II indicates a similar effect of substitution on reactivity toward the $\cdot SCH_2COOH$ radical, but even greater than that encountered toward maleic anhydride, the most powerfully "alternating" radical studied.[7] In the copolymerization experiments, the effect was suggested as arising from the presence of special (chiefly non-bonded) resonance forms in the transition state in which an electron had been donated from the styrene to the carbonyl-conjugated molecule. Similar structures such as (I) can be postulated here and stabilization anticipated both from the many structures available to the styrene carbonium-ion radical and the electronegativity of sulfur (the mercaptide ion is an even weaker base than the enolate ion postulated as stabilizing the transition state in the copolymerization reaction[1,2]).



I

Heretofore, discussions of radical addition reactions have been directed entirely toward a consideration of the resonance stability of the radicals produced.[8]

However, in view of our knowledge of copolymerization phenomena,[9] important contributions of polar resonance forms to the transition state in the attack of other free radicals on double bonds should probably be anticipated whenever the radical may gain stability by electron donation or acceptance. Thus, for example, in the attack of a bromine atom on a double bond, contributions involving the bromide ion should be important, and relative reactivities of olefins in the free radical chain additions of both bromine and hydrogen bromide should parallel those observed toward the radicals from mercaptans and carbonyl conju-

(7) In this paper no competitive experiments using p-dimethylamino-α-methylstyrene were attempted as it was presumed that the ratio of reactivities would be too great to measure.

gated monomers, rather than an order based solely on radical stabilization.[9]

Summary

1. Relative reactivities of six α-methylstyrenes toward the $\cdot SCH_2COOH$ radical derived from thioglycolic acid have been determined.

2. Reactivities lie in the order p-OCH_3 > p-CH_3 > p-H $\gtrsim$ p-halogen and closely parallel those toward the maleic anhydride type radical observed in copolymerization. Results are interpreted in terms of contributions of non-bonded resonance forms to the transition state.

3. The possibility that contributions of polar (probably non-bonded) forms to the transition state may be important in a variety of free radical reactions is discussed.

The Use of S^{35} in the Measurement of Transfer Constants

BY CHEVES WALLING

The use of radioactive tracer elements as a method of end-group analysis should provide an elegant means of following chain transfer with solvents in polymerizing systems. This paper describes the measurement of the transfer constant of n-butyl mercaptan containing S^{35} with styrene, methyl methacrylate, methyl acrylate and vinyl acetate. While the work was undertaken primarily to gain experience in the use of radioisotopes in polymer chemistry, the results, taken with recent measurements of the absolute rate of the chain-growth step in polymerization of vinyl acetate,[1] styrene,[2] and methyl methacrylate,[2] give further evidence of the importance of ionic forms in the transition state of free radical reactions.

Method.—The fundamental measurement employed in this work has been the comparison of the radioactivity of samples of polymer carried to different degrees of conversion in the presence of the same amount of S^{35}-containing mercaptan. Since the maximum penetration of the soft β-radiation from S^{35} in ordinary polymers is under 0.2 mm., for thicker films of identical area (as obtained by the technique described below) measured activity is proportional to the concentration of —SR groups in the polymer and independent of film thickness.[3] Mathematically, this may be expressed in the form

$$\frac{[S]_0 - [S]_1}{[M]_0 - [M]_1} \Big/ \frac{[S]_0 - [S]_2}{[M]_0 - [M]_2} = R \qquad (1)$$

where R is the ratio of measured activities of polymer from two experiments and [M] and [S] are concentrations of monomer and solvent (mercaptan), respectively, present initially (subscript zero) and at the end of the two experiments (subscripts one and two). Recalling that the usual integrated form of the transfer equation is given by

$$\log [S]/[S]_0 = C \log [M]/[M]_0 \qquad (2)$$

where C is the "transfer constant,"[4,5] (1) may be rewritten as

$$R \frac{1 - [M]_1/[M]_0}{1 - [M]_2/[M]_0} = \frac{1 - ([M]_1/[M_0])^C}{1 - ([M]_2/[M]_0)^C} \qquad (3)$$

Using data giving R and yields from two experiments, C may, in principle, be obtained by graphical solution of (3). However, in cases where the transfer constant of the system is greater than unity,[6] the calculation can be greatly simplified by choosing as one of the samples for the determination of R a polymer which has been carried to complete conversion. Here, equation (3) reduces to

$$C = \log (1 - R + R[M]/[M]_0)/\log [M]/[M_0] \qquad (4)$$

Since the only quantities needed for the determination of transfer constants by the tracer technique are yields and relative activities, measurements of absolute amounts of transfer agent or molecular weights are unnecessary. The chief requirement is the use of enough mercaptan for measurement of its activity yet little enough so that material is produced which can be handled as polymer (rather than the simple addition product). Some judgment is required, also, in the selection of the extent of reaction to which monomer–solvent mixtures are carried before polymer isolation, particularly when a high transfer constant is anticipated. In Fig. 1 is plotted the variation of R with per cent. reaction for various values of C, and it will be seen that the rapid consumption of active solvents with large transfer constants makes high conversion experiments useless for evaluating C. This phenomenon, of course, applies to *any* method of measuring transfer constants and a useful generalization is that experi-

(6) Even in cases where the transfer constant is less than unity (so that complete inclusion of the mercaptan in the polymer is not assured, even when polymerization is carried to completion) equation (4) may be employed by using a reference sample of a different monomer carried to complete reaction. Also, it is frequently advantageous (when the transfer constant differs widely from unity) to employ a reference sample prepared in the presence of a different (but known relative) mercaptan concentration.

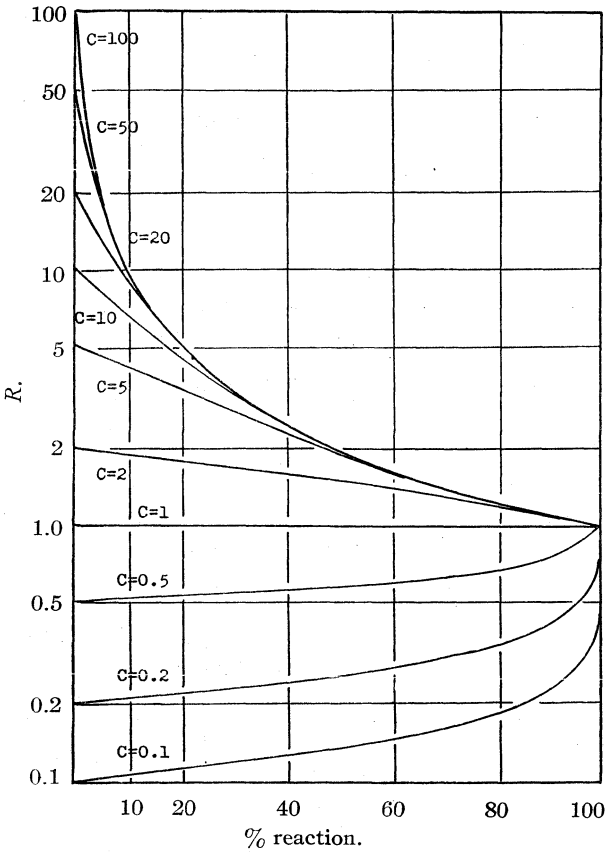

Fig. 1.—Variation of R, the relative activity of polymer samples, with % reaction for differing values of C, the transfer constant.

ments should not be carried to extents of reaction greater than the reciprocal of the anticipated transfer constant of the system. As a technique, the tracer method enjoys its greatest advantage in systems having a high transfer constant and in which the radioactive solvent is readily prepared, and should even compare favorably with titration of unreacted solvent[7,8] when the latter is possible. On the other hand in systems having low transfer constants (under $\sim$ 0.1) measurement by molecular weight determination is certainly to be preferred.[4,9]

Results and Discussion.—Experimental results and calculated transfer constants are listed in Table I. Experimental errors given are, in general, standard deviations of the separate experiments. For methacrylate, however, agreement seems fortuitously good and the error is taken as 5% of the measured value. Transfer constants for styrene and methyl methacrylate are in good agreement with the values reported for *n*-amyl mercaptan with these monomers (20 and 0.8, respectively) by W. V. Smith[7] and for other straight-chain mercaptans by Gregg, Alderman and Mayo.[8] Measurements at two temperatures with the methyl acrylate system indicate that the reaction of chain growth has a lower activation energy than chain transfer (by 600 calories), but, since it has a smaller PZ factor, proceeds more slowly. Although this is the reverse of the situation observed with styrene and mercaptans,[8] differences are too small to have much real significance.

TABLE I

TRANSFER CONSTANTS OF *n*-BUTYL MERCAPTAN SYSTEMS AT 60°

In an earlier paper[5] it was shown that a factor analogous to the "alternating effect" in copolymerization may be important in determining reactivity of olefins in simple free radical addition reactions. The data of this paper, taken with recent measurements of the absolute rates of the chain-growth reaction in vinyl polymerizations,[1,2] gives strong indication that similar forms are important in the conjugate reaction of chain transfer in which the radical from the olefin attacks the solvent, breaking a single bond. In Table II are listed rate constants for chain growth, transfer constants, and rate constants for reaction with *n*-butyl mercaptan for polymerizing styrene, methyl methacrylate, and vinyl acetate. Although in the general series of reactivities obtained from copolymerization studies methacrylate lies between styrene and vinyl acetate,[10] toward *n*-butyl mercaptan it has the lowest reactivity. In copolymerization[11] and addition of

[a] From Matheson, *et al.*,[2] in reasonable agreement with Bamford and Dewar[1c] (styrene) and Swain and Bartlett[1a] (vinyl acetate).

simple radicals to olefins[5] such anomalies have been explained on the basis of additional ionic forms in the transition state arising from electron transfer from radical to olefin or *vice versa*. In the present case, the analogous phenomenon would be contributions from non-bonded resonance structures such as

$$\underset{\text{I}}{R^+H\cdot{}^-S{-}R},\quad \underset{\text{II}}{R^+H{-}S^-\cdot R},\quad \underset{\text{III}}{R^+H{-}S\cdot{}^-R},\ \text{etc.}$$

if an electron were transferred from the attacking radical, and

$$\underset{\text{IV}}{R^-H\cdot S^+{-}R},\quad \underset{\text{V}}{R^-H^+\cdot S{-}R},\ \text{etc.}$$

if transfer were in the opposite direction. The heightened reactivity of styrene and vinyl acetate radicals (which are electron donors, rather than acceptors[10,11]) compared with methacrylate indicate that forms involving donation *to* the mercaptan are preferred, as might be expected from the relative electronegativities of sulfur and carbon. In short, in the case of a chain transfer reaction, as we have seen previously in copolymerization, certain structures increase the rates of both of two conjugate free radical reactions and give each more of an "ionic" character. Further confirmation is thus obtained for the suggestion made in previous papers from this laboratory that polar contributions to the transition state may be of importance in determining the effects of structure on reactivity in a great number of free radical reactions.

Experimental

Active *n*-Butyl Mercaptan.—This compound was prepared from active ZnS* by the sequence of reactions

$$ZnS^* \xrightarrow{HCl} H_2S^* \xrightarrow{H_2N{-}CN} NH_2CS^*NH_2 \xrightarrow{C_4H_9Br} C_4H_9{-}S^*{-}C(=NH_2^+)(NH_2)\ Br^- \xrightarrow[HCl]{NaOH} C_4H_9S^*H$$

Thiourea.—S^{35}, received originally as a trace constituent of potassium chloride supplied by the Clinton Laboratories of the Monsanto Chemical Company and subsequently diluted with inactive sulfur, was obtained from Dr. W. V. Smith of these Laboratories as a slurry of zinc sulfide in water containing some ammonia and zinc sulfate. Fifteen cc. of this suspension (containing approximately 2 mg. of sulfide sulfur and 30 microcuries of activity per cc.), 10 millimoles of inactive zinc sulfide, and 75 cc. of water were placed in a 500-cc. round-bottomed flask equipped with gas inlet tube, dropping funnel and reflux condenser. The gas inlet tube was attached to a hydrogen cylinder through a system consisting of a wash bottle containing sulfuric acid to act as a bubble counter and a side tube dipping into mercury serving as a safety valve. The exit tube of the condenser was connected to a Y-shaped reactor with a bottom limb of 10-cc. capacity containing a solution of 0.42 g. (10 millimoles) cyanamide (prepared from thiourea and mercuric oxide in ether, and purified by sublimation) in 5 cc. of 95% ethanol. The exit tube of the reactor led, in turn, to two wash-bottles in series each containing 10% zinc sulfate in 1:1 concd. ammonium hydroxide–water diluted five-fold.

After the entire system had been flushed with hydrogen, the reactor was cooled in liquid nitrogen and 60 cc. of 6 *N* hydrochloric acid added to the zinc sulfide slurry through the dropping funnel. Gradual heating of the slurry to boiling resulted in the smooth evolution of hydrogen sulfide and remaining traces were swept into the reactor by gently refluxing the mixture while slowly passing hydrogen through the system. Complete absorption was achieved, since no precipitate appeared in the wash-bottles. The reactor was next sealed off, warmed to −80°, shaken to insure solution of the hydrogen sulfide, and heated for twenty-four hours on the steam-bath. After cooling in liquid nitrogen, the reactor was opened and connected to a hydrogen source and two wash-bottles containing ammoniacal zinc sulfate. The reactor was then allowed to warm to room temperature, its contents refluxed for fifteen minutes, and finally swept slowly with hydrogen for an additional hour. Practically complete reaction was indicated since only a trace of precipitate appeared in the wash-bottles (pilot experiments in which the reactor was heated for three days at 60° gave a 67% yield of crystalline material), and, on cooling, beautiful needles of thiourea separated from the alcohol. For storage the thiourea was washed with additional alcohol into a 50-cc. volumetric flask.

Butyl Mercaptan.—In a 200-cc. flask equipped with dropping funnel and condenser which could be swiveled for either reflux or distillation was placed 10 cc. of the radioactive thiourea solution (*i. e.*, ~2 millimoles of thiourea), 0.76 g. (10 millimoles) of inactive thiourea and 3 cc. of butyl bromide, and the mixture refluxed for two and one-half hours under a hydrogen atmosphere. After cooling, the volatile material was distilled into a liquid nitrogen cooled trap under vacuum. With the condenser still in reflux position, hydrogen was readmitted and 10 cc. of *N* sodium hydroxide solution run in through the dropping funnel. The solution was then boiled for forty-five minutes to destroy the isothiourea. Next, the apparatus was arranged for distillation into a receiver consisting of a separatory funnel containing 10 cc. of chlorobenzene (chosen as an inert solvent with density greater than water), and 25 cc. of 0.5 *N* hydrochloric acid introduced through the dropping funnel.

Approximately half of the contents of the flask was now distilled, the receiver disconnected and shaken gently and the chlorobenzene layer run off into a small glass-stoppered bottle. The water layer was then extracted with the balance of 25 cc. of chlorobenzene and the chlorobenzene extracts all combined. Since experiments using inactive thiourea gave almost quantitative yields by this procedure, the chlorobenzene contained ~0.4 millimole mercaptan and 2 microcuries activity/cc. In the transfer experiments described in the next section the chlorobenzene solution was used directly without isolation or titration of the mercaptan since exact concentrations were not necessary. The absence of any contaminants which might interfere with the determination of transfer constants was shown by the good agreement of the constants for styrene and methyl methacrylate with those for *n*-amyl mercaptan and other normal mercaptans reported previously.

Transfer Experiments

Mixtures of freshly distilled monomer and mercaptan solution in mole ratios of 10 to 50:1, depending upon the expected transfer constant of the monomer, were placed in reaction tubes, degassed on a high vacuum line, sealed in absence of air, and heated for varying lengths of time in a 60° (or 30°) thermostat. In general, no catalyst

was added. With styrene the thermal polymerization proceeded at a convenient rate, while methyl acrylate and methacrylate apparently contained enough adventitious catalyst to effect reaction. Vinyl acetate samples were polymerized by irradiating with a mercury vapor lamp. Samples and heating times were chosen to yield 100–300 mg. of polymer. Methyl methacrylate and acrylate polymers were worked up by precipitating three times from ethyl acetate with petroleum ether in a 50-ml. centrifuge tube. The polymers were then redissolved in approximately 5 cc. of ethyl acetate and transferred in portions to tared aluminum dishes 26 mm. in diameter and 3 mm. deep and the solvent evaporated under an infrared lamp. The centrifuge tubes were washed with additional benzene and the dishes dried under the lamp overnight (approx. 8 in. from a 250-watt bulb was found to yield a smooth bubble-free film). Blank experiments showed that this treatment was adequate to remove all solvent, and yields were determined by weighing the dishes. Relative polymer activities were then measured by placing the dishes covered by a mask with a hole approximately 20 mm. in diameter under the thin mica window of a Radiation Counter Laboratories Mark I Model 2 Geiger–Mueller counter attached to an Instrument Development Laboratories Scaling Circuit. For the styrene and vinyl acetate experiments, the polymer isolation procedure was modified in that the partially polymerized samples were transferred to a large side-arm test-tube and unreacted monomer distilled off *in vacuo* at room temperature. The polymer was redissolved (in chlorobenzene or toluene, respectively) and the solvent again distilled off. This procedure was repeated twice more and the residual polymer transferred to an aluminum dish for counting.

Actually, for the determination of the relative activity, R, theoretical activities of completely polymerized samples were calculated from a completely polymerized polystyrene sample, correcting for differences in mercaptan concentration in the reaction mixtures and polymer densities. Thus the measured activity of the styrene sample was multiplied by 1.06/1.19 for comparison with methacrylate since, because polymethacrylate has a greater density, the measured β-radiation is coming from a thinner layer of the polymer surface. Counts of relative activities were always extended to several thousand impulses to avoid significant random variations and comparisons of any set of polymers with the standard were always carried out consecutively since background count and sensitivity of the instruments varied from day to day.

Acknowledgment.—The writer wishes to thank Dr. Herbert N. Campbell for aid in operating the electronic apparatus.

Summary

1. A convenient method for the synthesis of radioactive mercaptans from zinc sulfide containing S^{35} has been worked out.

2. The transfer constants of n-butyl mercaptan with styrene, methyl methacrylate, methyl acrylate and vinyl acetate have been measured using radioactive mercaptan, and the advantages of tracer methods in polymer chemistry are discussed.

3. The results are shown to indicate that ionic forms in the transition state, similar to those involved in radical addition reactions, may be important in determining reactivity in radical displacement reactions as well.

The Chlorination of Thiophene. II. Substitution Products; Physical Properties of the Chlorothiophenes; the Mechanism of the Reaction

BY HARRY L. COONRADT, HOWARD D. HARTOUGH AND GEORGE C. JOHNSON

The preceding paper[1] in this series reported the isolation and identification of chlorine addition products formed by the chlorination of thiophene. This paper describes the chlorine substitution products, reports their physical properties, and presents a mechanism for the reaction.

The substitution products formed by the chlorination of thiophene have been reported to be 2-chloro-,[2,3] 2,5-dichloro-,[2,3] 2,3,5-trichloro-,[2] and 2,3,4,5-tetrachlorothiophene.[2] In contrast with these results we have isolated and identified eight chlorine substitution products. The ninth and remaining possible substitution product, 3-chlorothiophene, was identified by infrared absorption spectrograms as present in small amounts.

The pure substitution products were separated by fractionation after the chlorine addition products had been removed. This prior removal or destruction of addition products generally was necessary because they decomposed into chlorothiophenes and hydrogen chloride during the course of the distillation and interfered with the fractionation. The method previously used[2,3,4] to destroy the addition products consisted of prolonged heating of the chlorination products with alcoholic potassium hydroxide. The preceding paper[1] described how addition products could be isolated from the reaction mixture. This had a pronounced effect on the ratio of the different substitution products.

The chlorine addition products were destroyed when chlorinated thiophene, like brominated thiophene,[5] was heated with solid sodium hydroxide or with potassium hydroxide. Calcium oxide was not effective. Other satisfactory procedures were prolonged pyrolysis or steam distillation of the reaction mixture from aqueous alkali or from a suspension of zinc or iron powder in water. Different

yields and ratios of substitution products resulted when different methods of converting the addition products were used.

The monochlorosubstitution product produced by the chlorination of thiophene (I) at 50° was 99.7% 2-chlorothiophene (II) and 0.3% 3-chlorothiophene (III). The latter was indicated to be present in the higher boiling monochlorothiophene fractions by infrared absorption at wave lengths characteristic of *beta*-substituted thiophenes. Chlorination of II gave a dichlorothiophene fraction of 99% 2,5-dichlorothiophene (IV) and 1% 2,3-dichlorothiophene (V). The far faster rate of substitution of α-hydrogen as contrasted with β-hydrogen was indicated by these two reactions. Substitution reactions occur less readily after both α-hydrogens have been replaced.

While the only dichlorothiophene previously reported from chlorinated thiophene was 2,5-dichlorothiophene (IV), fractionation of the reaction mixture revealed the other three possible dichlorothiophenes: 2,3-dichlorothiophene (V), 2,4-dichlorothiophene (VI), and 3,4-dichlorothiophene (VII). Direct and random substitution of thiophene cannot be the source of all of these isomers in view of the strong directive influence of the sulfur atom shown above. Further, if direct substitution were the only source of VII the yield would be limited by the intermediate III; but a much higher proportion of VII than of III was obtained.

The origin of these isomers was clarified by the study of the dehydrohalogenation of the chlorine addition products.[1] Pyrolysis of the α-isomer of 2,3,4,5-tetrachlorothiolane (XI) gave a dichlorothiophene fraction composed of about 50% V, 50% VI with a trace of IV and no VII. The same compound with ethanolic potassium hydroxide formed a dichlorothiophene fraction composed of approximately 54% VII, 44% VI, 2% IV and no V. Since XI consisted of at least two geometrical isomers, the composition of XI would also influence the ratio of isomeric dichlorothiophenes. *The principal source of V, VI and VII is, therefore, the dehydrohalogenation of tetrachlorothiolane.*

The structure of 2,5-dichlorothiophene (IV) has been established.[4] The general method of preparation of 2,3-dichlorothiophene reported[2] in the literature was used to prepare the compound for comparison with V. The structure of VII was established when further chlorination yielded a trichlorothiophene fraction consisting of 2,3,4-trichlorothiophene (VIII), rather than 2,3,5-trichlorothiophene (IX) which would be the expected isomer from the other dichlorothiophenes. The properties of VII also were in satisfactory agreement with those previously reported for 3,4-dichlorothiophene prepared by a different procedure.[2] VI, by elimination, must be 2,4-dichlorothiophene.

The proof of structure of the two isomeric trichlorothiophenes, VIII and IX, was necessary since their properties differed from those previously reported. Steinkopf and Köhler stated[2] that two substances which they believed to be 2,3,4-trichlorothiophene and 2,3,5-trichlorothiophene possessed amazingly similar physical properties, formed numerous derivatives with similar melting points, and gave no depression of the melting point when corresponding derivatives of the two compounds were mixed. Our results indicate that the two materials they studied were probably samples of the same isomer, VIII, of slightly different degree of purity. The structure of the two isomers obtained in the present study was indicated when chlorination of IV yielded a trichlorothiophene fraction composed solely of IX, thus indicating IX was 2,3,5-trichlorothiophene and VIII, by elimination, was 2,3,4-trichlorothiophene. Further evidence was that VIII reacted and IX did not react with mercuric chloride. This reaction is characteristic of thiophene compounds with an α-hydrogen atom.[4,6]

Since the principal dichlorothiophene formed in the reaction of thiophene with chlorine was 2,5-dichlorothiophene, it might be expected that the principal trichlorothiophene formed would be 2,3,5-trichlorothiophene. However, when the chlorination was conducted near room temperature and the product treated with solid alkali, the trichlorothiophene fraction was 98% 2,3,4-trichlorothiophene and 2% IX. The principal source of VIII cannot be a substitution reaction because the direct formation of its intermediate, VII, under these conditions is indicated to be small. In view of the dehydrohalogenation of 2,2,3,4,5-pentachlorothiolane (XII) to 65% VIII and 35% IX with ethanolic potassium hydroxide and the effect of the method of dehydrohalogenation upon the ratio of isomers,[1] *the mechanism accounting for the formation of most of VIII is the conversion of the reaction intermediate II to XII and subsequent alkaline dehydrohalogenation of the latter.*

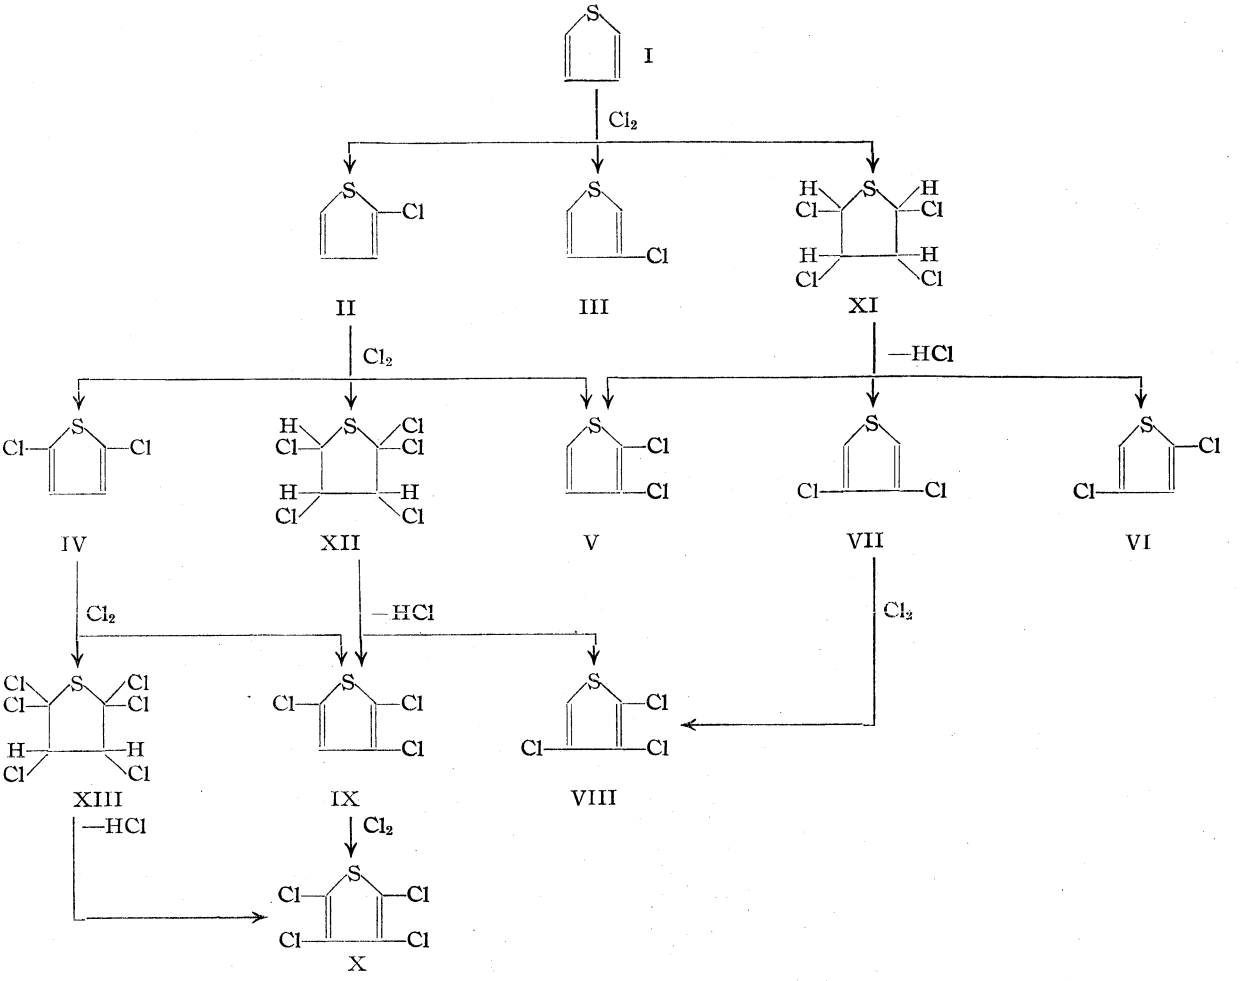
When chlorination at or near reflux temperatures and subsequent or concomitant pyrolysis was employed, however, the principal isomer obtained was IX, not VIII. This is in accord with the observation that pyrolysis of XII gave 92% IX and only 8% VIII. It was also found that the reaction intermediate IV could be converted to IX, preferably at elevated temperatures. *The source of IX in the chlorination of thiophene is thus both the dehydrohalogenation of XII and the direct substitution of IV.* Both of these reactions are favored by elevated temperatures.

The statement has been made[2,4] that trichlorothiophene was the most difficult of the substitution products to prepare since it was readily chlorinated further to 2,3,4,5-tetrachlorothiophene (X). However, it was found that IX was substituted by chlorine only with difficulty. For example, after a ten mole excess of chlorine was passed through

(6) Volhard, *Ann.*, **267**, 172 (1892).

TABLE I

ESTABLISHED CHLORINATION REACTIONS OF THIOPHENE



IX at 180°, 42% of IX was recovered unchanged. Furthermore, the other trichlorothiophene, VIII, arises mainly in the alkaline dehydrohalogenation reaction and forms only in minor amounts in the chlorination reaction itself.

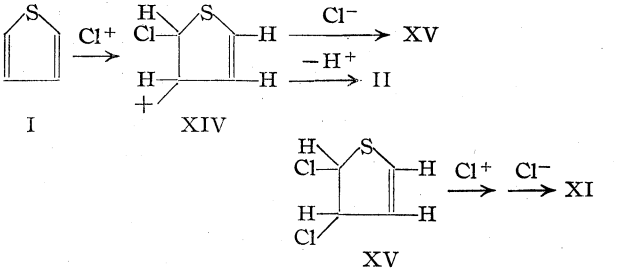
The yield and ratio of tetrachlorothiophene (X) and 2,2,3,4,5,5-hexachlorothiolane (XIII) is dependent upon the extent of chlorination and dehydrohalogenation. Extensive chlorination with concomitant pyrolysis gave a product containing 80% X and 14% IX. Extensive chlorination at lower temperatures, however, yielded primarily XIII. In the latter case substitution of IV was negligible and addition of chlorine to form XIII occurred. Dehydrohalogenation of XIII by pyrolysis or alkali yielded X.

A compound isolated in small yields from the still residues of products obtained by the action of excess chlorine on thiophene at elevated temperatures was identified as hexachlorodithienyl.[7]

(7) Eberhard, *Ber.*, **28**, 2385, 3302 (1895), reported the action of sulfuryl chloride on 2,2′-dithienyl gave 3,4,5,3′,4′,5′-hexachloro-2,2′-dithienyl, orange crystals, m. p. 189.5–190° (cor.).

Table I outlines the established parts of the course of the reaction of chlorine with thiophene in the absence of a catalyst.

Mechanisms have been postulated for the chlorination, alkaline dehydrohalogenation and pyrolysis. I adds first a positive chlorine ion to form a positive chlorothiolene ion (XIV) which either loses a positive hydrogen ion to give II or adds a negative chlorine ion to give a dichlorothiolene (XV) which then adds chlorine to form XI.



Similar ionic reactions account for the conversion of II to both IV and XII, and the conversion of

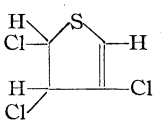
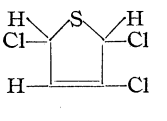
[a] Infrared analysis did not disclose the presence of any impurities in the specimen. [b] A second form freezes at −50.92°. [c] The properties are for a material containing 96 mole % 2,4-dichlorothiophene, 3% 2,5-dichlorothiophene and 1% 3,4-dichlorothiophene. [d] Infrared analysis showed a trace of 3,4-dichlorothiophene as impurity. *Anal.* Calcd. for C_4HCl_3S: Cl, 56.8; S, 17.0. Found: Cl, 57.0; S, 17.3. [e] *Anal.* Calcd. for C_4Cl_4S: Cl, 63.9; S, 14.5. Found: Cl, 64.2; S, 14.8. [f] Refs. 2 and 3 list m. p. 36°; ref. 14 lists 38°. These products were obtained by chlorination of 2,5-dibromothiophene. Repetition of this method using a large excess of chlorine gave a product, m. p. 51–52.5°, containing Br, 39.7%, Cl, 30.6%. The X froze sharply with a time–temperature cooling curve typical of highly purified materials.

IV to both IX and XIII. Ethanolic potassium hydroxide acts on the α-isomer of XI to effect the initial preferential elimination of the more negative α-chlorine ion and a β-hydrogen ion. This leads to the intermediate 3,4,5-trichloro-2-thiolene (XVI). XVI then loses α-chlorine and β-



XVI



XVII

hydrogen to give VII, or now since the chlorine on carbon atom four is allylic and more easily expelled, XVI also dehydrohalogenates in a different manner to give the other principal product VI. The mechanism of the pyrolytic dehydrohalogenation of the α-isomer of XI must differ from that of the ethanolic potassium hydroxide dehydrohalogenation in view of the greatly different products. The formation of the two isomers is consistent with the formation of 2,3,5-trichloro-3-thiolene (XVII) as an intermediate which dehydrohalogenates to V and VI.

Physical Properties.—The physical property data which have been obtained are collected in Table II. The methods used for the measurements of the physical properties have been described previously.[8] Some of the densities were determined with a 2-ml. pycnometer of the type described by Lipkin and co-workers[9] rather than by the suspended sinker method used before. The boiling points determined by measurements made relative to the freezing point of water and to the freezing point of tin were extensively checked by direct intercomparisons.

The chlorothiophenes dissolved at 25° in equal volume mixtures with *n*-heptane, diisobutene, cyclohexane, decalin, tetralin, benzene, thiophene, acetic acid, nitromethane, carbon tetrachloride, carbon disulfide, acetone, ethyl acetate, dioxane and *n*-propanol. The chlorothiophenes were not miscible with water, ethylene glycol or propylene glycol at 25°. The critical solubility temperatures of the chlorothiophenes lay close to 25° and varied from compound to compound in glycerol-α-mono-chlorohydrin, diethylene glycol, triethylene glycol, methanol and ethanol.

The chlorothiophenes changed from colorless to light yellow when stored for several months in partially filled bottles in diffuse light at room temperature. On boiling in air for a few hours a similar color change was noted. In both cases the change in refractive index did not exceed 0.0001.

Calculations from Table II show that substitution of a chlorine atom for a hydrogen atom at an α-position increases the molecular volume more than substitution at a β-position. This observation, together with arithmetic estimations, indicated that the molecular volume of 3-chlorothiophene at 20° is 91.73 ml. and d^{20}_4 1.292. Interpolations of the present data indicate that the previously reported values[2] are substantially correct for the b.p., 136–137°, and for the refractive index, n^{20}_D 1.5543 (calcd. from 22°).

It is believed that the values determined in this study supersede previously published determinations.[2,3,10–14] Most of the earlier preparations were made with very small quantities of materials with attendant difficulty.

Experimental

Chlorinations.—The conditions and results of nine chlorinations are given in Table III. Identification of products was made by the boiling points and by infrared absorption spectra.

Specimens for Physical Property Measurements.—The 2-chlorothiophene and 2,5-dichlorothiophene were first redistilled in a 10-theoretical plate column and then in a 90–95 theoretical plate column at a reflux ratio above 120:1. The 2,3-dichlorothiophene was made by chlorin-

ating 2-thiophenecarboxylic acid to 4,5-dichloro-2-thiophenecarboxylic acid and then decarboxylating the latter by the method of Steinkopf and Köhler.[2] The crude product, containing ether, acetic acid and 2,3-dichlorothiophene was distilled in a 28-theoretical plate column. The 2,3-dichlorothiophene fraction was shaken with sodium hydroxide solution to remove possible traces of acetic acid. The 2,4-dichlorothiophene and 3,4-dichlorothiophene were prepared from *alpha*-2,3,4,5-tetrachlorothiolane by dehydrohalogenation with ethanolic potassium hydroxide. After a preliminary fractionation in a 28-theoretical plate column at a 30–35:1 reflux ratio, each was redistilled in the same column. The 2,3,4-trichlorothiophene was redistilled in a 28-theoretical plate column. The 2,3,5-trichlorothiophene and 2,3,4,5-tetrachlorothiophene were each redistilled in a 25-theoretical plate column.

Acknowledgment.—The authors are grateful to Dr. D. E. Badertscher and Dr. C. C. Price for their advice and interest in this problem, to Mr. J. G. Ehlers for infared absorption spectra analyses, and to Miss Emily Burns for assistance in the laboratory work.

Summary

The substitution products formed by the reaction of chlorine with thiophene were investigated. Eight of the nine possible isomers were isolated. The remaining isomer, 3-chlorothiophene, was identified by infrared absorption spectrograms as present in small amounts.

Pronounced orientation during substitution in the thiophene nucleus was indicated by a monochlorothiophene fraction consisting of 99.7% 2-chlorothiophene and 0.3% 3-chlorothiophene. Similarly, chlorination of 2-chlorothiophene yielded a dichlorothiophene fraction composed of 99% 2,5-dichlorothiophene, 1% 2,3-dichlorothiophene and no 2,4-dichlorothiophene.

2,3-, 2,4- and 3,4-dichlorothiophenes were formed largely by the dehydrohalogenation of 2,3,4,5-tetrachlorothiolane and not by substitution. 2,5-Dichlorothiophene was formed by substitution.

2,3,4-Trichlorothiophene was prepared by low temperature chlorination and was formed largely after the chlorination by the action of alkali on 2,2,3,4,5-pentachlorothiolane. 2,3,5-Trichlorothiophene was prepared by high temperature chlorination and was formed both by the substitution of 2,5-dichlorothiophene and by the pyrolysis of pentachlorothiolane.

Tetrachlorothiophene was formed both by substitution of 2,3,5-trichlorothiophene and by pyrolytic or alkaline dehydrohalogenation of 2,2,3,4,-5,5-hexachlorothiolane.

Physical properties were determined on eight chlorothiophenes.

The Reversible Dissociation of *t*-Butyl Esters. Structural Effects and Reactions Mechanism

BY ROLF ALTSCHUL

The conversions of three carboxylic acids to the corresponding *t*-butyl esters by means of *i*-butene have been described in a previous paper.[1] Quantitative measurements defined this esterification as a reversible reaction, with its drive to the equilibrium state supported by catalytic amounts of sulfuric acid under anhydrous conditions in dioxane.

$$RCOOC(CH_3)_3 \underset{k_1}{\overset{k_2}{\rightleftharpoons}} RCOOH + CH_2{=}C(CH_3)_2 \quad (1)$$

The dissociation equilibrium constants K_d represent the relationship between the three components.

$$K_d = (\text{acid})(\text{isobutene})/(\text{ester}) \quad (2)$$

$$K_d = k_1/k_2 \quad (3)$$

The quantitative measurements in this present publication have been carried out on a larger series of esters to supplement the original exploratory data. This study has the dual objective commonly served by kinetics: its results permit a more accurate interpretation of the reaction mechanism, and they afford additional insight into the general problem of structure and reactivity in a manner to reveal a rigid law for some cases while facilitating at least semiquantitative predictions for all. In the outline below the experimental results will be tabulated first; their significance to the relationship between structure and reactivity will be discussed next, along with some conclusions about the elementary reaction steps.

Results

In Table I the K_d constants for seven esters are summarized. They were determined, as previously, by acidimetric and bromometric titrations of samples at equilibrium.[1] The pK_a values in the table refer to the known parent acid ionization constants.[2] These quantities as well as the k_2 data in the third column are included here for the subsequent discussion. The specific esterification rates (k_2) were computed by means of equation 3 from the experimental results for K_d and for k_1, the latter being summarized in Table II below. The K_d values above were substantiated later by readings on the equilibrated kinetic runs.

TABLE I

CONSTANTS FOR THE ESTERIFICATION OF CARBOXYLIC ACIDS WITH *i*-BUTENE IN DIOXANE CONTAINING 0.835 M./L. OF H_2SO_4, AT 25°

Ester	K_d m./l.	k_2 l./(hr. × m.)	pK_a
t-Butyl benzoate, I	0.68[a]	0.49[b]	4.203
t-Butyl *p*-nitrobenzoate, II	.28[a]	.24	3.425
t-Butyl acetate, III	.70[a]	.99	4.757
t-Butyl anisate, IV	.72	.82	4.47
t-Butyl *p*-chlorobenzoate, V	.35	.57	3.979
t-Butyl *m*-nitrobenzoate, VI	.44	.19	3.494
t-Butyl 3,5 dinitrobenzoate, VII	.11	.22	2.80

[a] These constants have been reported previously, *cf.* ref. 1. [b] This constant has been checked experimentally as reported below.

TABLE II

DISSOCIATION RATES OF *t*-BUTYL ESTERS IN DIOXANE CONTAINING 0.835 M./L. OF SULFURIC ACID AT 25°

Ester	Run	Method	k_1[a] (hr.)$^{-1}$	pk_1
I	..	Acidim., Manometr.	0.33[b]	0.48
II	8	Manometr.	.067	1.18
III	6H[c]	Acidim.	.69	0.16
IV	5	Manometr.	.59	0.23
V	10	Manometr.	.20	0.70
VI	6	Manometr.	.082	1.09
VII	11	Acidim.	.024	1.62

[a] These recorded k_1 constants are *corrected* values, the catalyst concentration varying within 1.5% of the indicated average value (0.835 m./l.). The corrections were easily applicable since k_1 has been previously determined as a function of sulfuric acid molarity (*cf.* ref. 1). The consequent shifts from the experimental values are small and insignificant even in the most extreme case. [b] This constant has been reported before, see ref. 3. [c] This run was carried out by Miss Joanne Herbert.

Manometric studies, based on the vapor pressure of *i*-butene, greatly facilitated the determinations of the k_1 rate constants in Table II. This method utilized a thermostated Van Slyke instrument; it has been described in detail before.[3] It could not be applied to the volatile ester III.

The preceding papers have described the mathematical analysis of the data to yield the rate constants.[1,3] All graphs were linear over the entire reaction course, thus precluding autocatalysis. The initial ester concentrations were selected according to considerations of maximum accuracy compatible with solubility requirements. The *primary* readings of typical runs are included in the experimental part.

An additional check on our formulations was afforded through the *experimental* constant k_2 for Compound I, for which the values of K_d and k_1 are most accurately known.[1,3] The calculated quantity (Table I) and the manometric measurement matched perfectly, better than the experimental accuracy would promise. Since this is our first experimentation with an esterification rate, the

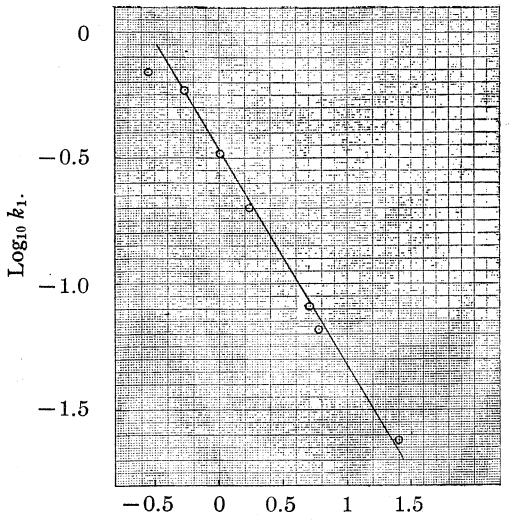

Fig. 1.—Evaluation of Hammett reaction constant for the dissociation rates of *t*-butyl esters in dioxane, containing 0.835 m./l. of sulfuric acid, at 25°: from left to right, compounds III, IV, I, V, VI, II, VII.

relevant data are fully reported in this publication (Table V). Over at least 80% of its course the addition reaction observes the linear relationship postulated by the mathematical function for a reversible bimolecular process.[4] The resulting rate constant is $k_2 = 0.49$ liter (moles × hours)$^{-1}$.

Interpretation.—The previously exposed nearly constant (k_1K_a) product[5] appears to prevail for all aromatic esters, over a forty-seven-fold

$$pk_1 + pK_a = 4.61 \pm 0.07 \qquad (4)$$

range of K_a constants within the indicated limits. This is perhaps relevant to the reaction mechanism,[1,6] for which the initiating step was written as a reversible conversion of the ester to its conjugate acid, necessary for the subsequent slow and rate-controlling dissociation.[7] The inverse function represented by Equation (4) above can be interpreted as progressively further displacements of the precursor equilibria to the left for the stronger carboxylic acids.

A more quantitative formulation is possible for the functional relationship between *Structure and Reactivity*. An apparent simple correlation, widely recognized between series of equilibrium or rate constants pertaining to reactions of para- or meta-substituted benzoic acid derivatives, has found its expression in the "Reaction Constants ρ" and "Substituent Constants σ."[8] Such rigid parallelism of reactivity is credited to identical entropy differences between reactants and products, thus reducing changes of chemical activity to elementary physical concepts, welcome and amenable in their simplicity.[9]

In line with the Hammett definition

$$\sigma = \log K_a - \log K_a^0 \qquad (5)$$

our substituent constants were computed either from the known K_a values (Table I), or were taken directly from the literature,[5] to be plotted against the logarithm of the k_1 constants. Our case exemplifies the fundamental relationship particularly well, as is evident from Fig. 1. The resulting reaction constant, derived graphically from the slope, $\rho = -0.841$. It is clearly relevant only to the aromatic esters, while the aliphatic compound III does not fall within the limitations of the rigid law.[10] The *negative* value of the reaction constant indicates least reactivity for the derivative of the strongest acid, in distinct contrast to other reaction of esters.[8]

Although all three series of constants (k_1, k_2, and K_d) rise with falling K_a values, this dependence is sensitive only for the k_1 data (Table I). For the others a ninety-fold depression of acidity effects only a 6.4-fold increase of K_d and a 4.5-fold increase of k_2 (compare III and VII). These differences are so small that a precise interpretation according to the Hammett formulation is incompatible with the relatively large experimental error.[1]

From a synthetic point of view, the K_d and k_2 constants are of course most essential, defining, as they do, the speed and extent of esterification with *i*-butene. Qualitatively speaking, the trend promises slightly *faster* yet *less complete* conversions for the *weaker* carboxylic acids.

Activation Energies.—In combination with preceding measurements at 35° the data provide for an estimate of the energies of activation for the dissociation of three esters in the presence of 0.835 m./l. of sulfuric acid.[1] Ester I, $\Delta E = 17$ kcal./mole[3]; Ester II, $\Delta E = 16$ kcal./mole; Ester III, $\Delta E = 20$ kcal./mole.

Experimental

Materials.—The previous batches of dioxane, 100% sulfuric acid and benzoic acid were used.[3] The esters were generally synthesized either by direct esterification of the carboxylic acids with *i*-butene,[1] or by the pyridine–acid chloride method.[6,11] Much of the relevant information is listed in Table III.

The solid esters were purified by crystallization, while distillations through all-glass distilling assemblies was applied to the liquids. Samples of esters prepared through the acid chloride were tested with alcoholic silver nitrate; the results were uniformly negative, with the exception of compound V which gave a very slow positive reaction,

presumably due to solvolysis of the nuclear-substituted halogen.

For more complete details as to synthetic procedures the previous publications should be consulted.[1]

Combustion analyses of the previously unrecorded esters IV, V and VI, were carried out by Dr. Carl Tiedcke: Calcd. for IV: C, 69.22; H, 7.75. Found: C, 69.71; H, 8.01. Calcd. for V: C, 62.11; H, 6.16. Found: C, 61.90; H, 6.10. Calcd. for VI: C, 59.21; H, 5.87. Found: C, 59.63; H, 5.96.

Quantitative Measurements. K_d Constants.—The previous technique was applied in all details. Samples of known initial molarities were stored in sealed ampoules in a thermostatic bath at 25 ± 0.1° until equilibrium was attained within a few days. They were then analyzed for the concentration of acid and of *i*-butene by means of acidimetric and by means of bromometric titrations, respectively.[1,3] The results are summarized in Table I in the text.

k_1 Constants.—Both the manometric and the volumetric methods have been outlined in detail before[1,3] and were followed throughout with only one minor change for the acidimetry involving compound VII, as follows: Aliquot samples were added to a slight excess of *warm* standard aqueous alkali. This prevented temporary precipitation of the organic acid, which, without this modification, tended to separate along with the ester and was slow to redissolve. After immediate rapid cooling, back-titration with standard hydrochloric acid followed as usual. Blank tests revealed absence of saponification under these conditions. The experimental results of two representative runs are tabulated below in the customary manner.

The terminology in the column heads of Table IV has been chosen in accord with the preceding publications[1,3]: p_i signifies the partial pressure of

The Q term stands for

$$Q = \frac{X + (X_e + c + K_d)}{X - X_e} \qquad (6)$$

to be substituted into the rate equation.[4]

Summary

The equilibrium and dissociation rate constants are reported for the acid-catalyzed reversible dissociation of seven *t*-butyl esters into the respective carboxylic acids and *i*-butene, in dioxane solution at 25°. The reverse esterification rate constant, determined experimentally in one case, matches the value calculated from the preceding data.

The relationship between these results and the known parent acid ionization constants, viewed in terms of the general problem of structure and reactivity, indicates faster yet less complete esterification for the weaker carboxylic acids. The dissociation rate constants yield to quantitative treatment, and the Hammett reaction constant is calculated graphically for the aromatic esters.

Additional clues for more intimate analysis of the reaction mechanism are interpreted.

Physical constants for three new *t*-butyl esters are presented.

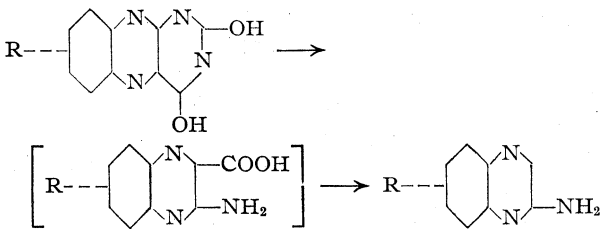
Substituted Sulfaquinoxalines. II. Some Derivatives and Isomers of 2-Sulfanilamidoquinoxaline[1]

BY F. J. WOLF, R. H. BEUTEL AND J. R. STEVENS[2]

In view of the promising chemotherapeutic action of sulfaquinoxaline[3,4] as well as its unique pharmacological properties,[5] the preparation of isomers and derivatives was undertaken.

The preparation of 6,7-dimethyl-2-aminoquinoxaline, 6(or 7)-chloro-2-aminoquinoxaline and a mixture of 2(and 3)-amino-5,6-benzoquinoxaline was carried out by degradative cleavage of the corresponding alloxazine under essentially the same conditions as those described in the literature for the cleavage of alloxazine[3] and substituted alloxazines.[6]



Only one of the two possible isomers was obtained when 7(or 8)-chloroalloxazine was cleaved; whereas, cleavage of benzalloxazine yielded 2- and 3-amino-5,6-benzoquinoxaline.

As the above method is not applicable to the preparation of 2-amino-3-alkylquinoxaline compounds, 2-amino-3-methylquinoxaline was prepared from 2-hydroxy-3-methylquinoxaline[7] by chlorination and amination of the resulting chloro compound.

Attempts to convert 2-hydroxy-3-methylquinoxaline into the amine by modifications of the Bucherer reaction were unsuccessful. However, when more rigorous conditions were applied to 2-hydroxyquinoxaline[8] the desired 2-aminoquinoxaline was obtained[9] in low yield.

In addition, the isomeric 5-aminoquinoxaline and 6-aminoquinoxaline[10] were prepared. The former was obtained from the reaction of 2,3-diaminoacetanilide with sodium glyoxal bisulfite followed by hydrolysis of the resulting 5-acetaminoquinoxaline to the desired product.

The amines were converted into the desired sulfonamides by the usual procedures and in addition the *p*-aminobenzoate of 2-aminoquinoxaline was prepared.

Acknowledgment.—The authors are indebted to Dr. R. T. Major and Dr. M. Tishler for their kind encouragement and advice.

Experimental

Alloxazines.—The preparation of 7(or 8)-chloroalloxazine is typical of the method.

7(or 8)-Chloroalloxazine.—A mixture of 60 g. of 4-chloro-2-nitroaniline and 200 g. of iron powder in 300 ml. of ethanol was stirred and refluxed and 12 ml. of 6 *N* hydrochloric acid was added dropwise during the first three hours. After eighteen hours the reaction mixture was filtered and concentrated *in vacuo*. The residue was dissolved in 135 ml. of 2.5 *N* hydrochloric acid and 400 ml. of water, heated to 85° and added to a solution of 50 g. of alloxan monohydrate in 400 ml. of water at 85°. The mixture was stirred for one hour at 85–90° (a yellow precipitate appeared almost instantly) and filtered. The precipitate, after washing with water and ethanol and drying, weighed 75.4 g. (88% yield based on the nitro compound). The product was sufficiently pure for degradation purposes and did not melt when heated at 360°.

2-Amino-6,7-dimethylquinoxaline.—7,8-Dimethylalloxazine[11] (lumichrome) is not attacked by prolonged boiling with 30% sodium hydroxide. It was cleaved to 2-amino-3-carboxy-6,7-dimethylquinoxaline by heating at 170–175° with concentrated aqueous ammonia.

[a] Based on 6-aminoquinoxaline.

A suspension of 28 g. of lumichrome in 150 ml. of 28% ammonia water was heated in bomb tubes at 170–175° for thirteen hours. The mixture was diluted with 10 volumes of water, heated to 90° and filtered. The amorphous orange precipitate was extracted with 300 ml. of hot 2 *N* ammonium hydroxide; the combined filtrates were acidified with acetic acid and the flocculent orange precipitate was filtered and dried. The product, 14.4 g. (60% yield), decomposed with evolution of gas at 215–220°.[12]

A mixture of 5.0 g. of crude 2-amino-3-carboxy-6,7-dimethylquinoxaline and 50 ml. of nitrobenzene was slowly heated to boiling. The elimination of carbon dioxide was rapid at first and was almost complete by the time the mixture had reached boiling temperature. The solution was refluxed for ten minutes, and the dark solution was allowed to stand for eighteen hours. The reaction mixture was filtered and the precipitate washed well with benzene. The combined filtrates were extracted three times with 25-ml. portions of 2.5 *N* hydrochloric acid. The aqueous extracts were combined, washed twice with benzene and made alkaline with sodium hydroxide. The crude product was filtered, taken up in 100 ml. of warm 2.5 *N* hydrochloric acid, treated with Darco G-60 and precipitated by the addition of 2.5 *N* sodium hydroxide. The yellow amorphous product, 2.97 g. (93% yield) melted at 270–273°. It was suitable for conversion into the sulfonamide compound. An analytical sample prepared by recrystallization from ethyl acetate melts at 275–278°.

Anal. Calcd. for $C_{10}H_{11}N_3$[13]: C, 69.35; H, 6.40. Found: C, 69.12; H, 6.67.

2(and 3)-Amino-5,6-benzoquinoxaline.—"Benzalloxazine,"[14] 60 g., was heated with 450 ml. of 28% aqueous ammonia at 175° for twelve hours. The reaction mixture was diluted with 2 l. of water, heated to 90°, treated with Norit and filtered. The filtrate was cooled and acidified with acetic acid, and the orange gelatinous precipitate was filtered and dried. The crude product, 15.5 g. (28.6% yield), melting with evolution of gas at 212–215°, was used in the next step.

The crude amino acid, 15.5 g., was decarboxylated as described for the 6,7-dimethyl derivative. The crude product, 8.0 g. (63.5% yield), was dissolved in 250 ml. of hot benzene. On cooling 5.4 g. of bright yellow material, m. p. 190–195°, was obtained. The mother liquor on concentration yielded solids 2.0 g., m. p. 140–180°. By fractional crystallization of the first crop, it was possible to obtain a low yield of analytically pure material, melting at 215–217°.

Anal. Calcd. for $C_{12}H_9N_3$: C, 73.89; H, 4.65; N, 21.52. Found: C, 73.79; H, 5.07; N, 21.64.

When the residue, obtained by evaporating the mother liquor from recrystallization of the second crop from benzene, was again recrystallized, evaporation of the mother liquor yielded a bright yellow analytically pure material, m. p. 150–152°.

Anal. Calcd. for $C_{12}H_9N_3$: C, 73.89; H, 4.65. Found: C, 73.91; H, 4.52.

The intermediate fractions contained most of the product and melted over wide ranges. Since preparation of either isomer in a pure state involved a large loss of material, the mixture was converted to the sulfonamides.

2-Amino-6(or 7)-chloroquinoxaline.—A mixture of 7.0 g. of 7(or 8)-chloroalloxazine and 30 ml. of 28% ammonia water was heated in a bomb at 165° for ten hours. The mixture was diluted with 10 volumes of water, heated to 90° and filtered. The filtrate was acidified with hydrochloric acid, and the gelatinous precipitate was filtered and dried. The crude product, 5.1 g. (81.5% yield), was difficult to purify and was used without purification in the next step. The compound melted with evolution of gas at 188–190°.

The amine was obtained when 4 g. of the crude amino acid was refluxed with 40 ml. of nitrobenzene for fifteen minutes. The product was extracted with dilute hydrochloric acid and precipitated with sodium hydroxide. The crude amine, 1.2 g. (37% yield) melted at 192–196° (skeleton unmelted at 225°). When 0.5 g. of the product was heated with 20 ml. of ethanol, 0.15 g. of insoluble material that did not melt at 400° was obtained. The ethanol filtrate when concentrated to 5 ml. and cooled yielded material, m. p. 193–195° (0.2 g.). An analytical sample, m. p. 197–200°, was obtained by sublimation at 150° in high vacuum.

Anal. Calcd. for $C_8H_6N_3Cl$: C, 53.50; H, 3.37; N, 23.39. Found: C, 53.36; H, 3.70; N, 23.19.

The amine was obtained more readily by cleaving 7(or 8)-chloroalloxazine with approximately 75% sulfuric acid. 7(or 8)-Chloroalloxazine was added to the solution obtained by mixing 50 ml. of water and 200 ml. of concentrated sulfuric acid. The mixture was heated to 200° as rapidly as foaming would allow and held at this temperature for twenty minutes and then poured on ice, and the solution was made strongly alkaline with sodium hydroxide. The precipitate, 7.0 g. (23% yield), was purified by dissolving in hot 1.3 *N* hydrochloric acid, treating with Darco G-60, and precipitating with sodium hydroxide. The product, 5.0 g. (16% over-all yield) melting at 198–199°, was used without further purification for the preparation of the sulfonamide derivative.

2-Chloro-3-methylquinoxaline.—200 ml. of phosphorus oxychloride was added to a refluxing mixture of 57.5 g. of 2-hydroxy 3-methylquinoxaline[7] and 300 ml. of benzene. After refluxing for two hours, most of the material had dissolved to give a dark purplish solution. The re-

(12) All melting points are uncorrected.

(13) Microanalyses were kindly performed by R. N. Boos, W. K. Humphry, E. H. Thornton and E. Meiss.

(14) Kuhn and Cook, *Ber.*, **70**, 761 (1937).

action mixture was added to a stirred mixture of 2 kg. of ice and water. The benzene layer was separated, and the water layer was extracted with six 250-ml. portions of benzene. The benzene extracts were combined, heated with 10 g. of Norit, and concentrated to dryness *in vacuo*. Recrystallization of the residue from ethanol gave the product (37.5 g.) in 52% yield, m. p. 84–86°.

Anal. Calcd. for $C_9H_7N_2Cl$: C, 60.50; H, 3.95. Found: C, 60.97; H, 4.61.

2-Amino-3-methylquinoxaline.—A mixture of 40 g. of 2-chloro-3-methylquinoxaline, 30 ml. of liquid ammonia and 250 ml. of absolute ethanol was heated for eight hours at 120°. The reaction mixture was evaporated to dryness *in vacuo*, and the residue was extracted with 200 ml. of warm 1.2 *N* hydrochloric acid. The insoluble non-reacted chloro compound weighed 8.0 g. The acid solution was filtered, heated with Norit for five minutes, filtered again and the crude amine precipitated with sodium hydroxide. The crude product was purified by recrystallization from 200 ml. of benzene, and the mother liquor was used for two extractions of the insoluble material, total yield 20.4 g. (70% of theoretical based on the chloro compound used), m. p. 163–165°.

Anal. Calcd. for $C_9H_9N_3$: C, 67.89; H, 5.70. Found: C, 68.20; H, 5.95.

5-Acetylaminoquinoxaline.—A solution of 6.0 g. of 2,3-dinitroacetanilide[15] in 150 ml. of methanol was shaken with hydrogen in the presence of Raney nickel catalyst until the reduction was complete. The reaction mixture was quickly filtered from the catalyst into a solution of 8.0 g. of sodium glyoxal bisulfite in 150 ml. of water. After removing the methanol and heating at 100° for one hour, the reaction mixture was cooled and made alkaline with 25 ml. of 2.5 *N* hydroxide. After cooling to 5° the product, 2.76 g. (55% yield), m. p. 131°, was obtained by filtration. Without further purification the product was converted into the amine.

5-Aminoquinoxaline.—A mixture of 2.5 g. of 5-acetylaminoquinoxaline and 25 ml. of 2 *N* sulfuric acid was heated one hour on the steam-bath, cooled and neutralized with sodium bicarbonate. After cooling to 5° the product was filtered and washed with ice-water, yielding 1.9 g. (87.5% yield) of bright yellow crystals, m. p. 92°.

Anal. Calcd. for $C_8H_7N_3$: C, 66.17; H, 4.86; N, 28.94. Found: C, 66.24; H, 4.78; N, 28.4.

2-*p*-Aminobenzamidoquinoxaline.—A mixture of 11.0 g. of *p*-nitrobenzoyl chloride and 8.5 g. of 2-aminoquinoxaline in 15 ml. of pyridine was heated on the steam-bath for one hour and poured into 170 ml. of water. The crude product, 13.6 g., was recrystallized from ethyl acetate. The purified material, m. p. 211°, weighed 7.8 g.

A suspension of 10 g. of the *p*-nitrobenzoate in 300 ml. of methanol was shaken with hydrogen in the presence of 2 g. of Raney nickel catalyst. The hydrogenation was stopped when 3.1 moles of hydrogen had been absorbed. After adding an equal volume of acetone the solution was filtered from the catalyst and concentrated to dryness *in vacuo*. The residue was dissolved in 50 ml. of 2.5 *N* hydrochloric acid, filtered from a small amount of insoluble material and precipitated by adding 1 *N* sodium hydroxide. The crude product, 7.9 g., was recrystallized from a mixture of equal parts of ethanol and ethyl acetate. The pure material, 5.5 g. (62% yield), melts at 229–230°

Anal. Calcd. for $C_{15}H_{13}ON_4$: C, 67.90; H, 4.58; N, 21.19. Found: C, 68.07; H, 4.73; N, 21.6.

Sulfonamides.—The amines were treated with *p*-acetylaminobenzenesulfonyl chloride in pyridine solution. The acetyl compounds were obtained in yields of 70–95%. The preparation of 2(and 3)-sulfanilamido-5,6-benzoquinoxaline is typical.

2(and 3)-[N⁴-Acetylsulfanilamido]-5,6-benzoquinoxaline).—At room temperature 5.6 g. of *p*-acetylaminobenzenesulfonyl chloride was added to a solution of 4.5 g. of 2(and 3)-amino-5,6-benzoquinoxaline in 25 ml. of pyridine. The mixture was stirred for one and one-half hours and then poured into 500 ml. of water. Heating and stirring the mixture made the gum that first separated solidify. The precipitate was filtered and dissolved in 200 ml. of 2 *N* sodium hydroxide and filtered from the insoluble material (0.2 g.). After being stirred for ten minutes with 1 g. of Norit, the solution was filtered and made acidic. The dried yellow product weighed 8.6 g. (95% yield). The acetyl derivatives were hydrolyzed with ethanolic hydrogen chloride.

2(and 3)-Sulfanilamido-5,6-benzoquinoxaline.—A mixture of 8.6 g. of the acetyl compound, 50 ml. of absolute ethanol and 25 ml. of concentrated hydrochloric acid was stirred and refluxed one and one-half hours. The solution darkened, and a reddish precipitate appeared. The mixture was poured into 300 ml. of water and 30% sodium hydroxide added until the solution was alkaline. After 2 g. of Norit was added the solution was heated to boiling, filtered, and the product precipitated by acidification with acetic acid. The light yellow powder weighed 6.0 g. (78% yield).

Summary

Isomers and nuclear substituted derivatives of 2-sulfanilamidoquinoxaline were prepared. The degradation of 7,8-dimethylalloxazine, 7(or 8)-chloroalloxazine and "benzalloxazine" to the corresponding 2-aminoquinoxaline has been carried out. The preparation of 2-amino-3-methylquinoxaline by another method has been described.

Some Physical Properties of 2-Picoline

BY HENRY FREISER[1] AND WILLIAM L. GLOWACKI[2]

Most of the work reported here was done as a part of an extensive program sponsored by the Koppers Company for the determination of physical constants of coal tar bases. A number of factors pointed to the need for this program. Interest in 2-picoline and other tar bases has mounted in recent years. Much of the physical constant data necessary for their full exploitation are either lacking or old. With large amounts of materials available it seemed desirable to purify 2-picoline carefully and redetermine its physical properties.

Purification of 2-Picoline.—Over two liters of commercial 2-picoline (Koppers Company 2° alpha picoline) was subjected to a careful fractional distillation at atmospheric pressure by means of a 40-in rectifying column of one-inch inner diameter, packed with 3/32 in. Fenske stainless steel helices. The temperature of the distilling picoline was measured with a single-junction copper–constantan thermocouple and a portable potentiometer. The product was collected at a rate of 30 ml./hr. Thirty-seven fractions of 50 ml. each, boiling within 0.1°, were collected. The distillate was protected from atmospheric moisture and carbon dioxide by a stream of dry nitrogen and was later stored in a dry box. The cuts were examined preparatory to further purification by the determination of the freezing points of selected fractions.[3] The freezing points of cuts 7–36 (*ca.* 1500 ml.) were substantially constant at −66.63° and of a purity estimated from the melting point slope of 99.76 mole %.

Distillation cuts 6–39 were further purified by crystallization and centrifugation. The recrystallized 2-picoline was dehydrated by distillation in the one-inch laboratory column, most of the material distilling over a 0.05° range. The purity of this material, which was used in the determination of the physical properties, was estimated from its melting point curve slope to be 99.85 mole %. It is of interest to note that the dehydration distillation data of the recrystallized picoline indicated that the total moisture picked up during the entire series of manipulations involved in the recrystallization was somewhat less than 0.5 weight % (the mother liquor fraction may have more than this amount). The literature reports about the extreme hygroscopicity of 2-picoline and perhaps those about the other tar bases may be somewhat in error.

Experimental

Determination of Properties

Freezing Point.—The apparatus and procedure was essentially a modification of that in use at the National Bureau of Standards.[4] The single-junction copper–constantan thermocouple was calibrated at the sublimation point of carbon dioxide. The potentiometer used was sensitive to 0.1 microvolt (0.003°) and reproducible from day to day to 1 microvolt (0.03°). Two modifications of crystalline 2-picoline were observed, needle-like prisms and white opaque platelets, the former being more stable at the freezing point. Due to excessive supercooling, melting curves instead of freezing curves were used to determine the freezing point for zero impurity. The freezing point of pure 2-picoline (saturated with nitrogen) was found to be −66.55 ± 0.08° at 730–740 mm. pressure, and the purity of the sample was estimated, from the slope of its melting curve, to be 99.85 mole %, assuming its cryoscopic constant to have the same value as that of 3-picoline.[5] This assumption is approximately confirmed by an experiment in which approximately 0.71 mole % water was found to depress the freezing point of 2-picoline by 0.31°. Previously reported values of the freezing point are −69.9°[6] and −64°.[7]

Density and Expansion Coefficient.—Two 20-ml. flask-type pycnometers having graduated 1-mm. capillary necks were used. The capillaries were calibrated by measuring lengths of weighed mercury threads by means of a traveling microscope. The volumes of the pycnometers were determined at 20, 40, 60 and 80° in a water-bath maintained to ±0.005°. The bath temperatures were measured by thermometers which had been compared with those certified by the Bureau of Standards and used at the points tested, with a probable accuracy of ±0.03°. When no further change occurred in the level of the liquid in the pycnometer, the level was read with the aid of a telescope, and suitable calculations made to relate the volume to a certain mark. Fillings with 2-picoline were made in the dry box using a filling tube constructed of stainless steel and nickel tubing. The picoline was protected from the atmosphere by a device which kept dry nitrogen flowing over it at all times, including that of level adjusting. The densities were determined in duplicate at 20, 40, 60, and 80° on the same sample of picoline, and pycnometers being refilled for the series at 30, 50, and 70°. Weighings were made using as tares identical pycnometers which received the same external treatment as the ones in which the measurements were made. The weights employed were certified by the Bureau of Standards. All weights were corrected to values *in vacuo*. The respective density values obtained at 10° intervals from 20 to 80° are 0.94432_0, 0.93491_3, 0.92556_5, 0.91607_2, 0.90665_8, 0.89706_6 and 0.88722_2 g./ml. with an average deviation of duplicate measurements of 0.000027 g./ml. The following equation, obtained by the application of least squares to the data, d_t (g./ml.) = $0.962809 - 9.0569 \times 10^{-4}t - 1.369 \times 10^{-6}t^2 + 2.45 \times 10^{-8}t^3 - 1.7 \times 10^{-10}t^4$, reproduces the experimental results with an average departure of 0.000017 g./ml. The density of 2-picoline at 25° calculated from the above equation is 0.93963 g./ml. The values previously reported in the literature are 0.9395,[8] 0.9400,[9] 0.9401,[10] 0.9494,[11] and 0.94099.[12]

The expansion coefficients of 2-picoline at various temperatures were calculated simply by dividing the instantaneous rate of change of density with temperature by the density at that temperature employing the density equation and its temperature derivative. The values thus obtained varied from 0.000992 at 20° to 0.001127 at 80° and are consistently from 2–7% lower than those calculated from the only other reported data.[13] This earlier work was done before any distinction between the isomeric picolines was recognized and probably was carried out on impure material.

Viscosity.—A Cannon–Fenske viscometer (size 50), having an efflux time for water at 20° of 265.22 seconds, was used for the determination of viscosities from 0–80° in 10° intervals. Efflux times were measured in triplicate with an electrical timer having an average reproducibility of 0.05 second. The viscometer, placed in a bath held constant to 0.01° was calibrated at each temperature with distilled water. Efflux times obtained from two separate fillings checked to within better than 0.1 second. The identical procedure was employed with 2-picoline with additional precautions taken to prevent contamination with atmospheric moisture. The viscometer was charged in the dry box and while in the bath was protected by means of devices which kept dry nitrogen in contact with the picoline. Results from two fillings checked to ±0.04 second.

Since the viscosity determinations were made at temperatures other than that at which the viscometer was charged, a correction for the change in the average driving head due to thermal changes in volume was applied to the observed efflux time. For water, this correction was always less than 0.3 second, while with the picoline, whose expansion coefficient is greater than that of water, the maximum correction amounted to 0.8 second.

Another correction applied to the efflux time was that needed to compensate for the change in driving head with surface tension of the liquid under test. This correction enters because of the difference of capillary action in the upper and lower reservoirs which are of different diameter. For the convenient calculation of this correction, water at 40° was used as a standard. The correction for the other water runs was always less than 0.4 second, but for the picoline, whose surface tension is about half that of water, the correction varied from 0.7 to 1.3 seconds. A graphical interpolation of Jaeger's data[7] for the surface tension of 2-picoline was employed for these calculations.

The corrected efflux times of the water determinations, in conjunction with the viscosity and density data for water in the "International Critical Tables," were used for the calculations of the viscometer constant. In an analogous manner, the observed efflux times for 2-picoline were corrected and employed along with the density data herein obtained to calculate the viscosities presented in Table I.

TABLE I

VISCOSITY OF 2-PICOLINE

Temp., °C.	Viscosity, cp.	Temp., °C.	Viscosity, cp.
0	1.0970	50	0.5621
10	0.9351	60	.5054
20	0.8102	70	.4585
30	0.7096	80	.4165
40	0.6296		

The results presented here have a probable accuracy of somewhat better than 1%. The value of the viscosity at 25° interpolated from a graphical representation of the data of Table I is 0.757 cp., as compared to the value of 0.7918 cp. reported in 1907.[12] The difference of 4.7% is probably due in large part to the use of insufficiently pure picoline by these early workers.

The relation between the viscosity and the temperature may also be expressed by the following equation obtained graphically from the data

$$\log_{10}\eta \text{ (centipoise)} = 504.4/T - 1.811$$

where T is the absolute temperature and which reproduced the data to an average of 5 p. p. m. with an extreme of 14 p. p. m. The activation energy of viscous flow, $E_{vis.}$, may be found from the above equation to be 2308 cal./mole.

Boiling Point.—A simple Swietoslawski ebulliometer, suitably modified to protect its contents from atmospheric moisture, was dried and charged with 2-picoline in the dry box. The condensation temperature was measured with a single-junction copper–constantan thermocouple that was calibrated with an accuracy of 0.02° at the melting point of a Bureau of Standards sample of benzoic acid. Barometric pressure readings were made simultaneously with boiling temperature measurements. The observed boiling temperatures were corrected to 760 mm. by means of the dT/dp value of 0.046° C./mm. calculated from the vapor pressure data of Riley and Bailey.[14]

The boiling point so obtained, 129.44°, remained constant even after several portions of the liquid were distilled away. The probable accuracy of the value is somewhat better than 0.1°. Previously reported values are 129.21,[15] 129.27–129.32,[9] 128.9,[14] and 129.1°.[8]

Refractive Index.—The refractive indices of 2-picoline at 20 and 30° in a Bausch & Lomb Precision Refractometer at three wave lengths, 5893 Å. (Na_D line), 5461 Å., and 4358 Å. (Hg green and blue lines). Circulating water from a constant temperature bath maintained the prisms to ±0.02° during the measurement. The refractometer was calibrated by means of highly pure benzene and chlorobenzene. These results, along with the molar refractions, are presented in Table II.

TABLE II

REFRACTIVE INDEX AND MOLAR REFRACTION OF 2-PICOLINE

Wave length, Å.	Temp., °C.	n	R_M
5893	20	1.50105	29.056
	30	1.49592	29.093
5461	20	1.50493	29.246
	30	1.49982	29.286
4358	20	1.52170	30.062
	30	1.51667	30.118

Other values of the $n^{20}D$ are 1.50122[14] (corrected from the value reported at 18° by means of the temperature dependence of n_D found in this work) and 1.501.[16]

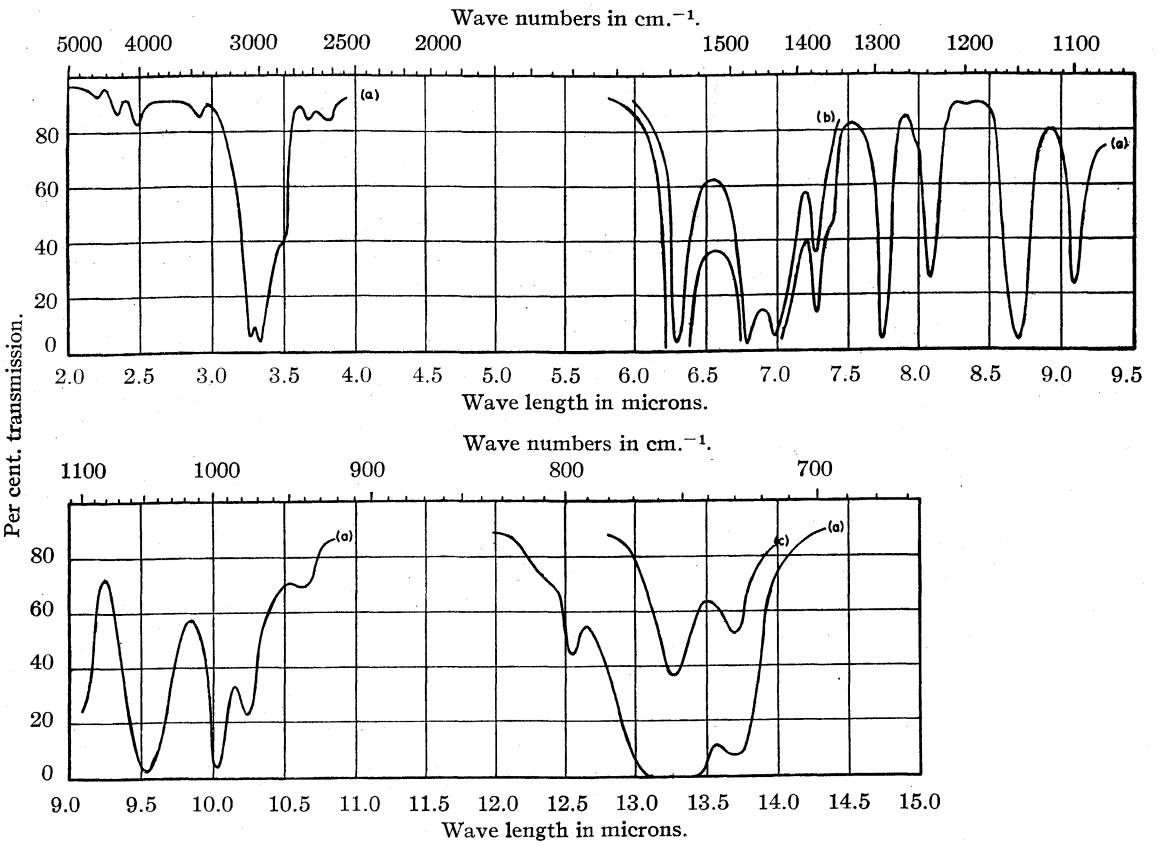

Fig. 1.—Infrared spectra of 2-picoline: α-picoline (2-methylpyridine), 99.8%, liquid at 27°; cell length, (a) 0.08 mm., (b) 0.04 mm., (c) 0.02 mm.

The n_∞^{30} and corresponding MR_∞ were calculated for use in the dipole moment work by means of a simple Sellmeier expression, $n - 1 = a\lambda^2/\lambda^2 - b$, using the refractive indices of two of the three reported above. In order to estimate the validity of this expression, the value of n_∞^{30} was calculated by using two pairs of $n\lambda$. In this manner n_∞^{30} was found to have an average value of 1.4729 ± 0.00016 with a corresponding MR_∞ = 27.94 ml.

Dipole Moment.—The dipole moment of 2-picoline in benzene solution at 30.00 ± 0.03° was measured by means of a heterodyne beat method. The apparatus used for the dielectric constant measurements will be described in a future publication. The densities of the solutions were measured in pycnometers of 100 ml. capacity similar to the ones described in the section on density.

The dielectric constants ϵ and d of the solutions containing mole fraction f_2 of the polar solute and the polarization of polar solute P_2 are given in Table III.

TABLE III

DIELECTRIC CONSTANTS, DENSITIES AND POLARIZATION

f_2	ϵ	d	P_2
0.042803	2.4860	0.871443	103.5
.053407	2.5421	.872239	102.8
.074254	2.6588	.873802	102.5

A value of 104.7 ± 0.4 ml. was obtained for P_∞ by extrapolating the P_2–f_2 curve to infinite dilu-

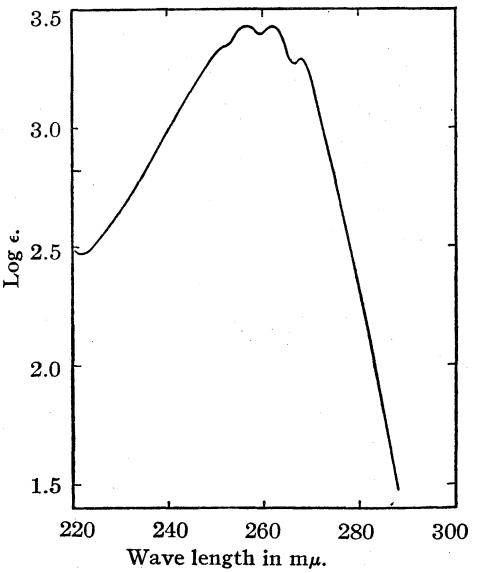

Fig. 2.—Ultraviolet spectra of 2-picoline: purity, 99.8 mole %; solvent, cyclohexane.

tion. The electronic polarization P_E was obtained from the molar refraction at infinite wave length, 27.9 ml. Assuming P_A to be 10% of P_E, the dipole moment of 2-picoline is calculated to be 1.92 D with a probable accuracy of $\pm 0.01°$. This value is not in good agreement with that of 1.72 D (the only previously reported work) obtained by Rau and Narayanaswany[7] because these workers employing the temperature solution method obtained a falsely high value, 23.2 ml. for P_A.[17] The value obtained by Rau and Narayanaswany for the total polarization at infinite dilution $P^{30}{}_{2\infty}$ is 111.36 ml., in fair agreement with the value obtained here.

Absorption Spectra.—In Figs. 1 and 2 are presented the infrared and ultraviolet absorption curves, respectively, for 2-picoline. The main infrared absorption maxima are presented in Table IV. The main ultraviolet absorption maxima are located at 252, 256.5, 262, and 268 millimicrons. The data were kindly determined by the Koppers Spectrographical Research Laboratory under the direction of Dr. J. J. McGovern.

TABLE IV

MAIN INFRARED ABSORPTION MAXIMA OF 2-PICOLINE

λ in μ	I^a	λ in μ	I^a
1.70	w	7.74	m
2.20	w	8.09	m
2.34	w	8.70	m
2.47	w	9.09	m
2.93	w	9.53	m-i
3.33	m	10.03	m-i
3.66	w	10.24	m
3.82	w	10.65	w
6.29	m-i	11.29	w
6.80	m-i	12.55	w
6.99	m	13.28	i
7.28	w	13.69	m

[a] Approximate intensity: w = weak, m = moderate, i = intense.

Summary

1. 2-Picoline has been purified by fractional distillation and recrystallization to an estimated 99.85 mole % purity.

2. The following properties have been determined for the purified material: freezing point, boiling point, density at 10° intervals from 20 to 80°, the expansion coefficients in the same temperature range, the viscosity at 10° intervals from 0 to 80°, refractive indices at 20 and 30° at 5893, 5461 and 4358 Å., the dipole moment, and the infrared and ultraviolet absorption spectra.

The Density of Aqueous Hydrogen Peroxide Solutions[1]

BY CHARLES E. HUCKABA AND FREDERICK G. KEYES

Introduction

A relatively small amount of exact density data exists for aqueous solutions of hydrogen peroxide, due to the decomposition caused by the catalytic activity of glass surfaces which introduces error in the density determination because of combined gas formation and loss of peroxide. A solution of this major problem was found in the preconstruction treatment of the interior surface of the glass from which the vessels were blown, combined with the employment of certain precautions during their use.

The literature reveals that the determinations of Maass and Hatcher[2] reported at both 0 and 18° are the most accurate data available. Independent verification of the data, however, has not appeared, and independent values in the region of high peroxide concentration are particularly desirable in view of the surface activity of the glass unless very special precautions are taken.

In this investigation a technique has been developed for preparing vessels whose interior surfaces are insensitive toward the decomposition of peroxide, determining with precision the densities of aqueous solutions of hydrogen peroxide at 0°. The mean coefficient of change of density with temperature to 20° has also been measured.

Treatment to Render Glassware Inactive to Hydrogen Peroxide.—The following procedure was found to produce inactive container Pyrex glass surfaces.

All glassware was constructed of Pyrex tubing, selected for freedom from visible surface imperfections. Prior to the glassblowing the tubing was cleaned with hot fuming sulfuric acid (150–175°), rinsed with conductivity water, and allowed to drain until dry in a dust-free case. This treatment is important in that it removes foreign matter which might otherwise decompose or "ash" and become embedded in the surface of the glass during the glassblowing operation. The air required in the glassblowing was passed through a filter of fresh medicinal cotton to prevent contamination through air-borne dust or decomposition of organic vapors from the breath.

After the vessels had been constructed, they were filled with hot fuming sulfuric acid and allowed to stand overnight. Following thorough rinsing with conductivity water, the vessels were tested with 90–95% peroxide. If no bubbles of oxygen appeared, the vessels were ready for use.

In the few instances where decomposition was detected,

(1) The authors express their acknowledgment to the Naval Bureau of Ordnance for the support and release of this work.

(2) O. Maass and W. H. Hatcher, THIS JOURNAL, **42**, 2548 (1920).

the peroxide was removed and the vessels re-rinsed with conductivity water. Then the vessels were treated with 10% hydrofluoric acid for three or four minutes. If, after this treatment had been repeated several times, the vessel still decomposed the peroxide, it was concluded that some foreign matter was deeply embedded in the surface of the vessel and the vessel was discarded.

Although precautions were taken to keep the vessels in a dust-free place, occasionally a vessel would become contaminated between times of use. This contamination, however, was always successfully removed by repeating the cleaning procedure with fuming sulfuric acid, hydrofluoric acid, and conductivity water. It was also found that the tendency of the vessels to become contaminated was reduced by keeping them filled with concentrated peroxide when not in use.

It has been found that cleaning a vessel with chromate–sulfuric acid cleaning solution usually increased rather than decreased the catalytic action of the vessel toward the decomposition of the peroxide.

Density Determinations at 0°

Experimental Procedure for Measuring Densities.—The densitometers consisted of Erlenmeyer-type glass bulbs of about 20 cc. capacity, to which was attached a short section of 2 mm. capillary tubing, and to which in turn was attached a ground glass cap. At a point at mid-distance along the capillary, a small scratch or level mark was made on the capillary tubing.

Calibration of the volume at 0° of the densitometers was carried out with conductivity water at 0°. The densitometer was filled with water to a level somewhat above the mark and placed in an ice-bath for approximately forty-five minutes. Tests showed that this time was more than sufficient to reduce the temperature of the water in the densitometer to 0°. The liquid level was finally adjusted to the mark by removing the excess liquid with a fine capillary. Any small drops of liquid clinging to the walls of the capillary above the mark were removed by using a fine capillary tube connected to a water aspirator.

The densitometer was transferred from the ice-bath to a water-bath at room temperature to warm the densitometer and contents quickly to room temperature in preparation for weighing. The densitometer was removed from the water-bath, dried and weighed. The precision of the calibrations was in round numbers a part in 10,000.

In making density determinations, the densitometers were filled with peroxide which had been twice distilled to ensure purity. The same manipulations were employed as were followed in the calibrations. Thus having determined the weight of a known volume of the peroxide solution at 0°, the density at 0° could be calculated easily. The precision of the density measurements was close to a part in 10,000.

Analytical Procedure

After density weighing, samples of peroxide for analysis were withdrawn by means of a capillary pipet constructed and treated according to previous indications relative to the densitometers. In a previous investigation,[3] it has been shown that the analysis of aqueous solutions of hydrogen peroxide can be carried out with great accuracy by titration with potassium permanganate provided a definite procedure is followed. To achieve the maximum possible accuracy, both the standardization of the permanganate and the titration of the peroxide were carried out according to the recommendations given in the reference cited.

To analyze concentrated peroxide solutions by titration with permanganate, a dilution step is necessary. All quantities of material involved in the dilutions were determined by weighing rather than by the less accurate volumetric method. Weight burets were also used for the titrations. The precision of the analyses was not inferior to a part in 5000.

(3) C. E. Huckaba and F. G. Keyes, THIS JOURNAL, **70**, 1640 (1948).

An attempt was made to determine directly the amount of impurities in the best obtainable grade of sodium oxalate[4] used to obtain the titer of the potassium permanganate by comparing the oxalate with purified anhydrous oxalic acid. Although the oxalic acid was sublimed in high vacuum eight times, for some undetermined reason the results showed a lack of uniformity to a part in 800.

The same oxalate as used in the comparison of the permanganate titration with the decomposition method was also used in the density determinations. The results of the earlier comparisons[2] by direct peroxide decomposition indicated that the oxalate purity is not inferior to a part in 3500. It is believed that the concentration determinations are reliable to a part in 5000.

Experimental Results

The experimental results of the density determinations at 0° are given in Table I.

TABLE I

DENSITIES OF AQUEOUS SOLUTIONS OF HYDROGEN PEROXIDE AT 0°

Weight fraction of water	Density at 0°, g. per cubic cm.	Weight fraction of water	Density at 0°, g. per cubic cm.
0.90343	1.0379	0.10621	1.4100
.80021	1.0803	.04013	1.4483
.59991	1.1660	.03772	1.4493
.40829	1.2539	.03718	1.4499
.28646	1.3139	.00521	1.4681
.19977	1.3590	.00395	1.4685

An attempt to express the data algebraically showed that no simple function would represent the densities as a function of weight fraction or mole fraction with sufficient precision. An equation of the following form was found to be the best approximation representation.

$$\log v_m = \log v_{H_2O_2} + \log (v_{H_2O}/v_{H_2O_2})x \qquad (1)$$

where

v_m represents specific volume of H_2O_2 solution cc./g.
$v_{H_2O_2}$ represents the specific volume of 100% H_2O_2 cc./g.
v_{H_2O} represents the specific volume of H_2O cc./g.
x represents the weight fraction of water

or

$$\log [(v_m)(10)] = 0.83241 + 0.16767x \qquad (1a)$$

The deviation of the data from this curve exhibits a maximum with a value of about a part in 400. Since representing the data algebraically to a part in 5000 appeared impractical, a table of densities for each 0.01 interval of weight fraction was prepared with the aid of a deviation chart. The density values are given in Table II, and the specific volumes in Table II R.

Linear interpolation between the values given in Table II is accurate to at least a part in 5000 as illustrated in Table III.

The interpolated densities were obtained by linear interpolation using the tabulated values of Table II. The calculated densities were obtained from Equation (1a) corrected by the use of the deviation plot.

The comparison of the results of this investigation with those reported by Maass and Hatcher[1] is shown in Table IV.

(4) A portion of this oxalate is being preserved and is available for further investigation.

1.4144	.0958	.0984
1.4596	.0111	.0202
1.4649	.0000	.0105

The densities reported by Maass and Hatcher are lower than the ones reported here. These investigators reported great difficulty in eliminating decomposition of the peroxide during the density measurements. However during the measurements here reported no visible decomposition occurred. It will be perceived that if decomposition occurs during a density measurement, the value obtained will be lower than the true value.

The Change of Density with Temperature.—The effect of temperature on the densities of peroxide solutions was found by using a dilatometer constructed to permit the observation of expansions of volume of solutions from 0 to 20°. The dilatometer differed from the densitometer only in that the capillary section was much longer (9.5 cm.) and accurately divided into millimeters and calibrated. The diameter of the capillary section was obtained by determining the amount of mercury at a known temperature that filled the space between successive portions of the millimeter division marks. The first mark above the bulb of the dilatometer was taken to be the zero mark, and the total volume of the dilatometer from this mark was determined with conductivity water in the same manner as with the simpler densitometers. The following procedure was used in making a dilatometer measurement.

The density of the peroxide solution was determined at 0° by adjusting the liquid level to the zero mark following the same procedure used earlier. From the density at 0°, the concentration was established from Table II. The dilatometer was then placed in a 20° bath, and after equilibrium had been attained, the new liquid level was read. To ensure that the reading was made at equilibrium the level was observed twice by ap-

proaching the 20°[5] from both a lower and a higher temperature. From the level reading and the diameter of the capillary tube, the volume of liquid at 20° above the zero mark was calculated. The volume of liquid below the zero mark was corrected from 0 to 20° using the coefficient of cubical expansion of Pyrex glass. Thus, the total volume at 20° of a known weight of peroxide and also the density at 20° are determined.

Since an adequate correlation of the volumetric coefficients with weight fractions of hydrogen peroxide is possible, the coefficients of change are presented on a specific volume rather than density basis. The average coefficients of expansion between 0 and 20° to be listed were obtained by using the data to determine the constant α of Equation (2).

$$v_{t_2} = v_{0°C}\,(1 + \alpha\Delta t) \qquad (2)$$

where

v represents specific volume cc./g.
Δt represents change in temperature ($t_2 - 0°$)
α represents average coefficient of expansion between 0° and t_2

The experimental results are given in Table V. The relationship between α and weight fraction is adequately represented by the expression

$$\alpha = \frac{\log\,[(1.10344 - x)(10)] + 0.16908}{1523} \qquad (3)$$

where

x = weight fraction water
α = average coefficient of change in specific volume between 0 and 20°

A comparison of the specific volumes at 20° computed from the coefficients using Equation (3) with the direct experimental specific volumes is shown in Table VI. The differences are negligible in each case, demonstrating the adequacy of Equation (3).

For convenience, the coefficients have been calculated using Equation (3) for each 0.01 interval of weight fraction, and appear in Table VII. Linear interpolation in this table is satisfactory.

To determine the specific volume at some temperature, t_2, intermediate 0 and 20° of a hydrogen peroxide solution, subject to the assumption of temperature independence of α, the specific volume at 0° is obtained from Table II; α is then either obtained from Table VII or calculated by Equation (3); and finally the specific volume at t_2 obtained by the use of Equation (2).

Summary

The densities of aqueous solutions of hydrogen peroxide at 0° have been determined with a precision of a part in 5000. The coefficients of change with temperature in these densities have been determined from 0 to 20° with a precision such that densities calculated using the coefficients also have a precision of a part in 5000.

The Vapor Pressure of Eleven Organic Compounds[1]

BY C. ERNST REDEMANN,[2] SAUL W. CHAIKIN AND RALPH B. FEARING[3]

In order to complete other work in progress in this Laboratory, it was necessary to have accurate data over the temperature range 0 to 60° for the volatility of the compounds reported in this study. The volatility is readily computed from the vapor pressure but a search of the literature revealed that trichloronitromethane (chloropicrin)[4] was the only compound in the group for which data were available. For the remaining compounds data were so scarce as to make it difficult even to estimate their volatility. The volatility was therefore measured for these compounds by the method described in earlier reports.[5] The vapor pressure has been computed from the experimentally measured volatility and is here reported since it is more generally useful than the volatility.

were repeated until a constant reproducible volatility was obtained. If in any series of measurements there was a trend from high values to lower ones this series was continued until the results varied only in a random manner.

All the compounds here reported were prepared in laboratories other than the authors'. The source of each compound is given in a footnote to Table I. The compounds were submitted to our laboratory as pure compounds; however, whenever the sample was large enough to allow further purification it was carefully fractionally distilled in all-glass equipment containing a short Vigreux column before making any measurements upon it. In a few cases the sample submitted was too small to allow any further purification before use. The boiling point (or range), refractive index, and density reported in Table I were those observed for the sample just prior to use. The identity of each compound was assumed to be that stated by the submitter.

Nitrogen was used as the inert carrier gas as in previous

Hurd, Northwestern University. [d] From Dr. C. A. Thomas, Monsanto Chemical Co. [e] From Dr. Henry Gilman, Iowa State College. [f] From Dr. G. H. Coleman, University of Iowa. [g] From Dr. Marvin Gold, Visking Corp. [i] Brühl, *Z. physik. Chem.*, **16,** 214 (1895), gave $n^{22.8}D$ 1.46075 and d^{20}_4 1.6539. [j] Karvonen, *C. A.*, **18,** 1981–1982, gives d^{20} 1.0719. [k] Dyson and Harrington, *J. Chem. Soc.*, 193 (1940), report a density of 1.285 at 15°. [l] Foster and Newman, *ibid.*, **97,** 2576 (1910), give the density as 1.2885 at 24°. [m] Schmidt and Rutz, *Ber.*, **61,** 2146 (1928), give $n^{20}D$ 1.4527 and d^{20}_4 1.0661. [n] Blomquist, Tapp and Johnson, THIS JOURNAL, **67,** 1519 (1945), give a density, which corrected to d^{20}_4 is 1.0509, appreciably less than we found. Their boiling range of 48–49° (59.5 mm.) agrees moderately well with the temperature calculated from our equation at which the pressure is 59.5 mm.

Experimental

A description of the apparatus used and details of the measurements were reported in an earlier paper.[5b] For each compound at each temperature studied determinations studies.[5] No evidence of polymerization or oxidation during any of the studies was observed.

Results

In Table I are recorded, in addition to the physical constants of the compounds, the three constants A, A' and B for the two equations

$$\log p = A - B/T \quad (1)$$

$$\log WT = A' - B/T \quad (2)$$

computed by the method of least squares from the experimental points. These constants apply when the pressure is expressed in millimeters of mercury, the temperature, T, is the absolute tem-

indicate a precision of about 1% for most of the measurements, the vapor pressure, as computed by the equations given, may have an error somewhat larger than this amount since the vapor pressures calculated from the volatility in an inert gas stream are too large according to Gerry and Gillespie.[6] The values from which the constants given in Table I were determined were not corrected for this factor since the volatility in an inert gas was the quantity desired at the time the experimental work was done and consequently no additional measurements were made by which these corrections could be made.

Discussion

Since considerable data[4] were available for trichloronitromethane, redetermination of its vapor pressure was primarily for comparison of results. In Table III the results of several workers are compared at four temperatures. Blaszkowska-Zakrzewska[4c] also give two different values for the vapor pressure at 100° from direct measurements by two different methods, 532.0 and 524.3 mm. From the above Table and these data, the Hertz equation would appear best for the entire temperature range. Both Baxter's equation and ours are satisfactory at lower temperatures where the measurements were made, but give values which are too large at elevated temperatures by 9–11%. In the range 0 to 40° the first three equations give values agreeing within 2%.

TABLE III

COMPARISON OF VAPOR PRESSURES COMPUTED FOR CHLOROPICRIN FROM VARIOUS EQUATIONS

Equation	Pressure in millimeters at ° C. 0	20	40	100
Our	5.70	18.57	52.02	590
Hertz[4c]	5.68	18.56	51.31	530
Baxter[4a]	5.64	18.30	51.32	579
Blaszkowska-Zakrzewska[4c]	6.88	20.75	54.40	527

The generalizations for chloropicrin probably are also approximately true for all the compounds reported here, namely: within the temperature range 0 to 60° the results are good to 1 to 2%, but outside this range the error may become much larger.

Acknowledgment.—We wish to acknowledge the assistance of Miss Drusilla Van Hoesen for her helpful work in making some of the measurements.

Summary

1. The volatility of eleven organic compounds has been measured by a dynamic method.

2. The corresponding vapor pressures have been computed from the volatilities, and the constants for logarithmic equations for both the volatility and vapor pressure have been calculated.

3. The vapor pressure found for trichloronitromethane has been compared with measurements made by previous workers.

Isomerization of Certain Olefins by Silica Gel at Room Temperature

BY W. S. GALLAWAY AND M. J. MURRAY

Silica gel adsorption techniques for the analysis and separation of hydrocarbon types have, in recent years, found wide application.[1] There has, however, been little published on the effect of the gel upon olefins although difficulty with this type of hydrocarbon has been mentioned by Mair.[2]

The present authors have made use of silica gel techniques together with infrared spectroscopy in a study of the composition of the various fractions of thermally cracked gasolines. The comparisons of the infrared spectra of these hydrocarbon mixtures before and after contact with the silica gel showed, in general, that the intensities of the absorption bands characteristic of olefin types were as expected. There were, however, two very striking exceptions. The strength of the 890 cm.$^{-1}$ band (normally associated with the structure RR'C=CH_2) in the spectrum of the starting material was always much greater than that found by summation over the cuts from the silica adsorption column. At the same time, the bands near 825 cm.$^{-1}$ (usually found in the spectra of tri-alkylethylenes) became stronger in the cuts than was anticipated. Such a change in double bond position might be caused either by polymerization or by isomerization.

The effect of silica gel upon two olefins of the type RR'C=CH_2 and one of the type RCH=CR'R'' was then investigated. All these olefins were found to isomerize rapidly at room temperature. 2-Ethyl-1-hexene isomerizes almost completely (90%) when passed through a silica gel column at 25° whereas 20% of 2,4,4-trimethyl-1-pentene is converted to the -2 isomer. The latter case was shown to have closely approached thermodynamic equilibrium by an experiment wherein 2,4,4-trimethyl-2-pentene was passed through the silica tower. A conversion of 80% was realized yielding an effluent found, by infrared, to be almost identical with that obtained on charging the 2,4,4-trimethyl-1-pentene. It appears probable that the composition of the effluent when 2-ethyl-1-hexene was charged also approximates the equilibrium mixture. 1-Hexene was not detectably isomerized under similar conditions.

The isomerization of the tertiary olefins which were studied occurs so readily at room temperature by contact with silica that the reaction was easily followed by an infrared examination of samples decanted from a vial containing the hydrocarbon and the gel. The results of this semi-quantitative study are given in Fig. 1a and 1b wherein the intensity of a characteristic band of each of the 2,4,4-trimethylpentene isomers is shown as a function of contact time.

As is to be expected, the rate of isomerization is dependent upon the ratio of gel to olefin. In the experiment just cited, in which there was a low gel to olefin ratio, only 29% of the 2,4,4-trimethyl-2-pentene was found to isomerize in two hours. However, in a silica gel adsorption column where the ratio was many times larger, the equilibrium composition was approached in a comparable time.

An infrared analysis of the effluent from the silica gel runs with the two diisobutylenes showed that, for these olefins, polymerization exerts a very minor effect compared to isomerization. As may be seen from Fig. 2, only 2,4,4-trimethylpentenes are present in measurable amounts in the main portion of the effluent. The last portion of the effluent was found to contain minor amounts of other materials, either polymers or oxidation products, which can account for no more than 3 or 4% of the total. A similar conclusion was reached in the case of 2-ethyl-1-hexene wherein by infrared study and by distillation of the effluent from the gel column, only minor amounts of higher boiling material were shown to be present.

The effect of temperature upon the degree of isomerization is very striking. When a C_7 fraction of a thermally cracked gasoline was passed through a silica gel adsorption column at room temperature, only 20 to 25% of the material having an 890 cm.$^{-1}$ infrared absorption band was recovered in the effluent. However, when the column was cooled to −20°, there was, within experimental error, no loss of this type of olefin.

In another test of the temperature effect, 2-ethyl-1-hexene was added to an excess of gel in each of two tubes which were held at −24° and +24°, respectively, for one hour. Infrared analyses of the recovered hydrocarbons showed that only 5% of this olefin isomerized at the lower temperature while 65% was converted at the higher temperature. The product recovered from the low temperature test had an odor similar to the charge, whereas the product obtained from the room temperature experiment had an odor suggesting contamination with oxygenated compounds. The infrared spectrum, however, showed only weak OH bands at 3300 cm.$^{-1}$ and no C=O absorption at 1725 cm.$^{-1}$.

The authors feel that the above-reported results though somewhat qualitative in nature, emphasize the necessity of carrying out the adsorption at low temperatures when certain types of olefinic hydrocarbons are present.

Experimental

The silica gel used in these experiments was from the

(2) B. J. Mair, *J. Research, Natl. Bur. Standards*, **34**, 435 (1945).

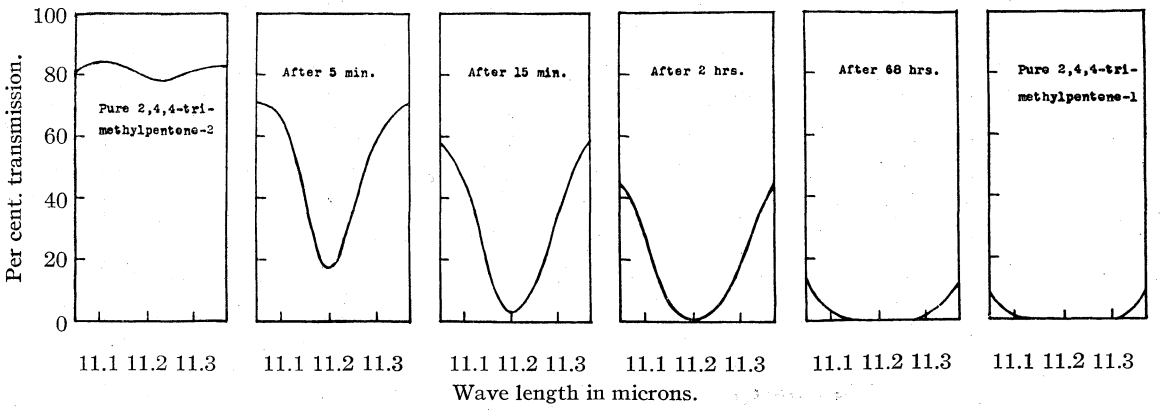

Fig. 1a.—The isomerization of 2,4,4-trimethyl-2-pentene to 2,4,4-trimethyl-1-pentene upon contact with silica gel at room temperature as evidenced by the increase in intensity of the 11.2 μ absorption band of 2,4,4-trimethyl-1-pentene.

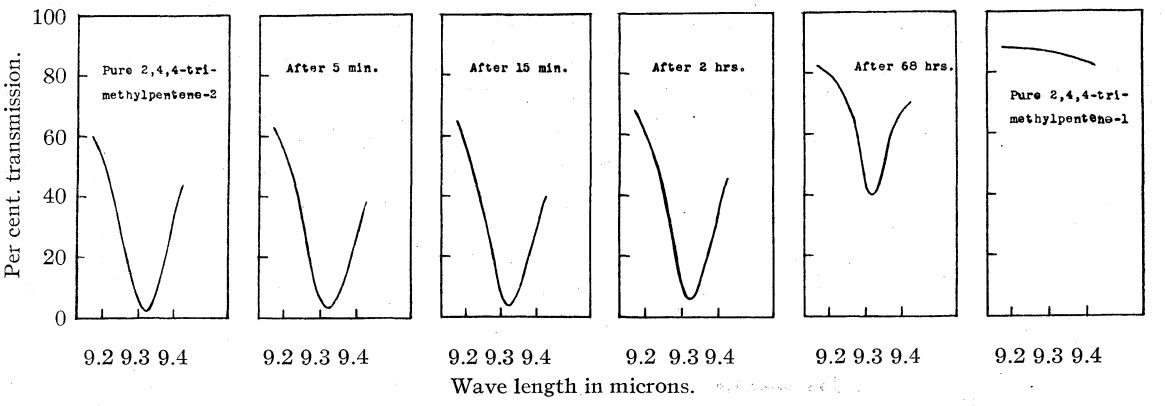

Fig. 1b.—The isomerization of 2,4,4-trimethyl-2-pentene to 2,4,4-trimethyl-1-pentene upon contact with silica gel at room temperature as evidenced by the decrease in intensity of the 9.3 μ absorption band of 2,4,4-trimethyl-2-pentene.

Davison Chemical Corporation. It had a mesh size of 28–200.

The two isomeric 2,4,4-trimethylpentenes were obtained by painstaking fractionation of the product from sulfuric acid polymerization of isobutylene. The infrared absorption spectra of the fractions selected for use followed closely those published by API Project 44. The spectra also showed that the samples of each isomer contained less than 0.5% of the other isomer.

The 2-ethyl-1-hexene was obtained by fractionation of the crude product supplied by the Connecticut Hard Rubber Co. using a Podbielniak Hyper-Cal column. Only the heart cut was used. From the intensity of the characteristic olefin band at 890 cm.$^{-1}$, the spectra of the distillation fractions, and the absence of bands characteristic of other types of olefins, the purity of the sample used is estimated to be of the order of 95%.

The 1-hexene used contained a small amount of other hexenes, both straight chain and of the tri-alkylethylene type. The conclusion drawn as to the non-isomerizing tendency of 1-hexene was based on spectroscopic data which showed no measurable increase in the total amounts of these other olefins.

The technique followed in the silica gel adsorption tests was essentially that described by Mair.[2] The desorbing agent was methanol which was removed from the final fraction of the effluent by water washing. For the low temperature runs, brine at $-20°$ was circulated through the jacket surrounding the adsorption tower.

The semiquantitative experiment involving the rate of isomerization of 2,4,4-trimethyl-2-pentene was performed by shaking intermittently 10 ml. of the olefin with 5 ml. of the gel. At specified times, samples of the hydrocarbon were pipetted out for infrared examination.

In order to study the effect of temperature upon the rate of isomerization of 2-ethyl-1-hexene, two tubes, each containing 15 ml. of silica gel, were cooled to $-80°$. To each was added 5 ml. of the olefin cooled to nearly the same temperature to minimize the effect of the heat of adsorption. One tube was then placed in iced hydrochloric acid at $-24°$ while the other was immersed in water at $+24°$. After one hour, ethanol cooled to about $-80°$ was added to each sample. Following the addition of water, the upper layer was removed, dried and examined by infrared.

The infrared spectra were obtained on a large Gaertner spectrometer equipped with automatic recording. The samples were examined in a rock-salt cell which provided a 0.10-mm. liquid film and allowed no contact with sealing compounds or waxes. The compositions of the mixtures of the 2,4,4-trimethylpentenes were calculated by standard methods[3] since all the components present were identified and reliable spectra of the pure hydrocarbons were at hand. However, in the case of the 2-ethyl-1-hexene samples, wherein the spectra of the other isomers were not available, it was not possible to allow for the interference of the other components. The results reported were calculated by direct comparison of the absorption intensities for the original material and the products, and therefore represent maximum amounts of 2-ethyl-1-hexene present.

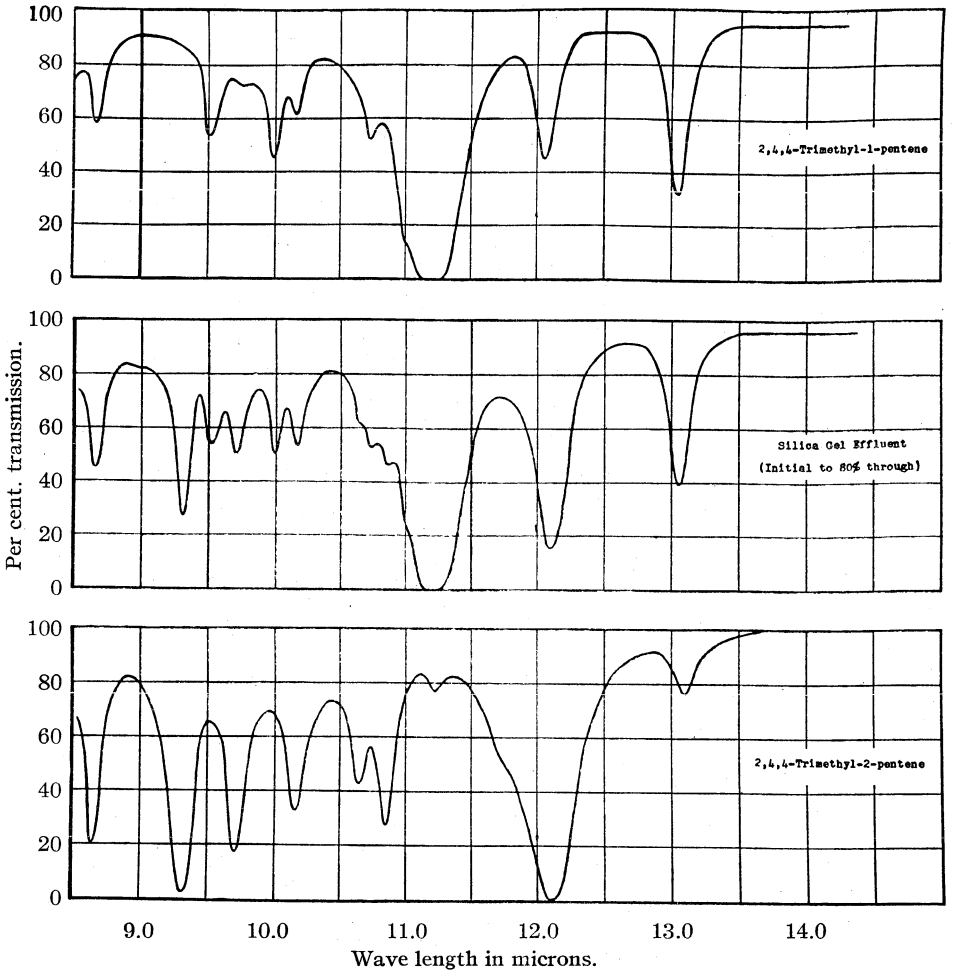

Fig. 2.—Comparison of the spectra of the 2,4,4-trimethylpentenes with the spectrum of the major portion of the effluent from a silica gel adsorption column to which the 2-isomer was charged.

Acknowledgment.—The authors wish to thank Mr. M. J. Stross for his coöperation in running the silica gel adsorption tests and Drs. Louis Schmerling and C. B. Linn for supplying the pure 2,4,4-trimethylpentenes.

Summary

1. At room temperature, each of the 2,4,4-trimethylpentenes is isomerized approximately to the equilibrium mixture of these olefins during passage through a silica gel adsorption column. Under the same conditions, 2-ethyl-1-hexene is almost completely isomerized, probably also to the equilibrium concentration.

2. Olefins of the $RR'C{=}CH_2$ type which are present in thermally cracked gasoline are also isomerized. The isomerization of hexene-1 is not appreciable.

3. Reduction of the temperature of the adsorption column to about −20° nearly halts the isomerization of the olefins studied.

RIVERSIDE, ILLINOIS RECEIVED FEBRUARY 26, 1948

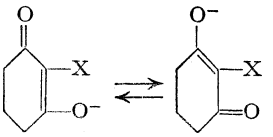
[CONTRIBUTION NO. 122 FROM THE RESEARCH LABORATORIES OF HOFFMANN-LA ROCHE, INC.]

Dihydropyrogallol, A New Ene-diol and its Oxidation Product. 1,2,3-Cyclohexanetrione Dihydrate—A Ketonic Isomer of Pyrogallol

BY B. PECHERER, L. M. JAMPOLSKY AND H. M. WUEST[1]

The ene-diols, compounds containing the group —COH=COH—, may be divided into two classes. The first class comprises about a dozen highly hindered stilbene diols which were studied by Fuson and his students[2] while the second class embraces those ene-diols containing a carbonyl group adjacent to the double bond. In the second group there are similarly a few well-defined members, which include ascorbic acid and its analogs,[3] reductone,[4] reductinic acid,[5] dihydroxymaleic acid, its salts and esters,[6] and hydroxytetronic acid.[7] To the second group may be added a miscellany of compounds such as 2,3-dihydroxy-1,4-benzoquinone, the corresponding naphthalene analog,[8] rhodizonic acid[9,10] and croconic acid.[9,10] A few other compounds containing the carbonyl group conjugated with the ene-diol group are mentioned in the literature, but if the further proviso is added that an ene-diol must react stoichiometrically with one molecule of iodine, then the rigid classification of these latter compounds is better deferred until this property has been demonstrated.

This paper describes a new ene-diol, dihydropyrogallol (I), prepared by the catalytic hydrogenation of pyrogallol in the presence of one mole of alkali. Previous workers[11,12,13,14,15] who studied the hydrogenation of pyrogallol obtained complex mixtures ranging from hexahydropyrogallols to cyclohexane, but the product after uptake of one mole of hydrogen has not been described previously. This method of reducing 1,3-dihydroxybenzenes, first used by Klingenfuss[16] for the preparation of dihydroresorcinol, works successfully for pyrogallol, but not for 4-substituted pyrogallols.[17] The success of this method is probably due to the formation of the resonating system



where X = H for resorcinol and X = OH for dihydropyrogallol.

Dihydropyrogallol is a typical ene-diol; it behaves as a monobasic acid and consumes two equivalents of iodine. With ferric chloride it gives a deep blue color which gradually fades. It has been further characterized by the preparation of a monoacetate and the bis- and tris-(phenylhydrazones) of 1,2,3-cyclohexanetrione.

Since dihydropyrogallol was originally prepared as a stabilizer for edible fats it was desirable to determine the nature of its oxidation products. Observations, recorded below, indicated that pyrogallol was not the primary oxidation product. On oxidation with iodine, using the method of Reichstein and Oppenauer[18] for reductinic acid, a white crystalline product melting at 106°, having the composition $C_6H_{10}O_5$, was obtained. This product was a neutral substance that did not decolorize iodine solution, slowly reduced silver nitrate, immediately reduced ammoniacal silver nitrate and gave a bis-(phenylhydrazone) identical with that obtained from dihydropyrogallol. Treatment with hydrogen sulfide gave dihydropyrogallol in high yield. These properties indicated the structure of a dihydrated 1,2,3-cyclohexanetrione (IIa or IIb).

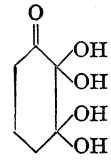
IIa



IIb

Attempts to dehydrate or isomerize II yielded impure pyrogallol. Treatment with acetic anhydride gave pyrogallol triacetate in further support of structure II. Borsche[19] attempted to prepare a ketonic isomer of pyrogallol[20] from 1,3-dioximinocyclohexanone without success.

The absence of color in II is explained by the hydration which destroys the conjugation of the carbonyl groups. Although other 1,2,3-triones, such as tetramethyl-1,2,3-cyclopentanetrione[21] and 2,3,4-pentanetrione[22,23] form colorless hydrates which can be converted to colored anhydrous forms, it is unlikely that II can be dehydrated without isomerization to pyrogallol in view of the stabilization afforded by formation of the resonating benzene ring.

Reichstein and Oppenauer[18] oxidized reductinic acid, the next lower homolog of dihydropyrogallol to 1,2,3-cyclopentanetrione but failed to isolate a crystalline product. These workers noted the appearance of crystals during the isolation but on continued distillation, the crystals were converted to a sirup which yielded only the tris-(phenylhydrazone) of 1,2,3 - cyclopentanetrione. Whether their failure to isolate the crystalline trione is due to a lower stability is difficult to judge; however, in the present case, strict adherence to the procedure described below is necessary to obtain any crystalline product.

Attempts to use hydrogen peroxide for the oxidation of dihydropyrogallol showed that a trace of ferric ion was necessary for reaction to occur. From this reaction, an unexpected product, m. p. 169–170°, having the composition $C_6H_7O_3$ was isolated. This product was not reduced by hydrogen sulfide and gave no color with ferric chloride, but on the steam-bath yielded the same tris-(phenylhydrazone) obtained from I and II. Molecular weight determinations in acetone solution gave values corresponding to a monomer, but since the simple formula $C_6H_7O_3$ is unlikely, further work is necessary to elucidate the structure of this substance.[24]

Experimental[25]

Dihydropyrogallol (I).—This was prepared by the method of Klingenfuss[16,26] taking precautions to protect the alkaline pyrogallol solution from atmospheric oxygen with nitrogen.

One kg. of pyrogallol (E. K. Practical) (7.95 moles on a 100% basis) was dissolved in 2 liters of water containing 320 g. of sodium hydroxide (8 moles) and reduced at 60° under 1000 lb. hydrogen pressure using 50 g. of Raney nickel. The reduction was complete in about five hours. When cool, the catalyst was filtered off, and the filtrate acidified at −5° with 675 ml. of concentrated hydrochloric acid whereupon a light tan solid precipitated. After thirty minutes at −5°, the mixture was filtered and yielded 816 g. (80%) of material melting at 89–93°. Another 87 g. of product of the same m. p. was isolated after taking to dryness under nitrogen and extracting with benzene.

For purification, the dried material was recrystallized from dry benzene (550 ml. for 100 g.) using iron-free charcoal[27] to decolorize the solution. Dihydropyrogallol crystallizes from benzene in clusters of needles which are transformed to plates of m. p. 109–112° on drying. A sample after repeated recrystallization melted at 114°.

Anal. Calcd. for $C_6H_8O_3$: C, 56.22; H, 6.28. Found: C, 56.20; H, 6.16.

The substance behaves as a monobasic acid on titration with standard alkali. Fifty mg. of dihydropyrogallol consumed 0.782 milliequivalent of iodine; theory 0.780.

At room temperature, 100 ml. of benzene, ethanol, glycerol and ether dissolve 1.2, 20, 3 and 0.33 g., respectively.

The substance is stable in dry air for a few days after which decomposition sets in at an accelerated rate. In an inert atmosphere dihydropyrogallol has been stored for two years without deterioration.

Ferric chloride gives a blue color which fades in a short time. This "vanishing blue" color test can be repeated until all of the dihydropyrogallol has been consumed, but further additions give only the color of dilute ferric chloride solution. This observation indicated that an abnormal oxidation product was present.

Monoacetate of Dihydropyrogallol.—This derivative was prepared from 5 ml. of acetic anhydride and 4.0 g. of dihydropyrogallol in 10 ml. of pyridine. After two recrystallizations from ethyl acetate 3.05 g. of long prismatic crystals were obtained, m. p. 154–155.5°. The position of the acetyl group is uncertain; a red-purple color is obtained with ferric chloride.

Anal. Calcd. for $C_8H_{10}O_4$: C, 56.46; H, 5.92. Found: C, 56.78; H, 6.15. Calcd. for one CH_3CO: 25.3. Found: 26.1, 26.4.

1,3-bis-(Phenylhydrazone) of 1,2,3-Cyclohexanetrione.—This was prepared by treating dihydropyrogallol in dilute acetic acid solution with an excess of phenylhydrazine at 100°. Recrystallization from methanol gave bronze-red crystals, m. p. 131–132.5°. The position of the phenylhydrazone groups is inferred from the work of Henle and Schupp[28] who found that the reaction of mesoxalic aldehyde with phenylhydrazine gave a 1,3-bis-(phenylhydrazone).

Anal. Calcd. for $C_{18}H_{18}ON_4$: C, 70.56; H, 5.92. Found: C, 70.09; H, 5.63.

tris-(Phenylhydrazone) of 1,2,3-Cyclohexanetrione.—After heating the above bis-(phenylhydrazone) with phenylhydrazine at 130° for two hours, the cooled mixture deposited a dark oil on dilution with water. The aqueous layer was decanted and the oil dissolved in a minimum of hot ethanol. On cooling, yellow crystals were obtained which were filtered and washed with a little ether. After three recrystallizations from ethanol the m. p. was con-

(25) All melting points are uncorrected.

(26) One of the Referees has pointed out that a detailed procedure for the preparation of dihydroresorcinol has been published by Thompson, "Organic Syntheses," **27**, 21 (1947). This volume was received on January 20, 1947; this paper submitted on January 9.

(27) Charcoal containing iron imparts a blue color to the product.

(28) Henle and Schupp, *Ber.*, **38**, 1372 (1905), gave the first rigorous proof for structure of the reaction product of phenylhydrazine with a 1,2,3-tricarbonyl compound. A few years earlier Sachs and Röhmer, *ibid.*, **35**, 3308 (1902), assigned a 1,3 structure for the bis-(phenylhydrazone) of 2,3,4-triketopentanetrione, but their evidence is not convincing.

stant at 186°. Borsche,[22] who prepared this substance in another way, reported 182–183°.

Preparation and Properties of 1,2,3-Cyclohexanetrione Dihydrate (II).—To a stirred solution of 32 g. of dihydropyrogallol (0.25 mole) in 250 ml. of water at 3–5°, 63.1 g. of finely powdered iodine was added in portions of 1 or 2 g. over a period of one and one-half hours.[29] After 45.2 g. of iodine had been added the solution was brown but a test for free iodine was negative; the brown color disappeared however on dilution. Freshly precipitated and washed silver chloride (0.75 mole) was then added to convert the hydriodic acid to hydrochloric acid. As the conversion took place the dark brown color faded. Next the bulk of the hydrochloric acid was neutralized with silver carbonate (0.385 mole); removal of more acid will result in reduction of the silver carbonate to metallic silver. After the evolution of carbon dioxide became very slow (twenty to thirty minutes), the silver salts were filtered off and washed with several portions of cold water. The clear yellow filtrate was then evaporated *in vacuo* below 35° until the volume was 20–30 ml. whereupon the contents set to a mass of white crystals. At this point evaporation should be stopped or the crystals will disappear and be converted to a red sirup from which no crystalline material can be isolated.

The crystals were filtered and copious amounts of ether used to rinse out the flask and wash the precipitate. The product was then stored for a day or two *in vacuo* over calcium chloride and sodium hydroxide to remove traces of adherent acid. If traces of acid remain, indicated by the formation of a pink color, the product should be ground under ether which dissolves only the colored material.

The yield of dry material, m. p. 104–105°, averages about 20 g. Repeated recrystallization from dry ethyl acetate, which results in considerable loss, raises the m. p. to 106°.

Anal. Calcd. for $C_6H_{10}O_5$: C, 44.44; H, 6.22. Found: C, 44.28; H, 6.32.

The substance has the formula of a dihydrated pyrogallol, $C_6H_6O_3 \cdot 2H_2O$, and has the following properties: It is very soluble in water and alcohol, but insoluble in ether and benzene. Silver nitrate solution gives no turbidity but is slowly reduced. Ammoniacal silver nitrate is reduced immediately. A five per cent. aqueous solution has a *p*H of 5 and gives no color with ferric chloride.

From 100 mg. of II and phenylhydrazine, 95 mg. of a red crystalline compound was obtained, m. p. 134–135°; mixed m. p. with a sample of the 1,3-bis-(phenylhydrazone) of 1,2,3-cyclohexanetrione, 131–133°.

A stream of hydrogen sulfide was passed into a solution of 0.5 g. of the substance in 10 ml. of water. Free sulfur was precipitated, and from the filtrate 0.44 g. of dihydropyrogallol, m. p. 108–110°, was recovered.

Attempts to dehydrate the substance by azeotropic distillation were unsuccessful but indicated that dehydration was accomplished by isomerization to pyrogallol.

A few mg. of II in pyridine gave a purple gray flash when heated to about 80° and after evaporation of the solvent a little impure pyrogallol, m. p. 125–130°, could be sublimed from the residue. Control experiments with pyrogallol gave about 50% recovery of impure pyrogallol of m. p. 132–135°.

Preparation of Pyrogallol Triacetate from II.—One and eighteen-hundredths g. of II was suspended in 5 ml. of acetic anhydride at 0°, and a drop of sulfuric acid added. The solution assumed a momentary pink color and warmed to about 35°. After standing overnight, the mixture was diluted with water whereupon a mass of fine white needles separated. The crystals were filtered off, washed with water and recrystallized from ethanol. The crystalline product, m. p. 160.5–162°, weighed 0.5 g.

One gram of pyrogallol treated similarly gave 1.49 g. of the triacetate, m. p. 162–163°.[30] The mixed melting point was 160.5–162°.

The Preparation of $(C_6H_7O_3)_n$.—Sixty-four grams of dihydropyrogallol (0.5 mole) was dissolved in 1 liter of water containing 2 drops of ferric chloride solution (10%). To the stirred solution 54 ml. of "30% hydrogen peroxide" (0.3164 g. of hydrogen peroxide per ml.) was added dropwise, whereupon the color of the dihydropyrogallol-ferric ion-complex reappeared. Considerable heat was evolved, but the rate of addition was so adjusted that the internal temperature was 45°. The pale yellow solution (*p*H 2) was concentrated *in vacuo* at 30° to about 75 ml. whereupon the residue set to a crystalline mass, which was filtered off and dried *in vacuo*. Twenty-six g. of slightly yellow product, m. p. 85–88°, was obtained. Recrystallization from ethyl acetate-ether gave 10 g. of white crystals, m. p. 169–170°, dec.

Anal. Calcd. for $C_6H_7O_3$: C, 56.68; H, 5.51. Found: C, 56.55, 56.62; H, 5.57, 5.61. Molecular weight, calcd.: 127. Found: 120 (by isothermal distillation against azobenzene in acetone).

Treatment of this product with phenylhydrazine and a few drops of acetic acid gave a red precipitate *immediately*. The mixture was warmed overnight on the steam-bath and worked up in the usual manner. On recrystallizing from ethanol orange crystals, m. p. 187°, were obtained that gave no depression with the tris-(phenylhydrazone) of 1,2,3-cyclohexanetrione.

The new product does not react with iodine nor hydrogen sulfide, but has not been investigated further.

Acknowledgment.—We are indebted to Dr. Al Steyermark and his staff for the microanalyses and molecular weight determination reported in this paper.

Summary

The preparation of a new ene-diol, dihydropyrogallol, is described.

Oxidation of dihydropyrogallol with iodine yields 1,2,3-cyclohexanetrione dihydrate, a ketonic isomer of pyrogallol; while oxidation with hydrogen peroxide in the presence of a trace of ferric ion yields a product $(C_6H_7O_3)$ of unknown constitution.

NUTLEY, N. J. RECEIVED JANUARY 12, 1948

(29) Addition of a few ml. of carbon tetrachloride, or any other indifferent organic solvent, accelerates the reaction. This is probably due to the better solubility of iodine in the organic solvent.

(30) The literature records melting points of 162–163, 165, and 172–173° for pyrogallol triacetate.

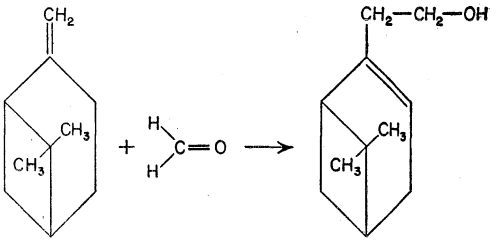
Preparation and Reactions of Methylenecyclohexane

BY RICHARD T. ARNOLD AND JOHN F. DOWDALL[1]

It has been shown repeatedly during the past few years that many monoölefins will react with maleic anhydride,[2,3] sulfur trioxide,[4] formaldehyde[5] and azodicarboxylic ester[2] to form 1-1 adducts in which the original olefinic double bond has migrated to an adjacent position.

β-Pinene, for example, undergoes a thermal reaction with formaldehyde at 180° to form "nopol" (I) in excellent yields.[5]



(I)

Assignment of the double bond position in (I) rests upon the fact that nopinone is not obtained on ozonolysis.

Our investigation was initiated in the hope that independent syntheses could be found for these 1–1 adducts if a symmetrical olefin of the "isobutylene type" were used as one of the starting materials. Consequently, we have examined the products formed when methylenecyclohexane is allowed to react (separately) with paraformaldehyde, maleic anhydride and sulfur trioxide. It appears that in each of these cases, the reaction is accompanied by a shift of the exocyclic double bond into the six-membered ring. A summary of the observed transformation is shown on the chart.

2-(Δ[1]-Cyclohexenyl)-ethanol (II) obtained from the reaction between methylenecyclohexane and formaldehyde was synthesized independently from ethyl Δ[1]-cyclohexenylacetate by reduction with sodium and alcohol.[6] Samples prepared by each of these two routes formed identical 3,5-dinitrobenzoates (m. p. 80–81°).

Location of the sulfonic acid residue in III was established by catalytic reduction to cyclohexylmethane sulfonic acid (V). This in turn was prepared independently from hexahydrobenzyl bromide.

Careful oxidation of compounds III and IV gave no identifiable cyclohexanone, thus indicating that the carbon–carbon double bond in these molecules does not occupy the exocyclic position.

During the course of this study, it was shown that highly reactive aldehydes other than formaldehyde will form 1–1 adducts with certain monoolefins. The product resulting from methylenecyclohexane and phenylglyoxal is tentatively regarded as having the structure VII.

We regard the formation of these adducts as occurring *via* a transient cyclic complex which is formed by a simultaneous attack of the reagent at an α-methylenic group and a carbon atom of the double bond which is furthest removed from this methylene group. A shift of the double bond

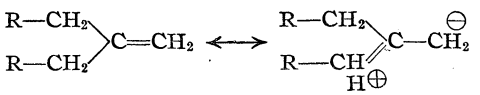
is a necessary consequence of this mechanism.[7]

The unusual reactivity shown by isobutylene type olefins is probably due, in large part, to hyperconjugation (*i. e.*, no bond resonance).



A study of the reactivity of methylenecyclopentane with formaldehyde, maleic anhydride, sulfur trioxide and azodicarboxylic ester is now in progress in this laboratory.

Experimental

Hexahydrobenzyl Acetate.—Three hundred grams of freshly distilled methyl benzoate was reduced to ethyl hexahydrobenzoate employing Raney nickel (10 g.) with hydrogen (2500 lb./sq. in.) at 125°. Reduction was complete in thirty minutes. After removing the catalyst, by filtration, the filtrate was reduced with hydrogen (4000 lb./sq. in.) and copper–chromite catalyst (15 g.) at a temperature of 250°. Direct acetylation of the product (after removing the catalyst) gave hexahydrobenzyl acetate; yield 275 g. (80%); b. p. 195–196° (745 mm.).

Anal. Calcd. for $C_9H_{16}O_2$: C, 69.20; H, 10.36. Found: C, 69.65; H, 10.10.

Methylenecyclohexane.—Hexahydrobenzyl acetate was passed continuously at the rate of 25 ml./hr. through a one-inch stainless steel pipe having a four-inch hot zone held at 570–575°. Dry nitrogen was passed slowly through the apparatus during the entire reaction. Removal of the acetic acid formed was effected by thorough extraction of the total liquid product with aqueous sodium carbonate (10%). Careful distillation of the neutral fraction gave pure methylenecyclohexane (72–88%) and unreacted hexahydrobenzyl acetate (8–22%). The olefin distilled sharply at 101–102° (738 mm.) and was identical with a sample prepared using the Tschugaeff[8] method following the directions of Faworski and Bergmann.[9]

2-(Δ-^{1}Cyclohexenyl)-ethanol.—To methylenecyclohexane (100 g.) contained in four Carius tubes was added paraformaldehyde (22.4 g., 95%). These tubes were cooled, flushed with nitrogen, sealed and heated at 200–205° for four hours. Direct fractional distillation of the combined products gave unused methylenecyclohexane (50 g.) and the 1-1 unsaturated alcohol; yield 50 g. (77%); b. p. 66–68° (1.8 mm.).

This alcohol gave a 3,5-dinitrobenzoate (m. p. 80–81°) identical with that formed from an authentic sample of 2-(Δ^1-cyclohexenyl)-ethanol.[6]

Anal. Calcd. for $C_8H_{14}O$: C, 76.14; H, 11.18. Found: C, 76.20; H, 11.10.

Reaction of Methylenecyclohexane with Phenylglyoxal.—A mixture containing phenylglyoxal (67 g.) and methylenecyclohexane (38.4 g.) was sealed under nitrogen and heated at 200° for twelve hours. Direct distillation gave a pale yellow oil; yield 80 g. (70%); b. p. 130–133° (0.4 mm.).

Anal. Calcd. for $C_{15}H_{18}O_2$: C, 78.23; H, 7.88. Found: C, 77.89; H, 7.92.

Δ^1-Cyclohexenylmethylsuccinic Acid.—A solution composed of methylenecyclohexane (40 g.) maleic anhydride (19.6 g.), and dry benzene was heated (under nitrogen) at 220–225° for eight hours. Distillation gave a viscous oil; b. p. 176–178° (12 mm.). This material failed to crystallize and was dissolved in warm potassium carbonate solution (10%). Careful acidification gave an oil which crystallized and, when pure, melted at 121°. It depressed the melting point of maleic acid 20°.

Anal. Calcd. for $C_{11}H_{16}O_4$: C, 62.25; H, 7.59; N. E. 106.1. Found: C, 62.37; H, 7.75; N. E. 105.8.

Oxidation of this sample at 30° with aqueous permanganate was rapid but no cyclohexanone could be detected.

Δ^1-Cyclohexenylmethane Sulfonic Acid.—Sulfur trioxide (22 g.) was distilled slowly into a mixture of dioxane (37 ml.) and ethylene chloride (20 ml.) maintained at −5°. To this was added over a period of one hour methylenecyclohexane (26.4 g.) dissolved in ethylene chloride (20 ml.). The solution, after standing overnight in an ice chest, was poured into ice water (800 ml.). When the aqueous phase was treated with barium carbonate (55 g.), reduced in volume (by evaporation on a steam-bath) to 200 ml. and chilled, there was obtained barium Δ′-cyclohexenylmethanesulfonate (20 g.). An additional 35 g. was produced on further evaporation. Treatment with one equivalent of sodium sulfate gave the sodium salt which in turn was converted into an S-benzylthiouronium salt[10]; m. p. 173–173.5°.

Anal. Calcd. for $C_{15}H_{22}O_3S_2N_2$: C, 52.60; H, 6.48. Found: C, 52.75; H, 6.61.

Cyclohexylmethanesulfonic Acid.—(a) Hexahydrobenzyl bromide (20 g.) was heated for thirty hours under reflux with sodium sulfite (10% excess) dissolved in water (100 ml.). When the solution cooled, a large quantity of sodium cyclohexylmethanesulfonate precipitated. Two recrystallizations from water gave a material which was free from bromide ion. An S-benzylthiouronium salt melted at 182–183°.

(b) Catalytic hydrogenation of an aqueous solution of sodium Δ^1-cyclohexenylmethanesulfonate was effected slowly with hydrogen (45 lb./sq. in.) and palladium–charcoal (10%) catalyst. Conversion to an S-benzylthiouronium salt in the usual manner[10] gave a product (m. p. 182–183°) which did not depress the melting point of the authentic sample described above.

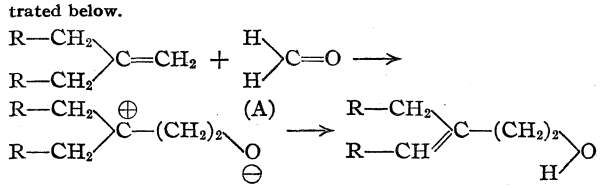
Summary

1. It has been shown that methylenecyclohexane reacts with formaldehyde, phenylglyoxal, maleic anhydride and sulfur trioxide to form 1–1 adducts.

2. A mechanism which necessitates a shift of the double bond to an adjacent position is suggested.

MINNEAPOLIS 14, MINN. RECEIVED JANUARY 10, 1948

(7) It does not appear possible at present to exclude an alternate mechanism involving a short-lived ionic intermediate (A) as illustrated below.



The rate of decomposition of (A) may be so rapid that its detection experimentally will be difficult or even impossible.

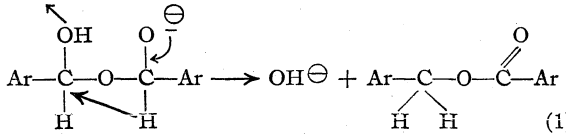
Studies on the Mechanism of the Cannizzaro Reaction. II. Hydroxy and Amino Aldehyde Derivatives

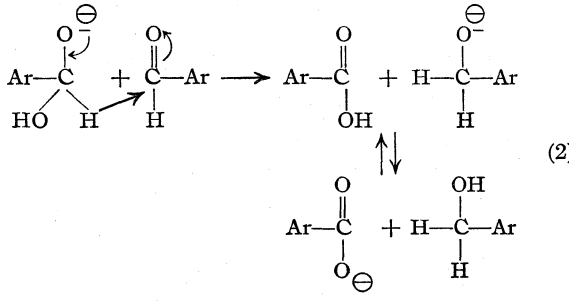
BY ELLIOT R. ALEXANDER

In an earlier communication[1] it was shown that the Cannizzaro reaction of benzaldehyde in a homogeneous system does not involve a chain reaction of the kind which is usually greatly influenced by the presence of peroxides or peroxide inhibitors. There are, then, two ionic mechanisms based upon the transfer of a hydrogen atom with its pair of electrons (*i. e.*, a hydride ion), which are in accord with much of the data. In one of the mechanisms which has been proposed by Geissman,[2,1] the essential feature of the reaction involves the *displacement* of a hydroxyl group from a saturated carbon atom (equation 1).



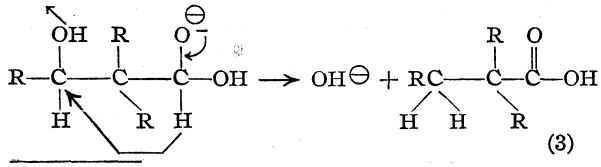
(1)

In the other mechanism, which is a slight modification of one originally proposed by Hammett[3,1] the *addition* of a hydride ion to a carbonyl group is postulated (equation 2).



(2)

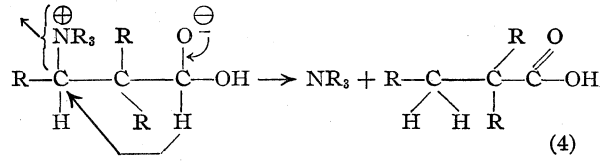
With respect to the first mechanism it appears that the direct chemical displacement of a hydroxyl group from a saturated carbon atom is unknown in alkaline solution.[4] If, however, such a displacement does occur over the carbon–oxygen–carbon system shown in equation 1, a similar displacement might be expected over the carbon–carbon–carbon system of a β-hydroxy aldehyde (equation 3).



(3)

Thus a saturated, non-hydroxylated acid should be a by-product in the transformation provided that the intramolecular reaction proceeded at a rate comparable to the normal Cannizzaro reaction or reverse aldolization. The normal reaction, of course, would be expected to give a molecule of a β-hydroxy acid and a molecule of a β-glycol.

A particularly favorable situation for such an intramolecular displacement is a quaternary aminoaldehyde. In this case the approach of the hydride ion to the carbon atom is favored by the positively charged nitrogen atom and subsequent bond-breaking would involve the separation of a neutral molecule.[5]



(4)

Accordingly it was the object of this work to isolate unsubstituted saturated acids from the Cannizzaro reaction of hydroxy and amino aldehyde derivatives.

Experimental[6]

Preparation of Starting Materials—With the exception of the methiodide of α-dimethylaminoisobutyraldehyde which is described below, all of the starting materials were known and were prepared by the procedures given in the footnotes of Table I. The physical properties of these compounds agreed with those which were recorded in the literature.

α-Bromoisobutyraldehyde and α-Bromoisobutyraldehyde Diethylacetal.—In a one-liter, three-necked round-bottomed flask fitted with a stirrer, a dropping funnel, and a reflux condenser were placed isobutyraldehyde diethylacetal (146 g., 1.0 mole), calcium carbonate (150 g., 1.5 moles) and 300 ml. of carbon tetrachloride. The flask was immersed in an ice–salt mixture, stirring was commenced, and bromine (51 ml., 1.0 mole) was added dropwise over the course of an hour. The reaction mixture was then filtered, the filter cake was washed with two 50-ml. portions of carbon tetrachloride and the filtrate was fractionally distilled through an eight inch column packed with glass helices. The distillation gave 23 g. (15%) of α-bromoisobutyraldehyde, b. p. 110–113°, and 108 g. (48%) of α-bromoisobutyraldehyde diethylacetal, b. p. 99–100° (40 mm.).

Additional quantities of α-bromoisobutyraldehyde were prepared by the hydrolysis of the acetal. The optimum conditions were found to be the following: α-bromoisobutyraldehyde diethylacetal (50.0 g., 0.22 mole), dioxane (100 ml.), water (50 ml.) and concentrated hydrochloric acid (10 ml.) were refluxed for about one minute at which time the cloudy solution abruptly became clear. The reaction mixture was then cooled rapidly in an ice-bath, poured into 300 ml. of cold water and extracted with

(3) Hammett, "Physical Organic Chemistry," McGraw-Hill Book Company, Inc., New York, N. Y., 1940, p. 350.

(4) The Strecker and Bücherer reactions may involve such a displacement, however.

(5) The author is indebted to Dr. T. A. Geissman for this suggestion.

(6) All melting points and boiling points are uncorrected.

ether. The ether solution was dried over anhydrous magnesium sulfate and distilled. The fraction boiling at 108–113° amounted to 15.6 g. (47%).

α-Dimethylaminoisobutyraldehyde and α-Dimethylaminoisobutyraldehyde Methiodide.—α-Bromoisobutyraldehyde (40.0 g., 0.265 mole) was added dropwise to a cooled solution of aqueous 35% dimethylamine (300 g., 2.33 moles) at such a rate that the temperature did not rise above 10°. The resulting homogeneous solution was then allowed to come to room temperature and to stand overnight. After extracting the solution thoroughly with ether and drying over anhydrous magnesium sulfate, the ether extracts were distilled through a small six inch column packed with glass helices. The yield of α-dimethylaminoisobutyraldehyde was 9.9 g. (32%), b. p. 126–129°.

Since this material appeared to absorb carbon dioxide from the air, it was quickly rinsed into a 300-ml. round-bottomed flask with 100 ml. of dry benzene and refluxed on a hot water-bath with excess methyl iodide for two hours. The white amorphous solid which formed was filtered with suction, washed with benzene and dried in a vacuum desiccator. The yield of α-dimethylaminoisobutyraldehyde methiodide was 20.3 g. (92%); m. p. 119–121° (dec.).

No suitable solvent was found for the large scale recrystallization of this quaternary salt. It was almost insoluble in hot acetone, absolute alcohol, and methanol. In methanol–water or ethanol–water mixtures the recovery was very poor and the material appeared to decompose with the evolution of methyl iodide. It was sparingly soluble in nitroethane and nitromethane from which it crystallized in the form of clear compact crystals, m. p. 119–121° (dec.).

Anal. Calcd. for $C_7H_{16}ONI$: C, 32.75; H, 6.28. Found: C, 32.88; H, 6.37.

The Cannizzaro Reaction.—The reaction itself was carried out with the amounts of material indicated in Table I. The aldehyde was added portion-wise to 5 molar equivalents of potassium hydroxide solution,[7] (50% in a mixture of equal parts of water and methanol) at such a rate that the temperature did not rise above 20°. The reaction mixture (which was sometimes non-homogeneous) was then stirred overnight at room temperature and finally refluxed one hour to complete the reaction.

The reactions were worked up in the usual way.[8] With the more water soluble products a continuous ether extractor was used to separate them from the aqueous solution of inorganic salts. The properties of the products which were obtained agreed well with those recorded in the literature with the exception of *o*-ethoxymethyl benzoic acid. Repeated recrystallization of this material gave a melting point of 83–84° rather than the reported 85–86°.[9]

The runs with the quaternary salts were acidified with concentrated hydrogen iodide, extracted thoroughly with ether and evaporated to dryness *in vacuo* on a steam-bath. Evaporation of the ether extracts left no higher boiling material showing that no unsubstituted acid was formed. The residue was then broken up with a spatula and taken to dryness twice with a mixture of 50 ml. of benzene and 50 ml. of absolute alcohol. This residue was then extracted three times with 50 ml. portions of absolute alcohol and these extracts fractionally crystallized. A similar procedure was used for the isolation of the hydrochloride of dimethylaminopivalic acid.

In the run with the methiodide of dimethylaminopivaldehyde only the methiodide of β-dimethylamino-α,α-dimethyl propyl alcohol was isolated. When the methiodide of α-dimethylaminoisobutyraldehyde was employed both the quaternary aminoalcohol and the hydrate of the quaternary aminoacid were isolated.

The methiodide of α-dimethylaminoisobutyl alcohol crystallized from absolute alcohol in which it was sparingly soluble in the form of clear compact crystals melting at 233–235° (dec.).

Anal. Calcd. for $C_7H_{18}ONI$: C, 32.50; H, 7.05. Found: C, 32.52; H, 7.15.

The hydrate of α-dimethylaminoisobutyric acid methiodide crystallized from hot absolute alcohol in which it was fairly soluble in the form of sponge-like microcrystalline clusters melting at 188–189° (dec.).

Anal. Calcd. for $C_7H_{18}O_3NI$: C, 28.90; H, 6.24. Found: C, 29.11; H, 6.50.

Discussion

In Table I are summarized the results which were obtained by carrying out the Cannizzaro reaction on several α, β and γ-hydroxy and amino

(7) In one run with *o*-ethoxymethyl benzaldehyde, sodium ethoxide in absolute ethanol was employed (see Table I).

(8) See ref. 2, p. 111–113.

(9) Footnote *q*, Table I.

aldehyde derivatives. Aldol and propionaldol formed aldehyde resins and isobutyraldol apparently underwent a simultaneous dealdolization and Cannizzaro reaction since the glycol was isolated but only isobutyric acid could be found in the acid fraction. In the other examples the normal Cannizzaro reaction occurred.

Obviously it cannot be concluded from this work that a displacement reaction such as the one shown in equation 1 does not occur, but it is quite clear that even in what appears to be the most favorable case (the quaternary amino aldehydes) the displacement shown in equations 3 and 4 does not proceed at a rate comparable to the Cannizzaro reaction.

Summary

A study of the products obtained by carrying out a Cannizzaro reaction on a number of hydroxy and amino aldehyde derivatives revealed that aldol and propionaldol formed aldehyde resins. Isobutyraldol gave the corresponding glycol and isobutyric acid, but in the other cases which were investigated the Cannizzaro reaction proceeded normally. These reactions are of interest since the occurrence of an intramolecular hydride ion displacement similar to one postulated for the Cannizzaro reaction would be expected to result in the formation of unsubstituted acids of the same carbon skeleton.

NOTES

Catalytic Oxidation of Alcohols at Low Temperatures

BY ROBERT H. BAKER AND DAVID STANONIS

By making use of the ease of oxidation of anthrahydroquinone by air, it has been possible to modify the usual Oppenauer reaction[1] and to demonstrate a catalytic oxidation of the alcohols. Thus, instead of anthraquinone being used as the oxidant in the reversible reaction,[2] RCH(OH)R + quinone $\rightleftarrows$ RCOR + hydroquinone, it is used only in catalytic amounts, and the progress of the reaction is followed manometrically. The conventional catalyst, aluminum *t*-butoxide, must be used in sufficient quantity to react with the water produced in the reaction, but this amount is no larger than that which is generally used.[1] The catalytic oxidation fails with aluminum *t*-butoxide made from certain batches of metal, but this is remedied by the addition of anhydrous cupric sulfate, or better cupric oleate, to the reaction mixtures.

Cholesterol was found to take up more than two atoms of oxygen while 4-cholesten-3-one with the same catalyst took up none. This is in agreement with the observations of Bergstrom and Wintersteiner[3] on the emulsion oxidation of steroid derivatives, in which those containing the 5,6 double bond are oxidized more extensively than those with 4,5 unsaturation.

Experimental

Apparatus.—The reactions were carried out in flasks shaken by a motor-driven eccentric and connected to a 100-ml. buret by means of a spiral of copper tubing bearing standard taper brass connections. Rubber connections were found to be unsatisfactory because of the rapid uptake of oxygen.

Oxidations.—The conditions of typical runs are shown in Table I. The amount of solvent used was 5 ml. per millimole of alcohol. Unpurified aluminum *t*-butoxide was used and the cupric salt was added only when necessary. The oxygen pressure was maintained at one atmosphere by means of a leveling bulb containing mercury.

TABLE I

Run	Compound	Millimoles	Al-(O-*t*-Bu)$_3$, millimoles	Cupric oleate, mg.	Quinone, millimoles	Solvent	*T*, °C.	O_2, atoms/mole compound	Time, hr.
1	Benzohydrol	50	30	..	5	*m*-Xylene	60	..	56
2	Same	3	4	50	0.3	Toluene	35	0.3	71
3	Fluorenol	3	4	50	0.3	Benzene	30	0.5	65
4	Same	3	4	..	0.3	Benzene	25	0.78	114
5	Cholesterol	15	20	..	15	Benzene	30	2.0	407
6	Cholestenone	3	4	..	15	Benzene	30	0.04	144

In numerous experiments fluorenol was found to take up oxygen more rapidly than benzohydrol, but duplicate rates on either compound could not be obtained. The yield of benzophenone from Run 1 was 56% (determined polarographically[2]). Fluorenone was isolated by steam

distillation of the reaction mixtures. From Run 4 its yield was 78%, corresponding to the oxygen uptake. In other experiments yields as high as 85% were encountered. Attempts to obtain crystalline products from the cholesterol oxidation products which had taken up from 0.7–2.0 atoms of oxygen were unsuccessful. The total oxygen uptake of cholesterol was not measured, the rate in Run 5 having diminished only slightly when the reaction was stopped.

The Synthesis of β-Oxoesters from Acyl Pyruvates

BY ALICE M. DESSERT AND I. F. HALVERSTADT[1]

β-Oxoesters were prepared by several methods for intermediates in the synthesis of thiouracils.[2] Another method used in this investigation was the decarbonylation of methyl acyl pyruvates. The procedure involved pyrolyzing the pyruvates by heating with powdered soft glass. In the case of the compounds which readily decomposed, a flash distillation procedure was used instead of batch heating.

The mechanism of this decarbonylation is not known but it is presumably similar to that by which ethyl pyruvate is pyrolyzed to ethyl acetate. In this latter case Calvin and Lemmon[3] found, by using C^{14}, that the carbon monoxide was evolved from the carbethoxy group.

Experimental

Pyruvates: The methyl acyl pyruvates were all prepared from methyl ketones by the method of Royals.[4] His method was slightly modified in that the alcohol was removed before working up the sodium salt. The methyl pyruvates prepared were: pivalo, b. p. 111–112° (11 mm.) (76% yield)[5]; butyl, b. p. 107–108° (5–6 mm.) (55%); propiono, b. p. 86–87° (2–3 mm.) (35%); and myristyl, a new compound, m. p. 52–53° (cor.).

Anal. Calcd. for $C_{18}H_{32}O_4$: C, 69.19. Found: C, 68.91.

β-Oxoesters: Methyl β-oxo-γ-dimethylvalerate[6] was prepared by heating a mixture of 18.62 g. (0.1 mole) of methyl pivalopyruvate and 2 g. of ground soft glass at 175°. In five hours approximately 95% of the theoretical volume of carbon monoxide was collected, so heating was discontinued and the residual liquid distilled. An 80% yield of the β-oxoester, b. p. 91–96°, chiefly 91–93°, at 20 mm. was obtained. A run using 950 g. (5.1 moles) of methyl pivalopyruvate yielded 80.1% of β-oxoester.

Methyl β-oxopalmitate was prepared by heating a mixture of 3.2 g. (0.01 mole) of methyl myristylpyruvate and 0.3 g. of ground soft glass at 185°. After twenty minutes heating was discontinued when more than the theoretical amount of gas had been collected. Most of the residue dissolved in alcohol. The alcoholic solution was evaporated and the residue distilled at 155–165° at 1 mm. The distillate solidified in the condenser. After recrystallization from dilute alcohol, the solid melted at 34–35°. The copper salt was made and recrystallized from petroleum ether, m. p. 78–81°.

Anal. Calcd. for $C_{34}H_{64}CuO_6$: Cu, 10.1. Found: Cu, 10.3.

In a typical run for the preparation of **methyl β-oxocaproate,**[7] 17.2 g. (0.1 mole) of methyl butyropyruvate was flash distilled over 2 g. of ground soft glass. The flask containing the glass was heated in a metal-bath kept at 365°. The pyruvate was forced over the hot glass in 0.5-cc. portions and distilled as rapidly as possible at 240° to prevent side reactions. On fractional distillation of the mixture, 4.46 g. (31% yield) of the β-oxoester, b. p. 85–95° at 14 mm. and 9.09 g. of methyl butyropyruvate, b. p. 110–112° at 7 mm., were collected. The yield corrected for recovered pyruvate was 65%.

Methyl β-oxovalerate[6] was prepared by flash distillation as was the methyl β-oxocaproate. On fractional distillation, in the most successful run, 4.44 g. (31% yield) of β-oxoester, b. p. 60–65° at 14 mm. and 6.52 g. of pyruvate were obtained. The yield corrected for recovered pyruvate was 50%. The crude copper salt, m. p. 155–157°, checked the melting point of the crude salt given in the literature.[6]

The Removal of Aluminum Chloride from Friedel–Crafts Mixtures Containing Water-Labile Phosphorus Halides

BY WILLIAM T. DYE, JR.[1]

The most useful of three methods developed by Michaelis for the synthesis of aromatic phosphine halides is the Friedel–Crafts reaction of aromatic hydrocarbons and phosphorus trichloride.[2,3] This method has one serious drawback, its incomplete and malodorous method of product isolation by extraction. Two new methods of separating the product have been developed. One is an adaptation of Robinson's method[4] to the recovery of phosphine halides. The other depends upon the precipitation of the complex $Al_2Cl_6 \cdot 2POCl_3$.[3] Although both of these methods have been successfully used in the preparation of several aromatic phosphine halides, only the application to phenyldichlorophosphine is presented in detail.

Experimental

Reagents.—The aluminum chloride, benzene (dried over phosphorus pentoxide) and phosphorus trichloride were J. T. Baker C. P. quality.

Preliminary Procedure.—In all experiments, various molar proportions of aluminum chloride, benzene and phosphorus trichloride were refluxed in three-neck flasks fitted with a rubber-sealed glass stirrer, thermometer, reflux condenser, hydrogen chloride trap, and mantle heater. Reaction times, usually one to four hours, were only long enough for practical cessation of hydrogen chloride evolution. The catalyst was then removed by either of the following methods.

(1) Present address: Central Research Laboratories, Monsanto Chemical Co.

(2) Michaelis, *Ber.*, **12**, 1009 (1879).

(3) Michaelis, *Ann.*, **293**, 198–200 (1896).

(4) Robinson, U. S. Patent 2,211,704; *C. A.*, **35**, 468 (1941).

With Water.—The reaction mixture was cooled to room temperature and diluted with benzene or low-boiling petroleum ether. An optimum quantity of 3 moles of water per mole of catalyst was stirred in as rapidly as foam control would allow. (Water was added either pure or as concentrated hydrochloric acid.) About 50 cc. more of solvent was then added. During the following brief period in which hydrogen chloride evolution ceased, the supernatant liquid was decanted. The solvent was then removed and the product vacuum-distilled.

Table I shows the effect of stirring different quantities of water, as concentrated hydrochloric acid, into 0.1:0.4:0.4-mole reaction mixtures of aluminum chloride, benzene and phosphorus trichloride.

TABLE I

YIELD OF PHENYLDICHLOROPHOSPHINE AFTER REMOVAL OF CATALYST WITH WATER

Moles water added	Yield $C_6H_5PCl_2$, g.
0.25	10.7
.275	15.3
.30	20.6
.325	20.9
.35	20.2
.40	16.8

The yield of phenyldichlorophosphine rose rapidly as the critical point of 3 moles water per mole aluminum chloride was approached, and as much as a 10% excess of water did no harm. When sufficient water was added, the hydrated catalyst separated as soft slightly coherent granules, free of product and easily filtered or decanted.

With Phosphorus Oxychloride.—One mole of phosphorus oxychloride per mole of aluminum chloride was added to the hot reaction mixture (with a temperature rise of about 5°), excess phosphorus trichloride and benzene were recovered by vacuum-stripping, the residue was cooled to 40° or below, the catalyst complex was completely precipitated by dilution with about three volumes of light petroleum, and the liquid layer was decanted and distilled. (Caution: In a few instances, involving large excess of phosphorus trichloride and benzene, the mixture separated into two layers when the oxychloride had been partly added, with consequent vigorous boiling of the more volatile layer. This can be prevented by stripping the excess of reactants before addition of phosphorus oxychloride.)

The utility of the latter procedure in Friedel–Crafts reactions in general seems limited only by the provision that the phosphorus oxychloride–aluminum chloride complex must be the most stable one possible in any given reaction mixture. The method has the advantage over the foregoing hydration process that there is no evolution of hydrogen chloride and consequently no tendency for the precipitate to float. Both of these methods appear suitable for isolating other Friedel–Crafts products decomposed by the conventional catalyst quenching process.

A Synthesis of α,β-Unsaturated Amides

BY ALEXANDER GALAT

In a previous communication[1] we have reported a synthesis of α,β-unsaturated esters which involved the condensation of an aldehyde with a monoester of malonic acid. It appeared that a similar direct synthesis of α,β-unsaturated amides could be accomplished by condensing an aldehyde with the mono-amide of malonic acid

$$R{-}CHO + CH_2\begin{matrix}CONH_2\\COOH\end{matrix} \xrightarrow[-CO_2]{-H_2O} R{-}CH{=}CH{-}CONH_2$$

It was found that malon-monoamide did, in effect, readily condense with several representative aldehydes (benzaldehyde, *p*-dimethylaminobenzaldehyde, naphthaldehyde and furfural) to give satisfactory yields of the expected unsaturated amides.

The monoamide of malonic acid was prepared by treating diethyl malonate with one mole of potassium hydroxide in methanol, followed by ammonolysis of the monoester thus formed. The amide is a white, crystalline solid which melts at 110–115° with evolution of carbon dioxide and quantitative formation of acetamide. Its solution in water is strongly acid and can be accurately titrated. Heated with salts of primary amines, malon-monoamide reacts as an acetylating agent

$$R{-}NH_2{\cdot}HCl + CH_2\begin{matrix}CONH_2\\COOH\end{matrix} \xrightarrow[-NH_4Cl]{-CO_2} R{-}NHCOCH_3$$

Experimental

Malon-monoamide.—To a solution of 160 g. (1 mole) of diethyl malonate in 450 ml. of methanol was added slowly with stirring 280 ml. (1 mole) of 20% methanolic potassium hydroxide. After the addition was completed the mixture was stirred until the reaction became neutral. The crystalline precipitate was filtered off and the filtrate evaporated to dryness *in vacuo*. The combined solids weighed 132 g. (85%). The product is the potassium salt of mono-methyl malonate (ester interchange takes place when working in methanol).

The potassium salt was dissolved in 500 ml. of concentrated ammonium hydroxide and the solution kept at room temperature for one week. It was then evaporated to dryness *in vacuo*, treated with 76 ml. of concentrated hydrochloric acid and stirred until homogeneous. To the mixture was added 275 ml. of isopropanol, the precipitated potassium chloride filtered off, washed with isopropanol and the filtrate evaporated to dryness *in vacuo*. To the resulting sirup was added 150 ml. of hot isopropanol and an additional amount of potassium chloride removed by filtration. Malonmonoamide crystallized upon cooling and was filtered off, washed with isopropanol and dried at room temperature; yield, 52 g. (61%), m. p. 110–115° (dec.).

Anal. Calcd.: N, 13.59; neut. equiv., 103. Found: N, 13.4.; neut. equiv., 103.5.

Cinnamamide.—One gram of benzaldehyde (*ca.* 0.01 mole), 2 g. (*ca.* 0.02 mole) of malon-monoamide, 2 drops of piperidine and 5 ml. of pyridine were heated on a water-bath until the evolution of gas ceased. To the mixture was added 25 ml. of boiling water, the solution cooled and the precipitated amide recovered by filtration; yield, 0.8 g. (57%), m. p. 146–147° (cor.), lit. 142°.

Preparation of Aliphatic Fluorides

BY FRIEDRICH W. HOFFMANN

The exchange of halogen in aliphatic —CHX— and $-CH_2X$ groups (X = Cl, Br) by means of an-

hydrous potassium fluoride has been described recently.[1,2,3] Since this reaction takes place only at higher temperatures, the use of pressure equipment is required and much trouble is due to coating of potassium fluoride with potassium chloride or potassium bromide, respectively. Only in the special case of the preparation of fluoroacetamide from chloroacetamide the use of xylene as reaction medium allows the reaction to be carried out at atmospheric pressure.[3]

By using suitable organic solvents for anhydrous potassium fluoride, it is possible to exchange the halogens in —CHX— and —CH_2X groups (X = Cl, Br, I) in a one-step reaction at atmospheric pressure in ordinary glass equipment. In order to obtain reasonably fast reaction rates, the method requires a temperature of about 140° and over, so that low-boiling solvents for potassium fluoride, such as methanol and ethanol cannot be used. Satisfactory solvents are aliphatic di- and polyhydroxy compounds such as ethylene glycol, glycerol, diethylene glycol, polyethylene glycol, etc., either singly or mixed.

In this procedure the yields are fair and frequently considerably higher than those obtained by the pressure method. *n*-Hexyl fluoride can thus be obtained from *n*-hexyl chloride in 54% yield, whereas the halogen exchange under pressure without solvent for the potassium fluoride gives only a 20% yield.[2] 2-Fluoroethanol, which could not be obtained by heating of ethylene chlorohydrin with potassium fluoride under pressure by Gryszkiewicz-Trochimowski[4], was, however, prepared by McCombie and Saunders[1] by the same method at 135–140° (no yield indicated). The subject method permits the preparation of this compound in 42.5% yield by using potassium fluoride in a glycol solvent at atmospheric pressure. Another advantage of the use of a solvent for the halogen exchange is the fact that the presence of small amounts of moisture in one of the reactants can lead to serious hazards by enormous pressure increase in the conventional method,[2] whereas in the described method only the yield of fluorinated product is correspondingly decreased.

Although the subject method is in some respects inferior to conventional methods using fluorides of mercury, etc., the ready availability of the inexpensive potassium fluoride makes it another convenient means for the preparation of aliphatic fluorides, especially since some fluorides such as 2-fluoroethanol, β-difluoroethyl ether, etc., which cannot be obtained by fluorination with silver or mercuric fluoride, are accessible from the corresponding chlorine compounds by fluorination with potassium fluoride.

A large number of new aliphatic fluorine compounds was synthesized by this method by the writer in collaboration with R. Geier in the laboratories of W. Bockemüller in Würzburg, Germany.

The syntheses of 2-fluoroethanol and *n*-hexyl fluoride from the corresponding chlorine compounds by halogen exchange with anhydrous potassium fluoride in glycol solution are described in detail in the following.

Preparation of FCH_2CH_2OH.—A mixture of dry, powdered potassium fluoride (350 g., 6 moles), ethylene glycol (320 g.), and diethylene glycol (130 g.) was heated to 170° in a 3-neck, 1-liter, round-bottom flask fitted with a stirrer, dropping funnel, and a 30-cm., 3-step Vigreux column with attached condenser and receiver. Ethylene chlorohydrin (322 g., 4 moles) was added dropwise in the course of three hours to the reaction mixture maintained at 170–180° with constant stirring at such a rate that the distillate at the still head showed a temperature of 95–105°. After addition of ethylene chlorohydrin was complete, a slow stream of air was sucked through the apparatus for one hour in order to distil off the fluoroethanol completely. In the receiver, 152.5 g. of crude reaction product was obtained as a colorless liquid. After standing with 10 g. of sodium fluoride for two days to remove traces of hydrogen fluoride, distillation of the reaction product yielded 109 g. (42.5%) of fluoroethanol (b. p. 101°,[1] 100–102°[2]) between 97° and 104°.

Preparation of $CH_3(CH_2)_4CH_2F$.—A mixture of dry, powdered potassium fluoride (116 g., 2 moles), ethylene glycol (200 g.), and diethylene glycol (50 g.) was heated to 180° in a 3-neck, 1-liter, round-bottom flask fitted with a stirrer, dropping funnel and a 30-cm., 3-step Vigreux column with attached condenser and receiver. *n*-Hexyl chloride (120.6 g., 1 mole) was added dropwise in the course of eight hours to the reaction mixture maintained at 175–185° with constant stirring. Since the reaction product boils at 93.2°, it distils out of the reaction mixture at about the same rate at which the reagent is added. After addition of hexyl chloride was complete, the reaction mixture was allowed to cool to 110°. A slow stream of air was sucked through the apparatus in order to distil off the remaining reaction product from the mixture. In the receiver, 79.6 g. of distillate was collected. This consisted of *n*-hexyl fluoride with some hexene and some unreacted hexyl chloride. Fractionation yielded 56.3 g. (54.1%) of *n*-hexyl fluoride, boiling at 91–93.5°.

The Terpenes of Oil Sweet Goldenrod

BY BRYANT R. HOLLAND

In a study of the production of essential oils, oil of Sweet Goldenrod (*Solidago odora*)[1] has been investigated. Miller and Moseley[2] examined this oil fairly extensively, but did not identify the terpenes. They identified methyl chavicol as the main constituent, and showed borneol to be present. To extend the findings of Miller and Moseley, the oil has been partially fractionated and the terpenes determined.

Experimental

A 600-ml. sample of fresh oil was fractionated using a Stedman column (24 inch packing, 1 inch diameter) at a pressure of 5 mm. with a reflux ratio of 0.5 (50% of the condensate returned to the column). The starch–glycerol

(1) The complete investigation is to be reported in a Texas Engineering Experiment Station Bulletin.
(2) Miller and Moseley, THIS JOURNAL, **37**, 1285 (1915).

stopcock lubricant described by Herrington and Starr[3] was a satisfactory lubricant for the stopcocks and ground joints used in the distillation apparatus. The following fractions were obtained:

Fraction	Volume, ml.	Temp., °C.	$n^{29}D$	$\alpha^{29}D$
1	20	30	1.4677	+84.17°
2	60	31	1.4683	+96.67°
3	10	32	1.4690	+92.00°
Residue	510	..	1.5173	− 0.50°

Fractions 1, 2 and 3 account for 15% of the oil. The physical properties of fraction 2 are similar to those of *d*-limonene. The presence of *d*-limonene was confirmed by preparing the β-nitrol anilide, m. p. 153°, and the tetrabromide, m. p. 103.5°, $[\alpha]^{30}D$ +72.0° (0.1785 g. of *d*-limonene tetrabromide in 5 ml. of carbon tetrachloride solution).

A 1500-ml. portion of the fresh oil was subsequently fractionated, as above, at a pressure of 22 mm., with a reflux ratio of 0.9 (90% of the condensate returned to the column). The first fraction, 3.1 ml., boiling at 55°, had a refractive index of 1.4628^{25}, and a rotation of −37.67°. Calculated for *l*-α-pinene this would be a specific rotation of −43.70°, which is near the reported −48.63°.[4] The presence of *l*-α-pinene was confirmed by the preparation of α-pinene nitrolpiperidine, m. p. 118.5°. The quantity found by distillation represents 0.2% of the oil.

The specific rotation of *d*-limonene as calculated from the rotation of fraction 2 would be +114°, as compared to a specific rotation for pure *d*-limonene of +126°.[5] This plus the refractive index of fraction 2 indicates the probable presence of dipentene. No direct evidence for the presence of dipentene or other terpenes was obtained. The negative rotation of the terpeneless residue indicates that the borneol is probably *l*-borneol. Methylchavicol, an isomer of anethol, is responsible for the anise-like odor and flavor. The odor and flavor of the oil are decidedly improved by the removal of the terpenes.

Preparation of Tetraacetyl-α-D-glucopyranosyl Bromide

BY C. G. JEREMIAS, G. B. LUCAS AND C. A. MACKENZIE

There are many references in the literature pertaining to the preparation of tetraacetyl-α-D-glucopyranosyl bromide. Most authors recommend the use of an acetic acid solution of hydrogen bromide with pentaacetyl-β-D-glucose. They differ in their experimental details, particularly with respect to the use of vacuum distillations, solvents and purifications methods. The description given below eliminates vacuum distillations, simplifies the purification process and gives a pure product in good yield with a minimum of effort.

Experimental

A mixture of 20 g. of pentaacetyl-β-D-glucose and 20 ml. of hydrobromic acid–acetic acid solution (Eastman Kodak Co. 30–32% hydrobromic acid–acetic acid) is stirred at room temperature for two hours in a flask protected from moisture. The clear, yellow solution is poured, in a thin stream, into 400 ml. of vigorously stirred ice water. A finely divided, crystalline material is obtained. If the addition is made too rapidly the product solidifies in the form of large lumps. The crude acetobromoglucose is filtered with suction and then transferred to a small separatory funnel. Fifty ml. of carbon tetrachloride is added to put the solid into solution. The water layer formed is drawn off with a suction pipet and the product remaining is washed once with 20 ml. of ice water and then with a few ml. of cold, saturated sodium bicarbonate solution until all free acid has been removed. The solution is finally washed with two 20-ml. portions of ice water. The carbon tetrachloride layer is filtered through glass wool into an erlenmeyer flask and dried over calcium chloride. The dry solution is poured slowly, with stirring, into 200 ml. of petroleum ether (35–75° boiling range was used; a good quality reagent is necessary or a yellowing of the product may occur at this point). When crystallization at room temperature is complete, an ice-salt-bath is placed around the container and an additional crop of crystals form. The crystals are filtered with suction and air-dried or dried in a vacuum desiccator. The product at this point has a m. p. 88–89°; yield, about 18 g. (80–85%).

Heats of Mixing of Some Fluorinated Ethers with Chloroform

BY J. R. LACHER, J. J. MCKINLEY AND J. D. PARK

It is well known that chloroform and monofluorodichloromethane will form hydrogen bonds with solvents containing donor atoms such as nitrogen and oxygen.[1] Diethyl ether[2] and polyethylene glycol ethers[3] show a considerable heat evolution when mixed with chloroform or monofluorodichloromethane. The substitution of chlorine in an aliphatic ether[4] or the replacing of an alkyl by an aryl group[5] reduces considerably the tendency for bonding. Recently[6] a number of polyfluoro alkyl ethers have been prepared in this Laboratory. If one interprets hydrogen bonds as the result of an interaction between dipoles,[7,8,9] one might expect that these fluorinated ethers would also show only a slight tendency for hydrogen bonding. The moments are not known for these molecules. However, one can calculate,

using bond moments,[10] the dipoles for similar compounds. Dimethyl ether has a moment of 1.32 debye units and the negative end may be regarded as being on the oxygen atom. Hexafluorodimethyl ether, on the other hand, has a calculated dipole moment of 0.40 debye unit and the direction of the moment is reversed. Methyl trifluoromethyl ether has a calculated moment of 1.31 and it makes an angle of 37° with the methyl–oxygen bond. Its negative end lies between the oxygen and the trifluoromethyl group. As a result the negative charge is spread out between the two. A similar situation will obtain for the ethers dealt with here. Experiments were undertaken to measure their hydrogen bonding tendencies and the method chosen involves measuring their heats of mixing with chloroform at 0°.

The mixing calorimeter was modified after those described by McLeod and Wilson,[2] Vold,[11] Von Steinwehr,[12] and Zellhoefer and Copley.[4] The mixing chamber consisted of a 170-cc. Pyrex dewar which could be evacuated by means of a diffusion pump. A tight fitting lid contained holes to receive two pipets and a long Pyrex tube. The latter contained a 12-junction copper–constantan thermocouple, nichrome heater, and also served as a stirrer. The lower end of the tube was fitted with a glass disk and stirring was accomplished by means of a reciprocating motor. The whole assembly was contained in a gallon dewar and maintained at 0° with ice. The output from the thermel was fed into a Leeds–Northrup "Speedomax" recorder. In making a run, the temperature change produced on mixing two liquids was compared with that produced by electrical heating in the usual way.

The preparation of the fluoroalkyl ethers has been previously described.[6] Diethyl ether was dried over sodium and distilled. Acetone was purified by the method of Shipsey and Werner[13] using sodium iodide. Monofluorodichloromethane, furnished us through the courtesy of Mr. A. F. Benning of the du Pont Company, was distilled in a twenty-plate column.

Discussion.—In order to check the reliability of the apparatus and develop the necessary technique, the heats of mixing of chloroform with diethyl ether and with acetone were measured. The former system has been studied by McLeod and Wilson[2] at 0° and the latter by Hirobe[14] at 25°. The data obtained are shown in Figs. 1 and 2. The heat evolved in calories per mole of solution may be represented by a parabolic curve of the type: $-\Delta H = (N - N^2)A$. N represents the mole fraction of the halogenated hydrocarbon and A is an adjustable constant. These curves, also shown in the figures, give heats of mixing of −670 and −470 cal./mole for diethyl ether and acetone, respectively, at $N = 0.5$. This compares with −714 and −460 cal./mole determined by McLeod and Wilson and by Hirobe, respectively.

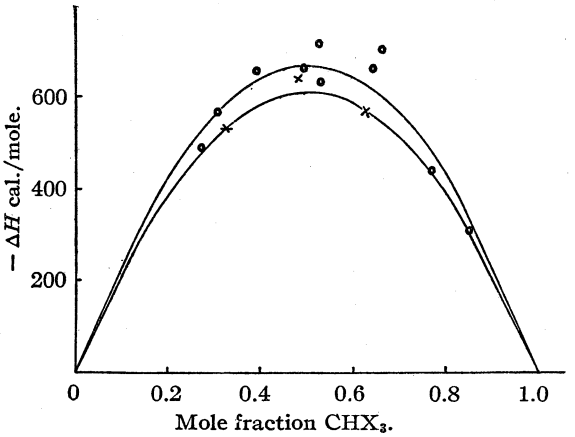

Fig. 1.—Heats of mixing in calories per mole of solution—systems: diethyl ether–chloroform, O, and diethyl ether–$CHFCl_2$, X.

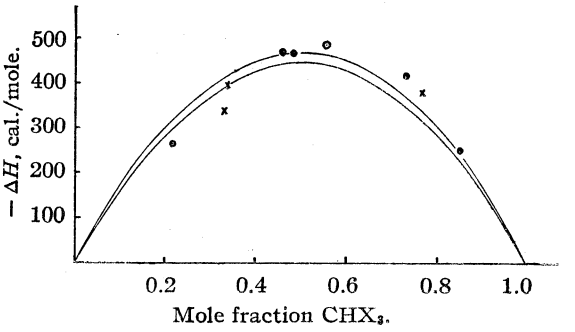

Fig. 2.—Heats of mixing in calories per mole of solution for the systems: O, acetone–chloroform; X, acetone–$CHFCl_2$.

A few runs using monofluorodichloromethane in place of chloroform were made. The results, shown in Figs. 1 and 2, suggest that less heat is liberated when the monofluorinated compound is used. The effect, however, is of the same order of magnitude as the experimental error. Zellhoefer and Copley[3] using polyethylene glycol ethers found a similar situation. The solubility[1] of chloroform in the dimethyl ether of tetraethylene glycol is, however, measurably greater than that of the monofluorinated derivative. This may be interpreted to mean that some C—H ← F bonds were present in $CHFCl_2$. It may also be explained by the fact that, whereas in chloroform the dipole moment is along the carbon–hydrogen bond, in $CHFCl_2$ it is askew. Consequently, a larger decrease in entropy will result when the latter forms a hydrogen bond with the ether. This will account for the larger difference shown between chloroform and $CHFCl_2$ in solubility measurements (which involve a free energy change) than is given in a measurement of ΔH.

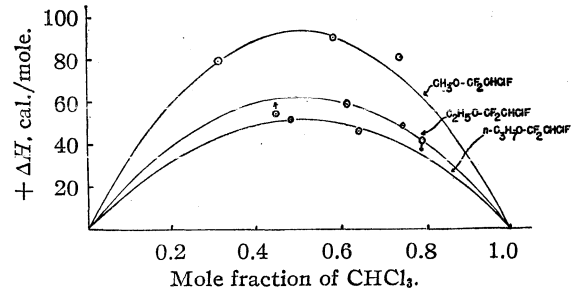

Fig. 3.—Heats of mixing in calories per mole of solution for the systems: chloroform with polyfluoro alkyl ethers.

The results obtained on mixing chloroform with the methyl, ethyl and *n*-propyl derivatives of 1,1,-2-trifluoro-2-chloroethyl alkyl ethers are shown in Fig. 3 and Table I gives the heats of mixing per mole of solution at a mole fraction of 0.5.

TABLE I

HEATS OF MIXING OF 1,1,2-TRIFLUORO-2-CHLOROETHYL ALKYL ETHERS WITH CHLOROFORM AT 0°

Ether	ΔH, cal./mole
Methyl	93 ± 3
Ethyl	62 ± 4
n-Propyl	52 ± 3

The isopropyl derivative gave heat effects of the same magnitude as the normal compound. Sufficient material was not on hand for quantitative study. In contrast to the behavior shown by diethyl ether and acetone, the heats of mixing were small and positive. The slight cooling effect produced indicates the lack of formation of hydrogen bonds, at least in large numbers.

The Structure of Dioxadiene Dibromide

BY GERALD R. LAPPIN[1] AND R. K. SUMMERBELL

Some time ago dioxadiene was found to react with only one molar equivalent of bromine to give a crystalline compound, dioxadiene dibromide, of unknown structure.[2] This was presumed to be 5,6-dibromo-*p*-dioxene. However, the possibilities that it had an oxonium bromide structure or that the dioxadiene ring had been ruptured were not excluded.

We have now found that I does not react with aqueous potassium iodide solution, a characteristic reaction of oxonium bromides.[3] Furthermore, I reacts with the magnesium–magnesium iodide dehalogenating reagent[2] and with phenylmagnesium bromide to regenerate dioxadiene in high yield. Thus the structure of I must be 5,6-dibromo-*p*-dioxene.

Attempted Reaction of I with Aqueous Potassium Iodide Solution.—To a solution of 1.0 g. of potassium iodide in 20 ml. of water was added 0.5 g. of I. No iodine was liberated on heating at 60° for twenty-four hours.

Reaction of I with Magnesium–Magnesium Iodide Reagent.—In a two-necked flask fitted with a mercury-sealed stirrer and a side-arm connected to a condenser arranged for downward distillation were placed 10 g. of magnesium turnings and 75 ml. of anhydrous butyl ether. To this was added slowly 4 g. of iodine. The solution was heated until distillation started and to it was added dropwise a solution of 10 g. (0.04 mole) of I in 50 ml. of butyl ether. A total of 100 ml. of distillate was collected during this addition. Redistillation through a 10-cm. Vigreux column gave 3.4 g. (97%) of dioxadiene, b. p. 74–75°, $n^{20}D$ 1.4351.

The Reaction of I with Phenylmagnesium Bromide.—To a solution of phenylmagnesium bromide prepared from 2.64 g. (0.11 atom) of magnesium and 17.3 g. (0.11 mole) of bromobenzene in 100 ml. of dry ether was slowly added a solution of 12.3 g. (0.05 mole) of I in 75 ml. of dry ether. After the moderately vigorous reaction subsided the mixture was allowed to stand for twelve hours and was then hydrolyzed by pouring into ice and ammonium chloride solution. The ether solution was separated and dried over magnesium sulfate. Distillation gave 5.9 g., b. p. 75–80°, and a sirupy residue. The distillate was dissolved in 50 ml. of carbon tetrachloride and to it was added dropwise a solution of bromine in carbon tetrachloride at 0° until a faint permanent color remained. Removal of the solvent *in vacuo* gave 9.6 g. of crystalline residue identified as I by mixture melting point. Assuming an average yield of 90% on the addition of bromine to dioxadiene this represents an 87% conversion to dioxadiene.

EVANSTON, ILLINOIS RECEIVED APRIL 12, 1948

The Solubility of Aluminum Bromide in Cyclohexane[1]

BY PHILIP A. LEIGHTON AND JOHN B. WILKES

During the course of a study of the isomerization of cyclohexane with aluminum bromide catalyst, the solubility of aluminum bromide in cyclohexane has been determined.

Materials.—Aluminum bromide was prepared and distilled into glass ampoules in the manner described by Leighton and Heldman.[2]

The cyclohexane was the gift of the Shell Oil Company. The stated analysis as received was 99.7 vol. % cyclohexane (by correlation of freezing point and mass spectrograph analysis), 0.0003 wt. % sulfur, less than 0.0005 vol. % benzene and less than 0.001 vol. % phenols. The freezing point was 6.0°. This material was further purified by "freezing out" cyclohexane crystals, followed by percolation of the remelted crystals through silica gel. The "freezing out" was performed as follows: About 300 ml. of cyclohexane contained in a 500-ml. Erlenmeyer flask was placed in a cooling bath of ice and water, and, with frequent hand stirring and scraping, a thick slurry of cyclohexane crystals was produced. The crystals were filtered off, melted, and the process repeated. The resultant cyclohexane was percolated through a column of silica gel to remove water and any trace of olefins. The product was stored over sodium in brown glass bottles. Physical properties of the purified cyclohexane were: m. p. 6.5°, $n^{25}D$ 1.4235.

(1) Present address, Chemistry Department, Antioch College, Yellow Springs, Ohio.

(2) Summerbell and Umhoeffer, THIS JOURNAL, **61**, 3020 (1939).

(3) McIntosh, *ibid.*, **32**, 1330 (1910).

(1) This work was supported by a grant from the Research Corporation.

(2) Leighton and Heldman, THIS JOURNAL, **65**, 2276 (1943).

Determination of Solubility.—The purified cyclohexane was placed in a flask attached to the vacuum system by a ground glass joint, thoroughly degassed, and distilled into the ampoules containing aluminum bromide. Each ampoule was sealed off from the vacuum line when it was estimated that it would be nearly full of solution upon reaching the solution temperature. Solution temperatures were determined as described by Heldman and Thurmond.[3] All the solutions were clear and colorless. Samples were analyzed as follows: The aluminum bromide was precipitated in finely divided form[2] and the ampoule placed tip down in a long narrow flask equipped with standard taper joint and glass stopper. The flask and contents were weighed, and the flask shaken to break open the ampoule. The flask was then connected to a trap by all-glass connections using unlubricated standard taper joints. The trap was in turn connected to a vacuum pump. The vacuum pump was turned on and the flask cooled by immersion in a slurry of dry ice, chloroform, and carbon tetrachloride. After the system was evacuated, the dry ice slurry was removed and pumping continued until some time after the flask had reached room temperature. The cyclohexane was condensed in the trap. The aluminum bromide remained behind as a finely divided, white powder. The flask and contents were weighed and the cyclohexane calculated by difference. The aluminum bromide was removed by washing successively with nitrobenzene, water, and acetone. The flask and glass parts were weighed and the aluminum bromide calculated by difference.

TABLE I

SOLUTION TEMPERATURES OF ALUMINUM BROMIDE–CYCLOHEXANE MIXTURES

	Al_2Br_6			Al_2Br_6	
t, °C.	Mole fract.	Wt. % liq. phase	t, °C.	Mole fract.	Wt. % liq. phase
6.2	0.0503	25.1	38.7	0.178	57.9
8.8	.0568	27.6	39.8	.183	59.4
17.2	.0788	35.2	44.5	.220	64.2
26.4	.115	45.1	57.0	.333	76.0
28.5	.124	47.4	60.3	.380	79.5
36.0	.162	55.0	61.7	.393	80.4
37.6	.169	56.4	97.5	1.000	100.0

Results

The solution temperatures and compositions of the solutions examined are given in Table I. The moles of aluminum bromide are calculated on the basis of the formula Al_2Br_6. No correction was made for the cyclohexane in the vapor phase because of the comparatively low vapor pressure of cyclohexane and the small vapor volume present in the ampoules. The results show that aluminum bromide is appreciably more soluble in cyclohexane than in *n*-butane[2] or *n*-hexane[4] when calculated on a mole fraction basis. On a weight basis aluminum bromide is more soluble in cyclohexane than in *n*-hexane throughout the temperature range for which data are available and is more soluble in cyclohexane than in *n*-butane throughout much of the lower temperature range.

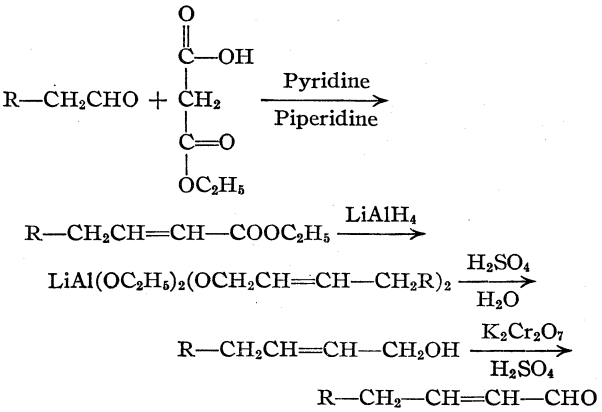
The Preparation of 2-Heptenal and 2-Nonenal

BY C. J. MARTIN, A. I. SCHEPARTZ AND B. F. DAUBERT[1]

Recent work in this Laboratory on the isolation and identification of flavor components in "reverted" soybean oil has necessitated the preparation of a number of α,β-unsaturated aldehydes of a high degree of purity. The recent availability of lithium aluminum hydride as a reducing agent[2] led to the development of a suitable method for the preparation of such aldehydes free of their saturated isomers.

The general scheme of reaction may be outlined as follows



Experimental

Preparation of 2-Heptenal.—Ethyl hydrogen malonate (256 g.) was condensed with *n*-valeraldehyde (83.3 g.) in pyridine (469 g.) with piperidine (1.2 ml.) as a catalyst, according to the method of Galat.[3] After removal of the pyridine and piperidine, the ethyl 2-heptenoate was distilled *in vacuo* under nitrogen: yield, 118 g. (78.2%), b. p. 58–58.8° (3 mm.), $n^{25}D$ 1.4355.

To a solution of lithium aluminum hydride (10.9 g., 14% excess) in absolute ether (450 ml.) there was added ethyl 2-heptenoate (78 g.) according to the method of Nystrom and Brown.[2] Although the crude yield of 2-heptenol was 45 g. (79%), distillation, under nitrogen, through a Vigreux column, resulted in a loss of approximately 50% because of partial polymerization of the alcohol. The 2-heptenol had a boiling point of 75–75.5° at 15 mm.

The 2-heptenol (21.7 g.) was oxidized by the low-temperature oxidation procedure of Delaby and Guillot-Allègre,[4] yielding 2-heptenal, 15.9 g. (74.6%).

The product was stabilized with hydroquinone and distilled in a glass helix-packed column; b. p. 80–85° at 14 mm., $n^{20}D$ 1.4314. The aldehyde was identified by preparation of the following derivatives: semicarbazone, m. p. 168–168.4° (Delaby, *et al.*,[4] 169°); *p*-nitrophenylhydrazone, m. p. 115.5–116° (Delaby, *et al.*,[4] 110–112°); 2,4-dinitrophenylhydrazone, m. p. 131.5–132°.

Anal. Calcd. for $C_{13}H_{16}N_4O_4$: C, 53.41; H, 5.52; N, 19.17. Found: C, 53.17; H, 5.23; N, 19.03.

Preparation of 2-Nonenal.—Ethyl hydrogen malonate (143.6 g.) was condensed with heptaldehyde (63 g.) in the manner described above: yield of ethyl 2-nonenoate, 79.4 g. (78.2%); b. p. 104° at 8 mm.

The ethyl 2-nonenoate (79.4 g.) was reduced with

The Vapor Phase Fluorination of Acetyl Fluoride[1]

BY WILLIAM T. MILLER, JR., AND MAURICE PROBER[2]

In the direct fluorination of aliphatic acids and their derivatives, Bockemüller[3] observed β- and γ- but no α-substitution. It was of interest to determine if hydrogen substitution occurred in the direct fluorination of acetyl fluoride, where only α-replacement was possible.

Equivalent quantities of fluorine and acetyl fluoride, both diluted with nitrogen, were passed into a steam-jacketed copper reactor, which was packed with copper gauze.[4] The products were condensed, caused to react with ethyl alcohol, and the resulting esters fractionally distilled. The fluorinated esters comprised approximately 50% by weight of the total esters plus some unreacted alcohol. The isolation of appreciable unreacted ethyl acetate was consistent with Bockemüller's observation on the low reactivity of the α-hydrogen. All of the possible substitution products were formed. Ethyl fluoroacetate and ethyl difluoroacetate were isolated in approximately 6:1 ratio. Only trace amounts of ethyl trifluoroacetate were isolated.

Experimental

Acetyl fluoride was prepared according to the procedures of Calloway[5] and Nesmejanov and Kahn.[6] Fractional distillation from antimony trifluoride and treatment with sodium fluoride yielded a product free of acetyl chloride and hydrogen fluoride, b. p. 18.0–18.2° at 734 mm.

The reaction was carried out in a steam-jacketed copper tube, 75 × 3.5 cm., packed with a roll of 40-mesh copper wire gauze. Fluorine diluted with dry, oxygen-free nitrogen, and acetyl fluoride carried by a stream of nitrogen, were passed into the reactor in an equal molar ratio. The molar ratio of nitrogen to fluorine varied from 2:1 to 3:1. The reactants were condensed in ice, Dry Ice, and liquid air traps, arranged in series. The hydrogen fluoride was removed by sodium fluoride which preceded the Dry Ice trap. The condensates were combined and the theoretical amount of absolute ethyl alcohol added at Dry Ice temperature. The reaction product was allowed to warm up to room temperature, kept at room temperature for a day, and refluxed for three hours. It was diluted with ether, and washed with cold, saturated solutions of potassium fluoride, potassium carbonate and calcium chloride. The reaction mixture was fractionally distilled at an atmospheric pressure of 740 mm.

In a typical run, 500 g. (0.804 mole) of acetyl fluoride was passed into the reactor, and 48.0 g. of organic products were condensed in the traps, with a 16.5 g. weight increase of the sodium fluoride. After distilling off the ether, the following fractions were obtained: 0.2 g., b. p. 37–68°; 15.4 g., b. p. 68–78° (ethyl acetate and ethyl alcohol–ethyl acetate azeotrope); 1.0 g., b. p. 78–96°; 0.5 g., b. p. 96–103°; 3.4 g., b. p. 103–114°; 6.4 g., b. p. 114–115°; 2.2 g. residue. Fluorinated compounds were present in all but the 68–78° b. p. fraction.

In order to obtain sufficient product to permit isolation of pure reaction products, six runs were made, and the appropriate fractions combined and distilled. A fraction boiling fairly sharply at 115–116° reacted with excess liquid ammonia at room temperature to form an amide, m. p. 107.5–108.0°. The earlier reported boiling points of ethyl fluoroacetate, 121.6°[7] and 126°[8] are higher than the value observed in the present work, but the m. p. of the amide is in excellent agreement with the literature value of 108°.[9] Recently a boiling point of 117–118° has been reported[10] which is in better agreement with our value. A second fraction, ethyl difluoroacetate, boiled at 98.2–99.2°, reported[11] 99.2°, and gave an amide m. p. 51.0–51.9°,[9] reported[9] 51.8°. A small amount of a low-boiling fraction gave a plateau at 53°, and yielded a fluorine containing amide, m. p. 72.7–74.0°. An azeotrope of ethyl alcohol and ethyl trifluoroacetate was reported to boil at 56°[12] and the melting point of trifluoroacetamide was reported to be 74.8°.[13] A trace amount of high boiling ester was obtained in one run, and it was hydrolyzed with 10% hydrochloric acid to yield an impure fluorine containing acid (or mixture) of m. p. 187–205°. All of the fluoroacetic acids are liquids, and the isolation of a solid acid indicated that coupling reactions had occurred during fluorination.

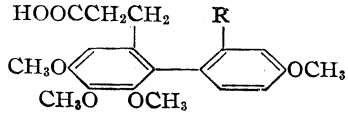
1-(β-Carboxyethyl)-3,4,7-trimethoxydibenzofuran

BY PAUL E. FANTA

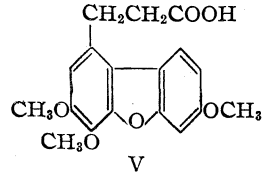
The attempted preparation of acid IV by a crossed Ullmann reaction[1] of methyl β-(2-iodo-3,-4,5-trimethoxyphenyl)-propionate and methyl 2-iodo-5-methoxybenzoate was described in an earlier paper.[2] This note concerns an alternative synthetic approach which was also unsuccessful.

(1) For a survey of the Ullmann reaction see Fanta, *Chem. Rev.*, **38**, 139 (1946).

(2) Frank, Fanta and Tarbell, THIS JOURNAL, **70**, (1948).



I, R = NO_2 II, R = NH_2
III, R = CN IV, R = COOH



V

A crossed Ullmann reaction of methyl β-(2-iodo-3,4,5-trimethoxyphenyl)-propionate and excess 4-bromo-3-nitroanisole yielded β-[2-(4,5-6,4′-tetramethoxy-2′-nitro)-biphenyl]-propionic acid (I), which was readily reduced to the corresponding amino compound (II). When II was diazotized and treated with cuprous cyanide under conditions calculated to yield the nitrile III, only 1-(β-carboxyethyl)-3,4,7-trimethoxydibenzofuran (V) was obtained. The formation of dibenzofuran from 2-amino-2′-methoxybiphenyl[3] and of 3,4,7-trimethoxydibenzofuran from 2,3,4,4′-tetramethoxy-2′-aminophenyl[4] under similar conditions has been reported.

The structure assigned to V is supported by a comparison of its absorption spectrum with that of 3,4,7-trimethoxydibenzofuran and compounds I and II as shown in Fig. 1. The spectrum of each dibenzofuran derivative exhibits a maximum near 300 mμ which has the same extinction coefficient as the corresponding maximum at 260 mμ. In the case of the biphenyl derivatives I and II, the extinction coefficients of the higher and lower wave length maxima differ greatly.

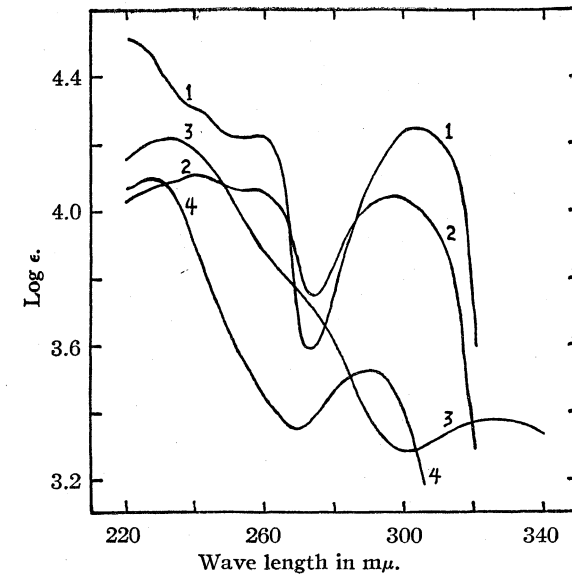


Fig. 1.—Molar extinction curves in ethanol: (1) 3,4,7-trimethoxydibenzofuran[4]; (2) dibenzofuran derivative, V; (3) nitrobiphenyl derivative, I; (4) aminobiphenyl derivative, II.

Experimental[5]

β-[2-(4,5,6,4′-Tetramethoxy-2′-nitro)-biphenyl]-propionic Acid (I).—A mixture of 7.60 g. (0.02 mole) of methyl β-(2-iodo-3,4,5-trimethoxyphenyl)-propionate and 27.8 g. (0.12 mole) of 4-bromo-3-nitroanisole was heated at 220–255° while 20 g. of electrolytic copper dust was added in small portions with stirring. The product was extracted with six 25-cc. portions of benzene. Evaporation of the benzene gave a red-brown tar which was refluxed for an hour with 25 cc. of Claisen alkali. Fifty cc. of water was added and the mixture was centrifuged to remove 4,4′-dimethoxy-2,2′-dinitrobiphenyl. Acidification of the aqueous solution with hydrochloric acid gave a dark oil which was purified by refluxing with Darco and Celite in aqueous methanol. Cooling and scratching gave a fine, yellow solid which was recrystallized from benzene with the addition of ligroin, when it formed granular, yellow crystals, yield 2.20 g. (28%), m. p. 100–102°.

Anal. Calcd. for $C_{19}H_{21}O_8N$: C, 58.30; H, 5.41. Found: C, 58.31; H, 5.54.

β-[2-(2′-Amino-4,5,6,4′-tetramethoxy)-biphenyl]-propionic Acid (II).—A portion of the nitro compound in ethanol was shaken for one-half hour with Raney nickel and hydrogen at 1000 lb. and 155°. Evaporation of the solvent and crystallization of the residue from benzene–ligroin gave a light tan crystalline powder, yield 42%, m. p. 125.5–126°.

Anal. Calcd. for $C_{19}H_{23}O_6N$: C, 63.15; H, 6.41. Found: C, 64.95; H, 6.61.

1-(β-Carboxyethyl)-3,4,7-trimethoxydibenzofuran (V).—A 360-mg. (0.001 mole) portion of the amino acid II was dissolved in a mixture of 10 cc. of water and 10 drops of sulfuric acid and diazotized at −5° by the addition of 74 mg. of solid sodium nitrite. Upon standing for an hour at room temperature gas was evolved and a flocculent orange precipitate separated. The yield of crude product melting at 132–145° was 76%. Crystallization from dilute methanol gave 191 mg. (58%) of tan needles, m. p. 146–148°. An analytical sample, m. p. 148°, was obtained by successive recrystallization from dilute methanol (Darco) and benzene.

Anal. Calcd. for $C_{18}H_{18}O_6$: C, 65.45; H, 5.49. Found: C, 65.16; H, 5.29.

The same product was obtained in lower yield when the diazonium solution was poured into a solution of cuprous cyanide in aqueous sodium cyanide.

The Fluorination of Periodic Acid

BY GILSON H. ROHRBACK AND GEORGE H. CADY

As part of the research now under way to produce compounds in which the hydrogen atoms of acids have been replaced by fluorine, the study of the reaction of fluorine with periodic acid was undertaken. Fluorination of both solid $HIO_4 \cdot 2H_2O$ and KIO_4 as well as an aqueous or sulfuric acid solution of the acid were carried out, but the desired compound fluorine periodate was not obtained. The reaction of fluorine with $HIO_4 \cdot 2H_2O$

was studied in some detail, however, and the complete reaction was found to take place in three stages. As the change commenced, water of hydration was removed from the acid without a change in the valence of iodine according to the equations

$$HIO_4 \cdot 2H_2O + 2F_2 \longrightarrow O_2 + 4HF + HIO_4 \quad (1)$$
$$HIO_4 \cdot 2H_2O + 4F_2 \longrightarrow 2OF_2 + 4HF + HIO_4 \quad (2)$$

In three experiments performed, the percentage of OF_2 in the gaseous product of O_2 and OF_2 varied from about 3 to 27%, the higher percentage being favored by a shorter reaction time. In the second stage, the continued action of fluorine caused the formation of iodine pentoxide, probably as the result of the dehydration of HIO_4, and in the final step iodine pentafluoride was formed by a reaction which became rapid only at temperatures above 250°.

$$HIO_4 \cdot 2H_2O \xrightarrow[\text{1st stage, Room temp.}]{F_2} HIO_4 \xrightarrow[\text{2nd stage, Room temp.}]{F_2}$$
$$I_2O_5 \xrightarrow[\text{3rd stage, Heat}]{F_2} IF_5$$

To investigate the first phase of the reaction a copper chamber with a volume of about one-half liter was employed. This was fitted with a brass ground-joint union which had been blanked off and polished to make a tight seal. Acid samples were placed in the reaction chamber which was then evacuated. A known volume of undiluted F_2 gas, freed of HF, was admitted and the course of the subsequent reaction was followed by observing an attached manometer. At the desired time the gas mixture within the reaction vessel was sampled by admitting a portion to an evacuated sample bottle.

Preliminary experiments showed that $HIO_4 \cdot 2H_2O$ could be caused to lose weight upon fluorination without a loss in total oxidizing capacity. However, it was found difficult during the steady fluorination of small samples to prevent some loss in oxidizing capacity before a weight loss had occurred which would correspond to the removal of all the water of hydration. Therefore to study the reaction of fluorine with the water of hydration alone, the described copper chamber was employed and relatively large samples of acid were used. Thus three samples of 3.083, 3.467 and 3.510 g. of the acid were successively fluorinated at room temperature in the apparatus for periods of one and one-third, five and twenty-four hours, respectively. After fluorination under these conditions the total oxidizing capacities were found by iodometric titrations to have been substantially unchanged, indicating that within experimental error there was no reduction in the valence of the iodine.

Gaseous reaction products of the above runs were determined by analysis of samples collected in glass bulbs. It was shown qualitatively that the gases produced were oxygen, oxygen difluoride, and hydrogen fluoride. They may be considered to have been formed from the water of hydration of the acid by the reactions (1) and (2). Since the hydrogen fluoride was removed from the gas by absorption on sodium fluoride held in a boat near the periodic acid, the observed drop in pressure during the reaction was equal to one-half of the decrease in the partial pressure of the fluorine. The amount of OF_2 was determined by analysis by allowing a sample of the gas to react with a solution of potassium iodide containing an excess of standard hydrochloric acid solution. One-half the equivalent weight of hydrogen ion consumed, as determined by back-titration with sodium hydroxide solution, was taken as equal to the moles of OF_2 in the sample. The following equation for the reaction of OF_2 indicates that this relationship should be correct.

$$OF_2 + 4I^- + 2H^+ = 2I_2 + 2F^- + H_2O \quad (3)$$

Using the two equations for the reaction of fluorine with water of hydration of the acid, the number of moles of oxygen formed was calculated to equal one-half the moles of fluorine consumed minus the number of moles of OF_2 produced. Likewise the number of moles of HF produced should be equal to 2 times (number of moles of F_2 consumed − number of moles of OF_2 formed). The values so calculated for the moles of HF produced should be equal to those obtained by determining the increase in weight of the sodium fluoride held in the reaction vessel.

Data for the three runs, which are given in Table I, show that the total effect of reactions (1) and (2) is to produce more oxygen than oxygen fluoride and that the latter substance appears to be consumed slowly with the consequent production of oxygen. There is good agreement between the calculated and observed hydrogen fluoride values.

TABLE I

REACTION OF FLUORINE WITH EXCESS PERIODIC ACID

Sample	I	II	III
Weight of acid, g.	3.08	3.47	3.51
Time of reaction, hr.	1⅓	5	24
Temp., °C.	24.3	23.0	25.2
Vol. of reaction vessel, liters	0.411	0.411	0.411
Initial pressure, cm.	42.0	41.0	40.0
Final pressure, cm.	38.3	28.6	21.8
Millimoles gas entering	9.32	9.10	8.88
Millimoles F_2 consumed	1.64	5.50	8.08
Millimoles OF_2 by analysis	0.22	0.72	0.13
Millimoles O_2 produced	0.60	2.0	3.9
Millimoles HF calculated	2.8	9.6	16
Millimoles HF observed, absorbed by NaF	2.7	9.6	16
% OF_2 by volume, in O_2–OF_2, total	27	26	3.2

Although no attempt was made to show the presence of the acid HIO_4 in the product, its existence may be reasonably inferred in the light of

Lamb's[1] work, which showed that the dihydrate was decomposed by dehydration directly to HIO_4 without intermediate compounds. He also found that stronger dehydrating conditions in no instance gave the seven valent anhydride, but rather resulted in decomposition to I_2O_5.

The second stage in the fluorination was studied by allowing samples of the acid to react in a continuous stream of fluorine at room temperature. The remaining white solid was shown to be iodine pentoxide. It was a non-hygroscopic substance which failed to oxidize manganous ion to permanganate in solution containing sulfuric acid, and its water solution gave a white precipitate with silver ion. During the fluorination of a 2.310-g. sample of $HIO_4 \cdot 2H_2O$, the loss in weight was 0.613 g. This may be compared with the theoretical loss of 0.619 g. according to the equation

$$2HIO_4 \cdot 2H_2O \longrightarrow I_2O_5 + 5H_2O + O_2$$

Likewise this sample should yield a product with a total oxidation equivalent of 0.0608; the equivalency found iodometrically was 0.0607. Such a change to give iodine pentoxide is in accord with the findings of Lamb.[1]

The final stage of the fluorination was accomplished by an increase in temperature to about 250°. On so doing, the iodine pentoxide disappeared while a white solid condensed in a product receiving trap cooled by Dry Ice. This solid was determined to melt at −8° to a colorless liquid which fumed in air. When a weighed sample of this liquid was treated with an acidified solution of potassium iodide and the liberated iodine titrated with standard sodium thiosulfate, an equivalent weight of 36.8 was found. This is in good agreement with the theoretical value of 36.9 for IF_5 (m. p. −8°, b. p. +97°).

The boiling point of the iodine pentafluoride was not determined as the reaction with the glass container was found to be too rapid above 30°. Such a behavior was also reported for IF_5 by Ruff and Braida.[2]

Acknowledgment.—This work was performed under contract with the Office of Naval Research, U. S. Navy Department.

The Esterification of Acylated α-Amino Acids

BY HEINRICH RINDERKNECHT AND CARL NIEMANN

Esters of the acylated α-amino acids or peptides are ordinarily prepared by the acylation of the α-amino acid or peptide ester or by the traditional acid catalyzed esterification of the acylated α-amino acid or peptide.[1] In seeking a more attractive procedure than either of the above it has been found that as with other carboxylic acids[2,3] certain of the acylated α-amino acids may be readily esterified by simply heating an alcoholic solution of the acid at approximately 180° in the absence of added catalyst. While this procedure appears to be useful for the esterification of many acylated α-amino acids it is to be anticipated that a number of acids will form products other than esters. For example with benzoyl-L-arginine the principal reaction product proved to be racemic 5-benzamido-piperidone-2.

Aside from convenience of the above method for the preparation of esters of acylated α-amino acids and carboxylic acids in general[3] it is one of the few procedures that can be used for the esterification of ketals of polyhydroxy acids such as 1;2,3;4-diisopropylidene-D-galacturonic acid.[4]

Experimental

Methyl Hippurate.—A solution of 18.0 g. of hippuric acid in 200 ml. of methanol under an initial pressure, at 25°, of 1000 lb./sq. in. of hydrogen was heated at 180–185° for ten hours. The reaction mixture was evaporated to dryness, the residue extracted with ether, the ethereal extract evaporated to dryness and the residue recrystallized from benzene to give 15.9 g. (82.5%) of methyl hippurate, m. p. 81–82°, uncor.

Benzoyl-DL-alanine Methyl Ester.—Benzoyl-DL-alanine (19.3 g.) in 200 ml. of methanol was heated at 180° for twelve hours. The reaction mixture was fractionally distilled and the distillate, b. p. 129–131° (0.15 mm.) was recrystallized from benzene to give 16.9 g. (91%) of benzoyl-DL-alanine methyl ester, m. p. 80–82°, uncor.

Carbobenzoxy-DL-alanine Methyl Ester.—A solution of 22.3 g. of carbobenzoxy-DL-alanine in 200 ml. of methanol heated at 180° for twelve hours was fractionally distilled and the fraction, b. p. 129–131° (0.2 mm.), recrystallized from ligroin to give 13.3 g. (59%) of carbobenzoxy-DL-alanine methyl ester, m. p. 49–50°, uncor.

Anal. Calcd. for $C_{12}H_{15}O_4N$: C, 60.8; H, 6.3; N, 5.9. Found: C, 61.0; H, 6.5; N, 5.6.

Attempted Esterification of α-Benzoyl-L-arginine.—α-Benzoyl-L-arginine (27.6 g.) in 200 ml. of methanol was heated at 170° for fifteen hours, the reaction mixture filtered (ppt. 7.0 g.), the filtrate evaporated to dryness and the residue recrystallized from hot water to give 8.5 g. (39%) of 5-benzamido-piperidone-2, m. p. 183–184°, insoluble in aqueous acid and alkali, soluble in hot water and ethanol.

Anal. Calcd. for $C_{12}H_{14}O_2N_2$: C, 66.1; H, 6.4; N, 12.8. Found: C, 66.4; H, 6.7; N, 12.5. The benzamidopiperidone was hydrolyzed with 20% hydrochloric acid and the dipicrate of DL-ornithine, m. p. 198–199°, isolated from the hydrolysate. A solution of α-benzoyl-L-nitroarginine in methanol heated at 170° for seventeen hours gave 68% of 5-benzamido-piperidone-2, m. p. 183–184°.

Methyl Benzoate—Fractional distillation of a solution of 12.2 g. of benzoic acid in 200 ml. of methanol previously heated at 185° for fifteen hours gave 12.2 g. (90%) of methyl benzoate, b. p. 83° (12 mm.).

Methyl Lactate.—A solution of 12.0 g. of freshly distilled lactic acid, b. p. 78° (0.1 mm.), in 250 ml. of methanol heated at 170° for fourteen hours upon fractional distillation gave 9.6 g. (69%) of methyl lactate, b. p. 143–145°.

An Approximate Method for the Determination of Active Halogens

BY JOHN R. SAMPEY, ANNE B. KING AND BARBARA C. BLITCH

The observation of Wanscheidt[1] that sodium bromide precipitates when 9-bromofluorene is dissolved in an acetone solution of sodium iodide has been made the basis for an approximate determination, within one or two per cent., of this active halogen in a mixture of bromofluorenes. Data are given to show that the method is applicable to two other compounds containing active halogen, namely, phenacyl bromide and benzyl bromide.

Analyses of 9-Bromofluorene, Phenacyl Bromide and Benzyl Bromide.—Samples (1.0000 g.) of the halogen compounds are dissolved in 20.00 ml. of a saturated solution of sodium iodide in acetone, and are filtered after standing several hours at 25°. Sodium bromide starts separating immediately upon solution of the halogen compounds, but in the case of 9-bromofluorene, if the sample stands too long, large amounts of difluorenyl precipitate; if this does occur, the difluorenyl and sodium bromide may be weighed together, and then the latter may be washed out with water; another weighing gives the amount of sodium bromide present before washing. The sodium iodide adhering to the sodium bromide after the filtration is readily washed out with 60 ml. of acetone; tests are made on the last washings for iodide ion (nitrous acid test). A correction is made for the solubility of the sodium bromide in the acetone. The sodium bromide is filtered and dried at 110°.

TABLE I

ANALYSES OF 9-BROMOFLUORENE, PHENACYL BROMIDE AND BENZYL BROMIDE

Compound	Sample, g.	NaBr ppt., g.	NaBr dissolved, g.	Sum, g.	%
9-Bromofluorene	1.000	0.407	0.003	0.410	97
9-Bromofluorene	1.000	.406	.003	.409	97
Phenacyl bromide	1.000	.501	.003	.504	97
Phenacyl bromide	1.000	.508	.003	.511	99
Benzyl bromide	0.907	.540	.003	.543	99
Benzyl bromide	1.285	.774	.003	.777	100

Solubility of Sodium Bromide in Acetone.—A correction must be applied for the solubility of sodium bromide in the acetone used. Column 4 of Table I gives the solubility of sodium bromide in the particular sample of acetone used in these analyses; other samples of reagent grade acetone dissolved as much as 0.119 g. of the salt; agitation of this moist sample of acetone with anhydrous calcium chloride reduced the amount of sodium bromide to less than 10 mg. on a second solubility determination. The solubility of sodium bromide in any sample of reagent grade acetone is determined by suspending 1.000-g. samples of the salt in 20.00-ml. portions of the acetone saturated with sodium iodide; to ensure solution, the flasks are placed on a shaking machine for several hours; the solutions are run through Gooch filters, and the adhering sodium iodide is washed out with 60 ml. of the same acetone used in making the solution.

The solubility of sodium bromide in acetone changes little with change in temperature. When the temperature is raised from 25 to 41°, the solubility decreased only two or three milligrams over that recorded in Column 4 of Table I. Sodium iodide shows a more marked decrease in solubility at elevated temperatures, for when a saturated solution of this salt in acetone is refluxed, large amounts of sodium iodide separate, and then on cooling redissolve.

The effect of changes in relative humidity on the solubility of sodium bromide in acetone has been noted. The acetone solutions were cooled to 0° and the samples were filtered slowly in an atmosphere in which the relative humidity was 95; under these conditions the solubility of sodium bromide increased five to six milligrams over that found by rapid filtration on a day in which the relative humidity was 40. The same quantities of salt and acetone were used as in previous runs. These effects of wide changes in humidity do not alter the usefulness of this approximate method for the determination of active halogens in the three classes of compounds analyzed in Table I.

This research was supported by a grant from the Office of Naval Research. The authors acknowledge the interest of Dr. E. Emmet Reid.

The Exaggerated Effect of Iodine as Carrier in the Bromination of Fluorene

BY JOHN R. SAMPEY AND ANNE B. KING

Discovery of the Exaggerated Effect of Iodine.—In an attempt to relate the rate of bromination to the intensity of the irradiation in the photobromination of fluorene the observation was made that a considerable amount of bromine disappeared regardless of the illumination. This led to experiments in the dark in which 10 cc. of a 1 molar solution of bromine in carbon disulfide was added to 0.01 mole of fluorene in 20 cc. of the same solvent. The reaction was stopped by adding potassium iodide solution after which the liberated iodine was titrated. The results were surprising. In 5 runs the bromination was 8 to 10% in one-half minute, in 3 runs, 8 to 11% in three minutes and in 2 runs, only 11 to 13% in ten minutes. Tests showed that none of the bromine had entered the side chain. The first supposition was that the fluorene contained an easily brominated impurity. To test this, samples of fluorene from three different sources were recrystallized repeatedly, vacuum distilled and sublimed. All three showed 8 to 11% bromination in one-half and three minute periods. This surprising result was finally traced to the effect of the iodine that was liberated on the addition of the potassium iodide solution. For a part of the time during the shaking, fluorene, bromine and iodine were present in the carbon disulfide solution. This led to a study of the effect of iodine on the bromination of fluorene.

Iodine as a Carrier in the Bromination of Fluorene in the Dark.—A saturated solution of iodine in carbon tetrachloride was found to contain 0.29 g. in 10 cc. Dilutions of this, 1 to 10, and 1 to 100 were made. Fluorene, 0.01 mole, was added to 10 cc. of the carbon tetrachloride solution and then 10 cc. of a 1 molar solution of bromine in the same solvent was added quickly. The reaction was stopped by the addition of potassium iodide solution as usual. The results are in Table I.

TABLE I

BROMINATION OF FLUORENE IN THE DARK WITH IODINE AS CARRIER

Time, min.	0.29 g.	0.029 g.	0.0029 g.
0.5	79%	..	8
0.5	80	..	..
3.0	89	20	..
3.0	89	19	..

For comparison the same concentration of toluene and bromine in the same solvent were tried with 0.29 g. of iodine. There was no bromination in three minutes.

The bromine used was freed from traces of iodine by prolonged shaking with concentrated sulfuric acid, washing with water, drying over phosphorus pentoxide and fractionally distilling.

The authors acknowledge the interest of Dr. E. Emmet Reid in this research.

The Optical Rotatory Power of *epi*-Ergostanol

BY KARL J. SAX, LOUIS DORFMAN[1] AND SEYMOUR BERNSTEIN

In their development of a theory on the relationship between optical rotatory power and constitution of the steroids, Bernstein, Kauzmann and Wallis[2] noted a number of compounds for which large discrepancies existed between observed and calculated values of the optical rotation. For *epi*-ergostanol it was stated that the observed value for this compound was in error by at least 10°.[3] Also it has been pointed out[4] that the C_3-diastereomers, ergostanol and *epi*-ergostanol, do not conform to the rule that the C_3 α-form of any steroid will have a higher positive rotatory power than the corresponding β-form.

Accordingly it was of interest to redetermine the optical rotations of ergostanol and *epi*-ergostanol for evaluating the above discrepancies. The rotation of ergostanol was found to be +15.3° which is in excellent agreement with the recorded values of +15.3°[5] and +15.9°.[6] However, for *epi*-ergostanol we have found the rotation to be +16.9° which is higher than the recorded values of +13.5°[7] and +14.6°.[8]

These results show that the diastereomers, ergostanol and *epi*-ergostanol, do not constitute an exception to the above stated rule. Also it may be assumed that the value (+2300) for the constant, E_t^2, derived from *epi*-cholestanol, and used in the calculation of the rotation of *epi*-ergostanol, is incorrect. Use of *epi*-stigmastanol, $[\alpha]_D$ + 25,[9] as the standard substance, gave a E_t value of 0. Recalculation of the rotation of *epi*-ergostanol with this revised value gave +19.1°, which is in good agreement with the observed rotation of +16.9°.

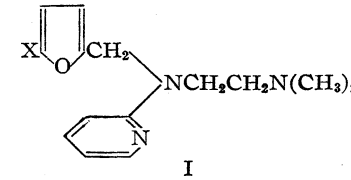
Antihistamine Agents. II. Furan Derivatives

BY J. R. VAUGHAN, JR., AND G. W. ANDERSON

In a continuation of our investigation on the effect of substituting various heterocyclic systems into compounds of known antihistamine activity,[1] we have prepared and tested N,N-dimethyl-N′-(2-pyridyl)-N′-furfurylethylenediamine (I, X = H) and N,N-dimethyl-N′-(2-pyridyl)-N′-(5-bromofurfuryl)-ethylenediamine (I, X = Br). The first of these (I, X = H) has been reported by Viaud to be an active antihistaminic.[2] The compounds may be considered as oxygen analogs of the thiophene substituted ethylenediamines previously reported in which the furan nucleus replaces the thiophene group.



I

They were synthesized by an initial reaction of furfuryl alcohol, or 5-bromofurfuryl alcohol, with thionyl chloride in toluene solution at −30 to −40°. The intermediate furfuryl chlorides obtained are extremely unstable[3] and were not isolated but were treated directly with the sodium salt of N,N-dimethyl-N′-(2-pyridyl)-ethylenediamine, also in toluene solution, at low tempera-

(3) Gilman and Vernon, THIS JOURNAL, **46**, 2576 (1924).

ture. Two molar equivalents excess of the sodium salt were used to neutralize the acidic by-products present from the chlorination reaction. After hydrolysis of the reaction mixture, the desired products were obtained by distillation of the toluene layer *in vacuo* as light yellow, unstable oils which decompose rapidly at room temperature and slowly even at −80°. In the presence of mineral acids, the compounds are destroyed within a few seconds to yield blue–violet solutions or tars. They are stable, however, to alkali and to organic acids and were isolated crystalline as their colorless, non-hygroscopic dihydrogen citrate salts.

When tested in guinea pigs by the histamine aerosol technique or by intravenous injection of histamine,[4] the furfuryl derivative (I, X = H) was found to be equally as effective as N,N-dimethyl - N′ - (2 - pyridyl) - N′ - benzylethylenediamine (Pyribenzamine)[5] in protecting against death while the bromofurfuryl derivative (I, X = Br) was only slightly less effective. The results on the furfuryl derivative are in agreement with those reported by Viaud.[2] When tested for acute, twenty-four-hour toxicity by intraperitoneal injection in white mice, the furfuryl derivative had the same toxicity as Pyribenzamine, whereas the bromofurfuryl derivative was approximately 50% less toxic.

We are indebted to Dr. J. T. Litchfield, Jr., and to the Misses Maxine R. Adams and Marion S. Jaeger of these Laboratories for the pharmacological data reported here.

Experimental[6]

N,N-Dimethyl-N′-(2-pyridyl)-N′-furfurylethylenediamine.—To a suspension of 36 g. (1.5 moles) of sodium hydride in 1500 cc. of dry toluene was added 248 g. (1.5 moles) of N,N-dimethyl-N′-(2-pyridyl)-ethylenediamine[5,7] and the mixture heated at reflux for one and one-half hours, or until the evolution of hydrogen ceased, and then cooled to 15° in an ice-bath. In a separate flask, 49 g. (0.5 mole) of redistilled furfuryl alcohol was placed in 300 cc. of dry toluene and the solution cooled with stirring to −30° in a Dry Ice–acetone-bath. A solution of 59.5 g. (0.5 mole) of thionyl chloride in 50 cc. of toluene was then added dropwise at this temperature over a twenty to thirty minute period while passing a steady stream of nitrogen through the apparatus. A large amount of tar and resin was formed toward the end of the addition. The clear, dark green toluene solution was decanted from the resin and added over a five- to ten-minute period to the previously prepared suspension of the sodium salt of N,N-dimethyl-N′-(2-pyridyl)-ethylenediamine also in toluene. The resulting exothermic reaction was maintained at 15° for forty-five minutes. The reaction mixture was then allowed to warm to room temperature and hydrolyzed cautiously with 750 cc. of water. The toluene layer was separated, concentrated, and the residue distilled *in vacuo* to yield 30.2 g. (25%) of impure product as a light yellow oil, b. p. 100–140° (0.4 mm.). Also obtained was 137.5 g. (83% of theoretical recovery) of the excess starting ethylenediamine, b. p. 70–85° (0.5 mm.). The crude material was refractionated to yield 18.6 g. (15%) of pure product, b. p. 136–137° (0.7 mm.); $n^{30}D$ 1.5486. This is obtained in 95% yield as a stable, non-hygroscopic dihydrogen citrate by precipitation of the salt from alcohol solution with ether and recrystallization from methyl ethyl ketone, m. p. 95–97°.

Anal. Calcd. for $C_{14}H_{19}N_3O \cdot C_6H_8O_7$: C, 54.91; H, 6.22; N, 9.61. Found: C, 54.96, 55.22; H, 5.98, 6.06; N, 9.34, 9.49.

N,N-Dimethyl-N′-(2-pyridyl)-N′-(5-bromofurfuryl)-ethylenediamine.—The sodium salt of N,N-dimethyl-N′-(2-pyridyl)-ethylenediamine was prepared as in the previous example from 13 g. (0.54 mole) of sodium hydride and 89 g. (0.54 mole) of the diamine in 200 cc. of toluene. In a separate flask 32 g. (0.18 mole) of 5-bromofurfuryl alcohol[8] dissolved in 150 cc. of toluene was treated with 21.5 g. (0.18 mole) of thionyl chloride in 50 cc. of toluene at −30°, as described above, and the reaction mixture was added to the previously prepared suspension of the sodium salt of N,N-dimethyl-N′-(2-pyridyl)-ethylenediamine. After reaction and hydrolysis were complete, the product was isolated as before and distilled *in vacuo* to yield 26.5 g. (44% of the theoretical recovery) of the excess ethylenediamine used, and 16 g. (28%) of impure product, b. p. 140–175° (1 mm.). This material was refractionated to yield 10 g. (17%) of pure product as a greenish yellow oil, b. p. 156–158° (0.5 mm.); $n^{30}D$ 1.5603. Treatment of this with one equivalent of alcoholic citric acid and precipitation with ether gave the stable dihydrogen citrate salt in 97% yield. After recrystallization from methyl ethyl ketone, the colorless crystals melt at 105–107°.

Concerning the Acylation of Kojic Acid at Elevated Temperatures

BY L. L. WOODS

The acylation of kojic acid at elevated temperatures with acetic anhydride in a modified Nencki[1] reaction is anomalous. The reaction described produces a ketone, I, having an empirical formula $C_{10}H_{13}O_7$. Under hydrolytic conditions the latter compound loses an acetyl group (compound II). Data are lacking for assignment of structures to these two compounds, although some pertinent observations should be noted. The compounds do not have the phenolic character of the parent compound and do contain one aceto group as evidenced by their reactivity toward carbonyl reagents.

(1) Blatt, "Organic Syntheses," Coll. Vol. 2, John Wiley and Sons, New York, N. Y., p. 304.

Experimental

Acylation of Kojic Acid (I).—Twenty grams (0.142 mole) of kojic acid was mixed with 125 g. (1.22 moles) of acetic anhydride and 10 g. of zinc chloride. The mixture was heated over a water-bath under reflux and protected from moisture with a calcium chloride tube until the first vigorous reaction had subsided. The water-bath was then removed and replaced with an oil-bath. The heating was continued by gradually increasing the temperature to 145°, and then maintaining the temperature between 135–145° for one and one-half hours. Upon completion of the heating of the mixture, the excess acetic anhydride and acetic acid were removed under reduced pressure.

The residue was then treated with 200 ml. of boiling water and set aside to cool. After cooling, the crystals were filtered off. The filtrate was extracted with three successive 100-ml. portions of benzene. The combined benzene fractions were added to the crystals, which immediately dissolved. The mixture was washed once with cold water, dried with anhydrous magnesium sulfate, and decolorized with Norite.

The benzene was allowed to evaporate and 24.8 g. of a pale yellow compound were obtained. The substance was recrystallized by dissolving it in the smallest quantity of boiling water necessary to obtain complete solution (500–600 ml.). The white compound thus obtained was air dried. The analytical sample was dried in the vacuum desiccator over sulfuric acid for three weeks, m. p. 106°. The compound was quite soluble in ether, alcohol, benzene and ethyl acetate as well as hot water.

Anal. Calcd. for $C_{10}H_{13}O_7$: C, 48.98; H, 5.30; mol. wt., 245. Found: C, 49.06, 49.28, 49.10; H, 5.39, 5.72, 5.62; mol. wt. 248. (Each of the three carbon–hydrogen analyses was on a sample from a different run.[2])

Impure samples of the compound always gave a faint red color with dilute ferric chloride solutions; however, the pure samples failed to give the test. The compound did not react with dilute sodium bicarbonate solution. When 1.6137 g. of the ketone was heated ten hours in the electric drying oven at a temperature of 100–102° it lost 0.0376 g. (2.31%) of its weight, one molecule of water would require a loss of 7.34%. This loss of weight, perhaps, cannot be entirely attributed to the loss of moisture because the material developed a faint odor at this temperature.

The 2,4-dinitrophenylhydrazine derivative of compound (I) had a melting point of 114°.

Anal. Calcd. for $C_{10}H_{13}O_8$ $(C_6H_4N_4O_4)_4$: N, 23.21. Found: N, 23.18, 23.40.

Hydrolysis of Compound (I) to Form Compound (II).—A small portion (1 g.) of purified compound (I) dissolved in 50 ml. of hot water was refluxed for fifteen hours. The solution was cooled, decolorized with a little Norite, and filtered. After the water was evaporated and the solid dissolved in absolute ethanol, the solvent was removed under reduced pressure; and the compound was completely dried in the vacuum desiccator. The compound was a colorless glassy material which had a m. p. of 55–57°. Its semicarbazide had a m. p. of 247°. The compound was very soluble in water and in alcohol, but insoluble in acetone and ether. The material was not acidic and did not give any color with dilute ferric chloride solution.

Anal. Calcd. for $C_8H_{11}O_6$: C, 47.29; H, 5.41. Found: C, 47.50; H, 5.84.

NEW COMPOUNDS

Esters of Mucic Acid

The new compounds[1] listed in Table I were prepared by refluxing and stirring mechanically a mixture of 50 g. of mucic acid and 500 g. of the corresponding alcohol in the presence of 2 g. of *p*-toluenesulfonic acid. The esters all crystallized directly from the cooled reaction mixtures, after removal of unreacted mucic acid by filtration, and were recrystallized from 95% ethanol.

TABLE I

ESTERS OF MUCIC ACID

Di-esters	M. p., °C.	Yield, %	Formula	Analyses: Carbon, % Calcd.	Carbon, % Found	Hydrogen, % Calcd.	Hydrogen, % Found	Sapon. equiv. Calcd.	Sapon. equiv. Found
n-Propyl	149–150	48	$C_{12}H_{22}O_8$	48.98	48.9	7.54	7.64	147.1	146.8
n-Butyl	142.5–143.5	93	$C_{14}H_{26}O_8$	52.16	52.2	8.13	8.17	161.2	160
n-Amyl	147–147.5	74	$C_{16}H_{30}O_8$	54.84	54.9	8.63	8.68	175.2	174.2
n-Hexyl	143–144	55	$C_{18}H_{34}O_8$	57.12	57.0	9.06	8.94	189.2	189.1

The *n*-propyl and *n*-butyl mucates were prepared by refluxing the reaction mixtures for thirty and ten hours, respectively. The *n*-amyl and *n*-hexyl esters were prepared in essentially the same manner except that 200 g. of xylene was added to the mixture, which was refluxed under a Bidwell–Sterling water trap for twenty and forty hours, respectively. In the preparation of allyl mucate, 250 g. of benzene was added, and refluxing and stirring continued for thirty hours, after which benzene, allyl alcohol and water were slowly distilled through a fractionating column until the final reaction solution was approximately 150 ml.

(1) Dimethyl and diethyl mucates were prepared by Fischer and Speir (*Ber.*, **28**, 3252 (1895)), the former by reaction of mucic acid and methanol–hydrochloric acid in a sealed tube at 100° and the diethyl ester by refluxing mucic acid with ethanol and hydrochloric acid.

N-(Acetylsalicyloyl)-piperidine

Fifty grams of acetylsalicylic acid and 250 ml. of thionyl chloride were refluxed for two hours. Excess thionyl chloride was removed on a steam-bath and with vacuum. The residue was taken up in dry benzene and a solution of 55 ml. (100% excess) of piperidine in dry benzene was added cautiously and with cooling. After filtering off the piperidine hydrochloride, the combined liquors and

washings were boiled down to a thick oil. This product was recrystallized from ligroin, the separation of unreacted, ligroin-insoluble acetylsalicylic acid being conveniently carried out in the same operation. Further recrystallization from dioxane–water and pyridine–water gave 24.5 g. (36%) of N-(acetylsalicyloyl)-piperidine in the form of white needles, m. p. 145–146°. *Anal.* Calcd. for $C_{14}H_{17}NO_3$: N, 5.66. Found: N, 5.51.

COMMUNICATIONS TO THE EDITOR

DESTHIOBENZYLPENICILLIN

Sir:

"From the standpoint of organic chemistry, the most convincing evidence"—for the lactam formula of benzylpenicillin—"was secured by a study carried out in the Merck laboratories of the action of Raney nickel catalyst upon sodium benzylpenicillinate." A monocarboxylic acid $C_{16}H_{20}O_4N_2$ benzyldesthiopenicillin and phenylacetyl-L-alanyl-D-valine were obtained.[1] Through the kindness of Dr. Ellis V. Brown and Mr. John L. Smith of Chas. Pfizer and Co., Inc., we were given an ample supply of sodium benzylpenicillinate and have studied its desulfurization with the active W-6 Raney nickel catalyst.[2]

It proved possible to remove the sulfur from sodium benzylpenicillin in alcohol at about 15° under 5000 p. s. i. of hydrogen, within one or two hours. However, under these conditions the phenyl group is hydrogenated to cyclohexyl, to some extent. The preferred procedure has been to carry out the desulfurization in 96% alcohol under about 45 p. s. i. of hydrogen for a period of four hours at 10–20°. The reaction appears to be complete after an hour or two.

Eleven desulfurizations, each on 500 mg. of sodium benzylpenicillinate with 16 g. of W-6 Raney nickel, have been carried out under the preferred conditions. A crude product was obtained by extracting with chloroform the reaction mixtures, made acid to *p*H 2, after the removal of the catalyst and alcohol. Chloroform soluble neutral products were then removed by converting the desthiobenzylpenicillin to its salt and extracting the alkaline solution with chloroform. The desired acid was then obtained by extraction of the acidified solution with chloroform. The average weight of crude desthiobenzylpenicillin obtained was 220 mg. This product is free of basic or neutral compounds and of those containing sulfur. After crystallization from an alcohol–water mixture, the average yield of product, m. p. above 100°, was 150 mg. from seven desulfurizations. In four cases where the product so obtained was recrystallized, there was obtained 120–130 mg. of desthiobenzylpenicillin, m. p. 106–109°, 108–110°, 108.5–110.5° and 110–113°. The product shows a neutral equivalent and analyses corresponding to the molecular formula given above.

These results, obtained under so mild conditions of reaction, support the conclusion of Kaczka, Mozingo and Folkers of the Merck laboratories that an intramolecular rearrangement is not involved in the formation of desthiobenzylpenicillin.

THE ENZYMATIC SYNTHESIS OF N-CARBOBENZOXY-D AND L-*o*-FLUOROPHENYLALANYLPHENYLHYDRAZIDES

Sir:

Previous studies on the resolution of acylated DL-amino acids by the asymmetric enzymatic synthesis of the anilide or phenylhydrazide of the acylated L-amino acid[1] have given no indication that appreciable quantities of the anilide or phenylhydrazide of the acylated D-amino acid may also be formed. We wish to report a case where substantial quantities of the D-phenylhydrazide have been synthesized despite the fact that the amount of amine present was insufficient to permit quantitative conversion of both the D- and L-acids.

25.0 g. (0.079 mole) of N-carbobenzoxy-DL-*o*-fluorophenylalanine was incubated with 20 g. of activated papain, 36.0 g. of L-cysteine hydrochloride, and 4.3 g. (0.040 mole) of redistilled phenylhydrazine at 40° for five days. The precipitated N-carbobenzoxy-*o*-fluorophenylalanylphenylhydrazide was recovered and recrystallized from toluene to give 11.0 g. of N-carbobenzoxy-*o*-fluorophenylalanylphenylhydrazide (I); m. p. 152–160°; 5.0 g. of additional papain, 12.0 g. of cysteine hydrochloride and 1.00 g. of phenylhydrazine was added to the filtrate from (I), the solution was incubated for five days at 40°, and the precipitate recrystallized from toluene to give 3.0 g. of N-carbobenzoxy-DL-*o*-fluorophenylalanyl-

(1) M. Bergmann and H. Fraenkel-Conrat, *J. Biol. Chem.*, **119**, 707 (1937).

phenylhydrazide (II); m. p. 153.5–155.7° (cor.); $[\alpha]^{25}D$ 0.0° (3% in acetone). (I) was fractionally recrystallized from toluene to give 4.0 g. of N-carbobenzoxy-L-*o*-fluorophenylalanylphenyl-hydrazide (III); m. p. 171.0–172.0° (cor.); $[\alpha]^{25}D$ −31.0° (3% in acetone). *Anal.* Calcd. for $C_{23}H_{22}O_3N_3F$: C, 67.8; H, 5.4; N, 10.3. Found: C, 67.9; H, 5.7; N, 10.3; and 4.0 g. of (II); m. p. 155.5–156.5° (cor.); $[\alpha]^{25}D$ 0.0° (3% in acetone). *Anal.* Calcd. for $C_{23}H_{22}O_3N_3F$: C, 67.8; H, 5.4; N, 10.3. Found: C, 67.9; H, 5.6; N, 10.3. The filtrate from (II) was concentrated under reduced pressure, acidified, and the oily solid recrystallized from toluene to give 5.6 g. of an approximately equimolar mixture of N-carbobenzoxy-D-*o*-fluorophenylalanine and N-carbobenzoxy-DL-*o*-fluorophenylalanine. Fractional recrystallization from toluene gave 1.0 g. of N-carbobenzoxy-D-*o*-fluorophenylalanine (IV); m. p. 103–105° (cor.); $[\alpha]^{25}D$ +15.7° (5% in acetone). *Anal.* Calcd. for $C_{17}H_{16}O_4NF$: C, 64.3; H, 5.1; N, 4.4. Found: C, 64.4; H, 5.1; N, 4.2; and 1.9 g. of N-carbobenzoxy-DL-*o*-fluorophenylalanine (V); m. p. 108.5–110.0° (cor.); $[\alpha]^{25}D$ 0.2° (5% in acetone). *Anal.* Calcd. for $C_{17}H_{16}O_4NF$: C, 64.3; H, 5.1; N, 4.4. Found: C, 64.5; H, 5.3; N, 4.5.

A simultaneous enzymatic resolution of N-carbobenzoxy-DL-alanine using an aliquot of the same enzyme preparation gave N-carbobenzoxy-L-alanylphenylhydrazide in 75% yield after one recrystallization; m. p. 154.5–155.5° (cor.); $[\alpha]^{25}D$ −27.2° (5% in acetone).

Other experiments not reported here indicate that the behavior noted with *o*-fluorophenylalanine is not unique and it is clear that further study on the effect of the nature of the side chain, of the base, and of the acyl group on the course of the enzymatic synthesis is required. Such investigations are now in progress.

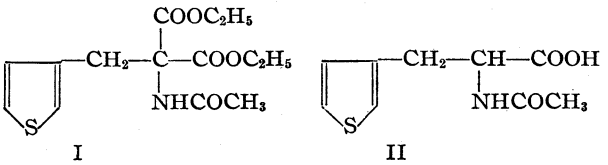
THE SYNTHESIS OF β-3-THIENYLALANINE

Sir:

Due to the current interest in metabolite–antimetabolite relations, and in particular to the discovery by du Vigneaud and associates[1,2] that β-2-thienylalanine functioned as a phenylalanine anti-metabolite with yeast, we are prompted to describe an isomer of this compound, β-3-thienylalanine, which we have prepared for testing as a phenylalanine antagonist.

The synthesis involves the reaction of 3-thienyl bromide with sodioacetamidomalonic ester to form 3-thenylacetamidomalonic ester (I). The 3-thenyl bromide was prepared by the peroxide-catalyzed reaction of N-bromosuccinimide with 3-methylthiophene, as previously described.[3] I melted at 90–91° after recrystallization from water.

Anal. Calcd. for $C_{14}H_{19}O_5NS$: S, 10.20. Found: S, 9.92. Alkaline hydrolysis of I, followed



I II

by acidification and heating, yielded N-acetyl-β-3-thienylalanine (II), m. p. 148–149°. *Anal.* Calcd. for $C_9H_{11}O_3NS$: S, 15.03; N, 6.57. Found: S, 15.14; N, 6.82.

β-3-Thienylalanine was prepared by complete hydrolysis of I in barium hydroxide, acidification with sulfuric acid, decarboxylation, and neutralization with barium carbonate. The water solution thus obtained was concentrated to dryness, and the residue recrystallized from water. β-3-Thienylalanine precipitated as fine white crystals, which browned at 260° and melted with decomposition from 265–267°. *Anal.* Calcd. for $C_7H_9O_2NS$: S, 18.71; N, 8.19. Found: S, 18.43; N, 8.10.

Complete details on the synthesis and biological testing of this compound will be published at a later date.

THE PREPARATION AND POLYMERIZATION OF MONOMERIC CYCLIC DISULFIDES

Sir:

Carothers extensively described the reversible polymerization relationships existing between monomeric cyclic anhydrides,[1] esters,[2] and formals.[3] Patnode and Wilcock[4] recently described the reversible conversion of methyl polysiloxanes to cyclic compounds. We have found that a similar reversible polymerization is possible between high-molecular weight disulfide polymers and the corresponding monomeric disulfide ring.

Steam distillation of aqueous dispersions of disulfide polymers yields very small amounts of

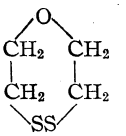
low-molecular weight organic compounds in the distillate. The rate of production of monomer is extremely slow but has not diminished with time, indicating that actually depolymerization is occurring. Addition of small amounts of sodium hydroxide to the polymeric dispersion significantly increases the rate of depolymerization.

The polymer resulting from the condensation of bis-(2-chloroethyl) ether and sodium disulfide[5] yields a pale yellow oil of characteristic odor. Attempts to distil it have resulted in decomposition. The compound is stable indefinitely if completely dry but water converts it slowly back to the original polymer. Aqueous sodium sulfide or polysulfide converts the oil rapidly to the polymeric form.

$(—CH_2CH_2OCH_2CH_2SS—)$

I

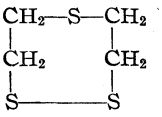


II

The physical properties of the oil were determined and compared with those calculated for structure II.

	Found	Calculated
Index of refraction $n^{20}D$	1.5823	...
Molecular refraction	36.7	36.3
Specific gravity	1.2737	...
Molecular weight	137	136
Sulfur, %	46.3	47.1

Cyclic compounds containing one or more heterocyclic sulfur atoms are well represented in the literature but heterocyclics with a disulfide group are not well known. Fromm and Joerg[6] reported on the ring



which they obtained by the reaction of $ClC_2H_4SSC_2H_4Cl$ with Na_2S or $ClC_2H_4SC_2H_4Cl$ with Na_2S_2. They reported a melting point of 74 to 75° for the product obtained by either method.

The production of polymer would appear more probable from this method of preparation than would the formation of a cyclic monomer. By substantially the same procedure, we have prepared polymeric products.

Cyclic compounds similar to that resulting from the ether disulfide have been obtained from disulfide polymers of different structures, but the products have yet to be characterized. A complete account of this work, together with theoretical considerations, will appear at a later date.

STREPTOMYCES ANTIBIOTICS. XIX. DIHYDROSTREPTOSONIC ACID LACTONE AND CONFIGURATION OF STREPTOSE AND STREPTOBIOSAMINE

Sir:

2-Methyl pentaacetyldihydrostreptobiosaminide[1] was allowed to react stepwise with ethyl mercaptan–hydrogen chloride, acetic anhydride, and mercuric chloride for the preparation of amorphous pentaacetyldihydrostreptobiosamine.[2] Acetylation of this compound gave hexaacetyldihydrostreptobiosamine.[2] Oxidation by bromine and hydrolysis by hydrochloric acid of pentaacetyldihydrostreptobiosamine gave the known N-methyl-L-glucosamine and the new dihydrostreptosonic acid lactone, m. p. 143–144°, $[\alpha]_D$ −32° (*c*, 0.40 in water). Reaction of the lactone with hydrazine gave dihydrostreptosonic acid hydrazide, m. p. 137–139°, $[\alpha]_D$ +23° (*c*, 0.9 in water).

Application of Hudson's rules of rotation to streptosonic acid diamide[3] and dihydrostreptosonic acid hydrazide shows that the hydroxyl group at C_2 of streptose lies on the right. Since it has already been shown[4] that the hydroxyl groups at C_2 and C_3 of streptose are *cis*, and that the configuration about C_4 is *levo*,[5] the configuration of L-streptose is represented by structure I. On the basis of these data, and the calculations of the glycosidic linkage between streptose and N-methyl-L-glucosamine to be α-L,[6] the configuration of streptobiosamine is represented by structure II. The levorotations of streptosonic acid lactone[3] and dihydrostreptosonic acid lactone support the applicability of Hudson's rules to these streptose derivatives, since it is established conclusively that the configuration about C_4 of these lactones is L. That the lactone of dihydrostreptosonic acid lactone involves the secondary hydroxyl group at C_4 is shown by the liberation of formaldehyde when the lactone reacts with two equivalents of periodic acid.

CHARACTERISTICS OF THE DROPPING MERCU ELECTRODE IN FUSED SALTS

Sir:

In a preliminary investigation of the applicability of polarographic techniques to fused salt media we have obtained typical polarographic reduction waves for the cations of a number of salts dissolved in a fused salt solvent. The results indicate that the Ilkovic equation[1,2] is applicable to the melt employed, a ternary eutectic consisting of 66.65 mole % ammonium nitrate, 25.76% lithium nitrate, and 7.59% ammonium chloride (m. p. 86.2°).[3]

Mercury was used for the dropping electrode and the stationary unpolarized anode pool in a cell maintained at 125 ± 0.5° in an oil-bath. Drops were collected in a Pyrex spoon, washed, dried, and weighed for tests of the Ilkovic equation.

Characteristic reduction waves were obtained with nickel(II), copper(II), and bismuth(III), the latter two exhibiting maxima. A trace of potassium iodide eliminated the maximum in the case of copper. Varying degrees of success have been had with other solute salts, prime difficulties being limited solubility in or reaction with the solvent electrolyte.

TABLE I

TEST OF THE ILKOVIC EQUATION

No.	C, mmol./l.	i_d, μ amp.	m mg./sec.	$t_{max.}$, sec.	$\frac{i_d}{Cm^{2/3}t^{1/6}_{max}}$
1	1.95	3.74	1.41	4.0	1.21
2	4.98	10.0	1.45	4.5	1.22
3	6.77	12.8	1.37	3.9	1.22
4	9.97	17.2	1.45	3.4	1.10
5	12.8	21.6	1.40	3.5	1.09
6	12.8	16.6	0.658	7.6	1.22

(1) D. Ilkovic, *Coll. Czechoslov. Chem. Commun.*, **6**, 498 (1934).

(2) I. M. Kolthoff and J. J. Lingane, "Polarography," Interscience Publishers, Inc., New York, N. Y., 1941, p. 38.

(3) E. P. Perman and R. H. Wilson, *J. Chem. Soc.*, **125**, 1709 (1924).

The results obtained by varying the concentration of nickelous nitrate in the ternary solvent are presented in Table I.

Test no. 6 was made on same solution as no. 5 but with a different capillary. With a value of 13.29 g./cc. for the density of mercury at 125°, the Ilkovic equation becomes

$$i_d = 614nD^{1/2}Cm^{2/3}t_{max}^{1/6}$$

with the symbols having the usual meaning given by Kolthoff and Lingane.[2] The agreement of the experimental data with the Ilkovic equation can be seen from the essential constancy of the ratio $i_d/Cm^{2/3}t_{max}^{1/6}$ in the last column of the table. The average deviation in the ratio is ±4.3%. Substitution of the average ratio, 1.18, into the Ilkovic equation gives a diffusion coefficient equal to 9.2×10^{-7} cm.²/sec. for the nickel bearing ion.

Work is in progress to eliminate the solubility and solvent instability difficulties by employing more stable solvent electrolytes, *e. g.*, alkali halides, at higher temperatures. This will also allow investigation of a number of metals for the dropping electrode.

EXCHANGE REACTIONS BETWEEN IODINE ATOMS AND ORGANIC IODIDES

Sir:

Several workers have reported exchange reactions between organic iodine compounds and inorganic iodides, but there are very few known examples of exchanges with neutral iodine atoms or molecules. Methyl iodide[1] and several diiodophenols[2] have been shown to exchange with elementary iodine in polar solvents, but the mechanisms of these reactions were not elucidated. Noyes, Dickinson and Schomaker[3] demonstrated that neutral atoms were involved in the exchange of 1,2-diiodoethylene with elementary iodine in saturated hydrocarbon solvents.

We have now observed atomic exchange reactions with some other representative organic iodides. The experiments were conducted with iodine-131 supplied by the Oak Ridge National Laboratory and obtained on allocation from the United States Atomic Energy Commission. Hexane solutions 0.002 molar (0.004 normal) in radioactive iodine and 0.04 molar in organically combined iodine were illuminated with a tungsten lamp at about 30°. The iodine in each solution was then extracted by shaking it with an acidic aqueous solution of sodium sulfite, and the activities in one or both of the separated solutions were measured with a jacketed counter. Comparative approximate rate constants based on *trans*-diiodoethylene as unity were as follows:

Allyl iodide	much greater than	200
Trans-diiodoethylene		1.0
Iodobenzene		0.002
Ethyl iodide	less than	0.001

The rate constant for allyl iodide could not be obtained with any precision, for exchange was 60% complete in twenty seconds under the normal illumination of the laboratory desk. This amount of exchange corresponds to a rate approximately 200 times as fast as the rate of exchange of *trans*-diiodoethylene under the much more intense illumination employed in the other experiments. When the laboratory was darkened to an extent such that the necessary operations could barely be carried out, exchange of allyl iodide was 25% complete in twenty seconds. Therefore, at least a large fraction of the exchange appears to involve free atoms, but the possibility of an accompanying dark reaction is not excluded. Studies of the separation procedure demonstrated that allyl iodide underwent no more than 1% of exchange with iodide ion under the conditions employed in the reduction of the iodine.

A solution of ethyl iodide which was illuminated for one week underwent a significant amount of exchange, but the data did not permit the calculation of a reliable rate constant.

That exchange in the last three compounds in the table requires free atoms is indicated by the fact that duplicate solutions stored in the dark for as much as one week underwent no more than 1% of exchange.

We are undertaking a more thorough investigation of the kinetics of these reactions.

AN INTERRELATIONSHIP OF THYMIDINE AND VITAMIN B_{12}

Sir:

In a series of studies on factors functionally related to folic acid and *p*-aminobenzoic acid, thymidine was isolated from liver as a factor preventing the toxicity of a competitive antagonist of folic acid.[1] The recently reported isolation of vitamin B_{12} as a growth factor for *Lactobacillus lactis* Dorner[2,3] necessitated a study of the function of the vitamin to determine whether or not it is identical with a factor found in this Laboratory to be concerned with the biosynthesis of thymidine. As vitamin B_{12} has been isolated using an assay with *Lactobacillus lactis* Dorner, this organism was utilized in the present investigation.

A medium suitable for assay techniques has not

been adequately described for this organism; however, a previously described medium[4] in which the phosphate buffer was replaced by sodium acetate and which was supplemented with an oleic acid source, "Tween 80," 10 mg. per 10 cc., enzymatic digest of casein,[5] 10 mg. per 10 cc., and Wilson's liver fraction LR, 100γ per 10 cc., supports good growth of the organism in the presence of liver extracts containing anti-pernicious anemia principles and can be used successfully as an assay medium. The enzymatic digest of casein replaces clarified tomato juice.[3] Tests were incubated for twenty-four hours at 37–38°.

With the above medium or one containing clarified tomato juice (0.5 cc. per 10 cc.) in place of the enzymatic digest of casein, thymidine adequately replaced the liver extracts containing anti-pernicious anemia principles. Half-maximum stimulation of growth was obtained at a concentration of 1–3 γ of thymidine per 10 cc. Thymine was inactive at concentrations as high as 100 γ per 10 cc.

When the medium containing tomato juice was utilized, as little as 1 cc. of sterile, aerated distilled water added aseptically to 10 cc. of medium replaced the liver extract, and this effect was enhanced by aseptic addition of ascorbic acid. However, when the enzymatic digest of casein was used in place of tomato juice, the aerated water was inactive, but ascorbic acid (1 mg. in 1 cc. of sterile, aerated water per 10 cc. of medium) added aseptically still adequately replaced the liver extracts containing anti-pernicious anemia principles for the nutrition of this organism. The function of ascorbic acid in replacing the liver extract will be reported separately.

Since thymidine adequately replaces vitamin B_{12} in the nutrition of *Lactobacillus lactis* Dorner, it appears probable that vitamin B_{12} functions in the biosynthesis of thymidine.

A NEW COLOR TEST FOR TRYPTOPHAN

Sir:

It has been observed that at room temperature perchloric acid converts trytophan to a fluorescent yellowish green compound. Fluorescence is particularly strong in ultraviolet light. Tryptophan may readily be identified in untreated proteins by this test. This reaction is not given by other amino acids and biologic substances with which it is usually associated. Indol acetic acid, however, gives a slight pink color and slight fluorescence under the conditions of the test.

The Test.—One-half of 1 cc. of water containing 0.5 mg. of tryptophan, or about 10 mg. of albumen (egg powder) or any other tryptophan-containing protein, is placed in a test-tube. The protein does not have to be in solution. Three cc. of perchloric acid (C. P. 70–72%) is added and the contents of the tube are well mixed. A quite stable, intense greenish-yellow color develops within a few minutes attaining maximum intensity in about ten minutes. Upon the addition of 0.1 cc. of a 1% ferric chloride solution, the greenish-yellow color becomes reddish-orange. If the ferric chloride solution is added to the tryptophan-containing solution before the perchloric acid, the reddish-orange color is formed instantaneously. For the detection of minute amounts of tryptophan, ultraviolet light and perchloric acid without ferric chloride should be employed.

The following tryptophan-containing materials gave the reaction: casein, albumen (egg powder), human blood serum, pepsin and crystalline soybean trypsin inhibitor.

The following amino acids did not give the reaction: glycine, alanine, leucine, isoleucine, valine, phenylalanine, tyrosine, cysteine, cystine, methionine, threonine, proline, hydroxyproline, histidine, arginine, lysine, serine, aspartic acid, glutamic acid, and *p*-aminobenzoic acid.

S. S. Cohen (*J. Biol. Chem.*, **156**, 691 (1944)) made the interesting observation that when carbohydrates and tryptophan were heated for ten minutes at 100° in 30% perchloric acid colored condensation products form. In Cohen's reaction boiling is an essential factor. The green fluorescent compound described in the present communication, however, forms readily at room temperature, carbohydrates do not interact and this reaction does not take place in 30% perchloric acid.

RECEIVED JUNE 7, 1948

NEW BOOKS

The Systematic Identification of Organic Compounds. By RALPH L. SHRINER, Professor of Chemistry, The State University of Iowa, and REYNOLD C. FUSON, Professor of Chemistry, The University of Illinois. Third Edition, John Wiley and Sons, Inc., 440 Fourth Avenue, New York 16, N. Y., 1948. viii + 370 pp. 15 × 22 cm. Price $4.00.

The first edition of this laboratory manual appeared in 1935 as 195 pages; for reviews of this edition, see THIS JOURNAL, **58**, 536 (1936), and *J. Chem. Education* **12**, 596–597 (1935). Five years later a second edition had grown to 312 pages; for reviews of it, see THIS JOURNAL, **62**, 2569 (1940), and *J. Chem. Education*, **17**, 501 (1940). The present third edition requires 370 pages.

Although the approach to its subject is broadly retained, the material has been substantially amplified and the new incorporated with the old in a different sequence. By inclusion of new methods the chapter on the preparation of derivatives has been increased from 51 to 65 pages; that comprising tables of derivatives occupies the same space, but many new constants have been inserted in what were formerly gaps in the tables. The two chapters on separation of mixtures and interpretation of experimental data appear to be unchanged, but the eleven pages of problems have by new additions been expanded to twenty.

The utility of the index has been increased and ease of location of a given tabular entry facilitated by the inclusion of the melting or boiling point of the compound in the index itself.

In recent years increasing attention is being given to the special values of adequate training in the field to which this treatment comprises a valuable introduction; the new edition is, therefore, timely and welcome.

ERNEST H. HUNTRESS

Répertoire des Composés organiques polymorphes. (Encyclopedia of Polymorphic Organic Compounds.) By LOUIS DEFFET, Assistant à l'Université de Bruxelles. Editions Desoer, 21 Rue Sainte-Véronique, Liége, 1942. 155 pp.

This book is a compilation of thermal and crystallographic data on organic compounds which exhibit polymorphism. After a very brief explanatory introduction, it lists, in its first section, 1188 organic compounds found to be polymorphic at atmospheric pressure, in its second section, 32 substances polymorphic under high pressure, in a third section, a bibliography of 994 references, and, in a fourth section, an alphabetical list of the substances, referring by number to those in the first two sections, which are arranged according to the system used by Richter. After the formula and name of each compound in the first two sections, abbreviations indicate the number of modifications, the occurrence of enantiotropy or monotropy, and the crystal forms, when known, and occasionally other information. Also listed are the melting and transition temperatures, and the heats of fusion and of transition, when available. The lists appear to have been prepared with the care that one would expect from a pupil of Professor Timmermans. On looking up a few familiar polymorphic substances, the reviewer has found no omissions of data published prior to December, 1941. The book should be very useful to investigators of polymorphism, and generally valuable as a reference work for data on the subject.

JOURNAL OF THE AMERICAN CHEMICAL SOCIETY

VOLUME 70 SEPTEMBER 1, 1948 NUMBER 8

[CONTRIBUTION FROM THE CONVERSE MEMORIAL LABORATORY OF HARVARD UNIVERSITY]

Preparation of *cis*- and *trans*-Decahydroisoquinolines and of Bz-Tetrahydroisoquinoline

BY BERNHARD WITKOP[1]

Of the possible hydrogenated derivatives of isoquinoline, the *cis*- and *trans*-decahydro compounds, py-tetrahydroisoquinoline, and very recently bz-tetrahydroisoquinoline, have been prepared mainly by ring-synthetic methods.[2,3] The latter has lately gained importance as an intermediate in the synthesis of morphane.[4]

In this communication a simple method for the preparation of 5,6,7,8-tetrahydroisoquinoline (bz-tetrahydroisoquinoline), and of the pure *cis*- and *trans*-decahydroisoquinolines directly from quinoline is reported.

Skita obtained by catalytic hydrogenation of isoquinoline in glacial acetic acid with colloidal platinum a substance which was very probably largely *cis*-decahydroisoquinoline; the physical properties of his substance, however, suggest the presence of a certain amount of the *trans*-isomer.[5] We have found that the hydrogenation of isoquinoline in glacial acetic acid with a trace of sulfuric acid gives a mixture of decahydroisoquinoline which contains 70–80% of the *cis*-isomer and 20% of the *trans*-compound.[6] The *cis*-compound was readily isolated from the crude mixture of isomers as the pure picrate (m. p. 150°). On the other hand, if the mixture of isomers was subjected to dehydrogenation over palladium at 210°, a mixture of bases was formed, from which 10% of *trans*-decahydroisoquinoline, 10–25% of 5,6,7,8-tetrahydroisoquinoline and isoquinoline were isolated by fractional extraction with 0.1 *N* hydrochloric acid.[7] These relationships are summarized in the chart. The 5,6,7,8-tetrahydroisoquinoline alternately was prepared by boiling *cis*-decahydroisoquinoline in tetralin with selenium for forty eight hours.

These experiments demonstrate the striking fact that *cis*-decahydroisoquinoline is much more readily dehydrogenated than the corresponding *trans*-isomer, a behavior which parallels that of the decahydroquinolines, and, to a lesser extent, that of the decalins (Ehrenstein[7]). Model considerations suggest that the determining factor may lie in the relatively easier approach of the *cis*-compound to the catalyst in a configuration favorable to the removal of hydrogen atoms in pairs.[8]

Experimental[9]

***cis*-Decahydroisoquinoline.**—The catalytic perhydrogenation of isoquinoline[7] was effected at room temperature and normal pressure as follows: isoquinoline (reagent, 1 g.) was dissolved in glacial acetic acid (10 cc.) and five drops of concentrated sulfuric acid was added.[10] In the presence of 1 g. of platinum oxide the tetrahydro stage was reached after about forty minutes, and the decahydro state after about four to eight hours. Omission of the concentrated sulfuric acid or use of less catalyst blocked the hydrogenation at the tetrahydro stage. The catalyst was removed by filtration, the diluted solution was made strongly alkaline and extracted with ether. After evaporation of the ether the base was neutralized with hydrochloric acid and evaporated to dryness. The crystallized hydrochloride (1.24 g., over 90%) showed an unsharp melting point, 165°. It was converted into the picrate. The dry picrate (2.5 g.) was treated five

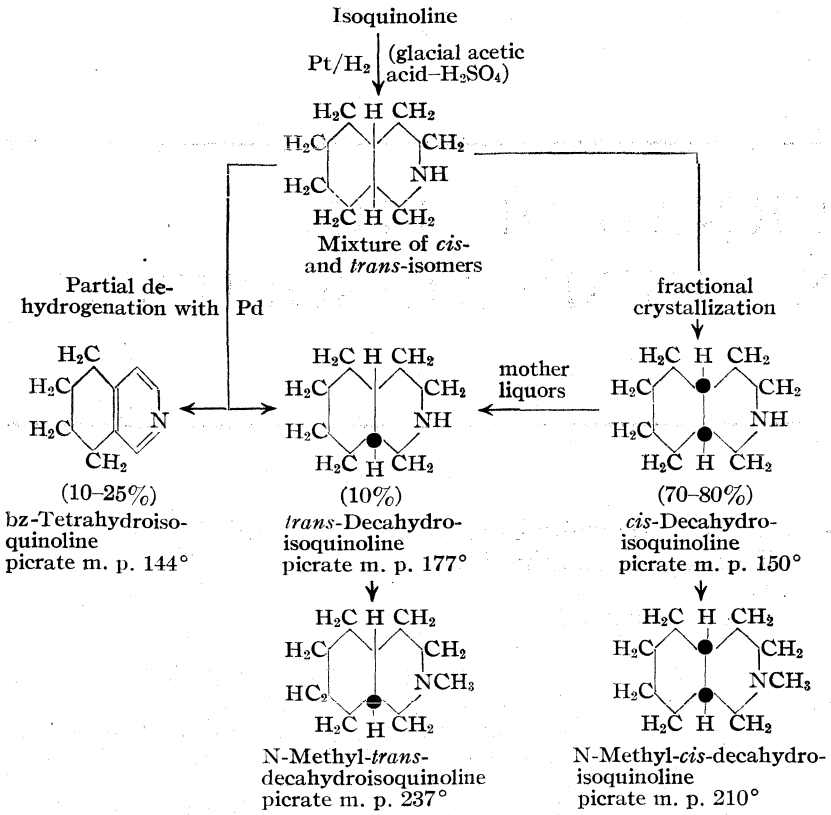
(9) All melting points corrected.

(10) Kindler and Kwok, *Ann.*, **554**, 9 (1942).



times with 1–2 cc. of cold methanol, which chiefly removed *trans*-decahydroisoquinoline. The residue was dissolved in hot methanol and filtered after an hour from the crystals which separated. The final solution yielded uniform crystals which were recrystallized twice from methanol; melting point 150° (1.91 g., 73%). The picrate was converted into the hydrochloride by adding hydrochloric acid to the methanolic solution and extracting the picric acid with ether. The dry hydrochloride was treated with 1 cc. of absolute alcohol and the residue was crystallized from alcohol–ether. The beautifully crystallized hydrochloride melted sharply at 183° (0.41 g.).

N-Methyl-*cis*-decahydroisoquinoline Picrate.—The above hydrochloride (100 mg.) was boiled under reflux with 2 cc. of 95% formic acid and 2 cc. of 40% aqueous formaldehyde for two hours. The solution was evaporated to dryness and converted into the picrate. The picrate of the N-methyl base is much less soluble in methanol than that of the original base. It crystallizes from methanol in tufts of small needles, m. p. 210°, yield over 90%.

Anal. Calcd. for $C_{10}H_{19}N \cdot C_6H_3O_7N_3$: C, 50.26; H, 5.7. Found: C, 50.52; H, 5.45.

***trans*-Decahydroisoquinoline. A. By Fractional Crystallization.**—The combined cold methanol extracts of the *cis*-picrate contained mainly *trans*-compound. It could be obtained by careful slow fractional crystallization. The *trans*-picrate formed large prisms possessing a full yellow color and was separated mechanically from smaller light yellow aggregates of crystals that consisted chiefly of *cis*-picrate. The recrystallized *trans*-picrate melted at 175–178°.

B. By Dehydrogenation of the Accompanying *cis*-Compound.—The mixture of the *cis*- and *trans*-bases (1 g.), as obtained directly by hydrogenation, was heated under reflux with 0.2 g. of palladium black. The reaction was carried out in an apparatus similar to the one designed by H. Heymann.[11] After about four hours 650 cc. of hydrogen was evolved. The major part of the reaction mixture was distilled at 210° (760 mm.). The distillate was taken up in 20 cc. of ether and extracted with consecutive portions of 2 cc. of 0.1 *N* hydrochloric acid. Every fraction was converted separately into the picrate. The fractions 1–4 (Table I) were recrystallized from absolute methanol. The accompanying small amount of isoquinoline picrate could be easily separated owing to its much smaller solubility. The pure *trans*-decahydroisoquinoline picrate melted at 177°. On admixture with the *cis*-picrate (m. p. 150°) the melting point was depressed to 143°.

Anal. Calcd. for $C_9H_{17}N \cdot C_6H_3O_7N_3$: C, 48.91; H, 5.44. Found: C, 49.07; H, 5.38.

Hydrochloride.—The picrate was dissolved in methanol, treated with hydrochloric acid and ether; the aqueous solution after evaporation left the hydrochloride which crystallized from alcohol in needles, m. p. 224°. The salt is not very hygroscopic.

Anal. Calcd. for $C_9H_{17}N \cdot HCl$: C, 61.5; H, 9.8. Found: C, 61.1; H, 10.2.

Dehydrogenation.—Treatment of 30 mg. of the above chloride with 30 mg. palladium at 210° for one-half hour failed to have any dehydrogenating effect (the *cis*-chloride was easily converted into isoquinoline under these conditions). When 30 mg. of *trans*-base was heated with 90 mg. of palladium for three hours under reflux, one obtained a reaction product which was no longer miscible with water, picrate 223°, identical with isoquinoline picrate.

TABLE I

The melting points (cor.) were carried out on a micro hot stage; the figures in parentheses are sintering points.

Picrate fraction no.	Weight, mg.	Appearance	M. p., °C.	Compound
1	260	lemon-yellow, crystalline	170 (160)	*Trans*-decahydro isoquinoline (isoquinoline)

Anal. Calcd. for $C_{10}H_{19}N \cdot C_6H_3O_7N_3$: C, 50.26; H, 5.7. Found: C, 50.57; H, 5.75.

Bz-Tetrahydroisoquinoline. A. By Partial Dehydrogenation with Palladium Black.—The picrate fractions 6–9 (Table I) were combined (270 mg.) and freed from the much less soluble isoquinoline picrate by sufficient recrystallizations from acetone. The pure product finally crystallized in golden-yellow needles of uniform appearance, m. p. 144°.

Anal. Calcd. for $C_9H_{11}N \cdot C_6H_3O_7N_3$: C, 49.73; H, 3.87. Found: C, 50.25; H, 3.87.

In another experiment, starting with the same amount (1 g.) of decahydro bases, dehydrogenation was stopped after the evolution of 310 cc. of hydrogen (calcd. for 5 moles of hydrogen, 781 cc.). In this case the medium fractions yielded 690 mg. of picrate, corresponding to about 25% yield of Bz-tetrahydroisoquinoline.

Picrolonate.—The free base, prepared from the above picrate, had a smell reminiscent of substituted pyridines (*e. g.*, collidine). Aqueous picrolonic acid precipitated from the solution of the hydrochloride the picrolonate which, recrystallized from methanol, melted at 214°.

Anal. Calcd. for $C_{19}H_{19}O_5N_5$: C, 57.43; H, 4.78. Found: C, 57.94; H, 5.03.

B. By Partial Dehydrogenation with Selenium in Tetralin.—*cis*-Decahydroisoquinoline (0.8 g.) was boiled under reflux in 15 cc. of freshly distilled tetralin with 0.5 g. of black selenium dust for forty-eight hours. The reaction mixture was filtered from the selenium, diluted with ether and extracted with 2-cc. portions of 0.1 *N* hydrochloric acid. The fractions were converted into the picrates, which had the properties: 1–3, *cis*-decahydroisoquinoline picrate (0.19 g.), m. p. 150°; 4, mixture, not crystallized, sticky; 5, Bz-tetrahydroisoquinoline picrate, m. p. (after removal of little accompanying isoquinoline picrate) 144°; 6, isoquinoline picrate, m. p. 223°. After evaporation of the ether and tetralin a small amount of naphthalene was obtained.

Summary

Catalytic hydrogenation of isoquinoline in glacial acetic acid with sulfuric acid leads to a mixture containing 70–80% *cis*- and at least 10% *trans*-isomer. The *cis*-isomer is more readily dehydrogenated with Pd than the *trans* isomer. By controlled dehydrogenation of the *cis*-isomer bz-tetrahydroisoquinoline was obtained.

Some Basically Substituted Quinoxalines

BY HENRY GILMAN AND H. SMITH BROADBENT

Of the many thousands of compounds synthesized and tested for antimalarial activity, those which have shown by far the greater promise, in general, are the derivatives of nitrogen-containing heterocycles bearing basic side chains, in particular the derivatives of quinoline. At the inception of this investigation very few basically substituted quinoxalines had been described in the chemical literature and even fewer had been tested for *antimalarial* activity.[1] Since quinoxaline differs from quinoline only in having a tertiary nitrogen substituted for the carbon in the 4-position of the ring, derivatives of quinoxaline appeared to have some interest as antimalarials.

In order to explore this possibility, a series of substituted aminoquinoxalines and their 2,5-dimethyl-1-pyrryl derivatives was prepared and subjected to pharmacological testing. In addition the rather high tuberculocidal activity of some related types of compounds prompted the synthesis of 2,3-bis-(*p*-aminophenyl)-quinoxaline, 2,3-bis-(*p*-hydroxyphenyl)-quinoxaline and 2,3-bis-(*p*-hydroxyphenyl)-6-aminoquinoxaline.

(1) While this investigation was in progress and since its completion three years ago, several papers have appeared dealing with the synthesis of quinoxaline derivatives for pharmacological purposes, *viz.*, (a) Gowenlock, Newbold and Spring, *J. Chem. Soc.*, 622 (1945); (b) Hall and Turner, *ibid.*, 699 (1945); (c) King and Beer, *ibid.*, 792 (1945); (d) Gawron and Spoerri, THIS JOURNAL, **67**, 514 (1945); (e) Mizzoni and Spoerri, *ibid.*, **67**, 1652 (1945); (f) Cavagnol and Wiselogle, *ibid.*, **69**, 795 (1947); (g) Stevens, Pfister and Wolf, *ibid.*, **68**, 1035 (1946); (h) Weijlard, Tishler and Erickson, *ibid.*, **66**, 1957 (1944); (i) Linsker and Evans, *ibid.*, **68**, 874 (1946); and (j) Wiedling, *Acta Path. Microbiol. Scand.*, **22**, 379 (1945), as well as a few notes.

The quinoxaline nuclei of the compounds synthesized in the course of this work were prepared by condensing appropriately substituted α-diketones with either *o*-phenylenediamine or 1,2,4-triaminobenzene dihydrochloride in acetic acid or aqueous ethanol solutions, respectively. In all cases the yields were satisfactory, although in the latter case, the removal of resinous by-products was troublesome.

The 1,2,4-triaminobenzene required was prepared and used in the form of its dihydrochloride. The original method of Hinsberg[2] for its preparation did not prove to be satisfactory. The complex formed between the amine and chlorostannous(ic) acids was often difficult to decompose completely and a tin-containing product was secured only difficultly purified by recrystallization. In addition, the frequent exposure to the air entailed in this process was deleterious to the very easily oxidized polyamine. In order to circumvent these difficulties, it was found that the catalytic reduction of 2,4-dinitroaniline in ethanol over Raney nickel was more rapid, convenient, and less expensive than the former method, and it yielded the product desired in greater yields of at least equal purity.

In the preparation of substituted benzoins, the experimental conditions necessary in order to get good yields of crystalline products are often quite rigid.[3] Rather than isolate the intermediate benzoins, anisoin and *o,o'*-dichlorobenzoin, in the prep-

(2) Hinsberg, *Ber.*, **19**, 1253 (1886).

(3) Dewar and Read, *J. Soc. Chem. Ind.*, **55T**, 347T (1936).

aration of the corresponding benzils, it was found that the crude nitrogenous mixtures containing less than 50% of the benzoin obtained from the potassium cyanide–aldehyde reaction could be oxidized directly with copper sulfate in pyridine.[4] This method converted the contained benzoin to the pure crystalline benzil in nearly quantitative yields.

The reported preparation of 4,4′-dihydroxybenzil by the demethylation of anisil[5] requires hydrobromic acid of 1.78 density, which is not conveniently available. Neither aqueous hydrobromic acid (d. 1.48, 48%) nor 33% hydrogen bromide in acetic acid was found to be efficacious alone; however, the use of equal parts of the two acid solutions was found to cleave smoothly the methyl groups from anisil resulting in a good yield of pure 4,4′-dihydroxybenzil.

The preparation of 2,3-bis-(*p*-aminophenyl)-quinoxaline was conveniently effected by Raney nickel reduction of the corresponding nitro compound (*cf.* ref. 1d and 1f) without reduction of the heterocyclic nucleus.[6]

The 2,5-dimethyl-1-pyrrylquinoxalines were synthesized from the corresponding amines by condensation with 2,5-hexanedione. In the case of 2-aminoquinoxaline we were not able to isolate any pure product other than starting material.

Solutions of 2,3-bis-(*p*-hydroxyphenyl)-6-aminoquinoxaline in strong acids are a bright, cherry-red color and in bases a brilliant yellow. On adding small amounts of the indicator dissolved in a dilute sodium hydroxide solution to a series of Clark and Lubs buffers, the transition point was found to lie between *p*H 3.4 and 3.6 indicating an approximate pK_{In} of 3.5 assuming the color intensities of the acidic and basic forms to be equal.

The 6-aminoquinoxalines and their pyrryl derivatives all have an intense yellowish-green fluorescence observable even in extremely dilute solutions, being red by transmitted light. An interesting observation on the effect of molecular structure on solubility is afforded by the 2,3-diphenyl-, 2,3 bis-(*p*-methoxyphenyl)-, and 2,3-bis-(*o*-chlorophenyl)-6-aminoquinoxalines and their pyrryl derivatives. The amino compounds are very soluble in ethanol and only moderately soluble in benzene whereas the corresponding pyrryl compounds are almost completely insoluble in hot ethanol and exceedingly soluble in hot benzene.

The results of the pharmacological tests on these compounds will be published elsewhere, and the authors are grateful to Parke, Davis and Company for arranging for the tests.

Experimental

1,2,4-Triaminobenzene Dihydrochloride.—(A) Tin and Hydrochloric Acid Method.—Following the general procedure of Hinsberg,[2] 0.5 mole of 2,4-dinitroaniline yielded 40 g. (41%) of 1,2,4-triaminobenzene dihydrochloride. A second 0.25-mole run gave a 35-g. (71.5%) yield.

(B) Catalytic Reduction Method.—In 300 ml. of absolute ethanol 61 g. (0.33 mole) of 2,4-dinitroaniline and 4–5 g. of "wet" Raney nickel catalyst were suspended and shaken under 1–3 atm. of hydrogen until the required amount for complete reduction of the nitro groups had been absorbed (*ca.* twelve hours). The violet solution was filtered free of catalyst and treated with an excess of concentrated hydrochloric acid with cooling in an ice-bath. A fine, purple, crystalline solid separated, which was filtered off, washed with ethanol and ethyl acetate, and finally dried *in vacuo*. The yields of dry, purplish solid in six successive runs were 81, 86, 93, 86, 98 and 85%, respectively, of a purity superior to that obtained by the Hinsberg procedure.

Anisil.—Anisoin was prepared from purified anisaldehyde according to the directions of Dewar and Read[3] in yields of 40% and 43% (m. p. 113°). A run made according to the procedure of Boesler[7] gave only a 22% yield.

Eleven grams (0.0405 mole) of anisoin, 45 g. (0.18 mole) of copper sulfate, 20 ml. of water, and 60 g. of pyridine were heated on a steam-bath with stirring for four hours. On filtering and washing with water, 10.5 g. (96%), of fine, pale yellow crystals melting sharply at 131–132° was obtained without crystallization (reported,[7] 133° by another technique). Two successive runs gave yields of 96% and 100%.

2,2′-Dichlorobenzil.—2,2′-Dichlorobenzoin was prepared from 100 g. (0.712 mole) of *o*-chlorobenzaldehyde following the procedure of Hodgson and Rosenberg[8]; however, the product was an oil which would not crystallize (reported,[8] m. p. 56–57° in 40% yield).

The crude mixture consisting of approximately 40% aryloin from the above reaction was stirred and heated at 100° for four hours with 180 g. copper sulfate, 80 ml. water, and 240 ml. pyridine. This crude product obtained on diluting with water was crystallized from benzene as beautiful, yellow needles melting at 128–129° (reported,[8] 128° by another method). The over-all yield was 38.5 g. (39%), nearly 100% based upon the contained aryloin.

4,4′-Dihydroxybenzil.—Ten grams (0.037 mole) of anisil, 50 ml. of aqueous hydrobromic acid (d. 1.48), and 50 ml. of 33% hydrogen bromide in glacial acetic acid were refluxed with vigorous stirring for six hours while a slow current of dry carbon dioxide was passed over the mixture. The solution was poured into water precipitating a fine gray powder, which was dissolved in a small volume of 15% sodium hydroxide, filtered, and then precipitated with hydrochloric acid. A light, gray powder melting at 245–247° was obtained. The melting point was unchanged on crystallizing from a large volume of boiling water. The yield was 8 g. (89%) (reported,[5] m. p. 235°).

6-Amino-2,3-bis-(*p*-methoxyphenyl)-quinoxaline: Procedure A.—A suspension of 10 g. (0.037 mole) of anisil and 7.5 g. (0.038 mole) of 1,2,4-triaminobenzene dihydrochloride in 100 ml. of ethanol and water (1:1) was refluxed with stirring for four hours on the steam-bath. Sodium hydroxide solution was added in slight excess, and the mixture was cooled. The hard cake of crude product was pulverized, taken up in hot ethanol, charcoaled and cooled. The dark purplish crystals separating out were then recrystallized to constant melting point from benzene giving a yield of 8.1 g. (61%) of light brown crystals melting at 194–196°.

2,3-bis-(*p*-Aminophenyl)-quinoxaline: Procedure B.—4,4′-Dinitrobenzil was prepared by the nitration of 4,5-diphenylglyoxalone according to the method of Chattaway and Coulson.[9] The yield of 2,3-bis-(*p*-nitrophenyl)-

[a] An example representative of each procedure is described in the experimental part. The others were prepared in analogous fashion. [b] All melting points are uncorrected. The two above 300° were taken with a Berl–Kuhlmann type block, the others by capillary or hot-stage methods. [c] This compound has been prepared by Hinsberg, *Ann.*, **292**, 254 (1896), and Bertels, *Ber.*, **37**, 2277 (1904), m. p. 175°. [d] See ref. 11. [e] See ref. 12.

quinoxaline, obtained from the benzil and *o*-phenylenediamine, on recrystallization from acetic acid was 2.45 g. (100%) of large, tan crystals melting at 203–204° (reported,[7] 201°).

Two and three-tenths grams (0.0062 mole) of the nitrophenylquinoxaline was suspended in 60 ml. of absolute ethanol with 1–2 g. Raney nickel and shaken under 3 atm. pressure of hydrogen until the required amount was absorbed. The insoluble deposit was dissolved in methyl cellosolve, and the solution filtered free of catalyst. On evaporation of most of the solvent and diluting with water, brownish-yellow crystals melting at 255–258° were obtained. The product was recrystallized successively from acetone and water, and then acetone and ethanol until the melting point was raised to 260–262°.[10] The final yield of shining yellow plates of product was 0.350 g. (18%).

2,3-bis-(*p*-Hydroxyphenyl)-quinoxaline: Procedure C.—In 75 ml. of glacial acetic acid, 1.1 g. (0.01 mole) of *o*-phenylenediamine and 2.4 g. (0.01 mole) of 4,4′-dihydroxybenzil were refluxed for three hours. On cooling, glistening, yellow crystals of product separated. They were recrystallized from ethanol to a melting point of 326–328°. The yield was 2.9 g. (94%). The compound is easily soluble in sodium hydroxide, but very difficultly soluble in hydrochloric acid.

2,3-Dimethyl-6-(2,5-dimethyl-1-pyrryl)-quinoxaline: Procedure D.—Three grams (0.017 mole) of 2,3-dimethyl-6-aminoquinoxaline in 12 ml. of absolute ethanol was refluxed for four hours with 2.18 g. (0.0191 mole) of 2,5-hexanedione and 1 ml. of glacial acetic acid. The mixture was poured with rapid stirring into 50 ml. of water, cooled and filtered. The granular product after treatment with Norit was crystallized from ethanol as long, straw-colored needles melting at 161–163°. The yield was 3.2 g. (74%).

Attempted Preparation of 2-(2,5-Dimethyl-1-pyrryl)-quinoxaline.—2-Aminoquinoxaline was prepared from alloxazine in 67% over-all yield.[11] From 3.5 g. (0.0242 mole) of 2-aminoquinoxaline refluxed for two hours in 15 ml. of absolute ethanol with 3 ml. of 2,5-hexanedione, and 1 ml. of glacial acetic acid, a dark brown gum, and 2 g. of crystalline material was isolated on drowning in water. The gum could not be readily purified. The crystalline portion after several recrystallizations from ethanol–water (1:3) followed by sublimation melted at 156–157°. It was shown by mixed melting point to be recovered 2-aminoquinoxaline.

On a second attempt only a dark unmanageable gum was obtained.

Summary

Several quinoxaline derivatives have been synthesized for testing for antimalarial activity and some of them, as noted, for tuberculostatic activity also.

They are strongly fluorescent in benzene solution and one of them, 6-amino-2,3-bis-(*p*-hydroxyphenyl)-quinoxaline has the properties of an acid-base indicator at *p*H 3 to 4.

The results of the pharmacological tests will be published elsewhere.

Synthesis of 2,3-Disubstituted Cinchoninic Acids from Propoxymethyl Alkyl (or Phenyl) Ketones by Means of the Pfitzinger Reaction[1]

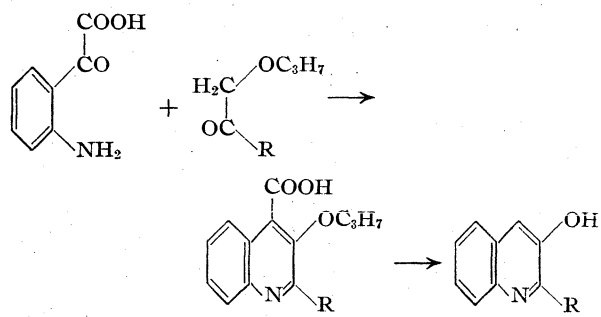
BY HENRY R. HENZE, JOE W. MELTON[2] AND EUGENE O. FORMAN

In 1925 Dilthey and Thelen[3] reported the initial utilization of an alkoxy ketone according to the Pfitzinger method[4] in preparing 3-methoxy-2-phenylcinchoninic acid. More recently, Cross and Henze[5] used this method to convert ethoxyacetone and ethoxymethyl ethyl ketone into the corresponding 2-alkyl-3-ethoxycinchoninic acids. Later, Lesesne and Henze[6] extended this reaction to include the utilization of alkoxy ketones in the synthesis of 2-alkoxyalkyl and 2-alkoxyalkyl-3-alkylcinchoninic acids. Thus, 1-alkoxyethyl methyl ketones appeared to yield cinchoninic acids having the 1-alkoxyethyl grouping attached to the 2-position.

In an attempt to extend the study to a higher homolog of the 1-alkoxyethyl alkyl ketone series, isoamyl 1-methoxyethyl ketone was warmed with isatin under the usual conditions without evidence of reaction. When the attempt was repeated, but using enough alcohol to make the reaction mixture homogeneous, only unsubstituted cinchoninic acid was isolated. Utilization of a 40% aqueous solution of alkali resulted in the formation of a molecular compound of anthranilic acid and 2-(1-methoxyethyl)-3-(2-methylpropyl)-cinchoninic acid.[7]

The availability of certain alkyl (or phenyl) propoxymethyl ketones[8] made it possible to study their behavior with isatinic acid in hot alkaline solution. By this procedure, twelve propoxymethyl ketones were converted into disubstituted cinchoninic acids. The structure of the two heterocyclic compounds derived from the phenyl propoxymethyl ketones was scarcely in doubt. However, their structure was completely established through conversion (by means of decarboxylation and ether group cleavage) into the known 3-hydroxy-2-phenylquinoline.[3]

Confirmation of the structure of this phenylcinchoninic acid did not establish that of the quinoline acids derived from the aliphatic keto ethers, since the latter contain the RCH_2COCH_2OR' grouping which might permit formation of either or both of two isomeric disubstituted cinchoninic acids depending upon which methylene group was involved in the ring closure. It is possible to distinguish between these two isomers by a study of the products of decarboxylation, of cleavage of the ether linkage, or of both. The cinchoninic acids derived from ethyl isopropoxymethyl ketone and *n*-propoxymethyl *n*-propyl ketone, respectively, could be converted into alkali-soluble quinolines, such as the known 2-ethyl-3-hydroxyquinoline.[9] Thus it was established that the hydrogens of the methylene group to which are attached both the ether and carbonyl groupings, are the more reactive in condensation with isatinic acid to form the heterocyclic nucleus



Experimental

The 2,3-disubstituted cinchoninic acids were prepared according to Pfitzinger's procedure by placing 25–50 cc. of 33% potassium hydroxide solution in a small flask and adding equivalent weights of isatin and an alkyl (or phenyl) propoxymethyl ketone. In most cases involving the isopropoxy ketones, enough alcohol was added to render the mixture homogeneous. The mixture was heated for forty-eight hours at about 100°, then was treated (hot) with Norite and filtered. After dilution with water, the filtrate was acidified with 50% acetic acid, usually causing immediate formation of a creamy precipitate. If necessary the acid solution was chilled before separation of the crystalline product. Each acid was purified by recrystallization to constant melting point from diluted alcohol or acetone. Only the purified products could be dried without decomposition in an oven. Data for the melting points and analyses of these acids are listed in Table I.

Proof of Structure of 2-Phenyl-3-propoxycinchoninic Acid.—This product, obtained through interaction of isatin and phenyl *n*-propoxymethyl ketone, was placed together with 15 cc. of concentrated hydrochloric acid in a sealed tube and heated at 175° for twelve hours. After opening the tube, the mixture was neutralized with sodium bicarbonate, and the substituted quinoline removed by filtration and recrystallized from an acetone–water solution. The melting point of the alkali soluble **3-hydroxy-2-phenylquinoline** (228° (cor.)) is somewhat higher than that (218–220°) reported by Dilthey and Thelen[3] for this product.

Anal. Calcd. for $C_{15}H_{11}NO$: C, 81.43; H, 5.01; N, 6.33. Found: C, 81.31; H, 4.89; N, 6.49.

One-half gram of the hydroxyquinoline derivative was dissolved in 75 cc. of alcohol and treated with 40 cc. of saturated aqueous picric acid solution. A picrate soon

separated and was recrystallized from alcohol; it melted[10] with decomposition at 245° (cor.).

Anal. Calcd. for $C_{21}H_{14}N_4O_8$: N, 12.44. Found: N, 12.59.

Proof of Structure of 3-(*n*-Propoxy)-2-(*n*-propyl)-cinchoninic Acid.—One gram of the product from interaction of isatin and *n*-propyl *n*-propoxymethyl ketone was dissolved in 15 cc. of concentrated hydrochloric acid, sealed in a tube and heated at 165° for twelve hours. When cooled, solid material separated from solution and, after drying in the oven at 110°, melted at 223° (cor.). This proved to be the hydrochloride of a substituted quinoline. It was dissolved in water and decomposed by addition of sodium bicarbonate; the liberated quinoline was recrystallized from an acetone–water mixture. The product, **3-hydroxy-2-*n*-propylquinoline,** melts at 256° (cor.), and is readily soluble in alkaline solution.

Anal. Calcd. for $C_{12}H_{13}NO$: N, 7.48. Found: N, 7.91.

A small amount of this disubstituted quinoline was dissolved in 95% alcohol, and mixed with 10 cc. of saturated aqueous solution of picric acid. After chilling the *picrate* separated as long crystals melting with decomposition at 158° (cor.).

Anal. Calcd. for $C_{18}H_{16}N_4O_8$: N, 13.46. Found: N, 13.73.

Proof of Structure of 2-Ethyl-3-isopropoxycinchoninic Acid.—Three methods were used in the conversion of this acid into 2-ethyl-3-hydroxyquinoline.

A. A mixture of 1.5 g. of 2-ethyl-3-isopropoxycinchoninic acid and 15 cc. of concentrated hydrochloric acid was sealed in a tube and heated at 175° for twelve hours. Upon dilution of the resulting solution with water, a white precipitate formed and was purified by solution in dilute sodium hydroxide solution with subsequent reprecipitation with dilute acetic acid solution. After recrystallization from acetone, the solid melted with decomposition at 205.5–208.0° (cor.).[11]

B. A sample of 2-ethyl-3-isopropoxycinchoninic acid was decarboxylated by heating to its melting point of 197°. The dark oil thus formed was distilled at 209–214° (42 mm.): 78% yield of 2-ethyl-3-isopropoxyquinoline. This material was sealed in a tube with concd. hydrochloric acid and heated to 200° for five hours. After diluting the solution with water, creamy white crystals separated and were purified as above; m. p. 205–208°.

Anal. Calcd. for $C_{11}H_{11}NO$: N, 8.07. Found: N, 8.22.

C. A mixture of 2 g. of 2-ethyl-3-isopropoxycinchoninic acid, 15 cc. of hydriodic acid and 1.25 g. of red phosphorus was refluxed for twenty-four hours. The hot mixture was filtered through asbestos and cooled to yield a yellow precipitate. The latter was filtered off, dissolved in sodium hydroxide solution and precipitated by addition of acetic acid. The solid was recrystallized to a constant m. p. of 206–207° (cor.) from alcohol and water.

Anal. Calcd. for $C_{11}H_{11}NO$: N, 8.07. Found: N, 8.27.

The yellow acidic filtrate from above was steam distilled and the residual solution concentrated by evaporation to 25 cc. It was neutralized with dilute sodium hydroxide solution; the yellow precipitate which first formed was redissolved in excess alkaline solution and reprecipitated with dilute acetic acid. The purified material melted at 179–182° with evolution of a gas and re-fused at 206–208° (cor.).[12]

Preparation of Picrates.—Certain of the cinchoninic acids were decarboxylated by being heated at a temperature approximately 40° above their melting points. After decarboxylation seemed complete, the resin was subjected to distillation under diminished pressure; about 90% of the theoretical yield of quinoline could be obtained. The quinoline was dissolved in alcohol and treated with a saturated solution of picric acid, which usually resulted in the immediate separation of the solid picrate. Re-

TABLE II

PICRATES OF CERTAIN 2-SUBSTITUTED-3-*n*-PROPOXYQUINOLINES

[a] Represents the picrate of 2-phenyl-3-isopropoxyquinoline.

(10) Bargellini and Berlingozzi, *Gazz. chim. ital.*, **53**, 3 (1923), reported m. p. 235–238° (dec.).

(11) Cross with Henze, ref. 5, reported m. p. 206–208° (cor.)(dec.).

(12) Cross with Henze, ref. 5, page 2732, reported m. p. of 2-ethyl-3-hydroxycinchoninic acid as 208–209° (dec.); the m. p. was noted after introducing the sample into the bath heated to about 200°. When warmed from room temperature at the usual rate, this material softens with evolution of gas at 179–181° (cor.) and melts at 206–208° (cor.).

crystallization was effected from alcohol. The melting points of the picrates were sharp with decomposition occurring only after fusion was complete. Data for the picrates are collected in Table II.

Summary

Twelve new 2,3-disubstituted cinchoninic acids have been prepared from alkyl (or phenyl) propoxymethyl ketones. Certain of these derivatives have been decarboxylated and their ether grouping cleaved to produce 2-alkyl (or 2-phenyl)-3-hydroxyquinolines, thus establishing the structures as 2-alkyl (or 2-phenyl)-3-propoxycinchoninic acids.

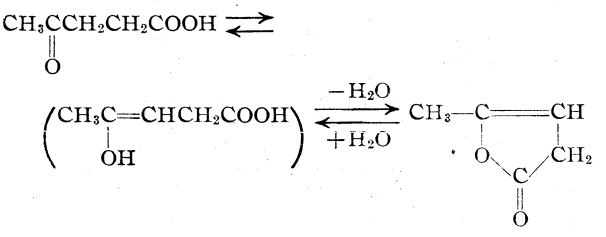
Pseudo Esters of Levulinic Acid

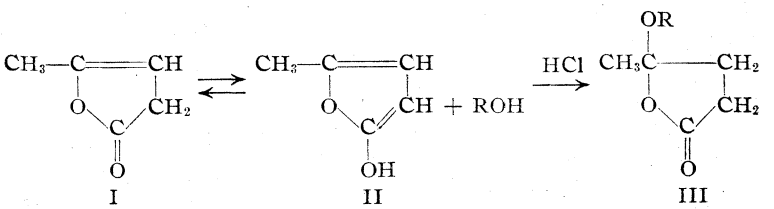
BY DAVID P. LANGLOIS AND HANS WOLFF

The dehydration of levulinic acid to α-angelica lactone is a reversible reaction. In the presence of traces of mineral acids water can be added to α-angelica lactone re-forming levulinic acid.[1] The enolic form of levulinic acid may be an intermediate in the reaction



If instead of water an alcohol is added to α-angelica lactone, the corresponding ester of levulinic acid would be expected as the reaction product. With the intention of preparing levulinic esters by this method, methanol and ethanol were added to α-angelica lactone in the presence of hydrogen chloride. The corresponding methyl and ethyl esters were obtained in quantitative yields.

Attempts to prepare cyclohexyl levulinate by this same method led to an unexpected result; an ester was obtained in 95% yield, but its physical and chemical properties differed from cyclohexyl levulinate prepared from levulinic acid and cyclohexanol by conventional methods. A further examination of the product revealed that it consisted predominately of the pseudo cyclohexyl ester of levulinic acid (III), which could result either from the addition of cyclohexanol to the double bond of α-angelica lactone (I) or from a 1–4 addition of the alcohol to the enol form of angelica lactone (II) followed by rearrangement to structure (III).



R = cyclohexyl

(1) Wolff, *Ann.*, **229**, 249 (1885).

The presence of an enol form of α-angelica lactone is indicated by a Zerewitinoff determination in which approximately one third of a mole of methane is liberated from one mole of α-angelica lactone. Additional evidence for an enol form is given by a comparison of the ultraviolet absorption spectra of furfuryl alcohol and α-angelica lactone (Fig. 1). Furfuryl alcohol was chosen for comparison because it possesses the same molecular weight as angelica lactone and has a structure quite similar to the enol form of α-angelica lactone. The maximum of absorption at 2170 Å., indicative of two double bonds in conjugation, is common to both compounds; the considerably lower absorption of the lactone would indicate that only a partial enolization occurs.

Pseudo esters of aromatic keto acids have been described. Meyer[2] prepared pseudo methyl 2-benzoylbenzoate; Lutz[3] reported the pseudo esters of substituted benzoylacrylic acid and Newman[4] discussed the synthesis of pseudo esters of the benzoylbenzoic acid type. It appears that the pseudo esters of levulinic acid described in this paper are the first examples of pseudo esters in the purely aliphatic series.

In studying the various alcohols it was observed that secondary alcohols form pseudo esters quite readily. This is also true in the case of reactive primary alcohols such as allyl and benzyl alcohols. On the other hand, normal primary alcohols, especially the lower members, give only the normal esters of levulinic acid unless special precautions are taken. The pseudo ester of methanol can be obtained, however, if ether is used as a solvent and the quantity of hydrogen chloride is regulated carefully.

The rate of reaction for each alcohol is controlled by the amount of catalyst used. The reaction is exceedingly violent if a large excess of hydrogen chloride is added at the start, and

(3) Lutz and Winne, THIS JOURNAL, **56**, 445 (1934); Lutz, *ibid.*, **56**, 1378 (1934); Lutz, *et al.*, *J. Org. Chem.*, **4**, 95 (1939); **6**, 77 and 91 (1941).

(4) Newman and McClearly, THIS JOURNAL, **63**, 1537 (1941); Newman and Lord, *ibid.*, **66**, 731 (1944).

the resulting product is largely, if not entirely, the normal ester. A pure pseudo ester can be rearranged quantitatively to the normal ester by the catalytic action of hydrogen chloride. Thus, hydrogen chloride appears to catalyze both the addition of an alcohol to the lactone and the rearrangement of the adduct to a normal ester. By carefully adjusting the amount of hydrogen chloride, it is possible to control the addition reaction without effecting an appreciable rearrangement of the pseudo ester to the normal ester.

Pseudo esters of levulinic acid can also be prepared from the alcohols and levulinyl chloride. This method of pseudo ester preparation is similar to the one employed by Meyer.[2] Levulinyl chloride has been shown to exist in the form of γ-chlorovalerolactone,[5] which may be regarded as a pseudo acid chloride.

The boiling points of the pseudo and normal esters (Table I) of any given alcohol are identical or differ only slightly. Therefore, it is not possible to separate a mixture of pseudo and normal ester by fractional distillation. However, a means for isolating some of the pseudo esters in pure form has been developed; it is based on the observation that pseudo esters do not react with carbonyl reagents whereas the normal esters give crystalline semicarbazones or 2,4-dinitrophenylhydrazones, which can be separated from the liquid pseudo esters. This procedure was successful for the preparation of pure pseudo methyl and allyl levulinate. The other pseudo esters listed in Table I contained small amounts of the normal ester which could not be separated by a carbonyl reagent on account of the slight solubility of these reagents in the reaction mixture.

TABLE I

PHYSICAL CONSTANTS OF NORMAL (N) AND PSEUDO (P) ESTERS OF LEVULINIC ACID

	B. p. °C.	Mm.	$n^{20}D$	d^{20}_4	Molecular refraction Observed	Calcd.
Methyl (N)	89–91	15	1.4225	1.0495	31.52	31.57
Methyl (P)	90–92	15	1.4390	1.1071	30.90	30.93
Isopropyl (N)	103–105	15	1.4220	0.9842	40.80	40.81
Isopropyl (P)[a]	103–105	15	1.4300	1.0151	40.22	40.16

Allyl (P)	106–108	10	1.4525	1.0677	39.46	39.70
Methyl isobutyl (P)[a]	107–108	2	1.4384	0.9828	53.56	54.02
Cyclohexyl (N)	108–110	1	1.4595	1.0308	52.43	52.46
Cyclohexyl (P)[a]	112–113	1	1.4668	1.0632	51.66	51.82

[a] Above 90% pseudo.

It will be noted in Table I that the densities and refractive indices of the pseudo esters are higher than those of the corresponding normal esters. The molecular refractions are accordingly lower. The close agreement of the observed values with the ones calculated from the Eisenlohr constants[6] furnishes a good evidence for the proposed structures of the pseudo esters. In the case of the pseudo esters an exaltation of −0.16 was introduced for the lactone ring.

(5) Helberger, *Ann.*, **522**, 269 (1936).

(6) Gilman, "Organic Chemistry," Vol. II, 1938, p. 1737.

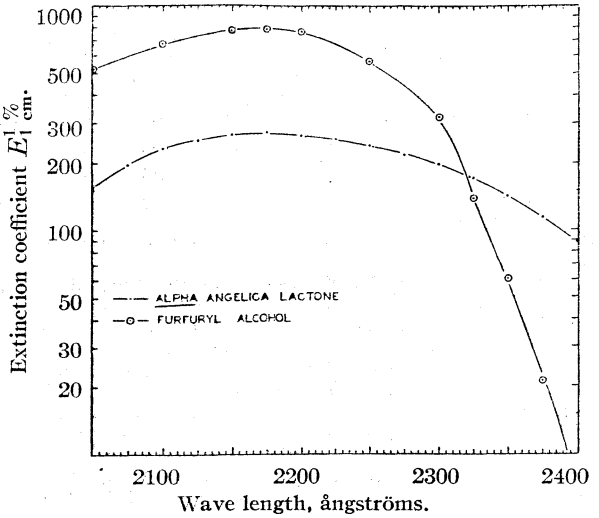

Fig. 1.—Absorption spectra of α-angelica lactone in neohexane and of furfuryl alcohol in water. Beckman Model D. V. used.

Chemically, the pseudo esters are distinguished from the normal esters of levulinic acid by their sensitivity to hydrolysis. The pseudo esters are saponified by treatment with cold 0.1 *N* sodium hydroxide. Advantage is taken of this reaction to determine the percentage of pseudo and normal esters in a reaction mixture. Total esters were determined by saponification at boiling temperature and pseudo esters by titration at room temperature. From the difference the percentage of normal esters can be determined.

Experimental

Preparation of Normal Esters of Levulinic Acid.—The method described in "Organic Syntheses" (Coll. Vol. I, p. 256) was used for the preparation of the esters. The esters were fractionated at reduced pressure, and the fractions boiling within a 2° range were collected. The foreruns and residues were small, and the esters were obtained in high yields.

Zerewitinoff Determination on α-Angelica Lactone: a sample of 0.2149 g. (0.00219 mole) of α-angelica lactone which had been standing at room temperature for several months gave 0.000777 mole of methane, corresponding to 28% of enol. A freshly distilled sample of 0.2079 g. (0.002122 mole) lactone yielded 0.000465 mole of methane; corresponding to 46% of enol.

Preparation of Pseudo Esters of Levulinic Acid.—Pseudo Methyl Levulinate: (a) From α-angelica lactone and methanol.—To a solution of 25 ml. of α-angelica lactone in 50 ml. of diethyl ether was added 25 ml. of methanol containing 0.1 g. of hydrogen chloride. The temperature of the mixture rose until the ether started to reflux. The mixture was kept at reflux in a water-bath for three hours. The ether and excess methanol were then removed under vacuum, and the residue was distilled, yielding 29 g. of a distillate, b. p. 88–92° (15 mm.).

Determination of Pseudo Ester in the Distillate.—A 0.187-g. sample was swirled in 50 ml. of water at 50° for a few minutes, then cooled and titrated with 0.1000 *N* sodium hydroxide; the cold titer found was 6.5 ml. of the 0.1 *N* sodium hydroxide. A saponification equivalent taken on the same sample required 14.4 ml. of alkali, thus

Alcohol used	Mg. HCl	Yield of ester	Pseudo, % ester in mixture	Sapn. equiv. Calcd.	Sapn. equiv. Found	Calcd. for	Analyses, % Carbon Calcd.	Carbon Found	Hydrogen Calcd.	Hydrogen Found
Isopropyl	6	90	92	158	156	$C_8H_{14}O_3$	60.7	60.7	8.9	8.8
Methylisobutylcarbinol	300	93	96	200	200	$C_{11}H_{20}O_3$	66.0	65.5	1.0	9.7
Cyclohexyl	38	95	90	198	197	$C_{11}H_{18}O_3$	66.7	66.7	9.1	9.3
Benzyl	25	92	93	206	206	$C_{12}H_{14}O_3$	70.0	69.8	6.8	6.7

indicating the presence of 45% of pseudo ester in the mixture.

Separation of the Pseudo Ester from the Normal Ester.—To 28 g. of the ester was added 80 ml. of methanol, 14.4 g. of semicarbazide hydrochloride, and 12.8 g. of potassium acetate. After shaking the mixture for twenty-four hours, 50 ml. of ether was added, and the mixture was filtered. The residue was washed with ether, and the ether added to the filtrate. The ether and methanol were evaporated at reduced pressure, and the pseudo methyl levulinate distilled b. p. 90–92° (15 mm.). Cold titer gave a neutral equivalent of 129 (calcd. 130). *Anal.* Calcd. for $C_6H_{10}O_3$: C, 55.4; H, 7.7. Found: C, 55.0; H, 8.0.

(b) **From Levulinyl Chloride and Methanol.**—To 50 g. of levulinic acid 60 g. of thionyl chloride was added dropwise with stirring; the reaction temperature was not allowed to exceed 50°. The mixture was then maintained at 50° under reduced pressure in order to remove hydrogen chloride, sulfur dioxide and excess thionyl chloride. The levulinyl chloride was then added under vigorous stirring to a mixture of 125 ml. of methanol and 50 g. of sodium carbonate. The addition rate was carefully controlled in order to keep the *p*H of the reaction mixture above 6 and avoid warming of the mixture above 30°. The mixture was stirred for thirty minutes after all levulinyl chloride had been added. Approximately 200 ml. of ether was then added, and the mixture was filtered. After evaporating the ether and excess methanol *in vacuo*, the ester b. p. 90–92° (15 mm.) was obtained in 62% yield; it titrated for 92% of the pseudo ester.

Pseudo Allyl Levulinate: To 25 ml. of α-angelica lactone 25 ml. of allyl alcohol containing 0.4 g. of hydrogen chloride was added. The temperature of the reaction mixture rose gradually to 60°. After allowing to stand for three hours the mixture was distilled yielding 36.5 g. of ester. Cold titer and saponification equivalent indicated the presence of 10% of normal ester in the distillate. Addition of 70 ml. of allyl alcohol, 5 g. of 2,4-dinitrophenylhydrazine and one drop of glacial acetic acid, shaking the mixture for twelve hours followed by filtration removed the normal ester. On distillation 25 g. of pseudo allyl levulinate was obtained b. p. 93° (3 mm.); sapn. equiv. calcd. 156, found 153 (cold titer 98% of sapn. equiv.). *Anal.* Calcd. for $C_8H_{12}O_3$: C, 61.5; H, 7.7. Found: C, 61.4; H, 7.5.

Pseudo Isopropyl, 4-Methyl-2-pentyl, Benzyl, and Cyclohexyl Levulinate: These esters were prepared from 25 ml. of α-angelica lactone and 35 ml. of the corresponding alcohol. The amount of hydrogen chloride used, yields obtained, and analytical data found are given in the table.

Rearrangement of Pseudo Esters to Normal Esters.—The pseudo ester was diluted with the corresponding alcohol containing a small amount of a mineral acid. As little as 0.3% hydrogen chloride was sufficient. The mixture was heated to boiling until the cold titer became constant and equal to the mineral acid present. The pure normal ester was obtained in a quantitative yield.

Summary

1. Alcohols add to α-angelica lactone to form pseudo esters of levulinic acid.

2. The pseudo esters of levulinic acid are quantitatively converted to the normal esters by heating in the presence of a mineral acid.

3. Pseudo esters do not form carbonyl derivatives and may thus be separated from the normal esters.

4. Pseudo esters of levulinic acid are readily hydrolyzed by cold water.

5. Several pseudo esters of levulinic acid have been prepared, and their properties are tabulated.

The Dipole Moments of Thiouracil and Some Derivatives

BY W. C. SCHNEIDER AND I. F. HALVERSTADT[1]

In certain molecules where oxygen or sulfur atoms are attached to carbon atoms adjacent to heterocyclic ring nitrogens, the amide-iminoalcohol, $-\overset{\overset{O}{\|}}{C}-NH- \rightleftarrows -\overset{\overset{OH}{|}}{C}=N-$, type of tautomerism may exist. The relative contributions of these tautomeric forms will be affected by changes in substituents, solvents, temperature, state, etc.

The thiouracil molecule contains two such groups, both of which are usually shown in the amide form. Classical structural formulas can be assigned to those derivatives in which the labile hydrogens of the amide groups have been replaced by alkyl, aralkyl, etc., substituents, but occasionally these formulas may not adequately represent the properties of the compound. In some of these cases the assumption of tautomeric forms having a separation of charge has proved helpful.

The structure of 2-thiouracil was of interest to us because of its marked antithyroid activity. Certain dipole moment and infrared absorption data on thiouracil and a large number of derivatives are reported in this paper. On this basis a tentative classification of the compounds according to classical structure is made.

Experimental

A heterodyne beat apparatus similar to that described by Hudson and Hobbs[1a] was used to make the electrical measurements. A cathode ray oscilloscope was used for a detector. The standard capacitor was a General Radio type 722-D variable condenser. By using the low capacity section of this condenser, it was possible to obtain a precision of about ± 0.002 $\mu\mu$f in the capacity measurements.

The dielectric constant cell was of the design used by Sayce and Briscoe as described in Le Fèvre.[2] The particular cell used had a replaceable capacity of approximately 30 $\mu\mu$f and a fixed capacity of about 4 $\mu\mu$f.

Densities were determined with a U-shaped pycnometer having calibrated capillaries in each arm. The 10-ml. pycnometer used allowed a precision of ± 0.00002 in the density.

All measurements were at 35°. This temperature was chosen to eliminate the need for cooling the bath during the summer months and to take advantage of any increased solubility at this temperature. An oil-bath was used to thermostat the dielectric constant cell and the pycnometer was thermostated in a water-bath. Both baths were regulated to ± 0.005°.

1,4-Dioxane, used as solvent, was purified by partial freezing, discarding the unfrozen liquid. After remelting, the partially purified material was dried by refluxing over sodium, and any remaining impurities were removed by

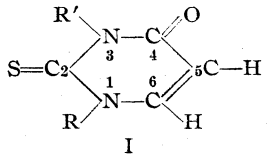
fractionation using an efficient distilling column. The best material obtained had the following physical properties: b. p. (uncor.) 100.5–100.7°, n^{35}_4 1.4150, d^{35} 1.01690 and ϵ_{35} 2.1776.

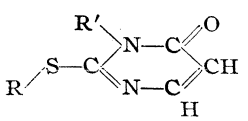
The compounds investigated and their melting points are listed in Table I. The experimental results are listed in Table II where w is weight fraction, ϵ is dielectric constant and d is density. Dipole moments were calculated by a modified Hedestrand method similar to that introduced by Halverstadt and Kumler,[3] differing in that densities were used rather than specific volumes. Atomic polarization was neglected, and the molecular refractions were calculated from the atomic refractions given in the Landolt–Börnstein "Tabellen." The values obtained from these calculations are listed in Table III where α and β refer, respectively, to the slopes of the dielectric constant and density curves as a function of concentration. $_\infty p_T$ is the specific polarization at infinite dilution and $_\infty P_T$ is the total molar polarization at infinite dilution. P_D and P_O represent the distortion and orientation polarizations, respectively, and μ is the dipole moment.

Discussion

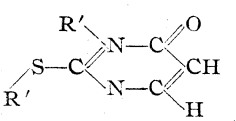
Five possible classical structures may be postulated from a consideration of the various tautomeric positions of the two acidic hydrogen atoms in 2-thiouracil. These structures may be represented as



I



II



III

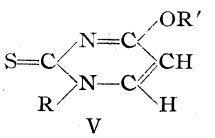
IV



V

where R and R′ may be hydrogen, methyl, ethyl or benzyl. Examples of all but Type V were found among the derivatives investigated.

Due to the complexity of the molecules, it was not feasible to assign structures by comparing the observed moments with theoretical, calculated moments. Instead the following procedure was used. Those thiouracils in which the two labile hydrogens were replaced by alkyl groups offered convenient starting points, inasmuch as at least their classical formulas were known. Structures were then assigned to the other compounds by a comparison of dipole moments, assuming that similar moments indicate similar structures. To illustrate the method, the dipole moment of 2-thiouracil is identical with that of 1,3-diethyl-2-thiouracil; accordingly, 2-thiouracil has a Type I structure. Following this procedure, the other derivatives were classified according to type and are listed in Table IV together with their moments. The classification of 3-ethyl-2-thiouracil is least certain since from dipole evidence alone it could have either a Type I or a Type II structure.

However, ultraviolet absorption measurements[4] indicate that the above assignment to a Type I structure is correct.

From a consideration of Austin's[5] work on the ultraviolet absorption spectra of uracils one would postulate a Type II structure for 2-thioura-

cil. Unfortunately, it was not possible to determine the dipole moment of uracil because the compound proved to be too insoluble in dioxane. However, there is no *a priori* reason why uracil and 2-thiouracil should have identical structures.

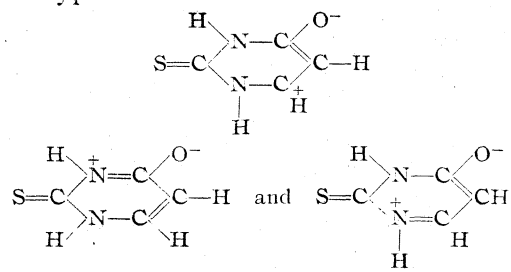
The above structure assignments are not consonant with some recent ultraviolet studies of Elion, Ide and Hitchings.[6] These workers concluded that uracil, thymine, 2-thiouracil, 4-thiouracil and 2,4-dithiouracil have a Type IV structure.

This conclusion was qualified by the statement that more work on substituted thiouracils was necessary to clarify the situation completely. However, it must be noted that although the present work was carried out in dioxane solution whereas the above workers employed aqueous solutions, the discrepancy between structure assignments cannot be simply attributed to a solvent effect, because ultraviolet studies in these laboratories,[4] using both dioxane solutions and aqueous solutions at various *p*H's, have indicated that in aqueous solution at the proper *p*H to assure the molecular form of the compound, the structures in dioxane and water are identical.

While most of the thiouracil derivatives are too complex for a detailed analysis of their electric moments, it is possible to attain fair agreement between observed and calculated moments for several of the Type I derivatives if certain assumptions are made concerning the carbon–oxygen and carbon–nitrogen link moments.

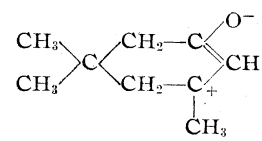
(6) G. Elion, W. Ide and G. Hitchings, THIS JOURNAL, **68**, 2137–2140 (1946).

The Carbon–Oxygen Moment.—The high moment of 2-thiouracil, 4.2*D*, would seem to indicate that the bond moment of the carbon-oxygen linkage is increased over its normal value of 2.5*D*. In all probability resonance structures of the types



with negatively charged oxygen are the direct cause of the observed high moment. Alkyl groups in the five and six positions seem to enhance the contributions from the ionic structures as can be seen from Table V. This behavior is reasonable when one considers that carbon is more negative than hydrogen and thus facilitates the transfer of negative charge to the oxygen. Although it is not possible to calculate the contributions of the various resonance structures to the total moment, one can estimate a value for the carbon–oxygen moment and then check the accuracy of this estimate by comparing the observed moments of a series of derivatives with calculated moments obtained using the assumed moment. In the present case a moment of 4.0*D* was assumed for the carbon–oxygen linkage.

This value is not unreasonable in view of the fact that Kumler and Fohlen[7] have observed a moment of 3.96*D* for isophorone where resonance structures of the type



which are similar to those proposed for 2-thiouracil, are assumed to account for the observed high moment. This high moment would indicate a carbon–oxygen moment of 3.6*D* in isophorone.

TABLE V

Compound	$\mu \times 10^{18}$	$\Delta\mu \times 10^{18}$
2-Thiouracil	4.21	....
6-Ethyl-2-thiouracil	4.64	+0.43
5-Ethyl-2-thiouracil	5.03	+0.82

The Carbon–Nitrogen Moment.—Although the classical structures for heterocyclic ring systems involving nitrogen are written with both single and double bonds between the nitrogen atom and adjacent carbon atoms, the situation is perhaps better represented by assuming some type of hybrid bond between the ring nitrogen and

(7) W. D. Kumler and G. M. Fohlen, *ibid.*, **67**, 437–441 (1945).

all attached atoms. The ring nitrogen will have a definite electronegativity, and the link moment between this nitrogen and attached atoms will depend upon the electronegativity difference. Measurements on simple heterocyclic compounds[8] indicate a moment of 1.9*D* for the carbon–nitrogen linkage. Further evidence supporting this value can be obtained by considering 2-thiouracil and its 1,3-diethyl derivative. These compounds have identical moments; accordingly, the carbon–nitrogen moment would seem to approximate the hydrogen–nitrogen moment which is about 1.3*D*.

If, as indicated above, a value of 4.0*D* is assigned to the carbon–oxygen linkage, a value of 1.9*D* to the carbon–nitrogen linkage and a plane hexagonal ring assumed, one obtains the calculated values listed in Table VI, together with observed values. The various bond moments used in these calculations are listed in Table VII. The agreement obtained is excellent and in view of the number of derivatives considered would seem to be more than simply fortuitous. Although the nature of the assumptions used in the above calculation precludes using the results in Table VI to confirm the structural assignments made earlier (Table IV), the agreement obtained is certainly good enough to indicate that the assumptions themselves are reasonably correct.

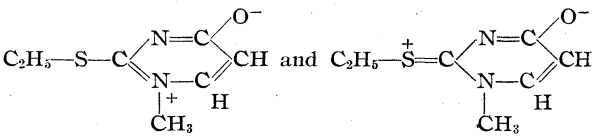
μ_{H-N}	1.3*D*	μ_{C-F}	1.4
μ_{H-C}	0.4*D*		

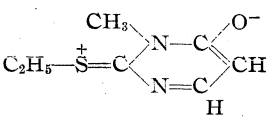
When the positions of the oxygen and sulfur atoms in 2-thiouracil are interchanged to give 4-thiouracil, the moment changes from 4.21*D* to 4.47*D*. This increase is probably a consequence of the larger size of the sulfur atom, since an additional increase in the electric moment results when the other oxygen is replaced by sulfur to give 2,4-dithiouracil with a moment of 4.67*D*, the average increase per sulfur atom being about 0.25*D*. However, these differences are relatively small and may result from solvent effects, atomic polarization, which was neglected in the moment calculations, or errors in the molecular refractions which were calculated from atomic refractions and not measured directly.

Measurements on several Type III compounds yielded rather unexpected results; an exceedingly large moment of 6.4–6.9*D* was obtained. Varying the substituent groups by measuring 1-methyl-2-benzylthiopyrimidone-4, 1-ethyl-2-benzylthiopyrimidone-4 and 1-methyl-2-ethylthiopyrimidone-4 resulted in no significant change in the order of the moment. Accordingly, this increased moment is attributed to the presence of forms having a separation of charge, which in the case of 2-ethylthio-1-methylpyrimidone-4 may be represented by



A structure analogous to the first form probably exists in 4-oxopyridine according to Leis and Curran,[9] who report a moment of 6.0 in dioxane solution.

The latter form provides a convenient correlation with the enhanced lability of the 2-alkyl group, which can be much more readily split from the sulfur atom by dry hydrogen chloride than it can in those isomers in which the N-alkyl group is in the 3-position. For the 3-isomer the analogous form having the positive charged sulfur



would involve a shift of the relatively fixed[10] 5,6 double bond and therefore might be expected to be less likely.

As a matter of general interest the vibration frequency of the carbonyl group in the compounds investigated was determined from infrared absorption spectra.[11] Since a carbonyl frequency was obtained for every compound where it might

(10) In the catalytic hydrogenation of uracil, the first product is 5,6-dihydrouracil, indicating that the double bond acts like an isolated double bond rather than a benzenoid bond.

(11) Measurements carried out by R. C. Gore, Stamford Research Labs., American Cyanamid Company, Stamford, Conn.

be expected, it is reasonably certain that no compound has a Type V structure. The experimental values of the vibration frequencies are listed in Table VIII. A relatively large number of these are considerably lower than the normal vibration frequency, 1710–1720 cm.$^{-1}$, of an isolated carbonyl group. Since the lowering of the carbonyl frequency can result from conjugation or electrical charging effects, the observed lowering can be considered as a measure of the relative contribution of ionic resonance structures. In the compounds studied these ionic forms tend to increase the dipole moment; accordingly, there should be an increase in dipole moment with decreasing carbonyl frequency.

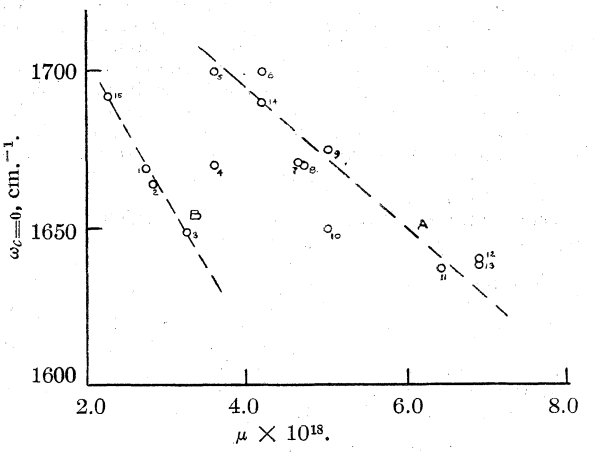

Fig. 1.—Relation between carbonyl vibration frequency and dipole moment for several thiouracil derivatives.

In Fig. 1 the vibration frequencies listed in Table VIII are plotted as a function of the dipole moment. As predicted, there is an increase in dipole moment with decreasing carbonyl frequency, and with the Type III compounds the lowest observed carbonyl frequency 1640 cm.$^{-1}$ is associated with the highest dipole moment, 6.9*D*. In the above plot the points are rather widely scattered and appear to be divided into two distinct groups, A and B. This results from neglecting the effects of different types of structures and substituent groups upon the dipole moment. These effects can be greatly reduced by considering a series of compounds having identical structures and similar substituent groups. 2-Thiouracil (6) and its 1,3-diethyl (14), 1-ethyl (8), 5-ethyl (10) and 6-ethyl (7) derivatives form such a series, which is plotted in Fig. 2. This plot clearly shows the nature of the relation between carbonyl frequency and dipole moment.

Acknowledgment.—The authors wish to express their indebtedness to Dr. P. H. Bell of the Chemotherapy Division, Stamford Research Laboratories, American Cyanamid Company, Stamford, Connecticut, for much helpful discussion and criticism and to the American Cyanamid Company for permission to publish these results.

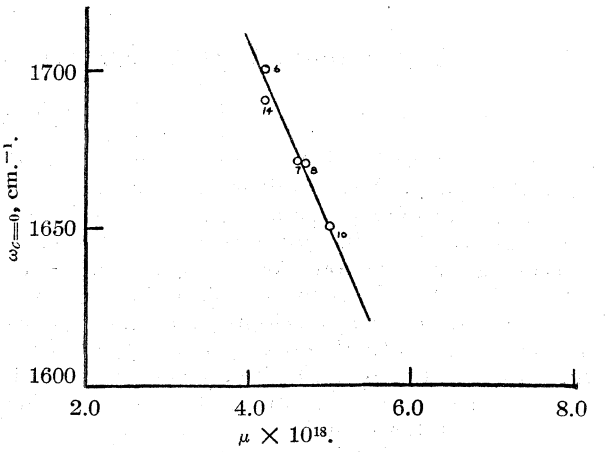

Fig. 2.—Relation between carbonyl vibration frequency and dipole moment for a series of thiouracil derivatives having similar structures.

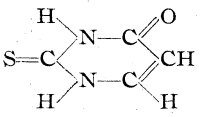
Summary

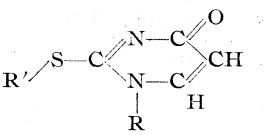
It must be emphasized that the following conclusions apply only to the form of the compound existing in dioxane solution. In aqueous solution the particular form present is a function of the *p*H, therefore, it is not permissible to make conclusive statements about the behavior of the compounds in water.

(1) The dipole moments in dioxane solution at 35° have been determined for 4-thiouracil, 2,4-dithiouracil, 2-methylthio-4-thiouracil and 2-thiouracil and seventeen derivatives.

(2) Thiouracil in dioxane solution is best represented by the formula



(3) Compounds of the type



have the abnormally high dipole moments of 6.4–6.9 *D*.

(4) The carbonyl group in 2-thiouracil seems to be activated in the same manner as in isophorone due to conjugation with a double bond.

(5) Alkyl groups substituted in the five or six position slightly increase this activation.

The Phenyl–Carbon–Phenyl Angle in 1,1-Diphenylcyclopropane[1]

BY M. GOLDSMITH AND G. W. WHELAND

Several recent theoretical[2-4] and experimental[5-7] papers have dealt with the exterior valence angle in cyclopropane. In the experiments which are reported in this present paper the value of the angle in question is determined from the dipole moments of 1,1-bis-(*p*-chlorophenyl)-cyclopropane, 1,1-diphenylcyclopropane and chlorobenzene; the method here employed is, of course, the same as the one which has been previously used for the measurement of the corresponding angles in diphenylmethane[8,9] and 1,1-diphenylethylene.[10] Evidence regarding the direction of the cyclopropyl–phenyl bond moment, discussed by Rogers,[11] has also been obtained.

Experimental

Materials

Benzene.—Eastman Kodak Co. White Label thiophene-free benzene was stored over, and distilled from, sodium hydride. The center cut (b. p. 80.0–80.1° at 760 mm., $n^{20}D$ 1.501) was redistilled from sodium hydride immediately before use.

***p*-Xylene.**—Eastman White Label *p*-xylene was purified in a manner identical with that described for benzene; b. p. 137.9–138.0° (751 mm.), $n^{20}D$ 1.496.

Tetrachloroethylene.—Eastman White Label tetrachloroethylene was dried over anhydrous calcium sulfate and fractionated; b. p. 120.8–121.0° (756 mm.), $n^{23.7}D$ 1.503.

Benzophenone.—Eastman White Label benzophenone was recrystallized from ethanol and from petroleum ether; m. p. 48.0–48.5°.

1,1-Diphenylcyclopropane.—This compound was prepared from 1,1-diphenylethylene and diazomethane by the method of Wieland and Probst.[12] The crude cyclopropane was freed of unreacted olefin by titration with bromine in carbon tetrachloride at 0° and by subsequent fractionation; b. p. 117.0–117.5° (2 mm.), $n^{20}D$ 1.590.

Anal. Calcd. for $C_{15}H_{14}$: C, 92.73; H, 7.27; mol. wt., 194. Found: C, 92.9; H, 7.3; mol. wt. (f. p. benzene), 193.

1,1-bis-(*p*-Chlorophenyl)-cyclopropane.—This compound was prepared by the reaction of 1,1-bis-(*p*-chlorophenyl)-ethylene with diazomethane. The conditions for this reaction are identical with those for the preparation of 1,1-diphenylcyclopropane. The compound separates from methanol in white needles, m. p. 105.5–106°, and reacts at room temperature neither with bromine in carbon tetrachloride nor with neutral 0.2 *N* potassium permanganate.

Anal. Calcd. for $C_{15}H_{12}Cl_2$: C, 68.45; H, 4.60; Cl, 26.95; mol. wt., 263. Found: C, 68.5; H, 4.5; Cl, 27.0; mol. wt. (f. p. benzene), 260.

1,1-bis-(*p*-Chlorophenyl)-cyclopropane has not been reported previously in the literature. A sample of this compound previously prepared by Mr. Joseph R. Schwartz of this Laboratory proved to be identical with our preparation.

Apparatus

Dielectric Constants.—The circuit diagram of our heterodyne beat apparatus is given in Fig. 1. "Locking in" of the oscillators is rendered negligible at 100 K. C. by the use of very light coupling. Any error due to frequency drift may be eliminated by measurement of the zero beat capacitance of the variable frequency oscillator both with and without the test condenser in the circuit. The test cell, which had a volume of 10 cc. and a capacitance of 80 $\mu\mu$f., was constructed according to Fairbrother's design[13] and was calibrated, at each temperature at which dielectric constants were measured, in the manner described[13] by him.

Temperatures.—The temperatures at which measurements were made were maintained, with a maximum variation of 0.03°, in an oil thermostat.

Densities.—The densities of the solutions were measured with a modified Ostwald Sprengel pycnometer which was calibrated at the temperatures below 80° with distilled water. The volume of the pycnometer at 98.6°, and at 122.0°, was obtained by extrapolation.

Refractive Indices.—Measurements were made with a refractometer of the Abbé type.

Experimental Results

Optical Determinations.—Values of the mole fractions f_2 of the solutes, the dielectric constants ϵ of the solutions, the densities d of the solutions, and the total molar polarizations P_1 and P_2, of the solvents and solutes, respectively, are given in Table I for some typical measurements. Table II contains the values of P_2^∞, the total molar polarizations of the solutes at infinite dilution, obtained by graphical extrapolation; the values of the molecular refractions for the sodium D lines MR_D of the solutes; and the values of the dipole moments μ calculated from the formula

$$\mu = 0.0128 \sqrt{[P_2^\infty - 1.05(MR_D)]T}\ D$$

Temperature Variation Determinations.—Table III contains values of P_2^∞ measured at a series of absolute temperatures T in tetrachloroethylene and in *p*-xylene. Equations of the form

$$P_2^\infty = A + B/T$$

were obtained by the method of least squares. The respective values of A and B are given in Table IV.

Discussion of Results

The dipole moment of benzophenone was measured as a test of our experimental technique. Our optical value 2.97 D agrees well with the value

2.98 *D* which is the average of twelve optical-solution values reported[14] in the literature.

The temperature variation values of the dipole moment of 1,1-bis-(*p*-chlorophenyl)-cyclopropane are in poor agreement with the values (Table II) obtained by the optical method. Presumably, these discrepancies are due, at least in part, to a variation of the solvent effect with temperature.[15]

2.690	146	2.839	145	2.690	204
2.531	145	2.690	145	2.531	197

TABLE IV

TEMPERATURE VARIATION DETERMINATIONS OF DIPOLE MOMENTS

Compound	Solvent	A	$B \times 10^{-4}$	μ	Temp. range, °C.
$C_{15}H_{12}Cl_2$	C_2Cl_4	83.6	2.18	1.89	23.7–98.6
$C_{15}H_{12}Cl_2$	*p*-Xylene	102	1.68	1.66	30.6–122.0
Benzophenone	*p*-Xylene	52.6	5.58	3.02	30.6–122.0

The possibility that the discrepancies are primarily due instead to unexpectedly large atom polarizations seems unlikely for two reasons. First, with compounds, such as *p*-benzoquinone, which do have large atom polarizations, the sum *A* of the electronic and atom polarizations is essentially independent of solvent[16]; with 1,1-bis-(*p*-chlorophenyl)-cyclopropane, on the other hand, *A* is 18.4 cc. per mole greater in *p*-xylene than it is in tetrachloroethylene (Table IV). Second, the atom polarizations of several closely analogous compounds, such as *p*-bromophenyl ether, are evidently small since, with these substances, the sums of the atom plus orientation polarizations have been found to be of the order of only 10 cc. per mole.[17] For these reasons, the optical values will be accepted in preference to the temperature variation ones, and the dipole moment of 1,1-bis-(*p*-chlorophenyl)-cyclopropane will be taken as 2.02 ± 0.03 *D*.

The phenyl–carbon–phenyl angle, θ, may be calculated in the manner previously described[9] by Sutton and his co-workers. If it is assumed that the optical-solution value of the dipole moment of chlorobenzene[14] is 1.57 *D*, and that the cyclopropylidene–phenyl and phenyl–chlorine bond moments are in the same direction, the angle θ is found to be equal to 116 ± 10°. If it is instead assumed that these bond moments are in opposite directions, the angle is found to be 81 ± 10°. A value of θ which is almost 30° less than the normal tetrahedral angle is improbable. It is therefore considered that θ is equal to 116 ± 10°; this conclusion supports the value, 112 ± 4°, assigned by electron diffraction to the Cl–C–Cl angle[8] in 1,1-dichlorocyclopropane. (The limits of error cited above are based merely on the internal consistency of the optical measurements reported in this paper. The true limits of error, as in all analogous measurements of bond angles, must be somewhat greater when allowance is made for the uncertainty in the value of the atom polarization and in the moment of chlorobenzene, and for the possibility of variations in bond angles, in bond moments, and in the solvent effect.)

Summary

The dipole moments of 1,1-bis-(*p*-chlorophenyl)-cyclopropane and 1,1-diphenylcyclopropane have been measured.

The phenyl–carbon–phenyl angle in 1,1-diphenylcyclopropane has been estimated as 116 ± 10°.

Quadridentate Amines. I. Some Coördination Compounds of Cobalt(III) and Triethylenetetramine[1]

BY FRED BASOLO

It was first shown by Mann[2] and later by Morgan and Burstall[3] that certain tetramines are capable of behaving as quadridentate donors to form complex inorganic compounds of cobalt(III). Mann[2] used β,β',β''-triaminotriethylamine and obtained *cis*-[Co tren(SCN)$_2$]SCN. Because of the structure of this amine, the corresponding *trans*-salt is sterically too unstable to exist. The amine used by Morgan and Burstall[3] was 2,2′,2″,2‴-tetrapyridyl and yielded *trans*-[Co tetrpyCl$_2$]Cl. They point out that the pyridine rings of the coordinated tetrapyridyl must remain in the same plane, and therefore the chloro groups must be in *trans*-positions. In both of these investigations the analyses of the resulting compounds agreed with those calculated for the respective compounds, but in neither case was any attempt made to establish conclusively the configuration of the complex cation.

More recently, Jonassen, Dexter and Douglas[4] have studied the complexes formed between triethylenetetramine and copper(II) and nickel(II) ions in water solution. They found that triethylenetetramine behaves as a quadridentate amine. The present work was undertaken to determine whether coördination compounds of triethylenetetramine and cobalt(III) can be isolated and also to study the configuration and stability of these compounds.

The dichlorotriethylenetetraminecobalt(III) ion can theoretically exist in three stereoisomeric forms

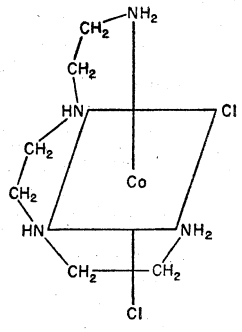
I

II



III

The salt, [Co trien Cl_2]Cl, was prepared by the air oxidation of a reaction mixture containing cobalt(II) chloride and triethylenetetramine. This cation has been assigned a *cis*-configuration, II or III, because the salt obtained is purple, which is a characteristic color for *cis*-dichlorotetrammine compounds of cobalt(III) and chromium(III). Additional indication that the salt has the *cis*-configuration was obtained by comparing the ultraviolet absorption spectrum (Fig. 1) of this salt with those for the corresponding ethylenediamine salts, *cis*- and *trans*-[Co en_2 Cl_2]Cl. The ions II and III are asymmetric and an attempt was made to resolve the purple salt by the method[5] used for the corresponding complex, *cis*-[Co en_2 Cl_2]Cl, but this was not successful. It would be extremely difficult to distinguish between II and III and, since it does not appear important, this was not done.

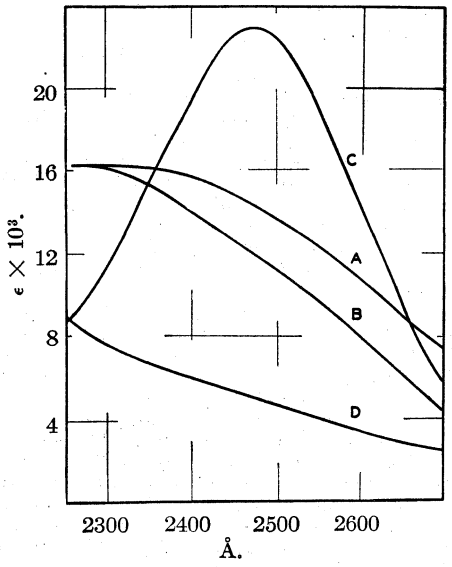


Fig. 1.—Absorption spectra of dichlorotetramminecobalt(III) chlorides: A, [Co trien Cl_2]Cl; B, *cis*-[Co en_2 Cl_2]Cl; C, *trans*-[Co en_2 Cl_2]Cl; D, unidentified mixture.

Although a study of molecular models indicates that I may exist, several attempts to prepare the *trans*-salt were unsuccessful. No rearrangement of the *cis*-salt occurred in concentrated hydrochloric acid, as is generally true of similar salts.[6] The reactions of both *cis* and *trans*-dinitrotetramminecobalt(III) chloride with triethylenetetramine in absolute alcohol gave the *cis*-salt [Co trien $(NO_2)_2$]Cl. This *cis*-configuration of this salt was indicated by its reaction with concentrated hydrochloric acid and by a comparison of its ultraviolet absorption spectrum (Fig. 2) with the spectra of the corresponding ethylenediamine salts, *cis* and *trans*-[Co en_2 $(NO_2)_2$]Cl, and also of the salt, [Co trien $(NO_2)_2$]Cl, obtained from the reaction of II or III with sodium nitrite. A third attempt was made by a slight modification of the method used by Morgan and Burstall[3] and a green product was obtained. This material dissolved in water to give an orange solution and did not have an absorption spectrum (Fig. 1) similar to that of the complex, *trans*-[Co en_2 Cl_2]Cl. The behavior of this unidentified substance suggests it may be a mixture of cobalt(II) chloride (blue)

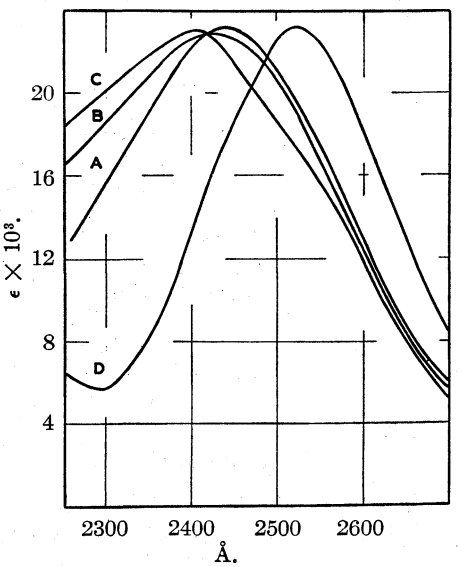

Fig. 2.—Absorption spectra of dinitrotetramminecobalt (III) chlorides: A, [Co trien $(NO_2)_2$]Cl obtained from *cis* or *trans* [Co $(NH_3)_4$ $(NO_2)_2$]Cl; B, [Co trien $(NO_2)_2$]Cl obtained from II or III; C, *cis*-[Co en_2 $(NO_2)_2$]Cl; D, *trans*-[Co en_2 $(NO_2)_2$]Cl.

and tris(triethylenetetramine) dicobalt(III) chloride (orange).

The fact that many inorganic complex compounds have been resolved is a good indication of the firmness with which the donor molecule is held or, in other words, of the stability of the coordination compound. The resolution of certain asymmetric complexes of cobalt(III) containing triethylenetetramine would conclusively show that the tetramine behaves as a strong quadridentate donor. Compounds similar to tris(ethylenediamine)cobalt(III) chloride were prepared and the method used by Werner[7] and also by Jaeger[8] for the resolution of this type of a cation was studied. These hexammine salts are all extremely soluble and could not be resolved by the methods employed. All of these salts, however, are highly crystalline and stable at temperatures as high as 150°.

The ultraviolet absorption spectrum obtained, particularly with the dinitrotetrammine series of compounds, is of interest. Shibata[9] showed that in addition to the two absorption bands always observed in the cobalt ammines, certain of these compounds have an additional absorption band in the shorter ultraviolet region which he designated as the "third band." A much more extensive study has been made by Tsuchida[10] who concludes that any two negative ligands, when in *trans*-positions to each other, cause a third absorption band at approximately 2500 Å., whereas if they occupy *cis*-positions, the third band is absent. Contrary to this, however, the ultraviolet absorption spectra (Fig. 2) obtained for some *cis*-dinitrotetrammine salts show very definite absorption bands at approximately 2425 Å. Although these results are not conclusive, they indicate that some cobalt(III) ammines with two negative ligands in the *cis*-positions also have additional absorption bands but in the shorter ultraviolet region. A more thorough investigation of this phenomenon is now in progress.

Experimental[11]

Reagents.—The cobalt(II) chloride hexahydrate was Merck reagent grade. The triethylenetetramine was obtained from Carbide and Carbon Chemicals Corporation. This amine was refluxed for six hours in presence of metallic sodium and then distilled *in vacuo* over sodium. The fraction collected had a boiling point range of 128–131° at 3 mm.

Spectral Measurements.—Ultraviolet absorption spectra were measured with the Beckman quartz spectrophotometer, using 1 cm. silica cells. Extinction coefficients were calculated from the familiar equation

$$\epsilon = 1/cd \log_{10}(I_0/I)$$

where I_0 is the intensity of the light passing through the solvent, I, the intensity of the light passing through the solution, c, the concentration of solute in moles per liter, and d, the thickness of the cell in centimeters.

Aqueous solutions (1.0×10^{-5} molar) of the complex salts were used and measurements were made at room temperature as rapidly as possible (total operation time less than twenty minutes) to keep the reaction of the complex with water at a minimum.

cis-Dichlorotriethylenetetraminecobalt(III) Chloride, (II) or (III).[12]—The procedure described by Bailar[5] for the preparation of *trans*-dichloro-bis-(ethylenediamine)-cobalt(III) chloride was slightly modified. A solution of 75 g. (0.50 mole) of triethylenetetramine in 525 cc. water was added, with stirring, to a solution of 160 g. (0.67 mole) of cobalt(II) chloride hexahydrate in 500 cc. of water contained in a two-liter flask. A vigorous stream of air, previously washed with a dilute solution of sodium hydroxide, was passed through the solution for approximately eleven hours. After 350 cc. of concentrated hydrochloric acid was added, the solution was concentrated on a steam-bath until finely divided crystals began to separate (650 cc.). Upon standing overnight at room temperature the bluish-purple crystalline product was collected on a filter and washed with a small amount of cold water followed by alcohol and ether. The salt was dried at 110° and 86 g. of material was obtained. Further concentration (400 cc.) of the combined filtrate and washings from this salt gave an additional 40 g. of product. This preparation was carried out six times and found to progress smoothly to give an over-all yield of 80% of crude dichlorotriethylenetetraminecobalt(III) chloride based on triethylenetetramine. The crude salt was recrystallized twice from dilute hydrochloric acid and dried at 110° for two days.

Anal. Calcd. for [Co trien Cl_2]Cl: C, 23.12; H, 5.82; N, 18.03; Co, 18.91; Cl, 34.13. Found: C, 23.42; H, 5.85; N, 18.18; Co, 18.68; Cl, 34.04.

The salt is purple in color, which is characteristic of the *cis*-dichlorotetrammine compounds of cobalt and chromium, indicating a *cis* configuration represented either by II or III. Additional indication for a *cis* structure was obtained from the fact that the ultraviolet spectrum (Fig. 1) of this salt closely resembles that of *cis*-dichloro-bis-(ethylenediamine)-cobalt(III) chloride.

The procedure described by Bailar[5] for the resolution of *cis*-[Co en_2 Cl_2]Cl was followed with *cis*-[Co trien Cl_2]Cl, but did not yield any crystals of the complex *dextro*-α-bromocamphor-π-sulfonate. The salt was obtained, however, by adding 15 cc. of a solution containing 9 g. (0.028 mole) of ammonium *dextro*-α-bromocamphor-π-sulfonate to 25 cc. of a solution containing 5 g. (0.016 mole) of *cis*-[Co trien Cl_2]Cl and immediately cooling the mixture in an ice–salt-bath. The crystals which separated were collected on a filter and washed with a very small amount of ice-water followed by alcohol and ether. A 0.32% solution of the air-dried crystals had a stable optical rotation of 0.18°, $[\alpha]^{25}D$ +55.6. One gram of the salt was ground in an ice-cold mortar with 10 cc. of an ice-cold mixture (1:1:1) of concentrated hydrochloric acid, alcohol, and ether. The purple residue was then collected on a filter and washed with absolute alcohol and ether. A 0.25% solution of this substance was immediately prepared and found to have no optical activity at the D line of sodium.

An attempt was made to effect the rearrangement of *cis*-[Co trien Cl_2]Cl to the *trans* configuration by the method which Jörgensen[6] used for the preparation of *trans*-[Co $(NH_3)_4$ Cl_2]HSO_4. Five grams of the *cis*-dichloro complex, II or III, was dissolved in 25 cc. of concentrated sulfuric acid and the solution was allowed to stand six hours at room temperature. The solution was then surrounded by an ice–salt bath and 25 cc. of concentrated hydrochloric acid was added dropwise with vigorous stirring. After standing for three days the well-defined purple crystals, which separated from the dark purple solution, were collected on a sintered glass filter and washed with dilute sulfuric acid, cold water, alcohol and ether. There were no signs of the *cis* (purple) salt rearranging to

the *trans* (green) configuration. This salt was dried at 110° overnight.

Anal. Calcd. for [Co trien Cl_2]HSO_4: C, 19.00. Found: Cl, 19.21.

The method used by Morgan and Burstall[3] for the preparation of *trans*-dichloro-(2,2′,2″,2‴-tetrapyridyl)-cobalt(III) chloride was modified in another attempt to obtain I. A solution which contained 10 g. (0.042 mole) of cobalt(II) chloride hexahydrate and 6 g. (0.041 mole) of triethylenetetramine in 10 cc. of water was kept on a steam-bath under an atmosphere of nitrogen for four hours. At the end of this time an excess of alcohol and ether was added and the reddish-brown oil which separated was washed three times with absolute alcohol. This oil was finally dried in a vacuum over sulfuric acid; analysis of the brown residue for chlorine checked favorably with that calculated for the cobalt(II) complex, [Co trien $(H_2O)_2$]Cl_2.

Anal. Calcd. for [Co trien $(H_2O)_2$]Cl_2: Cl, 22.72. Found: Cl, 22.97.

Three grams of this residue, ground to a fine powder and suspended in 50 cc. of absolute ethyl alcohol, was treated with an excess of dry chlorine. Almost immediately the brown particles became a bright green. This product was collected on a filter, washed with absolute alcohol and dried at 110° for two days. The green product appeared to be a mixture of the hexammine cobalt(III) chloride and unchanged cobalt(II) chloride. This was indicated by the fact that it dissolved to give an orange colored solution and the analysis for chlorine was consistently high. The ultraviolet spectrum of the green material (Fig. 1) showed no signs of any *trans*-salt.

Diammine-(triethylenetetramine)-cobalt(III) Chloride.—A solution of 3.2 g. (0.022 mole) of triethylenetetramine in 25 cc. of absolute ethanol was added to 5 g. (0.017 mole) of finely ground *trans*-dichlorotetramminecobalt-(III) hydrogen sulfate. The flask was equipped with a reflux condenser fitted with a calcium oxide drying tube, and the mixture was allowed to reflux on the steam-bath for five days. Ammonia was liberated and even after refluxing for five days traces of ammonia could still be detected. The grayish-orange reaction mixture was collected on a filter and washed with absolute alcohol and ether. A portion of this material was added to cold water and a small amount of slightly soluble violet-red residue was removed on a filter leaving an orange filtrate. An excess of alcohol and ether was added to the filtrate, causing an orange precipitate to separate. This precipitate was collected on a filter and washed with alcohol and ether and then dried at 110°.

Anal. Calcd. for [Co trien $(NH_3)_2$]Cl_3: Cl, 30.78. Found: Cl, 30.93.

cis-Dinitrotriethylenetetraminecobalt(III) Chloride.—A solution of 2.9 g. (0.020 mole) of triethylenetetramine in 25 cc. of absolute ethanol was added to 5 g. (0.020 mole) of finely ground *trans*-dinitrotetramminecobalt-(III) chloride. The flask was equipped with a reflux condenser fitted with a calcium oxide drying tube, and the mixture was allowed to reflux on the steam-bath for two days. A small amount of ammonia was still being liberated at the end of this time and the reaction mixture had not changed noticeably in appearance. The orange residue, which gave a qualitative test for ammonia, was purified by recrystallization from water. The crystals were washed successively with a small amount of cold water, alcohol and ether, and dried in a vacuum over sulfuric acid.

Anal. Calcd. for [Co trien $(NO_2)_2$]$Cl \cdot H_2O$: C, 20.60; H, 5.76; N, 24.03; Cl, 10.14; Co, 16.85. Found: C, 20.64; H, 5.79; N, 24.18; Cl, 9.98; Co, 16.93.

The *cis* configuration of this dinitro salt was suggested by the fact that boiling it with concentrated hydrochloric acid liberated nitrogen dioxide and formed a red solution which quickly turned purple. This is a qualitative test commonly used to distinguish between *cis*- and *trans*-dinitrotetramminecobalt(III) salts, the *trans*-salt forming a red precipitate of the corresponding chloronitro complex. No such precipitate separated from the purple hydrochloric acid solution even after prolonged standing at room temperature. It was likewise found that the ultraviolet spectrum (Fig. 2) of this salt is similar to that obtained for *cis*-dinitro-bis-(ethylenediamine)cobalt(III) chloride.

The same results were obtained when the experiment was repeated starting with the corresponding *cis*-salt, [Co $(NH_3)_4$ $(NO_2)_2$]Cl.

Anal. Found: C, 20.72; H, 5.80; N, 24.21; Cl, 10.05; Co, 16.89.

cis-Dinitrotriethylenetetraminecobalt(III) chloride prepared from II or III was found to have properties similar to the salt obtained from the *cis*- or *trans*-dinitrotetrammine complex. Six grams (0.019 mole) of II or III was mixed with 20 g. (0.218 mole) of sodium nitrite and 40 cc. of water. This mixture was heated to boiling and then cooled in an ice–salt-bath. The orange crystals which separated were collected on a filter and washed with a small amount of cold water followed by alcohol and ether. The ultraviolet absorption spectrum (Fig. 2) of this salt and its reaction with concentrated hydrochloric acid indicate the presence of the ion, *cis*-[Co trien $(NO_2)_2$]$^+$.

Carbonatotriethylenetetraminecobalt(III) dextro-Camphor-π-sulfonate.—Forty grams (0.129 mole) of II or III and 61 g. (0.219 mole) of freshly precipitated moist silver carbonate were ground in a mortar for two hours. The mixture was extracted with 200 cc. of distilled water and analysis of the filtrate revealed that it was free of chloride ion and contained 30 g. (0.051 mole) of the carbonate complex. It was mixed with a solution of 0.051 mole of barium *dextro*-camphor-π-sulfonate and the barium carbonate was removed on a filter. A portion of the filtrate was slowly concentrated in a drying oven at 40°. Crystals of the complex *dextro*-camphor-π-sulfonate were not obtained because the salt is extremely water soluble.

Oxalatotriethylenetetraminecobalt(III) dextro-Camphor-π-sulfonate.—The second portion of the carbonatotriethylenetetraminecobalt(III) *dextro*-camphor-π-sulfonate solution was allowed to react with 4.6 g. (0.051 mole) of oxalic acid. Carbon dioxide was liberated and the resulting solution was concentrated to 150 cc. This concentrate was cooled in an ice-bath and the pink crystals which separated were collected, washed with a small amount of cold water followed by alcohol and ether and the ether was removed at room temperature by a stream of air. A 1% solution of air-dried salt was immediately prepared and found to have an optical rotation of +0.12°, $[\alpha]^{25}D$ +12. The optical rotation of this solution had not changed after one week at 50°.

Two grams of this salt was also immediately ground, in an ice-cold mortar, with 30 cc. of an ice-cold mixture of concentrated hydrochloric acid, alcohol, and ether (1:1:1). After approximately ten minutes of constant grinding, the residue was collected on a filter and washed with cold alcohol and ether. A solution of a portion of this residue exhibited no optical activity at the D line of sodium. A major portion of the salt was dried in a vacuum over sulfuric acid.

Anal. Calcd. for [Co trien C_2O_4]Cl: Cl, 10.79. Found: Cl, 10.86.

Careful recrystallization of the oxalatotriethylenetetraminecobalt(III) *dextro*-camphor-π-sulfonate gave no indication of any separation of the optically active antipodes of the complex cation.

Ethylenediamine(triethylenetetramine)cobalt(III) Chloride.—Thirty grams (0.096 mole) of finely ground II or III, 12.8 g. (0.147 mole) of 69% ethylenediamine, and 500 cc. of absolute ethyl alcohol were placed in a three-necked round-bottomed flask containing some glass beads and equipped with an agitator and reflux condenser. The mixture was allowed to reflux with vigorous agitation for eight hours. The orange residue which formed was freed from any excess amine by washing with alcohol and ether. The theoretical yield of crude product was obtained and some of it was purified for analysis by recrystallization from water and drying at 110°.

Anal. Calcd. for [Co en trien]Cl_3: C, 25.84; H, 7.05; N, 22.64; Cl, 28.61; Co, 15.85. Found: C, 25.63; H, 6.98; N, 22.42; Cl, 28.57; Co, 15.93.

The salt can be purified more easily by conversion to the much less soluble iodide. Five grams (0.013 mole) of the salt in 20 cc. of water and 5 g. (0.033 mole) of sodium iodide in 10 cc. gave a crystalline iodide which was washed with cold water, recrystallized from 20 cc. of distilled water and dried in a vacuum over sulfuric acid.

Anal. Calcd. for [Co en trien]I_3: I, 58.92. Found: I, 58.67.

Attempts to resolve the ion, [Co en trien]$^{+++}$, from the bromide *dextro*-tartrate[7] and *dextro*-α-bromocamphor-π-sulfonate were not successful. The difficulty encountered was largely due to the extreme solubility of these salts.

Tetrakis-(ethylenediamine)-triethylenetetraminedicobalt(III) Chloride.—Thirty grams (0.105 mole) of finely ground *cis* or *trans*-dichloro-bis-(ethylenediamine)-cobalt(III) chloride, 11.5 g. (0.079 mole) of triethylenetetramine, and 500 cc. of absolute alcohol were allowed to react as described for the preparation of [Co en trien]Cl_3. An orange residue was formed, in practically theoretical amount. It was recrystallized from water and dried at 110°.

Anal. Calcd. for [Co_2 en_4 trien]Cl_6: C, 23.43; H, 7.02; N, 23.46; Cl, 29.65; Co, 16.43. Found: C, 23.23; H, 6.89; N, 23.58; Cl, 29.43; Co, 16.35.

Preparation and purification of the much less soluble iodide was accomplished by the method outlined for the corresponding [Co en trien]I_3.

Anal. Calcd. for [Co_2 en_4 trien]I_6: I, 60.14. Found: I, 59.93.

The resolution of this ion, [Co_2 en_4 trien]$^{+6}$, was not accomplished using the bromide *dextro*-tartrate[7] and the *dextro*-α-bromocamphor-π-sulfonate.

tris-(Triethylenetetramine)-dicobalt(III) Chloride.—Twenty grams (0.064 mole) of finely ground II or III, 9.6 g. (0.065 mole) of triethylenetetramine, and 300 cc. of absolute ethyl alcohol were allowed to react as described for the preparation of [Co en trien]Cl_3. A portion of the orange product was recrystallized from water and dried at 110°.

Anal. Calcd. for [Co_2 $trien_3$]Cl_6: C, 28.09; H, 7.07; N, 21.87; Cl, 27.64; Co, 15.32. Found: C, 27.87; H, 6.97; N, 21.93; Cl, 27.39; Co, 15.47.

The complex iodide was obtained by the addition of a small excess of sodium iodide solution to a solution of the complex chloride. This slightly soluble iodide was purified by recrystallization from water and dried in a vacuum over sulfuric acid.

Anal. Calcd. for [Co_2 $trien_3$]I_6: I, 58.92. Found: I, 58.67.

Again all efforts to resolve this ion, [Co_2 $trien_3$]$^{+6}$, from the bromide *dextro*-tartrate[7] and *dextro*-α-bromocamphor-π-sulfonate were without avail.

Summary

Salts of the following cations containing triethylenetetramine and cobalt(III) have been prepared and some of their properties are described: [Co trien Cl_2]$^+$, [Co trien $(NO_2)_2$]$^+$, [Co trien CO_3]$^+$, [Co trien C_2O_4]$^+$, [Co trien $(NH_3)_2$]$^{+3}$, [Co en trien]$^{+3}$, [Co_2 en_4 trien]$^{+6}$, and [Co_2 $trien_3$]$^{+6}$.

A *cis*-configuration seems to be indicated for the ions, [Co trien Cl_2]$^+$ and [Co trien $(NO_2)_2$]$^+$.

An absorption band was obtained at approximately 2425 Å. for several *cis*-dinitrotetramminecobalt(III) compounds and this same band was less clearly shown by the corresponding *cis*-dichloro compounds.

Determination of Position of Tracer Atom in a Molecule: Mass Spectra of Some Deuterated Hydrocarbons[1]

BY JOHN TURKEVICH,[2] LEWIS FRIEDMAN,[2] ERNEST SOLOMON AND FRANCES M. WRIGHTSON[3]

The problem of determining the position of a tracer atom in a complex molecule arose during the study of the mechanism of catalytic reduction of acetone to propane with deuterium. Since the mass spectrum of a molecule consists of fragment ions obtained by rupture of valence bonds it was thought that the relative abundance of appropriate ions would indicate the position of an isotopic atom. Thus C_3H_7D-1 should give among others, ions of mass 16 and 15.

$$H_3C—CH_2—CH_2D \longrightarrow \underset{16}{C_2H_5 + CH_2D^+} + E$$

$$\underset{15}{C_2H_4D + CH_3^+} + E$$

While C_3H_7D-2 should give no ions of mass 16.

$$CH_3—CH_2D—CH_3 \longrightarrow \underset{15}{C_2H_4D + CH_3^+} + E$$

The purpose of this study was to establish the validity of this approach and to study in general the changes in the mass spectrographic pattern of hydrocarbons produced by replacing some of the hydrogens with deuterium. With this in mind monodeuteromethane, tetradeuteromethane, monodeuteroethane, monodeuteropropane-1 and monodeuteropropane-2 were prepared and studied on two standard mass spectrographs, that of Nier and the one of the Consolidated Engineering Corporation.

A mass spectrometric study of dideuteroethylene has been made by Delfosse and Hipple.[4] More recently Evans, Bauer and Beach[5] have investigated the mass spectrum of monodeuteromethane and Mohler and Dibeler,[6] mono- and dideuteroacetylenes. These studies show that the

carbon–deuterium bond does not break as readily as the carbon–hydrogen bond.

Experimental

The mass spectrometer was a Nier type[7] instrument. The gas analyzed was introduced into the spectrometer tube through a capillary leak. The gas pressure in the sample system was kept at 10 mm. The bombarding electrons responsible for the ionization and dissociation processes were accelerated from an incandescent tungsten filament through a slit into the ion gun by a potential of 67.5 volts.

The mass spectra were also determined in a Consolidated Engineering Corporation instrument.[8] In this case the electron accelerating voltage was 55 volts and the gas analyzed was permitted to leak into the spectrometer tube from a sample reservoir at a pressure of approximately 20 microns.

Materials

The monodeuteromethane was prepared by decomposing methylmagnesium iodide with 100% heavy water. The Grignard reagent was prepared by adding 14.5 g. of C. P. methyl iodide to 20 cc. of dry Eastman Kodak butyl ether and 2.8 g. of magnesium turnings in a 250-ml. round-bottom flask. The magnesium was carefully drilled from a block of pure metal without the aid of any cutting oils or fluids. The flask was fitted with a vertical water cooled reflux condenser which in turn was fitted at the top with a calcium chloride tube. The reaction was initiated by gentle heating and then controlled by cooling in a water-bath. The flask containing the Grignard reagent was attached to a vacuum line by means of a standard taper ground glass joint, cooled in Dry Ice and evacuated. The reagent was thoroughly out gassed by melting, freezing and then evacuating several times. A small quantity of heavy water vapor (approximately 10–15 cc., N. T. P. estimated from the volume of the products formed) was distilled into the flask containing the Grignard reagent. The purity of the methane was determined by abundance ratio of masses 16 and 17. The first sample gave for this ratio a value of 0.83. The reaction mixture was cooled in Dry Ice and this sample of gas pumped off. A second batch of heavy water vapor was distilled into the Grignard reagent and the ratio of 16 to 17 in the deuteromethane formed was found to be 0.73. In the third and fourth batches the values were found to be 0.710 and 0.709. The constant values observed indicate that the reagent had been cleaned up of any light water contamination and the limit of purity had been reached. A larger sample of gas was then generated for final analysis.

Monodeuteroethane was prepared in a similar manner by the decomposition of ethylmagnesium bromide with heavy water. Ethylmagnesium bromide was prepared by adding 11 g. of ethyl bromide to 10 cc. of dry butyl ether and 2.8 g. of magnesium turnings in a 250-ml. round-bottom flask. Mild heating was used to initiate the reaction. The Grignard reagent was decomposed by using successive batches of heavy water. The ratios of the abundances of the ions of masses 30 and 31 were 0.80 for the first batch and 0.79 for the second, third and final batches prepared.

Propane-D-1 and Propane-D-2 were prepared from the corresponding normal and isopropylmagnesium bromides and heavy water. Both alkyl halides were purified by fractional distillation. In the preparation of propane-D-1 the ratios of the abundances of the ions of mass 44 and 45 were 1.05, 1.00, 0.895, and finally 0.863 for the following four successive batches. In the preparation of propane-D-2 the ratios for these ions were 0.83, 0.725, 0.74 and 0.74.

A sample of **tetradeuteromethane** containing approximately 7% monoprotium trideuteromethane was given to us by Mr. M. W. Wright. This material was prepared by the decomposition of aluminum carbide with heavy water. Excess hydrogen formed was removed by freezing the deuteromethane in solid nitrogen and pumping off the more volatile components.

It should be pointed out that in the preparation of deuterium compounds by the Grignard reagent extreme care must be observed to avoid introduction of light hydrogen into the molecule. The following precautions were observed. In the first place the heavy water was added in small successive portions to the Grignard reagent and samples were analyzed for the highest masses in the mass spectrograph. Two criteria of purity could then be applied. Successive samples should show a constant low value for the mass one smaller than the maximum, as the hydrogen impurity is removed from the sample (thus the relative abundance of mass 30 from C_2H_5D should reach a steady minimal value). Another criterion is that the sensitivity coefficient (absolute intensity) of the ion of parent mass be the same as that of the corresponding light hydrogen compound.

The second method of determining the purity of the preparation is to determine the hydrogen–deuterium ratio in the product. In this method the hydrocarbon was oxidized by copper oxide at 500°. The water formed was condensed in a Dry Ice trap and the carbon dioxide pumped off. The water was decomposed over zinc at 330°. The hydrogen so formed was analyzed in a Nier type mass spectrometer for the deuterium–hydrogen ratio. The instrument was calibrated by measuring the ratio of masses three and two of hydrogen from standard heavy water samples whose deuterium content was known from density determinations. The following two examples illustrate the results obtained using some early impure compounds. A preparation of monodeuteroethane has a sensitivity coefficient for the parent mass of 15 while the value of the corresponding light hydrogen ethane was 20.0. Assuming that the sensitivity coefficient is independent of deuterium content, this result would indicate that the preparation of monodeutero compound was 75% pure. Combustion and deuterium analysis indicated 12.0% deuterium and the monodeuteroethane (theoretical value is 16.7%). Thus deuterium analysis indicates again a 73% purity. Another example is furnished by the experiments on monodeuteropropane-2. The sensitivity coefficient for the mass of parent ion was 12.0 while that of the light hydrogen compound was 24.56. This would indicate 49% purity. The deuterium analysis showed 6.45% deuterium (theoretical value for a monodeuteropropane is 12.5%), or a purity of 50%. Thus the purity determinations based on an assumption of equal sensitivity coefficients of the ion of parent mass irrespective of deuterium substitution lead to the same result as an ultimate analysis based on hydrogen deuterium analysis.

Results

The experimental results obtained are expressed in terms of the sensitivity coefficients of the ion of parent mass and relative ion intensities. The sensitivity coefficient of the ion of parent mass is the relative value of the ion current of the parent mass at an inlet pressure of one micron under identical operating conditions. The relative ion intensities are expressed in the following way. The intensity of ion of parent mass is given the value of 100 and the intensities of the other ions are presented relative to the intensity of the ion of parent mass. Using the sensitivity coefficient as given and the relative ion intensity one can obtain intensities of all other ions at the standard operating conditions of the instrument.

The data presented in Tables I, II and III permit a comparison of the results obtained by the two standard instruments: that of Nier and that

[d] Unreliable. [e] Total ions includes all peaks recorded.

of the Consolidated Engineering Corporation. One should first note in Table I the concordance of our results for monodeuteromethane obtained on the Consolidated instrument of the M. W. Kellogg Company at Jersey City with the results obtained by Evans, Bauer and Beach on a similar instrument on the West Coast. The values obtained on the Nier instrument at Princeton University are slightly lower.[9] An examination of the results of Tables II and III shows more marked differences in the individual values of the relative ion intensities for the various ethanes and propanes as obtained on the two different instruments. One must note, however, that the two instruments agree on both the order of abundance of the various ions and their magnitude. For that reason the results will be discussed for the most part in terms of the values obtained on the Nier instrument. The values obtained on the Consolidated instrument are placed in parentheses in the text of the paper.

(9) This may be due to differences in the ambient temperatures of the ionization chambers in the two instruments.

Methane.—The sensitivity coefficients of the ion of parent mass for all three compounds CH_4, CH_3D and CD_4 is approximately the same.

The CH_3D pattern had been previously reported by Evans, Bauer and Beach and our results using the Consolidated instrument agree with those they reported. The results we obtained with the Nier instrument are slightly lower. The CH_3D pattern is different from that of CH_4 and CD_4. Evans, Bauer and Beach have made a detailed analysis of this difference in terms of statistics and the relative dissociation probabilities of the C–H and C–D bonds in CH_3D and of the CH bond in CH_4 compared to the C–H bond in CH_3D. We shall limit ourselves to a more elementary analysis. The number of processes of ionization increases from five to six when one goes from CH_4 to CH_3D while the sum total of the ion currents

remains the same (211.4, 216.8, 207.7). This brings of necessity a redistribution of the cracking pattern. This kind of redistribution is not statistical as has been pointed out by Evans, Bauer and Beach in the case of CH_3D and by Delfosse and Hipple for $C_2H_2D_2$.

The mass 16 in the spectrum of CH_3D results from the removal of a hydrogen atom and an electron from the molecule. Statistically this should correspond to $^3/_4$ the value obtained for the removal of a hydrogen from CH_4 or 60.9 (62.6). The observed values are 71.3 (78.2) indicating that the hydrogen removal is 1.17 (1.25) more probable if the carbon atom contains a deuterium atom. The mass 15 may arise from two processes. It may arise from a removal of two hydrogens from CH_3D and should have $^3/_6$ the value of the CH_2^+ produced from CH_4 or 6.2 (8.5). The second process is the removal of a deuterium from CH_3D. The statistical value should be one-quarter of the removal of a hydrogen from CH_4 or 20.3 (20.9). The total for the two processes is 26.5 (29.4) and is larger than the experimentally observed value 18.7 (22.3). If one assumes that the probability of breaking a deuterium–carbon bond is one-half that of breaking a hydrogen–carbon bond while the breaking of a hydrogen–carbon bond is 1.17 more probable if the carbon atom contains a deuterium atom we get a predicted value of 18.4 (21.1) in better agreement with experimental values 18.7 (22.3). The mass 14 arises again from two processes. The first produces a CD^+ which should be one-third of the CH^+ from CH_4 or 1.9 (2.8). If we multiply this by 1.17 we get 2.2 (3.5). The second is due to CH_2^+ which should be $^3/_6$ of the CH_2^+ peak of CH_4 or 6.2 (8.5). If we multiply this by (0.5) (1.17) we get 3.8 (5.0). The predicted value is thus 6.0 (8.5) where the experimental value is 6.8 (8.8).

A part of the CD_3H pattern can be obtained from the 7% CD_3H impurity in CD_4 sample by considering the relative intensities of the ions of odd mass in the spectrum of CD_4 (after correcting for the 1.1% C^{13} isotope). One then obtains 100 for the CD_3H^+ and 51.2 for the CD_2H^+. The other masses cannot be obtained from the data available. For CD_2H^+, on purely statistical grounds, one would expect three-quarters of 83.5, or 62.6. An interpretation of the CD_3H spectrum must await synthesis of pure CD_3H.

The CD_4 as prepared contained 7.2% CD_3H as revealed by ions of odd mass. The spectrum of CD_4 should consist solely of ions of even mass when a correction is made for the contribution due to 1.1% C^{13} isotope. The presence of an impurity of 7.2% CD_3H affects the spectrum but slightly since the currents for even masses from this molecule would be small in view of the small amount of the impurity present. The only correction applied was to the mass 18 where it was calculated on statistical grounds to be $7.2 \times 0.835 \times {}^1/_4 = 1.5$. The value in Table I is so corrected. The process of removing a hydrogen from CH_4 to give CH_3^+ has the value 83.5 while the similar process of removal of D from CD_4 has the value 82.8.

The removal of two hydrogens from CH_4 gives the value of 17.0 while the corresponding process in CD_4 has the value 14.5. The removal of three hydrogens from CH_4 gives a value of 8.34 while that of three deuteriums from CD_4 is 7.85. One thus sees that the probability of breaking a carbon–deuterium bond in tetradeuterium methane is the same as the probability of breaking a carbon–hydrogen bond in tetrahydrogen methane. The probability of breaking a carbon hydrogen bond is greater if there is a carbon–deuterium bond present and also the probability of breaking a carbon–deuterium bond is less if there is a carbon–hydrogen bond present.

Ethanes.—The mass spectra of ethane and monodeuteroethane are presented in Table II. The sensitivity coefficients of the parent masses were found to be approximately the same. The total number of ions formed from ethane (827–847) is slightly less than the total from monodeuteroethane (881). The relative ion intensities are different first because new masses 31 (C_2H_5D) and 16 (CH_2D) appear and secondly because alternative processes involving the removal of either D or 2H atoms give ions of the same mass. Ninety-five per cent. of the ions are in the C_2 group indicating that it is easier to break C–H bonds than the –C–C bonds. The total number of ions in the C_2 group in deuteroethane 857 is greater than in ethane 801 (824). In the C_2 group mass 30 arises from the loss of a hydrogen and an electron from deuteroethane. Its value should be $^5/_6 \times (1.17)$ of that observed for the 29 peak in ethane or 74.6 (81.2). The experimental value is 73.1 (74.3). The mass 29 arises by two processes: (a) the removal of a deuterium and an electron which should be equal to $^1/_6 \times (0.5)$ the value of removing a hydrogen from ethane 76.5 (78.0) or 6.5 (6.5); (b) removal of two hydrogens and an electron from deuteroethane which should be $^{10}/_{15} \times (1.17)$ of a similar process in ethane 393 (394) or 307 (328). The predicted value is 314 (335) while the observed value is 330 (320). The mass 28 arises again two processes (a) the removal of three hydrogens and an electron which should be $^{10}/_{20} \times (1.17)$ of analogous process for ethane 127.5 (130.3) or 74.6 (81.4) and (b) the removal of a deuterium, hydrogen and electron which should be $^5/_{15}$ of the removal of two hydrogens from ethane 393.4 (394) or 131 (131). The predicted value is 206 (213) while the observed value is 196. The agreement with experiment is better if one drops the weighing factors (1.17) and (0.5) for the simultaneous removal of an H and a D.

Mass 27 arises from (a) removal of 4 hydrogen atoms and an electron from C_2H_5D and should be equal to $^5/_{15}$ of (1.17) 87.2 (92.8) or 34.0 (38.6), (b) removal of 3 hydrogen and one deuterium atom

and an electron. The value for this process should be $^{10}/_{20}$ of 127.5 (130.3) or 63.8 (65.2). The total is 98 (104). The observed value is 96 (105.5). The mass 26 arises from (a) removal of five hydrogens and an electron from C_2H_5D and should be equal to $^1/_5 \times (1.17) \times 16.2$ (15.1) = 3.8 (3.8) and (b) removal of three hydrogen and one deuterium and electron. The value for this process should be $^{10}/_{20} \times 87.2$ (92.8) or 43.6 (46.4). The total predicted value is 47.4 (50.2) as contrasted with the experimental value of 49.9 (60.4). The mass 25 arises from sole process of removal of four hydrogens and a deuterium atom and an electron. This should be equal to $^5/_6$ of 16.2 (15.1) = 13.5 (12.6) whereas the experimental value is 10.8 (11.6).

The C_1 group constitutes about 3% of the total ions produced from ethane. The values for the ethane are 25.9 (36.4) and for the deuteroethane 24.8. The mass 16 in monodeuteroethane arises from a split of the molecule in two and should be one-half of the mass 15 from ethane or 6.2 (9.0). The experimentally observed values are 6.2 (8.5). The close concordance between the predicted and experimentally observed results indicates that the presence of the deuterium isotope does not appreciably affect the probability of breaking the C—C bond. The mass 15 in monodeuteroethane arises from CH_3^+ and CHD^+. The amount of the CH_3^+ can be calculated as one-half the 15 peak in C_2H_6 or 6.2 (8.5). The amount of the CHD^+ is $^1/_2 \times ^2/_3 \times (1.17)$ of the CH_2^+ from C_2H_6 or 3.3 (5.1). The total is therefore 9.5 (13.6) while the observed value is 9.7 (18.2).

The value of 14 peak in C_2H_5D is due to contributions of CH_2 and CD^+. The CH_2^+ that comes from CH_3 is $^1/_2$ of 8.4 or 4.2 and the amount that comes from CH_2D is $^1/_2 \times ^1/_3$ (0.5) $\times$ 8.4 or 0.7. The CD^+ that comes from CDH_2 should be $^1/_2$ (3.1) $\times$ $^4/_6$ = 0.7. The total is 4.2 + 0.7 + 0.7 = 5.6. The value obtained on the Nier instrument is 5.4.

Propanes.—The mass spectra of propane, propane D-1 and propane D-2 are presented in Table III. The presence of only one deuterium in the deuterated propanes is established by the absence of masses higher than 45. The sensitivity coefficients of the three propanes examined were the same. The total number of ions was 979.5 (1110), 1023 (1301) and 1160, respectively, and cannot be considered equal within the experimental error. The C_3 group contains about one-third of the ions. An analysis of the ions formed is difficult. The high value of the 44 peak in the D-1 and the low value in the D-2 compound seems to indicate that the primary carbon-hydrogen bond is more strongly held than the secondary and it is the secondary hydrogen that comes off first. A detailed discussion of the C_3 ions in the deuterium compounds must be postponed until further deuterium compounds are synthesized and studied. The C_2 group contains about two-thirds of the ions. The mass 30 results from the loss of a methyl radical and an electron from the deuteropropane. In the case of the D-1 compound its value should be equal to one-half of the mass 29 for propane or 156 (175). The observed value 151.5 (180) is in good agreement. In the case of the D-2 compound the value of the 30 mass should be equal to the value of the 29 mass in propane or 312 (350). The experimental values are 323 (330). The explanation for the value of the 29 mass in propane D-1 is satisfactory. It can arise in two ways

$$CH_3CH_2—CHD_2 \longrightarrow CH_4 + C_2DH_3 + E$$

and its value should be one-half times $^4/_5$ the value of the 28 peak in propane 75.5 (83). The other process is

$$CH_3{\cdot}CH_2{\cdot}CDH_2 \longrightarrow CDH_2 + CH_3{\cdot}CH_2^+ + E$$

which should be one-half the value of the 29 peak in propane or 156 (175). The total is 232 (258) to be compared with the experimental 223 (291). The value of the 29 mass in propane D-2 can arise only from a removal of a CH_4 from the molecule and should be equal to the 28 peak in propane, or 189 (208). The value found experimentally is 218 (218).

The C_1 group contains about 2% of the total ions. The mass 16 should occur only in the case of propane D-1 where it should be equal to one-half the value for the 15 mass in propane or 6.7 (11.2). The observed values are 7.4 (11.4) in good agreement with prediction. There should be no 16 mass in propane D-2. The small value obtained for this mass may be due to re-arrangement in the preparation of the deuterated propane. The mass 15 for propane D-2 should be the same as that from propane, *i.e.*, 13.5 (22.5). The experimental value is 12.3 (22.9) in good agreement with calculation. The value for propane D-1 arises by two processes

$$CH_3{\cdot}CH_2CH_2D \longrightarrow CH_3^+ + CH_2{\cdot}CHD$$

or one-half the value for propane 6.7 (11.2) and

$$CH_3{\cdot}CH_2CH_2D \longrightarrow CHD^+ + CH_3{\cdot}CH_3$$

or two-thirds of the value for mass 14 (2.7, 4.7) from propane to give a predicted value of 9.4 (15.9). The experimental value is 10.3 (18.7). Thus we see that the C_1 group provides unequivocal evidence for the disposition of the deuterium atoms in the molecule.

In conclusion it may be stated that one can determine the position of the tracer atom in a propane molecule by examination of the intensities of masses 30 and 16. Furthermore, one can reconstruct the fine details of the mass spectrum of monodeuteromethane, monodeuteroethane using the assumption of equal probability of rupture of hydrogen carbon bonds, a 7/6 factor for a carbon–hydrogen bond on a carbon atom that has deuterium and a one-half factor for a carbon–deuterium bond. One further drops these factors if both D and H are removed simultaneously.

Conclusion

1. Monodeuteromethane, tetradeuteromethane, monodeuteroethane, monodeuteropropane-1 and monodeuteropropane-2 have been synthesized and their mass spectra determined on a Nier type and a Consolidated mass spectrometer.

2. A method of calculating the mass spectrum of monodeuteromethane and monodeuteroethane from the corresponding light hydrogen compounds, has been indicated.

3. A method has been given to indicate the position of a deuterium atom in monodeuteropropanes.

The Quantum Efficiency of the Mercury Sensitized Photochemical Decomposition of Hydrogen

BY LLOYD B. THOMAS AND WM. D. GWINN[1a]

Introduction

The reaction between mercury atoms excited by absorption of light of λ 2537 Å. and hydrogen molecules to produce hydrogen atoms was reported by Cario and Franck[1] in 1922. The analogous reaction between hydrogen molecules and mercury atoms excited by streaming electrons of controlled energy through the gas mixture has been carried out.[2] These and more recent studies in this laboratory have indicated that the 6^3P_1 state of mercury to which the photochemical reaction is ascribed may play only a slight part, if any, in the electron initiated reaction. The immediate occasion for undertaking the present study is to obtain the necessary reaction rate data to compare the kinetics of the electron and photon activated reactions in the hope that the mechanism of the former will be clarified.

Attention has been devoted by a number of investigators—Stuart, Zemansky, Bates[3] and Evans[4]—to the quenching of fluorescent resonance radiation from Hg^3P_1 atoms by collision of the Hg^3P_1 atoms with added foreign gas molecules. An over-all effective cross section for quenching is obtained through the method but it is not possible to distinguish between processes which may contribute to the quenching. By the method of the present paper it appears possible to determine the effective cross section for a specific process, *i.e.*, the interaction of Hg^3P_1 atoms with hydrogen molecules to cause their removal from the gas phase, presumably through dissociation.

Experimental

The reaction system and light source are shown in Fig. 1. The reaction cell is a cylinder of fused silica which has an internal length of 3.53 cm. and an internal diameter of 2.25 cm. The walls of the cell are lined with a thin cylinder of oxidized copper. The ends of the cylinder are flat polished fused silica windows 2 mm. thick and are fused on. The cell is attached to the rest of the system, which is of Pyrex, by a graded seal. The Pirani gage consists of a 0.0025 cm. platinum filament mounted as shown and immersed in a kerosene filled thermostat which is maintained at 30°. Precaution was taken to prevent a film of kerosene, which was found to absorb λ-2537, from creeping over the entrance window. The system in the thermostat was connected through a U-tube and mercury cut-off to a conventional high vacuum system with mercury condensation pump, McLeod gage, mercury cut-offs, and with no stopcocks in the high vacuum line. Hydrogen was admitted from a gas flame through a palladium tube. The pressure was brought to the desired values, as shown by the McLeod gage, through manipulation of the flame and cut-offs.

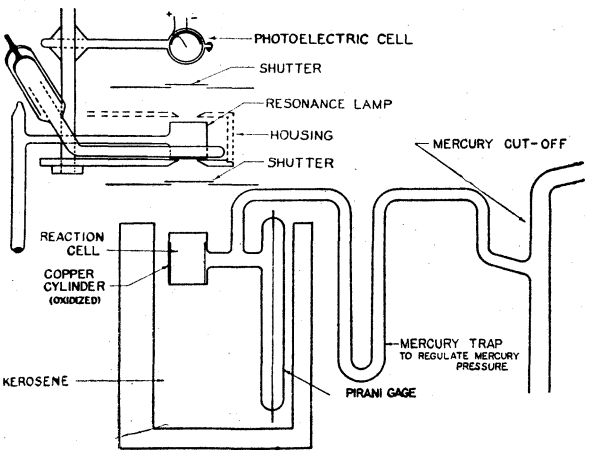

Fig. 1.—Experimental apparatus.

The light source is a monochromatic resonance lamp[5] which operates several degrees above room temperature and gives a very narrow line breadth—about 20% greater than the Doppler breadth at 30°. A fused silica photoelectric cell with a cadmiun coated cathode was mounted above the resonance lamp as shown and served as a check on the lamp intensity. The intensity of λ 2537 in this upper position was strictly proportional to that at the reaction cell window when the mercury vapor pressure in the resonance lamp cylinder was kept constant. The procedure in taking data is as follows: The thermostat is replaced by an oven. Oxygen is admitted to the system to about 10 mm. pressure. When the oven temperature becomes sufficiently high the oxygen pressure starts to diminish due to consumption by the copper of

the cylinder. After the oxygen pressure has diminished about 1 mm. the oxygen is pumped out and the system is baked and flamed while open to the pumps. The thermostat is then replaced, the temperature of a mercury droplet introduced to the U-tube is set at the desired value, hydrogen is introduced to the desired pressure, and the cut-off to the reaction system is closed. After bringing the Pirani gage to balance and bringing the lamp to a steady intensity, the foot-operated shutter below the resonance lamp is opened for a measured time interval. This interval is regulated from four to sixty seconds, depending on the pressures of hydrogen and mercury vapor in the system, to give a Pirani galvanometer excursion of from 10 to 30 scale divisions (readable to 0.1 division), which corresponds to the disappearance of less than 10^{-10} gram of hydrogen. After about five such average exposures the baking-out procedure is repeated. This is necessary because it was found that the observed rates of decomposition began to decrease measurably with total decomposition in excess of this amount. This effect seems to be attributable to the inability of the silica surface to maintain its full capacity for removal of the products of the reaction. All of the data reported in this paper were taken in the initial period after baking out and forming a fresh oxide surface when the reaction rates at a given set of concentration and radiation conditions were quite constant and at a maximum.

The lamp intensity was determined by use of two multiple junction bismuth–silver vacuum thermopiles, one bismuth–(bismuth, 5% tin) vacuum thermopile, two quartz–cadmium photocells, the chloroacetic acid actinometer, and two N.B.S. calibrated lamps along lines described earlier.[6] Ten sets of determinations of the resonance lamp intensity gave 25.6×10^{12} quanta entering the reaction vessel per second for unit (upper position) photocell galvanometer deflection. The absorption (including reflection) of light from the resonance lamp and N.B.S. standard lamps in thermopile and reaction cell windows was measured and the proper corrections were made. As a check on the reliability of the lamp standardization the quantum yield of the chloroacetic acid hydrolysis was run. A quantum yield of 0.29 at 26° was found, which is to be compared with the value 0.33 obtained by Smith, Leighton and Leighton.[7] (The value of 0.342 previously given by Thomas[6] should be revised to 0.29 when correction is allowed for absorption of the radiation of the N.B.S. lamps in the two mm. fused silica ground and polished windows of the thermopiles.)

The absorption for the resonance lamp by the mercury vapor in the reaction cell was calculated from measurements made in a cell similar to the reaction cell but of better optical quality and described with equations used in reference 5. The value of ω (ref. 5, p. 311) was found to be approximately 1.2 and the integral expression with this value of ω and the "l" for the reaction cell of Fig. 1 was used to calculate the absorption in the reaction cell at the various pressures of mercury vapor. This absorption, multiplied by the number of quanta entering the cell per second per unit photocell galvanometer deflection, is plotted in Fig. 2, Curve A.

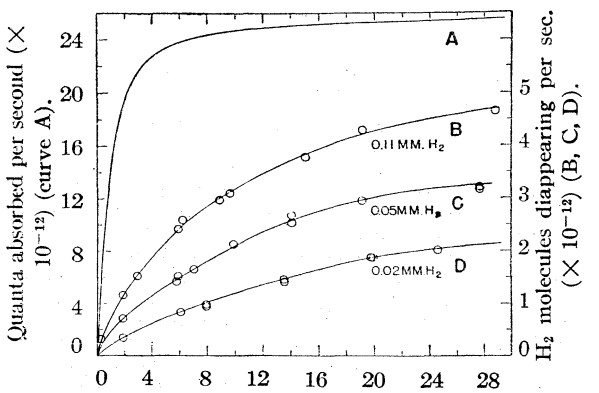

Fig. 2.—Experimental data.

The Experimental Data

The measurements were made at three hydrogen pressures, 0.02, 0.05 and 0.11 mm. over a range of mercury vapor pressures from 0.3×10^{-4} to 30×10^{-4} mm. These data, expressed in hydrogen molecules disappearing per second per unit photocell galvanometer deflection (photocell mounted above resonance lamp), are shown plotted against the pressure of mercury vapor in Fig. 2, Curves B, C, D. Most of the points shown in these curves represent an aggregate of several points so closely placed that they could not be plotted distinctly on a graph of this scale. The data considered in determining the curves are given below in Table I under the column headings I and II, representing, respectively, the mercury vapor pressure in mm. $\times 10^4$ and the rate of removal of hydrogen in molecules per second per unit photocell galvanometer current $\times 10^{-12}$. The number of separate measurements taken to obtain the average value given is indicated by the numbers in parentheses in case of more than one. Column III lists the quanta of λ 2537 ($\times 10^{-12}$) absorbed in the cell per second per unit photocell current over the range of mercury vapor pressures. These are plotted in Curve A, Fig. 2.

TABLE I

REACTION RATE MEASUREMENTS AND LIGHT ABSORPTION IN THE CELL

Discussion

To express the data in more significant form, curves were put through the experimental points (Curves B, C, and D of Fig. 2) and the ordinates of these curves were divided respectively by the ordinates of Curve A, Fig. 2 at corresponding abscissas. The resulting values are plotted in Fig. 3 for each of the hydrogen pressures investigated. The ordinates of these curves are the quantum efficiencies at the various mercury vapor

pressures. It is seen that the quantum efficiency rises markedly over the mercury pressure range—more than eight-fold at 0.02 mm. hydrogen and 4 fold at 0.11 mm. hydrogen pressure. At the pressure conditions of these experiments the chance that the Hg^3P_1 atoms will radiate is much greater than the chance that they will be quenched. The increasing quantum yield with increasing mercury pressure is due no doubt to the increasing reabsorption of fluorescent λ 2537 within the reaction cell. One of the problems of this paper is to give a quantitative statement of the contribution of this reabsorption process to the reaction kinetics.

The curves of Fig. 3 permit quite definite extrapolation to the axis of zero mercury vapor pressure. The limiting values of the quantum efficiencies at zero mercury vapor pressure are 0.0095 at 0.02 mm. of hydrogen; 0.023 at 0.05 mm. of hydrogen; and 0.045 at 0.11 mm. of hydrogen. These extrapolated values should give the probabilities that single mercury atoms excited to the $^3P_1$ state will react with hydrogen molecules at the specified pressures to cause disappearance of the hydrogen from the gas phase and they should be free from complications resulting from reabsorption of the fluorescent quanta. They may be used to calculate the effective cross section for the process through use of the collision frequency expression: $Z = 5.64 \times 10^5 n_{H_2} \cdot n_{Hg^*} \cdot \sigma^2$ (for hydrogen and mercury at 30°) in which σ^2 is often termed the "effective cross section" for the given process.[3] To apply the present case consider the absorption of one quantum per cc. per second. Then the number of effective collisions per cc. per second, Z, becomes the quantum efficiency, ϕ, and the n_{Hg^*} becomes the product of τ, the average life of the Hg^3P_1 state (1.07×10^{-7} sec.), and $(1 - \phi)$. Substitution of the appropriate values in (1) gives for the intercept with 0.02 mm. of hydrogen:

$$0.0095 = \frac{5.64 \times 10^5 \times 6.42 \times 10^{14} \times 1.07 \times 10^{-7}}{(1 - 0.0095)\sigma^2}$$

From this, $\sigma^2 = 2.45 \times 10^{-16}$ cm.^{2} at 0.02 mm. of hydrogen. Similarly σ^2 is found to be 2.43×10^{-16} and 2.21×10^{-16} at 0.05 mm. and 0.11 mm. of hydrogen, respectively. It appears likely that other quenching processes are competing with that resulting in disappearance of hydrogen. The over-all cross section for quenching of Hg^3P_1 atoms by hydrogen is variously given from 27 to 6.01×10^{-16} cm.^{2} by several investigators.[3,4] The last value of Zemansky,[3] confirmed by Evans[4] using the same apparatus and theory, should be most reliable. The ϕ value used in the $\tau(1 - \phi)$ term to calculate n_{Hg^*} should refer to total quenching rather than to dissociation of hydrogen. In calculating the σ^2 values below, the ϕ in $(1 - \phi)$ is multiplied by the ratio of the σ^2 for quenching (σ_Q^2) to the σ^2 for dissociation of hydrogen (σ_D^2). This gives σ_D^2 values 2.50, 2.50 and 2.37×10^{-16} cm.^{2} for $\sigma_Q^2 = 6.01 \times 10^{-16}$ cm.^{2}, or 2.53, 2.57 and 2.51×10^{-16} cm.^{2} for $\sigma_Q^2 = 8.6 \times 10^{-16}$ cm.^{2} given earlier by Zemansky.[3] The value 2.5×10^{-16} cm.^{2} is selected for σ^2 for the process resulting in disappearance of hydrogen from the intercept measurements.

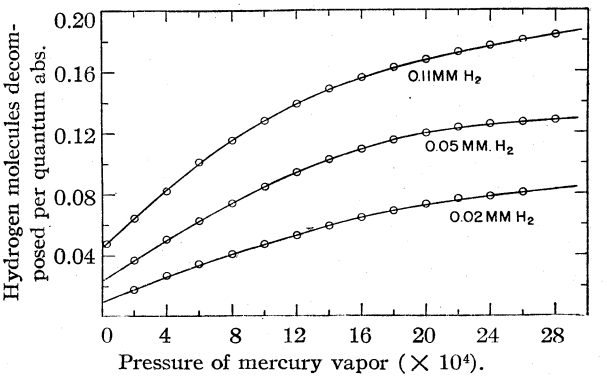

Fig. 3.—Quantum efficiency.

A series of reactions which constitutes the mechanism will be postulated and on the basis of this mechanism the rate constants and the contribution of the reabsorption of fluorescent radiation to the reaction rates will be determined. The reactions postulated are: 1, absorption of λ 2537 quanta by the mercury atoms in the gas mixture; 2, fluorescence of λ 2537 quanta followed by partial reabsorption to an extent depending on the mercury atom concentration; 3, reaction of Hg^3P_1 atoms resulting in dissociation of hydrogen; 4, collision of Hg^3P_1 atoms and hydrogen resulting in quenching of the Hg^3P_1 atoms but not resulting in dissociation of hydrogen. These processes may be written as

(1) $Hg^1S_0 + h\nu\ (\lambda\ 2537) \longrightarrow Hg^3P_1$
(2) $Hg^3P_1 \longrightarrow Hg^1S_0 + h\nu\ (\lambda\ 2537)$
(3) $Hg^3P_1 + H_2 \longrightarrow Hg^1S_0 + 2H + K.\ E.$
(4) $Hg^3P_1 + H_2 \longrightarrow Hg^1S_0 + H_2 + K.\ E.$

The removal of Hg^3P_1 atoms by Process (2) is greatly modified by reabsorption by the Hg^1S_0 atoms. It is desired that Process (2) represent the net fluorescence, *i.e.*, only those quanta that leave the reacting mixture should be counted as fluorescence. The remainder of the quanta are supplied for repetition of Process (1). It is seen from superficial examination of Fig. 3 that the number of quanta supplied for Process (1) by Process (2) may be of the order of eight times as great as that supplied directly from the lamp. The velocity constant for Process (2) is simply the Einstein "A" coefficient or the reciprocal of the mean life, τ, of the 6^3P_1 state, and this will be modified to represent the net fluorescence by multiplying by a factor which will be designated F (Hg^1S_0). This function of the concentration of Hg^1S_0, *i.e.*, F (Hg^1S_0), will have the characteristic that it approaches unity as the concentration of Hg^1S_0 atoms approaches zero, and it tends toward zero as (Hg^1S_0) becomes large. F(Hg^1S_0) may be defined as the mean probability that a quantum

of fluorescent radiation will escape reabsorption within the reaction system. It is of course a function of the size and shape of the reaction vessel as well as the mercury vapor pressure.

Reaction (3) represents the main feature of the Cario and Franck reaction, *i.e.*, a collision of the second kind with utilization of the energy of excitation of mercury atoms to supply the energy of dissociation of hydrogen.

It appears necessary to postulate reaction (4) to take into consideration the above-mentioned variance of σ_Q^2 and σ_D^2, and to develop a proper over-all kinetic expression to fit the data. Reaction (4) represents a process unspecified as to detail whereby mercury atoms lose their excitational energy at a rate proportional to the hydrogen pressure but the process does not result in a pressure decrease as would be expected if dissociation occurred. This proposed process would contribute to the over-all kinetics in somewhat the same manner as would failure of the apparatus to achieve complete clean-up of the H atoms by a factor proportional to the hydrogen pressure but this, as is discussed later, is not thought to be the case. Reaction (4) would, superficially at least, be considered improbable because of the larger (than reaction (3)) amount of kinetic energy developed. However, if the hydrogen molecule comes out of the collision in a high vibrational state, this kinetic energy term would not necessarily be much larger than the 0.3 e.v. of reaction (3).

One can write many other reactions which conceivably could occur under the conditions of this experiment. There is no doubt some production of Hg^3P_0 metastable atoms from collision of Hg^3P_1 atoms with Hg^1S_0 atoms or hydrogen molecules. The possibility was considered that the equivalent of reaction (4) might occur through conversion of Hg^3P_1 atoms to Hg^3P_0 atoms by collision with hydrogen if the Hg^3P_0 atoms were unable to react efficiently with hydrogen to give a pressure decrease. The results of Meyer[8] (which we have confirmed with monochromatic λ 2537) indicate that the Hg^3P_0 atoms can react with hydrogen. The effective cross section for the reaction may be quite low and still give the observed augmented reaction rate with nitrogen added because, with the great excess of nitrogen used, the diffusion time of the Hg^3P_0 atoms (formed by collision of Hg^3P_1 atoms with nitrogen) to the wall would allow a great many collisions with hydrogen. At the pressure conditions of the present work the Hg^3P_0 atoms would mostly reach the wall (if the Hg^3P_0–H_2 cross section were low). However, against this mechanism for reaction (4) is the fact that the first vibrational quantum of hydrogen is approximately 0.5 e.v. which leads one to expect low probability of conversion of Hg^3P_1 to Hg^3P_0 atoms which involves only 0.218 e.v.(see ref. (4), p. 450, or ref. (3), p. 225).

(8) Meyer, *Z. Physik* **37**, 639 (1926).

On the basis of Reactions (1) to (4) one obtains an expression for the rate $R = -\mathrm{d}(H_2)/\mathrm{d}t$ in terms of the constants, concentrations, and I_a, which is the number of quanta absorbed per (cc. $\times$ sec.). Noting that the quantum yield, $\phi = R/I_a$, one obtains the expression:

$$\frac{1}{\phi} = \frac{k_2 F(Hg^1S_0)}{k_3(H_2)} + \frac{k_3 + k_4}{k_3}$$

If the postulated mechanism fits the reaction, the data of Fig. 3 plotted as $1/\phi$ *vs.* $1/(H_2)$ should give straight lines with slopes $k_2F(Hg^1S_0)/k_3$ and a common intercept of $(k_3 + k_4)/k_3$. Figure 4 shows the data at the three hydrogen pressures plotted for seven values of pressure of mercury vapor. It is seen that the plots do give quite closely a family of straight lines with a common intercept. The intercepts lie between 4.0 and 5.5 with an average about 4.5 for $1/\phi$. Since Curve A, Fig. 4, is for $(Hg^1S_0) = 0$, the value of $F(Hg^1S_0)$ is unity and the slope of this curve, 1.96, is the ratio k_2/k_3. The value of k_2 is the Einstein "A" coefficient for the transition $6^3P_1 \rightarrow 6^1S_0$ and has the value $1/\tau = 1/1.07 \times 10^{-7}$, hence $k_3 = 1/1.07 \times 10^{-7} \times 1.96 = 4.77 \times 10^6$. This is the velocity constant for the reaction (3) in the postulated mechanism and this work constitutes, so far as we are aware, the only attempt at its measurement for this classic reaction. The above constant gives the rate at 30° in molecules of hydrogen per cc. decomposed per second per millimeter of hydrogen pressure per unit concentration of Hg^3P_1 atoms in atoms/cc. If the hydrogen concentration is expressed in molecules per cc. instead of millimeters of pressure, k_3 becomes $4.77 \times 10^6/3.20 \times 10^{16} = 1.49 \times 10^{-10}$. It is of interest to calculate the collision cross section from this constant and to compare with the result obtained previously. In the collision frequency expression Z may be set equal to k_3 when $n_{H_2} = 1$ and $n_{Hg^*} = 1$. The value of σ^2 is found to be 2.64×10^{-16} cm.^{2} as against 2.50×10^{-16} found from consideration of the intercepts of Fig. 3 and published values of σ_Q^2.

It has been pointed out that the intercepts of the lines on Fig. 4 on the $1/\phi$ axis average about 4.5 which is, according to the postulated mechanism, $(k_3 + k_4)/k_3$. The value of k_4/k_3 is 3.5 and $k_4 = 3.5 \times 1.49 \times 10^{-10} = 5.22 \times 10^{-10}$. One would expect so far as the extrapolation to infinite hydrogen pressure, *i.e.*, $1/(H_2) = 0$, is valid that the intercept value, 4.5, would agree with the σ_Q^2/σ_D^2 ratio. It is larger than the ratios obtained using either of the σ_Q^2 values previously mentioned (8.6 and 6.01×10^{-16} cm.^{2}) and σ_D^2 (2.64×10^{-16}) which give 3.3 and 2.3, respectively. Larger values of σ_Q^2 have been reported but are considered less reliable.[3] This discrepancy, if real, is perhaps explainable on the assumption of a collision-induced emission of λ 2537 (by hydrogen on Hg^3P_1 atoms) with the line sufficiently broadened to allow these quanta to escape reabsorption. These quanta would be quenched from the stand-

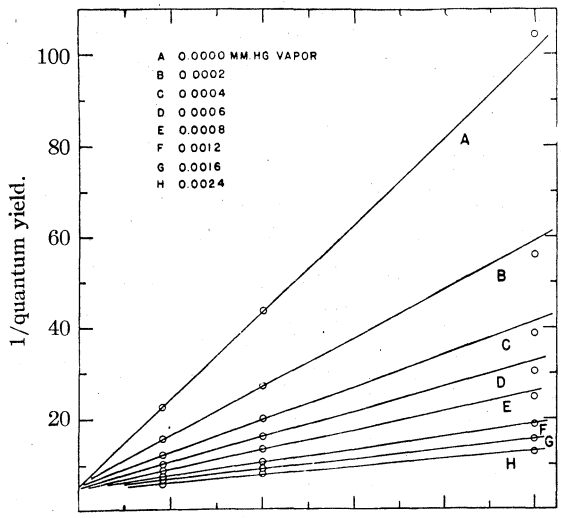

Fig. 4.

point of the present experiment but would show up as fluorescence in the quenching studies.

The ratios of the slopes of the lower lines of Fig. 4 to that of the upper line (A), for which $F(Hg^1S_0)$ is unity, are the values for $F(Hg^1S_0)$ for the various pressures of mercury vapor. These values are plotted in Fig. 5, Curve A. The ordinates of this curve are the probabilities, for the mercury vapor pressures in the particular vessel used, that a quantum of λ 2537 emitted as fluorescent radiation will escape reabsorption within the bounds of the vessel. The quantity $[1 - F(Hg^1S_0)]$ is then the probability that the fluorescent quantum will be reabsorbed, and, since the time spent by a quantum of energy as radiation is negligible compared to τ, the same quantity may be interpreted as the fraction of the quanta of energy, present in the system with the light source on, which are still present at the time, τ, after the light source is cut off. Also $[1 - F(Hg^1S_0)]^n$ is the fraction of quanta still in the system after $n\tau$. This leads to an exponential decay function for the intensity of radiation emitted after excitation is cut off and we may write approximately $I_t/I_0 = [1 - F(Hg^1S_0)]^n = e^{-\beta t}$ in which $t = n\tau$. The values of β calculated from $F(Hg^1S_0)$ are shown in Fig. 5, Curve C. It is possible to estimate β theoretically through a series of methods due to Milne, Zemansky, Samson, Kenty, summarized in reference (3), p. 228 *et seq.* It is necessary to consider a distance, l, through which the radiation must diffuse which we have estimated as 1.125 cm., the radius of the reaction vessel. The values of β so calculated are shown in Curve B, Fig. 5. The experimental values from $F(Hg^1S_0)$ deviate an average of 10% from the calculated values over the range of mercury vapor pressures shown. The agreement is of about the same order as that obtained by comparison of direct measurements of β with the calculated values.[3] Such close agreement must be regarded as fortuitous but the fact that it was possible to arrive, through treatment of the data of this paper, at the $F(Hg^1S_0)$ values which are consistent with existing theory and experiment applied to the "imprisonment" of resonance radiation in the strictly physical (not chemically reacting) system, mercury vapor, seems to support the essential validity of the data and its treatment.

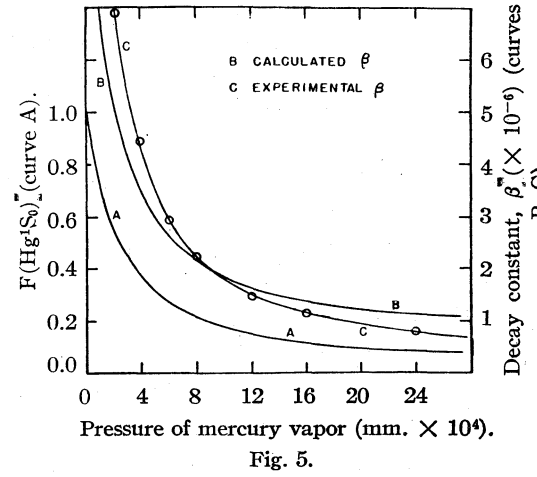

Fig. 5.

We have carried through an application of Milne's theory of the diffusion of "imprisoned" resonance radiation to calculate the number of Hg^3P_1 atoms present in the system and thence the rate of disappearance of hydrogen, *i. e.*, Curve B, C, D, Fig. 2. The expression for the rate involves two effective cross sections, one for reaction (3) of this paper and the other for over-all quenching of Hg^3P_1 atoms by H_2. It is found that rate curves of the general characteristics of B, C, D, Fig. 2 are obtained and that quantitative agreement with experiment is much better if the σ_D^2 and σ_Q^2 values 2.5×10^{-16} from this work and 8.6×10^{-16} cm.^{2} from ref. (3) both are used than if either value is used as the sole cross section involved.

The question arose in conversation with J. Franck as to the possibility that these experiments might be used to distinguish between the two proposed mechanisms involving direct dissociation of hydrogen molecules as against formation of mercury hydride in the process. If one assumes that the hydrogen in the mercury hydride is not cleaned up and is eventually returned as hydrogen to the gas and if one assumes that no other quenching processes than one of the two proposed are involved, a study of the quenching externally and hydrogen removal internally should be able to distinguish between the two mechanisms. One quantum per hydrogen molecule disappearing would be quenched in the first case and two quanta in the second case. Quenching measurements have been made giving an estimated quenching, averaged over the surface of a sphere concentric with and about the cylinder, of

3.5 times the quantum yield observed internally. This is again a measure of σ_Q^2/σ_D^2 and constitutes further confirmation that one or more other quenching processes than that resulting in hydrogen removal is in preponderance. It seems doubtful then that the two mechanisms can be distinguished by this means.

An important assumption upon which the validity of much of the interpretation of the data of this paper rests is that the cleanup of the supposed atomic hydrogen produced is complete. This would be a very difficult assumption to demonstrate conclusively by experiment but we have little doubt of its validity because of the evidence presented below. As mentioned in the **Experimental** section of this paper, all of the data presented were taken at the limiting condition of maximum rate following reoxidation of the copper and thorough outgassing of the vessel. The reproducibility and consistency of the data is in itself strong evidence of the essential completeness of the cleanup. It would be difficult to imagine a kind of adsorption process at the silicon dioxide and cupric oxide surfaces which consistently returned a constant fraction of the reaction products as hydrogen to the gas phase. The following experiment substantiates the assumption of complete clean-up. The reaction was carried out in a fused silica cell without any cupric oxide in it. The rate of reaction as observed on the Pirani gage under constant conditions (except for the inside walls) falls gradually to zero when the walls can no longer remove the products and complete recombination of hydrogen atoms then occurs. The rate becomes practically zero when amounts of hydrogen of the order of 100-fold those used in taking the data of this paper were consumed. When the reaction cell with its cupric oxide lining cylinder is used in a similar attempt to exhaust the capacity for removal of the reaction products it is found that the rate falls off less rapidly than in the former case and becomes flat at a fraction of the initial rate which agrees to within a few per cent. with the fraction of the internal area of the vessel which consists of cupric oxide. (These experiments were carried out with the mercury vapor pressure low in order to spread the reaction more uniformly through the vessel.) (One might be tempted to attribute the sustained behavior with cupric oxide to the steady conversion of hydrogen to water, hence due to the smaller heat conductivity of water, the Pirani gage would show a pressure decrease. However, the accommodation coefficients and C_V values of hydrogen and water are such that in the "free molecule" heat conduction range here applicable, water is 40% more effective than hydrogen in heat conduction from bright platinum.[9]) The interpretation then that we place on the above experiments is that both silicon dioxide and cupric oxide have the same initial efficiencies of removal of the reaction products and this is very unlikely unless both efficiencies are unity. That cupric oxide has sustained, constant efficiency is found in the extensive work done in this laboratory with the electron initiated mercury sensitized decomposition of hydrogen in which the reaction region is more completely surrounded with oxidized copper surface and the initial rates are maintained longer than with the silica, copper oxide cell. The electron work shows constancy of clean-up efficiency with varying reaction rate and with varying mercury pressure, complete quantitative reproducibility of data, and is entirely consistent with the assumption of complete clean-up efficiency.

Lastly, mentioned in connection with completeness of cleanup and general validity of the quantum yield measurements, an independent check was made of four points on Fig. 3. A new vacuum and gas handling system, new Pirani gage and electrical measuring system with new calibrations, new reaction cell with reaction volume more completely surrounded with cupric oxide, and a new photocell were used and the uranyl sulfate–oxalic acid actinometer, following the specifications and general procedures of Leighton and Forbes, was used to determine the lamp intensity. The quantum yields at each hydrogen pressure with mercury at 0° and with hydrogen at 0.11 mm. and mercury at 24° were determined. The four new values of ϕ averaged 1.5% (of ϕ) higher than the four original values with a maximum discrepancy of 5.5%, *i. e.*, a ϕ of 0.036 became 0.038 in the new determination.

Summary

The quantum efficiency of the Cario and Franck mercury sensitized decomposition of hydrogen with λ 2537 has been investigated as a function of mercury and hydrogen pressures. On the basis of the postulated mechanism the velocity constant and the effective cross section are determined for the interaction of Hg^3P_1 atoms and hydrogen resulting in disappearance of hydrogen from the gas phase, presumably through dissociation and removal of the resulting hydrogen atoms on cupric oxide or silicon dioxide walls. The contribution of the reabsorption of fluorescent radiation to the efficiency is singled out and from this the time decay constant of λ 2537 from pure mercury vapor in the reaction vessel after excitation is cut off is calculated and compared with physical theory and measurement. The evidence from several aspects indicates consistently that other quenching processes than that resulting in removal of hydrogen are effective and that the rate of quenching of Hg^3P_1 atom is several times as great as the rate of removal of hydrogen from the gas.

The Solubility of Quartz in Sodium Carbonate Solutions at High Temperature

BY I. I. FRIEDMAN[1]

This work was undertaken as a preliminary investigation of the system at 300, 350, 400 and 450°, and is restricted to solutions in equilibrium with quartz.

To define completely this system at the liquidus it would be necessary to fix three independent variables. The usual variables which are experimentally controllable are the temperature and two others, such as total pressure, the partial pressure of one of the components of the vapor, and the liquid or vapor composition. The apparatus available did not permit sampling the liquid or vapor phases, nor was it possible to get accurate pressure measurements. However, while the following data do not define the system completely, they provide a valuable preliminary basis for such investigations.

Experimental

The runs were made by placing weighed blocks of quartz in 18-ml. pressure bombs together with weighed amounts of sodium carbonate, pipetting in 10 ml. of distilled water, sealing the bombs and allowing them to remain at a predetermined temperature. The bombs were continuously rocked to provide agitation. Further details of the equipment are given in a previous paper.[2] After equilibrating for from forty to one hundred and fifty hours, the bombs were removed from the furnaces and quenched by directing a stream of cold water onto them.

The sodium carbonate was reagent grade, and was dried at 120° for several hours. Quartz slabs (2.5 × 1.5 × 0.5 cm.), cut from piezo-electric grade natural quartz were used throughout.

Results and Discussion

It was noted in many runs at 400° and in all runs at 450° that considerable pressure was released upon opening the bombs after quenching. Evidently at these temperatures silica displaces carbon dioxide from the sodium carbonate, resulting in a high partial pressure of carbon dioxide in the vapor. This parallels the results of Morey and Fleischer[3] in the system K_2O–SiO_2–H_2O–CO_2, who found that the distribution ratio of carbon dioxide between the liquid and vapor increased in the direction of the vapor at 500° and K_2O–SiO_2 ratios above 1:1.

As a check on the solubility curves many runs were equilibrated at 450° and slowly cooled to various temperatures from 425 to 300°. They were then allowed to equilibrate at the lower temperature and quenched. In all cases all of the excess quartz recrystallized on the remains of the original quartz block. This indicated that: (1) The curves represent true equilibrium values; (2) Quartz can be grown from sodium carbonate solutions by slowly cooling a saturated solution of quartz in sodium carbonate in contact with a quartz seed plate.

Figure 1 shows the solubility of silica in sodium carbonate solution as a function of sodium carbonate concentration at various temperatures. The spread of experimental points, particularly at 450° can be explained by the high temperature dependence of the solubility at the higher temperatures. The bombs that were used varied slightly (5% max.) in the size of the chamber. This variation in the degree of filling would also contribute to the error.

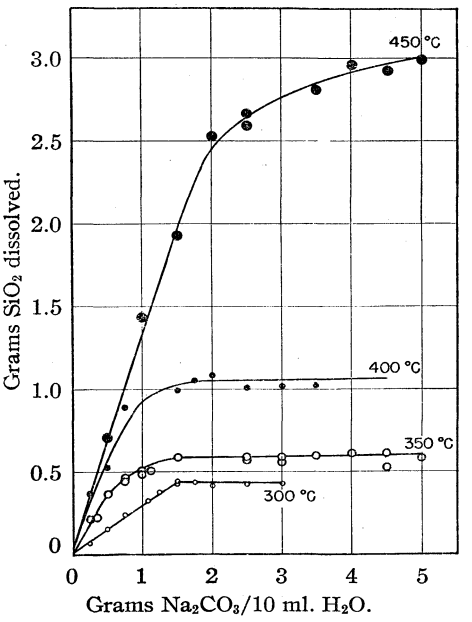

Fig. 1.

The leveling off of the solubility curves with increasing sodium carbonate concentration might be due to the formation of a solid phase containing sodium oxide. Sodium carbonate crystals were found in most runs, but it is not clear if the crystals formed during the quench or represent a stable solid phase at the temperature of the runs.

Upon opening the quenched runs a hard water-soluble glass was found in most of the bombs in addition to the liquid and crystalline phases. The glass was not found in runs made at 300° that contained less than 1.5 g. of sodium carbonate, nor was it observed in runs made at 450° that contained over 3.5 g. of sodium carbonate. These glasses are similar in character to the glasses observed in the Na_2O–SiO_2–H_2O system,[2] and can be assumed to have been liquid at the temperature of the runs. It seems quite probable that the liquid immiscibility reported in the Na_2O–SiO_2–H_2O sys-

tem extends into the Na_2O–SiO_2–H_2O–CO_2 system. However the correctness of this assumption will have to be checked by a more elaborate investigation of this system.

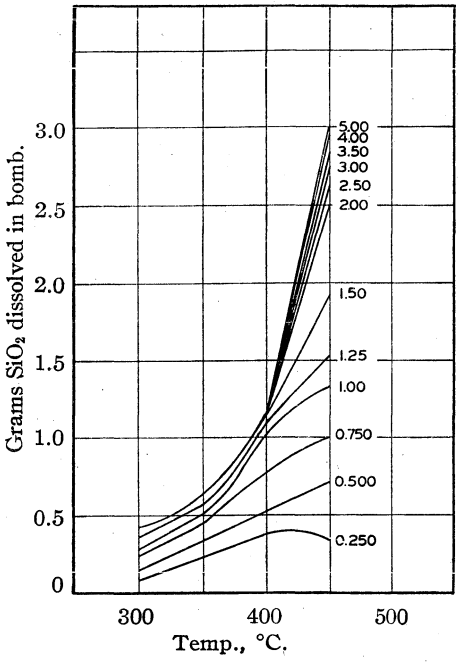

Fig. 2.

As can be seen from Fig. 2, this system would be a desirable one from which to grow quartz. The steep slope of the Solubility *vs.* Temperature curve would be favorable for growing quartz by the temperature lowering as previously stated, while the low solubility of quartz in sodium carbonate solutions as compared to its solubility in sodium hydroxide solutions, as shown in Table I, suggests that carbon dioxide might be used to displace quartz from sodium hydroxide solutions at constant temperature.

	15	560	285

The author again wishes to emphasize the preliminary nature of the present paper. Much careful experimentation remains to be done before our understanding of equilibrium in multicomponent systems containing volatile and non-volatile components can be extended very far.

The assistance rendered by Mr. Charles Jackson was of great aid in carrying out the experimental work.

Heats of Combustion of Some Organic Nitrogen Compounds

BY D. J. SALLEY AND J. B. GRAY[1]

The need for accurate values of heats of combustion for thermodynamic calculations has often been emphasized, and the lack of such data seems especially noticeable for organic compounds containing nitrogen. We therefore record here heats of combustion, determined with relatively high accuracy, of eight such compounds: cyanamide, dicyandiamide, melamine, 3-cyanopyridine, phthalonitrile, dimethylol urea, diisopropyl cyanamide, and diisopropyl carbodiimide.

Experimental

Apparatus and Procedure.—The bomb calorimeter used was modeled after that of Dickinson,[2] being a replica of that of Huffman and Ellis,[3] and of Richardson and Parks[4]; the calorimeter was in fact made in the shops of the California Institute of Technology.

The samples were burned in a Parr bomb (380 ml. capacity), containing initially 1 ml. of water and commercial tank oxygen at 30 atm. pressure at about 24°. The air was usually flushed out by two fillings with oxygen to 15 atm. pressure when solid samples were burned, but no flushing was made with liquids. The weight of water for the calorimeter, usually 2770 g., was measured to 0.05 g. on a high capacity balance.

Pellets of solid samples were weighed in a platinum crucible to 0.05 mg. on an analytical balance, after they had been kept in a desiccator over phosphorus pentoxide for several days. As far as is known, the compounds are not hygroscopic (except cyanamide, discussed below), and no changes in the heats of combustion with drying times of three to ten days were noticed. For liquids, thin-walled soft glass ampoules were completely filled by means of a fine hypodermic syringe, through a single stem, which was then sealed off. The liquids were not freed of any dissolved air.

Either of two methods of firing the sample have been employed, the platinum wire-string fuse of Richardson and Parks,[4] or the usual iron wire. In the former, the electrical energy (*EIT*) introduced was obtained by accurate measurements of voltage, current, and time. These

were facilitated by an auxiliary circuit so arranged that on closing the switch to fire the charge the current reached a steady value within a small fraction of the firing time. Nearly identical current and time conditions were maintained from run to run, and the *EIT* introduced was checked frequently by direct measurement of the rise in temperature of the calorimeter in blank runs. The string, conditioned and weighed at 73° F. and 50% R. H., had a heat of combustion of 3950 calories per gram. The energy correction when an iron wire fuse was employed was determined by independent measurement of the temperature rise produced by the burning fuse alone in blank runs.

The temperature rise in the calorimeter was measured by a platinum resistance thermometer calibrated by the Bureau of Standards, a Mueller resistance bridge, and a high sensitivity galvanometer. A change of 0.00003 ohm (0.0003°) in the resistance of the thermometer caused a shift of 1 mm. in the reflection from the galvanometer mirror on the scale. The galvanometer was used as a null instrument, the time at which a predetermined resistance was reached being recorded on a drum-type chronograph which was precise to 0.1 sec.

Two methods of determining the corrected temperature rise have been employed, that described by Dickinson,[5] and that by Eckman and Rossini.[6] When using the former method, the jacket was at 25°, and in the latter at 26.1°. In either case the initial temperature of the run was so arranged that the average temperature of the combustion was 25 ± 0.1°. Jacket temperatures were maintained constant to at least 0.001°.

The nitric acid produced in the combustion was determined by titration with standardized alkali using brom cresol green as the indicator. The thermal correction was calculated on the basis of $\Delta H_R = -15{,}070$ cal./mole,[7] which yields 13,950 cal. evolved for one mole of aqueous acid formed in the bomb process. For all the nitrogen compounds the nitric acid correction was relatively high, 0.3 to 0.7% of the total heat involved, and a change of 1000 cal. in the value of 13,950 cal. for nitric acid formation can effect changes of 0.02 to 0.05% in the final figures for the heats of combustion.

Units.—The unit of energy used is the defined calorie = 4.1833 int. joules. The unit of mass is the gram true mass derived from the weight in air against brass weights. The appropriate buoyancy correction depends on the density of the substance and this was obtained from the literature or measured independently. 1947 atomic weights[8] were used in calculating molecular weights.

Calibration.—The calorimeter was calibrated by burning benzoic acid (Bureau of Standards standard sample 39f; heat of combustion 26.4284 int. kj./g.) under conditions meeting as closely as possible the standard calorimetric conditions specified by the Bureau of Standards. Deviations from the specifications were so small as to require an entirely negligible change (0.003%) in the NBS value for the benzoic acid. Table I presents some early determinations which were carried out using the platinum wire-string fuse for firing, and the Dickinson procedure for correcting the temperature rise. The figures recorded are the experimental values of the energy equivalent of the bomb and contents. These runs give an indication of the precision of the experimentation; the calibration error shown is calculated according to Rossini.[9] Numerous calibrations made from time to time have shown an even better degree of precision. No marked advantage in precision has been found between the various procedures tested.

Materials.—All of the compounds were purified by various members of these Laboratories or of the Calco Chemical Division of the American Cyanamid Company, and analyses were made by our Analytical Department. Nitrogen analysis was obtained in several instances, but since it is not a very good criterion of purity with these compounds, whenever possible, analytical procedures or other means of characterization specific for the compound in question were employed.

Cyanamide.—Free cyanamide was recrystallized from ether, then vacuum distilled at whatever pressure was obtainable with a mercury pump when the melt was held at 80° and the distillate was trapped at 0°. Ampoules of the material, filled as described in the following, showed only a trace of dicyandiamide, the only likely impurity.

The handling of cyanamide deserves special mention. This material is a solid melting at about 41°, but its hygroscopic and corrosive nature precludes pelleting. However, its low melting point allowed it to be handled as a liquid. The door of an electric oven was fitted with two sleeves ending in rubber gloves. Trays of Drierite and Ascarite were placed in the oven to absorb water vapor and carbon dioxide. The temperature was kept at 50–60°. A hypodermic syringe and glass ampoules were placed in the oven several hours before use. The cyanamide, in an evacuated flask, was melted rapidly under a steam jet, then opened inside the oven. A glass tube having a fitted ground joint was substituted for the needle, and the molten material quickly drawn into the syringe; the needle was then replaced for filling the ampoules. Since the rather high viscosity of the melt made the expulsion of the liquid through the fine needle difficult, it was convenient to clamp the syringe firmly in a small stand which also carried a small adjustable platform on which the ampoule rested. After filling all the ampoules they were removed from the oven one by one and sealed off. Since supercooling often took place, each bulb was chilled with a piece of ice to induce crystallization. In the molten state cyanamide converts slowly to dicyandiamide so that all the operations were carried out as rapidly as possible. To insure consistent firing of these samples

when using the iron wire method, small weighed disks of filter paper (0.011–0.012 g.; heat of combustion, 3992 cal./g.) were stuck to the ampoule by a tiny smear of water glass. This technique of handling hygroscopic solids has been used satisfactorily with other such materials of sufficiently low melting point.

Dicyandiamide.—Commercial material was twice recrystallized from water. Nitrogen analysis showed 66.54%, indicating a purity of 99.82%.

Melamine. This sample was purified by recrystallization from dilute sodium hydroxide. Specific analysis for melamine showed it to be 99.7% pure, free of ammeline and ammelide, with less than 0.01% ash.

3-Cyanopyridine.—This compound, prepared from 3-bromopyridine by reaction with cuprous cyanide, was twice redistilled. The product of the second distillation boiled constantly at 98° at 23 mm. and melted at 49–50°. The nitrogen analysis was: found 26.66%, theoretical 26.90%.

Phthalonitrile.—A commercial material was purified by recrystallization from alcohol; m. p. 138.5–140°. Nitrogen analysis was 21.65% *versus* 21.87% theoretical.

Dimethylol Urea.—This compound was recrystallized from 75% alcohol. It showed a m. p. of 137–139° with decomposition. Nitrogen analysis was 23.18% found, 23.33% theoretical.

Diisopropyl Cyanamide and Diisopropyl Carbodiimide.—Both of these compounds were purified by several fractional distillations. The former boiled at 75° at 5 mm., the sample being a middle cut. The latter boiled at 25 mm., a middle cut being taken; infrared examination showed that it conformed to other samples of high purity.

Data

As a typical example, Table II presents the experimental data for the heat of combustion runs on melamine. The Rossini method of correcting for the temperature rise was followed in this case, K and U being the heat leak corrections. The calorimeter calibration had also been done using this method. ΔR_i is the ignition correction (*EIT* and string), and ΔR_n is the correction for the nitric acid formed. These quantities as well as the temperature rise R, are in ohms, while the energy equivalent obtained in calibration runs is stated in cal. per ohm. The quantity, $-\Delta U_{B/m}$, in this and the following table, represents the heat evolved per gram in the isothermal bomb process at 25°. Correction to the isothermal reaction using known or estimated specific heats was negligible, being in all cases less than 0.01%.

Reaction error ±0.021%; precision error ±0.028%. Energy equivalent of calorimeter 31777.1 cal./ohm.

In Table III there are collected the data on the eight compounds burned. The headings are self-explanatory, except perhaps that of the seventh column. This is the "precision error" calculated using an assigned error of 0.010% for the heat of combustion of benzoic acid, a "calibration error" of 0.016%, and the "reaction error" that obtained in each case. The Washburn correction[10] involved in calculating ΔU_R was derived on the basis that the ternary mixture of nitrogen, oxygen, and carbon dioxide behaved like the binary mixture, oxygen and carbon dioxide; we are indebted to Mr. A. B. Bestul for these calculations. The heats of formation of the compounds from the elements, ΔH_f, were calculated using 94,051.8 and 68,317.4 cal./mole for the heats of formation of gaseous carbon dioxide and of liquid water,[11] respectively.

Discussion

The precision of the calorimetric procedure, as indicated by the calibration runs, appears to be entirely satisfactory. This is further borne out by the fact that equally good results have been obtained with other non-nitrogen compounds (not published). However, the results with the nitrogen materials have never reached the same precision. This may have been due to irregularities in the course of the combustion process. Some support for this view is provided by the fact that ignition difficulties were often encountered, and that incompleteness of combustion (as evidenced by carbon deposition) was rather frequent. It seems evident that to obtain highest precision the combustion process for nitrogen compounds would require detailed study, and that direct determination of carbon dioxide and the nitrogen oxides

would be necessary. In the present work, no direct test for completeness of combustion by measurement of carbon dioxide or carbon monoxide formation was made on any of the compounds.

The accuracy of the values reported here is almost certainly poorer than the precision of the determinations, since the purity of the samples—in spite of the effort to obtain high-grade materials—probably is the limiting factor. The compounds were all taken as 100% pure even though in some instances the analysis throws some doubt on this, and in the case of the liquids no attempt was made to correct for any dissolved gases. This appears to be the best policy to follow, first, because the significance of the analysis may be questioned and, second, because the kind and amount of impurity is indeterminate. The cyanamide, dicyandiamide and melamine figures are considered to be the most reliable in this respect.

The heats of combustion of cyanamide, dicyandiamide and melamine were measured by Lemoult,[12] his figures being 171.6, 328.7 and 469 kcal./mole, respectively. These values are nominally 5.6, 3.2 and 2.8 kcal./mole lower than those obtained here. Since the corresponding heats of formation have rather low absolute values, these differences naturally result in large percentage differences between the old and new heats of formation. The present values are considered to be the more trustworthy. No values have been located in the literature for the other substances.

Acknowledgment.—Acknowledgment is made to Mr. P. Adams, Dr. P. R. Averell, Dr. I. Heckenbleikner, Dr. R. F. Stamm, and members of the Analytical Department of these Laboratories for the preparation, purification, and analysis of the compounds used, and to the Directors of these Laboratories for permission to publish these results.

Summary

A bomb calorimeter, calibrated with benzoic acid, has been used for determining the heats of combustion of eight organic nitrogen compounds at 25° and constant volume. From these data, the corresponding heats of combustion and of formation at constant pressure have been calculated. The substances burned were cyanamide, dicyandiamide, melamine, 3-cyanopyridine, phthalonitrile, dimethylol urea, diisopropyl cyanamide, and diisopropyl carbodiimide.

Some Amides and Esters of Fluoroacetic Acid

BY J. C. BACON, C. W. BRADLEY,[1] E. I. HOEGBERG, PAUL TARRANT[2] AND J. T. CASSADAY

The toxicity of certain derivatives of fluoroacetic acid to insects and rodents was established in these Laboratories several years ago and has led to the synthesis of additional compounds of this type.

The problem of preparing economically a simple derivative of α-fluoroacetic acid to be used as a starting material for the rest of these syntheses was solved by the discovery of a method for converting chloroacetamide into fluoroacetamide by reaction with potassium fluoride. This method is discussed below. The literature[3-5] has subsequently indicated that during the course of our investigations methods were simultaneously in the process of development in England, Poland, and elsewhere in the United States for the large-scale production of methyl, ethyl and sodium fluoroacetates, the latter being known as rodenticide "1080." Analytical methods have been reported[4] for the determination of extremely small traces of fluorine in these and similar types of materials and reports[6,7] have also been published covering the effect of "active" fluorine compounds on warm-blooded animals.

Numerous unsuccessful attempts were made to replace the chloro group of chloroacetic acid and ethyl chloroacetate using hydrogen fluoride alone or in combination with antimony trifluoride.

Fluoroacetamide was finally prepared by the reaction of chloroacetamide with potassium fluoride. A mixture of the fluoro- and chloroamides was obtained both by dry distillation under reduced pressure and by distillation at atmospheric pressure using xylene as a carrier. The yields of fluoroacetamide based upon the chloroacetamide consumed were greater than 50%. The mixture of amides was converted into a

mixture of ethyl chloro- and fluoroacetates by the use of ethanol and hydrogen chloride or sulfuric acid, and the combined esters were separated by fractional distillation. The pure ethyl fluoroacetate was then converted by customary methods into other esters or amides.

A similar conversion of ethyl bromoacetate into the corresponding fluoro ester was effected by refluxing with potassium fluoride or, in lower yield, with thallous fluoride. The use of bismuth trifluoride produced none of the desired ester.

Since potassium fluoride had proved useful in the production of fluoroacetamide from chloroacetamide as outlined above, other fluorides were tested. Sodium fluoride, when tried in the fusion method for the production of the amide and in the attempted conversion of ethyl bromoacetate to the fluoroacetate, gave none of the desired products. When ammonium fluoride was used in the fusion method, a small amount of fluoroacetamide was isolated.

Another relatively economical material, ammonium glycolamide sulfate, has been converted into fluoroacetamide by fusion with potassium fluoride.[8]

Experimental

The Preparation of Fluoroacetamide from Chloroacetamide

A. Dry Fusion Method.—Chloroacetamide, 187 g. (2.0 moles), and anhydrous potassium fluoride, 200 g. (3.5 moles), were ground together in a ball mill for two hours. The reagents were placed in a one-liter three-necked flask and heated with a Glas-Col mantle. The reaction was carried out at a pressure of about 25 mm. produced by a water pump. When the temperature of the mixture reached 130°, distillation began and continued until 121 g. of solid condensed in the receiver. This material, based on a fluorine analysis, appeared to be 82.2% fluoroacetamide, a yield of 64.5%.

B. Inert Carrier Method.—A method for preparing fluoroacetamide in xylene has been described by one of the authors.[9] Although the yield (55%) was somewhat lower than that obtained in the dry fusion method, a purer product was obtained. The use of tetrachloroethylene (b. p. 121°) instead of xylene resulted in a slightly lower yield of product.

The Preparation of Ethyl Fluoroacetate Using Potassium Fluoride.—Ethyl bromoacetate, 110 g. (0.66 mole), and 75 g. (1.32 moles) of anhydrous potassium fluoride were placed in a 500-ml., round-bottomed flask equipped with a 12″ Vigreux column and a variable take-off fractionating head. The column was maintained under total reflux until the vapor temperature reached 120°, whereupon the ethyl fluoroacetate was stripped off. Heating was continued for sixteen hours, during which time 59 g. of distillate was collected. Refractionation gave 32 g. (45% yield) of ethyl fluoroacetate, b. p. 117.5°.

The Preparation of Ethyl Fluoroacetate Using Thallous Fluoride.—Ethyl bromoacetate, 60 g. (0.36 mole), thallous fluoride, 72 g. (0.32 mole), and ethanol, 50 ml., were placed in a round-bottomed flask with a reflux condenser and heated on a steam-bath for twenty-eight and one-half hours. At the end of this period the mixture was filtered and the liquid distilled under reduced pressure. A refractionation gave 5 g. (13% yield) of ethyl fluoroacetate, b. p. 115.5–118°.

The Esterification of Crude Fluoroacetamide.—The esterification of fluoroacetamide was carried out by allowing it to react with ethanol in the presence of enough acid to neutralize the ammonia formed. A typical example of an experiment using gaseous hydrogen chloride as the neutralizing agent follows:

The esterification of the crude amides prepared from a mixture of chloroacetamide and potassium fluoride in a 1:2 ratio was carried out in a two-liter, three-necked flask equipped with reflux condenser, stirrer and inlet for hydrogen chloride. The hydrogen chloride was passed slowly into a mixture of 462 g. of crude amide and 328 g. (410 ml.) of absolute ethanol. During the first two hours 90 g. of hydrogen chloride was absorbed; 200 g. was added during the next hour. The mixture was then allowed to stand for about thirty-six hours.

The slurry of ammonium chloride and esters was centrifuged and the solid washed with 75 ml. of ethanol. The filtrate and wash solutions were treated with about 400 ml. of saturated calcium chloride solution. The organic layer was separated and washed with 400 ml. of a saturated sodium bicarbonate solution and again with a calcium chloride solution. The product was dried with anhydrous sodium sulfate and distilled at atmospheric pressure through a 24″ column packed with glass helices, giving 272 g. of ethyl fluoroacetate boiling at 115.5–120° and 133 g. of ethyl chloroacetate. Since analysis had shown the crude amide to contain 64.7% fluoroacetamide and 32.9% chloroacetamide, the conversions of the two amides to the corresponding esters were 66 and 67%, respectively.

It was later found that sulfuric acid could be substituted for hydrogen chloride without decreasing the yield of ethyl fluoroacetate. Although the recovery of ethyl chloroacetate was not complete, the ease with which the reaction could be carried out offset this disadvantage.

Preparation of Purified Fluoroacetamide.—Fluoroacetamide was prepared from ethyl fluoroacetate and aqueous ammonia by a method analogous to one commonly used for the preparation of chloroacetamide.[10] However, presumably because of the more stable fluorine atom in the molecule, the yields were usually 90% or better. Several small batches were synthesized to give a total of 457 g. melting at 107–108°.

Ammonium Glycolamide Sulfate.—Anhydrous glycolonitrile was added gradually with vigorous stirring to an equimolecular quantity of 100% sulfuric acid below 60°; then the reaction mixture was added to a slight excess of aqueous ammonia with cooling.[11] Because the reaction product of glycolonitrile and sulfuric acid often solidified immediately to a hard cake, a modification of this procedure was also used, whereby anhydrous glycolonitrile (114 g., 2 moles) was added gradually at 55–65° to 95.5% sulfuric acid (392 g., 3.8 moles) with mechanical stirring. The viscous, liquid reaction mixture was then added with ice-bath cooling to a slurry of powdered calcium carbonate (200 g., 2 moles) in 28% aqueous ammonia (750 ml., 11 moles), and the reaction mixture was allowed to stand for about twelve hours, followed by warming to 80° for one-half hour to insure complete reaction. The calcium sulfate was removed by filtration and the filtrate was concentrated under water pump vacuum to a small volume, cooled and filtered to give 402 g. of ammonium glycolamide sulfate contaminated with a little ammonium sulfate. Recrystallization of the crude product from hot water gave a purified product as colorless crystals melting at 183–185° (cor.).

Anal. Calcd. for $C_2H_8N_2O_5S$: N, 16.4; SO_4, 55.8. Found: N, 16.3; SO_4, 56.3.

Conversion of Ammonium Glycolamide Sulfate to Fluoroacetamide.—Ammonium glycolamide sulfate (180 g., 1.05 moles) and potassium fluoride (116 g., 2 moles) were mixed in a ball mill for three hours, during which time some ammonia was liberated. The resulting powdered mixture was placed in a one-liter, two-necked distilling flask equipped with a thermometer and air conden-

[a] Prepared by Procedure A. [b] Prepared by Procedure B; synthesized by a different method by C. C. Price and W. G. Jackson, PB 5904 (1946); THIS JOURNAL, **69**, 1065 (1947). [c] Corrected. [d] Crude yield; m. p. of purified sample checks with that of Price and Jackson. [e] Difficulties were sometimes encountered in obtaining fluorine analyses which checked closely.

ser. The flask was heated under reduced pressure with the temperature maintained below 200°. Twenty-nine grams of solid sublimed from the mixture at a vapor temperature of about 140°. The crude solid was recrystallized from ethanol to give 20 g. (25% of the theoretical) of fluoroacetamide, m. p. 104°.

Esters of Fluoroacetic Acid.—Esters of greater chain length than ethyl were prepared by heating ethyl fluoroacetate (usually in about 5% excess) with an equivalent amount of the higher alcohol to 100–170° in the presence of a trace of *p*-toluenesulfonic acid as catalyst, and distilling the liberated ethanol as it was formed, thus driving the reaction to completion. Two or three hours were normally required. The reaction product was washed with saturated sodium bicarbonate solution, dried over calcium sulfate, and distilled. Examples of esters prepared by this method are listed in Table I.

Amides of Fluoroacetic Acid.—Either of two procedures was used: **Procedure A.** Ethyl fluoroacetate was heated with an equivalent amount of the proper amine to 100–160° until approximately the theoretical amount of ethanol had been distilled off and measured. The reaction product was purified by distillation if a liquid, or by recrystallization from heptane if a solid. **Procedure B.** Fluoroacetamide and the proper amine were heated in equivalent amounts in glacial acetic acid on a steam-bath for about three hours, then thrown into excess cold water and separated. The crude product was recrystallized from aqueous ethanol for purification.

Several of the amides prepared are listed in Table II.

Acknowledgment.—We are indebted to the Analytical Laboratories for the analyses shown above, to the Chemotherapy Division for preliminary toxicological data, and to the Agricultural Chemicals Laboratories for numerous insecticidal evaluations as well as to Drs. R. C. Swain and J. T. Thurston who offered considerable helpful advice during the course of this problem.

Summary

1. Some new methods for the preparation of fluoroacetamide are described. Two convenient methods for the preparation of N-substituted fluoroacetamides are also given.

2. Three new amides and one new ester of fluoroacetic acid are listed.[13]

Polyalkylbenzenes. XXXIV.[1] The Reaction between Polymethyl-*p*-methoxyanilines and Formaldehyde

BY LEE IRVIN SMITH AND W. M. SCHUBERT[2]

If the reaction between formaldehyde, hydrochloric acid, and a polymethyl-*p*-aminophenol or some derivative of it (I, II, III) could be controlled in such a way that simple chloromethylation resulted, the products, such as IV, would be of great value as starting materials for synthesis of 6-hydroxytetrahydroquinolines, the nitrogen analogs of the tocopherols. The reaction between simple

aromatic amines and formaldehyde, under a variety of conditions has been rather extensively studied[3]; in general, when the *p*-position of the aromatic amine is occupied by a substituent, the primary products have included *o*-aminobenzylanilines, *o,o′*-diaminodiphenylmethanes, and substances produced from these by further action of formaldehyde: hydroxytetrahydroquinazolines, dihydroquinazolines, tetrahydroquinazolines, the N-methyl derivatives of the original amines, and "Troeger's base," the last type obtained only from *p*-toluidine, *p*-anisidine, and *p*-phenetidine.

When either 2,3,5-trimethyl-4-methoxyaniline (I) or its formyl derivative (II) was subjected to the action of formaldehyde and hydrochloric acid at room temperature for some sixty hours, it was converted in a yield of 86%, into a basic compound, A. Two other basic compounds, B and C, resulted when dilute hydrochloric acid was used and the time of the reaction was reduced. No compounds corresponding to IV were even obtained.

Base A was isolated from the reaction mixture as the hydrochloride, which could not itself be recrystallized, for it was insoluble in non-polar solvents, and solvolyzed in polar solvents. The free base A, however, was easily purified and the analytical values and molecular weight of it and of its hydrochloride showed that two molecules of amine, and two or three molecules of formaldehyde, were involved in the formation of A. On the basis of the analytical values, and in analogy with previous work described in the literature, four structures for A had to be considered: the azomethine dimer V; the tetrahydroquinazoline VI; the dihydroquinazoline VII; and the "Troeger's base" VIII.

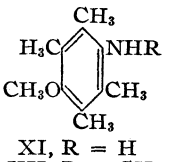
X



XI, R = H
XII, R = CH_3

Base A failed to react with acetic anhydride and sulfuric acid at 100°, and was unaffected by the action of sodium and alcohol, of stannous chloride and hydrochloric acid, or of hydrogen in the presence of Raney nickel catalyst. Moreover, base A was unchanged by boiling alcoholic sodium hydroxide, and when boiled in hydrochloric acid and acetic acid, the only effect was a partial cleavage of the methoxyl groups to hydroxyl groups (VIIIa). These properties showed that no amino hydrogen atom was present in A, and that the grouping —N=C was also absent; the structure VIII for A was strongly indicated. Final proof that structure VIII was the correct one was obtained when A was reductively cleaved by action of hydriodic acid and phosphorus at 170°; there resulted, in 71% yield, 2,3,5,6-tetramethyl-4-aminophenol, IX. On one occasion, the temperature during the reductive cleavage of A reached 280°, and in this case, the product was the hydrocarbon durene, a tetramethylbenzene. Thus, base A is a "Troeger's base"—and is the only example of such

a base completely substituted in the benzene rings.[4]

When I, formaldehyde and dilute hydrochloric acid were allowed to react at 65–70° for fifteen minutes, the yield of A was reduced to 25% and there appeared a greater yield of a lower-melting (137–138°) base, B; when the reaction was carried out at 50° for eight minutes, the yield of B was nearly doubled and no A at all resulted. The filtrate, after removal of B, deposited crystals of the hydrochloride of a third base, C, melting at 136–137°, almost the same temperature as B. Base B was converted into base C by the action of sodium and alcohol. Base B failed to react with acetic anhydride, whereas base C was converted to a monoacetyl derivative, soluble in dilute hydrochloric acid. These facts showed that the group —N=C was present in B and the group —NHCH— as well as a tertiary N atom, were present in C. Finally, base B, when reductively cleaved by action of hydriodic acid and phosphorus at 170°, gave a mixture of 2,3,6-trimethyl-4-aminophenol and 2,3,5,6-tetramethyl-4-aminophenol (IX) in a yield of 71%. These facts establish the structure of B as the dihydroquinazoline VII, and the structure of C as the tetrahydroquinazoline VI.

The question as to how the three bases VI, VII, and VIII are related chemically is difficult to decide. The fact that the yield of VIII increased with time at the expense of VI and VII may mean that the latter bases are intermediates in the formation of VIII; the fact that VI was precipitated (as the hydrochloride) from the acidic filtrate after removal of VII may mean that VI is formed later than, and perhaps by reduction of VII. The tetrahydroquinazoline VI was converted into VIII by action of formaldehyde and hydrochloric acid, or by action of formic acid, alone or in the presence of hydrochloric acid. Hence, VI is probably an intermediate in the formation of VIII, but a reduction must have occurred when VI was converted into VIII by action of formic acid. Some sort of oxidation process must have occurred during the formation of the dihydroquinazoline VII; it may have resulted from a condensation of formic acid with an *o*-aminobenzylamine, formed earlier in the reaction and the evidence, though indirect, indicates that VII is a precursor of VI. Thus, action of formalin and 4% hydrochloric acid upon I for eight minutes at 50° produced VII in 52% yield, and no VI or VIII was isolated; when the temperature was maintained at 65–70°, and the reaction time was prolonged to fifteen minutes, VII, VI, and VIII were produced in yields of 31, 7, and 25%, respectively. However, VII was not converted into VIII by action of formaldehyde, formic acid, and hydrochloric acid, so VII is certainly not a direct precursor of VIII.

Many attempts, and under a great variety of conditions, were made to condense 2,3,6-trimethyl-4-aminophenol, its N-formyl, N-acetyl derivatives and their *o*-methyl ethers (I, II, III) with dienes (isoprene, 2,3-dimethylbutadiene), allylic halides (allyl bromide, isoprene hydrobromide, α-methallyl bromide), and an allylic alcohol (methylvinylcarbinol), but without any success. In the great majority of experiments, the starting material was recovered unchanged or else the reaction consisted merely in cleavage of the N-acyl group. Likewise, no success attended any of the many attempts to introduce an aldehyde group into the vacant position of these compounds: zinc cyanide and hydrochloric acid, or N-methyl formanilide and phosphorus oxychloride, were without significant action. No useful product resulted when the free aminophenol or its *o*-methyl ether were condensed with β-methoxybutanone-2, and finally, the acetanilide III could not be chloromethylated.

In connection with the work on the structures of the bases derived from I, a comparative study was made of the action of formaldehyde and hydrochloric acid upon 2,3,6-trimethyl-4-methoxyaniline, X (a position isomer of I), and upon 2,3,5,6-tetramethyl-4-methoxyaniline, XI. Neither of these methoxyanilines was affected by the action of warm formaldehyde and hydrochloric acid and X was recovered unchanged after it was heated in a mixture of paraformaldehyde, acetic acid, hydrochloric acid and phosphoric acid. The completely substituted aniline XI, however, under the latter conditions, gave a good yield of the methylaniline XII. This is the first case in which a methylaniline has been obtained as the major product of the action of formaldehyde upon an aromatic amine.

Experimental Part[5,6]

2,3,5-Trimethyl-4-aminophenol, m. p., 149–152°, was prepared from 2,3,5-trimethylphenol by the method of Smith, Hoehn and Whitney.[7]

Trimethylquinone was prepared from the above aminophenol by the procedure of Carlin[8] and was converted into the 1-*p*-nitrophenylhydrazone by the procedure of Smith and Irwin.[9]

2,3,5-Trimethylquinone-1-semicarbazone.—A solution of trimethylquinone (10 g.) and semicarbazide hydrochloride (7.5 g.) in alcohol (40 cc.) and water (60 cc.) was allowed to stand at room temperature for a few hours. The yellow semicarbazone (12.7 g., 78%) was removed and crystallized from alcohol; it then melted at 252–253° (dec).

Anal. Calcd. for $C_{10}H_{13}O_2N_3$: C, 57.97; H, 6.32. Found: C, 58.09; H, 6.50.

(4) The failure of the Troeger's base A to react with acetic anhydride is noteworthy for all other such bases so far prepared react rather readily. The benzene rings of base A, however, are completely substituted, and molecular models of this base indicate that there should be a considerable hindrance to attack at the nitrogen atoms. Such hindrance is not present in the tetrahydroquinazoline (Base C) which readily undergoes acetylation.

(5) All melting points are corrected.

1-(2,3,5-Trimethyl-4-hydroxyphenyl)-semicarbazide.—Sodium hydrosulfite (5 g.) in water (25 cc.) was added to a suspension of the above semicarbazone (1.22 g.) in boiling alcohol (35 cc.). The mixture became homogeneous and colorless at once; the white solid (1.12 g.) was removed from the cooled solution. It melted at 194° (dec).

Anal. Calcd. for $C_{10}H_{15}O_2N_3$: C, 57.40; H, 7.22. Found: C, 57.65; H, 7.38.

The white semicarbazide, or a solution of it in alcohol, slowly became yellow when exposed to air; the oxidation was quite rapid when the semicarbazide (0.3 g.) was dissolved in aqueous sodium hydroxide (20 cc., 5%) and exposed to air for one hour. The product (0.28 g., 93%) was the semicarbazone, m. p., and mixed m. p. 250–251° (dec).

2,3,5-Trimethylquinone-1-oxime.—Hydroxylamine hydrochloride (56 g.) in water (75 cc.) was added to a solution of crude trimethylquinone (115 g.) in methanol (325 cc.). The mixture was warmed (40–45°) to bring about complete solution and was then allowed to stand at room temperature for two days. The solid was removed and washed with water until free from acid. It weighed 114 g. (91%), melted at 177–179°, and was sufficiently pure for use in subsequent operations. The analytical sample, crystallized from aqueous ethanol (50%), melted at 181–182°.[10]

Anal. Calcd. for $C_9H_{11}O_2N$: C, 65.43; H, 6.71. Found: C, 65.62; H, 6.63.

N-(2,3,5-Trimethyl-4-hydroxyphenyl)-hydroxylamine.—The above oxime (25 g.) was stirred with sodium hydroxide (7.0 g.) in water (300 cc.) while sodium hydrosulfite (40 g.) was added. The temperature rose to 35°, and a solid separated. The mixture was cooled to 10°, the solid was removed, and washed with water containing a little sodium hydrosulfite. The crude solid melted at 100–103° (dec.), and was very unstable, becoming oxidized to the oxime when attempts were made to recrystallize it. In alkaline solution, the substance was oxidized in air rapidly and quantitatively to the oxime, but addition of excess sodium hydrosulfite to the alkaline solution converted the hydroxylamine quantitatively into 2,3,6-trimethyl-4-aminophenol, m. p. 134–136° (dec.).

2,3,5-Trimethylquinone-1-oxime-O-methyl Ether.—A solution of the oxime (23 g.) in water (175 cc.) and sodium hydroxide (9 g.) was stirred at room temperature as methyl sulfate (29 g.) was added dropwise (one hour). Stirring was continued for one hour, and then the solid was removed, washed with water, and crystallized from aqueous ethanol (350 cc., 60%). The product (21.7 g., 87%) melted at 82–83°; the analytical sample, crystallized again, melted at 83–84°.

Anal. Calcd. for $C_{10}H_{13}O_2N$: C, 67.02; H, 7.30. Found: C, 66.78; H, 7.57.

The oxime ether (2 g.) in methanol (15 cc.) was catalytically hydrogenated (Raney nickel 1 g.) at 60° in fifteen minutes under an initial hydrogen pressure of 1900 lb. to 2,3,6-trimethyl-4-aminophenol, isolated as the N-acetyl derivative (93% over-all yield), m. p., 211–212°. The oxime ether did not react with sodio malonic ester; instead, it underwent self-condensation in the presence of alkali to give, in poor yield, an amphoteric substance which melted at 213–214°. This substance gave a positive Folin-Denis test for phenols, but a negative vat test. It was analyzed, but was not investigated further.

Anal. Found: C, 70.79, 70.40; H, 6.59, 6.81; N, 9.27.

2,3,6-Trimethyl-4-aminophenol.—The aminophenol could be obtained by reductive cleavage of any of the 1-carbonyl derivatives of trimethylquinone. From the *p*-nitrophenylhydrazone (1.69 g.) in boiling alcohol (35 cc.) by action of sodium hydrosulfite (6 g.) in water (35 cc.): yield 0.43 g. (48%), m. p. 132–134° (dec.).[9] From the semicarbazone (1.22 g.) by action of stannous chloride (3 g.) and hydrochloric acid (3 cc.) in hot water (20 cc.) and alcohol (30 cc.): yield 0.23 g. (33%) of material of poor quality, m. p., 119–123° (dec.). From the semicarbazone (1.5 g.) in alcohol (10 cc.) by catalytic reduction (Raney nickel catalyst, 1 g.) at 95° under an initial hydrogen pressure of 1000 lb.: yield 0.89 g. (65%), m. p. 132–134° (dec). From the oxime (111 g.) dissolved in aqueous sodium hydroxide (110 g. in 1600 cc.) by action of sodium hydrosulfite (280 g.) at 20–30° (one hour): yield nearly quantitative; m. p. 135–137° (dec.). It is important, in this reduction, that enough alkali be present to keep the intermediate hydroxylamine in solution, otherwise the reduction stops at the first stage.

From the oxime (18 g.) in methanol (125 cc.) by catalytic reduction (Raney nickel 2 g.) at 40–50° under an initial hydrogen pressure of 1200 lb.: yield quantitative; m. p. 133–136° (dec). The most convenient preparative method is that involving reduction of the oxime by action of sodium hydrosulfite and alkali.

2,3,6-Trimethyl-4-acetylaminophenol.—Crude trimethylquinone oxime (111 g.) was reduced by action of sodium hydrosulfite, as described above, and the wet cake of crude aminophenol was dissolved in hydrochloric acid (70 cc.) and water (1600 cc.) by warming. The solution was warmed with Norit, filtered, acetic anhydride (81.5 cc.) was added to the filtrate at 50°, followed by addition of a solution of sodium acetate (113 g.) in water (500 cc.). The solid was removed, washed thoroughly with water, and dried. It then weighed 95 g. (74% based on the oxime) and melted at 212–213°. The analytical sample, crystallized from aqueous ethanol (30%), melted at 213–214°.

Anal. Calcd. for $C_{11}H_{15}O_2N$: C, 68.37; H, 7.82. Found: C, 68.69; H, 7.87.

2,3,6-Trimethyl-4-formylaminophenol, m. p. 189–190° (9 g., 69%) was prepared by action of formic acid (40 cc., 87%) upon the aminophenol (11 g.) essentially according to the method of King[11] who reported the m. p. as 190–191°.

2,3,6-Trimethyl-4-(N,N-diformylamino)-phenol.—Phosphorus oxychloride (2 cc.) was added to a solution of the aminophenol (0.9 g.) in anhydrous formic acid (5 cc.). The solution was allowed to stand overnight, and was then poured into ice-water (50 cc.). The solid (0.6 g.) was removed and crystallized from aqueous methanol, when it melted at 153–154°.

Anal. Calcd. for $C_{11}H_{13}O_3N$: C, 63.76; H, 6.32. Found: C, 63.60; H, 6.51.

The substance was insoluble in dilute hydrochloric acid, but soluble in aqueous sodium hydroxide. The Folin–Denis test was positive. When warmed with hydrochloric acid (5%) it was hydrolyzed to the monoformyl derivative, m. p. 189–190°, and when refluxed for two hours with dilute acid, it was converted into the aminophenol, m. p. 133–135°.

2,3,6-Trimethyl-4-(N-acetyl-N-formylamino)-phenol.—Phosphorus oxychloride (5 cc.) was added to a solution of the acetylaminophenol (1 g.) in anhydrous formic acid (7 cc.), the mixture was allowed to stand overnight, and was poured into water. The solid (1 g.) was removed and crystallized from aqueous ethanol (40%), when it melted at 170–171°.

Anal. Calcd. for $C_{12}H_{15}O_3N$: C, 65.14; H, 6.82. Found: C, 64.97; H, 6.84.

The substance was insoluble in dilute acid, but soluble in dilute alkali, and the Folin–Denis test was positive. When warmed with dilute acid, it was hydrolyzed, first to the acetylaminophenol (m. p. 210–211°), and finally to the aminophenol (m. p. 132–134°).

2,3,5-Trimethyl-4-acetoxyformanilide.—This compound was obtained as the result of an attempt to bring about a condensation between the formylaminophenol and iso-

(10) Karrer and Leiser, *Helv. Chim. Acta*, **27**, 678 (1944), report the m. p. as 182°.

(11) J. A. King, Ph.D. Thesis, University of Minnesota, 1942. p. 134.

prene hydrobromide. The formylaminophenol (1 g.), isoprene hydrobromide (2.5 g.), and stannic chloride were allowed to stand in acetic acid (10 cc.) at room temperature for a week, and then the mixture was poured into water. The solid was removed and washed with ether. There remained 0.9 g. of material (m. p. 154–160°) which, after two crystallizations from aqueous ethanol, melted at 171–172°. The material was insoluble in both dilute hydrochloric acid and dilute sodium hydroxide; the Folin–Denis test was negative.

Anal. Calcd. for $C_{12}H_{15}O_3N$: C, 65.12; H, 6.83; N, 6.33. Found: C, 65.02; H, 6.84; N, 6.15.

2,3,5-Trimethyl-4-methoxyacetanilide III.—The crude acetylaminophenol (90 g.) was dissolved in aqueous sodium hydroxide (32 g. in 1000 cc.), and to the well-stirred solution, methyl sulfate (65 cc.) was slowly (one and one-half hours) added dropwise. Stirring was continued for one and one-half hours longer, and the precipitate was removed, washed thoroughly with water, and dried. It weighed 90 g. (93%), melted at 169–170°, and was sufficiently pure for use in subsequent operations. The analytical sample, recrystallized from aqueous ethanol (30%) with the use of a little Norit, was white and melted at 170–171°.

Anal. Calcd. for $C_{12}H_{17}O_2N$: C, 69.51; H, 8.27. Found: C, 69.56; H, 8.34.

2,3,5-Trimethyl-4-methoxyaniline I.—Crude III (89.5 g.) was refluxed overnight with water (1000 cc.) and hydrochloric acid (200 cc.). A little Norit was added, and the solution was filtered. The colorless filtrate, cooled and neutralized with sodium hydroxide, deposited a solid which was removed, washed and dried. It weighed 63 g. (88%) and melted at 106–107°. The analytical sample, recrystallized from aqueous ethanol (40%), melted at 108–109°.

Anal. Calcd. for $C_{10}H_{15}ON$: C, 72.70; H, 9.15. Found: C, 72.82; H, 9.47.

2,3,5-Trimethyl-4-methoxyformanilide II.—Methyl sulfate (4.5 cc.) was added dropwise and with stirring to a solution of the crude formylaminophenol (5.5 g.) in aqueous sodium hydroxide (50 cc., 4%). The solid (4.8 g.) was removed, washed with water, and dried. It melted at 142–144°; after crystallization from ethyl acetate, it weighed 4 g. (69%) and melted at 146–147°.

Anal. Calcd. for $C_{11}H_{15}O_2N$: C, 68.37; H, 7.82. Found: C, 68.47; H, 8.04.

2,3,5-Trimethyl-4-acetylaminophenol, m. p. 184–186°, was prepared in 81% yield from the aminophenol by the method of Smith, Hoehn and Whitney.[7]

2,3,6-Trimethyl-4-methoxyacetanilide (22 g., 90%), m. p. 176–178°, was prepared from the above acetylaminophenol in alkaline solution by action of methyl sulfate, as described for the isomeric methoxyacetanilide. The analytical sample, crystallized from aqueous ethanol (50%), melted at 181–182°.

Anal. Calcd. for $C_{12}H_{17}O_2N$: C, 69.51; H, 8.27. Found: C, 69.60; H, 8.39.

2,3,6-Trimethyl-4-methoxyaniline X.—The above crude methoxyacetanilide (21 g.) was hydrolyzed by refluxing it for thirty-six hours with water (300 cc.) and hydrochloric acid (100 cc.). The solution was diluted with water (300 cc.), decolorized with Norit, and neutralized with sodium hydroxide. The solid was removed, washed, and dried, when it weighed 14 g. and melted at 73–74°. The material was sublimed under 2–3 mm., when it formed white needles (13 g., 75%) melting at 74–75°.

Anal. Calcd. for $C_{10}H_{15}ON$: C, 72.70; H, 9.15. Found: C, 72.62; H, 9.14.

2,3,5,6-Tetramethyl-4-aminophenol IX.—A solution of sulfanilic acid (21.5 g.) and sodium carbonate (6.5 g.) in water (100 cc.) was cooled (12°) and mixed with a solution of sodium nitrite (7.4 g.) in water (20 cc.). The whole was poured, with stirring, into a mixture of cracked ice (80 g.) and hydrochloric acid (21 cc.) and allowed to stand for thirty minutes. The sludge of diazonium salt was added to a stirred mixture of durenol (15 g.) and sodium hydroxide, (20 g.) in water (100 cc.) and then allowed to stand overnight. Sodium hydrosulfite (40 g.) was added and the mixture was stirred and heated to 60–70° for about thirty minutes, when the red color disappeared. The mixture was cooled (20°) and the solid was removed and washed several times with water containing a little hydrosulfite. The crude product was light in color, weighed 15.5 g. (94%), and melted at 175–179°.[12]

2,3,5,6-Tetramethyl-4-acetylaminophenol (18 g., 91%, m. p. 260–262° dec.) was prepared from the crude aminophenol (15.5 g.) by acetylation in hydrochloric acid (9.1 cc. in 250 cc. of water) by action of acetic anhydride (11.7 cc.) and sodium acetate (15 g.) as described above. The analytical sample, recrystallized from aqueous ethanol, melted at 262–263°.

Anal. Calcd. for $C_{12}H_{17}O_2N$: C, 69.52; H, 8.27. Found: C, 69.68; H, 8.37.

2,3,5,6-Tetramethyl-4-methoxyacetanilide.—The above acetylaminophenol (18 g.) was dissolved in aqueous sodium hydroxide (6 g. in 200 cc. of water) and methylated by action of methyl sulfate (12 cc.) as described before. The crude product melted at 211–213°, and weighed 21 g. (95%). The analytical sample, recrystallized from aqueous methanol (80%), melted at 215–216°.

Anal. Calcd. for $C_{13}H_{19}O_2N$: C, 70.55; H, 8.65. Found: C, 70.57; H, 8.73.

2,3,5,6-Tetramethyl-4-methoxyaniline XI.—The above crude methoxyacetanilide (14 g.) was refluxed with hydrochloric acid (100 cc.) and water (300 cc.) for forty hours. The solution was diluted with water (300 cc.), decolorized with Norit, and made alkaline by addition of aqueous sodium hydroxide. The solid was removed, washed, and dried; it weighed 10 g. and melted at 60–65°. This material, sublimed under 2–3 mm., gave a white sublimate (6.7 g., 65%) which melted at 68–69°.

Anal. Calcd. for $C_{11}H_{17}ON$: C, 73.69; H, 9.56. Found: C, 73.70; H, 9.69.

1,3,4,7,9,10-Hexamethyl-2,8-dimethoxy-5,11(6,12)-methanodibenzo-[b,f][1,5]-diazocine (R. I. No. 2651). VIII.—A mixture of I (5 g.), formalin (7 cc.) and hydrochloric acid (40 cc.) was shaken mechanically for twelve hours and then allowed to stand for forty-eight hours. The mixture was diluted to 500 cc. with water, and the solid (5.5 g.) was removed, washed with water, and dried. The nearly white hydrochloride was warmed with ethanol (50 cc.), aqueous ammonia (5 cc.) was added, and the mixture was diluted to 250 cc. with water. The crystalline solid (5.1 g., m. p. 184–190°) was removed, washed with water, and recrystallized from ethanol (250 cc.). There resulted 4.7 g. (86%) of white needles melting at 191–192°.

Anal. Calcd. for $C_{23}H_{30}O_2N_2$: C, 75.38; H, 8.25; N, 7.64; mol. wt., 336. Found: C, 75.40, 75.29; H, 8.43, 8.41; N, 7.72; mol. wt. (cryoscopically in benzene), 340.

Hydrochloride.—Somewhat impure VIII (0.4 g., m. p. 187–188°) was added to hydrochloric acid (2 cc.). Immediate solution occurred, then deposition of a solid in a very short time. The mixture was allowed to stand overnight, and the solid was removed and washed thoroughly with dry ether. The solid was shaken with ether (30 cc.) for thirty minutes, and was then shaken with petroleum ether (100 cc., b. p. 60–68°) overnight. The residual white, amorphous solid (0.3 g.) melted at 224–226°.

Anal. Calcd. for $C_{23}H_{30}O_2N_2 \cdot HCl$: C, 68.29; H, 7.73; N, 6.95; Cl, 8.80. Found: C, 67.62; H, 7.83; N, 7.16; Cl (Volhard), 8.65.

Compound VIII (0.3 g.) was recovered unchanged after it was heated with acetic anhydride (3 cc.) and sul-

(12) W. B. Irwin, Ph.D. Thesis, University of Minnesota, 1940, p. 65, prepared this compound by a somewhat different method and reported it to melt at 178–181°.

furic acid (1 drop) for one hour or when it was refluxed for two days with alcoholic sodium hydroxide. Compound VIII was also recovered (75–90%) when attempts were made to reduce it by action (a) of sodium and ethanol; (b) of sodium and butanol; (c) of stannous chloride and hydrochloric acid in acetic acid; (d) of hydrogen in the presence of Raney nickel catalyst at 85° and hydrogen pressure of 2300 lb. Action of zinc dust and hydrochloric acid, or of zinc chloride and hydrochloric acid, brought about no reduction but did convert VIII into a high-melting (301–302°) stable solid which was difficult to purify. This substance was apparently a double compound of VIII and zinc chloride, for it reacted with ammonia in aqueous methanol, regenerating VIII. No simple formula for this "stable hydrochloride" could be deduced from the analytical values.

Anal. Found: C, 59.14; H, 7.14; N, 6.49; Cl, 14.39.

Compound VIII was reductively cleaved when it (1 g.) was heated to 170° for twenty-one hours in a Carius tube with hydriodic acid (15 cc., 48%) and red phosphorus (0.1 g.). The cooled mixture was diluted to 100 cc. with water, hydrochloric acid (10 cc.) was added, and the mixture was filtered. The filtrate was made alkaline by addition of aqueous potassium carbonate, and the solid was removed, washed with water, and dried. It weighed 0.64 g. (71%) and melted at 174–177°. When mixed with authentic 2,3,5,6-tetramethyl-4-aminophenol (m. p. 179–181°), the substance melted at 176–178°. A portion (0.5 g.) of this aminophenol was dissolved in hydrochloric acid (50 cc., 3%), ferric sulfate (5 g.) was added, and the mixture was distilled with steam. The distillate contained duroquinone (0.43 g., 86%), m. p. and mixed m. p. 111–112°.

1,3,4,7,9,10-Hexamethyl-2,8-dihydroxy-5,11(6,12)-methanodibenzo[b,f][1,5]-diazocine (R. I. No. 2651). VIIIa.—A solution of VIII (1 g.) in acetic acid (10 cc.) and hydrochloric acid (10 cc.) was refluxed for forty-four hours. The cooled solution was diluted with water (20 cc.) and made alkaline with aqueous ammonia. The solid (0.65 g.) was removed and crystallized twice from carbon tetrachloride and once from methanol. It then melted at 279–280° (dec.) and weighed 0.25 g. The Folin–Denis test was positive.

Anal. Calcd. for $C_{21}H_{26}O_2N_2$: C, 74.52; H, 7.80. Found: C, 74.43; H, 8.01.

The filtrates from the recrystallizations of VIIIa, on evaporation, yielded 0.1 g. of unchanged VIII.

3-(4-Methoxy-2,3,5-trimethylphenyl)-5,7,8-trimethyl-6-methoxy-3,4-dihydroquinazoline VII.—A solution of I (5 g.) in hydrochloric acid (40 cc., 4%) was prepared by warming the mixture on the steam-bath. The solution was cooled to 50° and formalin (4 cc.) was added. An oil separated almost immediately; the mixture was maintained at 50° for eight minutes, then it was quickly cooled (0°) and rubbed with a spatula. The solid was removed, washed with water (30 cc.) and dissolved in methanol (30 cc.). The solution was made alkaline with aqueous ammonia (5 cc.) and diluted with water (500 cc.). The product appeared as an oil which solidified when set aside in a refrigerator. The solid (3.4 g., m. p. 129–136°) was removed (filtrate, see preparation of VI below) and crystallized from *dry* petroleum ether (b. p. 60–68°). It then weighed 2.8 g. and melted at 136–138°. The analytical sample, crystallized once more from petroleum ether, melted at 138–139°.

Anal. Calcd. for $C_{22}H_{28}O_2N_2$: C, 74.97; H, 8.04. Found: C, 74.78; H, 8.06.

When the above preparation was duplicated, except that the temperature was held at 65–70°, and the reaction was allowed to proceed for fifteen minutes, there resulted VIII (1.39 g., 25%) and VII (crude, 2 g., recrystallized, 1.6 g., 31%). The dihydroquinazoline VII (0.3 g., 75%) was recovered unchanged (a) when it (0.4 g.) was heated for an hour in acetic anhydride (1 cc.); (b) when it was heated with 96% formic acid for an hour; and (c) when it was allowed to stand for a day at room temperature with formalin and hydrochloric acid.

3-(4-Methoxy-2,3,5-trimethylphenyl)-5,7,8-trimethyl-6-methoxytetrahydroquinazoline VI.—The first filtrate obtained in the first preparation of VII above, when allowed to stand overnight, deposited a crystalline hydrochloride (0.42 g., m. p. 163–164°). The salt could not be recrystallized, so it was analyzed directly.

Anal. Calcd. for $C_{22}H_{30}O_2N_2 \cdot HCl$: C, 67.59; H, 8.01. Found: C, 67.79; H, 8.31.

This salt (0.3 g.) was dissolved in a little methanol, and the solution was made alkaline with aqueous ammonia and diluted with water (25 cc.). The product appeared as an oil which soon solidified; the solid was removed and crystallized from petroleum ether (b. p. 40–70°). It weighed 0.15 g. and melted at 136–137°; when mixed with VII (m. p. 137–138°), the substance melted at 129–137°.

Anal. Calcd. for $C_{22}H_{30}O_2N_2$: C, 74.54; H, 8.54. Found: C, 74.70; H, 8.56.

1-Acetyl Derivative of VI.—The tetrahydroquinazoline (0.4 g.) in acetic anhydride (1 cc.) was heated on the steam-bath for one hour. The cooled solution was diluted with water (20 cc.), made alkaline with aqueous ammonia and allowed to stand for an hour. The solid (0.36 g.) was removed and crystallized twice from petroleum ether (10 cc., b. p. 40–70°). It then weighed 0.2 g., and melted at 136–137°. When mixed with VI (m. p. 136–137°) the substance melted at 110–120°.

Anal. Calcd. for $C_{23}H_{32}O_3N_2$: C, 72.64. H, 8.13. Found: C, 72.90; H, 8.33.

Conversion of VI to VIII. A.—The tetrahydroquinazoline (80 mg.) in formic acid (96%) was heated on the steam-bath for forty-five minutes. From the cooled and diluted solution there was obtained 50 mg. (54%) of VIII, m. p. and mixed m. p. 190–191°. **B.** The tetrahydroquinazoline (0.3 g.), in formic acid (0.3 cc., 87%) and hydrochloric acid (3 cc.) was maintained at room temperature for two days. From the cooled and diluted solution there was obtained 0.28 g. of VIII, m. p. and mixed m. p. 189–190°. **C.** A solution of the tetrahydroquinazoline (0.4 g.) and formalin (0.4 cc.) in hydrochloric acid (4 cc.) was maintained at room temperature for two days. The solution was diluted with water (30 cc.) and the solid was removed and dissolved in methanol (10 cc.). The methanol solution was made alkaline with ammonia (1 cc.) and diluted to 50 cc. with water. The solid was removed and crystallized from methanol; it weighed 0.32 g. (78%) and melted at 191–192° alone or when mixed with another specimen of VIII.

Reduction of VII to VI.—Sodium (2 g.) was added portionwise (thirty minutes) to a refluxing solution of VII (0.75 g.) in dry ethanol (30 cc.). The solution was cooled, neutralized with acetic acid, and diluted with water (150 cc.). The product (0.6 g.) separated as an oil which solidified on standing in a refrigerator overnight. The solid was removed and crystallized from dry petroleum ether (b. p. 60–68°), when it weighed 0.51 g. (75%) and melted at 136–137°, alone, or when mixed with VI from the above experiment.

Reduction Cleavage of VII.—The dihydroquinazoline (1 g.) was heated at 170° for twenty-two hours in a Carius tube with hydriodic acid (15 cc., 48%) and red phosphorus (0.1 g.). The mixture was cooled, and the solid hydriodide (0.72 g.) was removed and washed with water. The combined filtrate and washings were neutralized with aqueous potassium carbonate and extracted twice with ether (35 cc. each time). The ether extract was immediately mixed with hydrochloric acid (3%) and placed in a flask arranged for steam distillation. The solid hydriodide was dissolved in methanol (25 cc.); the solution was neutralized with aqueous ammonia, diluted with water (150 cc.), and the solid was removed, washed with a little water, and added to the ether extract in the steam-distillation flask. The ether was carefully distilled from the mixture with a gentle current of steam,

and then ferric sulfate (10 g.) was added and the mixture was steam distilled. The distillate was extracted with several portions of ether (total 70 cc.) and the combined yellow extracts were dried over sodium sulfate. Removal of the solvent left a yellow solid (0.58 g.). This solid was dissolved in methanol (4 cc.) and water (0.5 cc.). Hydroxylamine hydrochloride (0.25 g.) was added, and the mixture was allowed to stand at room temperature for one day. The mixture was diluted with water (30 cc.) and extracted with several portions of ether (total, 70 cc.). The combined ether extracts were then extracted three times with 15-cc. portions of aqueous sodium hydroxide (5%). The alkaline extracts, when neutralized with dilute hydrochloric acid, deposited 2,3,5-trimethylquinone-1-oxime (0.14 g., 16%) which, after one crystallization from aqueous alcohol (50%) melted at 180–182° alone or when mixed with an authentic specimen. The yellow ether solution remaining after the alkaline extraction was washed with water and evaporated. The residue (0.19 g., 21%) melted at 109–111° alone or when mixed with authentic duroquinone.

2,3,5,6-Tetramethyl-4-methoxy-N-methylaniline XII.—The tetramethylmethoxyaniline XI (0.8 g.) and paraformaldehyde (0.25 g.) were heated on the steam-bath for sixteen hours in a mixture of acetic acid (1 cc.), hydrochloric acid (1 cc.) and phosphoric acid (0.6 cc., 85%). The mixture was diluted with water (50 cc.), warmed to bring about complete solution, and decolorized with a little Norit. The cooled filtrate was made alkaline with aqueous sodium hydroxide (10%) and the precipitate (0.6 g., m. p. 77–82°) was removed and dissolved in ether (50 cc.). The solution was filtered and the solvent was allowed to evaporate. The residue was crystallized twice from aqueous ethanol (35%), when it melted at 83–85°. This was sublimed under 3 mm. pressure at a temperature of 70–80°. The first portion of the sublimate melted at 78–84°; the last portion at 84–87°. The high-melting fraction, when resublimed as before, gave 0.12 g. of material melting at 87–88°.

Anal. Calcd for $C_{12}H_{19}ON$: C, 74.56; H, 9.91. Found: C, 74.51; H, 9.86.

The tetramethylmethoxyaniline XI (1.4 g., m. p. and mixed m. p., 63–65°) was recovered unchanged when it (2 g.) was shaken with formalin (2 cc.) and hydrochloric acid (15 cc.) at room temperature for five days. The material was recovered when the reaction mixture was diluted with water (150 cc.) and made alkaline with aqueous sodium hydroxide (10%). The same result was obtained when the experiment was repeated, but for seven hours at a temperature of 75°.

2,3,6-Trimethyl-4-methoxyaniline X (0.32 g.) and paraformaldehyde (0.1 g.) were heated on the steam-bath for fifteen hours in a mixture of acetic acid (0.5 cc.), hydrochloric acid (0.5 cc.) and phosphoric acid (0.25 cc., 85%). The mixture, processed as described above for the tetramethyl analog, yielded a sublimate (0.13 g.) which was unchanged X, m. p. and mixed m. p. 71–73°.

Summary

1. It has been shown that action of formaldehyde and hydrochloric acid upon 2,3,5-trimethyl-4-methoxyaniline produces three basic substances: a new highly substituted "Troeger's Base" VIII, a dihydroquinazoline VII, and a tetrahydroquinazoline VI. The relative amounts of these three bases depend upon the experimental conditions, particularly upon the temperature and the time.

2. The dihydroquinazoline VII has been reduced to the tetrahydro compound VI; the latter has been converted to the "Troeger's Base" VIII by action of hydrochloric acid and formaldehyde or formic acid, whereas the former was not affected by these reagents. The dihydroquinazoline VII therefore cannot be a direct precursor of the "Troeger's Base," whereas the tetrahydroquinazoline VI probably is an intermediate in its formation from the methoxyaniline.

3. Tetramethyl-*p*-methoxyaniline and 2,3,6-trimethyl-4-methoxyaniline gave no compounds analogous to those obtained from the 2,3,5-trimethyl compound. The trimethylaniline underwent no change, whereas the tetramethyl compound was converted into 2,3,5,6-tetramethyl-4-methoxy-N-methylaniline.

4. A convenient five-step synthesis of 2,3,6-trimethyl-4-aminophenol from 2,3,5-trimethylphenol has been developed, and several new derivatives of the aminophenol have been prepared and characterized.

5. Using as starting materials 2,3,6-trimethyl-4-aminophenol and several of its derivatives, a number of synthetic approaches to 6-hydroxy-2,2-disubstituted-1,2,3,4-tetrahydroquinolines, the N-analogs of the tocopherols, have been investigated. None of the reactions was successful.

Hemihydrohalides of 3(α)-Hydroxy Steroids[1]

BY VERNON R. MATTOX, BERNARD F. MCKENZIE AND EDWARD C. KENDALL

The formation of a crystalline compound by treatment of 3(α)-hydroxy-12-keto-$\Delta^{9,11}$-cholenic acid in ether with hydrogen bromide has been observed.[2] The experimental details for preparation of this product have recently been published,[3] and the procedure was suggested as a method for separation of the cholenic acid. However, no structure was suggested for the product and no analysis was given.

In the presence of hydrogen bromide or hydrogen chloride, crystalline products have been prepared in this laboratory with the already mentioned cholenic acid and also with methyl 3(α)-hydroxy-12-ketocholanate. With both of these steroids it was found that the crystalline compounds separated in combination with 0.5 molecule of hydrogen halide.

Subsequently it was observed that, when methyl 3(α)-hydroxy-12(α)-methoxy-$\Delta^{9,11}$-cholenate was treated with hydrogen halides, the 12(α)-halogen derivative which was produced separated in crystalline form and contained in each instance 0.5 molecule of halogen acid.

The diverse nature of the material treated with hydrogen halide and the fact that only 0.5 molecule of halogen acid was combined with the crystalline product indicated that neither the double bond at C_9-C_{11} nor the substituent at C_{12} was essential. It occurred to us that it was desirable to determine what structure of the steroid was necessary for the formation of the hemihydrohalide derivatives. Such an investigation has revealed the fact that all derivatives of cholane, $\Delta^{9,11}$-cholene and Δ^{11}-cholene which have been studied (Table I) in which there was an (α)-hydroxyl group at C_3, form crystalline products and separate with 0.5 molecule of halogen acid. If the 3(α)-hydroxyl group is esterified, as with the acetyl group, addition products are not formed,[4] as shown in the last three lines of the table. No attempt has been made to prepare hemihydrohalides from 3(β)-hydroxy steroids or from steroids which have hydroxyl groups in other positions.

The general method of preparation consisted of the introduction of a stream of dry hydrogen halide into a solution containing from 1 to 3 millimoles of the compound in an appropriate solvent in an ice-bath. It was hoped that a single solvent or a mixture of solvents would be satisfactory for the isolation of all of the hemihydrohalides; however, it was found that this was not possible. For several of the methyl esters methanol was a satisfactory solvent; acetone was used for some of the acids and chloroform–petroleum ether was suitable in other cases.

The hemihydrohalides were dried under reduced pressure over sodium hydroxide or in air at room temperature for one to two days. Methyl 3(α)-hydroxy-12(α)-bromo-$\Delta^{9,11}$-cholenate hemihydrobromide retained 0.5 molecule of hydrogen bromide after it had been dried at 0.1 mm. pressure at room temperature for six hours. Most of the hemihydrohalides melt over a range of several degrees and the melting point is frequently dependent on the rate of heating. Their physical constants are given in Table I.

The halogen content of the compounds was determined by distribution between water and an immiscible solvent and titration of the halogen in the aqueous phase by the method of Volhard. In 6 experiments the amount of acid in the aqueous phase was determined. In each instance the concentration agreed with that of the halogen ion.

That no deep-seated change of the steroid molecule had occurred was shown by isolation of the starting material from the organic phase after removal of hydrogen halide. Two of the reaction products, methyl 3(α)-hydroxy-12(α)-bromo-$\Delta^{9,11}$-cholenate hemihydrobromide and methyl 3(α)-hydroxy-12(α)-chloro-$\Delta^{9,11}$-cholenate hemihydrochloride, were prepared by treatment of methyl 3(α)-hydroxy-12(α)-methoxy-$\Delta^{9,11}$-cholenate with the appropriate hydrogen halide. These two were reconverted into methyl 3(α)-hydroxy-12(α)-methoxy-$\Delta^{9,11}$-cholenate by treatment with methanol.[5,6]

It is thought that these hemihydrohalides of the 3(α)-hydroxy steroids are oxonium compounds. Favorskii[7] has prepared oxonium compounds from the aliphatic alcohols and reports that they are extremely hygroscopic. However, the oxonium compounds of the steroids reported in this paper are not hygroscopic. In addition, Favorskii also prepared from 2,2-dimethylpentanol-3 both a

(2) Reported by Dr. E. S. Wallis at a conference of the Committee on Synthesis of Adrenal Hormones held under auspices of the National Research Council, Washington, D. C., 1942.

(3) Hicks, Berg and Wallis, *J. Biol. Chem.*, **162**, 633 (1946).

(4) Since only the 3(α)-hydroxyl group appears to be necessary for formation of hemihydrohalides, separation of 3(α)-hydroxy-12-keto-$\Delta^{9,11}$-cholenic acid from 3(α)-hydroxy-12-ketocholanic acid cannot be made satisfactorily. For a discussion see McKenzie, Mattox, Engel and Kendall, *J. Biol. Chem.*, **173**, 271 (1948).

(5) Mattox, Turner, Engel, McKenzie, McGuckin and Kendall, *J. Biol. Chem.*, **164**, 569 (1946).

(6) When a solution of methyl 3(α)-hydroxy-12(α)-bromo-$\Delta^{9,11}$-cholenate hemihydrobromide in chloroform is repeatedly concentrated under reduced pressure and diluted with petroleum ether, methyl 3(α)-hydroxy-12(α)-bromo-$\Delta^{9,11}$-cholenate is obtained; however, because of its somewhat variable melting point, it is not satisfactory for identification. For this reason the 12-halogen compounds were converted into the 12(α)-methoxy compound, which has characteristic physical properties.

[a] All melting points were determined on the Fisher–Johns apparatus. [b] Samples were exposed to atmosphere. [c] This compound was prepared from methyl 3(α)-hydroxy-12(α)-methoxy-Δ^{9,11}-cholenate. The conversion of the 12(α)-methoxy compound to the 12(α)-halogen derivative has been shown to be nearly quantitative.[5] [d] P. E. is petroleum ether. [e] Analysis by combustion. [f] This figure is based on the halogen found in excess of that calculated for 1 atom of halogen at C_{12}. [g] For halogen determination the sample was heated in 1 *N* methanolic sodium hydroxide for ten minutes and the chloride ion was titrated by the Volhard method. [h] M. p. 112–115° when heated rapidly. [i] Crystals separated when the solution was about 2 *N* with HCl; as the solution became more concentrated with HCl the crystals dissolved. [j] M. p. 90–93° when heated rapidly. [k] Prepared from methyl 3,9-epoxy-11-ketocholanate[9] by treatment with phenylmagnesium bromide and dehydration of the resulting carbinol with acetic acid. The 3,9-epoxy linkage was opened with hydrogen bromide and the halogen was removed from C_{12} with zinc in acetic acid. [l] After 45 days in desiccator over solid sodium hydroxide.

hemihydrohalide, $(C_7H_{15}OH)_2 \cdot HBr$, and a hydrohalide, $C_7H_{15}OH \cdot HBr$. Only the hemihydrohalides of the 3(α)-hydroxy steroids could be isolated.

Favorskii represented the structure of the hemihydrohalide of the aliphatic alcohols by

However, Whitmore[8] suggested

$[Br]^-[OR]^-$ as being more probable.

The halogen content of some of the oxonium compounds was found to be less than the theoretical amount for a hemihydrohalide. This was observed more frequently with the hydrochlorides than with the hydrobromides and may be related to the intrinsic strengths of the two acids.

The steroid hemihydrohalides are unstable compounds and slowly lose halogen acid under atmospheric conditions. A comparison of the last two columns in the table shows the amount of halogen acid lost in forty-five days.

Summary

Crystalline oxonium compounds which contain a half molecule of hydrogen halide are formed by treatment of 3(α)-hydroxysteroids with hydrogen halides. Acetylation of the hydroxyl group prevents formation of the oxonium compound. The preparation of sixteen of these hemihydrohalides is described in this paper.

A Study of the Reaction of Phenol with Thionyl Chloride

BY WILLIAM E. BISSINGER AND FREDERICK E. KUNG

Studies on the reactions of phenol with thionyl chloride are greatly complicated by the existence of readily-occurring nuclear substitution reactions.[1,2,3,4,5,6] These probably account for the fact that the preparation of diphenyl sulfite by the direct reaction of phenol with thionyl chloride in the absence of hydrogen chloride acceptors had not been reported prior to this time, and that the successful preparation of phenyl chlorosulfinate has been accomplished[7] only recently.

In a previous paper[8] on the reaction of thionyl chloride with alcohols, we described a novel method of operation which appeared to greatly reduce the complicating side reactions resulting from the action of hydrogen chloride on the newly-formed sulfite ester. In that method the reactions were carried out in the presence of a large amount of a refluxing solvent in which the reactants and products were soluble. but in which the hydrogen chloride was insoluble. We have now applied this technique to the phenol–thionyl chloride reaction to determine if the complex reactions previously reported[1-6] could be eliminated. Preliminary experiments showed that diphenyl sulfite and phenyl chlorosulfinate underwent a fairly rapid decomposition in the presence of hydrogen chloride, thereby emphasizing the need for removing this material from the zone of reaction as rapidly as possible. Utilizing the refluxing solvent technique to expel the hydrogen chloride, we then investigated the reaction of phenol with thionyl chloride at temperatures of 10° to 180°, and at molar ratios of 2:1 to 1:4, while observing the effect of temperature and the ratio of reactants on the yields and types of products obtained.

Experimental

Preparation of Materials.—The thionyl chloride used was a purified grade manufactured by this Division. The phenol was Merck reagent grade.

For the preliminary studies the diphenyl sulfite was prepared by the method of Gerrard.[9] On distillation through a 1.5 × 20-cm. Vigreux column, the sulfite was collected at 141–144° (2 mm.), m. p. 13–16°.

The phenyl chlorosulfinate was prepared as follows: Molten phenol (1.0 mole) was added to refluxing thionyl chloride (4.0 moles) in one hour with stirring after which the mixture was refluxed one hour longer. Fractionated through a 1.7 × 20-cm. Fenske column, the phenyl chlorosulfinate, 125 g. (71% yield) distilled at 92–98° (10 mm.). The stability tests in the following section were made with a redistilled product boiling at 95° (10 mm.), m. p. −16° to −13°.

Anal. Calcd. for $C_6H_5SO_2Cl$: S, 18.1; Cl, 20.1. Found: S, 18.8; Cl, 20.6.

Stability of Diphenyl Sulfite and Phenyl Chlorosulfinate to Hydrogen Chloride.—Hydrogen chloride (0.25 mole) was passed into freshly distilled diphenyl sulfite (93 g.; 0.4 mole) over a six-hour period at 70°. A gain in weight of 7.5 g. resulted. Distillation yielded (a) 16.7 g. (0.178 mole) of phenol, b. p. 83–84° (20 mm.), m. p. 40°, which was further identified by its benzoate, m. p. 69°; (b) 51 g. (0.218 mole) of diphenyl sulfite, b. p. 143–157° (3 mm.); (c) 14.5 g. of a viscous residue containing 18.5% sulfur and 1.7% chlorine. The yield of phenol, based on the diphenyl sulfite not recovered, was 98%, assuming that one mole of phenol was formed per mole of sulfite decomposed.

Hydrogen chloride (0.30 mole) was likewise passed into freshly distilled phenyl chlorosulfinate (106 g., 0.60 mole) over a six-hour period at 70° while collecting all volatile products in a Dry Ice trap. A gain in weight of 1 g. occurred. Distillation at 10 mm. yielded (a) a Dry Ice trap fraction of 5.2 g., (b) 79 g. (0.448 mole) of phenyl chlorosulfinate b. p. 92–93.5°, (c) 10 g. (0.04 mole) of diphenyl sulfite, b. p. 152–158°.

Anal. Calcd. for $(C_6H_5)_2SO_3$: S, 13.65. Found: S, 13.9; Cl, 0.9.

Redistillation of (a) at atmospheric pressure gave 4.7 g. (0.04 mole) of thionyl chloride, b. p. 75–76°.

Anal. Calcd. for $SOCl_2$: S, 26.9; Cl, 59.6. Found: S, 26.8; Cl, 58.6.

The yield of thionyl chloride and diphenyl sulfite was 53% each, based on the phenyl chlorosulfinate not recovered.

When phenyl chlorosulfinate (160 g.) was heated for six hours at 70° in the absence of hydrogen chloride and then redistilled, 97% (155 g.) was recovered. Treatment of diphenyl sulfite in a similar manner resulted in a recovery of 96% of the original material.

Reaction of Phenol with Thionyl Chloride in Refluxing Solvents.—The apparatus and the techniques used were the same as had been described previously,[8] except that the phenol was generally maintained slightly above its melting point while being added to the refluxing solvent. The solvents used, and their boiling points, were: ethyl chloride (12°), methylene chloride (42°), carbon tetrachloride (76°), thionyl chloride (78°), chlorobenzene (130°), and *o*-dichlorobenzene (180°). The addition of the phenol and thionyl chloride was made in *one* to *two* hours (with one exception), after which the refluxing was continued for *one* to *three* hours more. In the experiment with ethyl chloride as solvent a forty-eight hour reflux period was used. The yields of diphenyl sulfite and phenyl chlorosulfinate were determined by distillation and redistillation of the product at the reduced pressures already mentioned, through a 1.5 × 15-cm. Vigreux column. The yields were based on the weights of starting materials and on the reactant present in deficiency. A black tarry residue remained from every distillation. The results are summarized in Table I.

In the experiments at 12° and 42°, *p*-chlorophenol was isolated during the distillation of the products. This material had b. p. 107–110° (20 mm.); m. p. 20–25°, $n^{20}D$ 1.5655.

Anal. Calcd. for C_6H_5OCl: Cl, 27.6. Found: Cl, 27.4; S, 0.2. As further identification, the *p*-chlorophenol was converted to *p*-chlorophenyl benzoate, m. p. 87°.

[a] Unreacted phenol (48%) was isolated along with 0.104 mole of *p*-chlorophenol. [b] This residue contained 5.4% chlorine and 16.6% sulfur. [c] Fifty-one per cent. of the phenol was recovered and 0.04 mole of *p*-chlorophenol appeared on distillation. [d] One hundred ml. of carbon tetrachloride was placed in the flask while the other 400 ml. was used to prepare equivolume solutions of the phenol and $SOCl_2$, which were then added dropwise. The addition time was extended to seven hours. [e] Phenol (36%) was recovered. [f] The phenol was dissolved in chlorobenzene (100 ml. per mole of phenol) to facilitate addition. [g] Phenol (15%) was recovered. [h] In this experiment the rate of reflux was much higher than in the preceding experiment. [i] On attempted distillation only acidic gases were evolved.

Discussion of Results

In general, the reaction of thionyl chloride with phenol, even in the presence of a refluxing solvent, was observed to be far more sensitive to slight variations in the operating conditions than had been noted in the reaction of thionyl chloride with aliphatic alcohols. For example, very vigorous stirring and strong refluxing of the solvent was found conducive to definitely improved yields in the phenol reaction; in the aliphatic series these factors were not particularly important. There are indications, also, that the time of addition of the phenol and the thionyl chloride to the refluxing solvent may bear very significantly on the results. In the studies reported here, the effect of this variable was investigated in only one experiment, as will be discussed later in the paper. It should be clearly recognized, therefore, that our results were obtained under specific reaction conditions, and any marked deviation from these conditions may lead to considerable differences in yields.

The preparation of diphenyl sulfite by the direct reaction of phenol and thionyl chloride in the absence of hydrogen chloride acceptors has been accomplished for the first time through the use of the refluxing solvent technique. The data of Table I illustrate that at a 2:1 molar ratio of phenol to thionyl chloride the maximum yield (87%) of diphenyl sulfite was obtained at a reaction temperature of 130° with chlorobenzene as the refluxing solvent. It is not fully understood why this maximum yield appeared at such a high temperature. In contrast to the other experiments, it will be noted that in most cases at 130° essentially no tarry residues were obtained. Assuming that these resinous bodies were formed through a reaction of thionyl chloride with the benzenoid ring, it might be concluded that at 130° the esterification reaction becomes very much faster than the coupling reaction, thereby resulting in the predominant formation of diphenyl sulfite.

The fact that no diphenyl sulfite could be isolated from the experiments at 12° and 42° with a 2:1 molar ratio of phenol to thionyl chloride is in accord with the results of earlier workers.[1-6] It is apparent that under these conditions the refluxing solvent method did not eliminate the formation of undesirable by-products, represented by the tarry residues obtained on distillation. The high yield (73%) of diphenyl sulfite obtained at 76° with carbon tetrachloride as solvent was only obtained when a seven-hour addition time for the reactants was used. When the addition time was the usual one-to-two hour period, the yield of diphenyl sulfite was only 17%. These results afford strong evidence that even relatively minor variations in the reaction conditions may materially affect the yield figures.

The refluxing solvent technique, using a 300% excess of thionyl chloride at 78° as the sole refluxing solvent, furnished a very simple means of preparing phenyl chlorosulfinate. The discrepancy between the yields of 71% and 83%, as reported in Table I, can probably be attributed to the less vigorous stirring and the decreased rate of reflux used in the former case.

In all preparations of phenyl chlorosulfinate with thionyl chloride as the sole refluxing solvent, it was found that not more than 3% of diphenyl sulfite was obtained, providing vigorous stirring[10] was employed. The low yield of diphenyl sulfite indicates that in the absence of hydrogen chloride acceptors, the reaction of phenol with phenyl chlorosulfinate at 78° may be a much slower reaction than the corresponding reaction of alkanols with alkyl chlorosulfinates at this temperature. For example, when *n*-propyl alcohol was added to a 500% excess of refluxing thionyl chloride in a four-hour reaction period with vigorous stirring, a 30% yield[8] of *n*-propyl sulfite was obtained, along with the expected chlorosulfinate.

Although phenyl chlorosulfinate can be distilled at 90–100° without decomposition, it was found to be unstable on prolonged standing at room tem-

(10) This is only true under conditions of strong agitation. In one experiment, phenol (2 moles) was added to refluxing thionyl chloride (8 moles), without stirring, over a two-hour period, followed by one additional hour of reflux. No phenyl chlorosulfinate was obtained, but a 41% yield of diphenyl sulfite was produced, along with a residue of 60 g.

perature. A purified sample, stored for about eleven months on the desk top in a glass-stoppered bottle, decomposed violently, rupturing the bottle and evolving heat.[11]

Acknowledgment.—We express our thanks to Dr. A. Pechukas, who suggested the refluxing solvent technique, and to Dr. F. Strain for helpful discussions.

Summary

1. The thermal stability of phenyl chlorosulfinate, although poor, was about equal to that of *n*-propyl chlorosulfinate and much greater than that of isopropyl chlorosulfinate.

2. Diphenyl sulfite reacted with hydrogen chloride producing phenol and a tarry residue; the other expected cleavage product, chlorobenzene, was not found. Phenyl chlorosulfinate, unlike the unreactive alkyl chlorosulfinates, underwent a disproportionation reaction in the presence of hydrogen chloride to form thionyl chloride and diphenyl sulfite.

3. The refluxing solvent technique afforded an excellent means of preparing phenyl chlorosulfinate and diphenyl sulfite in yields of 83% and 87%, respectively. This was the first successful preparation of the latter by the direct reaction of phenol with thionyl chloride without hydrogen chloride acceptors.

4. The variables of temperature and ratio of reactants have been studied in the reaction of phenol with thionyl chloride in a refluxing solvent. *Under the conditions used,* the lower reaction temperatures seemed to favor undesirable side-reactions; at a 2:1 molar ratio of phenol to thionyl chloride the best yield of diphenyl sulfite occurred at 130°, whereas with excess thionyl chloride the best yield of phenyl chlorosulfinate was obtained in refluxing thionyl chloride at 78°.

5. The reaction of phenol with thionyl chloride in a refluxing solvent is apparently very sensitive to relatively minor changes in the reaction conditions, such as stirring for example, and with such modifications quite different results from those reported here may be obtained. Such sensitivity was not apparent in the aliphatic series.

BARBERTON, OHIO RECEIVED MARCH 15, 1948

(11) Carré and Libermann, *Compt. rend.*, **195**, 799 (1932), reported that the decomposition of phenyl chlorosulfinate was instantaneous at room temperature. The presence of impurities in their material may have been responsible for this reduced stability.

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

The Preparation of Spermine Tetrahydrochloride[1] (1,12-Diamino-4,9-diazadodecane Tetrahydrochloride)

BY HARRY P. SCHULTZ[2]

The reported synthesis of spermine[3,4] appeared impractical for the preparation of the quantity of material required in the antimalarial program. Therefore, a synthesis of spermine tetrahydrochloride was developed, which consisted of the hydrogenation of succinonitrile to putrescine (I); the dicyanoethylation of putrescine to N,N′-bis-(2-cyanoethyl)-putrescine (II); followed by hydrogenation of II to spermine (III). The tetramine was then converted to the tetrahydrochloride.

$$H_2N(CH_2)_4NH_2 \qquad \text{I}$$

$$NC(CH_2)_2NH(CH_2)_4NH(CH_2)_2CN \qquad \text{II}$$

$$H_2N(CH_2)_3NH(CH_2)_4NH(CH_2)_3NH_2 \qquad \text{III}$$

The hydrogenation of succinonitrile was carried out at 140° in liquid ammonia over Raney nickel. Even under these conditions, which are usually quite unfavorable to formation of secondary amines, the yield of pyrrolidine was more than twice as large as that of the desired primary amine. The dicyanoethylation reaction proceeded well in water, alcohol, or ether. The yield of II was almost quantitative, judged by the amount of the dihydrochloride that was isolated in some experiments. The preferred procedure was to carry out the cyanoethylation in ether solution and, without isolating II, add liquid ammonia and hydrogenate over Raney nickel at 140° to III. The tetramine (III) was then distilled and isolated and purified as the tetrahydrochloride. The over-all yield of the tetrahydrochloride, starting with putrescine, was 51% of the theoretical.

Experimental

Putrescine.—A steel reaction vessel having a void of 1300 ml. was charged with 200 g. (2.5 moles) of succinonitrile,[5] 9 g. of W-2 Raney nickel,[6] and 350 ml. of liquid ammonia. The contents of the bomb was reduced for two and one-half hours at 140° under a hydrogen pressure of 1700 p. s. i. The catalyst-free reaction mixture was distilled to give 79.7 g. (45% yield) of crude pyrrolidine that boiled at 87–88° (740 mm.), and 43 g. (20% yield) of putrescine, b. p. 60–65° (16 mm.); m. p. 27–28°. Ladenburg[7] reported a m. p. of 23–24° for putrescine, while Ciamician and Zanetti[8] gave m. p. 27–28°.

N,N′-bis-(2-Cyanoethyl)-putrescine.—Acrylonitrile from the Rohm and Haas Company (35.0 g., 0.66 mole)

was added dropwise for eight hours to a stirred solution of 29.0 g. (0.33 mole) of putrescine in 10 ml. of ether. After all acrylonitrile was added, the solution was stirred at room temperature for fifteen hours, on a steam-bath for one hour, and again at room temperature for one hour. During the time of heating, all the ether distilled out, and the weight of the final reaction product was 64 g. All attempts to distil the dinitrile, even at a pressure of 0.01 mm., resulted in decomposition. When the reaction mixture was allowed to stand for a longer period (forty to fifty hours), the yield of spermine tetrahydrochloride was decreased from 50 to 30%.

A small exploratory run, made as above, when treated with ethanolic hydrogen chloride, gave a 100% yield of N,N′-bis-(2-cyanoethyl)-putrescine dihydrochloride, m. p. 222–228° (dec.). This salt was recrystallized from ethanol–water (3:1) to give an 84% yield of N,N′-bis-(2-cyanoethyl)-putrescine dihydrochloride, m. p. 232–233° (dec.).

Anal. Calcd. for $C_{10}H_{20}N_4Cl_2$: Cl, 26.6. Found: Cl, 26.6.

Spermine Tetrahydrochloride.—A 270-ml. steel reaction vessel was charged with 18 g. (0.092 mole) of crude N,N′-bis-(2-cyanoethyl)-putrescine, 5 ml. of ether, 60 ml. of liquid ammonia, and 3 g. of W-2 Raney nickel catalyst. The contents of the bomb was reduced for thirty minutes at 140° under a hydrogen pressure of 4900 p. s. i. The catalyst-free reaction mixture was distilled to give 10 g. of viscous distillate that boiled at 100–170° (0.1–0.2 mm.), and 3 g. of a yellow residue.

The crude spermine was dissolved in 130 ml. of absolute ethanol, and to it was added 65 ml. of 20% ethanolic hydrogen chloride. The precipitated amine salt was filtered and air-dried to give 23.5 g. of white, impure spermine tetrahydrochloride that melted at 290–310° (dec.), with darkening at 270°. The crude spermine tetrahydrochloride was dissolved in 130 ml. of 12% hydrochloric acid and added to 1300 ml. of hot, absolute ethanol. After cooling the alcohol solution, the crystals were filtered, washed, and air-dried to give 17 g. of crystals, m. p. 300–310° (dec.). This material was placed in 119 ml. of 12% hydrochloric acid, and added to 357 ml. of hot, absolute ethanol. After six hours at room temperature, the spermine tetrahydrochloride was filtered off, rinsed, and dried to give 16.1 g. (51% yield) of light pink crystals, m. p. 310–311° (dec.), darkening at 300°. The value previously reported[9] was m. p. 310–311° (dec.).

Anal. Calcd. for $C_{10}H_{30}N_4Cl_4$: C, 34.5; H, 8.7; Cl, 40.8. Found: C, 34.2; H, 8.6; Cl, 40.8.

The picrate of spermine melted at 246–247° (dec.), darkened at 240°. The value previously reported[9] was m. p. 248–250° (dec.), with darkening at 242°.

Spermine chloroplatinate was also prepared, and found to melt at 242° (dec.), dark at 235°. The value previously reported[9] was m. p. 242–245° (dec.).

Acknowledgments.—I am grateful to Dr. Carnahan, formerly of this Laboratory, for suggesting this method as a possible synthesis of spermine; and to Drs. Adkins and Wilds, of this Laboratory, for advice which made this synthesis successful.

Summary

Spermine tetrahydrochloride has been prepared from succinonitrile through the formation of putrescine, N,N′-bis-(2-cyanoethyl)-putrescine, spermine, and spermine tetrahydrochloride. The yield of putrescine from succinonitrile was low (20%), but the over-all yield for the three subsequent reactions was 51% of the theoretical.

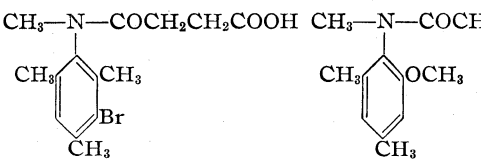
Restricted Rotation in Aryl Amines. IV. Preparation and Resolution of N-Succinyl-1-methylamino-2,4-dimethyl-6-substituted Benzenes

BY ROGER ADAMS AND N. K. SUNDHOLM[1]

A comparison of the relative interference effects of substituent groups, as deduced from the racemization rates of a series of analogous, optically active biphenyls,[2] showed these groups to fall in the following order: Br > CH_3 > Cl > NO_2 > COOH > OCH_3 > F. Two members of a series of aromatic amines in which restricted rotation exists have been previously described.[3] They are shown in I and II. Compound I, in optically active form, has a half-life of nine hours in boiling *n*-butanol (b.p. 117°) and compound II a half-life of two and seven-tenths hours in boiling methyl acetate (b.p. 57°). Although these values are not directly comparable due to the use of different solvents[4] and to the bromine atom in the former, qualitatively they can be accepted as indicative of the relative interference of the methyl and methoxyl groups in this type of molecule. These relative values coincide with those expected from the study of the biphenyls.



I II

Several new analogs of I and II, as shown in III and IV, have now been synthesized, resolved and their optically active forms racemized. The half-life periods were as follows: IIIa, three and

III IV

IIIa X = Br
IIIb X = I
IIIc X = NO_2

one-tenth hours; IIIb, twenty and one-half hours; IIIc, six-tenths hour; IV, one and one-tenth hours. All were taken in boiling *n*-butanol except IIIc which racemized so readily that boiling methyl acetate was employed. In these compounds, the bromine atom is only a third as effective as the methyl group (compare IIIa and I) in contributing to the restricted rotation of the molecule, and the nitro group is only one-fifth as effective as the small methoxyl (compare IIIc and II). It is thus obvious that factors other than the size of the groups are involved.

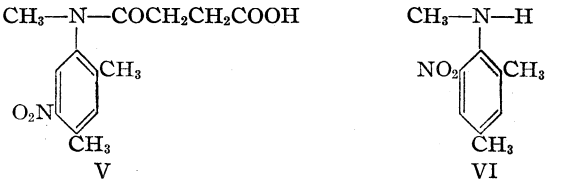
The basicity of aromatic amines is influenced profoundly by the presence of *o*-, *m*- or *p*-substituted electronegative groups as shown by the basic constants of *o*-toluidine, 2.9×10^{-10}; *o*-bromoaniline, 2.1×10^{-12}; *o*-iodoaniline, 0.36×10^{-12}; *o*-nitroaniline, 3.5×10^{-14}.[5a] The difference in basicity of these molecules is usually assigned to the effect of the bromine and iodine atoms or nitro group in inducing a positive nitrogen atom in the amino group. In the case of the nitro compound, a valence formula may be written which indicates the double-bond character of the carbon and amino-nitrogen linkage. For the halogens, an analogous structure cannot be written on a conventional basis but the mere fact that the basicity of the amines is reduced by the substitution of such atoms establishes the fact that the nitrogen is more positive, which condition is compatible with a linkage having double-bond character. For such a double bond to be produced the plane formed by the nitrogen and its two substituents must be coplanar with the ring. The racemization process, in which conversion of a *d*-form to an *l*-form and *vice versa* must take place through a coplanar configuration, should be facilitated by the presence in the optically active amines of groups favoring coplanarity. Thus the anomalous ease of racemization of hindered aromatic amines substituted with halogen or nitro groups in the *ortho* position is probably associated with their decreased basicity. The N-succinyl-1-methylamino-2-methyl-4,6-dibromobenzene (IV) was prepared in order to determine the effect of two electronegative bromine atoms in the *o*- and *p*-positions as compared with that of a single bromine in the *o*-position. The half-life of the former is only about a third of the latter, thus confirming the idea that the stability of these optically active aromatic amines is intimately connected with the base strength of the amino nitrogen atom and is greatly reduced by electronegative substituents. Apparently the larger size of the iodine atom overbalances the increase in ease of racemization induced by decrease in the basicity of the amine (compare I, IIIa, IIIb).

This relationship of basicity of the aromatic amines to the stability of their optically active hindered derivatives serves to explain the shorter half-life (four and one-tenth hours) of N-succinyl-1-methylamino-4-chloro-2-methylnaphthalene in comparison with that of N-succinyl-1-methylamino-2-methylnaphthalene (five and seven-tenths hours).[3c] It may also account for the non-resolvability of N-benzenesulfonyl-1-carboxymethylamino-2,4-dimethyl-6-nitrobenzene reported by Yuan.[5b]

The increase in double-bond character of the carbon and amino-nitrogen bond would result in a decrease in the bond length. The groups on the nitrogen would then be closer to the ring and interfere more readily with the adjacent substituents on the ring. It is assumed that this effect is so small in comparison to that already discussed that it may be disregarded.

The best synthesis of the bromo and iodo derivatives (IIIa and IIIb) was effected by brominating or iodinating 1-amino-2,4-dimethylbenzene, then monomethylating the amino group with dimethyl sulfate. Iodination of 1-methylamino-2,4-dimethylbenzene failed, using conditions successful for the iodination of the primary amine. Succinic anhydride in dry benzene with a drop of 85% phosphoric acid as catalyst was a satisfactory procedure for succinylation of the 1-methylamino compounds although the reaction was slow in the case of the molecules substituted with electronegative groups. 1-Methylamino-2-methyl-4,6-dibromobenzene was prepared by brominating the 1-methylamino-2-methylbenzene.

The production of the nitro compound (IIIc) was attempted first by the action of cold yellow nitric acid upon N-succinyl-1-methylamino-2,4-dimethylbenzene. A mono nitro derivative was readily formed but further study indicated the nitro group to be probably in the 5- (V) rather than in the 6-position. This orientation was observed by Gnehm and Blumer,[6] who nitrated N-acetyl-1-methylamino-2-methylbenzene in sulfuric acid with a nitric acid–sulfuric acid mixture and obtained the 5-nitro compound. The same compound was produced upon using cold yellow



V VI

(5a) Williams and Soper, *J. Chem. Soc.*, 2469 (1930); Bennett, Brooks and Glasstone, *ibid.*, 1821 (1935); Myrbäck, *Z. physiol. Chem.*, **158**, 261 (1926).

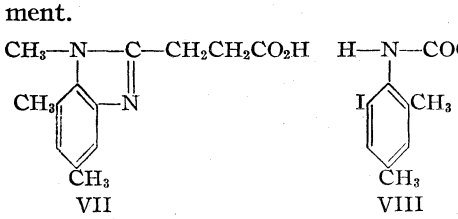
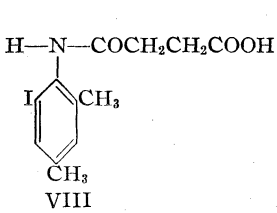
(6) Gnehm and Blumer, *Ann.*, **304**, 99 (1899).

nitric acid. Hydrolysis of the succinyl group of V resulted in the formation of a compound not identical with VI, which had been previously prepared by nitration of the N-nitroso-1-methylamino-2,4-dimethylbenzene followed by denitrosation. Compound IIIc was subsequently synthesized by succinylating VI.

The *d*-modification of the nitro compound (IIIc) was hydrogenated at room temperature in ether solution with platinum oxide as catalyst. The crude product was *dextro*-rotatory. After this product had been heated in boiling *n*-butanol for about an hour, a compound resulted which was optically inactive. This compound was not the amine (III, X = NH_2) since a molecule of water had been lost as shown by analysis. It must be the corresponding benzimidazole (VII). That this is so has been demonstrated by Betrabet and Chakravarti,[7] who obtained benzimidazole-2-β-propionic acid upon refluxing an absolute ethanol solution of N-succinyl-*o*-phenylenediamine. The product from the hydrogenation was undoubtedly the crude optically active amine which condensed to the benzimidazole during the subsequent treatment.



VII



VIII

Compound VIII, which differs from compound IIIb by having the N-methyl group missing, was not resolvable through its crystalline brucine salt. If the compound truly proves to be unresolvable, this would show the important contribution the N-methyl group makes to the restricted rotation in these compounds.

The optically active forms of the nitro compound (IIIc) and the dibromo compound (IV) were partially racemized during the process of crystallizing the crude acids obtained from the decomposition of their cinchonidine salts. For this reason the specific rotations of the crude optically active acids are reported since they should approximate the maximum specific rotations.

No particular complications were encountered in the resolution of the various compounds except in the case of the iodo derivative (IIIb). The salt tended to dissociate so that it was impossible to obtain a product of maximum rotation. The technique employed in the racemization determinations was that described in a previous communication.[3c]

Experimental

1-Methylamino-2,4-dimethyl-6-bromobenzene.—A mixture of 40 g. of 1-amino-2,4-dimethyl-6-bromobenzene,[8] 25 g. of dimethyl sulfate and 100 ml. of water was stirred with gentle warming on a steam-bath until homogeneous. The temperature was not permitted to go over 70°. The cooled solution was acidified with 30 ml. of concentrated hydrochloric acid, cooled to below 10°, and a solution of 14 g. of sodium nitrite in 50 ml. of water added dropwise with stirring, keeping the temperature between 5–10°. Stirring was continued for fifteen minutes after the addition of the sodium nitrite. The cold solution was extracted with ether, the ether layer washed with 5% aqueous sodium hydroxide, and then with water. The ether was evaporated by directing a stream of air over the surface of the solution.

The nitrosamine was reduced by careful addition in portions to a solution of 136 g. of stannous chloride dihydrate in 132 ml. of concentrated hydrochloric acid. The stannous chloride solution was heated to 40° before the first addition of the nitrosamine. In order to keep the temperature under 60° after several portions of the nitrosamine were added, cooling was necessary. After each addition the flask was shaken by hand. A precipitate of the tin complex slowly settled out. After standing overnight, the mixture was cooled in ice, and made strongly alkaline by addition of a solution of 176 g. of sodium hydroxide in 250 ml. of water. The mixture was steam-distilled until the distillate came over clear. The distillate was saturated with sodium chloride, extracted with ether, the extract dried over solid potassium hydroxide and the ether distilled. The secondary amine was distilled *in vacuo*, b. p. 92–94° (4.5 mm.); yield, 21 g. (49%); $n^{20}D$ 1.5682; d^{20}_4 1.3379.

Anal. Calcd. for $C_9H_{12}BrN$: C, 50.50; H, 5.60; M_D, 52.6. Found: C, 50.54; H, 5.78; M_D, 52.4.

N-Succinyl-1-methylamino-2,4-dimethyl-6-bromobenzene.—To a solution of 13 g. of succinic anhydride in 100 ml. of dry benzene was added 15 g. of 1-methylamino-2,4-dimethyl-6-bromobenzene and a drop of 85% phosphoric acid. The solution was refluxed for four hours, cooled, diluted with 100 ml. of ether, and extracted with 5% aqueous potassium hydroxide. The alkaline extract was washed with ether and acidified with 1:2 hydrochloric acid. The product separated as an oil which solidified on stirring in ice. It was recrystallized from a mixture of three volumes of carbon tetrachloride and one volume of petroleum ether (b. p. 60–110°); white crystals, m. p. 115.5–116.5° (cor.); yield, 9 g. (41%).

Anal. Calcd. for $C_{13}H_{16}BrNO_3$: C, 49.68; H, 5.09. Found: C, 49.79; H, 5.16.

Resolution of N-Succinyl-1-methylamino-2,4-dimethyl-6-bromobenzene.—A solution of 5 g. of N-succinyl-1-methylamino-2,4-dimethyl-6-bromobenzene and 4.68 g. of cinchonidine in 180 ml. of 9:1 ethyl acetate–methanol by volume was filtered and evaporated to 145 ml. by directing a stream of air over its surface. After four days in the refrigerator, 3.1 g. of salt had crystallized. These crystals were collected and the filtrate evaporated to 137 ml. Refrigerated, it yielded a second crop of 1.4 g. At 125 ml., 1.3 g. of salt crystallized; at 110 ml., 0.1 g.; at 90 ml., 1.3 g. The first three fractions were combined and recrystallized in the same manner to constant rotation; this produced white feathery crystals m. p. 164–165° (cor.); yield, 1.8 g.

Anal. (*l*B*d*A) Calcd. for $C_{13}H_{16}BrNO_3 \cdot C_{19}H_{22}N_2O$: C, 63.36; H, 6.27. Found: C, 63.44; H, 6.60. *Rotation.* (*l*B*d*A) 0.03 g. made up to 10 ml. with absolute ethanol at 28° gave α_D −0.13°; *l*, 1; $[\alpha]^{28}D$ −43°.

***d*-N-Succinyl-1-methylamino-2,4-dimethyl-6-bromobenzene.**—To 75 ml. of 1:1 hydrochloric acid at 0° was added 1.65 g. of the less-soluble salt. The mixture was stirred for fifteen minutes and then put in a refrigerator overnight. The next day the gummy material had solidified and it was broken up. The mixture was filtered and the solid material again stirred with cold 1:1 hydrochloric acid and put in a refrigerator overnight. This treatment was repeated until the filtrate gave a negative test with Folin's reagent.[9] The residue was dried in a vacuum desiccator; yield, 0.49 g. The acid was crystallized

from a mixture of benzene and petroleum ether (b. p. 60–110°). The rotation was unchanged by the crystallization.

The *d*-acid was obtained from the less-soluble salt; white crystals, m. p. 118.5–120.5° (cor.).

Anal. (*d*-acid) Calcd. for $C_{13}H_{16}BrNO_3$: C, 49.68; H, 5.09. Found: C, 49.95; H, 5.18. *Rotation.* (*d*-acid) 0.05 g. made up to 10 ml. with absolute ethanol at 28° gave α_D +0.125°; *l*, 1; $[\alpha]^{28}D$ +25°.

Racemization of *d*-N-Succinyl-1-methylamino-2,4-dimethyl-6-bromobenzene.—The racemization was carried out in a polarimeter tube constructed from Pyrex tubing (25 mm. outside diameter, 100 mm. internal length) and fitted at the center to a reflux condenser by means of a ground-glass joint.[30] A solution of 0.15 g. of the *d*-acid made up to 25 ml. with *n*-butanol was added to the polarimeter tube. The rotation was observed, several small carborundum boiling chips added, and the polarimeter tube with its contents weighed. The polarimeter tube was then placed on a hot-plate and the solution concentrated to 15 ml. by boiling without reflux. The reflux condenser was attached and the solution refluxed until the total boiling period was one-half hour. The solution was cooled rapidly by plunging the tube into cold water, made up to the previously determined weight with *n*-butanol, and the rotation observed. By repetition of this process, the following α_D values were obtained: at the start, +0.148°; after one-half hour, +0.133°; after one and one-half hours, +0.105°; after two and one-quarter hours, +0.091°; after three and one-half hours, +0.068°; after five hours, +0.050°; after seven hours, +0.030°. Calculated for a reversible unimolecular reaction, the half-life was three and one-tenth hours. A check racemization gave a half-life of three and two-tenths hours.

1-Amino-2,4-dimethyl-6-iodobenzene.—This procedure was modeled after that for the iodination of *p*-toluidine used by Wheeler and Liddle.[10] To 28.2 g. of 1-amino-2,4-dimethylbenzene 59.5 g. of ground iodine was added with stirring. The addition of the iodine took about forty-five minutes. The reaction mixture was kept below 45° by cooling with cold water. After the completion of the addition of the iodine, the stirring was continued until the heat of the reaction had subsided. After the addition of 60 ml. of ether, 60 ml. of water and 28 g. of calcium carbonate, the mixture was refluxed on a steam-bath until the evolution of carbon dioxide ceased. This took several hours. The ether was distilled on the steam-bath and the residue steam-distilled. The first portion of the distillate was a red oil but after a short time material began to solidify in the lower part of the condenser. The water in the condenser had to be allowed to run out occasionally to permit the solid material to melt and run into the receiver. The solid product was collected on a filter, dried and crystallized twice from ethanol; white crystals that darkened on contact with the air, m. p. 66–67° (cor.); yield, 24 g. (42%). Kerschbaum[11] reported a m. p. of 65°.

1-Methylamino-2,4-dimethyl-6-iodobenzene.—The procedure described for the methylation of 1-amino-2,4-dimethyl-6-bromobenzene was used with several changes. The dimethyl sulfate was added dropwise to a stirred mixture of the 1-amino-2,4-dimethyl-6-iodobenzene and water at 70°. About a 20% excess of dimethyl sulfate was used. It was found that the nitrosamine was not reduced appreciably at 50° in the stannous chloride–hydrochloric acid mixture. The optimum temperature for the reduction was 70°. Above 80° an appreciable amount of the iodine was reduced off. From 83 g. of the primary amine, 24 g. (27.4%) of the secondary amine was obtained; b. p. 108–110° (4 mm.); d^{20}_4 1.5588; $n^{20}D$ 1.6050.

Anal. Calcd. for $C_9H_{12}IN$: C, 41.38; H, 4.60; M_D, 57.7. Found: C, 41.43; H, 4.82; M_D, 57.5.

(11) Kerschbaum, *Ber.*, **28**, 2798 (1895).

N-Succinyl-1-methylamino-2,4-dimethyl-6-iodobenzene.—To a solution of 6.6 g. of succinic anhydride in 40 ml. of dry benzene was added 16 g. of 1-methylamino-2,4-dimethyl-6-iodobenzene and a drop of 85% phosphoric acid. The solution was refluxed for four hours, cooled, ether added, and the mixture extracted with 5% aqueous potassium hydroxide. The alkaline extract was acidified with 1:2 hydrochloric acid. After cooling and stirring for an hour, the product remained oily, so it was dissolved in ether and the ether solution dried with anhydrous magnesium sulfate. After removal of the magnesium sulfate by filtration and evaporation of the ether, first on a steam-bath, then *in vacuo*, the product slowly crystallized. The product was recrystallized from a mixture of three volumes of carbon tetrachloride and one volume of petroleum ether (b. p. 60–110°); white crystals, m. p. 103–104° (cor.); yield, 6.6 g. (30%).

Anal. Calcd. for $C_{13}H_{16}INO_3$: C, 43.21; H, 4.43. Found: C, 43.35; H, 4.57.

Resolution of N-Succinyl-1-methylamino-2,4-dimethyl-6-iodobenzene.—A solution of 5.6 g. of N-succinyl-1-methylamino-2,4-dimethyl-6-iodobenzene and 4.56 g. of cinchonidine in 55 ml. of 9:1 ethyl acetate–methanol by volume was filtered and evaporated to 45 ml. by directing a stream of air to the top of the flask. After four days in the refrigerator, 4 g. of salt had crystallized. Upon concentrating the mother liquor to 40 ml. and refrigerating, 1.5 g. of salt crystallized; at 30 ml., 1.6 g.; at 19 ml., 1.0 g.; at 4 ml., 0.5 g. It had been found while working with this salt previously that during recrystallization of the salt it dissociated, so the first crop was not recrystallized further; white crystals, m. p. 140–145° (cor.).

Anal. (*l*BdA) Calcd. for $C_{13}H_{16}INO_3 \cdot C_{19}H_{22}N_2O$: C, 58.62; H, 5.85. Found: C, 58.53; H, 5.97. *Rotation.* (*l*BdA) 0.05 g. made up to 10 ml. with ethanol at 26° gave α_D −0.23°; *l*, 1; $[\alpha]^{26}D$ −46°.

The fourth and fifth fractions were combined and crystallized once; white crystals; yield, 1.1 g.

Rotation. (*l*BlA) 0.05 g. made up to 10 ml. with ethanol at 31° gave α_D −0.315°; *l*, 1; $[\alpha]^{31}D$ −63°.

***d*- and *l*-N-Succinyl-1-methylamino-2,4-dimethyl-6-iodobenzene.**—The salts were decomposed in the same manner as the salt of the 6-bromo compound. From 4 g. of the less-soluble salt, 1.2 g. of the *d*-acid was obtained after one crystallization from a mixture of three volumes of carbon tetrachloride and one volume of petroleum ether (b. p. 60–110°); white crystals, m. p. 105–106° (cor.).

Anal. (*d*-acid) Calcd. for $C_{13}H_{16}INO_3$: C, 43.21; H, 4.43. Found: C, 43.22; H, 4.41. *Rotation.* (*d*-acid) 0.435 g. made up to 25 ml. with *n*-butanol at 33° gave α_D +0.21°; *l*, 1; $[\alpha]^{33}D$ +12°.

This *d*-acid did not have the maximum specific rotation since it was found that recrystallizing the less-soluble salt of another resolution several times, in spite of the dissociation of the salt, and then decomposing gave an acid with a specific rotation of +43° and a m. p. of 108° (cor.).

The decomposition of the more-soluble fraction did not give the pure *l*-acid; white crystals, m. p. 105–106° (cor.).

Rotation. (*l*-acid) 0.05 g. made up to 10 ml. with ethanol at 31° gave α_D −0.09°; *l*, 1; $[\alpha]^{31}D$ −18°.

Racemization of *d*-N-Succinyl-1-methylamino-2,4-dimethyl-6-iodobenzene.—The procedure described for the racemization of *d*-N-succinyl-1-methylamino-2,4-dimethyl-6-bromobenzene was used. A solution of 0.435 g. of the *d*-acid made up to 25 ml. with *n*-butanol was racemized. The following α_D values were obtained: at the start, +0.210°; after four hours, +0.182°; after nine hours, +0.154°; after fifteen hours, +0.127°; after twenty-one and one-half hours, +0.100°; after thirty and one-half hours, +0.075°; after forty-one and one-half hours, +0.052°. Calculated for a reversible unimolecular reaction, the half-life was twenty and one-half hours. A check racemization gave a half-life of nineteen and four-tenths hours.

1-Methylamino-2-methylbenzene.—By the same general procedure described below for the preparation of 1-methylamino-2,4-dimethylbenzene, 214 g. of *o*-toluidine was methylated to give 89 g. (37%) of product having a b. p. of 95° (15 mm.). Monnet, Reverdin and Nölting[12] report a b. p. of 207–208°.

1-Methylamino-2-methyl-4,6-dibromobenzene.—This compound was prepared by the method of Fries.[13] One minor change was made in his procedure in that anhydrous sodium acetate was added to bring the reaction to completion as well as heating. From 89 g. of 1-methylamino-2-methylbenzene was prepared 170 g. (82.5%) of product having a b. p. of 122–123° (1 mm.). Fries reports a b. p. of 187° (50 mm.).

N-Succinyl-1-methylamino-2-methyl-4,6-dibromobenzene.—To a solution of 27 g. of succinic anhydride in 210 ml. of dry benzene was added 69 g. of 1-methylamino-2-methyl-4,6-dibromobenzene and a drop of 85% phosphoric acid. This mixture was refluxed for twenty-two hours. The reaction mixture was worked up in the manner described in the preparation of N-succinyl-1-methylamino-2,4-dimethyl-6-iodobenzene. The product was recrystallized from a carbon tetrachloride–petroleum ether (b. p. 60–110°) mixture; white crystals, m. p. 116–117° (cor.); yield, 19 g. (20.2%).

Anal. Calcd. for $C_{12}H_{13}Br_2NO_3$: C, 38.00; H, 3.43. Found: C, 38.11; H, 3.66.

Resolution of N-Succinyl-1-methylamino-2-methyl-4,6-dibromobenzene.—A solution of 18 g. of N-succinyl-1-methylamino-2-methyl-4,6-dibromobenzene and 13.97 g. of cinchonidine in 200 ml. of 9:1 ethyl acetate–methanol by volume was filtered. This solution was concentrated by means of a gentle air stream to 170 ml. The crop of salt which had crystallized was collected. The dried product weighed 13.3 g. Concentration of the mother liquor to 130 ml. produced a second crop of 3.9 g. At 115 ml., 2.0 g. of salt crystallized; at 80 ml., 3.8 g.; and at 40 ml., 3.7 g. The first crop was recrystallized in the same manner to constant rotation. White feathery crystals were obtained; m. p. 161–163° (cor.); yield, 2.9 g.

Anal. (*l*B*d*A) Calcd. for $C_{12}H_{13}Br_2NO_3 \cdot C_{19}H_{22}N_2O$: C, 55.27; H, 5.20. Found: C, 55.63; H, 5.32. *Rotation.* (*l*B*d*A) 0.05 g. made up to 10 ml. with ethanol at 32° gave α_D −0.245°; *l*, 1; $[\alpha]^{32}D$ −49°.

Recrystallization of the fifth crop failed to change its rotation.

Rotation. (*l*B*l*A) 0.05 g. made up to 10 ml. with ethanol at 30° gave α_D −0.285°; *l*, 1; $[\alpha]^{30}D$ −57°.

***d*- and *l*-N-Succinyl-1-methylamino-2-methyl-4,6-dibromobenzene.**—The salts were decomposed in the same manner as the salt of the 6-bromo compound. From the less-soluble salt the *d*-acid was obtained. The rotation was observed before the acid was crystallized from a carbon tetrachloride–petroleum ether (b. p. 60–110°) mixture.

Rotation. (*d*-acid) 0.10 g. made up to 10 ml. with *n*-butanol at 32° gave α_D +0.07°; *l*, 1; $[\alpha]^{32}D$ +7°.

Crystallization of this acid produced white crystals; m. p. 118° (cor.).

Anal. (*d*-acid) Calcd. for $C_{12}H_{13}Br_2NO_3$: C, 38.00; H, 3.43. Found: C, 38.14; H, 3.52. *Rotation.* (*d*-acid) 0.51 g. made up to 15 ml. with *n*-butanol at 32° gave α_D +0.13°; *l*, 1; $[\alpha]^{32}D$ +3.8°.

Decomposition of the more-soluble salt gave the *l*-acid, which was not entirely pure.

Rotation. (*l*-acid) 0.45 g. made up to 10 ml. with ethanol at 30° gave α_D −0.245°; *l*, 1; $[\alpha]^{30}D$ −5.4°.

Racemization of *d*-N-Succinyl-1-methylamino-2-methyl-4,6-dibromobenzene.—A solution of 0.7 g. of the *d*-acid made up to 15 ml. with *n*-butanol was racemized. The solution was kept at this concentration throughout the racemization. This was done by weighing the polarimeter tube before the first period of refluxing and then making the tube up to this weight after each period of refluxing by adding *n*-butanol. Otherwise the procedure was the same as described for the racemization of *d*-N-succinyl-1-methylamino-2,4-dimethyl-6-bromobenzene. The following α_D values were obtained: at the start, +0.313°; after one-quarter hour, +0.268°; after one-half hour, +0.231°; after one hour, +0.166°; after one and one-half hours, +0.124°; after two and one-half hours, +0.066°. Calculated for a reversible unimolecular reaction, the half-life was one and one-tenth hours. This value was checked by repeating the racemization.

N-Succinyl-1-amino-2,4-dimethyl-6-iodobenzene.—To a solution of 9 g. of succinic anhydride and 21 g. of 1-amino-2,4-dimethyl-6-iodobenzene in 150 ml. of dry benzene was added one drop of 85% phosphoric acid. This mixture was refluxed for one hour, a white solid separating after fifteen minutes of refluxing. The mixture was cooled and allowed to stand at room temperature for several hours to complete the crystallization of the product. The solid was separated from the mother liquor by filtration and dried. It was recrystallized from a mixture of five volumes of ethanol and three volumes of water; white powder, m. p. 207–208° (cor.); yield, 8 g. (27%).

Anal. Calcd. for $C_{12}H_{14}INO_3$: C, 41.52; H, 4.04. Found: C, 41.87; H, 4.19.

Attempted Resolution of N-Succinyl-1-amino-2,4-dimethyl-6-iodobenzene.—A solution of 5 g. of N-succinyl-1-amino-2,4-dimethyl-6-iodobenzene and 5.68 g. of brucine in 230 ml. of ethyl acetate was filtered and concentrated to 210 ml. by directing a stream of air to the top of the flask. At this volume, 3.0 g. of salt had crystallized. At 190 ml., 2.8 g. crystallized and at 185 ml., 0.8 g. All of these crops showed the same rotation. The first two crops were combined and recrystallized in the same manner with no change of rotation; white crystals, m. p. 103–110° (cor.).

Anal. Calcd. for $C_{12}H_{14}INO_3 \cdot C_{23}H_{26}N_2O_4$: C, 56.67; H, 5.39. Found: C, 56.18; H, 5.62. *Rotation.* 0.05 g. made up to 10 ml. with ethanol at 25° gave α_D −0.140°; *l*, 1; $[\alpha]^{25}D$ −28°.

Decomposition of this salt in the previously described manner produced an optically inactive acid.

1-Methylamino-2,4-dimethylbenzene.—The procedure of Fichter and Müller[14] was improved.

A well-stirred mixture of 108.6 g. of 1-amino-2,4-dimethylbenzene and 450 ml. of water was heated to 50°. To this was added dropwise 100 g. of dimethyl sulfate over a period of about forty-five minutes. Cooling was applied to keep the temperature from rising above 50°. After the solution had become homogeneous, it was stirred for a half hour. When cool, it was acidified with 135 ml. of concentrated hydrochloric acid. It was cooled to below 10° and a solution of 62.3 g. of sodium nitrite in 175 ml. of water added dropwise. The cold solution was extracted with ether and the ether evaporated with a stream of air. The nitrosamine was reduced by adding it in portions to a solution of 610 g. of stannous chloride dihydrate in 630 ml. of concentrated hydrochloric acid. The temperature was kept below 60° during the reduction. A heavy precipitate of the tin complex settled to the bottom. After standing overnight, the mixture was made strongly alkaline with 40% aqueous sodium hydroxide and steam-distilled. The distillate was saturated with sodium chloride and extracted with ether. The ether extract was dried with solid potassium hydroxide, the ether removed by distillation and the amine distilled *in vacuo*, b. p. 89–91° (7 mm.); yield, 43 g. (35.5%). Pinnow and Oesterreich[15] report a b. p. of 220.5–221.5° (760 mm.).

N-Succinyl-1-methylamino-2,4-dimethylbenzene.—To a solution of 14.9 g. of succinic anhydride in 200 ml. of dry benzene was added 20 g. of 1-methylamino-2,4-dimethylbenzene and a drop of 85% phosphoric acid. The solution was refluxed for six hours, cooled, diluted

with ether and extracted with 5% aqueous sodium hydroxide. The alkaline extract was acidified with 1:2 hydrochloric acid. The product separated as an oil which solidified on stirring and cooling. It was recrystallized from benzene; white crystals, m. p. 133–134° (cor.); yield, 22 g. (63%).

Anal. Calcd. for $C_{13}H_{17}NO_3$: C, 66.38; H, 7.23. Found: C, 66.79; H, 7.42.

Nitration of N-Succinyl-1-methylamino-2,4-dimethylbenzene; N-Succinyl-1-methylamino-2,4-dimethyl-5-nitrobenzene.—To 25 ml. of well-stirred fuming nitric acid (sp. gr. 1.49) in a small flask cooled in an ice-bath was added in small portions 6 g. of N-succinyl-1-methylamino-2,4-dimethylbenzene. The mixture was allowed to stand for fifteen minutes and then poured onto ice. The mixture was made alkaline with concentrated aqueous ammonia, cooled with ice, and made acid to litmus with hydrochloric acid. The product settled out as an oil which solidified on standing a day in the refrigerator. The product was treated with Norit in methanol and recrystallized from benzene; light yellow crystals, m. p. 144.5–145.5° (cor.) with sintering at 139°; yield, 2.9 g. (40%).

Anal. Calcd. for $C_{13}H_{16}N_2O_5$: C, 55.71; H, 5.71. Found: C, 55.98; H, 5.48.

Hydrolysis of the Product of the Nitration of N-Succinyl-1-methylamino-2,4-dimethylbenzene; 1-Methylamino-2,4-dimethyl-5-nitrobenzene.—To 20 ml. of 1:1 hydrochloric acid was added 2 g. of the nitro compound. This mixture was refluxed for two hours, cooled, and made alkaline with 10% aqueous sodium hydroxide. The precipitate was removed by filtration, washed with water, and recrystallized from ethanol; orange-red needles, m. p. 140–141° (cor.).

Anal. Calcd. for $C_9H_{12}N_2O_2$: C, 60.00; H, 6.66. Found: C, 60.18; H, 6.55.

N¹-Succinyl-1-methylamino-2,4-dimethyl-5-aminobenzene.—To a solution of 13 g. of N-succinyl-1-methylamino-2,4-dimethyl-5-nitrobenzene in 150 ml. of absolute ethanol was added 0.2 g. of platinum oxide. At room temperature and an initial pressure of 45 lb. the calculated amount of hydrogen was absorbed. The catalyst was removed by filtration and the ethanol evaporated. The product was recrystallized from absolute ethanol; almost transparent crystals, m. p. 169–172° (cor.); yield, 9.3 g. (80%).

Anal. Calcd. for $C_{13}H_{18}N_2O_3$: C, 62.40; H, 7.20. Found: C, 62.61; H, 7.35.

Methyl Ester of N¹-Succinyl-1-methylamino-2,4-dimethyl-5-aminobenzene.—A solution of 2 g. of N¹-succinyl-1-methylamino-2,4-dimethyl-5-aminobenzene in 40 ml. of methanol containing 5% of dry hydrogen chloride by weight was allowed to stand for two days at room temperature. The methanol was evaporated at room temperature *in vacuo*. The resulting oil was poured onto a watch glass and allowed to stand one week. This did not cause complete crystallization, so it was shaken with dilute aqueous ammonia, the material solidifying nicely. The solid was removed by filtration, washed with dilute aqueous ammonia and with water, and recrystallized from a mixture of one volume of ethanol and two volumes of water; white crystals, m. p. 109–110° (cor.); yield, 1.5 g. (72%).

Anal. Calcd. for $C_{14}H_{20}N_2O_3$: C, 63.63; H, 7.60. Found: C, 64.37; H, 8.07.

N-Acetyl-1-methylamino-2,4-dimethylbenzene.—This was prepared by the acetylation of 1-methylamino-2,4-dimethylbenzene with acetic anhydride in acetic acid. The product had a m. p. of 63–63.5° (cor.). Pinnow and Oesterreich[15] report a m. p. of 65°.

N-Acetyl-1-methylamino-2,4-dimethyl-5-nitrobenzene.—Nitration of 25 g. of N-acetyl-1-methylamino-2,4-dimethylbenzene by the previously described procedure (acidification was unnecessary after treatment of the reaction mixture with concentrated aqueous ammonia) gave 6.3 g. (20%) of product; light yellow crystals from a mixture of three volumes of petroleum ether (b. p. 60–110°) and one volume of benzene, m. p. 109–110° (cor.).

Anal. Calcd. for $C_{11}H_{14}N_2O_3$: C, 59.46; H, 6.30. Found: C, 59.40; H, 6.31.

N¹-Acetyl-1-methylamino-2,4-dimethyl-5-aminobenzene.—To a solution of 16 g. of N-acetyl-1-methylamino-2,4-dimethyl-5-nitrobenzene in 150 ml. of absolute ethanol 0.1 g. of platinum oxide was added. At room temperature and an initial pressure of 47 lb. the calculated amount of hydrogen was absorbed. The catalyst was removed by filtration and the ethanol evaporated. The residue was recrystallized from benzene; white crystals, m. p. 134–134.5° (cor.); yield, 11 g. (80%).

Anal. Calcd. for $C_{11}H_{16}N_2O$: C, 68.75; H, 8.33. Found: C, 68.81; H, 8.50.

N-Acetyl-1-methylamino-2-methyl-5-nitrobenzene.—N-Acetyl-1-methylamino-2-methylbenzene[12] was nitrated in the previously described manner (acidification was unnecessary after treatment of the reaction mixture with ammonia). The product was recrystallized from dilute ethanol; light yellow crystals, m. p. 119° (cor.). Gnehm and Blumer[6] report a m. p. of 119° for the product they received on nitrating the same compound in sulfuric acid with a nitric acid–sulfuric acid mixture.

N-Nitroso-1-methylamino-2,4-dimethyl-6-nitrobenzene.—The method of Pinnow and Oesterreich[15] for the preparation of the same compound was used.

Methylation and nitrosation of 217 g. of 1-amino-2,4-dimethylbenzene following the procedure given for the preparation of 1-methylamino-2,4-dimethylbenzene gave 106 g. of wet, crude N-nitroso-1-methylamino-2,4-dimethylbenzene. Nitration in acetic acid gave 65 g. of N-nitroso-1-methylamino-2,4-dimethyl-6-nitrobenzene (17.4% based on the 1-amino-2,4-dimethylbenzene used); light yellow crystals (not pure), m. p. 58–61° (cor.). Pinnow and Oesterreich report a m. p. of 63°.

1-Methylamino-2,4-dimethyl-6-nitrobenzene.—The same procedure that Pinnow and Oesterreich used for the removal of the nitroso group was followed. From 60 g. of the nitrosamine, 25.4 g. (49%) of the secondary amine was obtained. The product was purified by steam distillation and recrystallization from methanol; dark red plates, m. p. 56–57° (cor.). Pinnow and Oesterreich report a m. p. of 58°.

N-Succinyl-1-methylamino-2,4-dimethyl-6-nitrobenzene.—To a solution of 28 g. of succinic anhydride and 24 g. of 1-methylamino-2,4-dimethyl-6-nitrobenzene in 100 ml. of dry benzene was added one drop of 85% phosphoric acid. This mixture was refluxed for seventy-two hours, cooled, diluted with ether and extracted with 5% aqueous sodium hydroxide. The alkaline extracts were acidified with dilute hydrochloric acid. The oil which was formed slowly solidified on standing. It was recrystallized from benzene. One treatment with Norit in benzene removed a tan color from the crystals; light yellow crystals, m. p. 129–131° (cor.); yield, 9 g. (24%).

Anal. Calcd. for $C_{13}H_{16}N_2O_5$: C, 55.71; H, 5.71. Found: C, 55.89; H, 5.92.

Resolution of N-Succinyl-1-methylamino-2,4-dimethyl-6-nitrobenzene.—A solution of 5.5 g. of N-succinyl-1-methylamino-2,4-dimethyl-6-nitrobenzene and 5.775 g. of cinchonidine in 100 ml. of 9:1 ethyl acetate–methanol by volume was filtered. The filtrate was evaporated to 65 ml. by directing a stream of air to the top of the flask. It was seeded with crystals obtained by allowing 1 ml. of the solution to evaporate slowly in a small test-tube. After five days in the refrigerator, 1.9 g. of salt had crystallized. Upon concentrating the mother liquor to 35 ml. and refrigerating, 4.7 g. of salt crystallized; at 20 ml., 1.8 g.; and at 5 ml., 0.25 g. The first two fractions were combined and recrystallized in the same manner to constant rotation. White feathery crystals were obtained; m. p. 141–143° (cor.); yield, 1.5 g.

Anal. (*l*Bd*A*) Calcd. for $C_{13}H_{16}N_2O_5 \cdot C_{19}H_{22}N_2O$: C, 66.90; H, 6.67. Found: C, 66.32; H, 6.60. *Rotation.* (*l*Bd*A*) 0.05 g. made up to 10 ml. with ethanol and 26° gave α_D −0.20°; *l*, 1; $[\alpha]^{26}D$ −40°.

***d*-N-Succinyl-1-methylamino-2,4-dimethyl-6-nitrobenzene.**—The less-soluble salt was decomposed with 0.5% hydrochloric acid in the same manner as the salt of the 6-bromo compound. Before crystallization from benzene the specific rotation was determined.

Rotation. (*d*-acid) 0.05 g. made up to 10 ml. with ethanol at 25° gave α_D +0.125°; *l*, 1; $[\alpha]^{25}D$ +25°.

Crystallization from benzene produced light yellow crystals; m. p. 130–131° (cor.).

Anal. (*d*-acid) Calcd. for $C_{13}H_{16}N_2O_5$: C, 55.71; H, 5.71; N, 10.00. Found: C, 56.22; H, 5.87; N, 10.07. *Rotation.* (*d*-acid) 0.05 g. made up to 10 ml. with ethanol at 25° gave α_D +0.05°; *l*, 1; $[\alpha]^{25}D$ +10°.

Racemization of *d*-N-Succinyl-1-methylamino-2,4-dimethyl-6-nitrobenzene.—The *d*-acid was completely racemized in a half hour in boiling *n*-butanol.

A solution of 0.25 g. of the *d*-acid made up to 15 ml. with methyl acetate was racemized using the technique described for the racemization of *d*-N-succinyl-1-methylamino-2-methyl-4,6-dibromobenzene. The following α_D values were obtained: at the start, +0.215°; after fifteen minutes, +0.164°; after thirty minutes, +0.121°; after forty-five minutes, +0.091°; after sixty minutes, +0.067°; after ninety minutes, +0.037°. Calculated for a reversible unimolecular reaction, the half-life was thirty-six minutes. A check racemization gave a half-life of thirty-eight minutes.

Catalytic Hydrogenation of *d*-N-Succinyl-1-methylamino-2,4-dimethyl-6-nitrobenzene; 1,5,7-Trimethylbenzimidazole-2-β-propionic Acid.—A solution of 0.25 g. of *d*-N-succinyl-1-methylamino-2,4-dimethyl-6-nitrobenzene in 125 ml. of ether was hydrogenated at room temperature and 40 lb. pressure with 0.1 g. of platinum oxide as catalyst. At the end of the reduction, the catalyst was removed by filtration and the ether evaporated by directing a stream of air onto the solution. The residue was dried in a vacuum desiccator.

No quantitative specific rotation was determined for this crude product. However, a qualitative reading showed the material to be *dextro*-rotatory.

When a solution of the crude product in *n*-butanol was refluxed for about an hour, and cooled, white crystals separated. Recrystallized from ethanol, the material melted at 265–267° (cor.). It was soluble in 5% aqueous sodium bicarbonate and was optically inactive.

Anal. Calcd. for $C_{13}H_{16}N_2O_2$: C, 67.24; H, 6.89; N, 12.06. Found: C, 67.22; H, 6.82; N, 12.06.

Summary

1. Several new N-succinyl-1-methylamino-2,4-dimethyl-6-substituted benzenes and N-succinyl-1-methylamino-2-methyl-4,6-dibromobenzene have been prepared, resolved and the half-lives of the optically active forms determined.

2. The half-lives of the series are as follows: bromine, three and one-tenth hours; iodine, twenty and one-half hours; nitro, six-tenths hour; and the dibromo compound, one and one-tenth hours. Boiling *n*-butanol was used as solvent except in the case of the nitro compound where boiling methyl acetate was employed. The corresponding methyl and methoxyl analogs have been prepared previously and their half-lives are nine hours in boiling *n*-butanol and two and seven-tenths hours in boiling methyl acetate, respectively.

3. From these values, after comparison with the interference effects produced by the same groups in the biphenyl series, it was concluded that factors other than size of the groups were influencing the rates of racemization.

4. The basicity of aryl amines is reduced by the substitution of electronegative groups in the *o*-, *m*- or *p*-positions. A decrease in the expected stability of the optically active amines is observed with similar substituents. From these facts it appears that the increased double-bond character of the carbon–nitrogen bond in these amines of decreased basicity facilitates racemization. The tendency to form a double bond will aid in forcing the substituents on the amino nitrogen into a coplanar configuration with the ring.

The Reaction of Formaldehyde with Proteins. V. Cross-linking between Amino and Primary Amide or Guanidyl Groups

BY HEINZ FRAENKEL-CONRAT AND HAROLD S. OLCOTT

According to the opinion of most experts in the field, the tanning or hardening action of formaldehyde is probably not due to its primary addition to the amino or any other type of protein group, but rather to a secondary condensation reaction which transforms the methylol (—CH_2OH) groups into cross-linking methylene (—CH_2—) bridges. The first experimental evidence for the occurrence of condensation was supplied by Nitschmann and his co-workers, who showed that there was a loss of water during the reaction of casein with gaseous formaldehyde.[2,3] Proof for cross-linking was obtained in studies from this Laboratory, in which it was demonstrated that the average molecular weights of salmine[4] and other proteins[5] could be increased by formaldehyde treatment.

The question arose: Which protein group or groups are available for such condensation reactions with formaldehyde? Nitschmann, *et al.*,[2] showed that the amino groups were directly concerned.[6] Thus casein, in which the amino groups were largely protected with acetyl groups, bound formaldehyde only by addition, while condensation occurred when unmodified casein was used. However, experiments with salmine,[4] which con-

tains no primary amino groups,[7] suggested that at 70° guanidyl groups also react with formaldehyde to form cross-linking methylene groups. The isolation of djenkolic acid ($HOOC-CHNH_2-CH_2-S-CH_2-S-CH_2-CHNH_2-COOH$) from reduced keratins that had been treated with formaldehyde at elevated temperature[8] indicated that, under these conditions, cross-linking occurred between sulfhydryl groups. Nitschmann and Hadorn[2] proposed that the formation of methylene bridges between amino and peptide groups accounts for the tanning action of formaldehyde but this was not proved. Reactions involving pairs of amino[6] or of peptide groups[9] have also been hypothesized but appear to be chemically improbable. On the basis of experiments with formaldehyde and casein or casein derivatives, Wormell and Kaye[10] proposed the hypothesis that acid-hardening of this protein "occurs largely by means of cross-linking on to the amide groups using the formaldehyde already attached to amino groups."

It will be shown in the present study that, at room temperature and over a wide *p*H range, formaldehyde can form cross-linking methylene bridges between *amino* groups on the one hand, and *primary amide* or *guanidyl* groups on the other. The

$$R-NH_2 + HCHO + H_2NCO-R \longrightarrow R-NH-CH_2-NHCOR + H_2O \quad (I)$$

$$R-NH_2 + HCHO + NH_2-C(=NH)-NHR \longrightarrow R-NH-CH_2-NH-C(=NH)-NHR + H_2O \quad (II)$$

secondary amide groups of peptide bonds do not participate in Reaction I at room temperature. It will further be shown that, by the same reactions, ammonia or simple primary amines can be bound to protein amide groups; and simple amides or guanidines to the protein amino groups. The data suggest that the tanning action of formaldehyde on proteins at room temperature may be due largely to Reactions I and II.

Condensation products of low molecular weight secondary amines, formaldehyde and primary amides were described by Einhorn[11] but the reaction apparently has not since been studied in detail nor have its implications for the tanning mechanism been previously recognized.

Results

A. Model Experiments.—Model experiments with simple compounds were helpful in ascertaining which types of protein groups might be expected to become cross-linked through methylene bridges. For most of these experiments, 0.4–0.5 molar solutions of two different compounds were treated with about 2 molar formaldehyde at room temperature and at a *p*H where each compound by itself bound little if any formaldehyde in a manner which was not reversed in the presence of dimedon at *p*H 4.6. The binding of appreciable amounts, under such conditions, was regarded as evidence for a condensation reaction involving both nitrogenous components of the system. This conclusion was usually corroborated by other means of analysis and, in some cases, by isolation of the reaction products.

The limitations of such an experimental approach are two-fold: (1) Results obtained with compounds which by themselves bind formaldehyde over a wide *p*H range, *e. g.*, guanidines,[12] cannot be unequivocally interpreted as evidence for cross-linking. (2) Some methylene compounds may be so unstable as to yield their formaldehyde in the presence of dimedon.[13]

With amides and most amines, however, these limitations do not apply. Pairs formed by a primary amide, on the one hand, and a primary or secondary amine or an amino acid on the other, give condensation products with formaldehyde over the range of *p*H 3.2 to 7.6 (Reaction I) (Tables I and II).[14] More alkaline or more acid solutions could not be studied in this manner, since they catalyze the stable fixation of increasing amounts of formaldehyde by the amides alone[12]

(11) Einhorn, *Ann.*, **343**, 207 (1905); **361**, 113 (1908).

(12) Unpublished experiments have shown that, at room temperature, guanidines bind formaldehyde slowly over the range of *p*H 3–7, but much more rapidly above *p*H 10 and below *p*H 2; between *p*H 10 and 11 about one-half mole of formaldehyde per mole guanidine was bound in eight hours. The reactivity at elevated temperature was studied previously.[4]

(13) The apparent non-participation of sulfhydryl groups in methylene compound formation (Table XI) is possibly ascribable to such lability. A reaction involving amino and sulfhydryl groups might be assumed to occur in view of the ease with which cysteine condenses with formaldehyde to form the cyclic thiazolidine carboxylic acid [Schubert, *J. Biol. Chem.*, **111**, 671 (1935); **114**, 341 (1936); Ratner and Clarke, THIS JOURNAL, **59**, 200 (1937)].

(14) Methylamine alone, of all amines studied, bound formaldehyde at *p*H 3.0 in a manner stable to dimedon but reversible by acid hydrolysis (Table II). The fact that the cyclic trimer of methylamine and formaldehyde also did not release most of its formaldehyde in the presence of dimedon suggests that this compound may form in the solution at *p*H 3.0. This trimer differs from other amine–aldehyde reaction products, including the butylamine–formaldehyde trimer, in yielding a water-soluble stable condensation product with dimedon at *p*H 4.6. Thus, if first exposed to buffers of *p*H 3–5 for twenty-four hours at room temperature, almost the entire formaldehyde of the trimer (94%) can be precipitated with dimedon, but if dimedon and *p*H 4.6 buffer are added as usual, simultaneously, only about 10% of the expected amount of the insoluble condensation product is obtained; and upon addition of excess free formaldehyde to the solution, only about 60% of the added dimedon is precipitated, indicating some fixation in soluble form. Higher aliphatic amines were found to bind formaldehyde in an acid-irreversible manner when acetic acid or its homologs were used as buffers. ε-Aminocaproic acid showed the same phenomenon by itself (Table II). It appears probable that this may be attributed to the availability of the $-CH_2-COOH$ group for a Mannich type of condensation[15] with the amines and formaldehyde. This reaction is largely suppressed in favor of Reaction I if amides are also present. In contrast to amine acetates, amino acids and amine hydrochlorides do not condense to an appreciable extent with formaldehyde and acetic acid within three days at room temperature and *p*H 3–5 (Table II).

[a] Unless otherwise stated, the amino acid or amide alone was treated in 0.8 *M* solution. Amino acid + amide solutions were 0.4 *M* in regard to each reactant; the formaldehyde, 1.5 to 2.5 *M*. Except as noted, the solutions at *p*H 3.2–4.3 were buffered with approximately 0.5 *M* acetic acid or acetate; those at *p*H 4.4–7.6 with approximately 0.6 *M* phosphate. Reactions were performed at room temperature (approximately 23°). [b] Or amide-N when no basic nitrogen was present. [c] No buffer was used. [d] For the rate curve of this reaction see Fig. 1. [e] Oxalic acid (0.3 *M*) used as buffer.

(Table III). However, indications were obtained by other techniques that a condensation reaction involving alanine and acetamide did not occur appreciably below *p*H 1 and occurred only to a small extent above *p*H 11 (Table III).

A comparison of the rate and extent of the reaction occurring at *p*H 3–4 and *p*H 6–7 indicated that with amino acids and amides the neutral medium was the more favorable (Table I, Fig. 1). With amines and amides, however, condensation occurred better in acid solution. This difference was attributed to the rapid formation and stability of cyclic trimers of the amines and formaldehyde in alkaline solution (*cf.* footnote 14) and could be demonstrated by treating such trimers with acetamide at both *p*H levels. Amine–methylene–amide formation occurred at *p*H 4 but not at *p*H 8.3 (Table IV).

As expected, the condensation reaction was favored by high concentrations of the reactants

[a] Reactions performed at room temperature. [b] Or amide-N if no basic nitrogen is present. [c] Similar results were obtained when acetic acid was also present. Concerning the fixation of formaldehyde by methylamine hydrochloride, *cf.* footnote 14. [d] Similar results were obtained with formic and butyric acid.

(Table V). It reached equilibrium within twenty-four to forty-eight hours, at which time the formaldehyde bound corresponded usually to 60–100% of that equivalent to the amine or amide used. As final proof for the occurrence of the reaction, the formaldehyde condensation products of acetamide with alanine and proline were isolated and characterized.

The non-reactivity of secondary amides (—CO—NHR) for the condensation reaction as contrasted to the primary amides (—CO—NH_2) is significant (Table I).[16,17] Cross-linking has often been postulated as involving mainly the peptide linkage. In the light of the present findings, it would appear that the peptide bonds cannot be involved in the tanning reactions occurring at room temperature.

(16) Einhorn[11] found that primary and secondary amides differed also in their ability to add formaldehyde to form methylol groups.

TABLE III

EFFECT OF EXTREMES OF *p*H ON ALANINE–ACETAMIDE–FORMALDEHYDE REACTION[a]

Alanine × 10^{-3} mole	Acetamide × 10^{-3} mole	Solvent	Final *p*H[b]	Apparent amino-N[c] × 10^{-3} mole	Formaldehyde bound × 10^{-3} moles
1.0	...	0.6 ml. 6 *N* HCl	0.85	1.0	0.0
1.0	1.0	0.6 ml. 6 *N* HCl	0.85	1.15	.63
...	1.0	0.6 ml. 6 *N* HCl	0.85	0.24	.52
1.0	...	0.6 ml. 2 *N* NaOH	11.3	.83	.01
1.0	1.0	0.6 ml. 2 *N* NaOH	11.1	.70	.49
...	1.0	0.6 ml. 0.33 *N* NaOH	11.45	.16	.58
1.0	...	0.6 ml. H_2O	4.7	.94	.01
1.0	1.0	0.6 ml. H_2O	4.7	.48	.57
...	1.0	0.6 ml. H_2O	4.5	.06	.02

[a] 24 hours at room temperature. All plus 0.5 ml. 7.5% formaldehyde (1.25 mM). [b] Measured after dilution to 10 ml. [c] See experimental part for discussion.

TABLE IV

USE OF CYCLIC TRIMERS OF METHYL- AND BUTYLAMINE AND FORMALDEHYDE FOR CONDENSATION REACTION WITH AMIDE

Reaction mixture	Final *p*H	Equiv. of formald. bound[a]
1,3,5-Tri*methyl*trimethylenetriamine (0.33)[b] + acetamide (1.0)	4.0	0.5[a]
1,3,5-Tri*methyl*trimethylenetriamine (0.33)[b]	4.0	0.11
1,3,5-Tri*methyl*trimethylenetriamine (0.33)[b] + acetamide	8.3	0.07[c]
1,3,5-Tri*methyl*trimethylenetriamine (0.33)[b]	8.3	0.0[c]
1,3,5-Tri*butyl*trimethylenetriamine (0.33) + acetamide (1.0)	5.0	0.55
1,3,5-Tri*butyl*trimethylenetriamine (0.33)[b]	5.0	0.13

[a] Stably in presence of dimedon at *p*H 4.6. [b] Figures in parentheses represent millimoles used. Each reaction mixture contained also 1.5 ml. 3 *M* acetic acid (*p*H 4 and 5) or phosphate buffer (*p*H 8.3). They were held for three days at room temperature. [c] To assure complete liberation of formaldehyde from 1,3,5-tri*methyl*trimethylenetriamine an aliquot of the diluted alkaline reaction mixture was held for 1 day in the *p*H 4.6 buffer before addition of the dimedon (*cf.* footnote 14).

TABLE V

EFFECT OF CONCENTRATION OF REACTANTS ON CROSS-LINKING REACTION (A); AND LACK OF EFFECT ON ACETAMIDE–FORMALDEHYDE (B); AND ALANINE–FORMALDEHYDE REACTION (C)[a]

	Molarity of					Formaldehyde bound, equivalents/basic N[b]		
	Alanine	Acetamide	Formaldehyde	Time, days	Final *p*H			
A:	0.14	0.14	1.4	3	3.4	0.17		
	.4	.4	1.5	2	3.4	.67		
	.4	.4	0.75	2	3.4	.44		
	.4	.4	0.5	3	3.4	.36		
B:	..	.8	1.5	2 5 12	3.4	.10	.20	.40
	..	.16	1.5	2 5 15	3.4	.08	.19	.50
C:	.8	..	1.5	5	7.6	.55		
	.16	..	1.5	5	7.6	.5		

[a] Reactions performed at room temperature, with acetic acid or phosphate as buffers. Alanine itself reacts at an appreciable rate with formaldehyde only at *p*H 7 or above. [b] Or amide-N if no basic N is present.

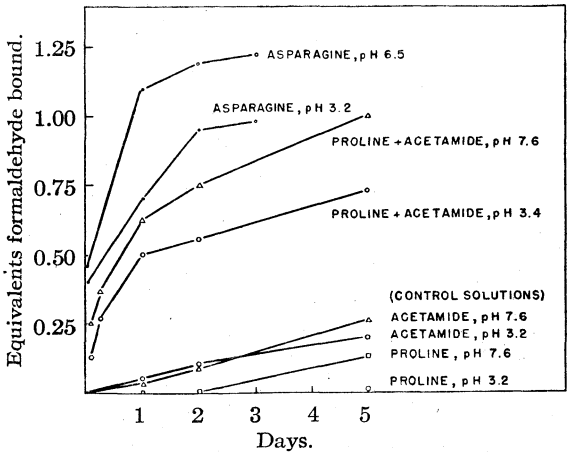

Fig. 1.—Rate of fixation of formaldehyde by various compounds at 23°: asparagine, 1 mM. in 3.5 ml. containing 2.5 mM. formaldehyde and approximately 0.5 molar acetate or phosphate buffer. For composition of other reaction mixtures, see Table I. The amount of unbound formaldehyde was determined by precipitation with dimedon.

The mechanism of Reaction (I) has not been clearly established. Like the Mannich reaction,[15] it is a condensation involving a primary or secondary base, formaldehyde, and a reactive hydrogen, furnished in this case by a primary amide group. It would appear probable that this occurs in two steps. Einhorn[11] believed that the amido-methylol compound formed first, but presented no conclusive evidence in support of this mechanism. However, addition of formaldehyde to the amide group in the absence of an amine proceeds much more slowly than the cross-linking reaction and thus probably does not represent an intermediate stage. This is further indicated by the inability of amido-methylol compounds to condense with the amines (see Experimental).

The alternate possibility is that the amine reacts first to give an aminomethylol (Reaction III) which then condenses with the amide (Reaction IV).

$$R{-}NH_2 + CH_2O \longrightarrow R{-}NHCH_2OH \quad (III)$$

$$R{-}NH{-}CH_2OH + NH_2{-}CO{-}R' \longrightarrow R{-}NH{-}CH_2{-}NH{-}CO{-}R' + H_2O \quad (IV)$$

In neutral and alkaline solution, amines are known to be transformed by formaldehyde to methylol and dimethylol compounds, but no evidence appears to be available that such reactions occur also at *p*H 3–4. Because of the lability of the amino–methylol linkage, the occurrence of this reaction cannot be demonstrated by the dimedon or Van Slyke amino nitrogen techniques.[18] That formaldehyde actually reacts with amino groups within a few hours at *p*H 3.6 or lower is indicated by (1) a fall in the *p*H of the reaction mixtures (Table VI)

(18) The *slow* decrease in the formaldehyde and amino nitrogen contents of amino acid–formaldehyde reaction mixtures[17] is evidence of secondary reactions, possibly of the Mannich type, rather than of the primary addition reaction.

TABLE VI

EFFECT OF FORMALDEHYDE ON SOLUTIONS OF AMINE HYDROCHLORIDES AT *p*H 3.6[a]

Amine	Drop of *p*H after addition of formaldehyde: Original *p*H	Final *p*H	Time until constant, min.	Equivalents of NaOH needed to titrate back to original *p*H
Methyl	3.6	1.2	120	0.170
Dimethyl	3.6	2.9	60	.0018
Butyl	3.6	2.5	60	.014
Ethanol	3.6	2.2	30	.029
Diethanol	3.6	3.1	10	.0014

[a] To 10 ml. of 1.5 *M* solutions of the amine hydrochlorides adjusted to *p*H 3.6 ± 0.1 were added 4 ml. of commercial 40% formalin (*p*H 3.6).

and (2) a change in optical rotation of solutions containing L-amino acids and formaldehyde. The rate of reaction (III), even in acid solution, appears to be sufficiently fast, compared to the cross-linking, to allow it to be the first step of the latter reaction.

While it is probable that in acid solution the equilibrium of Reaction III is greatly to the left, this may well be shifted by the occurrence of Reaction IV to permit the cross-linking to proceed to the observed extent. Changes in the optical rotation of reaction mixtures containing an optically inactive amide, an optically active amine, and formaldehyde lend independent support to the two-stage mechanism here proposed (see Experimental). The initial formation of the aminomethylol compound is also now favored as occurring during typical Mannich reactions.[15,19]

B. Experiments with Proteins or Macromolecular Model Compounds.—A second experimental approach consisted in studying the introduction, by means of formaldehyde, of simple amines, amides, or guanidines into proteins or other macromolecular materials rich in amide, amino, or guanidyl groups. The data generally support the findings obtained with the model systems. Gliadin and polyglutamine, both very rich in *amide groups*, bind in acid solution large amounts of ammonia, primary amines, or amino acids (Table VII). Imino acids appear to be bound only to a limited extent by gliadin and not above *p*H 2.0 by polyglutamine, although they were found to react readily with acetamide over a wide *p*H range (Table I). Since the resultant linkage was found to be relatively labile, the possibility exists that greater amounts of the secondary amines were actually bound by polyglutamine and gliadin than could be demonstrated after extensive periods of dialysis. It seems that in acid solution the amido–methylol linkage, though forming more slowly, is more stable than the methylene cross-links here described. This probably explains why in 50% acetic acid–formalin much more alanine is introduced into gliadin in two hours than after three days (Table VII).

When proteins or a tyrosine-formaldehyde polymer[20] rich in *amino groups* were treated with formaldehyde in the presence of acetamide, considerable amounts of this compound were introduced at room temperature over the range of *p*H 2–8 (Table VIII). As expected, this reaction did not occur appreciably, however, if most of the amino groups of the protein were blocked by acetylation.

The cross-linking of amino with guanidyl compounds by formaldehyde is demonstrated by the introduction, over the range of *p*H 4.2–8.5, of methylguanidine into proteins rich in amino groups (Table IX). On the other hand, the inability of amide and guanidyl groups to condense under similar conditions is shown with polyglutamine (Table VII) and salmine (Table VIII). Both of these latter conclusions were suggested but not conclusively demonstrated by the model experiments. The fixation of all low molecular compounds by proteins is usually accompanied by an analytically demonstrable increase in the amounts of formaldehyde bound over those bound under the same conditions in the absence of the added compounds.

A particular case of amine–amide interaction was studied in some detail, because of its special interest and possible practical importance. Swallen and Danehy[21,22] have described a remarkable catalytic effect of amines or ammonium ions on the reaction of formaldehyde with zein. When a 20% solution of zein in glacial acetic acid is treated with an equal volume of commercial formalin, a gel forms within a few minutes only if traces of ammonium ions or primary amines are added; otherwise, the mixture remains fluid for several hours.[23] Similar experiments have now been performed with gliadin. This protein also sets quickly to a gel only after the addition of small amounts (*e.g.*, 2 equivalents per 10^4 g.) of ammonia or primary amines. Commercial gliadin and a preparation made by a technique involving isoelectric fractionation from acetic acid solution behaved like zein in gelling slowly even without added amines, but gliadin carefully prepared from wheat gluten by fractionation with cold alcohol did not gel at all until an amine was added as "catalyst".[24] Gels formed in the presence of small amounts of "catalyst" were found to liquefy if the reaction mixture was held for one to three days at room temperature. In contrast permanent gels and insoluble products were obtained when greater amounts of amine had been added.

[a] Polyglutamine and gliadin contain 52 and 32 amide groups per 10^4 g., respectively. [b] Approximate values, obtained by Kjeldahl nitrogen analysis after thorough dialysis, except where otherwise noted. Nitrogen recoveries for gliadin were unreliable as a measure of the amounts of amine introduced since part of the protein became dialysable during the reaction. (Recovery in control samples consistently only 87%.) The uncertain values are in parentheses. [c] 5% solutions of the polyamide, 4% in regard to formaldehyde were treated for five days with 80 equivalents of the various amine salts or amino acids (per 10^4 g.), unless otherwise specified. The solutions contained 1.0–1.5 *M* acetic acid or acetate buffer. [d] In these cases gels formed within one and two days, respectively. When the reaction mixtures were made up five times more dilute, no gels formed, but only 2 and 0 equivalents of ammonia or methylamine were bound, respectively, and correspondingly small amounts of formaldehyde (2 and 1 equivalent). When the reactions were terminated before gelling occurred (after six and twenty-four hours, respectively), 8 and 5 equivalents of the amines were introduced, and 6 and 3 equivalents of formaldehyde. [e] Analyzed after many weeks of dialysis for the purpose of molecular weight determinations. [f] 10% gliadin in 50% glacial acetic acid–50% formalin mixture, with 32 equivalents of the additives. Reaction times indicated in parentheses. [g] Products largely insoluble. [h] Calculated from amount of sulfate sulfur introduced. [i] 4% gliadin, 8% formaldehyde, 0.6 *M* acetic acid, and 32 equivalents of the various amines were used. Reactions were allowed to proceed for four days at room temperature.

With regard to the nature of the amine, all primary amines used except α-aminoisobutyric acid, glucosamine, serine and threonine were effective. In equivalent amounts, the different amines caused gelling after varying time periods. Those acting most rapidly were: ammonia, glycine, alanine, arginine, ethanolamine, 2-aminoethylsulfuric acid and aniline. Glutamic and ε-amino-*n*-caproic acids, butylamine, hexadecylamine, semicarbazide, hydroxylamine and hydrazine acted more slowly. In contrast dimethylamine, diethanolamine, proline, hydroxyproline, sarcosine, benzoylalanine, N-mesyltyrosine, guanidine and urea did not favor gel formation. Piperazine

TABLE VIII

FIXATION OF ACETAMIDE BY MACROMOLECULAR COMPOUNDS CONTAINING AMINO OR GUANIDYL GROUPS THROUGH FORMALDEHYDE CONDENSATION[a]

Macromolecular compound	Reactive groups per 10^4 g.	Additive	Final *p*H	Equivalents bound per 10^4 g. Acetamide	Formaldehyde
Bovine serum albumin (BSA)	9.7 amino	Acetamide	1.4	1.9	
		Acetamide	2.1	7.4	
		Acetamide	3.2	6.2	
		Acetamide	4.2[b]	7.0	7
		Acetamide	4.8	5.9	
		Acetamide	7.4[c]	5.7	5
		Acetamide	11.0	1.5	
		None	4.2[c]		3
Amino-acetyl BSA	0.5 amino	Acetamide	7.4	1.4	0.6
Methylene-tyrosine polymer	34 amino	Acetamide	1.2	3.3	
		Acetamide	6.2	9.6	10
		None	6.2	...	3
Lysozyme	5 amino	Acetamide	5.0[b,d]	4.7	
		Acetamide	7.4[b,c]	1.7

		Acetamide	7.0	1.5[e]	
Salmine sulfate	38 guanidyl	Acetamide	4.2	1	2
		None	4.2	...	1

[a] 100 mg. protein and acetamide in approximately 1 ml. 4% formaldehyde, 0.4–0.8 *M* acetate or phosphate buffers, or 1 *N* and 0.1 *N* HCl for the first two experiments; held at room temperature for two or three days. Control experiments showed that no amide was introduced if the formaldehyde was omitted. [b] 8% formaldehyde was used in these experiments. [c] This reaction mixture gelled after addition of the formaldehyde. [d] Lysozyme remained water-soluble under these conditions, whereas gelation occurred and an insoluble product was obtained in the absence of acetamide. [e] Insulin dissolved during the course of the reaction with acetamide at *p*H 7 but not at *p*H 4, nor with other additives (Table IX).

TABLE IX

FIXATION OF METHYLGUANIDINE SULFATE (MGS) BY MACROMOLECULAR COMPOUNDS CONTAINING AMINO GROUPS THROUGH FORMALDEHYDE CONDENSATION[a]

Macromolecular compound	Amino groups per 10^4 g.	Additive	Final *p*H	Equivalents bound per 10^4 g. Methylguanidine (Kjeldahl)	(Colorimetric)	Formaldehyde
Bovine serum albumin (BSA)	9.7	MGS	2.7[b]	0	0.3	
		MGS	4.8	5.5	3.7	
		MGS	7.4[b]	5.5	3.3

Insulin	5.0	MGS	4.0[f]		0.8	
		MGS	7.0[f]		1.3	

[a] Conditions and control experiments same as used in experiments listed on Table VIII (footnote *a*) but with methylguanidine sulfate instead of acetamide. For techniques and limitations of analytical methods see Experimental Part. [b] Gels form at *p*H 2.7 overnight, at *p*H 7.4 instantaneously upon addition of formaldehyde. [c] Residual amino nitrogen in those preparation, 22 and 5 equivalents, respectively. [d] Reaction time only five hours. [e] Reaction mixtures gel, then liquefy. [f] Protein did not dissolve in reaction mixture.

and N,N′-diphenyl-*p*-phenylenediamine led to rapid stable gelation; N-phenylglycine caused slow and non-permanent gelation. Hexamethylenetetramine acted somewhat more slowly than ammonia.

The gelling effect of ammonium chloride, which was studied in more detail, was not dependent upon the above conditions, but occurred also in more dilute acetic acid (10%) or formaldehyde (4%) solution, as well as in aqueous ethanol with or without added acetic acid, but not in alkaline alcoholic solutions. No gelling could be produced if ammonium chloride or an effective amine was added after the protein–formaldehyde reaction mixture had stood for three days. High concentrations of urea neither prevented gel formation nor redissolved the gel, once it had formed.

No definite information was available concerning the mechanism of these phenomena. A plausible explanation was suggested by the results of the model experiments discussed above. Both zein and gliadin contain a very great excess of amide over amino groups. For gliadin this ratio is about 40, in contrast to 1–2 for many typical proteins. Therefore little cross-linking between the two types of groups can occur in proteins like gliadin and zein. There is thus ample opportunity for small-molecular-weight amines to be bound through methylene bridges to the amide groups of the protein molecule. If these amines are bifunctional in nature, they may act as cross-linking agents between protein molecules, according to reaction V.

In agreement with this hypothesis, only primary

$$2R{-}CONH_2 + HCHO + R'NH_2 \longrightarrow RCONH{-}CH_2{-}NR'{-}CH_2{-}NH{-}COR + 2H_2O \quad (V)$$

amines or secondary diamines (*e. g.*, piperazine) are effective gelation catalysts.[25] When greater than "catalytic" amounts of the cross-linking amines were used, their introduction into the protein under the conditions of gelling was demonstrated analytically (Table VII).

The course of the gelation reaction is in accord with the results of the model experiments with acetamide and alanine. These have shown that, at *p*H 3–6, the cross-linking proceeds considerably faster than does the fixation of formaldehyde by the amide alone. In conformity, gliadin gels within a few minutes after addition of an effective amine. If excessive amounts of amine are avoided, many amide groups remain unaffected by the cross-linking reaction and, more slowly, are

(25) In confirming studies now in progress (footnote 5), it has been found that only those amines that cause gelation favor the formation of derivatives whose average molecular weight is increased over that of the proteins.

transformed into amido-methylol groups.[26] This probably contributes to liquefaction of the gels within twenty-four hours and explains the water solubility of the final products. Further, when alanine was used as the cross-linking agent, its fixation was found to be reversed during prolonged exposure to the 50% acetic acid–formalin reaction mixture. It appears probable, though it was not demonstrated, that ammonia may also be slowly released under such conditions. No re-solution was observed, however, if more extensive cross-linking had been produced through the addition of somewhat more of the amine (with ammonium chloride, 10–20% of the weight of the protein, instead of 1–2%). The gels then were stable and the products after isolation were insoluble in water, acetic acid, and 10 *M* urea solution.

The reaction mechanism postulated for the simple systems is also supported by the experiments with gliadin. Thus, if the amine or ammonia was added to the reaction mixture only after several days of standing, *i. e.*, after the amide groups had been transformed to amido-methylol groups, no gelation nor fixation of the amine occurred.

The behavior of gliadin (and zein[21,22]) is largely duplicated by that of polyglutamine, thus removing the possibility of protein groups other than the amide playing a role in this reaction. Under the same formaldehyde reaction conditions usually used with gliadin (50/50 glacial acetic acid and formalin), this polyamide, in 10% solution, gelled within thirty minutes if traces of ammonium chloride were present, but otherwise only after two to three days. Also, in 4–8% formaldehyde solutions containing as little as 3% of the polypeptide and 3% acetic acid, gels or precipitates were obtained only in the presence of small amounts of ammonium chloride or primary amines. As previously stated, the introduction of the amine or amino acid could be analytically demonstrated when greater than "catalytic" amounts were used (Table VII).

Discussion

The data presented show that the amino groups of proteins may readily condense with formaldehyde and amide or guanidyl groups under conditions of temperature and *p*H at which each type of compound, separately, binds no, or very little, formaldehyde in stable manner. The reaction of asparagine with formaldehyde represents an intramolecular condensation of this same type.[28]

Marvel, *et al.*,[29] have recently expressed the stimulating idea that urea in condensing and polymerizing with formaldehyde may act as an amino acid amide. On the basis of this hypothesis they studied the reaction of some amino acid amides with formaldehyde, and obtained polymers. In the light of the present findings, the primary reaction would appear to be a chain condensation of amino and amide through methylene groups. It does not appear probable that cyclic trimers are involved, as was suggested by these workers,[29] since the polymerization reaction proceeds only under conditions unfavorable for the formation, or even for the existence, of such trimers (Table IV, *cf.* footnote 14). Further, the amount of formaldehyde bound by the polymer was only slightly in excess of that equivalent to the glycine amide units, whereas 1.5 equivalents would be needed for the extensively cyclized and cross-linked structure postulated.[29]

In view of the many amino as well as amide and guanidine groups present in most proteins, and of the ease with which pairs of these can condense with formaldehyde, it appears probable that these reactions may play an important role both in the hardening and tanning action of formaldehyde and in its use in the preparation of vaccines and toxoids. The reaction further may supply a useful means of introducing a great variety of primary amines, amides, or guanidines stably into proteins. In the presence of an excess of a small molecular amide, the methylol-amino groups of the protein appear to condense preferentially with this instead of with protein amide groups. Thus cross-linking between protein groups may be largely forestalled and soluble derivatives obtained at a *p*H which favors the formation of insoluble coagula in the absence of the simple amide (Tables VIII and IX). On the other hand, bifunctional amines furnish cross-links in proteins deficient in amino but rich in amide groups, and bifunctional amides or guanidines may be expected to act similarly in proteins rich in amino but deficient in these types of groups.

Besides methylene condensations involving two nitrogenous groups, other reactions can occur which may contribute to the tanning action of formaldehyde. Mannich reactions involving aromatic and heterocyclic side chains and amino groups will be discussed in a subsequent publication. Similar reactions between basic groups, formaldehyde and reactive aliphatic methylene groups (*e. g.*, R—CH_2—COOH),[14] possibly account for the large amounts of formaldehyde bound irreversibly by proteins at elevated temperature.

(26) Proteins and model polymers rich in amide groups bind much formaldehyde (a) at elevated temperature in dilute acetic acid solution[27] and (b) at room temperature in alkaline solution (*p*H 11–12) (unpublished). The present data (Table VII) show that the reaction occurs at room temperature also at high formaldehyde concentration (20%) in 50% acetic acid, but not to a similar extent in more dilute solutions, unless amines or ammonium salts are present.

(27) Fraenkel-Conrat, Cooper and Olcott, THIS JOURNAL, **67**, 950 (1945).

(28) Levy and Silberman [*J. Biol. Chem.*, **118**, 723 (1937)] and others (*cf.* French and Edsall, footnote 17) have shown that a tetrahydropyrimidine ring is formed through condensation of formaldehyde with the amino and amide groups of asparagine. In contrast to Levy and Silberman's observations, we found that this reaction, like similar intermolecular condensations between amino acids and amides, was favored by a higher *p*H (*p*H 6.5 *vs.* 3.2) (*cf.* Fig. 1).

Experimental

Methods and Materials.—Free, plus labily bound, formaldehyde was determined by means of dimedon at *p*H 4.6[30]; total recoverable (*i. e.*, free and acid hydrolyzable) formaldehyde, by combined hydrolysis and distillation followed by colorimetric[31] or dimedon[30] analysis of the distillate. Irreversibly-bound formaldehyde was estimated by the difference between the amount originally added and that recoverable by acid hydrolysis from reaction mixtures. Other analytical methods used were the Kjeldahl procedure for total nitrogen, and the manometric Van Slyke[32] and colorimetric ninhydrin[33] methods for amino nitrogen. The Folin uric acid reagent was used for SH tests according to Anson.[34]

The introduction of amides into proteins was demonstrated by increases in amide-nitrogen content: 10–25 mg. of protein was autoclaved with 1.2 *N* sulfuric acid at 120 lb. for two hours; the solution was then neutralized, buffered with phosphate at *p*H 7.4, and the ammonia distilled off in a Kjeldahl apparatus. Recoveries of nitrogen from acetamide by this technique averaged 98.5%.

The introduction of methylguanidine led to appreciable increases in the non-dialyzable nitrogen, which served as an approximate measure of the extent of fixation of this compound. More specific and possibly more accurate were colorimetric analyses of the increases in chromogenic activity by the Sakaguchi method, as applied by Brand and Kassell.[35] These data, however, may be somewhat low, since indications were obtained that hydrolysis of methylol arginine peptides leads to a partial destruction of the chromogenic group.

The introduction of amines into proteins represented the greatest analytical problem. When a polyamide, such as polyglutamic acid, was treated with an excess of amine, sufficient amounts were introduced so that Kjeldahl analyses could be relied upon as proof for its fixation. However, when only 1–5 equivalents (per 10^4 g.) of amine were introduced into a protein, increments in the total nitrogen by about 1–3% could not be demonstrated with sufficient accuracy, particularly when the reaction was performed in acid solution and caused some protein degradation. Tyrosine was used in some experiments and its fixation was demonstrated colorimetrically; however, only one equivalent was bound by 10^4 g. gliadin (32 amide groups), probably because of the insolubility of tyrosine. The use of 2-aminoethylsulfuric acid proved more advantageous. Its introduction into gliadin was demonstrated by sulfate-sulfur analyses[36] and supported by nitrogen analyses. Finally, the acid groups introduced into proteins or polyglutamine through methylene condensation with amino acids were demonstrated by a dye method.[37] This method supplied the most clear-cut and trustworthy evidence concerning the relative non-reactivity of secondary, as compared to primary, amines (*viz.* amino acids).

The gliadin preparations were kindly furnished by D. K. Mecham; lysozyme, by G. Alderton and H. L. Fevold; β-lactoglobulin, by E. F. Jansen; edestin, by D. M. Greenberg; salmine sulfate and insulin, by the Eli Lilly Company. Polyglutamine was prepared as previously described.[27] Aminoacetyl serum albumin was prepared from commercial crystalline bovine serum albumin by acetylation with acetic anhydride in concentrated sodium acetate solution.[38]

Isolation of Amino Acid–Formaldehyde–Acetamide Condensation Products—N-(N-Acetamido-methylene)-alanine.—To 8.9 g. (0.1 mole) of alanine and 5.9 g. (0.1 mole) of acetamide dissolved in water, was added 30 ml. of commercial 40% formalin and water to 100 ml. After three days of standing at room temperature, 93 ml. of the solution was cooled and poured into a five-fold amount of chilled acetone. The precipitate was washed with acetone and dried *in vacuo* (9.4 g.) (59% yield). Recrystallization was effected by dissolving 1 g. in 13 ml. of ice water, and then adding 20 ml. of chilled ethanol. The compound decomposes above 180°.

Anal. Calcd. for $C_6H_{12}O_3N_2$: C, 45.0; H, 7.50; N, 17.5; HCHO, 18.7. Found: C, 44.9; H, 7.56; N, 17.5; HCHO, 18.4.

N-(N-Acetamidomethylene)-proline.—1.15 g. of proline and 0.59 g. of acetamide were dissolved in 2 ml. of 40% formalin. After two days at room temperature the reaction product was precipitated with acetone and repeatedly redissolved in a little water and reprecipitated with acetone. Crystallization occurred both in the oily, insoluble fraction and in the mother liquor; 700 mg. was isolated (38%). Partial decomposition of the product during recrystallization from cold water–acetone mixtures may account for the low recoveries (15% or less). But the unrecrystallized material appeared to be quite pure; m. p. 135–138° (dec.).

Anal. Calcd. for $C_8H_{14}O_3N_2$: C, 51.6; H, 7.43; N, 15.1; HCHO, 15.4. Found: C, 51.5; H, 7.55; N, 15.1; HCHO, 15.4.

Stability of Condensation Products.—The crystalline condensation products of alanine or proline with formaldehyde and acetamide were found to be comparatively stable in the presence of dimedon at *p*H 4.6. This made it possible to use the dimedon technique to determine the extent of hydrolysis that occurred in aqueous solutions of varying *p*H. The alanine derivative was also stable under the conditions used for Van Slyke manometric amino nitrogen analyses, so that the liberation of amino nitrogen could be used as an additional measure of the extent of hydrolysis. The data obtained by these methods are listed in Table X. It is evident that the stability optimum of the alanine derivative is more alkaline than that of the proline derivative.

TABLE X

ABILITY OF REACTION PRODUCTS IN AQUEOUS MEDIA

Medium, buffer and/or solutes	Conditions *p*H	Temp., °C.	Time, days	Extent of hydrolysis[a] of acetamide-formaldehyde condensation product of Alanine, %	Proline, %
0.2% Dimedon,	4.6	23	1	9	5

Phosphate	11.7	23	1	15 (8)	35
2.5 *M* Sodium nitrite in 2 *M* acetic acid (manometric Van Slyke)		23	3 min.	6	
10% Pyridine (colorimetric ninhydrin)		100	30 min.	97	

[a] Figures in parentheses are based on Van Slyke manometric amino nitrogen analyses; all other figures are derived from dimedon analyses for liberated formaldehyde.

The finding that formaldehyde and amino nitrogen are liberated to a similar extent indicates that under the conditions used hydrolysis occurs first between the amide and methylene group—a true reversal of the two-stage reaction mechanism (Reaction IV, followed by III). A primary breaking of the amino-methylene linkage would yield methylol acetamide which would not liberate much formaldehyde at room temperature and *p*H 3.4. (N-Methylol-acetamide was hydrolyzed to only 2.4% in twenty-four hours under such conditions.)

Failure to Achieve Condensation of Amido-methylol with Amino Groups.—In the hypothetical reaction

$$R—CONH—CH_2OH + R'—NH_2 \longrightarrow R—CONH—CH_2—NH—R' + H_2O$$

there would be no fixation of formaldehyde, but measurable loss in amino nitrogen. In one experiment, the amido-methylol compound was formed by adding 0.1 ml. of 0.1 *N* sodium hydroxide to a solution of 0.5 mM. of acetamide in 1 ml. of 8% formaldehyde (2.5 mM.). After one hour at room temperature, the solution was neutralized with 0.1 ml. of 0.1 *N* hydrochloric acid, buffered at approximately *p*H 3.4 with 0.2 ml. of 3 *N* acetic acid, and then to it was added 0.5 mM. of alanine. After three days of standing at room temperature, the mixture was diluted and analyzed. The reaction of the amide with formaldehyde approached completion (0.47 mM.), as expected,[11] but there was no loss in amino nitrogen, *i. e.*, no cross-linking had occurred with the alanine.

In another experiment N-methylolacetamide was isolated prior to the treatment with alanine[11]; 0.48 mM. of the oily preparation was mixed with 0.5 mM. of alanine and 1.25 ml. of 0.6 *M* acetic acid. A similar sample was made up to contain also 0.5 mM. of free formaldehyde. Neither sample, after a three day reaction period and dilution, showed a loss in amino nitrogen. Thus no cross-linking occurred between amido-methylol and amino or amino-methylol groups.

Changes in Optical Rotation of Amino Acid–Formaldehyde Solutions with and without Added Acetamide at *p*H 3–4. A.—L-Proline (2% solution) in 0.72 *M* acetic acid, $[\alpha]^{25}D$ −83°.

Upon addition of 3 ml. of 40% formaldehyde to 12 ml. of this solution, the *p*H dropped from 3.0 to 2.9 in one hour, then remained constant. $[\alpha]^{25}D$ after ten minutes, two and one-half hours and twenty hours, was −92, −94 and −94°, respectively.

Addition of 3 ml. of 40% formaldehyde to 12 ml. of 2% L-proline solution (as above) containing also 1.04% acetamide (one equivalent) caused the rotation to rise to −91.5° after five to one hundred and twenty minutes, but to drop within 19, 43 and 67 hours to −85, −80.5 and −78°.

B.—L-Leucine (2% solution in 0.72 *M* acetic acid), $[\alpha]^{25}D$ −6.2.

After addition of 3 ml. of 40% formaldehyde to 17 ml. of amino acid solution, $[\alpha]^{25}D$ was −4.2, −3.5 and −3.0°, after ten minutes, three hours and twenty-one hours, respectively.

C.—L-Cystine (1% solution in 0.36 *N* hydrochloric acid containing 1% glycine, *p*H 0.85), $[\alpha]^{25}D$ −230°.

After addition of 3 ml. of 40% formaldehyde to 12 ml. of above solution, $[\alpha]^{25}D$ −212 to −214° after five to one hundred and eighty minutes.

Addition of amounts of acetamide to the formaldehyde-containing solution, equivalent to the sum of the amino acids present, caused a change of rotation within one hour to $[\alpha]^{25}D$ −180°, and after three, sixteen and forty hours to −182, −190 and −194°, respectively.

Attempts to Demonstrate Condensation between Alanine, Formaldehyde, and Acetamide in Strongly Acid and Alkali Solution.—The change in rotation noted in the case of the L-cystine–formaldehyde reaction mixture of *p*H 0.85 when acetamide was added suggested that interaction of the amino-methylol and amide had occurred. It was attempted to establish this more firmly in a simpler system by using Van Slyke amino-nitrogen analyses on alanine–acetamide–formaldehyde reaction mixtures of similar *p*H. Parallel experiments were also performed in alkaline solution (*p*H 11).

At both *p*H levels, acetamide alone binds formaldehyde readily, so that the aldehyde analyses could not be used as evidence for cross-linking. Amino-nitrogen analyses, performed after dilution and neutralization, gave high and erratic results until the free and dimedon-reversibly bound formaldehyde was removed from the solution (by means of dimedon). The presence of ammonia, formed through incipient hydrolysis of the acetamide, detracted from the quantitative significance of the data.

One typical experiment is shown in Table III. It appeared that there is little, if any, cross-linking in acid solution in twenty-four hours, and little cross-linking at *p*H 11. The (irreversible) fixation of formaldehyde and loss of amino nitrogen of alanine alone under the latter conditions interferes with quantitative interpretation of the amino-nitrogen data on the alanine–acetamide reaction mixture.

Search for Methylene-Condensation Reactions Involving Thiols and Guanidines.—When thioglycol reacted with formaldehyde over the range of *p*H 4.3–7.6 with or without added alanine or acetamide, no more formaldehyde was bound than could be accounted for by the added nitrogenous compound, and no loss in chromogenic activity of the thiol occurred (Table XI). This is regarded as evidence that no R–S–CH_2–NH-R bonds were formed unless these were so labile as to be hydrolyzed during dilution and analysis (*cf.* footnote 13).

TABLE XI

FIXATION OF FORMALDEHYDE IN REACTION MIXTURES CONTAINING ALANINE OR ACETAMIDE WITH THIOGLYCOL OR METHYLGUANIDINE

Reactants	Final *p*H	Time, days	Formaldehyde bound, equivalents[a]	% Thiol disappeared
Alanine (1)[b] + thioglycol (1)	7.6	4	0.18	0

Methylguanidine (0.5)	4.7	4	0.46	
Alanine (0.5)	4.8	4	0.10	

[a] In terms of alanine if present; otherwise in terms of the potential reactant present. [b] Figures in parentheses indicate millimoles used (in 2.5 ml. of reaction mixture containing usually 4–5 millimoles of formaldehyde).

At *p*H 1.5, the disappearance of one-half equivalent of formaldehyde for one of thioglycol suggests that it was transformed quantitatively to the methylene bis-(ethanol) thioether, (CH_2OH–$(CH)_2$–S–CH_2–S–$(CH_2)_2$–CH_2OH), both in the presence and the absence of alanine

(Table XI); the compound was not isolated. Armstrong and du Vigneaud[39] have recently described a method of synthesis of djenkolic acid from cysteine in strong hydrochloric acid, which represents an analogous reaction.

Methylguanidine sulfate binds formaldehyde by itself in solutions above *p*H 7 and below *p*H 5. However, much more formaldehyde is bound at *p*H 4.7 and 4.3 in the presence of alanine than in the presence of acetamide or in solutions of methylguanidine sulfate alone, which is regarded as evidence for cross-linking between guanidine and amino groups (Table XI). The formation of such cross-links was further indicated by the fixation, in the presence of formaldehyde, of methylguanidine residues by proteins or model substances rich in amino groups (Table IX).

Little, if any, cross-linking between guanidine and amide groups appears to occur in the experiments listed in Tables VII, VIII, and XI. This is borne out by a preparative experiment with methylguanidine sulfate. A mixture of 5 millimole each of this compound and acetamide in 2 ml. of 40% formalin was held at room temperature for three days and at 53° for three hours, then isolated and washed by repeated acetone precipitation. The final product contained 92% of the methylguanidine nitrogen and only approximately 0.1% amide of total N.

Polymerization of Glycine Amide with Formaldehyde.[29]—To 110.5 mg. of glycine amide hydrochloride (1 mM.), dissolved in 1 ml. of 3 *M* sodium acetate, was added 0.6 ml. of 7.5% formaldehyde (1.5 mM.). The reaction mixture solidified to a white gel within twenty-four hours. After two days of standing, the product was isolated by repeated cycles of trituration with water and centrifugation. The last washing was free from formaldehyde. The supernatant and washings were pooled; the insoluble polymer was dried (over sodium hydroxide flakes) from the frozen state.

The pooled solution (50 ml.) was at *p*H 4.8. It contained 0.435 mM. of glycine amide (by nitrogen analysis), and 0.525 mM. free formaldehyde (dimedon). The total formaldehyde in the solution represented 0.885 mM. From these results it may be calculated that the insoluble polymer contained 0.565 mM. glycine amide and 0.615 mM. of formaldehyde, *i. e.*, 1.09 equivalents of formaldehyde per glycine amide unit. Very similar results were obtained in two further experiments in one of which 2.0 equivalents of formaldehyde were used. In all experiments, the nitrogen recovery in the two fractions was only 96–97% (formaldehyde recovery 99–100%), and the reproducibility of Kjeldahl analyses on the polymer was poor. Dumas analyses gave a lower value (25.1%). C and H analyses performed on a preparation that had been dried at 100° in high vacuum and then permitted to equilibrate with laboratory air, were difficult to interpret because of the probable absorption of carbon dioxide by the basic polymer (C, 38.3; H, 6.86; N (Kjeldahl), 25.3–26.6; HCHO, 31.7; weight loss and regain, 12.1%). The dried polymer contained no acetate. It was insoluble in all solvents tried, including saturated lithium iodide, and 1,3-dichloropropanol, solvents for silk fibroin, and nylon, respectively.

Use of Cyclic Trimers (—NR—CH_2—)$_3$ in Condensation Reaction.—Cyclic trimers were prepared from formaldehyde and both methylamine and *n*-butylamine. When these compounds were held at *p*H 4 or 5 in the presence of acetamide, much formaldehyde was bound stably (to dimedon at *p*H 4.6), while in the absence of acetamide almost the entire formaldehyde was liberated and could be precipitated with dimedon (Table IV). When the trimer was held at *p*H 8.3, no interaction occurred with acetamide, and all formaldehyde could be precipitated with dimedon after dilution and one day of exposure to *p*H 4.6 acetate (*cf.* footnote 14).

Acknowledgments.—The authors are indebted to E. D. Ducay for untiring technical assistance. Carbon and hydrogen analyses were performed by L. M. White and G. E. Secor; Dumas-nitrogen, by G. Rose; arginine (guanidyl group) analyses, by J. W. Pence.

Summary

Simple primary and secondary amines react with formaldehyde and primary amides over the range of *p*H 3–8 within twenty-four to forty-eight hours at room temperature to give condensation products of the general structure: R—NR′—CH_2—NH—CO—R″. Representative compounds of this type have been isolated in pure form.

Evidence is presented that the primary reaction is the formation of methylol-amines, not methylol-amides.

N-Alkyl amides, including peptides (RNH—CO—R′), do not react in similar systems.

Simple amines also condense with formaldehyde and guanidines at *p*H 4–5, but amides and guanidines do not react under the same conditions.

Through methylene condensation reactions of these types, formaldehyde permits the introduction of simple amides or guanidines into proteins or macromolecular model substances rich in amino groups, and also permits the introduction of primary amines into proteins or model substances that are rich in amide groups.

Under suitable conditions, small amounts of ammonia or primary amines cause gelation of acid formaldehyde reaction mixtures of gliadin, zein, or polyglutamine, probably by introducing cross-links $\left(\text{—CH}_2\text{—N(R)—CH}_2\text{—}\right)$ between the numerous amide groups of these substances.

While not unequivocally demonstrated, it appears very probable that these cross-linking reactions between amino and primary amide or guanidyl groups contribute greatly to the tanning or hardening action of formaldehyde at room temperature and over the range of *p*H 2–9, on proteins of average composition.

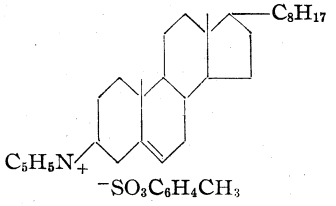
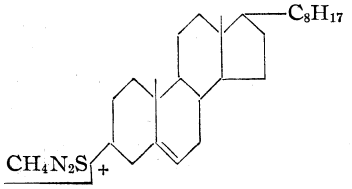
Preparation, Structure and Configuration of Some Salts Derived from Δ^6-*i*-Cholestadiene and *i*-Cholesten-6-one[1a]

BY L. CARROLL KING

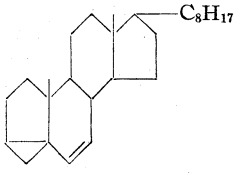
In a recent paper from this Laboratory[1b] it was demonstrated that *i*-cholesteryl methyl ether reacted with pyridine and *p*-toluenesulfonic acid to give cholesterylpyridinium tosylate (I) and with thiourea and *p*-toluenesulfonic acid in alcoholic solution to give cholesterylisothiuronium tosylate (II). This type of reaction has now been applied



I



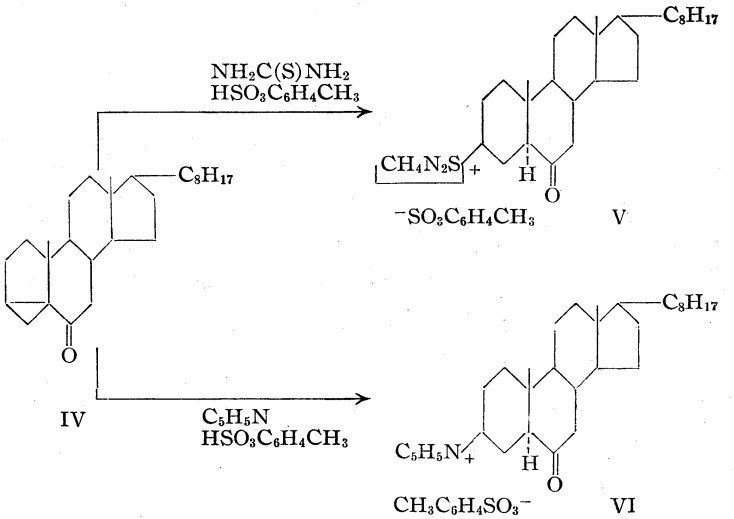
II



III

to two other molecules having the *i*-steroid structure.

The Δ^6-*i*-cholestadiene (III) described by Riegel[2] when it reacted with thiourea and *p*-toluenesulfonic acid in alcoholic solution gave compound II, identical with the corresponding substance obtained from similar treatment of *i*-cholesteryl methyl ether.[1b] Compound III, unlike *i*-cholesteryl methyl ether,[1b] would not react with pyridine and *p*-toluenesulfonic acid to give I.



IV V VI

i-Cholesten-6-one (IV) reacted with thiourea and *p*-toluenesulfonic acid in alcoholic solution to give 6-ketocholestanylisothiuronium tosylate (V) and with pyridine and *p*-toluenesulfonic acid to give 6-ketocholestanylpyridinium tosylate (VI).[3] These reactions may be formulated as shown.

When *i*-cholesteryl ethers react with reagents such as the halogen acids, or acetic acid containing a trace of sulfuric acid,[4] or with various alcohols in the presence of acids,[5] the products are invariably 3-β-substituted derivatives.[6] It was shown by Riegel[2] that in acidic media nucleophilic reagents reacted with Δ^6-*i*-cholestadiene at position 3 to give derivatives with the β-configuration. In view of these observations the cholesterylisothiuronium tosylate (II) described in this paper and in ref. 1 should be a 3-β-substituted compound. By a similar argument the cholesterylpyridinium tosylate I (described in ref. 1) should be a 3-β-substituted compound.

Wallis and co-workers[9] reported that *i*-cholesten-6-one (IV) reacted with dilute sulfuric acid to give 3-β-hydroxy-6-ketocholestane and with hydrochloric acid or hydrobromic acid to give a 3-α-halo-6-ketocholestane. Now the corrected configurations of the 3-substituted cholestyl and cholesteryl halides[6] can be directly related to the 3-halo-derivatives of

(5) The acid catalyzed conversion of *i*-cholesteryl methyl ether to the normal cholesteryl ether, isopropyl or *t*-butyl ether, according to the nature of the alcohol used as solvent, was reported by E. W. Meyer, Ph.D. Thesis, Northwestern University, 1943, p. 55 and pp. 96–101. A similar reaction wherein *i*-cholesteryl methyl ether is converted to normal ethers was recently reported by McKennis, *ibid.*, **69**, 2565 (1947); *J. Biol. Chem.*, **172**, 313 (1948). See also Hey and Hook, British Patent 591,955 [*C. A.*, **42**, 1028 (1948)].

(6) Previous to 1937 an incorrect formulation for the configuration of the 3-halogen substituted steroids existed. This inconsistency was apparent in the papers of Marker and co-workers, THIS JOURNAL, **59**, 619 (1937), and was corrected by Bergman, *Helv. Chim. Acta* **20**, 600 (1937). Recent papers by Shoppee[7] and by Dodson and Riegel[8] have reviewed the corrected formulation of cholesteryl and cholestyl halides in detail.

(7) Shoppee, *J. Chem. Soc.*, 1138, 1147 (1946).

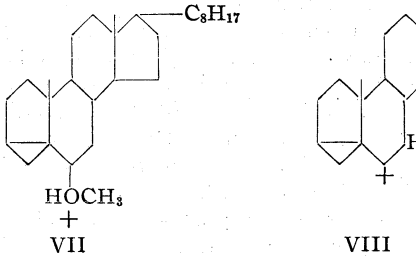
(9) Ford, Chakravorty and Wallis, THIS JOURNAL, **60**, 413 (1938); Ladenburg, Chakravorty and Wallis, *ibid.*, **61**, 3483 (1938); Heilbron, Hodges and Spring, *J. Chem. Soc.*, 759 (1938).

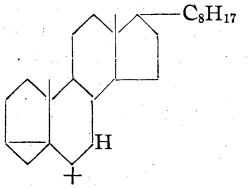
6-ketocholestane. In view of this the compounds formulated as 3-α-halo-6-ketocholestanes by Wallis and co-workers and by Heilbron and co-workers,[9] should be 3-β-halo-6-ketocholestanes.[10] Since all these known reactions of *i*-cholesten-6-one with nucleophilic groups of the type HX result in 3-substitution with β-configuration, it seems likely that compounds V and VI described in this paper are 3-β-substituted-6-ketocholestanes.

In the formation of compounds I, II, V and VI, it seems evident that a proton is first added to the *i*-steroid with formation of an intermediate such as VII, VIII or IX. The intermediate so formed then is attacked at the 3-position by the nucleophilic group. Thus *i*-cholesteryl methyl ether could form VII, compound III could form VIII, and compound IV could form IX. VII could then react with the appropriate reagents to give I or II, VIII could form II, and IX could react with the appropriate reagents to form V or VI.

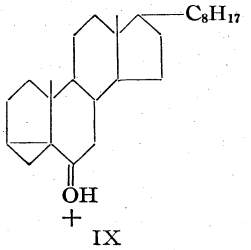
Our failure to obtain I from III is due to the limited availability of protons in pyridine solution so that VIII is not formed under these conditions.



VII



VIII



IX

In each of the reactions reported in this paper and in ref. 1 a change in the ionic nature of the solution takes place as the reaction proceeds. Hence it is possible to make a kinetic study of these reactions by electrical conductivity methods. Such a study is in progress in this Laboratory.

Experimental[11]

Δ^6-*i*-Cholestadiene.—This substance was prepared according to the directions of Riegel, Hager and Zenitz.[2] The use of chromatography on alumina was absolutely necessary to accomplish purification; m. p. 72.5–73°, $[\alpha]^{22}D$ −45.8° in chloroform.

***i*-Cholestene-6-one.**—This substance was prepared according to the direction of Windaus and Dalmer[12]; m. p. 95–97°, $[\alpha]^{22}D$ 47.9° in chloroform.

Cholesterylisothiuronium Tosylate (II).—A solution consisting of 0.50 g. of Δ^6-*i*-cholestadiene (III), 0.50 g. of *p*-toluenesulfonic acid monohydrate and 1.0 g. of thiourea in 20 cc. of methanol was refluxed for five hours. The methanol was partially removed and the product isolated as described in a previous paper[1]; yield 0.74 g. (88%), m. p. 234–235°, $[\alpha]^{22}D$ −27.4° in pyridine.

Attempted Preparation of Cholesterylpyridinium Tosylate (I) from Δ^6-*i*-Cholestadiene (III).—A solution consisting of 0.50 g. of III, 0.50 g. of *p*-toluenesulfonic acid monohydrate and 3.0 cc. of pyridine was refluxed for five hours. No product corresponding to I was obtained, but III was recovered unchanged. A twenty-hour heating period gave similar results.

6-Ketocholestanylisothiuronium Tosylate (V).—A solution consisting of 1.0 g. of *i*-cholesten-6-one (IV), 2 g. of thiourea and 1.0 g. of *p*-toluenesulfonic acid monohydrate in 20 cc. of methanol was refluxed for two hours and then allowed to stand overnight. The methanol was then removed by evaporation and the product thoroughly washed with water. The compound was crystallized from absolute alcohol; yield 1.5 g. (90%), m. p. 204–206°, $[\alpha]^{21}D$ −18.8° in chloroform.

Anal. Calcd. for $C_{35}H_{56}N_2S_2O_4$: C, 66.41; H, 8.91; N, 4.43. Found: C, 66.07; H, 8.47; N, 4.10.

This substance is insoluble in water and soluble in alcohol. It forms a very stable gel in water–alcohol solution.

6-Ketocholestanylpyridinium Iodide (VI).—A solution of 0.5 g. of *i*-cholesten-6-one, and 0.5 g. of *p*-toluenesulfonic acid in 3 cc. of pyridine was refluxed for twelve hours, then heated on the steam-bath for twenty-four hours, cooled and diluted with ether. The solid material which separated was taken up in absolute alcohol and hydroiodic acid was added. The crystalline solid which separated weighed 0.58 g. (75%) and melted at 285–295°. After crystallization from alcohol the melting point was 293–296°; $[\alpha]^{21}D$ 5.5° in chloroform.

Anal. Calcd. for $C_{32}H_{50}ONI$: C, 64.93; H, 8.51; N, 2.36. Found: C, 64.46; H, 8.43; N, 2.75.

Summary

Cholesterylisothiuronium tosylate was prepared from Δ^6-*i*-cholestadiene. Cholesterylpyridinium tosylate could not be prepared from this substance.

i-Cholesten-6-one reacted with thiourea and *p*-toluenesulfonic acid to give 6-ketocholestanylisothiuronium tosylate, and with pyridine and *p*-toluenesulfonic acid to give 6-ketocholestanylpyridinium tosylate.

A consideration of the reactions and steric relations involved indicates these compounds are all 3-β-substituted cholesteryl or cholestyl derivatives.

EVANSTON, ILLINOIS RECEIVED FEBRUARY 20, 1948

(10) In the paper by Dodson and Riegel[8] the corrected configuration of this class of compounds is considered in detail.

(11) All rotations were determined with 100–105 mg. of sample in 3.0 cc. of solvent using a 1-dm. tube of 2.5 cc. capacity. All melting points were observed on a Fisher–Johns melting point block.

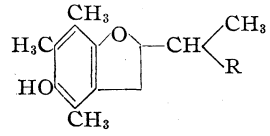
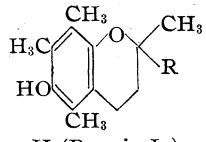
Vitamin E. XLVI.[1] Conversion of 4,6,7-Trimethylcoumaran-3-one into Some Homologs of 2-Isopropyl-4,6,7-trimethyl-5-hydroxycoumaran

BY LEE IRVIN SMITH AND GERALD A. BOYACK[2]

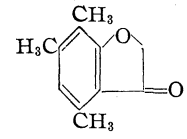
2-(2′-Alkyl)-4,6,7-trimethyl-5-hydroxycoumarans, I, are of interest because these substances are isomeric with, and closely related to, the 2,2-dialkyl-5,7,8-trimethyl-6-hydroxychromans, the structural type of the tocopherols, for example, α-tocopherol, II.



Ia, R = CH_3
b, R = n-C_5H_{11}
c, R = $C_{16}H_{31}$ (4,8,12-trimethyltridecyl)



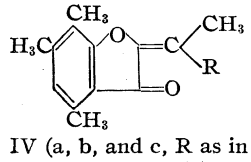
II (R as in Ic)



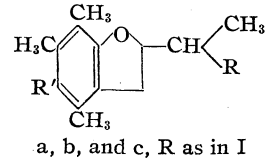
III

In an earlier paper[3] a method for the synthesis of 2-isopropyl-4,6,7-trimethyl-5-hydroxycoumaran (Ia) was described in which the last step involved introduction of the hydroxyl group by replacement of a bromine atom at position 5. Since the steps in this synthesis involved rather accessible intermediates and simple reactions, it was of interest to investigate the generality of the method for synthesis of higher homologs of I, with a view of ultimately synthesizing the coumaran Ic isomeric with α-tocopherol II. The model experiments were successful, and led to the synthesis of Ib but when applied to the synthesis of Ic, the synthesis failed because the last step was unsuccessful.

Methyl *n*-amyl ketone was condensed with 4,6,7-trimethylcoumaran-3-one, III, to give 2-(2′-heptylidene)-4,6,7-trimethylcoumaran-3-one, IVb, which was catalytically reduced in the presence of Raney nickel to 2-(2′-heptyl)-4,6,7-trimethylcoumaran Vb. The coumaran Vb was converted to the bromo compound VIb by bromination, and the bromo compound was converted into the Grignard reagent VIIb, which was oxidized to the bromomagnesium phenolate VIIIb. The salt, when hydrolyzed, gave the coumaran, Ib. Although the synthesis was successful, serious difficulties were encountered. Thus, neither Vb nor VIb could be obtained in pure form. Hydrogenation of IVb under a variety of conditions did not lead to a product from which pure Vb could be isolated. The crude bromo compound VIb, prepared from impure Vb, contained approximately 4% of halogen which was precipitated by action of alcoholic silver nitrate, and which was not removed by action of activated alumina or of hydrogen in the presence of a palladium catalyst.



IV (a, b, and c, R as in I)



a, b, and c, R as in I

V, R′ = H
VI, R′ = Br
VII, R′ = MgBr
VIII, R′ = OMgBr

This route to the coumaran Ib having proved successful, attention was turned to the synthesis of Ic. The coumaranone III condensed with 6,10,14-trimethylpentadecanone-2 in the presence of zinc chloride to produce IVc. Catalytic reduction of IVc failed to yield a product from which pure Vc could be isolated. However bromination of the impure Vc gave a product which when chromatographed on alumina, yielded pure VIc. When the bromo compound VIc was subjected successively to the action of magnesium and oxygen, the product was a red oil from which no Ic could be isolated.

The ultraviolet absorption spectra of several of these compounds are given in Figs. 1, 2 and 3. The spectra of the coumaran-3-ones IVa, b and c (Fig. 1) are very similar; likewise the spectra of the bromocoumarans VIa and c (Fig. 2) are very similar. The spectra of the hydroxycoumarans Ia and b are very similar to that of 2,4,6,7-tetramethyl-5-hydroxycoumaran.[4]

Experimental Part[5]

2,3,5-Trimethylphenoxyacetic Acid.—The following modification of the procedure previously reported[3] was found to give higher yields and more uniform results. A mixture of 2,3,5-trimethylphenol (68 g.), potassium carbonate (69 g.), ethyl bromoacetate (92 g.), and acetone (150 cc.) was refluxed for seventy-two hours—a necessary period of time if good yields are to be obtained. Water (200 cc.) was added, acetone was removed by distillation, and the oily suspension was extracted with ether. The solvent was removed and the oily residue was mixed with a solution of sodium (10 g.) in ethanol (200 cc., 95% —not dry ethanol, as specified in the earlier report). When the vigorous reaction subsided, more ethanol (300 cc., 95%) was added, the mixture was heated for five minutes, and the solid was removed. Hydrochloric acid was added slowly to a stirred suspension of the solid

(5) Microanalyses by R. Amidon, Mrs. R. A. Barnes, J. Kerns, P. Morgan and S. Sundet.

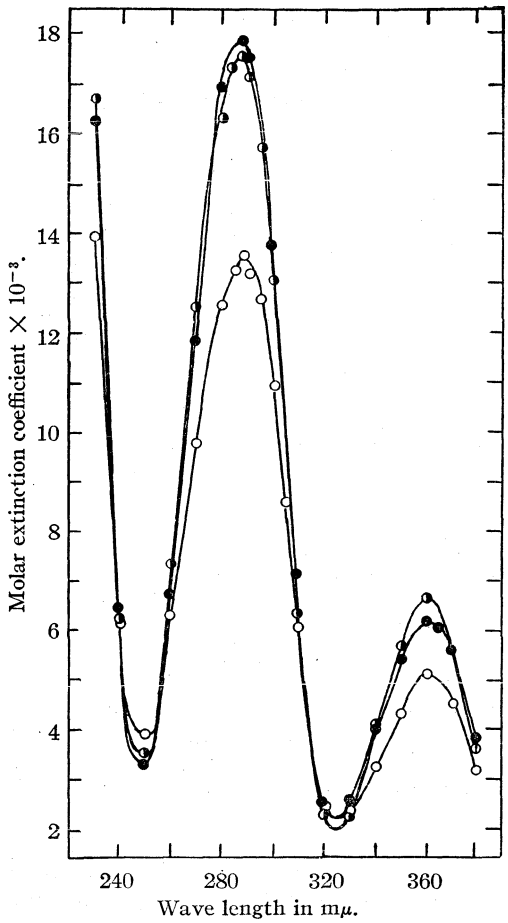

Fig. 1.—Absorption spectra: O, 2-(6′,10′,14′-trimethyl-2′-pentadecylidene)-4,6,7-trimethylcoumaran-3-one: ◑, 2-(2′-heptyl)-4,6,7-trimethylcoumaran-3-one: ●, 2-isopropyl-4,6,7-trimethylcoumaran-3-one: solvent, 95% ethanol.[3]

in warm water, and then the suspension was cooled and the solid (m. p. 129–131°) was removed and crystallized from benzene, when it melted at 130° and weighed 75 g. The alcoholic mother liquors were refluxed for ten hours, alcohol was removed by distillation, and water was added. The cooled solution was extracted with ether (extract discarded) and acidified with hydrochloric acid. The solid was removed and crystallized from benzene, when it melted at 127° and weighed 9.3 g. The total yield, 84.3 g., represents 86%.

4,6,7-Trimethylcoumaran-3-one, III.—The above phenoxyacetic acid (20 g.) was added, with shaking, to sulfuric acid at 90°. The cherry-red solution was heated for ten minutes at 90° and then poured into water (7000 cc.). The solid was removed, washed well with water, and the moist material was recrystallized from methanol, when it weighed 13.4 g. (76%) and melted at 89–91°. This procedure is superior to that previously reported,[3] although it must be followed exactly, otherwise the results are erratic and frequently the sole product will be an impure material of unknown structure, melting at 155–175°.

2-(2′-Heptylidene)-4,6,7-trimethylcoumaran-3-one, IVb.—A mixture of methyl *n*-amyl ketone[6] (44.1 g.) and zinc chloride (100 g., powdered, freshly fused) was stirred and heated on a steam-bath while a solution of III (13.6 g.) in methyl *n*-amyl ketone (44.1 g.) was slowly added (five hours), after which the mixture was heated and stirred for twenty-four hours. The mixture was poured into ice and water (500 g.) and the emulsion was filtered. The layers were separated and the aqueous

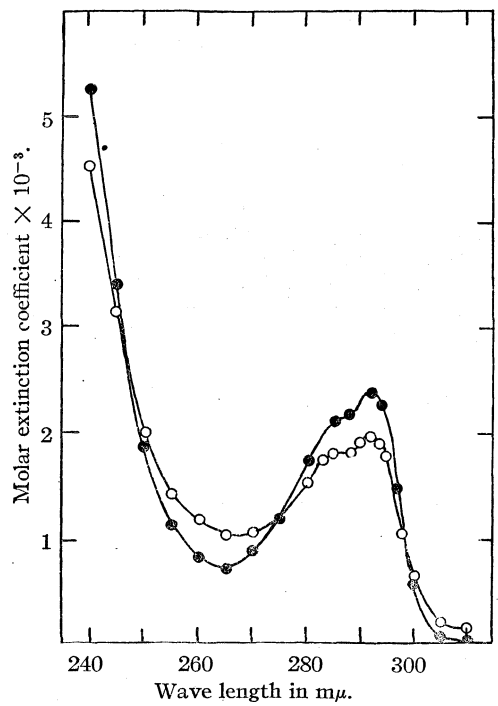

Fig. 2.—Absorption spectra: O, 2-(6′,10′,14′-trimethyl-2′-pentadecyl)-4,6,7-trimethyl-5-bromo-coumaran: ●, 2-isopropyl-4,6,7-trimethyl-5-bromocoumaran[3]; solvent, absolute ethanol.

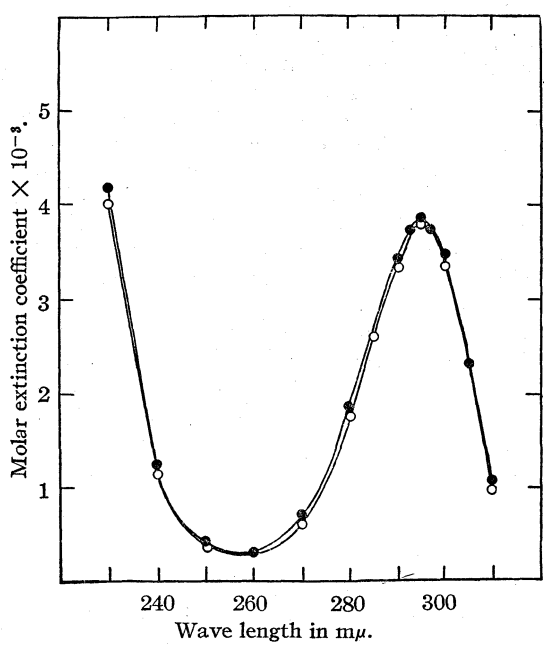

Fig. 3.—Absorption spectra: O, 2-(2′-heptyl)-4,6,7-trimethyl-5-hydroxycoumaran; ●, 2-isopropyl-4,6,7-trimethyl-5-hydroxycoumaran[3]; solvent, 95% ethanol.

layer was extracted with ether. The combined organic solutions were washed with water and dried over sodium sulfate, and the solvent was removed. Excess ketone was removed by heating the residue at 100° under 25 mm. pressure, and the residual material was distilled molecularly from a pot-still under 0.0001 mm. With the bath temperature at 130–160°, a yellow oil (14.8 g., $n^{25}D$ 1.5576) distilled. Redistilled twice under the same conditions, the oil weighed 9.65 g. (46%), had $n^{25}D$ 1.5614, and gave the U. V. spectrum shown in Fig. 1.

Anal. Calcd. for $C_{18}H_{24}O_2$: C, 79.36; H, 8.88. Found: C, 79.61; H, 8.62.

2-Isobutylidene-4,6,7-trimethylcoumaran-3-one, melting at 81.5–82.5° after crystallization three times from petroleum ether (b. p. 40–70°), was prepared in the same way, substituting butanone-2 for methyl *n*-amyl ketone.

Anal. Calcd. for $C_{15}H_{18}O_2$: C, 78.22; H, 7.88. Found: C, 78.43; H, 7.79.

2-(2′-Heptyl)-4,6,7-trimethylcoumaran Vb.—A solution of the coumarone IVb (3.6 g.) in dry ethanol (4 cc.) was subjected to the action of hydrogen in the presence of Raney nickel catalyst at 225° for four hours, under an initial hydrogen pressure of 3500 lb. The catalyst and the solvent were removed, and the residue was distilled molecularly from a pot-still under 0.001 mm. at a bath temperature of 75–80°. The pale yellow oil weighed 2.78 g. and had $n^{25}D$ 1.5045. It was still quite impure, but was nevertheless used for the next step.

Anal. Calcd. for $C_{18}H_{28}O$: C, 83.02; H, 10.84. Found: C, 79.32; H, 10.19.

No better results were obtained when the reduction was carried out (a) as above, but at 250° for four and one-half hours; (b) as above, but at 200° for four hours and an initial hydrogen pressure of 3000 lb.; (c) as above, at 225° for five hours and an initial pressure of 3600 lb.; (d) as above, but in the presence of a small amount of sodium hydroxide; (e) using copper chromium oxide catalyst; (f) by the Clemmensen method. Neither fractional distillation nor chromatography was effective in producing pure Vb from any of these products.

2-(2′-Heptyl)-4,6,7-trimethyl-5-bromocoumaran VIb.—The above impure Vb (2.8 g.) was dissolved in chloroform (5 cc.) and brominated by slow addition of a solution of bromine (1.9 g.) in chloroform (5 cc.). The solution remained colorless until nearly all of the bromine had been added; there was a copious evolution of hydrogen bromide. The solvent was removed and the residue was distilled in a pot-still at 120–135° bath temperature and under 0.001 mm. The distillate (2.73 g., active Br, 4.0%) was dissolved in benzene (10 cc., thiophene-free) and shaken with hydrogen under 35 lb. in the presence of a palladium–barium carbonate catalyst for three and one-half hours. After removal of the catalyst and solvent, the residue was dissolved in petroleum ether (20 cc.) and the solution was passed through a 5 × 0.5-cm. column of alumina (Brockman). Additional petroleum ether (20 cc.) was passed through the column, the solvent was removed from the combined solutions and the residue was distilled as before. The yellow oil distilled at a bath temperature of 100–110°, weighed 1.7 g., had $n^{25}D$ 1.5334, and contained 2.3% of active bromine. It was not analyzed, but was used directly in the next step.

2-(2′-Heptyl)-4,6,7-trimethyl-5-hydroxycoumaran, Ib.—The above impure bromo compound (1.68 g.) and cyclohexyl bromide (1.61 g.) were dissolved in ether (10 cc.). A portion (2.5 cc.) of a solution of ethyl bromide (1.62 g.) in dry ether (10 cc.) was added to magnesium (1.08 g.) covered with boiling ether, and as the magnesium dissolved, the solution containing VIb, together with more (5 cc.) of the solution of ethyl bromide, were added over a period of two and one-half hours, with stirring. The remainder of the solution of ethyl bromide was then slowly added, and the whole was refluxed for two hours. The mixture was then cooled to −15° and dry oxygen was bubbled through it for two hours. The green solid was decomposed by addition of hydrochloric acid, the ether layer was removed, washed with water and dried. The solvent was removed and the residue was molecularly distilled from a pot-still under 0.001 mm. At 120° (bath) a yellow oil (0.43 g.) distilled; at 150° a waxy solid (0.40 g.) sublimed. The solid was dissolved in petroleum ether and the solution was cooled to −70°. The solid was removed by centrifugation and crystallized twice from petroleum ether. It was then dissolved in methanol and water was added slowly; the dark oil was removed by centrifugation and then addition of more water brought about deposition of a solid. This was removed and crystallized from petroleum ether, when it melted at 72–75°. The Folin–Denis test was strongly positive. The U. V. spectrum is shown in Fig. 3.

Anal. Calcd. for $C_{18}H_{28}O_2$: C, 78.21; H, 10.21. Found: C, 78.39; H, 10.51.

6,10,14-Trimethylpentadecanone-2.—Phytol (24 g.) in purified ethyl acetate[7] (200 cc.) was ozonized (4% O_3 in O_2) at −5° and the ozonide was reductively decomposed. The ketone (14.4 g., 67%) boiled at 120–122° (1 mm.) and had $n^{25}D$ 1.4441.[8]

2-(6′,10′,14′-Trimethyl-2′-pentadecylidene)-4,6,7-trimethylcoumaran-3-one IVc.—The coumaranone III (1.81 g.), the above ketone (27.6 g.) and zinc chloride (10 g. freshly fused and powdered) were heated on the steam-bath for twenty-four hours, with stirring during the first hour. The mixture was dissolved in chloroform, the solution was washed with water, dried over sodium sulfate, and the solvent was removed. Excess ketone was removed by distillation from a pot-still at 150° (bath temperature) under a pressure of 0.1 mm. The recovered ketone (19.6 g.) was heated with more III (1.29 g.) and zinc chloride (10 g.) and the mixture was processed as before. Again the recovered ketone (16.1 g.) was heated with III (1.06 g.) and zinc chloride and the mixture was similarly processed. The dark oils remaining after removal of excess ketone were combined and distilled and redistilled from a pot-still under 0.001 mm. The yellow oil distilling at 175–185° (bath temperature) weighed 3.5 g. (40%) and had $n^{25}D$ 1.5140. The U. V. spectrum is shown in Fig. 1.

Anal. Calcd. for $C_{29}H_{46}O_2$: C, 81.63; H, 10.87. Found: C, 81.33; H, 11.14.

2-(6′,10′,14′-Trimethyl-2′-pentadecyl)-4,6,7-trimethylcoumaran Vc.—The above coumaranone IVc (1 g.) in ethanol was subjected to the action of hydrogen for four hours in the presence of Raney nickel catalyst at 250° under an initial hydrogen pressure of 3600 lb. The catalyst was removed by centrifugation, the solvent was removed by distillation, and the residue was distilled from a pot-still under 0.001 mm. at a bath temperature of 160–190°. The pale yellow oil weighed 0.85 g. and had $n^{25}D$ 1.5036; analysis showed that it was not pure Vc, though it was sufficiently pure for use in the next step.

Anal. Calcd. for $C_{29}H_{50}O$: C, 83.99; H, 12.15. Found: C, 81.66; H, 12.41.

The hydrogenation did not always proceed uniformly; in an experiment duplicating the one described above, the product had $n^{25}D$ 1.4886 and also was not pure Vc.

2-(6′,10′,14′-Trimethyl-2′-pentadecyl)-4,6,7-trimethyl-5-bromocoumaran VIc.—The above impure coumaran (0.72 g.) in carbon tetrachloride (10 cc.) was brominated by dropwise addition of a solution of bromine (0.312 g.) in carbon tetrachloride (2 cc.). The solution remained colorless until about two-thirds of the bromine was added, after which it became orange. The solution was washed successively with aqueous sodium bicarbonate and aqueous sodium bisulfite, dried, and the solvent was removed. The residue was distilled from a pot-still under 0.001 mm. The yellow oil distilling at 165–210° (bath temperature) weighed 0.72 g. It was dissolved in petroleum ether (30 cc., b. p. 40–70°) and passed through a 20 × 0.5-cm. column filled with alumina (Brockmann). Additional petroleum ether (30 cc.) was passed through

(7) Fieser, "Experiments in Organic Chemistry," D. C. Heath and Co., New York, N. Y., 1941, p. 364.

(8) Smith and Sprung, THIS JOURNAL, **65**, 1271 (1943).

the column. The solvent was removed from the combined solutions and the residue was distilled under 0.001 mm. as before. It weighed 0.42 g., had $n^{25}D$ 1.5059, and gave the U. V. spectrum shown in Fig. 2.

Anal. Calcd. for $C_{29}H_{48}OBr$: C, 70.56; H, 10.00. Found: C, 70.54; H, 9.83.

The bromocoumaran VIc (0.33 g.) and cyclohexyl bromide (0.22 g.) in ether (10 cc.) was stirred with magnesium (0.163 g.) while the magnesium was reacting with ethyl bromide (0.21 g.) in ether (10 cc.). The procedure and processing of the reaction mixture were carried out as described above in the preparation of Ib. The crude product was distilled from a pot-still at 170–200° (bath temperature) under 0.001 mm.; the orange distillate weighed 0.25 g. It gave a positive Folin–Denis test, and contained a trace of halogen. A solution of the oil in petroleum ether (30 cc.) was passed through a column of alumina (Brockmann); the column was washed with additional petroleum ether and the combined organic solutions were evaporated. The residue was distilled as before. The distillate (about 0.1 g.) gave an absorption spectrum in the U. V. which in no way resembled those of Ia and Ib. The column of alumina was eluted with ethanol, but very little material was present in the eluate and this material, likewise, was not a hydroxycoumaran.

Summary

1. Three ketones—methyl ethyl ketone, methyl *n*-amyl ketone, and "phytol" ketone—have been condensed with 4,6,7-trimethylcoumaran-3-one (III) to give the 2-alkylidene coumarones.

2. The alkylidene coumarones from the last two ketones were reduced to the coumarans, and the latter were brominated in the 5-position.

3. The 5-bromocoumaran thus obtained from methyl *n*-amyl ketone was converted to a Grignard reagent, and the latter was oxidized, producing the 5-hydroxycoumaran. Conversion of the 5-bromocoumaran derived from phytol ketone into the analogous 5-hydroxycoumaran was not achieved.

4. Curves are given showing the absorption spectra in the ultraviolet of several of the intermediates and final products.

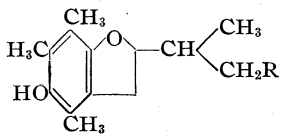
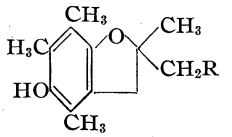
Vitamin E. XLVII.[1] The Coumaran Isomer of α-Tocopherol

BY LEE IRVIN SMITH AND GERALD A. BOYACK[2]

Early in the history of the work upon the structure and synthesis of α-tocopherol, there was some discussion as to whether the vitamin was best represented as a coumaran, I, or as the isomeric chroman, II.[3]





I, R = $C_{15}H_{31}$ = 3,7,11-trimethyldodecyl. II, R = $C_{15}H_{31}$

Although the structure was definitely settled in favor of II,[4] a synthesis of the isomeric coumaran I would be of some interest, in view of the vitamin E activity of many compounds related to II. This paper describes a successful synthesis of I and one of its homologs X (R = *n*-$C_{13}H_{27}$). The coumaran I was obtained as a yellow oil and, although it showed vitamin E activity, the activity was only about 5% of that of α-tocopherol.

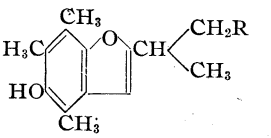
The synthetic route to I involved the sequence of compounds III to VII (R as in formula I): the coumaron VII was then catalytically reduced to I.

III, $RCH_2C(CH_3)=CHCH_2OH$
IV, $RCH_2CH(CH_3)CH_2CH_2OH$
V, $RCH_2CH(CH_3)CH=CH_2$
VI, $RCH_2CH(CH_3)R'$
VIa, R′ = COOH
VIb, R′ = COCl
VIc, R′ = $COCH_3$
VId, R′ = $COCH_2COCH_3$



VII

Phytol (III) was catalytically reduced to dihydrophytol (IV) and the latter was converted to the stearate. When the crude stearate was pyrolyzed, phytene-1 (V) resulted. Although phytene-1 had been reported twice previously[5] no proof that the double bond is terminal has ever been given. The phytene-1 prepared in the present work had the proper iodine number and its reaction with perbenzoic acid was very slow—much slower than the rate with which oleic acid reacts, and slower even than the reaction of undecylene-1, indicating in this phytene the absence of a disubstituted double bond. Finally, ozonolysis of phytene-1 followed by oxidative decomposition of the ozonide, led to apophytoic acid VIa. The acid was converted into the acid chloride VIb and from this the methyl ketone VIc was prepared by action of dimethylcadmium.[6] A solid derivative of the methyl ketone VIc was not obtained; both the

(6) Cason and Prout, THIS JOURNAL, **66**, 46 (1944).

semicarbazone and the 3,5-dinitrophenylhydrazone were liquids.

When the methyl ketone VIc reacted with ethyl acetate in the presence of sodamide, the diketone VId resulted. This gave a red color with ferric chloride, but no solid derivative was obtained; although VId formed a copper derivative, this was a liquid. Condensation between methyl apophytate and acetone in the presence of sodamide, which likewise would lead to VId, was unsuccessful—the chief product was apophytoic acid.

When a mixture of the diketone VId, trimethylquinone, and sodium ethoxide was allowed to stand for a week, the coumaron VII was obtained as a dark oil. The coumaron was characterized by analysis and by the U.V. absorption spectrum (Fig. 1), which exhibited maxima at the same wave lengths as shown by the spectrum of 2,4,6,7-tetramethyl-5-hydroxycoumaron.[7] The coumaron VII was reduced by action of hydrogen at 68° in the presence of a palladium catalyst; the product was the coumaran I, characterized by analysis, by conversion to a solid allophanate melting at 176–180° (m. p. of the allophanate of α-tocopherol, 158–160°)[8] and by the U. V. absorption spectrum (Fig. 1) which was quite similar to that of the simple isopropyl homolog (I, R = H).[1] The absorption spectrum of I was similar to that of α-tocopherol.[9] Curiously enough, the absorption spectrum of the allophanate of I was somewhat different from that of α-tocopheryl allophanate[10] but was almost identical with that of β-tocopheryl allophanate.[3a] The coumaran I was assayed biologically for Vitamin E activity[11] and the results showed that I possessed about 5% of the activity of *dl*-α-tocopherol. This is somewhat surprising, in view of the comparable activity of many compounds much less closely related structurally to α-tocopherol than I is, and in view of the fact that α-tocopherylamine is about as active as is α-tocopherol itself. It thus appears that the size of the ring—5 or 6—is a critical factor for vitamin E activity.

Before the experiments described above were undertaken, many model experiments were carried out. The route to the coumarans was based upon the work of Smith and Kaiser,[12] who added the enolate of acetylisobutyrylmethane to trimethylquinone and converted the resulting phenylated diketone, by action of hydrochloric acid, into a mixture of two 2-alkyl-4,6,7-trimethyl-5-hydroxy-

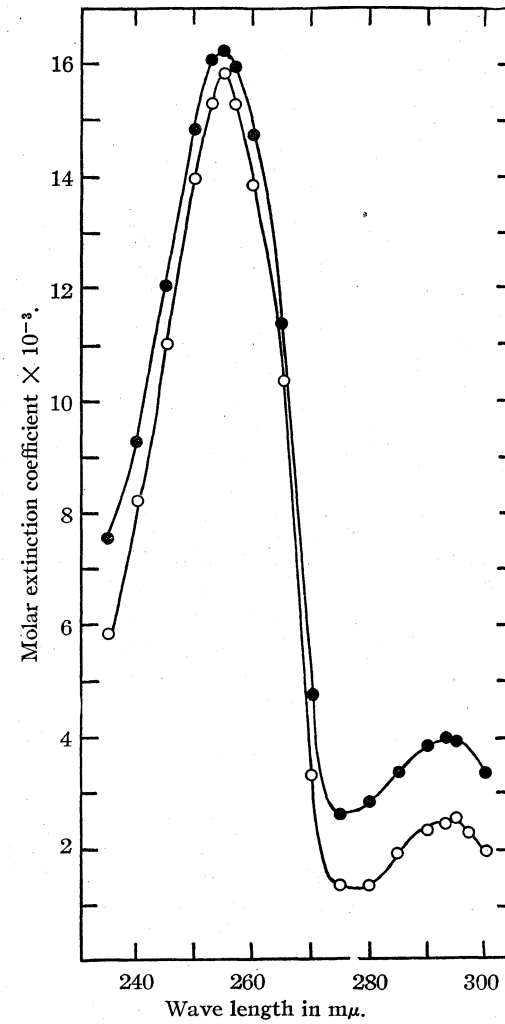

Fig. 1.—Absorption spectra: ○, 2-(6′,10′,14′-trimethyl-2′-pentadecyl)-4,6,7-trimethyl-5-hydroxycoumaron; ●, 2-tridecyl-4,6,7-trimethyl-5-hydroxycoumaran: solvent, 95% ethanol.

coumarons—the 2-methyl and the 2-isopropyl. This situation always arises when the starting diketone is unsymmetrical and the two alkyl groups have molecular weights close together; moreover, the resulting coumarons are separated only with great difficulty. Because of these facts, Smith and King[4f] in their synthesis of 2-isopropyl-4,6,7-trimethyl-5-hydroxycoumaran (I, R = H) used the symmetrical diisobutyrylmethane as the starting diketone and so obtained only one coumaron. However, application of King's synthesis to the preparation of I offered formidable difficulties, for preparation of the intermediates necessary for conversion to the proper diketone involved many steps from the most accessible material, phytol. All of these intermediates, as well as the final product of the Claisen condensation, are liquids with very high boiling points, extremely difficult to purify. Consequently, if the approach to the synthesis of I could be made via Kaiser's method, the

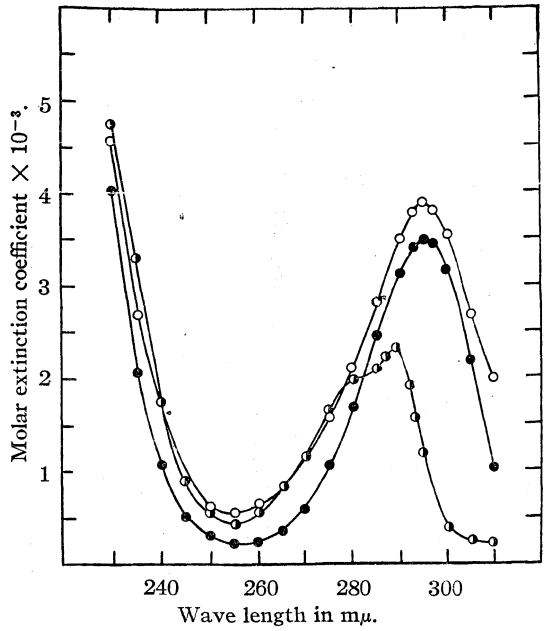

Fig. 2.—Absorption spectra: O, 2-(6′,10′,14′-trimethyl-2′-pentadecyl)-4,6,7-trimethyl-5-hydroxycoumaran: ●, 2-tridecyl-4,6,7-trimethyl-5-hydroxycoumaran: ◑, 2-(6′,10′,14′ - trimethyl - 2′ - pentadecyl) - 4,6,7 - trimethyl-5-hydroxycoumaran allophanate: solvent, 95% ethanol.

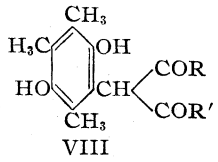
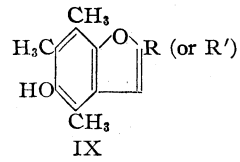
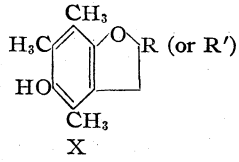
synthetic problems would be much simplified. Since the phenylated diketone VIII is an intermediate, the point of cleavage of this diketone during the ring closure determines the nature of the alkyl group in the 2-position of the coumaron



VIII



IX



X

IX. Kutz and Adkins[13] have shown that, when an acetylacylmethane CH_3COCH_2COR, is hydrolyzed by action of alkali, cleavage on the acetyl side of the molecule is promoted by increasing length and complexity of the group R. Therefore it appeared that if the group R in the diketone were large, the synthesis would lead to a mixture of coumarons in which the simpler 2-methylcoumaron would constitute but a minor proportion. If so, separation of the two coumarons should not offer much difficulty because the simple 2-methylcoumaron is quite volatile with steam. These expectations were fully justified; when myristoylacetylmethane was added to trimethylquinone and the resulting phenylated diketone was converted into coumarons, about three moles of IX, R = n-$C_{13}H_{27}$, were formed for every mole of IX, R = CH_3. The two coumarons were readily separated for IX, R = CH_3, is quite volatile with steam whereas IX, R = n-$C_{13}H_{27}$, is only slightly so. In the synthesis of I, none of the simple 2-methylcoumaron was obtained; ring closure led entirely to VII (R as in I).

The route to IX, R = n-$C_{13}H_{27}$, involved the same sequence of reactions that was used for synthesis of I. Myristoyl chloride was converted into pentadecanone-2 by reaction with dimethylcadmium.[6] In this reaction, a considerable amount of dimyristoylmethane was also formed. Pentadecanone-2 was converted into heptadecandione-2,4 by condensation with ethyl acetate in the presence of sodamide, in yields slightly better than those obtained when metallic sodium was used.[14] The diketone existed 100% in the enolic form, a finding in accord with the results of Weygand and Baumgartel[15] that the amount of enolic form at equilibrium in an acetylacylmethane increases with the length of the acyl group. Only poor yields of the diketone, accompanied by much myristic acid, were obtained when methyl myristate was condensed with acetone in the presence of sodium hydride according to the procedure of Hansley,[16] who stated that the diketone was produced in good yields. Condensation of the diketone with trimethyl quinone in the presence of sodium ethoxide, according to the procedure of King,[4f] offered no difficulty although a considerable amount of the diketone was recovered unchanged. Conversion of the phenylated diketone VIII to coumarons was effected by action of boiling dilute sodium hydroxide, although during the reaction air had to be carefully excluded. The phenylated diketone VIII was unaffected by hot hydrochloric acid, in contradistinction to the lower homologs, which are converted to coumarons by this reagent.[12] The coumaron IX (R = n-$C_{13}H_{27}$) was reduced to the corresponding coumaron (X, R = n-$C_{13}H_{27}$) by the action of hydrogen in the presence of a palladium catalyst.[17] Raney nickel catalyst under conditions of high temperature and pressure was without effect upon IX; this catalyst has been found effective for reduction of the lower homologs of IX.[18]

The melting points of the coumaran IX (R = n-$C_{13}H_{27}$) and the corresponding coumaran X are close together and a mixture of the two compounds does not show a depressed melting point. Nor does elementary analysis serve to distinguish between them. However, the absorption spectra in the ultraviolet are quite different for the two

compounds; the curves are given in Figs. 1 and 2. The curve for this coumaran is very similar to those reported for other known 2-alkylcoumarans.[7]

Experimental Part[19]

Dihydrophytol IV.—Phytol (III, 200 g.)[20] was subjected to the action of hydrogen at 175° for one hour in the presence of Raney nickel catalyst, and under an initial hydrogen pressure of 2800 lb. The catalyst was removed and the product was distilled. The fraction boiling at 164–166° (0.01 mm.) did not decolorize bromine in carbon tetrachloride; it weighed 176 g. (85%) and had $n^{20}D$ 1.4520.[21]

Phytene-1 (V).—Dihydrophytol (166 g.) was heated at 125° (bath temperature) with stearoyl chloride (180 g.) for three hours. The cooled mixture was washed twice with double its volume of cold (10°) methanol. The crude liquid ester (329 g., free from chlorine) was pyrolyzed by dropping it slowly into a distilling flask immersed in a bath at 420°. The solid distillate (318 g.) was heated at 160° (bath temperature) under 0.01 mm. until there was no further distillate (phytene-1). The residue was washed with cold methanol to remove stearic acid, and was then distilled from a pot still at 340–380°. The olefin in the distillate was removed at 160° under 0.01 mm. as before, and the two olefin fractions (130 g.) were combined and allowed to stand over sodium for four days, with removal of the gelatinous material each day. The material was then distilled; the fraction boiling at 120–127° (0.01 mm.) weighed 86 g. (55%) and had $n^{25}D$ 1.4430.

Anal. Calcd. for $C_{20}H_{40}$: C, 85.63; H, 14.37; iodine number, 90.8. Found: C, 85.47; H, 14.09; iodine number, 91.4.[22] In three hours at 25° phytene-1 reacted with perbenzoic acid to the extent of 34.5%; under the same conditions, undecylene-1 and oleic acid gave the respective values of 44% at 100%.[23]

Apophytoic Acid (VIa).—Phytene-1 (V, 28 g.) in petroleum ether (200 cc., b. p. 28–38°, washed with sulfuric acid and dried over sodium) was ozonized at −50 to −40° by passing through the solution a stream of ozone–oxygen (0.4% O_3)[24] until approximately a third of the ozone was coming through unabsorbed. The solution was added to a stirred suspension of silver oxide (from silver nitrate, 46 g. and 1 *N* sodium hydroxide, 250 cc.) in aqueous sodium hydroxide (220 cc., 5%) at 95°. Petroleum ether distilled rapidly, and after all this solvent was removed, the mixture was stirred and heated on the steam-bath for eight hours. Chloroform (100 cc.) was added to the cooled and stirred suspension, which was then slowly acidified with nitric acid (80 cc.). The chloroform layer was removed, washed with water, dried over sodium sulfate, and the solvent was removed by distillation. The residues (28.3, 28.6 and 27.5 g.) from three such runs were combined and distilled from a Clarke flask under 0.01 mm. A low boiling fraction (6 g., odor of butyric acid) and an intermediate fraction (16 g., neutral), were followed at 175–185° by a fraction of apophytoic acid (51 g., 57%) having $n^{25}D$ 1.4489.

Anal. Calcd. for $C_{19}H_{38}O_2$: C, 76.45; H, 12.83; neut. equiv., 298. Found: C, 76.57; H, 12.80; neut. equiv., 297.

The methyl ester (49.8 g., 98%) prepared from the acid (48 g.) by action of diazomethane (from 25 g., nitrosomethylurea) in ether (100 cc.) boiled at 125–133° (0.01 mm.) and formed a neutral liquid.

Anal. Calcd. for $C_{20}H_{40}O_2$: C, 76.86; H, 12.90. Found: C, 76.97; H, 12.83.

Apophytoyl Chloride (VIb).—The acid VIa (27 g.) was refluxed in thionyl chloride (53.5 g.) for one hour. Excess thionyl chloride was removed at 120° (bath temperature) under 20 mm., and the residual acid chloride was distilled under 0.01 mm. It boiled at 165–170° and weighed 23.2 g. (81%).

Anal. Calcd. for $C_{19}H_{37}OCl$: C, 72.01; H, 11.77; Cl, 11.2. Found: C, 72.86; H, 12.30; Cl (Volhard), 10.7.

3,7,11,15-Tetramethylhexadecanone-2 (VIc).—A Grignard reagent was prepared by passing a current of methyl bromide into a stirred suspension of magnesium (3.58 g.) in ether (200 cc.) until the metal dissolved completely. To this solution, cadmium chloride (14.8 g., dried at 100° and powdered) was added all at once and the mixture was stirred and refluxed for ten minutes. Ether was removed by distillation until a mush of solid remained, then dry benzene (100 cc., thiophene-free) was added and distillation was continued until the temperature of the vapors reached 70°. More benzene (100 cc.) was added, the mixture was heated to the boiling point, and apophytoyl chloride (VIb, 23 g.) was added to the refluxing suspension as rapidly as the exothermic reaction would permit. The mixture was stirred and refluxed for thirty minutes longer, and was then poured over ice and acidified with hydrochloric acid until most of the solid dissolved. The organic layer was removed, and the aqueous layer was extracted with benzene. The combined organic layers were washed with water until the washings were neutral. The solution was dried over sodium sulfate and the solvent was removed by a flash distillation at 150°. The residue, distilled under 0.01 mm. gave a fraction boiling at 180–185° (11.1 g.) which had $n^{25}D$ 1.4453.

Anal. Calcd. for $C_{20}H_{40}O$: C, 81.01; H, 13.60. Found: C, 80.87; H, 13.71.

Additional ketone (1.3 g.) slightly less pure, was obtained by heating the residue from the above distillation in a pot still under 0.001 mm. at 130° (bath temperature). The total yield of ketone was 12.4 g. (58%). The residue remaining after removal of all the ketone, when distilled from a pot still at 210° (bath temperature) under 0.001 mm. gave a yellow oil (3 g.) having $n^{25}D$ 1.4650. It gave a red color with ferric chloride. This was probably a mixture of the 1,3-diketone $RCH_2CH(CH_3)COCH_2COCH(CH_3)CH_2R$ and the aldol product of the ketone, $RCH_2C(CH_3)=CHCOCH(CH_3)CH_2R$.

Anal. Calcd. for $C_{39}H_{76}O_2$ (diketone): C, 81.87; H, 13.28. Calcd. for $C_{40}H_{78}O$ (aldol): C, 83.56; H, 13.68. Found: C, 82.83; H, 13.36.

The semicarbazone of VIc, distilled from a pot still at 145° (bath temperature) under 0.001 mm., was a viscous oil having $n^{25}D$ 1.4713 and which could not be induced to crystallize. Likewise, the 2,4-dinitrophenylhydrazone of VIc was a viscous red oil, insoluble in ethanol (VIc was quite soluble in ethanol).

5,9,13,17-Tetramethyloctadecandione-2,4 (VId).—Small pieces of sodium were added to liquid ammonia (100 cc.) until the blue color was permanent, whereupon a small crystal of ferric chloride was added and air was drawn through the solution until the blue color disappeared. Then sodium (3.42 g.) was added and the mixture was stirred until the blue solution became a gray suspension. The ammonia was allowed to evaporate, being replaced by dry ether so that the volume remained constant. The ketone VIc (11 g.) in dry ether (30 cc.) was added and the mixture was refluxed for twenty minutes, then dry ethyl acetate (32.2 g.) was added slowly (ten minutes). The mixture first became very viscous, even though more ether (50 cc.) was added, but soon became thin enough to stir. It was stirred for seven hours at room temperature and then poured over ice and acidified (congo red) with hydrochloric acid. The organic layer was removed, combined with an ether extract of the aqueous layer, and dried over sodium

sulfate. The solvent was removed and the residue, when distilled under 0.01 mm. gave a distillate (7.3 g., 58%) boiling at 150–153° and having $n^{25}D$ 1.4630.

Anal. Calcd. for $C_{22}H_{24}O_2$: C, 78.05; H, 12.51. Found: C, 77.85; H, 12.54.

The diketone gave a red color with alcoholic ferric chloride: when a solution of the diketone in a little methanol was shaken with warm aqueous cupric acetate, a blue oil separated. All attempts to crystallize this blue oil were unsuccessful.

When the enolate of acetone (19.1 g.) was prepared in liquid ammonia, essentially as described above, and brought into reaction with methyl apophytoate (49 g.) a product (59.7 g.) was obtained which, after distillation, had $n^{25}D$ 1.4500, and which consisted essentially of apophytoic acid, VIa.

Anal. Calcd. for $C_{19}H_{38}O_2$: C, 76.45; H, 12.83; neut. equiv., 298. Found: C, 76.82; H, 13.09; neut. equiv., 313.

2-(6′,10′,14′-Trimethyl-2′-pentadecyl)-4,6,7-trimethyl-5-hydroxycoumaron (VII).—A solution of the diketone VId (6.64 g.) in dry ethanol (10 cc.) was added to a solution of sodium (0.376 g.) in dry ethanol (50 cc.). The solution was stirred at room temperature for fifteen minutes, then was cooled to 15° and to it was slowly (one hour) added a solution trimethylquinone[25] (2.94 g.) in dry ethanol (30 cc.). The air in the flask was replaced by dry nitrogen and the flask was tightly stoppered and allowed to stand at room temperature for six and one-half days. The reaction mixture was poured onto ice, acidified with hydrochloric acid, and extracted three times with ether (100-cc. portions). The combined extracts were thoroughly washed with water and dried over sodium sulfate. The solvent was removed and the oil was subjected to distillation with steam; the distillate contained no organic material (*i. e.*, no IX, R = CH_3). The residue was taken up in ether, the solution was dried, the solvent was removed in a current of nitrogen. A red oil (1.76 g. unchanged VId) was removed from the product by distillation from a pot still under 0.001 mm. at a bath temperature of 130°. The residual oil from this distillation was stirred with petroleum ether (100 cc., b. p. 60–68°) and an insoluble black powder (1.12 g.) was removed. The solvent was removed in a current of nitrogen and the oil was distilled from a pot still under 0.001 mm. As the temperature of the bath was gradually raised, a dark oil (1.26 g.) distilled, followed by the coumaron VII (1.43 g., 21%) at 180°.

Anal. Calcd. for $C_{29}H_{48}O_2$: C, 81.25; H, 11.29. Found: C, 81.25; H, 11.08.

The absorption spectrum in the ultraviolet is shown in Fig. 1.

2-(6′,10′,14′-Trimethyl-2′-pentadecyl)-4,6,7-trimethyl-5-hydroxycoumaran (I).—The coumaron VII (100 mg.) in acetic acid (15 cc.) was subjected for four hours to the action of hydrogen at 68° under a pressure of 20 lb. and in the presence of palladium–charcoal catalyst (10%). The catalyst was removed by centrifugation and the solvent was removed under reduced pressure (5 mm.) at 70°. The residual light brown oil weighed 92 mg.

Anal. Calcd. for $C_{29}H_{50}O_2$: C, 80.87; H, 11.70. Found: C, 80.56; H, 11.76. The absorption spectrum in the ultraviolet is shown in Fig. 2.

Allophanate.—A stream of cyanic acid was passed for ten minutes through a solution of the coumaran I (90 mg.) in dry benzene (5 cc., thiophene-free). The solution was set aside in a refrigerator for six and one-half days. The solid was removed and washed with hot benzene; the filtrate and benzene washings were combined and the solvent was removed in a stream of nitrogen. The gummy residue was crystallized from methanol, when it weighed 45 mg. and melted at 160–174°. Recrystallized twice more from methanol, the substance melted at 176–180°.

Anal. Calcd. for $C_{31}H_{52}O_4N_2$: C, 72.05; H, 10.15. Found: C, 72.35; H, 10.37.

The absorption spectrum in the ultraviolet is shown in Fig. 2.

Pentadecanone-2.—This was prepared exactly as described above (for compound VIc) from magnesium (20.4 g.), methyl bromide, cadmium chloride (83.5 g.) and myristoyl chloride (104 g., b. p. 154–160° at 10 mm.). The product was distilled under 3 mm. pressure; the fraction (59.8 g., 63%) boiling at 122–135° solidified on cooling and then melted at 35–39°.[26] The semicarbazone melted at 124–125°.[27] Considerable residue remained after removal of the ketone; this was distilled from a pot still under 0.001 mm. at a bath temperature of 240°. The distillate, recrystallized from dry ethanol, gave 1.3 g. of dimyristoylmethane, melting at 62–63°.

Anal. Calcd. for $C_{29}H_{56}O_2$: C, 79.75; H, 12.92. Found: C, 79.49; H, 12.93.

The copper derivative, recrystallized from dry ethanol, melted at 101–102°.

Heptadecandione-2,4.—This was prepared as described above (for VId) from sodium (17.75 g.), liquid ammonia, pentadecanone-2 (58 g.), and ethyl acetate (55.5 g.). Cupric acetate dihydrate (50 g.) in water (500 cc.) was added to a solution of the crude product in warm methanol, the copper derivative was removed, washed with water, triturated with warm ethanol and the suspension was cooled and filtered. A small portion of the copper compound, crystallized from dry ethanol, was blue-gray and melted at 118–119°. The copper compound, suspended in petroleum ether (b. p. 40–70°), was shaken with dilute sulfuric acid until the solid disappeared. The organic layer was removed, washed thoroughly with water, and the solvent was removed by distillation. The residue (41.5 g., 60%) melted at 43–45°. The diketone gave a cherry-red color with alcoholic ferric chloride, and the enol content, determined by the method of Cooper and Barnes[28] was 98%. Condensation of methyl myristate (24.2 g.) in petroleum ether (200 cc., b. p. 100–140°) with acetone (2.9 g.) in the presence of sodium hydride (2.4 g.) gave only small amounts (5–8 g.) of the diketone, which was impure (m. p. 41–48°, enol content, 53%). The bulk of the condensation product was myristic acid.

3-(2′,5′-Dihydroxy-3′,4′,6′-trimethylphenyl)-heptadecandione-2,4 (VIII, R = CH_3; R′ = n-$C_{13}H_{27}$).—A solution of heptadecandione-2,4 (14.8 g.) in dry ethanol (50 cc.) was added, with stirring and some cooling (20°) to sodium methoxide (from sodium, 1.15 g.) in ethanol (50 cc.). Trimethylquinone (7.5 g.) in dry ethanol (25 cc.) was slowly (one and one-half hours) added to the cooled (15–20°) solution of the enolate. The solution was stirred for two hours at room temperature, then cooled (0°) and acidified with iced hydrochloric acid and extracted three times with ether. The combined extracts were washed with water, filtered, and the solvent was removed. The oily residue was dissolved in warm methanol and the solution, when cooled, deposited 9.5 g. of material melting at 40–70°. This material, recrystallized first from petroleum ether and then from methanol, weighed 3 g. (14%) and melted at 90–91°. The analytical sample, crystallized twice from petroleum ether and three times from methanol, melted at 95–96°.

Anal. Calcd. for $C_{26}H_{42}O_4$: C, 74.60; H, 10.11. Found: C, 74.44; H, 10.23.

Heptadecandione-2,4 (6.3 g., m. p. 43–45°) was recovered by recrystallization from methanol of the residue obtained when all the mother liquors from the above purification were combined and evaporated.

(26) Dreger, Keim, Miles, Shedlovsky and Ross, *Ind. Eng. Chem.*, **36**, 610 (1944), report the m. p. as 40.5°.

(27) (a) Baumgarten, *Ber.*, **76**, 213 (1943), reported the m. p. as 124–125°; (b) Pickard and Kenyon, *Proc. Chem. Soc.*, **27**, 312 (1911), reported 126.5°.

(28) Cooper and Barnes, *Ind. Eng. Chem., Anal. Ed.*, **10**, 379 (1938).

2-*n*-Tridecyl-4,6,7-trimethyl-5-hydroxycoumaron (IX, R = *n*-$C_{13}H_{27}$).—The diketone VIII (560 mg.) was warmed on the steam-bath for one hour with aqueous sodium hydroxide (1 *N*, 20 cc.) in an atmosphere of nitrogen. (When air was allowed to come into contact with the reaction mixture, the product was a red oil which could not be crystallized.) The cooled mixture was acidified with hydrochloric acid and then steam-distilled. From the distillate there was obtained 51 mg. (20%) of 2-methyl-4,6,7-trimethyl-5-hydroxycoumaron (IX, R = CH_3), m. p. and mixed m. p., 136–137°. The residual oil in the distillation flask solidified on cooling; it was removed and crystallized from methanol, when it weighed 260 mg. (54%) and melted at 101–102°. The analytical sample, crystallized from methanol, melted at 102–104°.

Anal. Calcd. for $C_{24}H_{38}O_2$: C, 80.39; H, 10.68. Found: C, 80.41; H, 11.04.

The absorption spectrum in the ultraviolet is shown in Fig. 1. The diketone VIII (430 mg.) was recovered unchanged after 500 mg. of it was boiled with hydrochloric acid (10 cc.) and ethanol (2 cc.) for seven hours; likewise, action of hydrogen chloride in refluxing acetic acid (10 cc.) for one hour upon the diketone (500 mg.) did not bring about ring closure; the recovery of diketone was 275 mg.

2-*n*-Tridecyl-4,6,7-trimethyl-5-hydroxycoumaran (X, R = *n*-$C_{13}H_{27}$).—The coumaron IX (75 mg.) in acetic acid (10 cc.) was shaken with hydrogen at 46° and under a pressure of 20 lb. for four hours in the presence of a palladium–charcoal catalyst. The solvent was removed under reduced pressure at 40°; the residue was dissolved in methanol and the catalyst was removed by centrifugation. The solution, when concentrated and cooled, deposited a white solid melting at 93–94°. When mixed with the coumaran (m. p. 102–104°), the substance also melted at 93–94°.

Anal. Calcd. for $C_{24}H_{40}O_2$: C, 79.94; H, 11.18. Found: C, 79.76; H, 11.22.

The absorption spectrum in the ultraviolet is shown in Fig. 2. The coumaron IX (360 mg.) in dry ethanol (10 cc.) was heated on the steam-bath for fifteen minutes with Raney nickel catalyst. The catalyst was removed, fresh catalyst was added, and the mixture was subjected to the action of hydrogen for one hour at 125° and 1600 lb. The product weighed 230 mg. and melted at 101–103°. This material, subjected to the same conditions as before, but at 140°, gave a product which melted at 97–99°, alone or when mixed with known IX. The absorption spectrum in the ultraviolet indicated that no reduction had occurred.

Summary

1. The coumaran 2-(6′,10′,14′-trimethyl-2′-pentadecyl) - 4,6,7 - trimethyl - 5 - hydroxycoumaran, I, an isomer of α-tocopherol, II, has been synthesized. The coumaran has been characterized by its absorption spectrum, by conversion into an allophanate melting at 176–180° and by the absorption spectrum of the latter. Although I differs from II only in the size of the hetero ring, I has only about 5% as much vitamin E activity as II.

2. The synthesis of Smith and King, whereby 2-isopropyl-5-hydroxycoumaran and homologs are produced, has been modified in such a way that the more accessible unsymmetrical acetylacylmethanes may be used instead of the symmetrical diketones. When the R of the acyl group has a relatively high molecular weight, the coumaron with the higher alkyl group is formed exclusively or in preponderant amounts; if two coumarons are formed, the simple one may be removed from the reaction product by steam distillation. In this way, 2-*n*-tridecyl-4,6,7-trimethyl-5-hydroxycoumaron (IX) R = *n*-$C_{13}H_{27}$, has been prepared and separated from 2,4,6,7-tetramethyl-5-hydroxycoumaron (IX, R = CH_3), formed in the same reaction. The coumaron IX (R = *n*-$C_{13}H_{27}$) has been reduced to the corresponding coumaran X (R = *n*-$C_{13}H_{27}$).

3. The absorption spectra of a number of intermediates in the above syntheses have been determined.

MINNEAPOLIS 14, MINNESOTA RECEIVED APRIL 2, 1948

Preparation and Cyclization of Certain Insecticidally Active α-Acetyl-δ-keto Esters

BY HERMAN WACHS AND OSCAR F. HEDENBURG

The condensation of ethyl acetoacetate with hexyl 3,4-methylenedioxystyryl ketone[1] at room temperature yields a mixture having high insecticidal activity. When allowed to crystallize, 3-hexyl - 5 - (3,4 - methylenedioxyphenyl) - 2 - cyclohexene-1-one (III) is obtained, which has been found to have the same insecticidal activity as the original mixture or the remaining mother liquor. This mother liquor contains resinous material and approximately 50% of 3-hexyl-5-(3,4-methylenedioxyphenyl) - 6 - carbethoxy - 2 - cyclohexene - 1 - one (IV). Proceeding on the assumption that the resinous portion was of little activity, it appeared desirable to devise a method by which the above ester (IV) could be obtained as the main product. The present paper describes the procedure developed to accomplish this purpose. This procedure also made it possible to obtain esters other than ethyl esters and to compare their relative effectiveness. The work was expanded to include compounds containing the furfuryl group in the 3 position of the cyclohexenone ring.

It was assumed that a Michael addition[2] takes place intermediate to the formation of the cyclohexenone ring. Taking advantage of the fact that such addition reactions are reversible,[3] by employing a large excess of ethyl acetoacetate and by

working at a temperature of +5° we obtained α-acetyl-β-(3,4-methylenedioxyphenyl)-δ-ketoethyl undecylate (II) from hexyl 3,4-methylenedioxystyryl ketone (I), in a yield of 65%. Compound (II) was a white crystalline solid melting at 149°; above its melting point it yielded ethyl alcohol, carbon dioxide and the cyclohexenone (III) in stoichiometric proportions.

When compound (II) was refluxed in benzene solution in the presence of a small quantity of toluene sulfonic acid or trichloroacetic acid, until no more water would distil over with the benzene, one molecular equivalent of water collected in the water trap, indicating that cyclization had taken place with a minimum of decomposition of the ester group. Only traces of liberated carbon dioxide were observed. The product was a light-colored, viscous liquid, which dissolved in most of the common organic solvents; it would not crystallize on cooling to −30° and could not be distilled *in vacuo* without decomposition; the saponification value indicated the presence of more than 90% of ester. On saponification, partial resinification occurred, but it was possible to isolate a good yield of crystals, which were identical with the decarboxylated cyclohexenone (III).

Hexyl 3,4-methylendioxystyryl ketone was also condensed with butyl, octyl, benzyl and allyl acetoacetates in an analogous manner and the corresponding α-acetyl-δ-keto esters were obtained in pure form. Upon cyclization by the aid of trichloroacetic or toluene sulfonic acid, the resulting allyl and butyl compounds had an insecticidal activity equal to that of the ethyl compound; the octyl and benzyl compounds were definitely inferior.

By the condensation of furfural with methyl isobutyl ketone, furylidene isobutyl ketone was prepared. It was condensed with ethyl acetoacetate and with butyl acetoacetate at 5° and the α-acetyl-δ-keto esters were isolated and purified. Upon cyclization the insecticidal activity was found to be poor.

The Table I summarizes certain characteristics of the products.

TABLE I

PROPERTIES OF SUBSTITUTED α-ACETYL-δ-KETO ESTERS

Ketone used	Aceto-acetate used	Melting point of α-acetyl-δ-keto ester, °C.	Formula	Carbon % Calcd.	Carbon % Found	Hydrogen % Calcd.	Hydrogen % Found
Hexyl-	Ethyl	149	$C_{22}H_{30}O_6$	67.67	67.92	7.75	7.55
3,4-me-	Allyl	134	$C_{23}H_{30}O_6$	68.64	68.41	7.51	7.30
thylene	Butyl	131	$C_{24}H_{34}O_6$	68.87	68.69	8.19	8.01

Experimental

α-Acetyl-β-3,4-methylenedioxyphenyl-δ-keto-ethyl Undecylate (II).—Metallic sodium (5.7 g., 0.25 mole) was dissolved in 150 cc. of anhydrous ethyl alcohol, 97 g. of ethyl acetoacetate was added, the solution cooled to 5° and, during one hour, a solution of 65 g. (0.25 mole) of hexyl 3,4-methylendioxystyryl ketone in 65 g. of benzene was added under agitation. The temperature was kept at 5 to 7° during the addition. The mixture was then agitated for an additional two hours and allowed to stand overnight at a temperature of 5 to 7°. It was neutralized with dilute hydrochloric acid under cooling, then warmed on the steam-bath to allow the benzene solution of the reaction product to separate. The benzene solution was drawn off and allowed to crystallize in an ice-box. The crystals were filtered off and washed with benzene. The dry crystals weighed 252 g. After recrystallization from benzene they melted at 149°.

Cyclization of (II).—A solution of 25 g. of (II) in 75 g. of benzene was refluxed in the presence of 1.5 g. of trichloroacetic acid or toluenesulfonic acid until no more water would distil over. The residue in the flask was neutralized with sodium carbonate solution, the benzene solution dried and filtered, the solvent distilled and the product dried *in vacuo*. It was a light colored viscous oil, the saponification value indicating about 90% of the ester, IV.

Furylidenemethyl Isobutyl Ketone.—Methyl isobutyl ketone (60 g.) was dissolved in 96 g. of methanol, 15 g. of a 20% aqueous solution of sodium hydroxide was added, and to this mixture 57.5 g. of freshly distilled furfural was added over a period of 0.5 hour under agitation at a temperature of 18 to 20°. The agitation was continued for two hours at the same temperature. The mixture was allowed to stand overnight. Water, 100 cc., and 100 cc. of benzene were added and the mixture neutralized with acetic acid. The benzene solution was separated, the solvent removed, and the remainder distilled *in vacuo*.

The final product distilled at 108° at 1.4 mm. It was a yellowish oil which darkened rather rapidly.

Anal. Calcd. for $C_{11}H_{14}O_2$: C, 74.12; H, 7.92. Found: C, 73.97; H, 7.84.

The melting points and the analyses of other α-acetyl-δ-keto esters, similarly prepared, are given in Table I. In each case, saponification indicated about 90% of the cyclic ester in the crude cyclized product.

Summary

The preparation of 3,4-methylenedioxyphenyl substituted α-acetyl-δ-keto esters in pure form and in good yield is outlined. A method of their cyclization which yields cyclohexenone esters of high insecticidal activity with a minimum of splitting of the ester group is described.

Furyl substituted α-acetyl-δ-keto esters were prepared and cyclized to cyclohexenone esters and were found to be of much lower insecticidal activity than the 3,4-methylenedioxyphenyl substituted products.

Synthetic and Degradative Studies in the Isoquinoline Series. III

BY V. BRUCKNER, G. FODOR, J. KOVÁCS AND J. KISS

In previous communications[1,2] the structure of different 1,3-dimethyl-6,7-dialkoxy- and aralkoxyisoquinolines (Ia-If), of 1-benzyl-3-methyl-6,7-methylenedioxyisoquinoline (II), synthesized by us,[3,4] was established by exhaustive methylation followed by oxidation. In all cases investigated by us, degradation gives rise either to metahemipinic acid (IIIa), or to hydrastic acid (IIIb). To complete our first paper,[1] the structure of 1,3-dimethyl-6,7-methylenedioxyisoquinoline[5] (Ig) is now ascertained, by preparing it from the 6,7-dihydroxy derivative Ia of known structure.[1] Ring closure of α-(3,4-disubstituted phenyl)-β-acylaminopropanols to the isoquinolines takes place, consequently, in all cases studied by us in *m,p*-position to the alkoxy groups, to form 6,7-disubstituted 3-methylisoquinolines, independently of the substituents.

Pfeiffer, *et al.*,[6] obtained from brasiline a compound and suggested for its structure IV 1-(2′-hydroxy-4′-methoxyphenyl)-3-methyl-6,7-dimethoxyisoquinoline by analogy with the structure of the compound obtained by them from hematoxyline. They attempted to confirm its constitution by synthesis from α-(3,4-dimethoxyphenyl)-β-(2′-carbethoxy-oxy-4′-methoxybenzoylamino)-propanol. Ring closure yielded only a small amount of an oily phenolic isoquinoline; its picrate was, however, not identical with that of the compound obtained from brasiline. Ring closure of the amorphous α-(3,4-dimethoxyphenyl)-β-(2′,4′-dimethoxybenzoylamino)-propanol led to a crystalline isoquinoline isomer, but which was not identical with the methyl ether of the compound from brasiline. Therefore they assign structure V, 1-(2′-hydroxy-4′-methoxyphenyl)-3-methyl-7,8-dimethoxyisoquinoline, to the synthetic isoquinoline.

The present work was undertaken to synthesize through crystalline, well-defined intermediates the same phenolic isoquinoline whose picrate was described by Pfeiffer, *et al.*[6] As the structure of this synthetic compound and of its isomer have not been confirmed by degradation, it seemed desirable to carry out the oxidative degradation of the former.

We started with the stereoisomeric α-(3,4-dimethoxyphenyl)-β-aminopropanols. One of these (m. p. 128°) was prepared according to Bruckner[5]; another (m. p. 138°) according to Iwamoto and Hartung.[7] 2-Benzyloxy-4-methoxybenzoic acid was prepared from β-resorcylic acid *via* methyl 2-hydroxy-4-methoxybenzoate and methyl 2-benzyloxy-4-methoxybenzoate. On condensation of 2-benzyloxy-4-methoxybenzoyl chloride with the aminopropanol (m. p. 138°) the amide VI is formed; on ring closure it yielded smoothly the corresponding isoquinoline derivative (benzyl ether of IV). The stereoisomeric aminopropanol gave on a similar treatment the identical isoquinoline. The benzyloxyisoquinoline derivative afforded on hydrogenolysis (Pd charcoal) the crystalline hydroxyisoquinoline IV in nearly quantitative yield. Its picrate shows m. p. 275°; its methyl ether prepared by diazomethane, m. p. 144°; its methyl ether picrate, m. p. 231–232°. The same data are recorded by Pfeiffer, *et al.*[6], for the compound formulated by them as V (*cf.* table of m. p.'s), they are consequently identical, whereas the product obtained from brasiline is different.

As a degradative approach to the structure of this phenolic isoquinoline we have chosen the oxidation with alkaline permanganate. Metahemipinic acid alone could be detected as a fragment, identified by its m. p., analysis and conversion into its ethylimide (m. p. 228°). For the synthetic hydroxyisoquinoline derivative the structure 1-

(2′-hydroxy-4′-methoxyphenyl)-3-methyl-6,7-dimethoxyisoquinoline IV is thus proved; its formulation as the 7,8-dimethoxyisoquinoline derivative V suggested by Pfeiffer, *et al.*[6], is evidently erroneous, the ring closure taking place in these cases also in *m,p*-position to the alkoxy groups.

Moreover, as the product obtained from brasiline is not identical with 1-(2′-hydroxy-4′-methoxyphenyl)-3-methyl-6,7-dimethoxyisoquinoline IV, it remains to decide whether the difference is to be found in the isoquinoline nucleus or in the radical attached at position 1.

TABLE I

MELTING POINTS OF THE ISOQUINOLINES, °C.

Compound	From brasiline, °C.	Synthesized, °C. By Pfeiffer	By us
Phenolic isoquinoline	188–189	.....	143–144
Picrate	224–225	272–275	274–276
Methyl ether	110	144–145	142–144
Methyl ether picrate	212–215	233–235	232–235

Experimental

1,3-Dimethyl-6,7-methylenedioxyisoquinoline (Ig).—A mixture of 0.6 g. (0.003 mole) of 1,3-dimethyl-6,7-dihydroxyisoquinoline (Ia) in 60 ml. of ethanol, 0.18 g. (0.0078 atom) of sodium in 5 ml. of ethanol and 1.26 g. (0.004 mole) of methylene iodide was refluxed for six hours. The non-phenolic part was isolated in the usual manner: yield, 0.28 g. of Ig, m. p. 144°, alone and mixed with an authentic specimen.[5]

α-(3,4-Dimethoxyphenyl-) β-aminopropanol. A. From O-Methylisoeugenol-ψ-nitrosite the free base was obtained (m. p. 128°). **B. From α-Isonitroso-3,4-dimethoxypropiophenone,**[8] principally by the same method as recorded by Iwamoto and Hartung[7] the base, m. p. 138°, resulted.

Methyl 2-Hydroxy-4-methoxybenzoate.—Fifteen and five tenths grams (0.1 mole) of β-resorcylic acid was dissolved in a solution of 16.8 g. (0.3 mole) of potassium hydroxide in 100 ml. of water; then 20 ml. (0.2 mole) of dimethyl sulfate added under stirring. The mixture was heated one hour on the steam-bath. The aqueous layer was decanted, the ester dissolved in 50 ml. of ether, washed with water, dried and the solvent removed. The brown oily residue was dissolved in 40 ml. of methanol, 20 ml. of concentrated sulfuric acid added and refluxed for two hours, then cooled with an ice–salt mixture, the separated crystals filtered, washed with water until neutral; yield 11 g. (59%) of colorless plates, m. p. 50–52°.[9]

2-Benzyloxy-4-methoxybenzoic Acid.—A mixture from 2.3 g. (0.1 atom) of sodium in 100 ml. of ethanol, 18 g. (0.1 mole) of the ester obtained above and 13 ml. (0.1 mole) of benzyl chloride was refluxed for twelve hours, and the resulting solution of the benzylated ester boiled with 6 g. (0.11 mole) of potassium hydroxide in 20 ml. of water for saponification. The benzylated acid was isolated by the usual manner: yield 12 g. (47%). Recrystallization from 40 ml. of ethanol yielded 9.5 g. of colorless prisms, m. p. 103°.

Anal. Calcd. for $C_{15}H_{14}O_4$: C, 69.76; H, 5.47. Found: C, 69.61; H, 5.51.

α-(3,4-Dimethoxyphenyl)-β-(2′-benzyloxy-4′-methoxybenzoyl-amino)-propanol (VI).—Nine and a half grams (0.037 mole) of the foregoing acid was suspended in 20 ml. of toluene, treated with 16 ml. of thionyl chloride, heated on a water-bath at 35–40°, until hydrogen chloride evolved. The thionyl chloride was removed *in vacuo*, the remainder dissolved in 50 ml. of hot absolute toluene. The crude product is satisfactorily pure for use in acylation process. Twenty-one and three-tenths grams (0.1 mole) of the aminopropanol above (m. p. 138°) was dissolved in 500 ml. of boiling anhydrous toluene, and there was added, drop by drop under vigorous stirring, the toluenic solution of 2-benzyloxy-4-methoxybenzoyl chloride prepared above. The hydrochloride of the aminopropanol separates instantaneously. The mixture was then refluxed for fifteen minutes and filtered hot: yield 13 g. (0.052 mole) of aminopropanol hydrochloride. The filtrate (washed twice with 100 ml. of 2 *N* hydrochloric acid, then with 100 ml. of 2 *N* sodium hydroxide and finally with water) was dried and concentrated to 180 ml. On cooling, the amide separated as colorless needles: yield 15.1 g. (91%), m. p. 139–140°.

Anal. Calcd. for $C_{26}H_{29}O_6N$: C, 69.16; H, 6.47. Found: C, 68.96; H, 6.26.

1-(2′-Benzyloxy-4′-methoxyphenyl)-3-methyl-6,7-dimethoxyisoquinoline (Benzyl Ether of IV). A.—Fourteen and a half grams (0.032 mole) of the amide VI was dissolved in 300 ml. of hot toluene, then 15 ml. of phosphoryl chloride added on heating and occasional stirring. The mixture was refluxed for an hour, the isoquinoline salt formed being partly precipitated during this time. The reaction mixture was allowed to cool, then exhaustively extracted with one liter of water, cleared with charcoal, filtered and made alkaline with 5 *N* potassium hydroxide. The separating oily free base solidifies on standing in the ice-box overnight. The crude product was washed with water and dried, yield 10 g. (75%) of a yellow microcrystalline powder. On recrystallization from 180 ml. of

(8) Karg, *Arch. Pharm.*, **282**, 49 (1944).
(9) Mutschler, *Ann.*, **185**, 222 (1877).

alcohol–water (1:8), delicate needles, m. p. 83–84°, resulted. The hydrochloride prepared by the customary method forms a yellowish green crystalline powder, m. p. 221–222°.

Anal. Calcd. for $C_{26}H_{25}O_4N \cdot HCl$: C, 69.10; H, 5.79. Found: C, 69.10; H, 5.88.

B.—From 0.4 g. (0.002 mole) of the aminopropanol (m. p. 128°) in 15 ml. of toluene and 0.16 g. (0.0006 mole) of acid chloride—in the manner described above—0.3 g. of an amorphous amide was obtained which could be converted without further purification into the isoquinoline derivative. It yielded 0.2 g. of snow white clusters of crystals, m. p. 68°, which rises on recrystallization to 81°, alone and in admixture with the specimen obtained under A (its hydrochloride melted alone and mixed with that of A at 219–221°).

1-(2′-Hydroxy-4′-methoxyphenyl)-3-methyl-6,7-dimethoxyisoquinoline. IV.—Fifteen grams (0.033 mole) of the benzyloxyisoquinoline in 300 ml. of anhydrous ethanol absorbed 825 ml. of hydrogen (Pd charcoal) (calcd. for 1 mole H per mole, 809 ml.). The yellowish green crude product (10.75 g.) was recrystallized from aqueous ethanol to give 7.25 g. of delicate needles, m. p. 143–144°. This, together with a further crop (3.1 g.) of needles of the same m. p., yielded 10.35 g. (96%), equally soluble in cold dilute alkali and acid.

Anal. Calcd. for $C_{19}H_{19}O_4N$: C, 70.14; H, 5.88. Found: C, 69.48; H, 5.38.

The free base was converted into the **hydrochloride,** forming yellowish needles, m. p. 271°.

Anal. Calcd. for $C_{19}H_{19}O_4N \cdot HCl$: C, 62.89; H, 5.56. Found: C, 62.64; H, 5.62.

Picrate.—Yellowish microcrystals, m. p. 274–276° (dec.). Pfeiffer, *et al.*,[6] recorded 274–275° (dec.).

Anal. Calcd. for $C_{25}H_{22}O_{11}N_4$: C, 54.13; H, 4.00. Found: C, 54.25; H, 3.95.

1-(2′,4′-Dimethoxyphenyl)-3-methyl-6,7-dimethoxyisoquinoline (Methyl Ether of IV).—Twenty-six-hundredth gram (0.001 mole) of the phenolic isoquinoline IV dissolved in 10 ml. of anhydrous methanol was methylated by means of a 0.5 *N* ethereal diazomethane solution, until the yellowish color of the latter did not disappear: colorless plates, m. p. 144°. Pfeiffer[6] recorded m. p. 143–144°.

Anal. Calcd. for $C_{20}H_{21}O_4N$: C, 70.78; H, 6.24. Found: C, 70.42; H, 6.19.

Picrate.—Yellow plates, m. p. 231–232° (dec.). Pfeiffer[6] recorded m. p. 232–235°.

Anal. Calcd. for $C_{26}H_{24}O_{11}N_4$: C, 54.91; H, 4.26. Found: C, 55.01; H, 4.33.

Degradation of IV to Metahemipinic Acid.—Seven and twenty-four-hundredth grams (0.022 mole) of IV and 3 g. (0.075 mole) of sodium hydroxide were dissolved in 1.1 liter of hot water, then 50 g. of potassium permanganate in one liter of hot water was added by dropping within ten minutes under vigorous stirring and heating on the steam-bath, the solution becoming after twenty minutes nearly colorless. The hygroscopic solid residue of the solution was treated twenty-four hours continuously in a Soxhlet extractor with ethanol, the solvent removed *in vacuo* to give 1.5 g. of a yellowish crystalline mass. This was dissolved in 10 ml. of water, cleared with charcoal, filtered and then acidified (nitric acid) to congo. After the solution has been neutralized with ammonia, the lead salts were precipitated by means of lead acetate at *p*H 7–8, separated in the centrifuge, washed with a small amount of water. The acid was liberated with hydrogen sulfide, the filtrate concentrated to 3 ml. and allowed to stand overnight in an ice-box; 72 mg. of brief needles was obtained, which melted alone and in admixture with metahemipinic acid at 175–177°. For the analysis it was twice recrystallized from water.

Anal. Calcd. for $C_{10}H_{10}O_6$: C, 53.10; H, 4.45. Found: C, 52.66; H, 4.34.

Further identification was made converting 26 mg. of the acid into its ethylimide on treatment with 1 ml. of 25% aqueous ethylamine. The water was then evaporated the remainder sublimed *in vacuo*, and 23 mg. of crystals obtained. Recrystallization afforded colorless long needles, m. p. 228°.[10] The ethyl imide of hemipinic acid shows m. p. 93°.[11]

Anal. Calcd. for $C_{12}H_{13}O_4N$: C, 61.25; H, 5.57. Found: C, 61.50; H, 5.59.

Acknowledgment.—The authors are grateful to Dr. D. Varsányi and Dr. T. Horváth for their assistance in preparing some of the compounds and to Dr. M. Kovács Oskolás for the microanalyses.

Summary

The ring closure of α-(3,4-dialkoxyphenyl)-resp. (3,4-methylenedioxyphenyl)-β-acylaminopropanols takes place in all cases investigated in *m,p*-position to the alkoxy groups, to form 6,7-disubstituted 3-methylisoquinolines. This is supported by a study of the oxidative degradation even in the case of 1-(2′-hydroxy-4′-methoxyphenyl)-3-methyl-6,7-dimethoxyisoquinoline IV first obtained as picrate by Pfeiffer, *et al.*,[6] and described erroneously as a 7,8-dimethoxyisoquinoline derivative V. Consequently, the structure of the isomeric compound, obtained by Pfeiffer, *et al.*, from brasiline, and formulated as IV, becomes doubtful.

[COMMUNICATION NO. 1179 FROM THE KODAK RESEARCH LABORATORIES]

Investigation of the Properties of Cellulose Oxidized by Nitrogen Dioxide. VI. The Effect of Alkali on the Celluronic Acids[1]

BY P. A. MCGEE, W. F. FOWLER, JR., C. C. UNRUH AND W. O. KENYON

The initial investigations[2] of the action of nitrogen dioxide on cellulose showed that the resulting celluronic acids are alkali-soluble when the carboxyl content is sufficiently great. The celluronic acids undergo further reaction in alkaline solution which complicates the application of the copper number determination or direct determination of carboxyl groups by alkaline titration.[3] The reducing values obtained by copper number determinations were exceptionally high. It appeared probable that the reducing groups were not present to such an extent in the celluronic acids, but were generated by decomposition under the severe conditions of high *p*H and temperatures used in the determinations. Attempts to prepare sodium celluronate solutions, even at *p*H values only slightly above 7, showed that whenever solution was effected, concomitant degradation had occurred. The calcium acetate and carbon dioxide evolution methods which operate at *p*H values below 7 were chosen for carboxyl determinations to avoid the degradation which appeared to accompany the direct determination by alkaline titration.[2,3]

The evidence accumulated to date indicates that free carboxyl groups in celluronic acids are substantially contained in uronic acid units. The carboxyl values by carbon dioxide evolutions are at least as high as the values from potentiometric titration or the calcium acetate method.[4] Aside from carboxyl groups which should not produce alkali-instability in celluronic acids, oxidation of hydroxyl groups could form aldehyde or ketone groups or an enediol structure by isomerization of the latter. Aldehyde groups in simple organic compounds are attacked rapidly—sometimes almost explosively—by nitrogen dioxide; hence, their presence in substantial amounts in celluronic acids is doubtful. Ketone groups in certain compounds are less readily attacked[5] by this oxidant and such groups may be present in this oxidized cellulose.

The concept of the roles of keto or ene-diol groups as a source of alkali-sensitivity in carbohydrates and oxidized celluloses is not new and has been used recently to explain the alkaline fission of cellulose oxidized by periodates.[6]

Though the presence of ketone groups has earlier been considered as the cause of alkaline breakdown of celluronic acids, this communication represents the first systematic attempt to determine such groups by direct chemical methods. Quantitative data on degradation by alkali are included.

Experimental

Materials.—Celluronic acids were prepared by treating oven-dried 500-second cotton linters (ground to 100 mesh) with carbon tetrachloride solutions of nitrogen tetroxide for various periods of time to produce the desired degree of oxidation. Products containing substantial amounts of combined nitrogen were prepared by treating the cellulose with anhydrous nitric acid in the nitrogen tetroxide–carbon tetrachloride solutions. Details of these techniques and purification of the reagents have been given previously.

Published methods were used to obtain the alginic acid and simpler reference materials.[4] The samples of periodate-oxidized cellulose were obtained by the method of Jackson and Hudson[7] as modified by Davidson.[8]

Analyses of the celluronic acid employed are shown in Table I.

was employed, for it gives reliable results at *p*H values below 7 where the celluronic acids are stable. The data are given in Table I. Accurate carboxyl values are necessary for the calculation of carbonyl content.

Purves states that carboxyl values tend to be low when oxycelluloses react with the calcium acetate solution at *p*H values below 6.3. The effects of the *p*H of the calcium acetate solution upon the carboxyl values were examined using alginic acid and celluronic acid, as shown in Table II.

TABLE II

EFFECT OF *p*H ON CALCIUM ACETATE CARBOXYL

Polyuronide	*p*H of calcium acetate solution	Carboxyl, %
Alginic acid	6.4	21.36
Alginic acid	6.5	21.41
Alginic acid	5.3	(1) 22.04
		(2) 22.04
Celluronic acid	6.5	(1) 20.21
		(2) 20.17
Celluronic acid	5.4	(1) 20.22
		(2) 20.22

Since higher values were not obtained on these materials, when the *p*H of the calcium acetate–uronic acid reaction mixture was adjusted to between 6.3 and 7.0, this adjustment was omitted.

Dilution of the calcium acetate solution to raise the equilibrium *p*H has been recommended[10] to force the reaction with the oxidized cellulose nearer to completion. Table III shows the effect of greater and less dilution than the 50 ml. of water employed in our calcium acetate method.

TABLE III

EFFECT OF DILUTION ON THE CALCIUM ACETATE DETERMINATION OF CARBOXYL

Celluronic acid, 0.50 g.; 0.5 *N* calcium acetate, 30.0 ml.; reaction time two hours

H_2O, ml.	Aliquot titrated, ml.	0.1123 *N* NaOH used, ml.	% COOH (dry basis)	Deviation, %
500	198.70	6.23	18.92	+0.48
100	48.76	6.21	18.87	+0.21
50	30.00	6.20	18.83	0.00
25	20.63	6.12	18.58	−1.33
0	11.25	6.07	18.34	−2.60

Dilution caused a 3% change in the apparent carboxyl values over the full range studied. However, dilution of our standard analytical mixture by a factor of 10, *i. e.*, from 50 to 500 ml., caused a change of only 0.5% in carboxyl value. This deviation is probably less than the precision obtained in sampling solid products from heterogeneous oxidation systems.

Potentiometric titrations were run by the following general method with such minor changes as are noted. One (1.000) gram (moist basis) of the celluronic acid suspended in 100 ml. of 1 *N* sodium bromide, with mechanical agitation, was titrated with small increments of 0.1 *N* sodium hydroxide to the desired *p*H. Since most of the maximum *p*H values desired were over 9.5, a special lithium glass "Type E" Beckman glass electrode was used with the Laboratory Model G Beckman *p*H meter. The suspended celluronic acids usually dissolved at the high *p*H values. The solutions were allowed to stand, usually at room temperature, for the desired times, then titrated to the original *p*H with hydrochloric acid of exactly the same normality as the alkali used. The extra amounts of alkali consumed were determined from the titration curves, as indicated in Fig. 1. These amounts, hereinafter referred to as the alkali consumption, are defined as the amount, *y*, in the complete titration curve shown. All results are calculated to the dry basis.

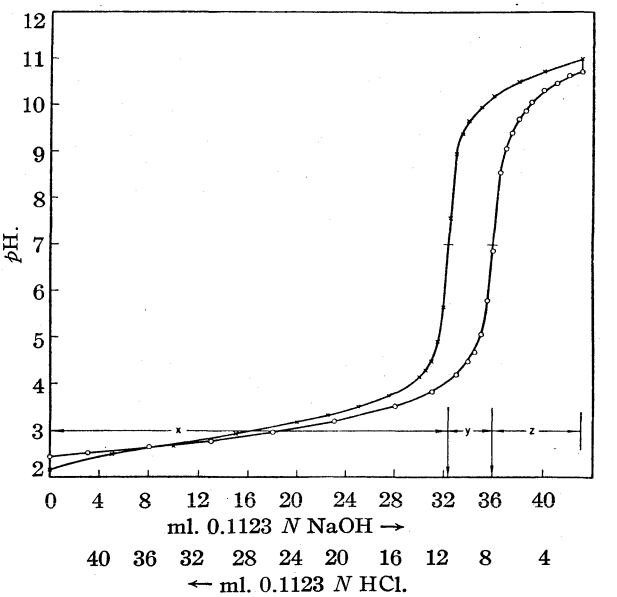

Fig. 1.—Potentiometric titration of a 1-g. sample of a sixteen-hour oxidized cellulose showing acidity developed in two hours at *p*H 11: X, titration with NaOH; O, back titration with HCl; ×, ml. alkali to reach equivalence in initial titration (zero time); Z, ml. acid to reach equivalence in final titration (two hours time); Y, ml. extra alkali consumed at *p*H 11 in two hours.

Air was not excluded during the action of alkali on the celluronic acids, but this was not a factor in the decomposition, as shown by the data of Table IV.

Kinetics data for determining the mechanism by which celluronic acids are acted upon by hydroxyl ion were obtained by a modified procedure. The celluronic acid was titrated with 0.1 *N* sodium hydroxide to a *p*H value representing the maximum desired in the experiment. These data were plotted and the resulting "master" titration curve was used for reading off the volumes of standard alkali necessary to produce definite *p*H values with a standard weight of sample. Samples of the same celluronic acid were suspended in 1 *N* so-

Table IV

Acidity Developed in Celluronic Acids at *p*H 11 in Two Hours Under Different Atmospheres

Basis: 1.0000 g. anhydrous celluronic acid

Oxidation time, hours	*y* in ml. 0.1123 *N* NaOH	*y* in mole NaOH × 10^4	Atmosphere
4	2.42	2.72	Nitrogen
16	3.84	4.31	Nitrogen
63	8.25	9.25	Nitrogen
4	2.50	2.82	Air
16	4.35	4.87	Air
63	8.24	9.24	Air

dium bromide solution, and the amounts of alkali added very rapidly to produce solutions (or suspensions) at the *p*H desired. This procedure minimizes the decomposition encountered while bringing the solutions to the proper high *p*H of the experiment. After two hours at room temperature, the samples were titrated rapidly with 0.1 *N* hydrochloric acid to a *p*H of 7.0. Calculation of extra alkali consumption was done as explained in Fig. 1. For a more meaningful comparison between samples of different degrees of oxidation, the ratio, *R*, between moles of extra alkali consumed and initial moles of alkali needed for equivalence is used in this paper.

Results and Discussion

The oxidation of the number six carbon atom in the anhydro-glucose unit of cellulose by nitrogen dioxide is essentially complete at the end of twenty-four hours reaction time under the experimental conditions used in preparing these particular samples. However, it is obvious that a secondary oxidation continues. While the calcium acetate, uronic acid, and titrated carboxyl values of Table I have about reached their maxima at the end of twenty-four hours reaction time, the data of Fig. 2 show that the extra moles of alkal. consumed continued to increase beyond this time of oxidation. A sample which has been oxidized for sixty-three hours consumed roughly twice as much extra alkali as that consumed by a sample having a sixteen-hour oxidation.

The celluronic acids contain small amounts of nitrogen presumably combined as nitrate groups. It is well known[11] that cellulose nitrates decompose intramolecularly in alkali with reduction of nitrate nitrogen to nitrite and oxidation of the cellulose molecule to simple organic acids. The data of Table V show that this is not the mechanism of alkali consumption by celluronic acids, since the consumption increases (column 4) and the nitrogen content decreases (column 2) with increase in time of oxidation.

Table V

Acidity Developed in Celluronic Acids of Various Nitrogen Contents at *p*H 11 in Two Hours

Basis: 1.0000 g. anhydrous celluronic acid

Oxidation time, hours	Nitrogen, %	*y* in ml. 0.1123 *N* NaOH	*y* in moles NaOH × 10^4
1	4.82	1.53	1.72
4	2.46	2.74	3.08
8	1.73	4.22	4.74
12	0.63	5.19	5.83
1	.29	1.65	1.86
4	.41	3.06	3.45
8	.46	3.99	4.48
16	.27	5.27	5.86

The alkali consumption is not due to oxidation of the alkaline solutions by atmospheric oxygen (Table IV). Dissolved oxygen is present but its role is believed to be negligible in this instance.

Typical curves of the generation of acidity as measured by alkali consumption are shown in Fig. 3, using the celluronic acid resulting from sixteen hours oxidation with nitrogen dioxide. Curve A shows that consumption during initial alkaline decomposition at *p*H 11 is nearly linear with respect to time. Extended reaction at *p*H 12 indicates that the consumption may approach completion at very long reaction times.

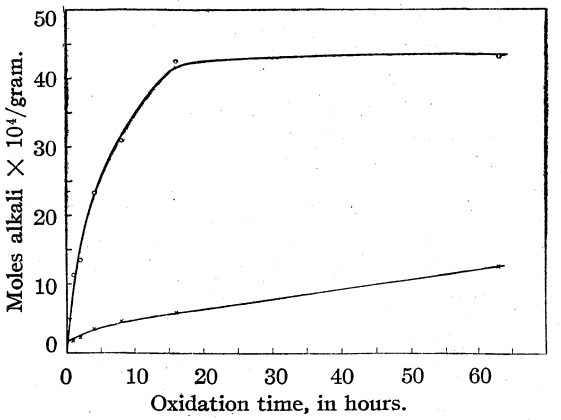

Fig. 2.—Relation between oxidation time and consumption of alkali in two hours at *p*H 11: O, initial equivalence; ×, extra moles alkali.

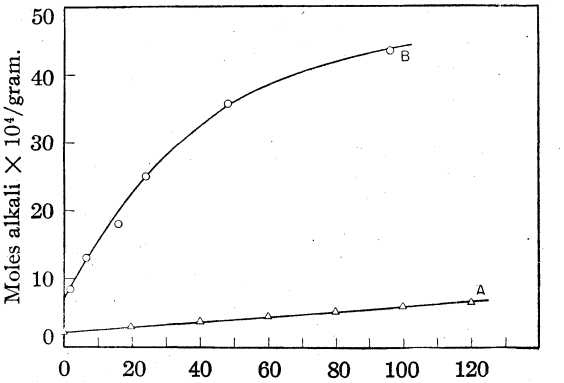

Fig. 3.—Rate of alkali consumption at high *p*H: plot A at *p*H 11; plot B at *p*H 12.

(11) Kenyon and Gray, This Journal, **58**, 1422 (1936).

Three celluronic acids of diverse oxidation history (*i. e.*, one-, four- and sixteen-hour oxidation, Table I) were each treated with alkali for two hours at several *p*H values greater than 7. The log of alkali consumption expressed as R was a linear function of *p*OH of the solution (Fig. 4). The equation for these curves is

$$\log R = -B[p\mathrm{OH}] + \log A \qquad (1)$$

where $-B$ is the slope of each curve and $\log A$ is the log R intercept. Equation (1) converts to

$$R = A[\mathrm{OH}^-]^B \qquad (2)$$

The constants A and B for these three celluronic acids are given in Table VI.

TABLE VI

CONSTANTS RELATING HYDROXYL-ION DEPENDENCY OF ACIDITY GENERATED BY CELLURONIC ACIDS AT *p*H 7

Oxidation time, hours	A	B
1	3.72	0.50
4	1.21	.34
16	1.31	.33

Thus, the catalyst in the generation of extra acidity at high *p*H appears to be hydroxyl ion. When a *p*H of 7 is exceeded, the celluronic acids begin to decompose even before dissolving.

The evidence thus accumulated indicates that the extensive oxidation of the primary hydroxyls of cellulose by nitrogen dioxide to form carboxyl groups is accompanied by some oxidation at another position forming an alkali-labile linkage. Systematic consideration will show that a variety of structures are theoretically capable of formation by oxidizing one or more positions in the anhydroglucose unit.[12] Oxidation of the glucoside links should be considered, as nitrogen dioxide is a powerful oxidant for simple ethers. All the possible resulting structures could not be examined, but data on a few typical ones are shown in Table VII.

TABLE VII

ACIDITY DEVELOPED IN REFERENCE SUBSTANCES AT ELEVATED *p*H (DRY BASIS)

Substance	*p*H max.	Time at *p*H max., hours	—% COOH— Theory	Potentiom. titra.	Extra moles alk. consumed per gram
Potassium acid saccharate	10.93	2	18.14	18.20	3.5×10^{-5}
D-Galacturonic acid monohydrate	10.92	2	21.22	20.41	6.6×10^{-5}
L-Ascorbic acid	11.12	2	25.56	25.42	1.07×10^{-3}
L-Ascorbic acid	11.04	48	25.56	25.42	7.80×10^{-3}
L-Ascorbic acid	11.20	96	25.56	25.42	8.15×10^{-3}
Tartaric acid	10.92	2	60.00	58.91	1.1×10^{-5}
D-Gluconic acid	10.98	2	22.96	24.76	6.0×10^{-5}
D-Glucono-γ-lactone	11.00	2	25.30	24.22	6.2×10^{-5}
Periodic acid-oxidized cellulose	12.00	64			5.79×10^{-3}

(12) Unruh and Kenyon, *Textile Research J.*, **16**, 1–12 (1946).

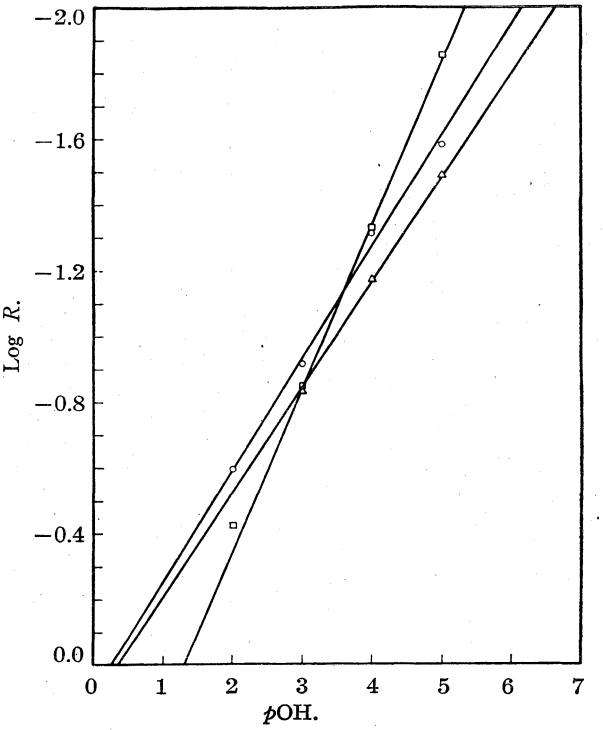

Fig. 4.—Relation between log of ratio of extra and initial moles alkali needed for equivalence and *p*OH: △, sixteen-hour oxidation; O, four-hour oxidation; □, one-hour oxidation.

Though the number of possible compounds or structures resulting from oxidation of the glucose unit is large, these compounds must contain, in addition to unreacted hydroxyls, one or more of the three following groups, *i. e.*, carboxyl (ester or lactone), ketone (ene-diol) or aldehyde (enol). Carboxylic acids typified by saccharic, gluconic and tartaric did not generate significant acidity in alkali. The slow hydrolysis of lactones is not the source of the acidity, for glucono-γ-lactone opened completely and was titrated as the free acid as the *p*H was raised. It is doubtful whether generation of acidity is due to a slow hydrolysis of ester groups. The saponification of esters is the the classical illustration of a bimolecular reaction. Mathematical analysis of the acidity generated at constant time as a function of alkali concentration (Fig. 4) did not fit the second-order kinetics.[13] Galacturonic acid generated only little acidity even though an aldehyde group is present. Periodate cellulose known to contain a high percentage of aldehyde groups, generated much acidity but as previously stated, aldehyde groups are so vigorously oxidized by nitrogen dioxide that their presence in celluronic acids must be considered with reserve.

Ketone groups appear the most probable source of alkali-lability. Measurement of their presence by the methyl hydroxylamine method

(13) We wish to thank Dr. L. K. J. Tong, of these Laboratories, for this analysis.

of Purves indicated small but significant amounts as shown in Table I. A celluronic acid from a sixteen-hour oxidation appeared to possess 1.7% of carbonyl group by weight, or about one carbonyl for each ten of the original glucose units. Analyses of the data indicate a possible mechanism by which extra alkali is consumed. Extrapolation of Fig. 3, Plot B, to infinite time indicates that a total of about 50×10^{-4} mole of alkali would finally be neutralized. The same sample contains approximately 6×10^{-4} mole of carbonyl per gram (Table I). If this is in the form of a keto-glucuronic acid, it may be calculated that there are 37.3×10^{-4} mole of carbonyl per gram. Therefore, one mole of keto-glucuronic acid unit consumes 1.34 moles of alkali. *l*-Ascorbic acid (Table VII) will ultimately consume approximately 80×10^{-4} mole of alkali per gram, or about 1.41 moles per mole.

Figure 5 shows that the relation between the carbonyl content and the extra alkali consumption in two hours of the various celluronic acid is linear, the slope being 1.02. The small positive intercept of the experimental curve (plotted by a least-squares analysis of the data) lies within the experimental error of the measurements.

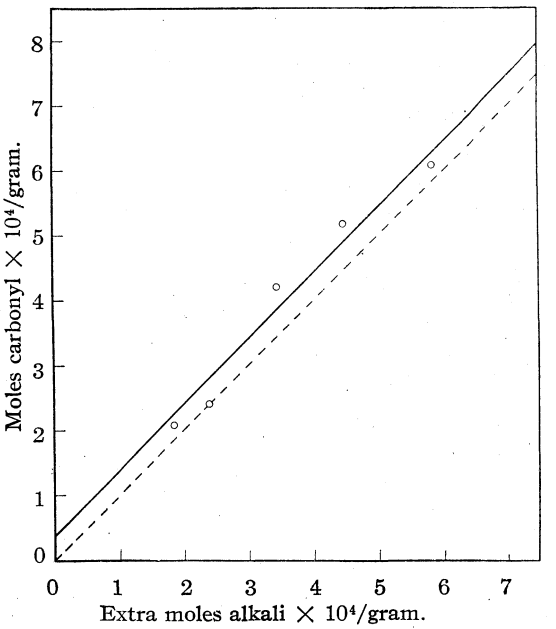

Fig. 5.—Relation between moles of carbonyl and extra moles of alkali consumed in two hours by various celluronic acids: solid line is experimental, broken line is exact equimolar relation.

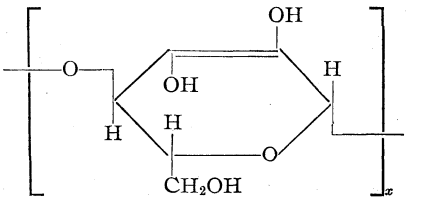
This equimolar relationship would be greatly exceeded at longer reaction times in the alkali and at high *p*H values. Figure 3, Plot B, shows that several times as much alkali is consumed at about 100 hours as that consumed at two hours.

Evans and his collaborators[14] have explained the steps by which both simple sugars and glycosides are acted upon by alkali. Ivanov and Kaversneva[6] have applied these findings to the reaction of various oxidized celluloses with aqueous alkaline solutions so as to arrive at satisfactory mechanisms for explaining the changes in physical properties resulting from treatment of cellulose with several different oxidizing agents. They ascribed the increase in fluidity of oxidized celluloses after treatment with alkali to the shift of the keto form of different oxidized carbon atoms to the enols which render the glycosidic link unstable. Applying this concept to celluronic acids, the presence of a ketone group would constitute a weak point[15] in the chain as indicated by the enol structure shown.



Evans has shown that such enediols in simpler carbohydrates are ruptured by alkali, the generated aldehyde groups enolize, then the adjacent glucoside groups become alkali-labile. In an analogous manner, the units of celluronic acids containing ketone groups are readily split by alkali and the groups so split as well as the lower polyuronic acid fragments may undergo fission into reducing and acidic fragments. In other words, once the alkaline scission is initiated it continues, thus producing degradation far more extensive than indicated by the initial ketone content. Such fission along the chain would account for the extreme decrease in viscosity often observed even in lightly oxidized celluloses.[16] Davidson,[17] using oxidized celluloses prepared by a number of methods other than those involving the use of nitrogen dioxide, has demonstrated that the decrease in viscosities of nitrated oxidized celluloses in cuprammonium is not necessarily due to oxidative fission of the cellulose, but may be ascribed to the scission of alkali-sensitive links in the oxidized celluloses. The alkali-sensitivity of the periodic acid-oxidized celluloses appears to be related to the instability of the glyoxal and/or erythrose units (aldehyde groups).

Pacsu[18] has postulated that periodate-oxidized celluloses are reacted upn by alkaline solutions in the manner of an inner Cannizzaro reaction, supporting the theory in a qualitative way by showing that alkali reacted with such an oxidized cellulose to generate acidity. Since Davidson[8] has

(14) Evans and Benoy, THIS JOURNAL, **52**, 294 (1930); Evans and Hockett, *ibid.*, **53**, 4384 (1931); Gehman, Kreider and Evans, *ibid.*, **58**, 2388 (1936).

(15) Staudinger [*Ber.*, **72**, 1709 (1939)] has postulated such "defective" celluloses with carboxyl instead of carbonyl units.

(16) We wish to thank Dr. D. D. Reynolds, of these Laboratories, for criticism helpful in arriving at these conclusions.

(17) Davidson, *J. Textile Inst.*, **32**, 132–148 (1941); **32**, T109–131, (1931); **29**, T195–218 (1938).

(18) Pacsu, *Textile Research J.*, No. 10, **15**, 354 (1945).

demonstrated that a variety of breakdown products (such as formaldehyde and carbon dioxide) are produced during this type of cellulose oxidation, indicating that the oxidizing agent is not confined in its action to oxidation at the number two and three carbon atoms of the anhydro-glucose unit, this hypothesis may be viewed with some reserve. Head[19] recently has shown that in both mono- and polysaccharides, dialdehydes are converted to carboxyl slowly in the presence of dilute alkali.

The criticisms of Davidson and Purves on the calcium acetate method for carboxyl determination do not appear valid when the method is used for celluronic acids.

While this paper was being prepared, an investigation appeared of the structure of celluronic acids by absorption spectra.[20] The data indicate large contents of carboxyl groups with possibly a small carbonyl group content. These results agree with our chemical findings.

(19) Head, *Shirley Inst. Mem.*, **21**, 11 (1947).

(20) Rowen, Hunt and Plyler, *J. Research Natl. Bur. Standards*, **39**, 133–140 (1947).

Summary

1. Potentiometric investigations show that celluronic acids degrade in alkaline solutions to generate acidity.

2. Small amounts of carbonyl groups appear to be present in the celluronic acids.

3. The acidity generated in alkaline solution at a constant reaction time appears directly related to the carbonyl group content and is an exponential function of the alkali concentration.

4. The ketone groups are believed to enolize in alkali, the enediols split as in simple carbohydrates, the adjacent glucoside links hydrolyze and an extensive alkaline degradation is thus initiated which continues along the chain producing reducing and acidic substances.

The Migration of Acetyl and Benzoyl Groups in *o*-Aminophenol

BY ARTHUR L. LEROSEN AND EDGAR D. SMITH

A considerable amount of experimental data has been collected on the general subject of acyl migrations in *o*-aminophenols since interest was first drawn to this problem by Stieglitz[1] in 1898. The great majority of this work has been published by Raiford and co-workers[2–4] and has indicated that when two different acyl groups, derived from carboxylic acids, are introduced into an *o*-aminophenol generally the same acyl derivative is obtained regardless of the order of introduction. On hydrolysis the heavier acyl group has usually been found on nitrogen.

No satisfactory general explanation has been given for all the phenomena observed in the acylation or hydrolysis of these compounds. The best discussion to date, in the opinion of the authors, was that of Bell,[5] and this work has generally been neglected by other workers in this field.

The present work was undertaken because it seemed probable that it would be possible to give an adequate explanation of these acyl migrations in terms of a combination of the theory of resonance and inductive effects. Accordingly a general theory was derived for these reactions and was found to agree in many respects with the data found in the literature. Nevertheless there were discrepancies and these were of such a nature that a reëxamination of the reported data was advisable, especially since at present new and powerful aids to this study are available in the form of absorbtion spectroscopy for the determination of structure, and chromatographic techniques for the quantitative analysis of mixtures.

It is premature to present the details of our theories of acyl migrations here, but three resulting conclusions are important: first, no migration should be complete, but instead there should be a reversible equilibrium; second, in the acetyl–benzoyl migration the N-acetyl isomer should predominate; and third, if a "migration" occurs in acylation, the opposite migration should be observed during hydrolysis. There are no conclusive data on this first point in the literature, Raiford found only one product in the acetyl–benzoyl mixed acyl derivative, while Bell reported the formation of different isomers, depending on the acylation sequence. Bell based his conclusions on mixed melting point data. Both of these men reported that hydrolysis yielded only *o*-benzoylaminophenol.

The experiments here were concerned with the determination of the nature of the acylation product when acetyl and benzoyl groups were introduced into *o*-aminophenol in different sequence. The method was to prepare the crude derivatives by acylation with the corresponding anhydrides in pyridine solution, and to separate the product into its constituents chromatographically. The determination of structure was accomplished by comparison with spectroscopic curves determined for all of the possible mono- and diacyl deriva-

tives of *p*-aminophenol using acetyl and benzoyl groups.

Our experimental results show that two mixed diacyl derivatives are present in both crude products which, however, are predominantly N-acetyl-O-benzoyl and N-benzoyl-O-acetyl depending on the acylation sequence. Acetylation of *o*-benzoylaminophenol gave 91% of the unrearranged N-acetyl-O-benzoyl derivative, while benzoylation of *o*-acetylaminophenol gave 62% of the unrearranged isomer. Both of the pure mixed diacyl derivatives were isolated in their pure form for the first time and their physical properties and relative stabilities under the influence of several factors were studied.

Solution of either of the isomeric mixed diacyls in alcohol or pyridine produced equilibrium mixtures containing 85 and 77% of the more stable N-acetyl-O-benzoyl form, respectively. Water and heat also served to isomerize these diacyls, while benzene, hexane, acetone, ethyl ether and dioxane were much less effective, if not inert, in this respect. It seems probable that this is a case of general acid and base catalysis.[6]

The absorption curves of the derivatives studied are shown in Fig. 1. It will be noted that the total area under the curves roughly indicates the number of phenyl groups in the molecule, while whenever a N-benzoyl structure is present, one of the peaks (previously superimposed) shifts to longer wave lengths. No attempt will be made here to interpret these curves in terms of theory, but it may be indicated that they offer a good possibility of interpreting the peaks in terms of the contributions of the different resonating structures. The spectra for the mixed diacyls were determined in hexane to avoid the isomerization which occurred in alcohol and these curves are shown in the figure. The absorption spectra of the other acyl derivatives of *o*-aminophenol are not shown since there was no essential change from the spectra found in alcohol. The wave lengths and molar extinction coefficient in both of these solvents is, however, included in the tabulation shown in Table V.

The analytical data are summarized in Tables I through IV below. Table I shows the analyses obtained on the crude products of the acylations in pyridine solution, and also the analysis of these two products after a single recrystallization from alcohol.

Table II shows the analyses found on the residual products obtained by dissolving mixed diacyl samples of varying composition in a few ml. of alcohol and then evaporating off the solvent under vacuum. It will be seen from this table that the isomerizations in alcohol were complete for all except the pure N-benzoyl-O-acetyl isomer. No explanation can be given here for the peculiar behavior of this isomer, but it may be significant that the sample recovery in these runs was consistently low.

Table II

Analysis of Alcohol Isomerization Products

[a] Analyses based on amount of sample eluted by acetone. [b] N-acetyl-O-benzoyl-*o*-aminophenol. [c] N-benzoyl-O-acetyl-*o*-aminophenol.

Table IV shows the results of heating the two pure isomers for varying lengths of time at two different temperatures near their melting point. While the results of these runs are inconclusive since equilibrium was not reached in either of these runs, it appears that, as expected, the N-acetyl-O-benzoyl compound isomerized much more slowly than its isomeride.

In conclusion, it seems that the predictions of theory have been verified for the first two of the possibilities mentioned above, and that the con-

flicting results obtained by Raiford and Bell may be explained as being due to the use of alcohol as a recrystallization solvent by the former. In such a case isomerization would occur, leading to the isolation of the predominant isomer, in this instance the N-acetyl-O-benzoyl compound. It now seems desirable to reëxamine much of the past work in this field in the light of these facts. We are continuing this study at present.

Experimental

Preparation of Compounds.—The acyl derivatives studied are listed in Table V. Except as noted in the table, they were prepared by heating a pyridine solution of the aminophenol with a 10% excess of the acid anhydride for about thirty minutes on a steam-bath. The product was isolated by cooling the solution and pouring it into ice water. With the exception of the mixed *o*-acyl derivatives the products were purified by crystallization from alcohol.

Table V

Acyl Derivatives Studied

Compound	Melting point, °C. (cor.) Found	Literature	Ultraviolet abs. maxima λ	$\epsilon^f \times 10^{-3}$
p-Aminophenyl-benzoate[a]	153–155	153[7]	239	22.5

[a] Prepared by reduction of corresponding nitro compound with $SnCl_2$. [b] Prepared by method of Galatis[8] except that tar formation and resultant necessity of vacuum distillation was eliminated by the addition of a few crystals of hydroquinone and sodium bisulfite before neutralizing the acid hydrolysis mixture with sodium bicarbonate. [c] This high melting compound was prepared during an attempted acetylation of benzylidine *o*-aminophenol. It gave the same spectra as, and raised the melting point of, the 204° compound. [d] Refers to the absorption maxima found in hexane. All other absorption data were taken in alcohol. [e] The usual acylation method gave a mixture of mono and diacetyl derivatives which proved very difficult to separate. This compound was therefore prepared by heating the usual mixture of reactants under reflux for one and one-half hours, and then evaporating pyridine solution until crystals separated. [f] Molar extinction coefficient. [g] Alcohol equilibrium mixture.

Isolation and Purification of Mixed *o*-Acyl Derivatives.—It was found impractical to purify the mixed diacyl derivatives of the ortho series by recrystallization procedures since, in alcohol, isomerizations occurred, while in the other solvents tried the solubilities of the two isomers were too similar. These crude products were therefore chromatographed from benzene solution on a column of 1:1 silicic acid and Cellite using a 1.5% solution of acetone in benzene as the developing agent. The adsorbate zones were located by streaking the column first with a 3% solution of *p*-methoxybenzenediazonium fluoroborate, and then with a 5% solution of potassium hydroxide in methanol. This combination produced a distinct orange color with both isomeric mixed diacyls which could be further intensified by a third streaking with 6 *M* hydrochloric acid which caused the orange color to change to a deep red. The streaked areas were cut away, the column divided into the two sections containing the acyl derivatives, and the pure isomers recovered by eluting them from the adsorbent with acetone. (Determination of the ultraviolet absorption spectra of the two materials in hexane showed that the top zone was the N-acetyl-O-benzoyl derivative.)

Analysis of Diacyl Mixtures.—The crude mixture of isomers was chromatographically separated as outlined above, but, before eluting, the two portions of the adsorbent containing the pure isomers were powdered and dried under vacuum to remove any solvent which might absorb in the ultraviolet. The isomers were then eluted with

absolute alcohol and the resulting solutions quantitatively determined by comparing their ultraviolet absorption at 230 millimicrons with that found for 0.01 *M* solutions of the mixed acyls.

Determination of Ultraviolet Absorption Curves.—All ultraviolet absorption data shown in Table V were taken on a Beckmann Ultra Violet Spectrophotometer, Model DU. Hundredth molar solutions of each acyl derivative were made up, and these solutions diluted as became necessary by pipetting a 1-ml. aliquot and diluting to 10 ml. No attempt was made to calibrate the volumetric flasks or pipets used.

In hexane solution, due to the extreme insolubility of the acyl derivatives, it was necessary to determine the spectra of the saturated solutions of the compounds in this solvent. The concentrations of these solutions were found by pipetting a 10-ml. aliquot, evaporating to dryness under vacuum, and taking up the residue in 10 ml. of absolute alcohol. The concentration of this alcohol solution, and hence that of the hexane solution, was then determined by comparing its ultraviolet absorption intensity at 230 millimicrons with that of an alcohol solution of known concentration.

Summary

1. In the benzoylation of N-acetyl-*o*-aminophenol and the acetylation of N-benzoyl-*o*-aminophenol, mixtures of the two possible isomers were obtained showing that a partial rearrangement occurred in each case. These mixtures were quantitatively separated by chromatography, and the identity of the two isomers established by comparison of their ultraviolet absorption spectra with that of the corresponding derivative of *p*-aminophenol.

2. It has been shown that alcohol, pyridine, water and heat cause either pure mixed diacyl derivative to isomerize to yield an equilibrium mixture of the two isomers. In alcohol and in pyridine solutions an equilibrium mixture containing 85 and 77%, respectively, of the N-acetyl-O-benzoyl form was obtained. It was pointed out that this isomerization in alcohol probably accounts for the conflicting results reported by Raiford and by Bell.

3. In the light of the above facts it seems desirable to reëxamine much of the past work in this field.

Synthesis of Multichain Polymers and Investigation of their Viscosities[1]

BY JOHN R. SCHAEFGEN AND PAUL J. FLORY

Polymerizations in which the structural units are combined in other than strictly linear sequences generally yield gelled, insoluble products owing to the eventual formation of infinite network structures. Established exceptions are so few that thermoplasticity and solubility have sometimes been regarded as exclusive characteristics of linear polymers. On the other hand, non-linear structures have been postulated on various occasions for some of the thermoplastic vinyl polymers,[2,3] and it has been recognized,[4] in principle at least, that monomer units may be assembled in non-linear patterns which do not lead to network formation and the manifestations of gelation resulting therefrom. Chain transfer with previously formed polymer molecules in vinyl polymerizations doubtless leads to some degree of branching without producing network structures.[5-7] However, the extent of such branching, like the cross-linking produced in diene polymers, is not easily measured or controlled.

Effects of departure from linear structure on physical properties of non-gelled polymers have been the subject of frequent speculation, but little information of a quantitative nature is available as a result of the difficulty of isolating the non-linearity variable. In the first place, the extent of branching or of cross-linking (prior to gelation) in the polymer as a whole usually is difficult to estimate quantitatively. Secondly, such reactions ordinarily occur in a random manner such that the co-existing polymer molecules vary widely in degree of non-linearity, ranging from linear to highly branched structures. Finally, random cross-linking and branching reactions usually broaden the molecular weight distribution, sometimes severely; consequently, alteration of the molecular weight distribution, rather than non-linearity, may be primarily responsible for the effects observed.

In the present investigation a convenient general procedure for synthesizing non-linear condensation polymers of controlled structure has been demonstrated. The principle employed here involves the co-reaction of an A—B type monomer, *e.g.*, an amino acid or hydroxy acid, with a small proportion of a multifunctional reactant of the type RA_b or RB_b where R is a *b*-valent radical and A and B are co-reacting functional groups; such multifunctional reactants may be, for example, a polyamine or a polybasic acid. Polymers so produced can be represented by the formulas

$$R[-A(B-A)_{\overline{y}}-]_b \text{ or } R[-B(A-B)_{\overline{y}}-]_b$$

These "multichain" polymer molecules are therefore composed of b chains, of average length $\bar{y}$ units each, radiating from the central radical R. It is to be noted that network formation is precluded so long as the terminal groups A, or B as the case may be, cannot co-react. Also, the degree of branching is fixed according to the functionality of the central unit. The average length, $\bar{y}$, of the chains is controlled by the proportion of multifunctional unit employed; it is also dependent on the extent of condensation, which, however, ordinarily is carried very nearly to completion.

The multichain polymers employed in the present investigation were prepared from ϵ-caprolactam (instead of the corresponding amino acid) using either a tetrabasic or an octabasic carboxylic acid as the multifunctional reactant. For comparison, monochain and dichain ϵ-caproamide polymers (stearic and sebacic acid, respectively, were used as the "multifunctional" reactant) have been prepared as well. Thus, the various polymers for which data are reported herein can be represented by the formula

$$R\{—CO[—NH(CH_2)_5CO—]_{\bar{y}}\ OH\}_b$$

where $b = 1, 2, 4$, or 8, $\bar{y}$ being varied in each case by manipulating the proportion of the multifunctional reactant. Cyclohexanone-tetrapropionic acid[8] and the analogous octabasic acid, dicyclohexanone-octapropionic acid[9] were used in preparing the tetrachain and octachain polymers, respectively.

Theoretical

Stoichiometric Relationships. The Number Average Molecular Weight.—Let Q represent the number of equivalents of the multifunctional reactant, RA_b, that reacts with one mole of A—B monomer. If the reaction were carried to completion, no unreacted B groups remaining, there would be obtained Q/b moles of polymer molecules, each molecule having b chains. Since it is never possible to carry the condensation process to absolute completion, a small fraction of the B groups will remain unreacted, and each unreacted B group will subtend a linear chain. Letting L represent the number of equivalents of unreacted groups per mole of A—B monomer, there will be L moles of linear molecules and Q/b moles of multichain molecules in the polymer. The ratio of L to Q/b depends on the degree of completion of the reaction and is very small if the reaction is carried reasonably near to completion. (In the examples discussed below, A = COOH and B = NH_2; the proportion L of the latter remaining unreacted in the polymer can be determined by titration of the free amino groups.)

As a consequence of the assumed equal reactivity of the carboxyl groups dealt with here, the average number, $\bar{y}$, of monomer units subtended by an A group of a multifunctional unit will equal the number attached to the terminal unit of a linear chain. Therefore $\bar{y}$ will equal the total number of monomer units excluding those with unreacted B groups, divided by the total number of chains, or

$$\bar{y} = (1 - L)/(Q + L) \qquad (1)$$

Letting y_L represent the average number of units in a linear molecule (including the terminal unit bearing the unreacted B group)

$$\bar{y}_L = \bar{y} + 1 = (Q + 1)/(Q + L) \qquad (2)$$

The number average molecular weights of the linear molecules ($\overline{M}_{n,L}$) and of the multichain molecules ($\overline{M}_{n,Q}$) are therefore

$$\overline{M}_{n,L} = m\bar{y}_L = m(Q + 1)/(Q + L) \qquad (3)$$

and

$$\overline{M}_{n,Q} = b(m\bar{y} + m_b) = b[m(1 - L)/(Q + L) + m_b] \qquad (4)$$

where m is the molecular weight of an A—B structural unit and m_b is the molecular weight of the multifunctional unit divided by b. The number average molecular weight ($\overline{M}_n$) of the entire polymer containing L moles of linear molecules and Q/b moles of multichain molecules can now be expressed as

$$\overline{M}_n = \frac{LM_{n,L} + (Q/b)M_{n,Q}}{L + (Q/b)} = \frac{(Qm_b + m)}{(Q/b) + L} \qquad (5)$$

It can be shown further that w_L, the weight fraction of linear molecules present in the mixture, is given by

$$w_L = L/\left\{L + Q\left[1 + \left(\frac{m_b}{m} - 1\right)\left(\frac{Q + L}{Q + 1}\right)\right]\right\} \qquad (6)$$

which reduces to

$$w_L = L/(Q + L) \qquad (7)$$

when Q and L are both small or when m_b is similar in magnitude to m. This relationship will be used in the next section (see equation 25) in deriving the expression for the weight average molecular weight of a mixture of multichain and linear molecules.

Molecular Size Distribution. The Weight Average Molecular Weight.—Schulz[10] has derived approximate relationships expressing the molecular weight distribution in polymers composed of a fixed number of chains of random length. His molecular weight distribution relationships were derived for the purpose of treating vinyl polymers believed to be branched. Since branching in vinyl polymers must necessarily be random, his relationships actually are of little value for the purpose intended, except in the $b = 2$ case representing polymers resulting from diradical chain growth in two directions. Schulz's approximate relationships may be applied to multichain polymers of the present type, provided the chain length is sufficiently great; at low chain lengths the approximations employed by

(8) Bruson and Riener, THIS JOURNAL **64**, 2850 (1942).

(9) J. R. Schaefgen and P. J. Flory, *ibid.*, **70**, 2823 (1948).

(10) G. V. Schulz, *Z. physik. Chem.*, **B43**, 25 (1939).

Schulz became invalid. Instead of these approximate equations, we have preferred to use exact relationships, the derivation of which is set forth below. They are as easily applied as the approximate forms of Schulz.

Let p represent the fraction of the A groups which have undergone reaction, *i. e.*

$$p = (1 - L)/(1 + Q) \tag{8}$$

If the A groups of the multifunctional units and those of the bifunctional units can be assumed to be equally reactive, p represents the probability that any given A group has condensed with a B group, since condensation polymerization reactions are known to proceed in a random manner.[11] The probability that a given multichain molecule possesses exactly x_1 bifunctional units in the first chain, x_2 in the second, etc., will be given by

$$Px_1x_2\cdots x_b = p^{x_1}p^{x_2}\cdots p^{x_b}\,(1 - p)^b \tag{9}$$

Let x represent the total number of structural units, counting the multifunctional constituent as a single unit. Then

$$x_1 + x_2 + \cdots + x_b + 1 = x \tag{10}$$

and

$$P_{x_1x_2\cdots x_b} = p^{x-1}\,(1 - p)^b \tag{11}$$

All combinations of the x's consistent with equation (10), the individual values of the x's ranging from 0 to x_b, are equally probable. It is to be noted that a given combination is specified by $b - 1$ of the x's, the remaining one being defined by equation (10) above. The number of ways the $x - 1$ units may be distributed over the b chains is given, therefore, by the combinatory factor

$$(x + b - 2)!/(b - 1)!(x - 1)!$$

which represents the number of combinations of $(x - 1) + (b - 1)$ elements (allowing for the permissible zero values) taken $b - 1$ at a time. Hence, the probability that a given multichain molecule contains $x - 1$ bifunctional units arranged in any manner is given by

$$P_{x,b} = (1 - p)^b p^{x-1}(x + b - 2)!/(b - 1)!(x - 1)! \tag{12}$$

$P_{x,b}$ represents the mole fraction of x-mers among the multichain molecules.

In order to obtain the weight fraction distribution and to deduce the weight average degree of polymerization, the summations

$$\sum_{x=1}^{\infty} xP_{x,b} \text{ and } \sum_{x=1}^{\infty} x^2P_{x,b}$$

must be evaluated.

$$\sum_{x=1}^{\infty} xP_{x,b} \equiv \sum_{x=2}^{\infty}(x - 1)P_{x,b} + \sum_{x=1}^{\infty} P_{x,b} \tag{13}$$

Substituting from equation (12)

$$\sum_{x=1}^{\infty} xP_{x,b} = \sum_{x=2}^{\infty}(1 - p)^b\, p^{x-1}\,\frac{(x + b - 2)!}{(x - 2)!(b - 1)!} + \sum_{x=1}^{\infty} P_{x,b}$$

Shifting limits in the first summation on the right, there is obtained

$$\sum_{x=1}^{\infty} xP_{x,b} = bp/(1 - p)\sum_{x=1}^{\infty} P_{x,b+1} + \sum_{x=1}^{\infty} P_{x,b}$$

Since

$$\sum_{x=1}^{\infty} P_{x,b+1} = \sum_{x=1}^{\infty} P_{x,b} = 1$$

$$\sum_{x=1}^{\infty} xP_{x,b} = (bp + 1 - p)/(1 - p) \tag{14}$$

Replacing x^2 with $(x - 2)(x - 1) + 3x - 2$ in the summations over $x^2P_{x,b}$ and proceeding similarly, there is obtained

$$\sum_{x=1}^{\infty} x^2P_{x,b} = \frac{p^2(b - 1)^2 + (3b - 2)p + 1}{(1 - p)^2} \tag{15}$$

The weight fraction distribution is given by

$$w_x = xP_{x,b}\Big/\sum_{x=1}^{\infty} xP_{x,b}$$

which on substituting from equation (14) reduces to

$$w_x = \left[\frac{(1 - p)^{b+1}}{(bp + 1 - p)}\right](p^{x-1})\,\frac{x(x + b - 2)!}{(b - 1)!(x - 1)!} \tag{16}$$

The corresponding weight fraction distribution expression derived by Schulz,[10] when expressed in the present symbols, is

$$w_x = (-\ln p)^{b+1}\, p^x(x^b/b!) \tag{17}$$

which approximates equation (16) when p is near unity (high *average* molecular weight) except for small values of x, since

$$-\ln p \cong (1 - p)$$
$$p^x \cong p^{x-1}$$
$$x^b/b! \cong \frac{x(x + b - 2)!}{(bp + 1 - p)(b - 1)!(x - 1)!}$$

The molecular weight distribution is narrower the greater the number b of chains. The dependence of the molecular weight distribution on b is illustrated in the curves published by Schulz,[10] which are qualitatively similar to the corresponding curves calculated from our equation (16).

The number and weight average degrees of polymerization, respectively, derived from the mole fraction size distribution as given by equation (12) are

$$\bar{x}_n = \sum_{x=1}^{\infty} xP_{x,b}\Big/\sum_{x=1}^{\infty} P_{x,b} = (bp + 1 - p)/(1 - p) \tag{18}$$

and

$$\bar{x}_w = \sum_{x=1}^{\infty} x^2P_{x,b}\Big/\sum_{x=1}^{\infty} xP_{x,b} = \frac{(b - 1)^2p^2 + (3b - 2)p + 1}{(bp + 1 - p)(1 - p)} \tag{19}$$

Substituting for p from equation (8) reduces the expression for the number average to

$$\bar{x}_n = 1 + \frac{b\,(1 - L)}{Q + L} \tag{20}$$

(11) P. J. Flory, THIS JOURNAL, **61**, 3334 (1939); **64**, 2205 (1942).

The ratio of the weight to number average degree of polymerization is

$$\frac{\bar{x}_w}{\bar{x}_n} = \frac{(b-1)^2p^2 + (3b-2)\,p + 1}{(bp + 1 - p)^2} \qquad (21)$$

Substituting from Equation (8) for p

$$\bar{x}_w/\bar{x}_n = 1 + \frac{b(1-L)(1+Q)}{[b(1-L) + (Q+L)]^2} \qquad (22)$$

For small values of Q and L, this equation reduces approximately to

$$\bar{x}_w/\bar{x}_n \cong 1 + 1/b \qquad (23)$$

which is the result obtained by Schulz. The narrowing of the molecular weight distribution with increase in b is reflected in the approach of this ratio to unity.

Equation (23) is too coarse an approximation on the one hand and (22) is unnecessarily cumbersome on the other. An intermediate approximation, which can be used with negligible error when $L << 1$ and $Q^2 << (b^2 + 2bQ)$, is the following

$$\bar{x}_w/\bar{x}_n = 1 + (1+Q)/(b+2Q) \qquad (24)$$

For a mixture of Q/b multichain polymer molecules with L linear polymer molecules the expression for the weight average molecular weight is[12] (see equations 3, 4, 7, and 24)

$$\overline{M}_w = w_L\,\overline{M}_{w,L} + w_Q\overline{M}_{w,Q} = w_L\overline{M}_{n,L}\,(\bar{x}_w/\bar{x}_n)_1 + (1 - w_L)\,\overline{M}_{n,Q}\,(\bar{x}_w/\bar{x}_n)_b \qquad (25a)$$

$$\cong \frac{L}{(Q+L)}\,\frac{m(1+Q)}{(Q+L)}\left[1 + \frac{(1+Q)}{(1+2Q)}\right] + \frac{Qb}{(Q+L)}\left[\frac{m(1-L)}{(Q+L)} + m_b\right]\left[1 + \frac{(1+Q)}{(b+2Q)}\right] \qquad (25b)$$

Since the first term in equation (25b) is small, $(1 + Q)$ can be set equal to unity therein. The second term can be simplified since $L(m_b - m)$ is small in comparison with m. Then

$$\overline{M}_w \cong 2\,mL/(Q+L)^2 + [Qb/(Q+L)^2](m + m_bQ)[1 + (1+Q)/(b+2Q)] \qquad (26)$$

The Viscosity Average Molecular Weight.—Interpretation of dilute solution viscosities requires evaluation of the viscosity average molecular weight[13] defined as

$$\overline{M}_v = \left[\sum_{x=1}^{\infty} w_x M_x^a\right]^{1/a} \qquad (27)$$

where a is a constant which usually is in the range of 0.6 to 0.9. Substituting from equation (16) for w_x and replacing M_x with xm

$$\overline{M}_v^a = m^a\left\{\frac{(1-p)^{b+1}}{[p(b-1)+1]p}\right\}\sum_{x=1}^{\infty}\left\{\left[(x+b-2)(x+b-3)\cdots(x+1)\right]x^{2+a}\,p^x/(b-1)!\right\}$$

Employing the ratio of $\overline{M}_v$ to $\overline{M}_n$, the latter being the product of m and x_n as expressed by equation (18), and expanding the products of the summation

$$(\overline{M}_v/\overline{M}_n)^a = \left[\frac{1-p}{p(b-1)+1}\right]^a \left\{\frac{(1-p)^{b+1}}{p[p(b-1)+1]}\right\}\sum_{x=1}^{\infty}\left\{\left[x^{b+a} + (1/2)(b-1)(b-2)x^{b-1+a} + (1/24)(b-1)(b-2)(3b^2 - 13b + 12)x^{b-2+a} + \cdots\right]p^x/(b-1)!\right\}$$

The summation is made up of terms of the form

$$S_m = \sum_{x=1}^{\infty} p^x\,x^{m+a}$$

where m is a positive integer. Replacing the summation by an integral and setting $y = -x \ln p$

$$S_m = (-1/\ln p)^{m+a+1}\int_0^{\infty} e^{-y}\,y^{m+a}\,dy = (-1/\ln p)^{m+a+1}\;\Gamma(m+a+1) = (-1/\ln p)^{m+a+1}\,[(m+a)(m+a-1)\cdots(1+a)\,\Gamma(1+a)]$$

Substituting this evaluation of S_m in the previous equation, the ratio of the viscosity average to the number average may be expressed conveniently as

$$(\overline{M}_v/\overline{M}_n) = (C/b)[(1/b!)(a+b)(a+b-1)\cdots(a+1)\Gamma(a+1)]^{1/a} \qquad (28)$$

where

$$C = \left(\frac{1-p}{-\ln p}\right)\left[\frac{b}{p(b-1)+1}\right]\left\{\left(\frac{1-p}{-\ln p}\right)^{b+1}\left[\frac{b}{p^2(b-1)+p}\right]\left[1 + \frac{(b-1)(b-2)(-\ln p)}{2(b+a)} + \frac{(b-1)(b-2)(3b^2-13b+12)(-\ln p)^2}{24(b+a)(b+a-1)} + \cdots\right]\right\}^{1/a} \qquad (29)$$

The series in brackets converges rapidly when

$$-b \ln p < 1$$

When, in addition to this condition, p is not less than about 0.8, C differs inappreciably from unity. To illustrate for $a = 0.8$, $b = 8$, and $p = 0.8$, C as calculated from equation (29) has a value of 1.03 (making a suitable estimation of the values of the unexpanded terms). For all higher values of p (and/or lower values of b), C is closer to unity. Within the limit of error introduced on replacing summations by integrals, C may therefore be set equal to unity in equation (28).

Experimental

Materials.—ϵ-Caprolactam was prepared from cyclohexanoneoxime by a Beckmann rearrangement[14] in 77% yield. The product was distilled at reduced pressure and then crystallized from acetone to a constant freezing point of 68.7–68.8°, determined by a cooling curve.

Stearic Acid.—A commercial grade was crystallized once from acetone and then several times from alcohol; m. p. 71–72°[15]; neutral equivalent 284, calcd. 284.5.

Sebacic Acid.—An Eastman Kodak Co. product was crystallized several times from distilled water; m. p. 128.5–130°, uncor.; neut. equiv. 101, calcd. 101.1.

(12) The subscript b on the ratio $(\bar{x}_n/\bar{x}_w)_b$ in equation (25a) refers to the value of b for the multichain molecules. The subscript "1" must be used for the co-existing linear species.

(15) All melting points are corrected for stem exposure unless marked "uncor."

2,2,6,6-Tetra-(β-carboxyethyl)-cyclohexanone (cyclohexanonetetrapropionic acid) was prepared by the method of Bruson.[8] Attempts to convert this acid or its nitrile to cyclohexane-tetrapropionic acid by the Clemmensen method were uniformly unsuccessful. The acid after several crystallizations from water melted at 182.5–184.5°, although one sample prepared by acid hydrolysis of the tetranitrile melted at 195–197°. However, mixed melting points showed that this sample was identical with the lower melting material indicating the existence of allotropic forms. The neutral equivalent was 96.6, calcd. 96.6. A sample of this acid when heated to 253° for three hours in an argon atmosphere turned black and tarry and underwent extensive decomposition with the liberation of gaseous products. When the acid was mixed with three times its weight of ε-caprolactam and initially polymerized at 200° (see section on Method of Polymerization), little decomposition occurred on further heating at 253° for a period of three hours, thus indicating that the amide is considerably more stable than the free acid.

bis-[3,3,5,5-Tetra-(β-carboxyethyl)-4-ketocyclohexyl] (Dicyclohexanoneoctacarboxylic Acid).—The preparation of this acid from *p,p'*-diphenol is described elsewhere.[9] Material melting at 274–277° and having a neutral equivalent of 96.6 to 96.8 (calcd. 96.4) was used in making polymers.

Method of Polymerization.—The polymerizations were carried out in two steps. In the first step weighed amounts of ε-caprolactam and the multifunctional coreactant together with a small amount of distilled water (*ca.* 17 mole per cent.) were polymerized[16] in a sealed tube at a temperature of about 200° until a low molecular weight polymer was produced (four hours or more). The tube was alternately evacuated and filled with argon or nitrogen (containing in either case less than 0.01% of oxygen) several times before sealing. In the second step the white brittle polymer produced in the first step was heated in an inert gas atmosphere at 253° (diphenyl vapor-bath) alternately at atmospheric pressure and at reduced pressure (down to 15 mm.) until the melt viscosity became constant, or for a period of from six to seven hours (see section on results). The distillate in each polymerization was collected and analyzed for evolved ε-caprolactam. The amount of ε-caprolactam used in the calculation of the polymer composition was corrected accordingly.

The apparatus used in the second step was essentially that described previously[17] except that the side-arm attached to the vertical polymerization tube sloped downward. This facilitated the complete removal of the unreacted ε-caprolactam. The trap in which the distillate was collected was cooled in an ice-bath.

Melt Viscosity.—The melt viscosities of the polymers were determined by the method previously described.[17] It was found convenient to use viscometers with two bulbs (or four marks in the case of the straight tube type) using the lower bulb to measure the changing viscosity as the reaction proceeded and saving the clean upper bulb to determine the final viscosity. Melt viscosities were ordinarily taken at the end of a given cycle, a cycle consisting of a fifteen-minute period of heating at reduced pressure followed by a fifteen-minute period at atmospheric pressure during which time the inert gas was bubbled through the molten polymer. When two consecutive viscosity determinations gave values within 5% of each other the reaction was assumed to be substantially complete and a final viscosity was determined. In preparing the higher molecular weight polymers, the heating period at 253° was prolonged to six or seven hours which was several times the length of time required for the lower molecular weight polymers to reach maximum viscosity. After this length of time the reaction was assumed to be complete, and a final viscosity was taken.

Solution Viscosities.—Relative viscosities of the polymer solutions in concentrated sulfuric acid were measured at 25.0 (±0.1°) using a Ubbelohde number 2 suspended level viscometer. The efflux time of the solutions was of the order of two minutes or more, making the kinetic energy correction negligible. The density of the solution was equal to that of the solvent within the experimental error.

Solutions were prepared by shaking a suspension of the finely divided polymer in ordinary commercial concentrated sulfuric acid until solution was complete, and making up to volume. To obtain polymer samples in a form which would dissolve readily, the brittle lower molecular weight polymers were ground in a steel mortar, whereas samples of the tough higher molecular weight polymers were drilled out from a solid plug thereof with a one-half inch drill. Concentrations were suitably chosen to obtain relative viscosities in the range 1.15 to 1.25. Values of $(\ln \eta_r)/c$, where c is expressed in g./100 cc. solution, calculated from relative viscosities in this range differed by 3% or less from the infinite dilution values, and were therefore accepted as intrinsic viscosities (*i. e.*, $(\ln \eta r)/c$ at $c = 0$)[18] without extrapolation. In a few representative cases the change of $(\ln \eta_r)/c$ with concentration was measured. Solutions for these experiments were made up either individually or by dilution of a more concentrated solution.

The observation of Matthes[19] that degradation of the polymer in concentrated sulfuric acid solution at room temperature is negligible within a twenty-four hour period was confirmed.

Amine Titer.—The amino end-group concentration in a polymer was determined by titrating a 50-ml. sample of a 6% by weight solution of the polymer in *m*-cresol with standard 0.1 *N* *p*-toluenesulfonic acid solution using thymolsulfonphthalein as an indicator. The solutions were prepared by shaking and gently warming the finely divided polymer suspension in *m*-cresol until solution was effected. The *m*-cresol (1500 ml.) used for these titrations was distilled at reduced pressure from sulfuric acid (5 ml.) and zinc dust (5 g.), and then redistilled from barium oxide (10 g.) to give a water-white neutral product. The amino group concentration is expressed as equivalents per mole of ε-caprolactam in the polymer. This value is equal to L, the equivalents of linear molecules present in the polymer per mole of ε-caprolactam.

Melting Points.—Polymer melting points were measured[20] on the heated stage of a microscope, plane polarized light being used for illumination. One Polaroid film was located between the light source and the sample, and another was placed in the objective of the microscope. With the Polaroids at right angles to each other, the crystalline portions of the sample were seen as light areas against a dark background. As the temperature of the stage was gradually increased, a range of temperature was reached in which the light areas disappeared into the dark background. This range of temperature is recorded as the melting point.

Results

Calculations and Errors.—Viscosity, molecular weight, and melting point data for monochain, dichain, tetrachain, and octachain polymers ($b = 1$, 2, 4, and 8) are recorded in Tables I, II, III, and IV, respectively. The quantities Q and L, defined earlier, were calculated in each case from the data in columns 1 and 2, and from the amine titer. The weight fraction of linear molecules, w_L, was calculated using equation (7). The number average, M_n, and weight average, M_w, molecular weights were calculated using equations (5) and (26), respectively. All poly-

merizations were carried very nearly to completion, as shown by the low values obtained for w_L (Tables III and IV), hence the final polymers contained a preponderant number of multichain molecules.

The preceding deductions of structure and the formulas for the computation of molecular weights are based on literal application of stoichiometric considerations. Deviations from these idealized conditions doubtless occur owing to side reactions. These include oxidation, thermal decomposition, anhydride and imide formation.

Oxidation was minimized by carrying out the polymerizations in an argon or nitrogen atmosphere containing, in either case, less than 0.01% of oxygen. However, some oxidation occurred, especially in the higher molecular weight polymers for which the heating period at 253° was prolonged over a six to seven hour period. Small amounts of oxygen were also introduced during the melt viscosity measurements. Such oxidation as occurred presumably lowered the molecular weight by oxidative cleavage of the polymer chain. The magnitude of this effect is difficult to ascertain, but it is believed to have been small compared to the other side reactions mentioned; its effect was therefore neglected.

The most likely reaction to occur in thermal decomposition is decarboxylation. In support of this conclusion, the distillate in some of the polymerizations was found to be slightly acidic. To investigate the magnitude of the decomposition the number of carboxyl end-groups in a given polymer was determined by the method of Waltz and Taylor.[21] The results (Table V) show that loss of carbon dioxide does occur, but that in no case is the magnitude of the deviation between the observed value and that calculated from stoichiometric relationships greater than 9%. The fact that the major part of the octabasic acid used in a polymer could be recovered unchanged by hydrolysis is further proof that decomposition was slight. Loss of carbon dioxide, especially from the multichain molecule, would lower the degree of branching but would leave the molecular weight essentially unchanged since as b decreases $\bar{y}$ increases (see equation 4). The molecules which are formed may, for example, contain an average of 7.5 branches instead of eight.

(21) J. E. Waltz and G. B. Taylor, *Anal. Chem.*, **19**, 448 (1947).

When the study of octachain polymers was extended to include polymers of higher molecular weight than reported herein, the melt viscosity of a given polymer continued to rise slowly on prolonged heating without seeming to approach a limit, and polymers of very high viscosity gave evidence of being partially gelled. This may have been due to the gradual formation of a small number of anhydride and/or imide linkages. All the polymers reported in this paper, however, were completely soluble and gave no evidence of gelation. It is quite possible, however, that a small number of such anhydride and/or imide linkages (short of gelation) were formed.

Furthermore it was found impossible to remove the last traces of monomeric ϵ-caprolactam from the polymer, owing to the occurrence of interchange reactions which constantly evolve small quantities of ϵ-caprolactam. This error would tend to make the observed viscosity low. Small amounts (*ca.* 0.15 g. in 16 g. of polymer) of a high melting (m. p. > 295°) sublimate which analyzed correctly for ϵ-caprolactam were also formed. The material is undoubtedly di-ϵ-caprolactam, a fourteen-membered ring compound.

Data reported here were obtained under conditions chosen with the object of minimizing errors arising from these various sources. While the results may nevertheless be vitiated by them to some extent, these errors are doubtless inconsequential insofar as the conclusions regarding the effects of branching are concerned.

Melt Viscosity.—It has been shown previously[17] that the viscosities of molten polyesters can be represented precisely by the equation

$$\log \eta = A + C\overline{M}_w^{1/2}$$

Graphs of the logarithm of the melt viscosity as a function of the weight average molecular weight for multichain polymers are shown in Fig. 1. The relationships are linear over the range of molecular weight considered just as in the case of polyesters, and the effect of branching is noticeable only in the octachain polymers. The equations for the lines are

$$b = 1, 2 \text{ or } 4 \quad \log_{10} \eta = 2.6 \times 10^{-2} \overline{M}_w^{1/2} - 1.32$$

$$b = 8 \quad \log_{10} \eta = 2.0 \times 10^{-2} \overline{M}_w^{1/2} - 1.00$$

The values of C are similar to those obtained for polyesters.[17,22] If the logarithm of the melt viscosity is plotted as a function of the square root of the number average molecular weight, individual linear relationships are obtained for each series of polymers.

Solution Viscosity.—The change of relative viscosity (η_r) with concentration for representative linear and multichain polymers was determined in sulfuric acid and in *m*-cresol solution. The function $(\ln \eta_r)/c$ was plotted against concen-

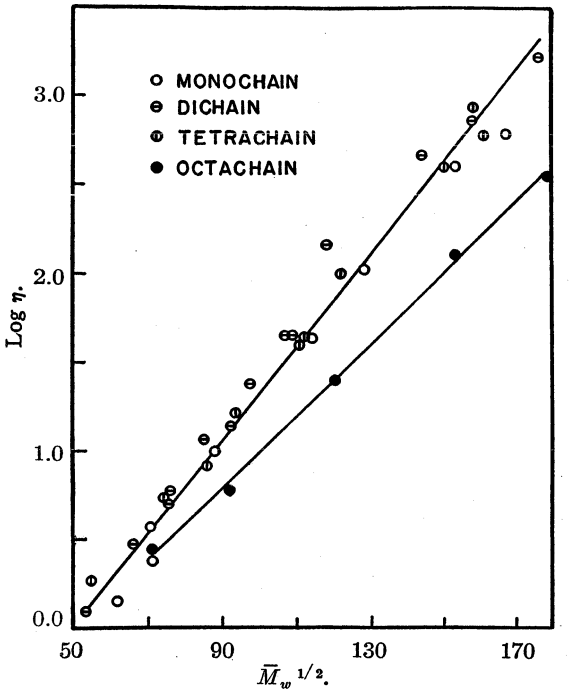

Fig. 1.—Relationships between melt viscosity and weight average molecular weight.

TABLE VI

THE CHANGE OF $(\ln \eta_r)/c$ WITH CONCENTRATION FOR SELECTED LINEAR AND MULTICHAIN POLYMERS

Branching	$[\eta]$	$d[(\ln \eta_r)/c]/dc$	$(\ln \eta_r)/c$ at $\eta_r \cong 1.2$	Error in %
(1) in sulfuric acid solution				
Linear $b = 2$	0.393	-29×10^{-3}	0.381	3.1
Tetrachain	.401	-26×10^{-3}	.390	2.7
Octachain	.428	-21×10^{-3}	.421	1.6
Octachain	.608	-16×10^{-3}	.603	0.8
Octachain	.828	-102×10^{-3}	.809	2.3
(2) in *m*-cresol solution				
Linear $b = 1$	.553	-31×10^{-3}	.542	2.0
Linear $b = 2$	.556	-37×10^{-3}	.542	2.5
Tetrachain	.541	-35×10^{-3}	.528	2.4
Octachain	.755	-103×10^{-3}	.730	3.3

tration and the slope and intercept, corresponding to the intrinsic viscosity, $[\eta]$, were determined. Values of the slopes, intrinsic viscosities, and the error involved in calculating the "intrinsic viscosity" from the relative viscosity at $\eta_r \cong 1.2$ are shown in Table VII. The data fail to show a definite correlation of the slope with the degree of branching.

Intrinsic viscosities of linear polymers generally depend on molecular weight according to a relationship of the form

$$[\eta] = K\bar{M}_v^a \qquad (30)$$

where $\bar{M}_v$ is the viscosity average molecular weight and K and a are constants for a given polymeric series. According to equation (28) the ratio $\bar{M}_v/\bar{M}_n$ is practically independent of molecular weight for a given value of b. Hence, if equation (30) can be applied to the multichain polymers, plots of log $[\eta]$ *vs.* $\bar{M}_n$ for polymers having the same b value should be linear. That this is the case over the molecular weight ranges investigated is shown in Fig. 2. The effect of branching is to lower the intrinsic viscosity at fixed *number average* molecular weight.

Treatment of the data by the method of least squares yields the following empirical relationships[23] corresponding to equation (30):

$b = 1$ $\log_{10}[\eta] = 0.764\ (\pm 0.016) \log_{10} \bar{M}_n - 3.20$ (31)

$b = 2$ $\log_{10}[\eta] = 0.794\ (\pm 0.018) \log_{10} \bar{M}_n - 3.38$ (32)

$b = 4$ $\log_{10}[\eta] = 0.736\ (\pm 0.084) \log_{10} \bar{M}_n - 3.26$ (33)

$b = 8$ $\log_{10}[\eta] = 0.857\ (\pm 0.027) \log_{10} \bar{M}_n - 3.87$ (34)

Within the experimental error, the slopes for the first three cases ($b = 1$, 2, or 4) are the same.

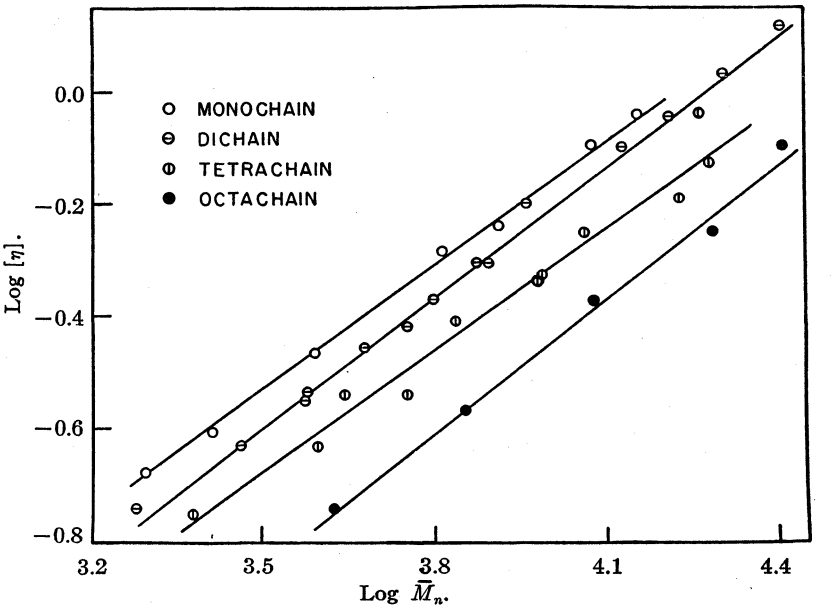

Fig. 2.—Relationships between intrinsic viscosity and number average molecular weight.

Matthes,[19] working with low molecular weight (400 to 5,000) poly-ε-caproamides, obtained values of $a = 0.67$ and $K = 12 \times 10^{-4}$ from measurements of molecular weight by end-group analysis and intrinsic viscosities in sulfuric acid. Staudin-

(23) The errors in the slopes shown in parentheses in equations (31) to (34) were estimated as $2\Delta y/(x_r - x_1)$ where x_1y_1, x_2y_2, ... x_ry_r are experimental points fitted by the equation $y = ax + b$ and Δy is the standard error in y.

ger and Schnell[24] carried out similar measurements (viscosities in *m*-cresol) over a wider range of molecular weights (1300 to 20,000), from which they concluded that the exponent a becomes equal to unity at higher molecular weights. In each case the measurements were carried out on precipitated polymers; consequently, the degree of heterogeneity of their samples cannot be appraised. Within the experimental uncertainties indicated by the scattering of the data, however, their results fit the line drawn through the points for linear polymers in Fig. 2. The values $a = 0.72$ and $K = 11 \times 10^{-4}$ obtained by Taylor[25] for poly-hexamethyleneadipamide polymers are similar in magnitude to our values for linear poly-ε-caproamide polymers.

A part, at least, of the apparent influence of the degree of branching b on the intrinsic viscosity–*number average* molecular weight relationship arises from the dependence of the molecular weight distribution on b. This effect of molecular weight distribution may be eliminated by converting the molecular weights to *viscosity averages*, using for this purpose equation (28) and the values of a obtained from the above empirical equations representing the log $[\eta]$ *vs.* $\overline{M}_n$ plots. Taking $a = 0.78$ for $b = 1$, 2 or 4 and $a = 0.86$ for $b = 8$, the ratios of $\overline{M}_v$ to $\overline{M}_n$ deduced from equation (28) for $b = 1$, 2, 4 and 8, respectively, are 1.90, 1.45, 1.22 and 1.12. If the rather trivial allowance which should be made for the small proportions of linear molecules is neglected, the number average molecular weights given in Tables I, II, III and IV may be converted to viscosity averages through the use of these respective factors.

A log–log plot of intrinsic viscosities *vs.* viscosity average molecular weights is shown in Fig. 3. Within the experimental error the data for polymers in which $b = 1$, 2, and 4 all fall on the same straight line, while the data for polymers in which $b = 8$ fall on a somewhat lower line. Thus the effect of branching on dilute solution viscosity becomes noticeable only in the octachain polymer series, a result paralleling the melt viscosity behavior.

Melting Points.—An increase in branching at the same molecular weight lowers the melting point (*cf.* Tables I, II, III, IV), and the relative amount of the depression of the melting point by branching depends on the molecular weight, decreasing as the molecular weight increases. In each case the melting points of the high molecular weight polymers ($\overline{M}_n$ = 20,000 or more) approach a constant value of about 225°.

Discussion

The results which have been presented demonstrate the feasibility of the scheme outlined in the introduction for preparing polymers with controlled degrees of branching. The principle should be capable of numerous extensions. We have found, for example, that polyacrylic acids may be employed as the multifunctional centers. Some of the products obtained in this manner are of much higher molecular weight than those herein reported, and they likewise exhibit the characteristics of ungelled materials. It should be noted that since the degree of polymerization of the polyacrylic acid molecules is non-uniform, b in this case is not constant.

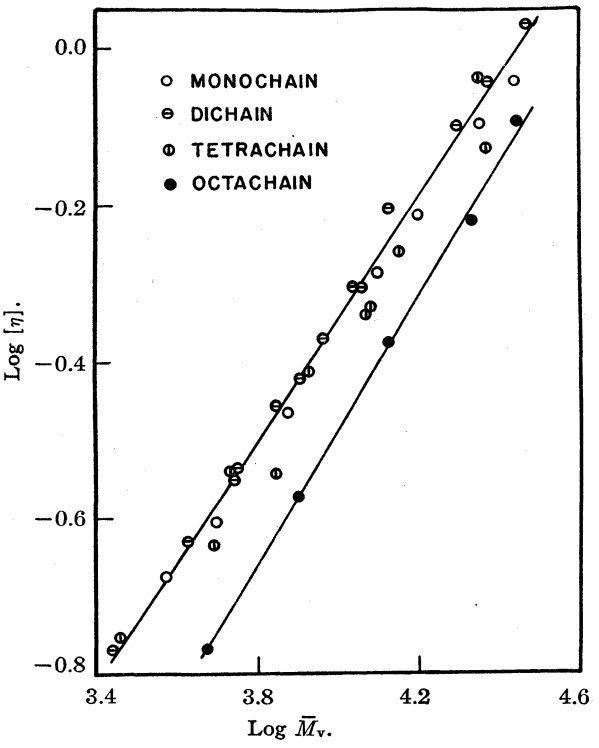

Fig. 3.—Relationships between intrinsic viscosity and viscosity average molecular weight.

In place of a polymerizable lactam, an amino acid, N-carboxyamino acid anhydride, hydroxy acid, or lactone may be employed in the preparation of multichain polymers and, similarly, other types of multifunctional reactants can be used (*e. g.*, polyamines or polyhydric alcohols). In any case, it is essential that the reactants be so chosen that all terminal groups of multichain molecules be of such a character that they cannot condense with any terminal groups (or other functional groups) of other multichain molecules.

The essential difference between multichain polymer molecules and the various non-linear polymers, obtained for example by polymerizing polybasic acids and glycols (or polyhydric alcohols and dibasic acids[26]) or by introducing cross linkages subsequent to the polymerization[27] is that

(27) W. O. Baker, THIS JOURNAL, **69**, 1125 (1947).

the molecules of the former are uniformly branched whereas those of the latter vary widely in their degree of branching or cross-linking. As a result of this difference, the latter molecules may join together to form infinite networks and gelation may be observed. Multichain polymers are incapable (barring side reactions) of yielding network structures and gelation therefore is not observed. Thus the present observations on multichain polymers lend further support to the hypothesis that gelation is the direct consequence of infinite network formation, that is, non-linearity of polymer molecules does not of itself cause gelation to occur.

The observed effects of branching on both melt and solution viscosities are smaller than might have been expected according to various speculations on this subject. Only in the case of the octachain polymers does the influence of branching (at a given molecular weight) become noticeable within the range and precision of the present experiments. It should be emphasized, however, that the influence of non-linearity may become more pronounced at much higher molecular weights. (This behavior is indicated by the melt viscosity results.)

The intrinsic viscosity probably reflects as a first approximation the effective volume of the polymer particle including the solvent which in effect flows with the particle.[28,29,30] Increase in branching at a fixed molecular weight should therefore be expected to decrease the intrinsic viscosity, in accordance with observation. This decrease, however, is much smaller than would be expected according to the change in effective volume predicted from consideration of random chain configuration.

The present results show that the intrinsic viscosity is not determined, even in rough approximation, by the length of the longest chain of the structure, as Staudinger has contended. Thus, Staudinger's[31] use of the deviation of the intrinsic viscosity from the value normally expected for a linear polymer as a direct measure of the degree of branching is wholly unjustified.

The effect of branching on melting points is small except in the low molecular weight region where the relatively large proportion of the multifunctional unit is probably primarily responsible for the observed effect because of its inability to enter the crystallites.

Note Added in Proof.—Recently Melville and Youngson[32] have reported the synthesis of branched polyesters in which the degree of branching is allegedly the same in all molecules. Their method consists in treating a polyhydric alcohol such as pentaerythritol with polymeric ethylene adipate. Contrary to the contentions of these authors, the ester interchange process whereby these multifunctional reactants are incorporated into the polymer can be counted upon to introduce the polyalcohols at random, giving rise to a statistical array of molecular species in which the number of branching units per molecule is zero, one, two, etc. Evidence that this is so is afforded by the inference that gelation[33] occurs on further polymerization.

The addition of a multifunctional reactant (RA_b) to a polymerizing system derived from A—A and B—B type bifunctional reactants leads to structural differences in the resultant polymer which must be clearly differentiated from those occurring in a system containing A—B units exclusively. Uniformity of molecular pattern is impossible to achieve in polymerizations of the former type owing to the capacity of the reactants to unite variable numbers of the multifunctional reactant in the same molecule, and owing to the inherent random nature of the reactions involved (including ester or amide interchange). In experiments not reported here[34] we have investigated the influence of our tetrabasic acid on the polymerization of a diamine with a dibasic acid, a system analogous to those investigated by Melville and Youngson. In contrast to the polymerizations reported in this paper, such a system is highly susceptible to gelation. Gel points are in satisfactory agreement with statistical theory,[33] which again substantiates the random nature of these reactions.

Summary

A general method for the synthesis of branched chain polymers, in which all chains in a given molecule are united at a central multifunctional unit, has been demonstrated. Four series of polymers have been prepared in which the number of chains subtended by the central unit is one, two, four and eight, respectively.

The logarithm of the melt viscosity for a given series of polymers varies linearly with the square root of the weight average molecular weight; $[\eta]$ is proportional to M^a.

The effect of branching in the melt viscosity and in the intrinsic viscosity relationships becomes noticeable only when the amount of branching becomes large, that is, when the branching unit functionality is increased to eight.

The Specific Refractive Increment of Some Purified Proteins

BY GERTRUDE E. PERLMANN[1] AND L. G. LONGSWORTH

A quantitative interpretation of the electrophoretic patterns of protein mixtures obtained with the aid of the Tiselius method is based, in part, on a knowledge of the specific refraction of the proteins to be analyzed. Since the patterns are recorded at 0.5° and since no precise refractive index measurements of proteins at this temperature are available, an investigation has been made of the specific refractive increment of some purified proteins. A differential prism method, developed in this Laboratory,[2] has been used in conjunction with the optical equipment of the electrophoresis apparatus. This permits data to be obtained under the same conditions as those encountered in the routine electrophoretic analysis of protein mixtures. The results of this investigation are presented in this report.

Experimental

The proteins that have been studied in this research are listed in Table I. The egg albumin and β-lactoglobulin were prepared in this Laboratory; the bovine serum albumin was obtained from the Armour Company, Chicago, and the samples of human serum albumin and γ-globulin were kindly supplied by the Department of Physical Chemistry, Harvard Medical School.[3] In the case of egg albumin the purification procedure, including three recrystallizations, was that used by Sørensen and Høyrup[4] whereas β-lactoglobulin was prepared by a modification of Palmer's method[5] and was recrystallized four times. The modification consists of the removal of casein by the addition of solid ammonium sulfate to 40% saturation. The ammonium sulfate concentration of the filtrate was then increased to 55% saturation, the precipitate discarded and the β-lactoglobulin prepared from the filtrate.

Except for the egg albumin, which was kept as a paste in a concentrated ammonium sulfate solution, all of the protein samples were stored at 2° as dry powders until used. Salt-free solutions of the albumins were prepared by dialysis against distilled water. In the case of the protein solutions containing neutral or buffer salts, a sample was dissolved in the appropriate electrolyte solution and then dialyzed against this solution.

The concentrations of all of the protein solutions, except those dissolved in the sodium diethylbarbiturate buffers, have been determined from nitrogen analysis of weighed portions by the Pregl micro Kjeldahl method with the precautions recommended by Chibnall.[6] The factors for conversion of these results to a dry weight basis have been determined as follows. In the case of the albumins, weighed portions of a salt-free isoelectric solution were used for both the nitrogen and dry weight determinations. The dried residue presumably consisted entirely of protein. In the case of γ-globulin, an isoelectric solution in aqueous sodium chloride was used and correction for the weight of the salt in the residue was made with the aid of the assumption that this was the same as in a mass of the dialysate equal to that desiccated. The factor for the β-lactoglobulin was obtained from a nitrogen determination on a desiccated sample of the solid protein, thus eliminating any uncertainty as to correction for salt in the residue.

TABLE I

NITROGEN CONTENT OF THE PURIFIED PROTEINS

		Egg albumin	Bovine serum albumin	Human serum albumin	β-Lactoglobulin	Human γ-globulin
1	Method of desiccation	100° *in vacuo*	110° in air	110° in air	110° in air	110° in air
2	Percentage of nitrogen	15.72	16.05	15.95	15.53	15.9
3	Nitrogen factor	6.36	6.23[a]	6.27	6.44	6.29
4	References to nitrogen content	4, 6	7	7, 8	6, 9	7, 8

[a] The same value is obtained with water-dialyzed and electrodialyzed samples.

Under the conditions of desiccation given in line 1 of Table I, it was found that the dried residue attained a constant weight in twenty-four hours. The resulting nitrogen factor, line 3, is in good agreement with the best values found in the literature, references to which are indicated in line 4.

The determination of the protein concentration in the presence of the barbiturate buffer will be described later in this paper.

All weight concentrations have been converted to a volume basis, *i. e.*, gram protein per 100 ml. solution, with the aid of the density data in the "International Critical Tables"[10] and in Svedberg and Pedersen's "The Ultracentrifuge."[11] In estimating the density of a given solution the specific volumes of the components have been taken as additive. Moreover, all of the proteins of Table I have been assumed to have the specific volume, 0.741, of the "average protein" as given by Svedberg.[12]

Results

Effect of Protein Concentration in Salt-Free Solutions.—As the results presented in Table II indicate, the specific refractive increment, $k = (n_{\text{solution}} - n_{\text{solvent}})/p$, of a protein is independent of its concentration, p, over a wide range of this variable, if the concentration is expressed on a volume scale, *e. g.*, g./100 ml. solution. The results in Table II, and also those in Fig. 1 below, indicate that, although the specific refractive increment varies with the protein, this variation is

Effect of Temperature on the Specific Refractive Increment.—Since the differential prism method can readily be adapted for work over a range of temperature, selected solutions have been studied at 0.5, 5, 10, 15, 20 and 25°.

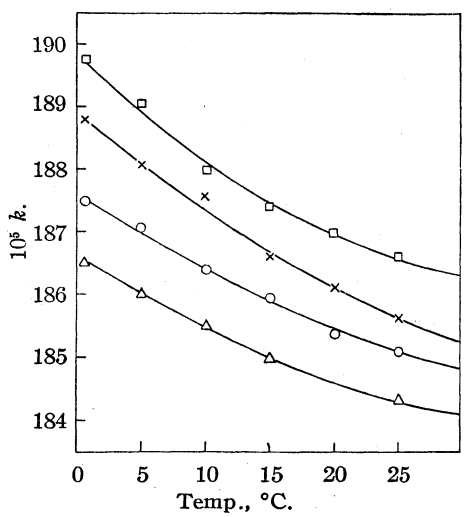

Fig. 1.—Effect of temperature on the specific refractive increment of proteins: □, bovine serum albumin; ×, human serum albumin; O, egg albumin; △, β-lactoglobulin.

These results are presented in Fig. 1 for the three albumins and β-lactoglobulin. Here the specific refractive increment, k, is plotted as ordinate against the temperature as abscissa. Contrary to the general impression, the effect of temperature on the refractive increment is not negligible for most proteins although it is smaller than that observed in the case of salts. This is shown in Table III, which also includes the results that have been obtained on some low molecular weight materials having electrical properties between those of salts and proteins. Of the substances investigated only γ-globulin had a negligible temperature coefficient.

TABLE III

COMPARISON OF THE EFFECT OF TEMPERATURE ON THE SPECIFIC REFRACTIVE INCREMENT, k, OF PROTEINS WITH ITS EFFECT ON OTHER SUBSTANCES

Substance	$k_0 \times 10^6$	$(k_0 - k_{25}) \times 10^6$

Human serum albumin	1887	+ 33
Egg albumin	1876	+ 25
β-Lactoglobulin	1865	+ 23
Human γ-globulin	1875	0

The Specific Refraction at Different Wave Lengths.—Although most of the refractive index measurements have been made at λ = 5780 Å., the mean value of the mercury yellow doublet that is isolated with the Wratten filter number 22, a few solutions have also been studied at other wave lengths. In these measurements a cadmium–mercury lamp of the H4 type is used without a filter, the cell is filled with a fairly concentrated protein solution and, with the aid of the cylindrical lens attachment, the spectral lines are observed directly in the focus of the schlieren camera. With the yellow line as reference the displacements of other lines are measured and the corresponding values of $k_\lambda - k_{5780}$ computed. In Fig. 2, values of $(k_\lambda - k_{5780})/k_{5780}$ are plotted as ordinate against the reciprocal of the square of the wave length as

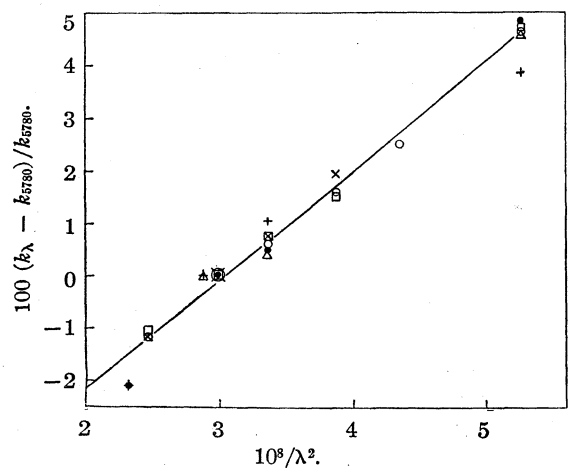

Fig. 2.—Effect of wave length on the specific refraction: □, bovine serum albumin; ×, human serum albumin; O, egg albumin; △, β-lactoglobulin; +, horse serum albumin; ●, horse serum globulin.

(13) Adair and Robinson, *Biochem. J.*, **24**, 993 (1930).

abscissa. As will be seen in the figure, all of the points, including those for horse serum albumin and globulin, and β-lactoglobulin taken from the work of Pedersen and Andersson,[14,15] can be adequately represented by a single straight line. Although the specific refraction varies somewhat with the nature of the protein it thus appears that the dispersion is essentially the same for all the proteins that have been studied. Since the slope of the line in Fig. 2 is 0.1946 the relation $k_\lambda = k_{5780}\,(0.940 + 2.00 \times 10^6/\lambda^2)$, where λ is in ångström units, may be used to obtain the specific refraction at any (visible) wave length.

The Specific Refraction of Sodium Proteinates.—The protein solutions employed in an electrophoretic analysis are usually prepared by dialysis against an appropriate buffer solution. The proteins are then present as charged particles in a solution of buffer ions whose composition is given, as a first approximation, by the Donnan equations. If the *p*H of the solution is above the isoelectric *p*H of the protein and if, as is usually the case, sodium buffer salts are employed, the protein is present as a sodium proteinate whose specific refraction differs from that of the isoelectric protein. Moreover, in addition to the acquisition of a net charge the protein may also bind some of the buffer salt. In order to distinguish between the effect of the charge and of bound salt it is essential to determine the refraction of sodium proteinate in the absence of buffer salts for comparison with the values obtained in their presence. Consequently the specific refractions of salt-free isoelectric protein solutions, to which small amounts of sodium hydroxide have been added, were determined with the results given in Table IV.

TABLE IV

EFFECT OF CHARGE ON THE SPECIFIC REFRACTIVE INCREMENT OF CRYSTALLINE EGG ALBUMIN AND BOVINE SERUM ALBUMIN

				Mean	46

In this table the quantity of alkali added is given in column 1 and the resulting *p*H of the solution in the next column. The protein concentration, column 3, is the value for the isoelectric solution after correction for the dilution due to the added alkali. If this is divided into the observed refractive increment, column 4, a specific refraction, k', column 5, is obtained that differs from the specific refraction k, of the isoelectric protein by an amount that is proportional to the net charge, e, of the protein, *i. e.*

$$k' = k(1 + ae)$$

Here the net charge is given by the values of column 1 since all of the added alkali reacts at the *p*H values studied. The computed values of the proportionality factor, a, column 6, are approximately constant and are essentially the same for the two proteins studied.

Refraction Measurements in Solutions in Sodium Chloride.—In view of the possibility that ions other than the hydrogen ion may be involved in the dissociation equilibria of the proteins, refraction measurements on these materials in solutions of the neutral salt, sodium chloride, have been made as an additional prerequisite to the study of proteins in buffer solutions. The results presented in Table V, where the specific refraction is taken as the difference, per unit concentration of protein, between the refractive indices of the equilibrated solutions, illustrate the two types of behavior that have been encountered. Thus the specific refraction of egg albumin is essentially independent of the concentration of the sodium chloride against which it has been dialyzed, whereas in the case of the bovine and human serum albumin small but significant changes occur. This is consistent with the findings of Scatchard and his associates[16] that these two materials bind some sodium chloride.

An additional feature of the bovine serum albumin used in this research also emerges from the data of Table V. Thus the k-values of 1923 and 1921 $\times 10^{-6}$ for the electrodialyzed solutions Nos. 11 and 13 differ significantly from that of 1902 $\times 10^{-6}$ for the water-dialyzed solution No. 6. If, however, water dialysis is used to remove the salt from solutions that have been equilibrated with aqueous sodium chloride, solutions Nos. 10 and 15, the values obtained, 1919 and 1920 $\times 10^{-6}$, then agree well with those for the solutions prepared by electrodialysis. The origin of these effects is obscure but, together with the observed constancy of the nitrogen factor, suggests the presence in the bovine serum albumin of a volatile, poorly refracting contaminant that is removed by electro- and saline dialysis but not by the or-

dinary water dialysis. Alcohol or decanol as the contaminant might satisfy these requirements.

Refraction Measurements in Buffer Solutions.—In the following interpretation of the refraction measurements in buffer solutions the assumptions have been made (a) that the refractions due to the various components are additive, (b) that the net charge on the protein may be obtained from the titration curve and (c) that the buffer electrolyte concentrations are given by the first term in the expansion of the Donnan equation. With the aid of these assumptions, together with the measured refractive increment, Δn-obsd., of the protein solution and that, $\Delta n'$-obsd., of the buffer solution against which it has been equilibrated, the specific refraction of the sodium proteinate has been computed as will be described in connection with Table VI. In that table, the concentrations, in equivalents per liter, of the buffer electrolytes in the dialysate, the *p*H of the protein solution in equilibrium therewith and the protein are given in the first four lines. The protein concentrations in line 5 marked with an asterisk were obtained by mixing weighed amounts of the buffer solution and the protein. Corrections were made not only for moisture content of the protein but also, by rapid weighing of the Cellophane bag and its contents before and after dialysis, for the rather large volume changes that occur during this process. In the case of the concentrations marked with a dagger a weighed sample of the equilibrated protein solution was dialyzed salt-free, transferred quantitatively to a volumetric flask and nitrogen determinations were made on weighed portions of this salt-free solution. It will be noted that the two methods of analysis lead to closely agreeing results for the specific refraction in the one instance where a comparison is possible, *i. e.*, columns III and IV of Table VI. In the phosphate buffers the protein concentration was obtained in the conventional manner since these buffer salts do not interfere with the nitrogen determination.

The sources of the values for the net charge, line 6 of Table VI, are given as footnotes whereas the equivalent concentration of the sodium proteinate, line 7, is simply $C_{NaP} = -10pe$. In the case of the diethylbarbiturate buffers the electrolyte concentrations in the protein solutions, lines 8 and 9, are given by the relations[17]

$$C_{NaR} = C'_{NaR} - {}^1/_2 C_{NaP} \text{ and } C_{HR} = C'_{HR}$$

whereas for the phosphate buffers[18]

$$C_{NaR} = C'_{NaR}\,(1 - 5C_{NaP}) \text{ and } C_{HR} = C'_{HR}\,(1 - 2.5C_{NaP})$$

Owing to small variations of the equivalent refraction with concentration and also to the difficulties of preparing some of the buffer salts for weighing, deviations of as much as 1×10^{-5} in the measured refractive increments of the buffer solutions from those computed by means of the relation

$$\Delta n' = K_{NaR} C'_{NaR} + K_{HR} C'_{HR}$$

have been observed. Here K is the equivalent refraction and, for the computations of Table VI, has been assigned the following values: sodium diethylbarbiturate, 0.04055; diethylbarbituric acid, 0.02905; Na_2HPO_4, 0.01502; and NaH_2PO_4, 0.0172. Correction for the deviations has been made by adding to the observed increment for the protein solution the small difference between the computed and observed increments for the buffer solution. The corrected values of the refractive index increment for the protein solutions are given in line 10 of Table VI.

The contribution of the buffer electrolytes to the

[a] Interpolated from data of Table IV. [b] From Cannan, Palmer and Kibrick, *J. Biol. Chem.*, **142**, 803 (1942). [c] Cohn, Strong, Hughes and Blanchard, see Edsall, *Annals N. Y. Acad. Sci.*, **47**, 223 (1946).

increment of the protein solution is given by the relation

$$\Delta n(\text{NaR} + \text{HR}) = K_{\text{NaR}}C_{\text{NaR}} + K_{\text{HR}}C_{\text{HR}}$$

line 11 of Table VI, and the difference

$$\Delta n(\text{NaP}) = \Delta n - \Delta n(\text{NaR} + \text{HR})$$

line 12, divided by the protein concentration is the specific refraction of the sodium proteinate, line 13. For comparison, the values of k for the sodium proteinates in the absence of salt have been interpolated from the data of Table IV for the pH values of Table VI and are given in the last line of that table. It will be noted that the specific increment in the phosphate buffer is essentially the same as in the absence of salt whereas in the presence of the diethylbarbiturate it is significantly greater. Although several explanations for this observation could be advanced an attractive one is that this large organic ion is bound by the protein.

Comparison with Previous Work.—As a test of the validity of the differential prism method used in this research two of the salt solutions studied by Hölemann and his associates[19,20] have been prepared and their refractive increments determined over a sufficient range of temperature and wave length to permit a direct comparison with their results. At 25° and λ = 5876 Å., the increments for 1.6692 molal sodium chloride and 1.2983 molal potassium chloride are 0.015385 and 0.011906, respectively, and are in agreement with the values of 0.01538 and 0.01190 reported by Hölemann. Additional evidence that the precision of our refractive index measurements is about $\pm 1 \times 10^{-5}$ is afforded by the following fact. At 0.5° and λ = 5780, the refractions of the solutions of potassium chloride recently used in diffusion studies[21] follow, with an average deviation of $\pm 7 \times 10^{-6}$, the simple relation, $\Delta n/C = 0.011405 - 0.00100\sqrt{C}$, over the concentration range studied, *i. e.*, 0.1 to 1.0 normal.

(21) Longsworth, THIS JOURNAL, **69**, 2510 (1947).

In the case of the specific refractions of proteins, however, the precision of the results is limited by the uncertainty in the protein concentration. As Armstrong, Budka, Morrison and Hasson have shown,[22] the presence of lipid in the protein renders particularly difficult the concentration determination. In the present research this source of error has been reduced by restricting our studies to proteins that contain minimal amounts of lipid and by controlling the nitrogen determinations with dry weight measurements. In spite of these precautions, however, in unfavorable cases the uncertainty in the protein concentration may amount to as much as one per cent. In some instances this is sufficient to mask the variation of the specific refraction from one protein to another or between different preparations of the same protein.

It is of interest that at 20° our values of the specific refraction of human albumin, 1862×10^{-6}, Fig. 1, and γ-globulin, 1875×10^{-6}, agree well with those, 186×10^{-5} and 188×10^{-5}, reported by Armstrong and associates. In the case of β-lactoglobulin, Pedersen reports[14] 1809×10^{-6} and 1812×10^{-6} as the specific refraction, at 20° and λ = 5799 Å., of two different preparations. In these measurements he used nitrogen factors of 6.61 and 6.55, respectively, that were obtained from nitrogen and dry weight determinations on aliquots of a solution of the protein in 0.5 molar sodium chloride. When analyzed similarly, our preparation of this protein gave a factor of 6.62, in essential agreement with Pedersen's values. However, when analyzed, as described earlier in this paper, in such a manner as to eliminate the uncertainty concerning the amount of salt in the dried residue, the nitrogen factor is 6.44. Correction of Pedersen's refraction data to this new factor gives $10^6 k$ = 1858 and 1843, in satisfactory agreement with our value of 1846 at 20°.

ries for his interest in this research and for suggestions in the preparation of this paper.

Summary

With the aid of a hollow, prismatic cell and the optical equipment of the Tiselius electrophoresis apparatus, the refractive index increments of solutions of some purified proteins have been measured as a function of the protein concentration, the temperature, and the wave length of the incident light. The changes in the specific refractive increment that occur on titration of the protein with alkali, in the presence of neutral salts and after equilibration with buffers have also been determined. Such data are necessary for a quantitative interpretation of the electrophoretic patterns of proteins.

Equilibrium of Iron–Carbon–Silicon and of Iron–Carbon–Manganese Alloys with Mixtures of Methane and Hydrogen at 1000°

BY RODNEY P. SMITH

Measurements of the equilibrium of iron–carbon alloys with mixtures of methane and hydrogen have been reported in an earlier paper.[1] Since most commercial steels contain various amounts of alloying elements, it is of considerable importance to know the effect of these additional elements on this equilibrium. Accordingly measurements were made of the carbon content of iron–silicon alloys containing up to 15% silicon and of iron–manganese alloys containing up to 15% manganese equilibrated at 1000°, with methane–hydrogen atmospheres of known composition. At this temperature the crystal structure of the silicon alloys may be either face-centered cubic (austenite or gamma iron) or body-centered cubic (ferrite or alpha iron) depending on the concentration of carbon and silicon. For these alloys measurements were made in the region in which austenite is stable and in the region in which ferrite is stable and an estimate is given of the phase boundaries in a portion of the isothermal section of the iron–silicon–carbon system. At 1000° the structure of the manganese alloys is austenitic at all compositions investigated. For the iron–manganese–carbon system an estimate is given of the position of the phase boundaries of the austenite–austenite+graphite and a portion of the austenite–austenite+carbide fields.

Experimental

The experimental procedure was similar to that previously described.[1] The dimensions of the samples used were about 1 × 1 × 0.4 cm. For each gas mixture a number of samples of either series of alloys and a sample of electrolytic iron were equilibrated simultaneously. The carbon content of samples containing more than 0.05% carbon were analyzed by the usual combustion method; those with less than 0.05% carbon by the low pressure combustion method described by Gurry and Trigg.[2] The silicon alloys were either milled or broken up in a steel mortar prior to combustion; the manganese alloys were burned without milling, 0.5 to 1.0 g. of Bureau of Standards sample 55b, 0.010% C, being added to start combustion.

The gas composition for each set of samples was derived from the carbon content of the electrolytic iron and the equilibrium data previously published[1] rather than from the analysis of the primary hydrogen–methane mixture and the flowmeter constants. This method has the following advantages: (1) an accurate knowledge of the composition of the primary hydrogen–methane mixture is not required; (2) it is not necessary to make corrections for the small deviations (less than ±1°) from 1000° of the furnace temperature. The minimum equilibration period was one week; that this time was sufficient was established by comparison of the analysis of the electrolytic iron, equilibrated together with a typical set of alloy samples using a primary mixture of known composition, with the results for pure iron–carbon alloys previously published.[1]

The silicon alloys of composition within the range 1.2 to 5.0% Si were commercial quality steels,[3] those between 7.0 and 15.0% Si were prepared from a high-grade ferrosilicon and electrolytic iron. Analysis of a sample of electrolytic iron and of the alloys containing 1.2 to 5.0% Si before and after equilibration with respect to carbon indicated a silicon pick up from the silica furnace tube of 0.02 to 0.06%. The results were not corrected for this small change in silicon content since its effect on the carbon concentration is nearly balanced by that of the manganese present in these alloys.

The manganese alloys were of commercial quality,[4] produced in a 250 lb. arc furnace. Since an alundum furnace tube was used in the equilibration of these alloys with respect to carbon, there was no change in their silicon content. There was, however, a small change in manganese content, that of the electrolytic iron increasing by 0.25%, that of the 14.67% Mn decreasing by 0.41%, the change in the other samples being nearly linear with the manganese content.

Results—Silicon Alloys

Equilibrium with Austenite.—The left portion of Table I gives the carbon content of the austenitic silicon alloys equilibrated with several CH_4–H_2 mixtures containing from 0.14 to 0.86% methane. The marked effect of silicon on this

equilibrium is shown better in Fig. 1, in which the weight per cent. carbon at equilibrium at 1000°, for various gas ratios, $r_1 = p_{CH_4}/p_{H_2}^2$ is plotted against the weight per cent. silicon. For a given gas ratio the decrease in carbon for each per cent. increase in silicon is roughly 10% of the carbon content of pure iron. The activity of dissolved carbon is proportional to r_1, thus each line for a given value of r_1 represents an iso-activity line, with respect to carbon.

Austenite, Austenite + Graphite Boundary.—At the gas ratio, $r_1 = 0.00950$, the gas phase is in equilibrium with graphite.[1] Therefore the iso-activity line for $r_1 = 0.00950$ gives the boundary of the single phase austenite field and the two phase austenite + graphite field. This boundary, line FB in Fig. 1, was determined by extrapolating curves of r_1, plotted against weight per cent carbon for each silicon alloy to $r_1 = 0.0095$. It may be noted that the decrease caused by silicon in the solubility of graphite in gamma iron is similar to that found by Herty and Royer,[5] in the case of liquid iron (see Fig. 2). The solubility of graphite in austenitic silicon alloys as given in Fig. 1 is somewhat higher than that given by Charpy and Cornu-Thenard,[6] and considerably higher than that given by Becker.[7] The solubility of graphite in pure iron given by Becker is lower than the value given by more recent determinations and it is probable that his values for the silicon steels are also low.

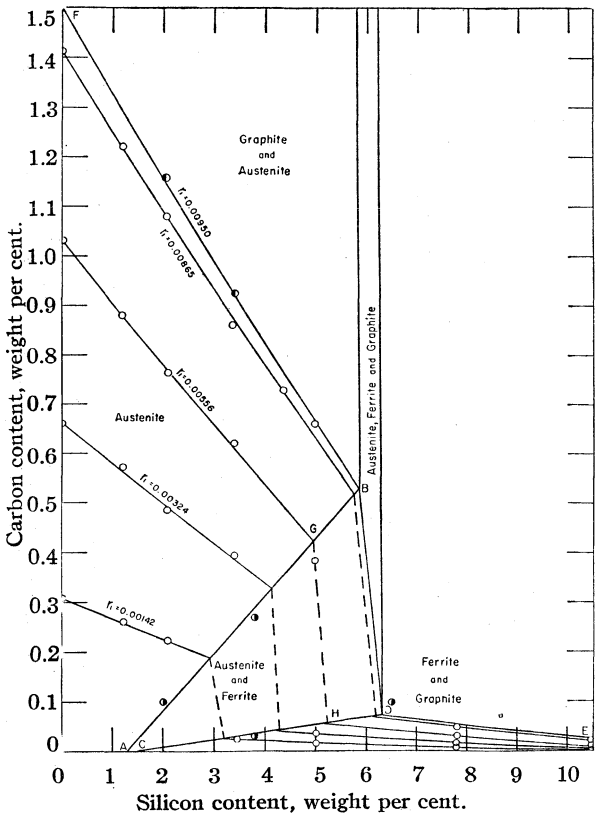

Fig. 1.—A portion of the iron–carbon–silicon equilibrium diagram at 1000°: O, experimental; ◐, extrapolated; ◑, "Alloys of Iron and Silicon"[12]; $r_1 = p_{CH_4}/p_{H_2}^2$.

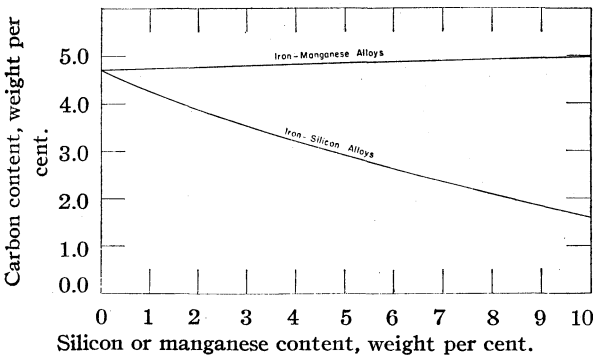

Fig. 2.—Effect of silicon and manganese on the solubility of graphite in iron at 1300° as given by Herty and Royer.[5]

Equilibrium with Ferrite.—The right portion of Table I gives the carbon content of the ferritic silicon alloys equilibrated with several CH_4–H_2 mixtures. These results are shown graphically in Figs. 1 and 5. The consistency of these results

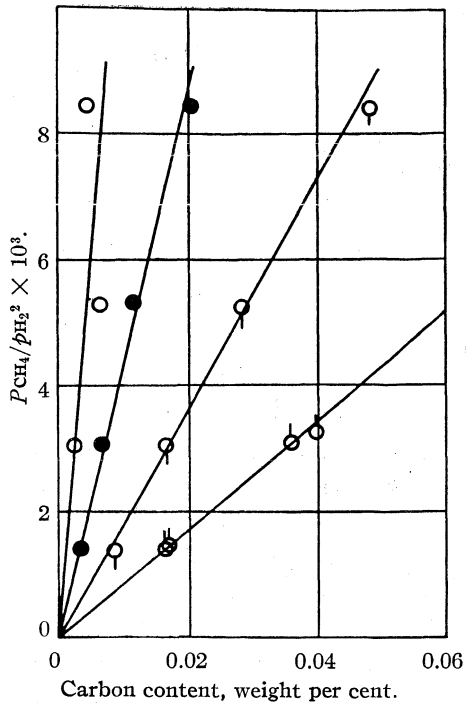

Fig. 3.—Carbon content of ferrite in relation to $p_{CH_4}/p_{H_2}^2$: ♂, 5.0% Si; ♀, 7.8% Si; ●, 10.3% Si; O, 15.6% Si.

may be illustrated better in the following manner. The activity of carbon is proportional to r_1, and its activity coefficient is inversely proportional to $\%C/r_1$ where $\%C$ is the weight per cent. carbon of a sample equilibrated with a gas whose $p_{CH_4}/p_{H_2}^2$ ratio is r_1. Since the carbon content of ferrite is always less than 0.08 weight per cent. it is reasonable to assume that, for a given silicon alloy, the activity coefficient of carbon is independent of the carbon concentration. The validity of this assumption is illustrated in Fig. 3 in which r_1 is plotted against weight per cent. carbon for the alloys containing 5.0, 7.8, 10.3 or 15.6% Si; the points fall on straight lines, within the experimental error, demonstrating that the system conforms to Henry's law, or the activity coefficient of carbon in these alloys does not change with the carbon concentration. The activity coefficient of carbon does, however, change appreciably with the silicon content for the range of concentration of 0 to 15% Si. In general log $\%C/r_1$, rather than $\%C/r_1$, will be a nearly linear function of %Si; thus if $\log \frac{\%C}{r_1}$ is plotted against weight per cent. silicon all points should fall on the same curve which will be either straight or nearly so. Fig. 4 shows such a plot; except for results for the alloy containing 15.6% silicon all the points fall on a straight line with ±10%. The curves of Fig. 5 represent smoothed results calculated from the straight line of Fig. 4 for the experimental values of r_1.

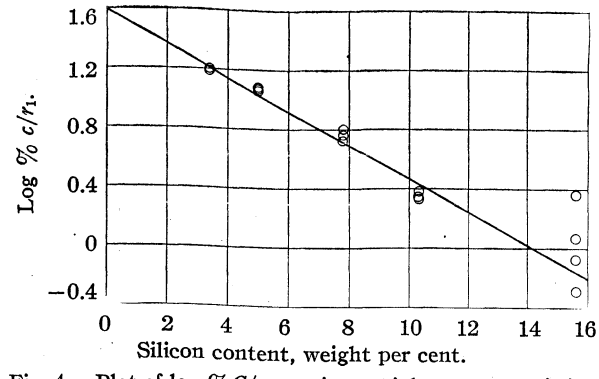

Fig. 4.—Plot of log $\%C/r_1$, against weight per cent. of silicon; $r_1 = p_{CH_4}/p_{H_2}^2$, % C = weight per cent. carbon.

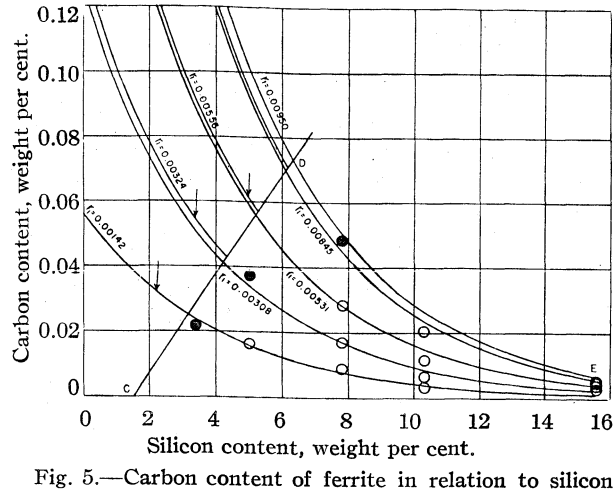

Fig. 5.—Carbon content of ferrite in relation to silicon content for various values of r_1 at 1000°: curves calculated from straight line of Fig. 4; O, ●, experimental points.

Extrapolation of the straight line, Fig. 4 to zero per cent. silicon allows the calculation of the hypothetical carbon content of alpha iron at 1000° for any given value of r_1; the corresponding carbon content of gamma iron is known,[1] thus a distribution coefficient for carbon between alpha iron and gamma iron may be calculated. The distribution coefficient, K, may be defined as

$$K = a_1/a_2 = \gamma_1 C_1/\gamma_2 C_2 \cong \gamma_1 C_1/C_2 \qquad (1)$$

where a_1 is the activity of carbon in gamma iron, when its concentration is C_1 weight per cent., a_2 is the activity of carbon in alpha iron, when its concentration is C_2 weight per cent., γ_1 and γ_2 are the activity coefficients of carbon in gamma iron and alpha iron, respectively. The standard state in each case is chosen so that the activity is equal to the weight per cent. when the latter approaches zero. The value of K at 1000° may then be compared with values calculated from the data of Smith[1] (at 800 and 1000°) and of Mehl and Wells[8] for the temperature range 723 to 849° and those of Adcock[9] at 1490° by the relation

(8) Robert Mehl and Cyril Wells, *Trans. Am. Inst. Mining Met. Engrs.*, **125**, 429 (1937).

(9) Frank Adcock, *J. Iron Steel Inst.*, **135**, 281 (1937).

$$\Delta H = -4.575 \, d \log K/(d1/T) \qquad (2)$$

where ΔH is the heat of transfer of carbon from alpha iron to gamma iron and T is the absolute temperature.

Since C_2 is always small, it is assumed that $\gamma_2 = 1$; γ_1 at 800 and 1000° may be determined from the deviation from Henry's law of the solid solution of carbon in gamma iron.[1] Within the experimental error γ_1 is the same at 800 and 1000° and in the calculation of K it is assumed to be independent of temperature. Fig. 6 shows a plot of log a_1/C_2 against $1/T$. The straight line through the points calculated from the data of Smith,[1] Mehl and Wells[8] and Adcock[9] gives 0.916 for log a_1/C_2 at 1000°. The value calculated from the equilibrium of CH_4–H_2 mixtures with austenite and the extrapolated value for ferrite, Fig. 4, is 0.826. Considering the uncertainties in each method of calculation, the agreement is satisfactory. The heat of transfer of carbon from alpha iron to gamma iron determined by equation (2) is −15,600 cal. per gram atom.[10] It may be noted that the quantity $RT \ln (3N_1/N_2)$ where N_1 and N_2 are the equilibrium atom fractions of carbon in gamma iron and alpha iron, respectively, which is considered constant with temperature by Zener,[11] varies from 9000 to 5400 cal. per mole for the temperature range 800 to 1490°.

Ferrite, Ferrite + Graphite Boundary.—The solubility of graphite in silicon ferrite, line DE, Figs. 1 and 5, was determined from the straight line of Fig. 4 and $r_1 = 0.0095$, the value for equilibrium of the gas phase with graphite.[1]

Ferrite, Ferrite + Austenite Boundary.—For the binary iron–silicon system the limit of the ferrite field at 1000° is 1.5% silicon.[12–14] This locates one terminus, C, in Fig. 1, of the boundary between the ferrite and the ferrite + austenite fields, line CD Fig. 1, for the three component system. Other points on this boundary, may be estimated in the following manner. In Fig. 5 the circles represent experimental data when the solid phase is ferrite, the vertical arrows indicate samples whose carbon content is too great for the solid phase to be ferrite for the particular value of r_1. The boundary between the ferrite and the ferrite + austenite fields lies at compositions to the right of those represented by the vertical arrows and to the left of the solid circles and is best represented by the straight line, CD Fig. 5, starting at 1.5%Si, 0%C, and which averages the difference in composition of points known to be in the ferrite field and those known to be in the austenite or austenite + ferrite fields. The other terminus of this boundary line is given by the intersection of line CD, Fig. 5, with the curve for $r_1 = 0.0095$. This intersection gives the composition for one corner of the three phase, austenite, ferrite, graphite, triangle. The position of the boundary is in fair accord with the best estimate from previous results.[12]

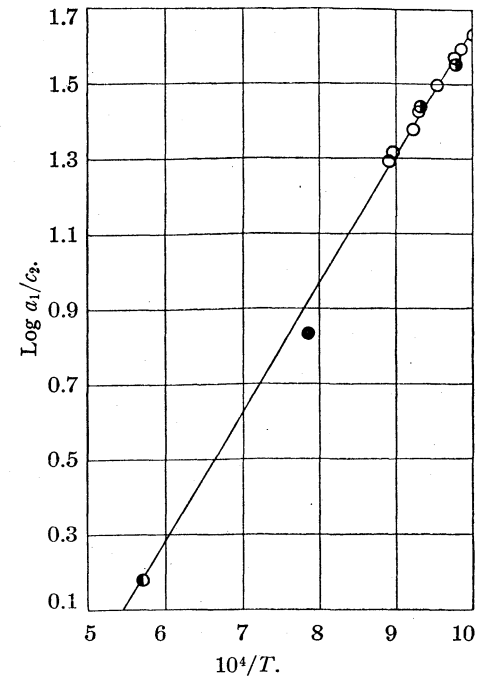

Fig. 6.—Plot of log a_1/C_2 against $10^4/T$: ◑, Smith[1]; ●, extrapolation of data for silicon alloys; ○, Smith,[1] Mehl and Wells[8]; ◐, Adcock.

Austenite, Austenite + Ferrite Boundary.—One terminus of this boundary, line AB, Fig. 1, is at 0%C, 1.3%Si.[12–14] A second point on this boundary may be estimated in the following manner. The carbon content, 0.383%C of the 5.0% silicon sample for $r_1 = 0.00556$ is below that of the smooth curve through the other points, Fig. 1, in the austenite field by an amount considerably greater than the probable experimental error. It is therefore reasonable to assume that this point lies in the austenite + ferrite field. The composition of ferrite at the ferrite, ferrite + austenite boundary in equilibrium with the gas mixture $r_1 = 0.00556$ is 0.057%C and 5.25%Si. The gross composition of all mixtures of ferrite and austenite in equilibrium with a gas of this composition will lie on a straight line, GH Fig. 1 (an isoactivity line with respect to carbon), through these two points. The intersection, G Fig. 1, of this straight line with the curve, $r_1 = 0.00556$, through the points in the austenite field gives a second point on the austenite, austenite + ferrite boundary. From these data the boundary may be represented by a straight line through points A and G, the other terminus will be at the intersection of this line with the austenite–graphite boundary. Although

(10) This result is in good agreement with the value −15,900 cal. given by the difference in heat of solution of graphite in alpha iron and gamma iron.[1]

(11) C. Zener, *Trans. Am. Inst. Mining Metal Engrs.*, **167**, 513 (1946).

the location of this boundary depends mainly on a single experimental point, it agrees well with previous estimates,[12] especially in the range 1.3 to 4% silicon.

The Activity of Carbon Relative to Graphite.—The activity, a_c, of carbon relative to graphite is given by the equation

$$a_c = p_{CH_4}/p_{H_2}^2 K_3 = r_1/K_3 = r_1/0.0095 \quad (3)$$

where K_3 is the equilibrium constant for the reaction $2H_2 + C$ (graphite) $= CH_4$.[1] Table II gives values of a_c at 1000° for austenitic silicon alloys interpolated to even values of the concentration of carbon and silicon.

TABLE II

THE ACTIVITY OF CARBON, RELATIVE TO GRAPHITE IN AUSTENITIC IRON SILICON ALLOYS AT 1000°

	%Si				
%C	0.2	0.4	0.6	0.8	1.0
0	0.097	0.195	0.301	0.424	0.563
1	.107	.226	.358	.507	.674
2	.127	.267	.427	.607	.810
3	.157	.334	.533	.762	
4	.197	.415	.662	.945	

Values of a_c for ferritic silicon alloys may be calculated from the equation of the straight line in Fig. 4 and the equilibrium constant K_3 by the equation

$$-\log a_c = 1.60 - 0.113\ (\%Si) + \log K_3/\%C \quad (4)$$

where 1.60 is the intercept of the straight line at zero silicon and −0.113 is its slope.

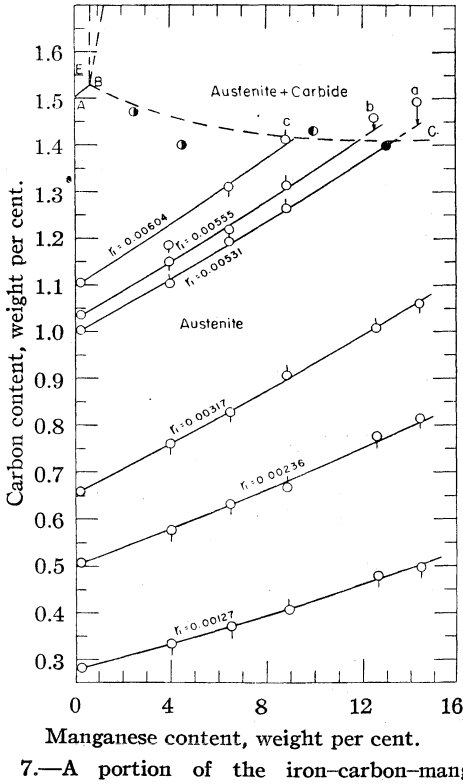

Fig. 7.—A portion of the iron–carbon–manganese equilibrium diagram at 1000°: ♁, equilibrium by carburization; ♀, equilibrium by decarburization; ◑, Gensamer[15]; ◐, Eckel and Krivobok[16]; ●, Wells and Walters[17]; $r_1 = p_{CH_4}/p_{H_2}^2$.

Results—Manganese Alloys

Equilibrium with Austenite.—The experimental results for equilibrium of CH_4–H_2 mixtures with iron–manganese alloys containing from 0 to 15% Mn, are given in Table III and shown graphically in Fig. 7. For a given gas atmosphere the carbon content increases markedly with increase in manganese. A similar, but less pronounced, effect has been observed in the case of the solubility of carbon in liquid iron–manganese alloys[5] (see Fig. 2).

[a] Microscopic examination of a polished sample indicated carbide at temperature.

The consistency of these results may be illustrated better by a plot suggested by the semi-empirical equation

$$\log r_1/N_2 + 1.86\ (1 - N_2)^2 = kN_3\ (1 - N_2) + I \quad (5)$$

where N_2 and N_3 are the atom fractions of carbon and manganese respectively at equilibrium with a gas atmosphere whose $p_{CH_4}/p_{H_2}^2$ ratio is r_1; k and I are constants. If this relation is valid all the experimental points should fall on one straight line when the left side of equation (5) is plotted against $N_3\ (1 - N_2)$. Such a plot is shown in Fig. 8, and

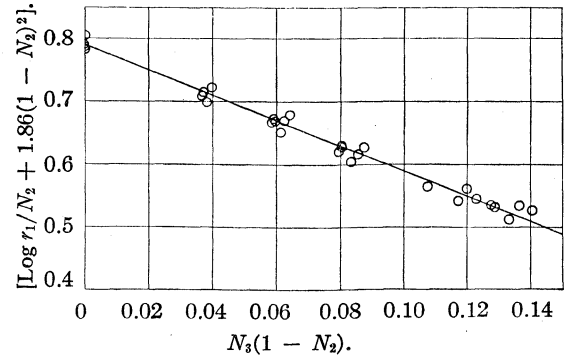

Fig. 8.—Plot of $\log r_1/N_2 + 1.86\ (1 - N_2)^2$ against $N_3\ (1 - N_2)$: $r_1 = p_{CH_4}/p_{H_2}^2$; N_2 = atom fraction of carbon; N_3 = atom fraction of manganese.

since there is no consistent deviation from a straight line it would appear that equation (5) is valid in this system within the experimental error. The greater number of the points fall on the straight line within ±5%. The slope of this line (k) is −2.05 and the intercept, I, at $N_3 (1 - N_2) = 0$ is 0.792.

Austenite, Graphite + Austenite Boundary.—It has been shown that equation (5) is valid, within the experimental error, for $r_1 = 0.0013$ to 0.006 and it is not unreasonable to assume that it also holds for $r_1 = 0.0095$, the value for equilibrium with graphite.[1] The concentration of carbon at this boundary when $N_3 = 0$ given by equation (5) is 1.47 weight per cent. A better estimate of this value, determined from a consideration of several investigations, is 1.50 weight per cent. carbon.[1] The boundary, line AB, Fig. 7, is drawn parallel to the line given by equation (5) but higher in carbon by 0.03 weight per cent. The other terminus of this line will be its intersection with the line representing the austenite, austenite + carbide boundary.

Austenite, Austenite + Carbide Boundary.—The limiting solubility of carbide in pure iron–manganese alloys has been determined by microscopic examination of quenched samples for 2.5 and 4.5% Mn alloys by Gensamer,[15] for a 10% Mn alloy of Eckel and Krivobok,[16] and for a 13% Mn alloy by Wells and Waters[17]; also for commercial quality alloys of the same range of composition by Bain, Davenport and Waring.[18] These two sets of measurements do not agree too well as to the carbide solubility but do give the same general form for the solubility curve at a given temperature. Since manganese forms an orthorhombic carbide, Mn_3C, which is isomorphous with cementite, Fe_3C, and apparently forms a continuous series of solid solutions with it,[19] it is to be expected that the extension of the solubility curve to zero Mn will intersect the carbon axis at the composition of gamma iron in equilibrium with cementite, E, Fig. 7. The boundary, line BC Fig. 7, is estimated from these data. While our equilibrium data are not sufficiently extensive to establish this boundary it may be shown that they are consistent with it. Point a, Fig. 7, has a carbon content considerably higher than that indicated by the smooth curve through the points in the austenite field and may be assumed therefore to be in the austenite + carbide field, and the boundary at 14.3% Mn must lie below 1.44%C (extension of the austenite curve to 14.3% Mn, indicated by arrow). Likewise at 12.5% Mn, point b, the boundary lies at a carbon content below 1.43%C.[20] Within the experimental error, point c, 8.84% Mn, 1.413%C, is on the smooth curve through the points for $r_1 = 0.00604$ and is therefore considered to be in the austenite field. Thus the boundary for 9 to 15% Mn lies between 1.40 and 1.43% carbon, which is consistent with the boundary as determined from microscopic examination of quenched alloys.

Activity of Carbon Relative to Graphite.—The activity, a_c, of carbon relative to graphite in austenitic iron manganese alloys is given in Table IV. The method of calculation was identical with that described for austenitic silicon alloys.

TABLE IV

THE ACTIVITY OF CARBON, RELATIVE TO GRAPHITE, IN AUSTENITIC IRON–MANGANESE ALLOYS AT 1000°

14	.050	.107	.167	.237	.318	.408

Summary

The carbon content of several iron–silicon alloys (1.2 to 15% Si) and of a number of iron–manganese alloys (4.0 to 14.5% Mn) in equilibrium with various mixtures of methane and hydrogen of known composition at 1000° has been determined. For the silicon alloys the measurements cover both the region in which the crystal structure is face-centered cubic (austenite) and body-centered cubic (ferrite).

The activity of carbon, relative to graphite, is given for each system.

An estimate is given of the phase boundaries in a portion of each of the two three component systems. The phase boundaries determined by equilibrium measurements are in good agreement with those determined by others by microscopic methods.

The Chemical Isolation of Samarium from Lanthanide Mixtures[1]

BY A. F. CLIFFORD AND H. C. BEACHELL

In efforts to separate the rare earth elements from each other a number of workers have successfully reduced from solution and isolated the elements europium[2] and ytterbium[3] in the divalent state. Samarium, however, has proved to be much more difficult to reduce in solution, although Marsh[4] has reported preparation of samarous compounds by dissolution of samarium amalgam in dilute acid and also by the simultaneous reduction of samaric and europic compounds in the presence of sulfate to precipitate the divalent ions. However, Marsh apparently found the reduction of samarium directly to the divalent state in the absence of europium to be extremely difficult.

In order to utilize the well-characterized divalency of samarium in its separation, it was proposed to employ a non-aqueous solvent to slow up the reoxidation of the divalent samarium by hydrogen ion. Inasmuch as the rare earth trichlorides are fairly soluble in ethanol and the dichlorides, like barium chloride, are reasonably insoluble, the chlorides were selected as the most likely to lead to a successful reduction. Most other rare earth salts were automatically ruled out because of insufficient alcohol-solubility in the trivalent state (fluorides, sulfates, acetates, etc.) or excessive solubility in the divalent state (iodides, etc.).

Experimental and Discussion

Preliminary experiments were carried out with a dilute solution of pure samarium trichloride (hydrated salt) (in which only faint traces of europium were detectable spectroscopically) in absolute ethanol containing a few drops of aqueous 12 *N* hydrochloric acid. It was found that when pieces of zinc, manganese, aluminum (in the presence of mercuric chloride), beryllium, thorium (which contained considerable carbide) and magnesium were added, although all reacted vigorously, only on the magnesium was there evidence of production of samarous chloride, $SaCl_2$. On the magnesium a deep red solid material formed, turning brown and disappearing when the acid became exhausted. Attempts to use calcium lithium and sodium were unsuccessful.

Identification of the substance as samarous chloride was based on its color,[5] its solubility in water to give momentarily a Bordeaux red solution,[6] its metathesis by aqueous sulfuric acid to a water-insoluble orange sulfate,[7] which was slowly dissolved and destroyed by aqueous acids, and by its metathesis by alcoholic ammonium or sodium hydroxide to a green compound,[8] insoluble in ethanol but soluble in the polar solvent formamide (with decomposition), as would be expected of a pseudo-alkaline earth hydroxide. Samarous chloride was observed to dissolve in formamide to yield momentarily a deep green solution. Since the formamide had not been especially purified, this was probably samarous hydroxide or some basic samarous salt. Also, by metathesis with aqueous solutions of the appropriate alkali salts, were prepared the fluoride (deep brownish or purplish red, water insoluble), the citrate (orange, insoluble in, but unstable to, water) and the carbonate (brownish-orange, water-insoluble). These preparations show that the green compound which Holleck[8] reported as being either "carbonate or hydroxide" was in fact the hydroxide.

Metathesis of samarous chloride with ethanolic hydrogen peroxide or formic acid or aqueous oxalate or iodate resulted in immediate oxidation of the samarous ion, in the last case with reduction of the iodate to iodine.

It was found possible to obtain an unstable orange suspension of samarous sulfate, $SaSO_4$, by treating aqueous samarium chloride containing 5–10% ethanol with magnesium and a little sulfuric acid or better by treating a solution of samaric chloride and magnesium sulfate in 1:1 aqueous methanol with magnesium and a little hydrochloric acid. This approach had the dual disadvantage of the instability of the divalent sulfate and the low solubility of the trivalent sulfate.

It was observed also that samarous sulfate was produced by magnesium amalgam in neutral or slightly acid aqueous sulfate solutions. Likewise magnesium amalgam produced samarous chloride in neutral ethanolic chloride solutions. Both reactions, however, were complicated by simultaneous precipitation of trivalent hydroxides. Thorium amalgam had no effect on an ethanol solution from which magnesium amalgam would precipitate samarous chloride.

It was decided that the optimum conditions for reduction could be obtained by using a 50–50 mixture of dioxane with ethanol saturated with strontium and barium chlorides. (The reduction was found to be successful also in acetone and isopropanol.)

Using commercial didymium chloride or chloride prepared from didymium carbonate—both being chlorides of the mixed rare earths minus cerium in the proportion in which they occur in monazite) containing about 3% samarium, and the ethanol–dioxane solvent described above, a saturated solution of the trichlorides was made. To this were added magnesium and sufficient aqueous 12 *N* hydrochloric acid to give a vigorous reaction on warming gently. When the magnesium was completely coated with red samarous chloride the mixture was cooled to allow the magnesium to settle and the liquor decanted. The product was washed with 1:2 ethanol–acetone saturated with alkaline earth chlorides (found to destroy the samarous chloride less rapidly than ethanol–dioxane). The process was repeated several times with fresh magnesium, replenishing the acid as required. From time to time it was necessary to boil the solution to near dryness and redissolve to get rid of the accumulated water. The process was brought to a halt when the magnesium content rose to the point where mixed magnesium–rare earth chlorides began to crystallize out. (This series of salts

apparently has minimum solubilities in alcohol for the lightest rare earths.) The collected product in dilute hydrochloric acid solution was analyzed spectrophotometrically for samarium and neodymium. By comparison of the two values, the samarium content was found to have been increased from 3 to about 30% of the total rare earths. A reprocessing of the product further increased the samarium content (on the same basis) to 74%.

Using ethanol without dioxane and bubbling in hydrogen chloride gas instead of using the aqueous acid, the reduction was repeated with somewhat better separation. Too high a hydrogen chloride concentration was found to prevent the formation of samarous chloride, but when only sufficient gas was present to cause gentle evolution of hydrogen from the magnesium, samarous chloride formed readily on the metal. Using the didymium chloride previously described, after a short initial period of reaction, a suspension of particles of free samarous chloride began to appear. The free samarous chloride thus formed was stable in the medium and could be readily centrifuged down. One batch of solid samarous chloride was observed to be apparently unchanged after being in contact with this liquid for twenty-four hours. It was possible to wash the free salt with acetone without much oxidation, but not with ethanol. This product was of greater purity, as regards rare earths, than that of the previous run, the first product in this case having better than 55% samarium as compared with 30% in the former case.

It was found that addition of dioxane under these conditions resulted in an orange-colored product much more sensitive to hydrogen chloride concentration. The use of dioxane in the anhydrous method was therefore considered undesirable.

It was attempted to reduce samarium out of similar solutions containing all the rare earths in their ratio in monazite sand (cerium about 48%, samarium 1–2%). The material used contained considerable iron. Neither hydrous nor anhydrous reduction was successful. However, when the material was freed from iron and the ethanolic solution diluted with more than an equal volume of dioxane, the hydrous method did give a reduced samarium compound. The compound obtained, however, was not the expected red chloride but the green hydroxide, even with fairly large quantities of hydrochloric acid. That this compound was the hydroxide, or at least a basic salt, was strongly indicated by the fact that it was metathesized by ethanolic hydrogen chloride to the red samarous chloride. Furthermore, it had previously been observed that in solutions containing too much water for formation of samarous chloride, a very thin film of greenish material formed on the surface of the reacting magnesium where presumably the hydrogen ion concentration was depleted.

No reduction was obtained from these solutions by the anhydrous method even with iron-free material. This particular reaction is probably of no use as a separation method due to the tendency of the trichlorides to crystallize out of the dioxane solution, but may be of use as a qualitative test.

Specific tests on more concentrated samarium solutions showed that the presence of iron in small quantity, although apparently making reduction more difficult, did not completely prevent reduction. Much more harmful was the presence of platinum. Reduction was never obtained in a solution which had contained platinum even after repeated reduction by magnesium and centrifuging out of the platinum metal. Apparently very minute traces of platinum (presumably under these conditions colloidal metal) catalyzed the reverse reaction, the oxidation of samarous by hydrogen ion, faster than the samarium could be reduced. The effect of colloidal metals on similar reductions has already been noted by Marsh.

The specificity of magnesium (E_0 = 2.3 v.) in the reaction and the inability of thorium (E_0 = *ca.* 2.0 v.) to perform the reduction seem to place the normal oxidation potential for the samarous–samaric couple in ethanolic chloride solution between 1.9 and 2.3 v.

Compared with Laitinen's[9] experimental result of 1.15 v. for the ytterbous–ytterbic couple (for which Latimer[10] estimated 0.6 volt) a potential around 2 v. is much more likely than Latimer's estimate of 0.8 v. The extreme sensitivity to even the small hydrogen-ion concentration in absolute ethanol would appear to support the evidence for this high potential. It should be noted that this is somewhat greater than the normal reduction potential which would be deduced from the first wave of Noddack and Bruckl's[11] polarographic reduction of aqueous samarium sulfate—E_0 = 1.72 v.

Considering the relative reduction potentials of samarium, ytterbium, and europium, it becomes apparent that the first batch of samarium reduced should carry with it all the europium and ytterbium in the solution in the same way as their concentration by sulfate precipitation has been reported by Marsh, thus affording a very convenient means of concentrating these elements to the point where they can be separated from the samarium by the methods already reported in the literature. It is highly possible that thulous chloride, $TmCl_2$, can be prepared from thulium concentrates in the same way.

Acknowledgments.—We should like to express our gratitude to the Wolff–Alport Chemical Corp. of New York, and especially to the Lindsay Light and Chemical Company of Chicago for their very generous contributions of rare earth concentrates for this research.

Summary

Samarium has been separated from the other rare earth elements (except europium and ytterbium) by reduction of ethanolic solutions of rare earth trichlorides with magnesium and hydrochloric acid (aqueous or anhydrous), yielding red samarium dichloride, $SaCl_2$. Using aqueous hydrochloric acid and diluting largely with dioxane, even from very low samarium concentrations green samarous hydroxide is produced directly instead. This reaction may be of significance for qualitative detection of samarium. By metathesis of the dichloride, the sulfate (previously prepared), the hydroxide, citrate, carbonate and fluoride (new compounds), all water-insoluble, have been prepared. The poisoning effect of iron and particularly platinum on the reduction has been noted. In neutral ethanolic solution, samarous chloride was precipitated by magnesium amalgam. The reaction, however, was complicated by hydroxide precipitates. In neutral aqueous sulfate solution, samarous sulfate was likewise precipitated by magnesium amalgam, with the same complications. Addition of a little methanol in the last case aided the reaction. The potential for the samarous–samaric couple in ethanolic chloride solutions has been placed in the region of 1.9–2.3 v.

Long Range Enzymatic Action on Films of Antigen

BY ALEXANDRE ROTHEN

The work reported here deals with the mode of action of two proteolytic enzymes, trypsin and pepsin, as well as that of the specific enzyme capable of depolymerizing the polysaccharide from Type III pneumococcus. This is a logical continuation of work previously published[1] on reactions between films of antigen and antibody molecules, where it was shown that specific forces between antigen and antibody seemed to extend considerably in space. In these experiments antigenic protein films were spread on water from which they were transferred onto polished metal slides. The slides were then coated with blankets of various inert materials and finally a drop of dilute solution of the corresponding immune serum was spread over each blanket. After the slide was washed, specific adsorption of antibody could be detected, the amount of which decreased regularly with the increase in thickness of the blanket. The probability that the antibody molecules reached the antigenic layers by diffusing through the blanket was for several reasons considered to be remote. The conclusion was therefore reached that the antibody molecules might actually be held on top of the slide by specific forces extending through the thickness of the blanket.

The analogy between immunological and enzymatic reactions naturally led to the question whether enzymes might not also exert their action through a blanket. In this case the interaction would be of such a nature as to bring about the breakdown of substrate molecules. Therefore, the film technique was extended to investigate possible long range enzymatic action.

When a slide covered with one or many monolayers of protein antigen is treated with a homologous immune serum, a specific adsorption of antibody occurs. However, no such adsorption takes place if the layers have been first treated for a few seconds with a pepsin or trypsin solution at the proper *p*H. Similarly, a monomolecular layer of the polysaccharide from Type III pneumococcus will adsorb a considerable thickness of homologous antibody but is no longer able to do so after being treated briefly with a solution of the enzyme which depolymerizes the polysaccharide. Thus the immunological reaction occurring between films of antigen and antibody molecules may be utilized as a very convenient and highly sensitive detector of enzymatic action.

The experiments devised to detect a long range enzymatic action were very simple. The antigenic layers—bovine albumin or polysaccharide from Type III pneumococcus—were deposited on a metal slide and coated with a screen of inert material, such as barium stearate or formvar (a formaldehyde polyvinyl polymer). A drop of the appropriate enzyme solution was then spread on the screen and allowed to remain for five to ten minutes. After the enzyme solution was washed off, the slides were treated directly with homologous antibody and the increase in thickness which followed was compared to that obtained on a screen of similar thickness when no enzyme treatment had been applied. (Advantage is thus taken of the long range interaction between antigenic films and antibody molecules to disclose a possible long range enzymatic action on the antigen films.) A far more satisfactory method, however, was to dissolve away the blanket after the enzyme treatment, and then to apply the antiserum directly on to the antigenic layers. It was found possible to remove formvar films with ethylene dichloride without impairing the immunological reactivity of either the protein antigen films or the adsorbed polysaccharide molecules underneath. The removal of the barium stearate screens was more difficult to carry out and was always accompanied by a partial loss of the immunological reactivity of the layers.

The experiments showed indeed, as reported in two preliminary notes,[2] that enzymatic action takes place in spite of an intervening blanket and that this action does not appear to result from actual diffusion of the enzyme molecules through the blanket. If our conclusions are correct it means that no intimate contact between substrate and enzyme molecules is necessary for the enzymatic action to proceed. This is of fundamental importance from a physical as well as from a biological point of view.

Experimental

The technique used in this work is essentially the same as that described in the preceding paper[1] dealing with immunological reactions. The thickness of transferred or adsorbed films was determined optically by measuring the change that occurs in the ellipticity of polarized light after reflection from a film coated slide. The instrument developed for this purpose is the ellipsometer, which is characterized by a half shadow end-point made possible by reference films deposited on the slides to serve as optical gage.[3] Previous papers[1-3] should be consulted for the description of this instrument as well as for the experimental details concerning the preparation of the optical gages and their conditioning with uranyl acetate, the spreading of films and their transfer onto metal slides, the deposition of the blankets or screens, the treatment with antisera, the washing of the slides, and the optical measurement of the film thickness.

Enzymes.—Crystalline pepsin and crystalline trypsin in concentrations of 0.04% with respect to protein were used, unless otherwise stated. The samples of crystalline trypsin contained 60% magnesium sulfate. Pepsin was

(1) A. Rothen, *J. Biol. Chem.*, **168**, 75 (1947).

(2) A. Rothen, *ibid.*, **163**, 345 (1946); **167**, 299 (1947).

(3) A. Rothen, *Rev. Sci. Instruments*, **16**, 26 (1945).

dissolved in 0.02 *M* hydrochloric acid and trypsin in a veronal buffer *p*H 7.5 (0.05 *M*). The solution containing the depolymerase for the polysaccharide was of unknown concentration but a range of dilutions from one to five were used.[4] The medium was a phosphate buffer *p*H 7.2.

Antisera.—Antisera were diluted 0.1 with a phosphate buffer *p*H 7.2 containing 1% sodium chloride as described previously. Rabbit antibovine albumin sera and rabbit and horse antipneumococcus Type III sera were used.

Bovine Albumin Films—Antibovine Albumin Rabbit Sera. Pepsin Action.—Two to six unfolded monolayers of bovine albumin were transferred onto slides covered with an uranyl conditioned optical gage of one and three (or two and four) monolayers of barium stearate. A drop of pepsin solution deposited on the layers for one minute brought about a decrease in thickness from 8 to 30 Å. depending on the number of monolayers of bovine albumin. No increment in thickness occurred after subsequent treatment with homologous antiserum, which demonstrated that the remaining unfolded antigen films had been completely inactivated by the enzyme. A solution of 0.02 *M* hydrochloric acid alone could detach in one minute all layers transferred onto a slide except the first two. In this case, however, these remaining layers were not inactivated, as was indicated by an increase in thickness of 60 Å. after homologous antiserum treatment. When a blanket of one double layer of barium stearate about 50 Å. thick was deposited on two transferred double layers of bovine albumin, no change in thickness resulted from pepsin treatment and no adsorption of antibody occurred on subsequent antiserum treatment. If a drop of 0.002 *M* hydrochloric acid was substituted for the pepsin–hydrochloric acid solution, the antiserum treatment produced an increment of 40 Å. Similarly, slides with three double layers of bovine albumin coated with two double layers of barium stearate exhibited significant differences between those treated with hydrochloric acid alone and those treated with pepsin. A layer of antibody about 40 Å. thick could be adsorbed on the hydrochloric acid treated slide, but no change or even a considerable decrease in thickness occurred on the pepsin treated slides.

These experiments demonstrate that pepsin solutions are capable of destroying, through at least two double layers of barium stearate, the specific capacity of bovine albumin layers to react with antibody molecules. The fact, however, that the acid medium used for dissolving the pepsin is by itself capable of detaching some of the antigenic layers from the slides, made this enzyme unsuitable for a systematic research on account of the difficulty in differentiating the true enzymatic action from that of the medium.

Trypsin Action.—Trypsin proved an ideal enzyme to investigate, since a veronal buffer at neutral *p*H, in which the enzyme is most active, does not remove multilayers of protein from the metal slides except in one case which will be discussed later.

Conditioned slides covered with one, two or three double layers of bovine albumin were treated for three minutes with trypsin. A decrease in thickness of about 9 Å. occurred when there was one and a decrease of about 18 Å. when there was more than one double layer of bovine albumin. No significant increase in thickness followed antiserum treatment. No change in thickness and no inactivation resulted from treating the slides with the buffer alone.

When one to three double layers of bovine albumin were coated with one double layer of barium stearate, no change in thickness followed trypsin treatment. There was an increase of 9 to 17 Å. when the blanket consisted of two or more double layers of barium stearate. Subsequent treatment with a homologous antiserum caused the removal of most of the stearate layers except when there was only one underlying double layer of bovine albumin, in which case no change or a very slight decrease of a few Å. units was observed.

The results showed that in spite of a blanket as thick as five double layers of barium stearate, the trypsin molecules were capable of undermining the architecture of two or three double layers of bovine albumin underneath. The anchorage of the blanket was weakened to such an extent that the barium stearate molecules were washed away by the antiserum treatment. It appears as if the foundations upon which the structure of the layers of barium stearate were built had disintegrated under trypsin action. No such removal of the blanket took place after serum treatment if the slides were not submitted to trypsin action.

It was shown in a preceding article[1] that conditioning deposited layers of bovine albumin with uranyl acetate reduced the amount of antibody which could subsequently be adsorbed. In an analogous way, trypsin action on antigenic layers of bovine albumin is considerably reduced by conditioning. For example, inactivation of conditioned multilayers of bovine albumin does not occur following a two-minute trypsin treatment. The results obtained on inactivation by trypsin of three conditioned double layers of bovine albumin through intermediate blankets of barium stearate are summarized in Table I.

TABLE I

TEN MINUTE TRYPSIN ACTION THROUGH BLANKETS OF BARIUM STEARATE MULTILAYERS ON THREE CONDITIONED DOUBLE LAYERS OF BOVINE ALBUMIN (U BOV ⇵)$_3$ DEPOSITED ON A GAGE OF BARIUM STEARATE

The figures in the table stand for the increase in Å. units observed after treatment with antiserum

	Blanket, number of monolayers of barium stearate					
	0	1	2	4	6	10
Trypsin treatment	40[a]	70	30	15	18	10
No trypsin treatment	135	110	100	85	60	25

[a] 10 Å. in 20′.

There was one conditioning treatment after each "round trip" (⇵) deposition but none after the last one. The system of layers can be represented by the symbol (U bov ⇵)$_3$ where U stands for one uranyl conditioning. The trypsin solution was left for ten minutes on the slides. If we compare the figures of the two horizontal rows it appears that a significant difference in the thickness of the adsorbed layers of antibody, between the slides treated with trypsin and the slides not so treated, is still noticeable with blankets up to three double layers of barium stearate ($\simeq$150 Å.). These experiments indicate that the range of action of trypsin extends at least as far as the distances at which interaction between antigenic layers and antibody molecules can be demonstrated. By the very nature of the test, it cannot be said whether this action extends even farther. Uranyl conditioning between the deposited antigenic layers produced such a stabilizing influence that, in spite of the enzyme treatment, the blanket of barium stearate was never removed by the antiserum treatment. This stabilizing action of the uranyl ions may be twofold, first, in restricting the disintegrating effects set up in the bovine albumin layers by the enzyme, second, in holding together the fragments of the broken down molecules of the layers in such a way as to offer still a firm anchorage for the molecules of the blanket.

Obviously, in order to evaluate the maximum thickness of blankets through which trypsin molecules can act, the blanket should be removed after the enzyme treatment and prior to the deposition of the antiserum. It will be seen later than this can be accomplished easily with blankets of formvar. The removal of the blankets of barium stearate without impairing the optical gage of barium stearate underlying the antigenic layers proved a more

(4) I am very much indebted to Dr. M. Kunitz for the samples of crystalline trypsin, and to Dr. O. T. Avery for the depolymerase solution.

delicate task. The problem was solved by using an optical gage of one and three, or three and five monolayers of octadecylamine instead of barium stearate. The slides were conditioned by uranyl acetate as usual. To remove the barium stearate blankets the slides were first treated with a citrate buffer *p*H 3.6 (0.057 *M*) for a minute or so to liberate the free stearic acid which was then leached off with ethylene dichloride or benzene. The optical gage of octadecylamine was unaffected by virtue of the insolubility of the salt of the amine in organic solvents.

Some experiments were made with blankets of octadecylamine which could be removed without affecting an optical gage of barium stearate layers. The blankets of amine were removed by treating the slides with a dilute solution of ammonia (0.01%) and then with benzene. Thus by taking advantage of the large difference in solubility in organic solvents between the salt of the acid and the free base (or between the free acid and the salt of the amine) it was possible to remove a blanket made of barium stearate without affecting an amine optical gage and vice versa.

The influence of blankets of octadecylamine on trypsin action have been summarized in Table II.

TABLE II

SIX MINUTE TRYPSIN ACTION THROUGH BLANKETS OF OCTADECYLAMINE COVERING MULTILAYERS OF BOVINE ALBUMIN DEPOSITED ON CONDITIONED BARIUM STEARATE GAGES

The figures represent the increment in Å. units observed after treatment with the immune serum, following removal of the blanket. The subtitles "buf." and "try." indicate whether the slides were submitted to "buffer" or "trypsin" before the dissolution of the blanket. The duration of the "trypsin" or "buffer" treatment was six minutes. The letter R indicates that the blanket was detached by the trypsin treatment.

Blanket, number of double layers of octadecylamine	Number of bovine albumin double layers (⇃↾) 1 Buf.	1 Try.	2 Buf.	2 Try.	3 Buf.	3 Try.
0	60	0	120	0	185	0
1	57	25		17		
2	38	38		17		
3	34	36		18		
4		37		48		R0
5			59	58		R0
6				54		
7			58			18
8				58	73	46
10					67	67 or less

In all these experiments the blankets were dissolved before the application of the antiserum. It is shown in the table that the removal of the screen sufficiently disrupted the system of multilayers of bovine albumin so that even without enzyme treatment the thickness of the antibody layer which could subsequently be adsorbed was considerably reduced. The thickness of the antibody layer dropped from 185 to 73 Å. in the case of three double layers of antigen. The difference, however, between "buffer" and "trypsin" treated slides is sufficiently large to permit definite conclusions to be drawn. A screen of two double layers of octadecylamine completely protects one underlying double layer of bovine albumin. Five double layers of octadecylamine are necessary when there are two double layers of bovine albumin underneath. Finally, a blanket as thick as ten double layers was needed to protect three double layers of bovine albumin. It also appears that with two double layers of bovine albumin, whether the blanket had been one, two, or three double layers thick, the thickness of antibody adsorbed was about 17 Å. This probably results from the fact that the first antigenic layer directly attached to the gage is more resistant toward trypsin than the others. Indeed, without a blanket, multilayers were nearly completely inactivated in a few seconds; there remained, however, a small but definite power for adsorbing specific antibody, corresponding roughly to that of one single layer. Even after a three-minute trypsin treatment a specific increment of antibody of 10 Å. could still be observed. Complete inactivation occurred, however, in a few seconds if the slides coated with a conditioned gage were first covered with one single or one double layer of egg albumin before the deposition of the bovine albumin layers. This procedure thus ensured a more uniform sensitivity of the bovine albumin multilayers toward trypsin and it is for this reason that it has been used in nearly all the following experiments.

Some of the results obtained with screens of barium stearate have been summarized in Table III.

TABLE III

SIX MINUTE TRYPSIN ACTION THROUGH BLANKETS OF BARIUM STEARATE COVERING MULTILAYERS OF BOVINE ALBUMIN DEPOSITED ON CONDITIONED GAGES OF ONE AND THREE LAYERS OF OCTADECYLAMINE

All slides after deposition of the blanket were treated for six minutes with a trypsin solution (active) or a solution of trypsin which had been brought to a boil for a few minutes (inactivated). After dissolving the blankets, the slides were treated with the antiserum. The figures stand for the increments observed in Å units. The letter R indicates when the blanket was removed by trypsin treatment. "ov" and "bov" stand for ovalbumin and bovine albumin, respectively.

System of antigenic layers	Enzyme treatment	Blanket, number of double layers of barium stearate 1	2	3	4	5
ov ↑ bov ↑	Active	25				
	Inactivated		45			
ov ↑ bov(↑)$_2$	Active	15	26			
	Inactivated		46			
ov ↑ bov(↑)$_3$	Active	0	2			
	Inactivated		57			
ov ↑ bov(↑)$_4$	Active	0	0	0	0	0
ov ↑ bov(↑)$_5$	Active	0	0	R	R	R
ov ⇃↾ bov ↑	Active	10				
ov ⇃↾ bov(↑)$_2$	Active	0	0	8		
ov ⇃↾ bov(↑)$_3$	Active	0	0	0		
ov ⇃↾ bov(⇃↾)	Active	0	18	36	42	45
	Inactivated		48			
ov ⇃↾ bov(⇃↾)$_2$	Active	0	0	0		10
	Inactivated			86		
ov ⇃↾ bov(⇃↾)$_3$	Active	0	0	0	0	0

As in the experiments of Table II, the removal of the blanket produced partial inactivation (see Fig. 4 of ref. 1). The table shows that the greater the number of layers of bovine albumin the thicker the blanket needed for protection. It also appears that the mode of deposition of the antigenic layers is of importance. Inactivation could occur through blankets of greater thickness when the bovine albumin layers were deposited on the way up (↑↑)$_n$ by successive emersions than when they were deposited by successive immersions and emersions (⇃↾)$_n$. The depositions by emersion were accomplished by immersing the slides into the tray before the protein had been spread. In the deposition by successive immersion and emersion the protein film was spread before immersing the slides. With the antigenic system ov ⇃↾ bov (↑)$_6$, complete inactivation occurred through twenty double layers of barium stearate and twenty-five double layers were needed to ensure complete protection. This very

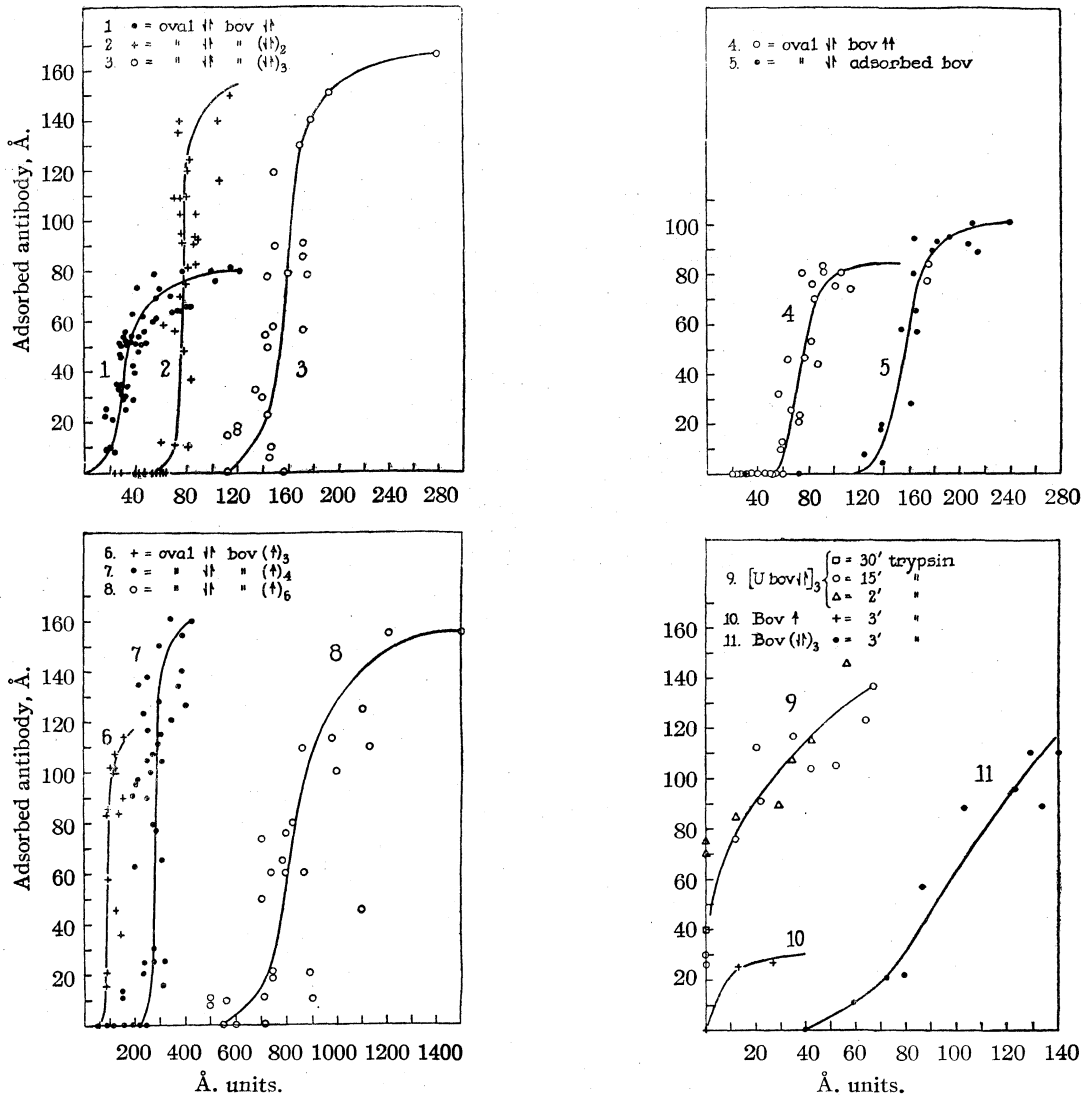

Fig. 1.—Inactivation of films of bovine albumin by trypsin through intervening blankets of formvar.

fundamental difference in the behavior of "up" and "down-up" layers will appear even more strikingly in the results obtained with blankets of formvar described in the next section.

Formvar Blankets.—Blankets of barium stearate or octadecylamine were not entirely satisfactory for two reasons, first the removal of the blankets produced a certain amount of inactivation, second the blankets were often removed by the enzyme treatment when there were three double layers of antigen underneath. Such disadvantages were not encountered with formvar blankets.

All the results obtained with screens of formvar have been summarized in Fig. 1. The abscissas give the thickness in ångström units of the formvar blankets present during the trypsin treatments and the ordinates, the amount of antibody adsorbed after removal of the blanket.

The conditions required for reproducibility of the results are very rigorous and traces of impurity appear to play an important role. Variations in results were more apt to occur between experiments carried out on different days than between results obtained with slides treated simultaneously. Experiments with one or two monolayers were more consistent than similar experiments made with multilayers. In other words, the phenomenon of coöperation between successive layers is very sensitive to small variations in experimental conditions.

Figure 1 summarizes experiments made with one, two and three double layers of bovine albumin deposited by the "down-up" process or the "up" process on slides covered with a conditioned gage of three and five layers of barium stearate plus one double layer of egg albumin. The abscissas show the thickness of the blanket of formvar upon which the trypsin solution was deposited, and the ordinates, the thickness of antibody specifically adsorbed after removal of the screen with ethylene dichloride. It is evident from the curves that the thickness of a formvar blanket needed for protection against trypsin action increases with the number of bovine albumin layers, in harmony with what was found with blankets of barium stearate and octadecylamine. A blanket of formvar about 180 Å. thick is necessary to protect three double layers of bovine albumin whereas for one double layer of bovine albumin 70 Å only will suffice. It is to be noted that all curves rise very sharply ($\partial y/\partial x \rightarrow \infty$) at a critical thickness of blanket.

Time Factor.—In all these experiments, the trypsin solution was left on the blankets for ten minutes. The time factor was investigated wtih the system ov ⇵ bov

$(\Updownarrow)_2$. It was found that essentially the same curve was obtained whether the enzyme solution stayed for five minutes or fifteen minutes on the slides. The amount of specifically adsorbed antibody, however, was only 35 Å. instead of 80 to 85 Å. if the trypsin solution was left for four hours on a blanket 160 Å. thick deposited on one double layer of egg albumin plus one double layer of bovine albumin.

When the layers of bovine albumin were deposited on the way "up" curves 4, 6, 7, 8 and 10 of Fig. 1 were obtained. It is evident from comparing the results presented in Fig. 1, that the mode of deposition of the antigen layers has a tremendous effect on the thickness of the blanket needed for protection. A blanket of 100 Å. is sufficient to protect the antigenic pile ov $\Updownarrow$ bov $(\Updownarrow)_2$, but the protective thickness has to be increased to about 260 Å. when the antigenic pile has the structure ov $\Updownarrow$ bov $(\uparrow\uparrow)_2$. The total thickness of the protein layers was the same in both cases.

A formvar blanket 600 Å. thick offered practically no protection at all for six layers of bovine albumin deposited on the way up and the impressive thickness of 1,000 Å. was necessary to keep the protein layers completely active. It was, therefore, of importance to determine whether or not a system of "up" layers without blankets was much more labile toward trypsin action than a system of "down-up" layers. If this were so, it could be argued that the difference in behavior of the two types of systems toward trypsin in the presence of a blanket was due to a small amount of trypsin which might have diffused through the blanket and would be capable of inactivating the "up" layers and not the "down-up" layers on account of difference in stability. The inactivation of the two types of multilayers without blanket, was therefore investigated as a function of the concentration of the trypsin solutions. The experiments were carried out at 4° for the following reasons. It was observed that at room temperature (20°) the veronal buffer was by itself capable of removing the equivalent of three to four layers of an "up" system of multilayers, but none at all if the layers had been built up by the "down-up" process. At 4°, however, the veronal buffer did not remove any of the layers of either system. It is of importance to note that a system of six "up" layers once coated with a formvar blanket does not lose any thickness following a veronal buffer treatment of ten minutes at room temperature. In other words, unfolded bovine albumin molecules cannot diffuse through a formvar blanket. The results which have been summarized in Table IV show that a system of "up" layers is inactivated slightly faster than a system of "down-up" layers, but this small difference cannot account for the large difference in the thickness of formvar blankets needed for protection against trypsin action.

TABLE IV

INACTIVATION OF MULTILAYERS OF BOVINE ALBUMIN BY TRYPSIN

Figures in columns 2 and 3 represent the thickness in Å. units of adsorbed antibody after treatment of the multilayers by trypsin solutions at 4° for ten minutes.

Concentration trypsin mg. per cc.	ov $\Updownarrow$ + bov $(\uparrow)_6$	ov $\Updownarrow$ + bov $(\Updownarrow)_3$
0.4	0	0
.008	48	66
.004	80	95
.0008	160	160

The case represented by curve 5 of Fig. 1 is particularly interesting. All the bovine albumin films described so far were formed on a water surface and then transferred onto the slides. Bovine albumin molecules, however, can be adsorbed directly by depositing a drop of solution on the metal slides. In this case whatever unfolding of the molecules takes place is not complete, since the average thickness of an adsorbed layer was consistently found to be between 17 and 18 Å. This thickness is equal to that of two monolayers of unfolded molecules. The thickness of the blanket needed for protection, however, was about 180 Å., twice the thickness necessary to protect two "up" layers.

Conditioning of the antigen layers with uranyl acetate greatly diminished the thickness of the blankets in formvar needed for protection, as is plainly shown in curves 9 and 11 of Fig. 1. Fifty ångströms of formvar offer no protection for three double layers of bovine albumin, but ensure nearly total protection for the system of layers (U bov $\Updownarrow)_3$.

Curve 10 shows that a blanket of formvar as thin as 20 Å. completely protected against inactivation one monolayer of bovine albumin deposited on the way "up."

Since the thickness of a blanket needed for protection increases with the number of layers of bovine albumin underneath, it was of interest to determine whether a thicker blanket was also needed if layers of egg albumin were substituted for some of the bovine albumin layers. As it will be seen later trypsin acted upon egg albumin layers just as easily as upon bovine layers in destroying their property of reacting with immune sera. The following systems of layers were deposited on conditioned gages of barium stearate: (ov $(\Updownarrow)_2$ bov $\Updownarrow$), (ov $(\Updownarrow)_4$ bov $\Updownarrow$) and (ov $\Updownarrow$ bov $\Updownarrow$ ov $\Updownarrow$). The curve of inactivation as a function of the thickness of the screen was very much the same for all three systems and intermediate between curves 1 and 3 of Fig. 1.

Polyvinyl Chloride Blankets.—A few experiments carried out with blankets of polyvinyl chloride indicated that the screening action was analogous to that offered by blankets of formvar.

Metallic Blankets.—Metallic blankets of gold were deposited by evaporation in high vacuum directly onto transferred films of bovine albumin. It was found, however, that a thin blanket of gold 20 Å. thick evaporated onto three double layers of bovine albumin prevented any specific adsorption of homologous antibody. (In the case of the polysaccharide from pneumococcus Type III, a specific adsorption of antibody still occurred through 50 Å. of gold.) It was impossible to remove the gold once it was evaporated on the protein layers. Thus slides coated with bovine albumin layers and a blanket of gold obviously could not be used to detect any trypsin action through the blanket because of the lack of means to determine whether or not inactivation had occurred. Of all the methods tested to detect trypsin action through metallic blankets the one most satisfactory was as follows. Gold films were deposited by evaporation *in vacuo* on clean microscope slides. Thin films of formvar were then deposited on top of the gold by dipping the slide into a solution of formvar in ethylene dichloride. When the formvar film was detached from the slide and floated on a water surface, the gold film adhered to the formvar, with the result that the gilded face of the formvar film was in contact with the water surface. Such gilded blankets were transferred from the water surface onto the antigenic films coating a metallic slide in such a manner that the gilded surface was on top. Trypsin solution was deposited on the gilded blanket for ten minutes. After washing off the enzyme solution the slides were treated with a strong jet of ethylene dichloride which dissolved the formvar and removed the gold at the same time. If the blanket was transferred with the gilded face in contact with the antigenic layers, the gold could not be removed by ethylene dichloride treatment. It was observed that a blanket consisting of a formvar film 130 to 200 Å. thick, plus a gold film 40 to 60 Å. thick, offered complete protection against trypsin to six "up" layers of bovine albumin. Partial protection was ensured if the gold film was ≃30 Å. thick, and with no gold, as it has been shown above, complete inactivation still occurred with films of formvar as thick as 600 Å.

Ovalbumin and Antiovalbumin Rabbit Sera

The inactivation of ovalbumin films by trypsin was not studied extensively, because the amount of rabbit anti-

body which can be specifically adsorbed is independent of the number of deposited ovalbumin layers (1) and, therefore, does not afford a sensitive indication of inactivation. Some of the results are presented in Table V, which shows that a blanket of 70 Å. of formvar offers ample protection for two as well as for four double layers of ovalbumin.

TABLE V

TRYPSIN ACTION THROUGH BLANKETS OF FORMVAR COATING MULTILAYERS OF OVALBUMIN

The protein layers were deposited on conditioned gages of two and four layers of barium stearate. The blankets of formvar were dissolved in ethylene dichloride before treatment with the antiserum. The figures in the last column represent the thickness of the adsorbed antibody layer in Å. units.

Protein films	Thickness formvar blanket, Å.	Trypsin treatment, min.	Antiovalbumin rabbit serum treatment
ov(⇵)$_2$	96	0	23
ov(⇵)$_2$	71	5	18
ov(⇵)$_4$	50	5	11
ov(⇵)$_4$	74	5	18
bov ⇵ ov(⇵)$_2$	64	5	0
bov ⇵ ov(⇵)$_4$	60	5	0
bov ⇵ ov(⇵)$_4$	51	0	20

It should be noted, however, that if the ovalbumin layers were deposited on one double layer of bovine albumin complete inactivation occurred in spite of a screen of 64 Å. This would seem to indicate that a layer of ovalbumin anchored directly on the barium stearate gage is much more resistant to trypsin action than if it is anchored on a double layer of bovine albumin. As mentioned earlier, an analogous situation was encountered with films of bovine albumin.

Action of the Specific Enzyme Hydrolyzing the Polysaccharide from Type III Pneumococcus

The interaction between polysaccharide from Type III pneumococcus and homologous rabbit antibody through blankets of various kinds was described in the previously mentioned article.[1] In the present experiments horse as well as rabbit antisera were used, and interesting differences were brought to light.

The polysaccharide was adsorbed by placing a drop of solution on the slide, as described previously. The layer of polysaccharide, whether adsorbed on a conditioned gage of octadecylamine or on barium stearate, was about 5 Å. thick. When, however, the octadecylamine gage was not conditioned the adsorbed layer was 12 to 15 Å. thick, but the amount of antibody which could be specifically adsorbed was independent of the thickness of the layer of polysaccharide.

Horse Antipneumococcus Sera.—The thickness of the layer of horse antibody specifically adsorbed by the polysaccharide was about 70 Å. Reproducible results were difficult to obtain, values as large as 80 Å. and as low as 30 Å. were occasionally observed. The thickness was not dependent on the nature of the underlying gage, barium stearate or octadecylamine, nor did the coating of the gage with one double layer of protein prior to the adsorption of the polysaccharide influence the results. These findings are in direct contrast to the events observed with rabbit sera where it was found that a layer of antibody about 300 Å. thick could be adsorbed if the polysaccharide was anchored on an amine gage whereas the increment was only 120 Å. if the polysaccharide was on a barium stearate gage. No increment was observed following treatment with an antiserum against Type I pneumococcus or upon treatment of an adsorbed layer of polysaccharide from Type I with a Type III antiserum.

When a drop of a solution of the depolymerase was left for ten minutes on a polysaccharide layer adsorbed on a barium stearate gage or on a barium stearate gage coated with one double layer of protein, complete inactivation of the polysaccharide occurred. The increment observed after treatment with an antiserum was from 0 to 10 Å. If, however, the polysaccharide was adsorbed on an amine gage or an amine gage coated with one double layer of protein, little or no inactivation resulted from the enzyme treatment, the thickness of the subsequently adsorbed layer of antibody being 30 to 60 Å. In other words, the anchorage of the polysaccharide was such that the enzyme was ineffective. It could be argued that the amine by itself acted as an inhibitor for the enzyme. This assumption is disproved by the fact that if a blanket of octadecylamine is deposited on top of a polysaccharide adsorbed on a barium stearate gage, complete inactivation occurred through a blanket of at least one double layer of amine. It was also found that if one double layer of barium stearate was deposited on top of an amine gage prior to the adsorption of the polysaccharide, the enzyme was then capable of inactivating the polysaccharide just as well as if there had not been any amine layer underneath. Thus the direct anchorage of the polysaccharide to the amine is necessary to prevent the enzymatic action.

Rabbit Antipneumococcus Sera.—On account of the thick layers of rabbit antibody which could be adsorbed on a polysaccharide layer from Type III pneumococcus, this system was particularly suited for investigating the screening effect of blankets on the action of the depolymerase. The results have been summarized in Fig. 2, where the abscissa represents the thickness of the formvar or barium stearate blanket which was removed prior to the antiserum treatment. The curve shows that a blanket of about 180 Å. is necessary to protect the polysaccharide whether it was adsorbed on an amine or barium stearate gage. Also, a blanket of barium stearate has the same screening effect as that of an equivalent thickness of formvar. The same curve of inactivation was obtained whether the slides were treated for ten or twenty minutes with the enzyme solution. With no blanket present the enzyme produced complete inactivation when the polysaccharide was adsorbed on a barium stearate gage, but on an octa-

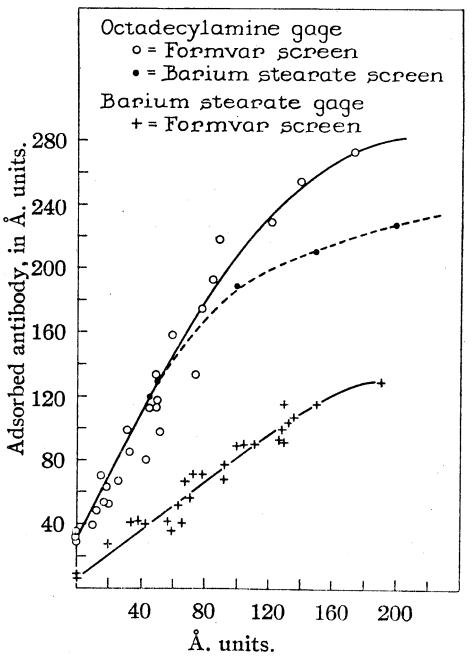

Fig. 2.—Inactivation of polysaccharide from Type III pneumococcus through intervening blankets.

decylamine base enough activity of the polysaccharide remained to produce an increment of 30 to 40 Å. of antibody, the same thickness found when horse serum was used. These experiments show that the enzyme is capable of altering the polysaccharide adsorbed on an amine layer to a much greater extent than the results with the horse serum indicated. The large increment of rabbit antibody adsorbed only a polysaccharide layer anchored to an octadecylamine gage results probably from a delicate adjustment between the structures of the antigen and the antibody. The small increment observed with the horse antiserum under similar conditions indicates that the horse antibody molecules do not respond to the whole antigenic pattern of the polysaccharide permitting the specific fixation of thick layers of antibody, but only to that part of the pattern responsible for short range action.

The enzyme is apparently capable of destroying the "fine" structure of the polysaccharide adsorbed on amine gage but cannot disrupt the whole of the pattern responsible for the specific reaction.

Discussion

All the data presented indicate that pepsin and trypsin, as well as the enzyme depolymerizing the polysaccharide from Type III pneumococcus can act through various blankets made of formvar, polyvinyl chloride, barium stearate and octadecylamine. The question of fundamental importance to answer is: Do the enzyme molecules come in contact with the antigenic layers underneath, or do they act at a distance through the blanket by some mechanism yet unknown? A similar question was raised in the previous study on immunological reaction where it was concluded that the mesh of the fabric of blankets similar to those used in the present experiments did not appear large enough to permit the diffusion of the antibody molecules, and that all available evidence tended to indicate that long range action operated between antigenic layers located on one side of the blanket and antibody molecules adsorbed on the other side.

In the case of enzymatic action, one should keep in mind that a single enzyme molecule diffusing through a blanket might damage an extensive area of the antigenic film. It should also be remembered that the size of a trypsin molecule ($M \simeq$ 30,000) is considerably smaller than that of a rabbit antibody molecule ($M \simeq$ 180,000), and that nothing is known about the size of the enzyme depolymerizing the polysaccharide except that it is a non-dialyzable protein molecule.

However, the results obtained with trypsin acting on multilayers of bovine albumin layers through blankets of formvar offer the strongest kind of evidence against diffusion of the enzyme through the blanket. It was shown that the thickness of the blanket needed for protection against trypsin action increased with the number of underlying bovine albumin layers, and that the thickness needed to protect three double layers of bovine albumin was nearly three times that needed for one double layer. It was shown also that the mode of deposition of the layers $(\downarrow\uparrow)_n$ or $(\uparrow\uparrow)_n$ was just as important as their total number. A much thicker screen was needed to protect a system of layers deposited upwards $(\uparrow\uparrow)_n$ than a system of the same total thickness deposited by a round trip process $(\downarrow\uparrow)_n$. It is an amazing fact that a blanket 600 Å. thick offered no appreciable protection to six monolayers deposited upwards, a total thickness of only 48 Å. There is no reason to believe that the permeability of the blanket should depend on the number or mode of deposition of the antigenic layers underneath, especially when the fact is considered that the blanket can be made first on a clean glass slide, floated on water and transferred as one single unit onto the antigenic layers. If the enzyme molecules do actually diffuse through the blanket, they must then diffuse faster or slower depending on the mode of deposition and number of the antigenic layers underneath, a process which in itself would involve a long range action. The fact that the enzymatic action is to a certain extent independent of the time, the same degree of inactivation occurring after ten or twenty minutes in the case of the enzyme depolymerizing the polysaccharide, or after five or ten minutes with trypsin, speaks against a diffusion process. Curve 9 of Fig. 1 indicates that the amount of inactivation of uranyl conditioned layers of bovine albumin through blankets of formvar is the same after two or fifteen minutes. With no screen present, however, the thickness of the adsorbed layer of antibody for slides treated for two minutes with trypsin was more than twice the thickness obtained with slides treated for fifteen minutes. It may be that in the absence of a blanket, the trypsin molecules diffuse slowly through the disintegrating layers and are able to inactivate each layer in turn whereas no diffusion of enzyme molecules could take place through the blanket.

Slides covered with protein multilayers are hydrophilic; they become hydrophobic when the layers are coated with a formvar blanket and are still hydrophobic after trypsin treatment. One must assume, nevertheless, that water and buffer ions must diffuse through the blanket and that the range of action of trypsin molecules should depend on the diffusibility of the buffer ions. It is a fact that trypsin in a phosphate buffer acts at markedly longer distances than in a veronal buffer. There was no appreciable difference in the action of trypsin whether the formvar blankets were formed directly on top of the antigenic layers or whether they were transferred as one unit from a water surface. There was, however, a difference in the shielding action if the blankets were made in two steps, either by forming a blanket directly on the slide and then transferring a second blanket on top of it from a water surface, or by successively transferring two blankets from a water surface. When the antigenic layers consisted of six "up" layers, a screen of formvar 500 Å. thick made in two steps was adequate to protect the system from trypsin action. A considerable amount of inactivation still occurred with a "two step"

blanket 300 Å. thick. This difference in the behavior of the two types of blankets may be due to a diminished permeability to the buffer ions when the blankets have been made in two steps.

It has sometimes been questioned whether, during the treatment of the slides with enzyme solution or antisera, the different layers stay in their original position or whether these are sufficiently mobile to be displaced. Previously mentioned experiments showed that successively deposited layers remain in their order of deposition. It may be added that some of the experiments on the enzymatic action on the polysaccharide from Type III pneumococcus point to the same interpretation. The enzyme can completely inactivate the polysaccharide molecules adsorbed on a stearate layer deposited on an octadecylamine base. The inactivation is incomplete if the polysaccharide is adsorbed directly on an amine base. Consequently the polysaccharide stays on the barium stearate layer and does not diffuse downward toward the amine layer or vice versa the amine base does not migrate upwards. Also the fact that a blanket of amine, deposited on the polysaccharide adsorbed on a barium stearate base, does not prevent inactivation by the enzyme demonstrates that the polysaccharide molecules stay anchored on the stearate and are not displaced when the blanket of amine is deposited on top of them.

It was shown in the study on interaction between films of antigen and antibody molecules that the amount of specific adsorption in the presence of a blanket was practically independent of the nature of the blanket. In the case of the action of the enzyme on the polysaccharide from Type III pneumococcus, a barium stearate blanket has the same protective effect as that of a formvar blanket of equivalent thickness. A different condition prevails when trypsin acts on multilayers of bovine albumin. Inactivation occurs through a larger thickness of barium stearate than of formvar. The interaction between antigenic layers and trypsin is so strong that very often, as we have seen, the blanket of barium stearate is removed following enzyme or serum treatment. When the interaction is diminished by conditioning with uranyl acetate in between the deposition of the antigenic layers, the blankets of barium stearate are never removed and it was shown (Table II) that trypsin acts at least through six, possibly ten, monolayers of barium stearate blanketing three double layers of bovine albumin deposited by the round trip process. In contrast, a blanket of formvar 60 Å. thick entirely cuts off trypsin action on similarly treated layers of bovine albumin.

It has been suggested that the metal slides onto which the layers were deposited have such rough surfaces on a molecular scale, that the results observed might be artifacts due to the valley-mountain profile of the slide. It is known, however, from electron micrographs that an ordinary microscope glass slide has a remarkably smooth surface. Therefore, some glass slides were coated by evaporation *in vacuo* with a film of chromium or gold thick enough to ensure metallic reflection. The same experiments were carried out using these slides and identical results were obtained.

The evidence just presented would indicate that the enzyme does not penetrate the blanket. Nevertheless, the effect of the enzyme does extend through the blanket and this fact should be considered in connection with theories of enzymatic action. The general mechanisms of enzymatic action postulated so far can be classified in two groups. One group assumes an intermediate complex between enzyme and substrate. The existence of such complexes has been demonstrated in the case of peroxidase and catalase by Chance.[5] In the second group, the reaction proceeds from inactivation by collision and by taking a quantum of the energy liberated during the reaction.[6]

It would be very difficult to explain our results on the basis of either type of mechanism if contact between our substrate films and enzyme does not really occur. In the case of proteolytic enzymes, enzymatic activity does not seem to be located in a prosthetic group, but results from steric architecture of the whole molecule. The following experiments, which show that trypsin as well as pepsin requires the native configuration of its molecules to retain enzymatic activity, are in harmony with this view. One or two monolayers of unfolded trypsin deposited on a slide are incapable of inactivating subsequently transferred layers of bovine albumin, even if a drop of a buffer solution at *p*H 7.5 is deposited on the slide for ten minutes. Similar results are obtained if trypsin films are transferred on top of the antigenic films; no inactivation occurs. Unfolding of the enzyme molecule should not abolish its activity altogether if the origin of the enzymatic activity resided in a prosthetic group. Thus this activity must originate from an extensive portion of the active molecule.

One plausible explanation of the long range action at present would appear to be through some resonance phenomenon perhaps involving a characteristic frequency of the substrate and of the enzyme. Appropriate tuning could then result by correspondence in the frequency and polarization of the vibrations, and the vibrations set up in the substrate layers could break down certain bonds characterizing the antigenic pattern. This interpretation has already been proposed by Chaudhury,[7] but is carried one step further. If such hypothetical resonators are extended, and as we have seen the evidence is in favor of an extended "active" part of the enzyme molecule, it is conceivable that resonance may occur at distances of an entirely different order of magnitude from

(5) B. Chance, *J. Biol. Chem.*, **151**, 553 (1943); *Acta Chem. Scandinavica*, **I**, 236 (1947).

(7) A. K. R. Chaudhury, *Curr. Sci.*, **14**, 261 (1945).

those involved when small molecules or individual atoms are considered. Resonance might occur in spite of intermediate blankets, no immediate contact being necessary between substrate and enzyme. It might also be conceived that, depending among other things on the frequency involved, certain vibrations would be better transmitted than others by the intermediate blankets. Some types of blankets may have a stronger specific adsorption than others for the particular frequencies involved. The experiments made with blankets of evaporated gold show that such blankets are extremely efficient in preventing enzymatic as well as immunological reactions.

Thus, long range enzymatic action through a resonance phenomenon could be an explanation of the observed facts. If, as the presented data seem to indicate, long range enzymatic action occurs between films of antigen, or adsorbed molecules of antigens, and enzyme molecules, it would seem also likely that the same mechanism could apply to a substrate in solution and should be considered in a discussion of any theory of enzymatic action.[8]

Also it is important to note that in these experiments one is not justified in considering the behavior of single molecules of the substrate independently. The effect of the number and mode of deposition of monolayers of bovine albumin on its range of action is already an indication that considerable interaction takes place between the layers and presumably between the molecules within one single layer. The phenomenon of long range action could be considered as due to the cooperation of a group of molecules. Coöperation phenomena may play a role in biological processes, the degree of coöperation possibly determining the distance at which an enzyme may act. Finally, the possibility of enzymatic action through a thin cell membrane offers a new vista on physiological events.

(8) It is interesting in this connection to mention an article by Vlasow, *J. Physics, U. S. S. R.*, **9**, 25 (1945). The author shows that when considering large polyatomic systems one cannot neglect weak forces of interaction at long distances and that "these interactions reveal new dynamic properties of polyatomic systems, putting the problem of the transition from 'micro' to 'macro' anew." When collective interaction is taken into account, then follows according to the author "the presence and spontaneous origin of eigen frequencies in polyatomic systems." It is worth mentioning that in 1939 Langmuir, *Proc. Phys. Soc.*, **51**, 592 (1939), considered the possible importance of vibrations for the specificity of protein molecules.

Most of the data presented in this work were obtained with the able assistance of Miss Marjorie Hanson. I am indebted to her for her help in the preparation of this article. My thanks go also to Dr. Lyman C. Craig who read with care the manuscript and offered valuable criticism.

Summary

Multilayers of bovine albumin were submitted to the action of trypsin, and films of polysaccharide from Type III pneumococcus to that of a specific depolymerase. In both cases, following enzymatic action, the layers were altered to such a degree that they became incapable of specifically adsorbing homologous antibody. It was observed that blankets of barium stearate, of a plastic polymer (Formvar), and of polyvinyl chloride polymers deposited on the layers did not prevent enzymatic action from occurring when the enzyme solution was deposited on the blanket. The thickness of the blanket necessary to prevent any enzymatic action varied within a wide range depending on the number and mode of deposition of the underlying layers. It seemed unlikely that the enzyme molecules penetrated the blanket and the assumption was made that enzymatic action took place at a distance, the enzyme and substrate molecules being actually separated by an intervening blanket.

The Determination of Primary Hydroxyl Groups in Cellulose Acetate by Tosylation and Iodination

BY CARL J. MALM, LEO J. TANGHE AND BARBARA C. LAIRD

A study was undertaken of the amounts of primary and secondary hydroxyl groups in various samples of cellulose acetate to determine whether any difference could be detected depending on the history of the sample.

The method of tosylation and iodination for the determination of primary hydroxyl groups in glucose and its derivatives depends on (a) complete tosylation of primary hydroxyl groups and partial or complete tosylation of secondary hydroxyl groups, and (b) subsequent replacement of all primary tosyl groups by iodine and no reaction of secondary tosyl groups. These reactions have been applied to a commercial cellulose acetate by Purves and co-workers,[1,2] who found that slightly more than one third of the hydroxyl groups were primary. Their work indicated that the method should be suitable for comparing the amounts of primary hydroxyl in various samples.

This method, with minor modifications, was used, and the samples chosen for comparison in the

TABLE I

STARTING MATERIALS

Sample		% acetyl	Hydroxyl per g. u.	Approximate % primary hydroxyl found
A	Acetylated and hydrolyzed with moderate amount of H_2SO_4	40.4	0.48	33
B	Same as A	31.6	1.27	25
C	Acetylated and hydrolyzed with $ZnCl_2$ and HCl	40.0	0.52	28
D	Acetylated with a large amount of H_2SO_4; combined sulfate split off with $MgCO_3$ and acetone	41.4	.38	60
E	From a sample similar to B, by tritylating, acetylating and detritylating	40.3	.49	33
F	Same as A	39.6	.57	33
G	Same as A	32.3	1.22	25
H	From A, deacetylated with 14% NH_4OH	None	3.00	33

present work are listed in Table I. These included cellulose acetates made by differing techniques, which possibly could affect the proportions of primary hydroxyl groups. They were tosylated with *p*-toluenesulfonyl (tosyl) chloride in the presence of pyridine for varying lengths of time (Fig. 1). The tosylated products were iodinated in acetonylacetone solution with sodium iodide, and the results obtained on the first five samples are given in Table II, from which the following points merit consideration:

1. Upon iodination of the tosylated samples, increasing amounts of iodine were introduced as the time of tosylation was extended. By determining the point at which the reaction slowed down, an approximate value for the amount of primary hydroxyl could be obtained. The estimated percentages of primary hydroxyl in the various samples are given in the last column of Table I.

2. The samples showed variations in the per cent. of primary hydroxyl groups as measured by this method. Samples A and E were in qualitative agreement with the results of Gardner and Purves,[2] but sample C, made with zinc chloride, contained slightly less, and sample D, made with a large amount of sulfuric acid catalyst, contained considerably more primary hydroxyl groups.

3. Sample E, made through the trityl derivative to contain substantially all primary hydroxyl groups, actually contained no more than sample A, made by commercial methods. This is indicative of migration of acetyl groups from secondary to primary hydroxyl during the detritylation step. Note that the tosylation time curves of samples A and E were almost identical (Fig. 1).

4. In sample D the amount of tosyl reached a maximum after eight hours. Also, in the last two samples of this tosylation time series the molecular amount of iodine introduced exceeded the amount of tosyl present.

This behavior was traced to the displacement of tosyl by chlorine during tosylation, and of chlorine by iodine during iodination. Qualitative analysis[3] of the iodinated samples showed only a trace of chlorine, and the amount of iodine introduced was always less than the sum of tosyl and chlorine. Comparison of the degree of iodine substitution in Samples D-1 through D-6, Table II, where the chlorine is neglected, and in Table III, where it is taken into account, shows that the introduction of chlorine during tosylation does not

[a] Based on replacement of all the chlorine and part of the tosyl.

To obtain further evidence for the replacement of chlorine by iodine during iodination, a sample high in chlorine was prepared by treating a tosylated cellulose acetate with pyridine hydrochloride.[1] This was iodinated along with the original tosylated sample and comparable amounts of iodine were introduced to each.

The increasing amounts of iodine introduced throughout the tosylation time series were disturbing. However, when the procedure described by Gardner and Purves[2] was exactly followed using sample F, the same increase in iodine content was again observed. Small amounts of chlorine were found in the products even with short time of tosylation. The minimum amount of chlorine was introduced when the tosylation was carried out at 0°.

Even including samples where variations were also made in the temperatures and the amount of tosyl chloride, the amount of iodine introduced on iodination increased with the amount of tosyl present.

Iodination time series were then carried out on some of the samples of Table IV and the results are presented in Table V. Upon iodination of a sample low in tosyl, a constant amount of iodine was introduced as the time of iodination was extended; but with increased amounts of tosyl in the sample, the amount of iodine increased considerably as the time of iodination was extended.

This behavior was even more pronounced when tosylation and iodination time series were carried out on sample G, containing 32.3% acetyl (Tables VI and VII, and Fig. 2). Increased amounts of sodium iodide in the iodination of the last sample of this series were not helpful in obtaining a sharper break in the iodination reaction.

The upward drift in the amount of iodine introduced as the times of tosylation and iodination were extended suggested that secondary hydroxyl groups were slowly reacting. Although the original work of Oldham and Rutherford[4] contained several examples of the non-reactivity of tosyl groups on secondary hydroxyls, a review of the more recent literature showed several instances of their reactivity. Levene and Raymond[5] treated xylose derivatives tosylated in the 3-position (*i. e.*, on secondary hydroxyl groups) with sodium iodide and found a slow iodination at 110°. Hess[6] degraded tritosyl starch to a tritosyl glucose derivative into which he was able to introduce two atoms of iodine with sodium iodide at 130°. Levene[7] replaced all three tosyl groups in tritosylglycerol by this method. Tetratosyl erythritol

showed irregular behavior,[8] losing all of its tosyl groups with the formation of butadiene. Tosylates of certain simple secondary alcohols, such as isopropyl-*p*-toluenesulfonate showed considerable reactivity toward sodium iodide even at room temperature.[9] Hockett and co-workers[10] applied the reaction to a sorbitol derivative tosylated at positions 2 and 5 (*i. e.*, on secondary hydroxyl groups). In solvents such as acetone, acetonylacetone or acetic anhydride at 120–140°, one of the tosyl groups was replaced with iodine.

Accordingly, the tosylation and iodination reactions were applied to cellulose itself where the introduction of more than one iodine per glucose unit would be clear evidence for the participation of secondary hydroxyl groups.

Previous investigators[11] have found it necessary to use an active cellulose and to avoid high temperature in the tosylation reaction. Cellulose regenerated from the acetate was chosen for this work because of its reactivity. Even then but little tosyl was introduced without suitable conditioning of the cellulose. Pretreatment with aqueous pyridine gave a starting material which reacted with tosyl chloride at room temperature to yield a soluble product containing 1.5 to 1.8 tosyl groups per glucose unit. At steam-bath temperature according to the directions of Honeyman[12] products were obtained containing large amounts of nitrogen and chlorine. At 0° less than one tosyl per glucose unit was introduced and the product failed to dissolve in the reaction mixture. Successful iodinations could be carried out, however, in acetonylacetone suspension. The results on tosylation of regenerated cellulose are given in Table VIII, and on iodination of the tosylated products in Tables IX and X.

TABLE VIII

TOSYLATION OF CELLULOSE

Where excess tosyl had been introduced, slightly more than one iodine per glucose unit was introduced when the time of iodination was extended. Two possible explanations for the increase in iodine content beyond one iodine per glucose unit, other than replacement of secondary tosyl groups by iodine, have come to our attention[13] and have been investigated.

An increase in weight per cent. iodine could result from the loss of tosyl without entrance of iodine. Gardner and Purves[2] found that no tosyl was lost which was not replaced by iodine, and occasional analyses of our iodinated products showed the required amount of tosyl remaining. To investigate this point more fully, sulfur and iodine analyses were made on samples from two iodination time series (Table X), and the degrees of iodine and tosyl substitution were calculated.

H-2-13	120	37.0	1.14		5.5	.67	.13
H-2-14	360	40.2	1.14		4.1	.46	.34

[a] Corrected for loss of tosyl. [b] Samples H-2-10 to H-2-14 were soaked overnight in 0.1 *N* sodium thiosulfate to remove any absorbed iodine.

When the time of iodination was one hour or less the loss of tosyl was negligible, but as the time of iodination was extended to six hours, there was a considerable loss of tosyl without entrance of iodine. Hence, the degree of iodine substitution of samples iodinated for six hours, calculated on iodine content alone (as in Table IX), is slightly high, but even when it is corrected for the amount of tosyl lost, is still slightly more than 1.00 per glucose unit. A similar correction should apply to six-hour iodinations of samples derived from cellulose acetate, since the iodine substitutions were calculated from iodine content alone, assuming no loss of tosyl without entrance of iodine.

Absorbed iodine would likewise contribute to high iodine content of the products. Extraction of iodinated samples with dilute sodium thiosulfate solution has been used[14] to remove absorbed iodine. Typical iodinated products reported herein were soaked overnight in 0.1 *N* sodium thiosulfate, and a loss of 0.6–0.8% iodine was observed. No iodine was lost, however, on refluxing the products for one hour with ethyl alcohol or with carbon tetrachloride.

In Table X, iodination time series without (Samples H-2-4 to H-2-9) and with (Samples H-2-10 to H-2-14) thiosulfate extraction gave comparable results.

The gradual increase in iodine content beyond one per glucose unit is interpreted as a slow replacement of secondary tosyl groups by iodine. This situation closely parallels that observed in a study of cellulose trityl ether[15] where slightly more than one trityl group per glucose unit could be introduced under extended reaction conditions.

Trityl derivatives were prepared from cellulose acetate sample F to determine the amount of primary hydroxyl to compare with the results of tosylation and iodination. About one-third of the hydroxyl groups could be tritylated, the exact amount of trityl introduced depending on the reaction conditions.

When applied to samples lower in acetyl, tritylation indicated slightly more primary hydroxyl than tosylation and iodination. In the preparation of sample E, about one-third of the hydroxyl groups in cellulose acetate, 31.0% acetyl, could be tritylated. In the tosylation and iodination of similar materials, samples B and G, only about 25% of the original hydroxyl groups could be readily replaced with iodine.

The results herein reported show that the tosylation and iodination method does not fulfil the conditions required for the exact determination of primary hydroxyl groups in cellulose acetate. All primary hydroxyl groups must be tosylated. However, large amounts of secondary tosyl groups are objectionable, since they interfere with the subsequent iodination, and in the iodination step the iodine content does not level off satisfactorily with the time of reaction. On samples low in tosyl where all of the primary hydroxyl groups may not have been tosylated the iodine levels off but at

too low a level. It was possible, however, by maintaining identical reaction conditions throughout, to determine the approximate primary hydroxyl content and to detect differences from sample to sample depending on their past histories. Especially noteworthy was the sample (D) of cellulose acetate prepared using a large amount of sulfuric acid catalyst, with subsequent removal of combined sulfate groups at the completion of the esterification. In this sample, approximately 60% of the hydroxyl groups were primary, indicating a preferential reactivity of the primary hydroxyl groups of cellulose toward the sulfuric acid catalyst during the esterification process.[16]

Experimental

Starting Materials.—Samples A, B, F and G, Table I, were made by commercial methods using sulfuric acid as the catalyst, both for the acetylation and the subsequent hydrolysis. The amount of acetyl in the products was controlled by the time of hydrolysis.

Sample C, Table I, was made by acetylation of cotton linters using acetic anhydride and zinc chloride catalyst. The amount of zinc chloride used was equal to the weight of the cellulose. In addition, 20 ml. of concentrated hydrochloric acid was added per pound of cellulose to aid the esterification. At the completion of the esterification of the cellulose, water was added to hydrolyze the product to the desired acetyl content.

Sample D, Table I, was made by acetylation of cotton linters using acetic anhydride and a comparatively large amount of sulfuric acid (28% of the weight of the cellulose). With this large amount of catalyst, good cooling was necessary to prevent excessive rise in temperature. The esterification was complete after a reaction time of one-half hour, as indicated by absence of fiber and grain. At this point an amount of magnesium carbonate was added, equivalent to three-fourths of the sulfuric acid catalyst. After stirring fifteen minutes at 100° F. the reaction mixture was diluted with half its volume of acetone, and the mixing was continued for one hour at the same temperature. The magnesium carbonate and the acetone aided the removal of combined sulfate without hydrolysis of acetyl. The product was then precipitated and washed in water.

Sample E, Table I, was prepared in three steps, by tritylation, acetylation, and detritylation of cellulose acetate according to the details immediately following:

1. **Tritylation.**—Twenty grams of cellulose acetate (31.0% acetyl; 1.68 acetyl groups per glucose unit) was dissolved in 100 ml. of anhydrous pyridine and 30 g. of triphenylchloromethane was added. The reaction mixture was heated at 70° for sixteen hours, at which time it was diluted with acetone, precipitated and washed in alcohol. The yield was 25.8 g. of a white, fluffy product containing 22.1% acetyl.[17] When several similar products were combined and tritylated again with fresh reagents, there was a slight increase in the amount of trityl introduced.

Anal. Calcd. for tritylation of one-third of the available hydroxyl groups (1.68 acetyl and 0.44 trityl per glucose unit): acetyl, 21.2; trityl, 31.6. Found: acetyl, 21.4; trityl, 31.4, 32.0.[15]

2. **Acetylation.**—Forty grams of the above product was dissolved in 200 ml. of anhydrous pyridine, and 40 ml. of acetic anhydride was added. After seventy-two hours at 50° the reaction mixture was diluted with 200 ml. of methanol. Considerable heat was evolved, indicating an excess of acetic anhydride. The product was precipitated and washed in alcohol, yielding 43.1 g. of a white, fluffy product.

Anal. Calcd. for complete acetylation of remaining hydroxyl groups (2.56 acetyl and 0.44 trityl per glucose unit): acetyl, 29.2; trityl 28.5. Found: acetyl, 29.4, 29.5; trityl, 27.8, 28.2.

3. **Detritylation.**—Ten grams of the above product (2.56 acetyl and 0.44 trityl per glucose unit) was dissolved in 70 ml. of acetic acid. A mixture of 14 ml. of acetic acid and 7 ml. of concentrated hydrochloric acid was added with stirring. Upon standing two hours at room temperature, crystals of triphenylcarbinol had separated out. The reaction mixture was diluted with 25 ml. of acetone and the product was precipitated and washed in methanol. The dried product was redissolved in acetone and precipitated in methanol to ensure complete removal of triphenylcarbinol. The yield was 6.3 g. of a white, fluffy product.

Anal. Calcd. for 2.56 acetyl per glucose unit: acetyl, 40.8. Found: acetyl, 40.2, 40.3; trityl, absent.

The above material represents sample E, Table I. It displayed the same solubilities in organic solvents as commercial cellulose acetate of comparable acetyl content, such as sample A, Table I.

Sample H, Table I, was prepared by the deacetylation of sample A by treatment with 14% ammonium hydroxide for two days at room temperature. The product remained in suspension throughout the process and retained the flaky appearance of the cellulose ester. The viscosity at 25° of the regenerated cellulose was 14 centipoises when dissolved in 2.5% concentration in cuprammonium solution.

Tosylation of Cellulose Acetate.—All tosylations were carried out at room temperature or lower with the cellulose acetate dissolved in anhydrous pyridine.

For the samples of Table II, the cellulose acetate was dissolved in 10 parts of pyridine and 2 g. of tosyl chloride per gram of cellulose acetate was added. After stirring for a few minutes to dissolve the latter, the bottles were placed in the 25 ± 0.1° bath. At the times indicated samples were diluted with acetone and precipitated and washed in alcohol. The tosylated products[18] acquired a slight color after a long time of reaction, but were all obtained in a fluffy, fibrous texture.

When small amounts of chlorine were found[19] in the tosylated materials measures were taken to eliminate or minimize this side-reaction. The tosyl chloride was dissolved in pyridine and the solution was cooled before it was added to the solution of the cellulose ester. Various samples of tosyl chloride were compared, and one sample was recrystallized from cyclohexane before use. These measures were without avail, although lowering of the reaction temperature to 0° did decrease the amount of chlorine entering.

In repeating the experiment of Gardner and Purves[2] a sample of cellulose acetate of comparable acetyl content was selected and all details were modified to conform to their experimental conditions. The results are given in samples F-1 through F-6, Table IV, and in Fig. 2. In the remaining samples of Table IV, variations were made in the temperature and in the amount of tosyl chloride.

In an attempt to eliminate the introduction of chlorine, some experiments were made with *p*-toluenesulfonic anhydride as the tosylating agent. This material was prepared from the acid and thionyl chloride, and melted

(17) Acetyl analyses were carried out by the Eberstadt method as described by L. B. Genung and R. Mallatt, *Ind. Eng. Chem., Anal. Ed.*, **13**, 369 (1941).

(18) Sulfur analyses were carried out by the Parr bomb or by the method described by C. J. Malm and L. J. Tanghe, *Ind. Eng. Chem., Anal. Ed.*, **14**, 940 (1942).

(19) The chlorine determinations were carried out by a saponification procedure developed in this Laboratory by Dr. J. W. Mench. This has been found adaptable to small amounts of chlorine in cellulose esters and has given results in agreement with a standard combustion method.

at 128°, in good agreement with the literature.[20] A tosylation reaction was carried out in pyridine solution using four parts of the anhydride to one part of cellulose acetate (Sample A, Table I). When only 0.30% sulfur was found in the product after a reaction time of twenty-four hours on the steam-bath, this method was abandoned.

Tosylation of Regenerated Cellulose.—When dried regenerated cellulose was treated with tosyl chloride in pyridine suspension, only a small amount of sulfur was introduced after several days of reaction at room temperature.

For activation, 30 g. of regenerated cellulose (Sample H, Table I) was tumbled overnight with 450 g. of pyridine and 150 g. of water. The water was then displaced by four changes of anhydrous pyridine, the cellulose being pressed out on a Buchner funnel with a sheet of rubber after each treatment.

To obtain samples H-1, H-2 and H-3, Table VIII, the cellulose, wet with pyridine, was divided into three parts of 48 g. each. To each was added 100 ml. of pyridine and 70 g. of tosyl chloride, and the mixtures were tumbled at room temperature for the times indicated. Sample H-1 gave a reaction dope with considerable grain. As the reaction time was extended the grain diminished, and was absent from sample H-3. In each case the reaction mixture was diluted with an equal part of pyridine and the product precipitated and washed in alcohol. The products were all light tan in color and fluffy in texture.

In order to obtain samples with lower amounts of tosyl and to minimize the introduction of chlorine, a reaction time series was carried out at 0°. The regenerated cellulose was activated in the same way, and the mixture was stirred continuously throughout the reaction (Samples H-5 through H-8, Table VIII). Less than one tosyl group per glucose unit was introduced under these conditions, and the cellulose failed to dissolve. The products were washed in alcohol and were unchanged in appearance from the starting material.

Iodination of Tosylated Cellulose Derivatives.—After a few trials using acetone at 100° in sealed tubes as the solvent for the iodination, this solvent was abandoned in favor of acetonylacetone.[2]

Where iodination time series were not taken, 1 g. of the tosylated sample and 1 g. of sodium iodide were dissolved in 30 ml. of acetonylacetone and heated in the electric oven at 120 ± 2°. In Table II the reaction time was six hours, and in Table IV, two hours, with occasional stirring. Crystallization of sodium *p*-toluenesulfonate took place during the course of the reaction. The products were isolated by precipitation and washing in distilled water.

A yellow color was always indicative of a large amount of iodine in the product. Most of these iodinated products were fluffy in texture and isolated in good yield. However, iodinated derivatives of Samples B-5 and B-6, Table II were too powdery to be isolated after iodination for six hours.

The iodinated derivatives of tosyl cellulose (Table IX) were isolated in poor yield when the time of iodination was extended to six hours. With shorter times of iodination, good yields were obtained on these products.

For the iodination time series 2.5 g. of tosylated derivative was dissolved in 75 ml. of acetonylacetone and heated in an oil-bath to 120 ± 1.0° in a three-necked flask fitted with thermometer and stirrer. After the solution had come to temperature 2.5 g. of sodium iodide was added. Approximately 15-ml. portions were pipetted out at the indicated intervals, and the products were precipitated and washed in distilled water.

All the tosylated derivatives except the cellulose *p*-toluenesulfonates containing less than one tosyl per glucose unit were soluble in hot acetonylacetone. Satisfactory iodinations were achieved in insoluble derivatives by carrying out the reaction in suspension.

Chlorination of Tosylated Cellulose Acetate.—Sample F-9, Table IV, was treated on the steam-bath with an equal weight of pyridine hydrochloride in pyridine solution. A large portion of the tosyl was replaced by chlorine, yielding a product containing 2.7% chlorine. Upon iodination, a product was obtained with 7.1% iodine, the chlorine having undergone the same displacement reaction as the tosyl.

Summary

The method of tosylation and iodination did not give exact results in the determination of primary hydroxyl in cellulose and cellulose acetate; since as the reaction conditions in both the tosylation and iodination steps were extended, increasing amounts of primary hydroxyl were indicated.

In view of these difficulties the reaction conditions must be standardized in comparing the amounts of primary hydroxyl in different samples of cellulose acetate.

Different proportions of primary hydroxyl were found in samples of cellulose acetate depending on their methods of preparation.

The introduction of slightly more than one iodine per glucose unit into tosylated cellulose indicated a slow participation of secondary hydroxyl in the tosylation–iodination reaction.

The Influence of Substituents on the Course of Addition of Maleic Anhydride to Diarylethylenes

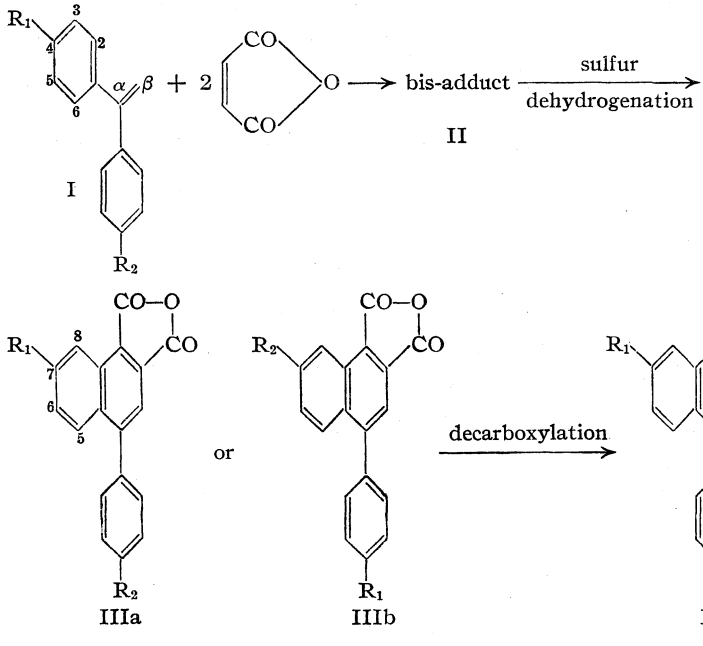
BY FELIX BERGMANN AND JACOB SZMUSZKOWICZ[1]

When an unsymmetrical diarylethylene of the general formula I is subjected to a Wagner–Jauregg type addition of maleic anhydride,[2] the reaction can lead to two isomeric products (IIIa or IIIb). However, as indicated in our earlier paper[3] and elaborated upon in the present investigation, only a single product is obtained in every case.[4] Proof of the structure of the addition product was obtained either by degradation of the aromatic anhydrides III to simple naphthalene derivatives, which could be synthesized in an unequivocal way or identified by exclusion of the isomeric structure, or by spectrographical analysis.[5]

TABLE I

FORMATION OF 4-ARYLNAPHTHALENE-1,2-DICARBOXYLIC ACID ANHYDRIDES (III)

	Ethylene used (I)		Aromatic anhydride (III)		
	R_1 =	R_2 =	R_1 =	R_2 =	Proof of structure
1	Phenyl	H	Phenyl	H	By exclusion
2	CH_3	H	H	CH_3	By independent synthesis
3	C_2H_5	H	H	C_2H_5	By spectroscopic analogy
4	$(CH_3)_2CH$	H	H	$(CH_3)_2CH$	By spectroscopic analogy
5	$(CH_3)_3C$	H	H	$(CH_3)_3C$	By spectroscopic analogy
6	OCH_3	H	OCH_3	H	By independent synthesis
7	OCH_3 (and OCH_3 at C_5)	H	OCH_3 (and OCH_3 at C_6)	H	By spectrographical analysis
8	F	H	H	F	By independent synthesis
9	Cl	H	H	Cl	By independent synthesis
10	Br	H	H	Br	By analogy
11	F	CH_3	(F	CH_3?)	None



Our results, which are summarized in Table I, enable us to divide all the aromatic substituents investigated into two classes: (a) substituents which promote participation of the substituted ring in the addition reaction (methoxyl, phenyl); (b) substituents which prevent participation of the substituted ring (halogen, alkyl).

For a full understanding of this classification we have to take into consideration that a substituent of group b does not interfere *per se* with the successful addition to the substituted ring. Thus, although in the unsymmetrical halogenated ethylenes (I,8 and 9) the substituted ring is excluded from reaction, the symmetrical dihalogenated derivatives (I,13 and 14) react very smoothly with maleic anhydride and the same is true for the di-(*p*-tolyl)-ethylene (I,12). Therefore in the unsymmetrically substituted ethylenes very accurately balanced electronic effects must result from the presence of two different aromatic rings.

If methoxyl and chlorine are taken as representatives of the two groups, it appears probable that the reaction starts by electrophilic attack of maleic anhydride to the β-carbon atom of the side chain. This attack is favored by the +T − effect of methoxyl and hindered by the −I − effect of chlorine (as compared to the unsubstituted ring), the effects being transmitted through the whole

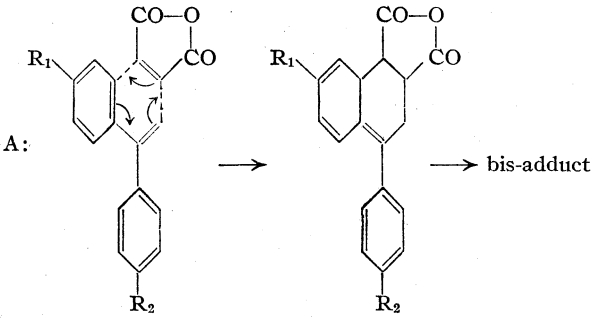
conjugated system to the β-carbon atom. However, in electrophilic substitutions methyl usually behaves like methoxyl, whereas in the reaction under discussion the alkyls parallel the halogen group. This apparent contradiction can, however, be solved easily, if it is realized that the reaction involves a two-step addition to the β-carbon and the ortho position. If the first addition is electrophilic, the second step must be nucleophilic in character, so that the reacting system can pass through a complete electronic cycle, in which all electron shifts occur simultaneously (scheme A).

A:



The course of the reaction is therefore dependent on the electronic influence of a given substituent upon both the β- and ortho-position. If we assume that a substituent would—at least qualitatively—exert a similar influence on the diphenylvinyl system as it does on an isolated benzene ring, we can make use of Hammett's σ-constants for an estimate of the electronic shifts to be expected.[6] The pertinent figures are given in Table II and show very clearly, that an increased positive charge in the 2-position is at least as important as an increased electron density at the β-carbon atom. This is borne out especially by example I,1. The *p*-phenyl group has such a small positive σ-value, that no prediction can be made on this base. However the large positive δ-value for the *m*-position, directs addition toward the substituted ring. The figures of Table II thus support the reaction scheme A, as formulated above, and make it very probable that all Diels–Alder reactions follow a similar "polar" pattern.

An interesting case is represented by the dimethoxy compound I,7. Superficially both positions involved in the cyclization bear a negative charge and thus addition should be directed to the unsubstituted ring. However, the Wagner–Jauregg reaction involves a simultaneous addition of the dienophil at both the β-carbon and the *o*-position, and it is clear that the two methoxyl groups cannot resonate at the same time to produce a negative charge on their respective para positions and that the more extended conjugated systems associated with the 4-methoxyl is favored for resonance. Therefore, the 5-methoxyl can exert only its inductive effect. Although the I-effect of an aromatic methoxyl upon its para position cannot be determined separately, we have tried to estimate the electronic displacements in I,7 in the following way:

The β-carbon atom is under the *p*-effect of the resonating C_4-methoxyl ($\sigma = -0.268$) and the *m*-effect of the C_5-methoxyl ($\sigma = +0.115$). Assuming additivity of the two effects, we come to an over-all value of $\sigma_\beta = -0.153$. For the 2-position in the ring we have the *m*-effect of the resonating C_4-methoxyl, which certainly is $> +0.115$ and the purely inductive *p*-effect of the C_5-methoxyl, which is unknown, but certainly smaller than the *m*-effect (compare the values for *m*- and *p*-chlorine, *m*- and *p*-bromine), so that the increase of the meta-inductive effect of the C_4-methoxyl would be approximately balanced by the decrease of the para-inductive effect of the C_5-methoxyl. We assume σ_{ortho} to be approximately $2 \times 0.115 = +0.230$. Conditions in the 4,5-dimethoxylated ring are thus very favorable for the addition of maleic anhydride according to scheme A.

The symmetrically substituted diarylethylenes represent a different case. In general, resonance and coplanarity between the ring and the vinyl group in styrene is increased by the introduction of a second ring as in I. If both aromatic systems are identical, the symmetry of resonance favors the Wagner–Jauregg addition so much, that adversary electronic effects of individual substituents are overcome. If the two rings are not identical, any small difference in resonance energy is enlarged by the fact that only one aromatic group can be coplanar with the vinyl group at a time, whilst the other one is twisted out of the plane.[7]

The reaction scheme, as developed here, permits several predictions to be made about the course the reaction will take, if a single substituent is introduced in I into a *m*-position. This aspect of the problem is now under investigation.

TABLE II

σ-VALUES FOR *m*- AND *p*-SUBSTITUENTS

Substituent	σ-Value for *p*-Position	σ-Value for *m*-Position
Group a: Methoxyl	−0.268	+0.115
Phenyl	+ .009	+ .218
Group b: Fluorine	+ .062	+ .337
Chlorine	+ .227	+ .373
Bromine	+ .232	+ .391
Methyl	− .170	− .069

Experimental Part[8]

A. Preparation of Diarylethylenes (I)

Three methods are available for the synthesis of 1,1-diarylethylenes: (a) interaction of ethyl acetate with two moles of a Grignard compound (applicable only for cases with identical aryls); (b) reaction of an acetophenone with an arylmagnesium halide; (c) reaction of a benzophenone with methylmagnesium iodide.

Method (c) gives the best yields (nearly quantitative), but method (b) is often more economical inasmuch as a number of different diarylethylenes can be prepared from

(7) R. N. Jones, THIS JOURNAL, **65**, 1818 (1943); F. Bergmann and Israelashvili, *ibid.*, **68**, 1 (1946).

(8) All m. p.'s are uncorrected.

the same acetophenone, whereas with method (c) a special synthetic route is required for every individual ethylene. The yields in reaction (a) are usually low, and this method is of little preparative value.

I,3: *p*-Ethyldiphenylethylene (I, $R_1 = C_2H_5$, $R_2 = H$).—*p*-Ethylbenzophenone was originally described by Söllscher.[9] The yield is reported as 75%. Norris and Blake,[10] however, found it necessary to purify the ketone, obtained "in the usual way," by four fractionations. We have observed that the Perrier modification[11] gave a 70% yield of a product of excellent purity. The reaction proceeded at room temperature and was completed by heating to 80° for one hour; b. p. 130–135° (0.5 mm.). The crude carbinol obtained from *p*-ethylbenzophenone and methylmagnesium iodide, was dehydrated by heating to 150° for one hour. Distillation yielded 85% of pure *p*-ethyldiphenylethylene; b. p. 118–120° (0.2 mm.); $n^{27.5}D$ 1.5864.

Anal. Calcd. for $C_{16}H_{16}$: C, 92.3; H, 7.7. Found: C, 91.9; H, 7.8.

I,4: *p*-Isopropyldiphenylethylene (I, $R_1 = CH(CH_3)_2$; $R_2 = H$).—*p*-Isopropylbenzophenone was prepared in 80% yield by Smith[9b] from cuminyl chloride and benzene. We applied again the Perrier technique. The benzoyl chloride–aluminum chloride complex reacted with isopropylbenzene at 0°; the reaction was completed at +15°. The ketone was obtained in 79% yield, b. p. 145–148° (0.1 mm.).

The Grignard reaction with methylmagnesium iodide was carried out as before. *p*-Isopropyldiphenylethylene boils at 122–123° (0.1 mm.); yield 86%; $n^{17}D$ 1.5823.

Anal. Calcd. for $C_{17}H_{18}$: C, 91.9; H, 8.1. Found: C, 92.1; H, 8.0.

I,5: *p*-*t*-Butyldiphenylethylene (I, $R_1 = C(CH_3)_3$; $R_2 = H$).—*p*-*t*-Butylbenzophenone was prepared by adding *t*-butylbenzene (60 g.) to the Perrier complex, prepared from benzoyl chloride (75 g.) and aluminum chloride (70 g.) in carbon disulfide (350 cc.) at +5°. The main reaction proceeded at room temperature and was completed by heating on a water-bath for one half-hour: yield 53%; b. p. 132–134° (0.1 mm.); $n^{25}D$ 1.5725.

Anal. Calcd. for $C_{17}H_{18}O$: C, 85.7; H, 7.6. Found: C, 85.3; H, 7.9.

The ethylene I,5 was prepared according to method (c). Dehydration of the intermediary tertiary carbinol was effected by heating to 150° for one hour: yield 95%; b. p. 123° (0.1 mm.); $n^{27}D$ 1.5767.

Anal. Calcd. for $C_{18}H_{20}$: C, 91.5; H, 8.5. Found: C, 91.2; H, 8.7.

I,8: *p*-Fluorodiphenylethylene (I, $R_1 = F$; $R_2 = H$).—*p*-Fluorobenzophenone was obtained by Dunlop and Gardner[12] in 66% yield from benzoyl chloride and fluorobenzene. The Perrier technique yielded in this case only 45% of the ketone; b. p. 110–115° (0.4 mm.); m. p. 48°. The Grignard reaction with methylmagnesium iodide was carried out as before and yielded 96% of the ethylene I,8. It possesses a b. p. of 105–110° (0.3 mm.) and shows a strong blue fluorescence; $n^{19}D$ 1.5840.

Anal. Calcd. for $C_{14}H_{11}F$: C, 84.8; H, 5.6. Found: C, 84.7; H, 5.8.

I,9: *p*-Chlorodiphenylethylene (I, $R_1 = Cl$; $R_2 = H$) was prepared according to Bergmann and Bondi.[13]

I,10: *p*-Bromodiphenylethylene[14] (I, $R_1 = Br$; $R_2 = H$) was prepared according to method (b) in 67% yield.

I,11: 1-(*p*-Tolyl)-1-(*p*-fluorophenyl)-ethylene (I, $R_1 = CH_3$; $R_2 = F$) was obtained from *p*-methylacetophenone and *p*-fluorophenylmagnesium bromide in 40% yield as a clear yellow oil of b. p. 141–142° (0.03 mm.); $n^{27.5}D$ 1.5738.

Anal. Calcd. for $C_{15}H_{13}F$: C, 84.9; H, 6.1. Found: C, 85.1; H, 6.1.

I,12: 1,1-Di-(*p*-tolyl)-ethylene (I, $R_1 = R_2 = CH_3$) was prepared in an unspecified yield by Anschütz and Hilbert[15] according to method (a). Repetition of their experiment gave only an 18% yield of the required ethylene. However, application of method (b) yielded the di-(*p*-tolyl)-ethylene in 58% yield, m. p. 60–61°.

I,13: 1,1-Di-(*p*-chlorophenyl)-ethylene[13] (I, $R_1 = R_2 = Cl$) was prepared according to method (b) from *p*-chloroacetophenone and *p*-chlorophenylmagnesium iodide in 73% yield, m. p. 91°.

I,14: 1,1-Di-(*p*-fluorophenyl)-ethylene (I, $R_1 = R_2 = F$).[16]—Method (a) yielded about 15% of this ethylene. As the preparation of *p,p'*-difluorobenzophenone according to Coates and Sutton is very tedious, we prepared the ethylene from *p*-fluoroacetophenone[17] and *p*-fluorophenylmagnesium bromide in 63% yield; b. p. 150–160° (30 mm.); m. p. 46°.

II. Condensation with Maleic Anhydride—Formation of bis-Adducts (II)

The formation of the bis-adducts (II) was carried out as before.[3] The optimal temperature had to be determined in each individual case, as the success of the condensation of the ethylenes I with maleic anhydride depends on narrowly defined temperature limits. When halogen was present in the ethylene, the bis-adduct always crystallized.[18] Among the alkyl-substituted ethylenes, only the mono- and di-tolyl derivative allowed the isolation of crystalline bis-adducts. In all other cases, the products were too soluble to permit crystallization. They were therefore dissolved in ethanol and precipitated by water as brownish powders. These crude, amorphous materials were purified by dissolution in sodium hydroxide and reprecipitation with hydrochloric acid. The white powders, so obtained, were then dried in an oven at 50–70° and used directly for the next step.

The properties of the bis-adducts (II) are summarized in Table II.

III. Dehydrogenation of bis-Adducts

All the aromatic anhydrides (III) were prepared by sulfur dehydrogenation of the bis-adducts. Details of these reactions together with the properties of the dehydrogenation products are given in Table III. Under the heading "Temperature of Dehydrogenation" two figures are given: The lower one designates the temperature at which the evolution of hydrogen sulfide started. The reaction mixture was usually kept at this temperature for ten to fifteen minutes. Thereafter the mixture was heated for five minutes to a temperature determined by the higher figure in the table, in order to complete the reaction. All the aromatic anhydrides are intensely yellow, beautifully crystalline substances, with a blue to violet fluorescence. When their alcoholic solutions were kept for some days, however, the color faded gradually due to the opening of the anhydride ring. The "dichloro" derivative (III,13) was so hygroscopic, that it could not be obtained in an anhydrous form, but rather as the semihydrate of the free dicarboxylic acid.

We have reported already in our first paper,[3] that some of the aromatic anhydrides are dimorphic, *e. g.*, the 4,7-diphenyl derivative (III, R_1 = phenyl; $R_2 = H$). We have observed now a further case of dimorphism: the fluoro derivative (III,8) crystallizes from acetic acid as

(18) In these cases, the crude melt was dissolved in ethanol and left for twenty-four hours. In the case of di-(*p*-fluorophenyl)-ethylene (I, $R_1 = R_2 = F$), the bis-adduct crystallized already in the hot melt and was isolated by treatment with methanol.

[a] e/m = ethylene/maleic anhydride. [b] A = butyl acetate; B = acetic anhydride; C = acetic–acid + acetic anhydride; D = butyl acetate + toluene; E = acetic anhydride + butyl acetate. [c] s. n. = short needles; t. c. = triangular columns; f. h. p. = flat hexagonal prisms; h. c. = hexagonal columns; t. r. = thin rods. [d] Because of the amorphous condition of the products, no exact yield can be stated.

a mixture of elongated rods (main form), and prisms (a very small portion) both of m. p. 179° (no depression upon mixing!). The two forms were separated mechanically and recrystallized from acetic acid.

The methyl derivative III,2 formed a mixture of brownish rods of m. p. 183–184°, and pale yellow needles of m. p. 186–187°. The m. p. of a mixture of both forms was 183–184°. Analysis showed that the second form contains half a molecule of water.

The amorphous bis-adduct II,5 gave, upon dehydrogenation, a mixture of two (isomeric ?) anhydrides (III, 5a and b), which again were separated mechanically. The main form crystallized from petroleum ether as yellow blocks of m. p. 158–159°. The second isomer, which was obtained only in a small amount, formed thin rods when recrystallized from the same solvent, m. p. 184–185°. Absorption spectra of the two products give no indication, as to whether they possess isomeric structures.[5]

IV. Decarboxylation

For decarboxylation, the anhydrides were either mixed directly with barium hydroxide (5 parts) and copper bronze (1.5 parts) and subjected to heating (method A) or a dioxane solution of the anhydride was added dropwise to a warm aqueous solution of barium hydroxide, the precipitated salt washed and dried, and then mixed with copper bronze (1.5 parts) (method B).

The degradation of III,2 (III, R_1 = H; R_2 = CH_3) has already been described.[3] The higher alkyl homologs of this compound gave only oils, which upon nitration gave amorphous and non-crystallizable nitro derivatives, unsuitable for comparison. In these cases, therefore, assignment of a certain structure depends entirely on spectrographical evidence.[5] 4-(*p*-Chlorophenyl)-naphthalene-1,2-dicarboxylic acid anhydride (III,9; R_1 = H; R_2 = Cl) was decarboxylated according to method A at 320°. The clear, colorless oil, 1-(*p*-chlorophenyl)-naphthalene (IV,9), could not be induced to crystallization or converted into a crystalline picrate. It was therefore nitrated directly by heating its acetic acid solution with one equivalent of fuming nitric acid to 60° for thirty seconds and pouring on ice. The yellow oil, so obtained, was dissolved in alcohol. The filtered solution, upon cooling, deposited yellow prismatic rods of m. p. 119°.

Anal. Calcd. for $C_{16}H_{10}O_2NCl$: C, 67.8; H, 3.5; N, 4.9. Found: C, 67.7; H, 3.7; N, 5.1.

An authentic sample of IV,9 was prepared in the following manner. To a Grignard solution, prepared from *p*-chloroiodobenzene (18.5 g.), magnesium (2.2 g.) ether (40 cc.) and benzene (40 cc.), was added at 0° a solution of tetralone (10 g.) in benzene (25 cc.). The mixture was refluxed for four hours and then decomposed in the usual way. The crude reaction product was dehydrated by heating to 150° for one hour in the presence of an equal weight of sodium bisulfate. Distillation gave a colorless oil of b. p. 150–152° (0.2 mm.). This product represents 1-(*p*-chlorophenyl)-3,4-dihydronaphthalene; yield 45%.

Anal. Calcd. for $C_{16}H_{13}Cl$: C, 80.0; H, 5.4. Found: C, 80.0; H, 5.6.

The dihydronaphthalene derivative was dehydrogenated with sulfur at 190 → 270° and the product distilled over copper bronze. 1-(*p*-Chlorophenyl)-naphthalene (IV,9) was obtained in quantitative yield; b. p. 151–153° (0.4 mm.).

Anal. Calcd. for $C_{16}H_{11}Cl$: C, 80.7; H, 4.6. Found: C, 80.9; H, 4.9.

Nitration in acetic acid, under the same conditions as described before, gave a mononitro derivative, which crystallized from ethanol in yellow prismatic rods, m. p. 121–122°; mixed m. p. with the above nitro derivative, 119°.

Both nitro compounds were converted by reduction with tin and hydrochloric acid in ethanol into the corresponding amine, which was acetylated directly by acetic anhydride. Water precipitated the crude acetamino derivative, which was recrystallized from dilute acetic acid; short rods of m. p. 215–216°. The mixed m. p. of both acetamino compounds showed no depression.

Anal. Calcd. for $C_{18}H_{14}ONCl$: C, 73.2; H, 4.7. Found: C, 73.5; H, 4.9.

4-(*p*-Fluorophenyl)-naphthalene-1,2-dicarboxylic acid anhydride (III,8) was decarboxylated according to method B at 320°. The colorless oil (IV,8), obtained in 27% yield, could not be induced to crystallize and was therefore nitrated directly in the same manner as described before. The nitration product, x(4?)-nitro-1-(*p*-fluorophenyl)-naphthalene, crystallized from ethanol in long yellow blocks of m. p. 104°.

Anal. Calcd. for $C_{16}H_{10}O_2NF$: N, 5.2. Found: N, 5.2.

[c] This substance was already described in the first paper of this series.[3] The purest sample, now obtained, melts four degrees higher than before. On working with larger amounts, we obtained a second form; yellow needles of m. p. 186–187° (from acetic acid). Analysis shows this form to be a semihydrate of the anhydride III,2. *Anal.* Calcd. for $C_{19}H_{12}O_3 \cdot {}^1/_2H_2O$: C, 76.8; H, 4.4. Found: C, 77.1; H, 4.6. [d] This anhydride appeared in two crystalline modifications of identical m. p. (see Experimental).

An authentic sample of IV,8 was prepared as in the foregoing case by interaction of tetralone with *p*-fluorophenyl magnesium bromide. 1-(*p*-Fluorophenyl)-3,4-dihydronaphthalene distilled at 120–125° (0.05 mm.) as a nearly colorless oil. It was obtained in 69% yield.

Anal. Calcd. for $C_{16}H_{13}F$: C, 85.7; H, 5.8. Found: C, 85.9; H, 6.0.

Dehydrogenation with sulfur proceeded at 200 → 220°. The product was distilled twice over copper bronze, b. p. 116–118° (0.04 mm.). This sample of 1-(*p*-fluorophenyl)-naphthalene (IV,8) formed a light yellow oil, which crystallized very slowly on standing; from methanol as colorless plates of m. p. 71–72°; yield, quantitative.

Anal. Calcd. for $C_{16}H_{11}F$: C, 86.5; H, 5.0. Found: C, 86.7; H, 4.8.

An acetic acid solution of IVa was heated with one equivalent of fuming nitric acid to 50° for ten seconds and the mixture poured onto ice. The nitro derivative crystallized from ethanol in yellow blocks of m. p. 104–105°, not depressed by admixture of the above nitration product.

Acknowledgment.—The authors wish to thank Prof. L. P. Hammett for his advice and criticism in the theoretical discussion of this investigation.

Summary

Unsymmetrically substituted 1,1-diarylethylenes react with maleic anhydride to yield only one of the two possible isomeric addition products. Substituents can be arranged in two groups: (a) substituents which promote addition to the substituted ring (methoxyl, phenyl); (b) substituents which prevent addition to the substituted ring (halogen, alkyl).

These effects are explained by the electronic influence of substituents on a meta and para position, applying Hammett's σ-values. The reaction mechanism is represented by an electronic cycle, involving electrophilic attack on the β-carbon atom and nucleophilic attack on the ortho position of the diarylethylene.

Symmetrically substituted diarylethylenes undergo the reaction even if they contain substituents of group b.

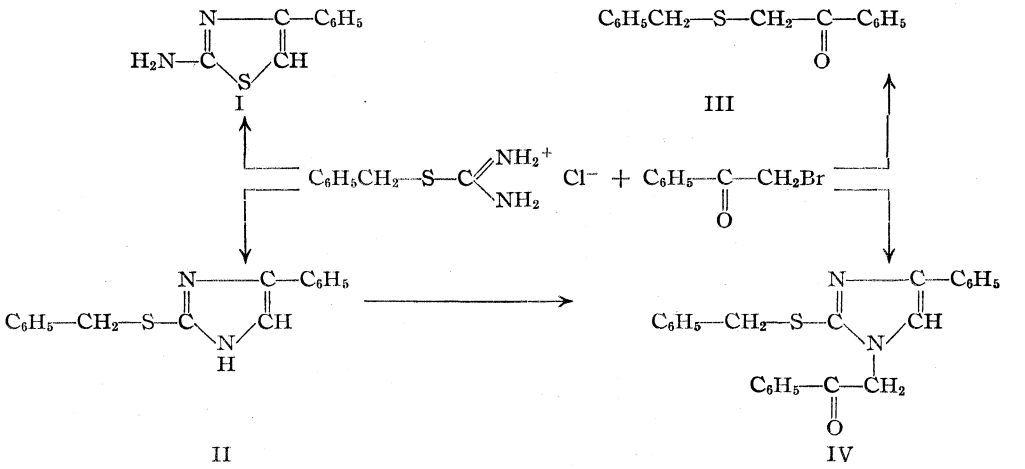
The Reaction of S-Benzylisothiourea with Phenacyl Bromide

BY R. M. DODSON

Although thiourea[1] has been used very extensively in the synthesis of heterocyclic compounds the use of S-alkylisothioureas for this purpose has been rather limited. Wheeler[2] and co-workers have used S-methyl- and S-ethylisothioureas in the synthesis of 2-alkylthiopyrimidines. Deck and Dains[3] have used a number of substituted S-methylisothioureas in the synthesis of various heterocyclic rings, but in their syntheses the methylthio group was eliminated. The purpose of this investigation was to extend the use of S-alkylisothioureas to the preparation of alkylthioimidazoles.

It is well known that thiourea reacts with α-haloketones to form 2-aminothiazoles.[1a] This reaction illustrates the preferential alkylation of the thio group in thiourea with alkyl halides. If, however, the thio group is first protected by alkylation, reaction of the S-alkylisothiourea with an α-haloketone should lead to the formation of an alkylthioimidazole. Kunckell[4] has demonstrated that α-haloketones will react with amidines to form imidazoles, and S-alkylisothioureas are merely readily available amidines.



The first attempted preparation of 2-benzylthio-4(5)-phenylimidazole (II) was made by heating equivalent amounts of S-benzylisothiourea hydrochloride and phenacyl bromide over a free flame until a clear melt was obtained. From this reaction 2-amino-4-phenylthiazole (I) rather than the expected imidazole was isolated. The benzyl group was eliminated, and the product was identical with that obtained from the reaction of thiourea with phenacyl bromide.

Condensation of equivalent amounts of S-benzylisothiourea hydrochloride and phenacyl bromide in alcohol in the presence of sodium bicarbonate formed 2-benzylthio-4(5)-phenylimidazole (II) in moderate yield (38%). The product was accompanied by smaller amounts of benzyl phenacyl sulfide (III) and 1-phenacyl-2-benzylthio-4-phenylimidazole (IV). The benzyl phenacyl sulfide (III) was formed concurrently with 2-benzylthio-4(5)-phenylimidazole (II) by the cleavage of the S-benzylisothiourea to benzyl mercaptan, followed by condensation of the mercaptan with phenacyl bromide. The 1-phenacyl-2-benzylthio-4-phenylimidazole (IV)[5,6] was formed by the further reaction of the 2-benzylthio-4(5)-phenylimidazole with phenacyl bromide. The relative quantities of these substances produced in the reaction depended on the conditions. Thus, in 50% aqueous alcohol, cleavage of the S-benzylisothiourea led to the formation of much (50%) benzyl phenacyl sulfide (III), but the 2-benzylthio-4(5)-phenylimidazole (II) (33%) was not alkylated. In absolute alcohol, on the other hand, most of the imidazole was alkylated to 1-phenacyl-2-benzylthio-4-phenylimidazole (IV). When potassium hydroxide was substituted for sodium bicarbonate, cleavage of the S-benzylisothiourea predominated and benzyl phenacyl sulfide (III) was formed in very good yield (81%). The 1-

(5) It is realized that this compound could be alternately formulated as 1-phenacyl-2-benzylthio-5-phenylimidazole. Structure IV is preferred by the author because Pyman and co-workers have found that 4(5)-phenylimidazole, on treatment with methyl sulfate, yields 1-methyl-4-phenylimidazole and 1-methyl-5-phenylimidazole in the proportions of 4.8 to 1.

(6) C. E. Hazeldine, F. L. Pyman and J. Winchester, *J. Chem. Soc.*, **125**, 1431 (1924).

phenacyl-2-benzylthio-4-phenylimidazole (IV) was best prepared (73%) by heating an alcoholic solution of one mole of S-benzylisothiourea hydrochloride and two moles of phenacyl bromide under reflux with sodium bicarbonate. The concurrent formation of benzyl phenacyl sulfide (III) and the further reaction of the imidazole with phenacyl bromide satisfactorily explain the moderate yield of 2-benzylthio-4(5)-phenylimidazole obtained.

The formation of 2-amino-4-phenylthiazole on fusion of S-benzylisothiourea hydrochloride with phenacyl bromide introduced the possibility that compound II was 2-benzylamino-4-phenylthiazole, formed by the migration of the benzyl group. This necessitated a proof of structure of the compound. On treatment with acetyl iodide[7] the 2-benzylthio-4(5)-phenylimidazole (II) was cleaved to 2-thiol-4(5)-phenylimidazole, identical with the compound previously prepared by Clemo and coworkers.[8]

Experimental[9]

2-Amino-4-phenylthiazole (I).—A dry mixture of 5.10 g. (0.025 mole) of S-benzylisothiourea hydrochloride, m. p. 172–175°, and 5.00 g. (0.025 mole) of phenacyl bromide was cautiously heated over a free flame until molten. The reaction was stopped when the solution started to boil. The resulting melt was cooled and extracted with 100 ml. of dilute (1:10) hydrochloric acid. The acid extract was decanted through a filter, and the excess acid was neutralized with sodium bicarbonate. The precipitate was separated by filtration and crystallized from benzene. From this reaction 1.57 g. (36%) of 2-amino-4-phenylthiazole, m. p. 149.5–150°, was obtained.

Anal. Calcd. for $C_9H_8N_2S$: C, 61.34; H, 4.58. Found: C, 61.55; H, 4.67.

The acetyl derivative, prepared by the action of acetic anhydride, melted at 212.5°. 2-Amino-4-phenylthiazole and its acetyl derivative are reported to melt at 151–152° and 214–214.5°, respectively.[10]

2-Amino-4-phenylthiazole was also formed in the same yield when the mixture of S-benzylisothiourea hydrochloride and phenacyl bromide were heated under vacuum in an oil-bath at 150–160° until distillation of volatile material ceased.

2-Benzylthio-4(5)-phenylimidazole (II).—A solution of phenacyl bromide in 100 ml. of chloroform, prepared by the bromination of 30.0 g. (0.25 mole) of acetophenone, was added to a solution of 51.0 g. (0.25 mole) of S-benzylisothiourea hydrochloride in 300 ml. of 84% ethyl alcohol. To this combined solution 84.0 g. (1.0 mole) of sodium bicarbonate was added slowly and the suspension heated under reflux for three hours. The solvent was then distilled from the reaction mixture. The residue was treated with 300 ml. of warm water and heated on the steam-bath until all of the inorganic salts had dissolved. The suspension was cooled and decanted through a filter. The product was washed a second time with warm water and dried. It was next treated with 100 ml. of boiling benzene; all lumps were broken; the resulting suspension was cooled in ice, and the product was separated by filtration. The process was repeated with 50 ml. of benzene and the product finally washed on the filter with two 25-ml. portions of cold benzene. From this reaction 25.1 g. (37.7%) of 2-benzylthio-4(5)-phenylimidazole, m. p. 173–177°, was obtained. One crystallization of the compound from alcohol raised its melting point to 176.5–177.5°.

Anal. Calcd. for $C_{16}H_{14}N_2S$: C, 72.17; H, 5.30; N, 10.52. Found: C, 72.01; H, 5.38; N, 10.23.

The picrate was prepared in boiling alcohol, m. p. 145–145.5°.

Anal. Calcd. for $C_{22}H_{17}N_5O_7S$: C, 53.33; H, 3.46. Found: C, 53.59; H, 3.52.

The benzene mother liquors from the above preparation were thoroughly shaken with 150 ml. of dilute (1:6) hydrochloric acid. The hydrochloride was separated by filtration and washed on the filter with 100 ml. of water, 100 ml. of ether, and finally 30 ml. of water, then crystallized from alcohol. A solution of this salt in alcohol was made basic with ammonium hydroxide, heated to boiling, diluted with water until slightly cloudy, then cooled. The product was separated by filtration and washed on the filter with 20 ml. of 70% ethyl alcohol. In this way 7.2 g. (15% based on the phenacyl bromide consumed) of 1-phenacyl-2-benzylthio-4-phenylimidazole, m. p. 141.5–143°, was obtained. Crystallization of the compound from alcohol raised its melting point to 143–143.5°.

Anal. Calcd. for $C_{24}H_{20}N_2OS$: C, 74.95; H, 5.24. Found: C, 74.96; H, 5.36.

The organic mother liquors from the filtration of the above hydrochloride were distilled and the residue was crystallized from 95% alcohol. Very crude benzyl phenacyl sulfide (18.2 g.), m. p. 64–76°, was obtained. Repeated crystallizations from alcohol failed to give a pure product. Crystallization from a mixture of benzene and petroleum ether (b. p. 60–70°) gave 11.2 g. (18.5%) of benzyl phenacyl sulfide, m. p. 87.5–88°. A mixture with an authentic sample of benzyl phenacyl sulfide showed no depression of melting point.

From the above benzene and petroleum ether mother liquors a small quantity (1.6 g.) of dibenzyl disulfide, m. p. 69.5–70° was isolated. For purposes of identification this was oxidized to benzyl benzylthiolsulfonate ("dibenzyl disulfoxide"), m. p. 106.5–107°. The reported melting points of these compounds are 72 and 108°, respectively.[11]

Benzyl Phenacyl Sulfide (III).—To a boiling solution of 5.10 g. (0.025 mole) of S-benzylisothiourea hydrochloride and 5.00 g. (0.025 mole) of phenacyl bromide in 50 ml. of ethyl alcohol was added a solution of 3.50 g. (0.0625 mole) of potassium hydroxide in 20 ml. of ethyl alcohol. The resulting suspension was heated under reflux for two hours. It was then cooled to 5°, and the product separated by filtration. The product was washed on the filter with 10 ml. of cold alcohol, then suspended in warm water and stirred thoroughly to free it from potassium bromide and potassium chloride, then again separated from the solution by filtration. From this reaction 4.90 g. (81%) of benzyl phenacyl sulfide, m. p. 86–87°, was obtained. Crystallization of the compound from alcohol raised its melting point to 87.5–88.5°. Oxidation with potassium permanganate gave benzyl phenacyl sulfone, m. p. 112°. The reported melting points of benzyl phenacyl sulfide and benzyl phenacyl sulfone are 89° and 113°, respectively.[12]

1-Phenacyl-2-benzylthio-4-phenylimidazole (IV).—To a solution of 5.10 g. (0.025 mole) of S-benzylisothiourea hydrochloride and 10.00 g. (0.050 mole) of phenacyl bromide in 50 ml. of absolute alcohol was added 8.4 g. (0.10 mole) of sodium bicarbonate. The resulting suspension was heated under reflux for two and one-half hours with periodic shaking, then diluted with water. The product was separated by filtration, powdered, and treated with 200 ml. of ether. The resulting suspension on filtration yielded 5.33 g. of 1-phenacyl-2-benzylthio-4-phenylimidazole, m. p. 139–143°. The ether mother liquors were next extracted with 75 ml. of dilute (1:2)

hydrochloric acid, and the insoluble hydrochloride treated according to the directions given above. An additional 1.68 g. of 1-phenacyl-2-benzylthio-4-phenylimidazole, m. p. 136–139°, was obtained. The total yield of crude product was 7.01 g. or 73%. One crystallization from dilute alcohol gave 6.37 g. of material, m. p. 141.5–142.5°. A mixture with the previously prepared sample showed no depression of melting point. This same product can be made in 78% yield by alkylating 2-benzylthio-4(5)-phenylimidazole with phenacyl bromide in alcohol in the presence of sodium bicarbonate.

The picrate of 1-phenacyl-2-benzylthio-4-phenylimidazole was prepared by mixing the base and picric acid in hot alcohol, m. p. 169–171°.

Anal. Calcd. for $C_{30}H_{23}N_5O_8S$: C, 58.72; H, 3.78. Found: C, 58.90; H, 3.74.

2-Thiol-4(5)-phenylimidazole.—Red phosphorus (3.7 g.) was added to 15 g. of iodine in 25 ml. of glacial acetic acid, and the resulting suspension was heated under reflux for twenty minutes. Then 3.00 g. of 2-benzylthio-4(5)-phenylimidazole was added and the solution was heated under reflux for three and one-half hours. The solution was filtered to free it from phosphorus, decolorized with sodium bisulfite, diluted with two volumes of water, and neutralized with ammonium hydroxide. The resulting suspension was cooled in ice, and the product was separated from the solution by filtration. To free the 2-thiol-4(5)-phenylimidazole from starting material, it was dissolved in 50 ml. of 10% sodium hydroxide solution. After separating the insoluble 2-benzylthio-4(5)-phenylimidazole (0.34 g., m. p. 172–175°), the filtrate was neutralized with 8 ml. of glacial acetic acid, and cooled. On filtration 1.13 g. (64% on the basis of the starting material consumed) of 2-thiol-4(5)-phenylimidazole, m. p. 249–255°, was obtained. Crystallization of the compound from a mixture of acetone and benzene raised its melting point to 261–262°. The picrate, formed in absolute alcohol, crystallized as garnet-red prisms, m. p. 178–179° (dec.). For further identification of 2-thiol-4(5)-phenylimidazole was oxidized with dilute nitric acid to 4(5)-phenylimidazole, m. p. 130–131°; 4(5)-phenylimidazole nitrate, m. p. 167–167.5° (dec.). These physical constants agree well with those previously recorded for these compounds.[8,13]

Summary

1. It has been shown that the reaction of S-benzylisothiourea with phenacyl bromide can form any one of four products, 2-amino-4-phenylthiazole, benzyl phenacyl sulfide, 2-benzylthio-4-(5)-phenylimidazole and 1-phenacyl-2-benzylthio-4-phenylimidazole, depending upon the conditions of the reaction.

2. The 2-benzylthio-4(5)-phenylimidazole was cleaved to the known 2-thiol-4(5)-phenylimidazole by the action of acetyl iodide.

The Synthesis of Some Substituted 2-Thiouracils

BY HENRY GILMAN AND H. SMITH BROADBENT

Considerable interest has developed within the last few years in the treatment of hyperthyroid disturbances by chemical means.[1] Among the most effective substances employed have been 2-thiouracil and some of its derivatives. In the course of a study of the chemotherapeutic properties of several types of nitrogen and sulfur containing compounds, it was decided, therefore, to synthesize several derivatives of 2-thiouracil for examination.

The 6-substituted-2-thiouracils were prepared by the usual method of condensing β-oxo esters with thiourea in the presence of sodium ethoxide.

Three different methods were employed in the preparation of the necessary β-oxo esters. They were the alkylation of ethyl acetoacetate, the Claisen condensation of esters, and the carbethoxylation of ketones with ethyl carbonate.

By alkylating sodio ethyl acetoacetate with γ-diethylaminopropyl chloride and with γ-diethylaminopropyl β-chloroethyl sulfide, the respective β-oxo esters, 1-diethylamino-4-carbethoxyhexanone-5 and 1-(γ-diethylaminopropylmercapto)-3-carbethoxypentanone-4, were prepared, isolated, and some of their important physical constants determined as well as those of some of their precursor compounds.

We were unable to condense successfully these two complex β-oxo esters with thiourea to form 2-thiouracils by the usual procedures. Only polymeric, gummy residues, quite unlike the probable properties of the expected compounds, were obtained. Anderson, *et al.*,[2] report the formation of unidentified by-products in considerable amount in preparing some of the longer chain (butyl, *n*-amyl, *n*-hexyl) 6-substituted-2-thiouracils. The yields in these condensations are not high at best.

The α-, β-, and γ-pyridoylacetates were prepared by the Claisen condensation of the pyridinecarboxylic acid esters and ethyl acetate. Although these β-oxo esters have been reported heretofore,[3,4,5,6] it was found possible to prepare the first two of them in greatly improved yields by a suitable modification of the Claisen condensation procedure using benzene as a diluent. The preparation of the necessary sodium ethoxide *in situ* in benzene suspension also obviates the necessity of preparing fresh, anhydrous, solid sodium ethoxide for the condensation as is usually done. The isolation of pure liquid ethyl picolinoylacetate does not appear to have been done. Pinner[3] isolated it as its sodium salt; Burrus and Powell[4] obtained it as

[a] All melting points were taken on a Berl–Kullman block. [b] Two years after this work was completed the preparation of this compound was reported by others.[6,8] The first group gives its melting point as 296–298°. The second gives *ca.* 291°. [c] Two years after this work was completed, the preparation of this compound was reported by others[6] who report its melting point as 226–227°, a value we were unable to substantiate. [d] Insoluble in all ordinary organic solvents. It was purified by dissolving it in alkali, filtering, reprecipitating with acetic acid, and washing with water.

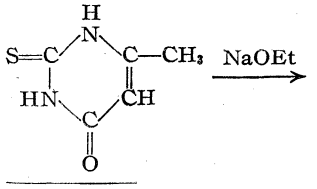
its hydrochloride; however, it was found possible to distil the free base with little decomposition and isolate the slightly impure liquid, which can be kept for a long time with very little change.

The method of Camps[7] has usually been used in esterifying the pyridinecarboxylic acids. He reports yields of 90, 90 and 91%, respectively, for the α-, β- and γ-isomers; however, later workers have not been able to duplicate his yields. Burrus and Powell[4] obtained yields of 61 and 30% of the β- and γ-isomers, respectively, by Camps' method. We were able to prepare ethyl nicotinate in 72% yield by Camps' method. By employing a different esterification procedure, ethyl isonicotinate was conveniently secured in 61.4% yield.

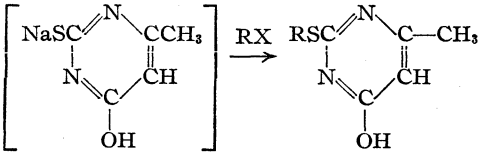
The 6-pyridyl-2-thiouracils (see table) are very high melting solids, quite insoluble in organic solvents. In fact, the γ-isomer is almost completely insoluble in acetic acid, nitrobenzene, carbitol, aniline, pyridine, quinaldine, tri-*n*-butyl phosphate, and all common solvents at their boiling temperatures; however, all three of them are readily soluble in strong acids and bases.

Ethyl *p*-anisoylacetate and ethyl β-(2-thienyl)-oxopropionate were prepared by the carbethoxylation with ethyl carbonate and sodamide of the corresponding ketones. The former tends to decompose on distilling even at low pressures.

Mercapto derivatives of 6-methyl-2-thiouracil were prepared as follows



(7) Camps, *Arch. Pharm.*, **240**, 346 (1902).



Neither *o*- nor *p*-nitrobromobenzene were found to be sufficiently reactive to undergo metathesis in our hands with a suspension of the sodium salt of the thiouracil in absolute ethanol, although they will readily condense with ordinary sodium mercaptides under such conditions. With 2,4-dinitrochlorobenzene a very insoluble product was secured; however, its isolation in a pure form was not accomplished.

γ-Diethylaminopropyl chloride, *p*-nitrobenzyl chloride and *p*-nitrophenethyl bromide, all substituted aliphatic halides, condensed easily with the sodium salt of 6-methyl-2-thiouracil forming the corresponding mercapto derivatives.

The attempted preparation of 2-(*p*-aminobenzylmercapto)-4-hydroxy-6-methylpyrimidine and 2-(*p*-aminophenethylmercapto)-4-hydroxy-6-methylpyrimidine by the catalytic reduction of their corresponding nitro compounds over Raney nickel catalyst resulted in the formation of resinous polymers containing less than the required amount of sulfur in both cases. The correct amount of hydrogen was absorbed for complete reduction of the nitro groups and then hydrogenation ceased. Johnson and Bailey[9] report that 2-ethylmercapto-4-hydroxy-5-ethyl-6-methylpyrimidine slowly reacts with aniline in ethanolic solution forming 2-anilino-4-hydroxy-5-ethyl-6-methylpyrimidine. It appears probable, therefore,

(8) Jackman, Bergman and Archer, THIS JOURNAL, **70**, 497 (1948).

(9) Johnson and Bailey, *ibid.*, **35**, 1010 (1913).

that the desired aminoaralkylmercaptouracils were first formed on reduction, but later polymerized forming the anilino linkage with adjacent molecules to some extent.

The pharmacological results are to be published elsewhere, and the authors are grateful to Parke, Davis and Company for arranging for the tests.

Experimental

1-Diethylamino-4-carbethoxyhexanone-5.—Sodio ethyl acetoacetate, 0.22 mole, was prepared in 80 ml. of absolute ethanol, and the mixture was gently refluxed while 30 g. (0.2 mole) of γ-diethylaminopropyl chloride was added dropwise over a two-hour period. After six hours of refluxing it was cooled, and filtered free of 10.6 g. of sodium chloride (11.6 g. theoretical).

After the bulk of the ethanol was distilled from the filtrate, the residue was poured into water and extracted with ether. From the aqueous layer considerable polymeric gum, likely arising from quaternization of the γ-diethylaminopropyl chloride, was obtained on evaporation. After drying the ether extract and evaporating the solvent, the residue was distilled through a ten-inch Vigreux column. The principal fraction amounted to 23 g. boiling at 116–129° (1 mm.). On refractionation 17.8 g. (36.5%) of product was collected at 107–109° (0.5 mm.): $n^{20}D$ 1.4514; d^{20}_4 0.956; $M^{20}D$ calcd. 69.06 (keto) 70.10 (enol); $M^{20}D$ obs. 69.0.

On another 0.35-mole run using freshly distilled γ-diethylaminopropyl chloride about 60% of it was added all at once to the refluxing sodio acetoacetic ester solution, and two hours later the remainder was added. After twenty hours of refluxing, the mixture was worked up as before. The residue on distillation gave 53.6 g. (63%) of clear, colorless product at 100–107° (largely at 104–105°) (0.4 mm.): $n^{20}D$ 1.4509.

Anal. Calcd. for $C_{13}H_{26}O_3N$: N, 5.73. Found: N, 5.57.

1-(γ-Diethylaminopropylmercapto)-3-carbethoxypentanone-4.—γ-Diethylaminopropyl β-chloroethyl sulfide was prepared according to the directions of Gilman and Tolman.[10] From 91 g. (1.17 moles) of β-hydroxyethanethiol and 174.5 g. (1.17 moles) of γ-diethylaminopropyl chloride, 191.5 g. (86%) of γ-diethylaminopropyl β-hydroxyethyl sulfide boiling at 105° (1.1 mm.) was obtained. Some physical constants which have not been determined heretofore are: $n^{20}D$ 1.4957; d^{20}_4 0.9830; M_D calcd. 57.3, found 56.8. This was converted to the corresponding chloro compound with thionyl chloride giving 53.5 g. (57%) of product boiling at 84–95° (0.3–0.4 mm.) (bath 112–132°). The constants, which have not been determined heretofore, are: $n^{20}D$ 1.4890; d^{20}_4 1.000; $M^{20}D$ calcd. 60.7, found 60.5. It was conveniently stored as its hydrochloride and recovered as the free base, just prior to use. The freshly distilled γ-diethylaminopropyl β-chloroethyl sulfide, 22.6 g. (0.108 mole) was added dropwise with stirring over a five-hour period to a refluxing solution of 0.12 mole of sodio ethyl acetoacetate in absolute ethanol. Upon working up the product and two fractionations 11 g. (33.5%) of the desired β-oxo ester was obtained boiling at 147–150° (0.4 mm.): $n^{20}D$ 1.4811; d^{20}_4 1.005; $M^{20}D$ calcd. 85.2 (keto), 86.3 (enol), found 86.0.

Anal. Calcd. for $C_{15}H_{29}O_3NS$: S, 10.6. Found: S, 10.8.

Ethyl Picolinoylacetate.—This ester was prepared according to the method of Gilman, Tolman and Massie,[11] who did not, however, isolate the product but hydrolyzed it directly to the ketone *in situ*.

To 13.8 g. (0.6 atom) of sodium sand in 550 ml. dry benzene, 27.6 g. (0.6 mole) of absolute ethanol was added dropwise at such a rate as to promote gentle reflux until all the sodium had reacted. Then a mixture of 60.4 g. (0.4 mole) of ethyl picolinate[12] and 70.4 g. (0.8 mole) of dry ethyl acetate was slowly run into the refluxing suspension. After the addition was complete, the thick sludge was filtered. The precipitate was dissolved in water, treated with an excess of acetic acid, and the liberated ester extracted with ether, dried, and distilled. One portion weighing 24.4 g. was collected at 115–120° (0.4 mm.), $n^{20}D$ 1.5181, and another weighing 29.9 g. at 122–124° (0.5 mm.), $n^{20}D$ 1.5184, d^{20}_4 1.1639, M_D obs. 50.37; M_D calcd. 50.37.[13] Both portions were red when first collected, but soon changed to a straw color on standing; total yield, 54.3 g. (70%).

The identity of the product was established by refluxing a 0.01-mole portion with an equivalent of phenylhydrazine in 10 ml. of ethanol containing a few drops of acetic acid as a catalyst. On cooling, yellow needles of 1-phenyl-3-(α-pyridyl)-pyrazolone-5 melting at 177–178° were obtained: yield, 2 g. (85%) (reported,[3] 179°).

Ethyl Nicotinate.—One hundred grams (0.813 mole) of nicotinic acid was warmed on the steam-bath with a mixture of 250 ml. ethanol and 125 ml. concd. sulfuric acid until all the solid dissolved. After cooling the mixture was poured into 2 kg. of cracked ice and 350 g. of potassium carbonate, then filtered. The filtrate was saturated with sodium carbonate and extracted with ether. On evaporation of the ether the residue yielded on distillation, 88 g. (72%) of colorless, liquid ester boiling at 107–108° (16 mm.).

Ethyl Nicotinoylacetate.—A suspension of 0.75 mole of sodium ethoxide was prepared in 690 ml. of benzene in the manner described above. To this a mixture of 88 g. (1.0 mole) of anhydrous ethyl acetate and 75.5 g. (0.5 mole) of ethyl nicotinate was added slowly under reflux. After twelve hours of refluxing the liquid became clear. The benzene was distilled off on the steam-bath and the residual gum hydrolyzed with an excess of dilute acetic acid. After adding an excess of potassium carbonate, the ester was extracted with ether, dried and distilled. The product was collected as 64.5 g. (67%) of pale, slightly straw-colored oil boiling at 121–123° (0.4 mm.) (reported, by other modifications of the Claisen condensation: 37%[4] as the hydrochloride, and 58%[5]).

Ethyl Isonicotinate.—Isonicotinic acid was prepared by oxidizing 200 g. (2.15 mole) of γ-picoline (technical grade) in 3 l. of water with a total of 680 g. (4.30 mole) of potassium permanganate added portionwise (the reaction easily becomes violent.) A yield of 155 g. (59%) of pure acid was obtained from the acidified filtrate without reworking the mother liquors.

One hundred and forty grams (1.14 moles) of isonicotinic acid suspended in 980 ml. of absolute ethanol was cooled to 0° while dry hydrogen chloride was bubbled in until the solution was saturated. Then with the gas still being slowly passed in, it was refluxed until the solid all dissolved. The excess ethanol was removed under reduced pressure, the solid dissolved in water, cooled and treated with an excess of saturated sodium carbonate solution, filtered and extracted with ether. On distillation 105.5 g. (61.4%) of clear, colorless ester was obtained boiling at 105–108° (16–17 mm.) (reported[4]: 30% yield by the method of Camps).

Ethyl Isonicotinoylacetate.—The technique used in this preparation was parallel to that used in synthesizing the β-pyridoyl isomer. From 0.5 mole of ethyl isonicotinate 66.4 g. (69%) was obtained boiling at 118–120° (0.4 mm.), m. p. 53–55° (reported[5]: m. p. 54°, in 85% yield by another technique).

(10) Gilman and Tolman, THIS JOURNAL, **67**, 1847 (1945).

(11) Gilman, Tolman and Massie, *ibid.*, **68**, 2399 (1946).

(12) Kindly supplied by S. P. Massie of these laboratories.

(13) The calculated value will vary a great deal depending on the numerical contribution to the total molecular refraction assigned to the pyridine moeity of the molecule. The calculated value shown was obtained using the atomic and structural factors given in Gilman, "Organic Chemistry," Vol. II, 2nd ed., John Wiley and Sons, New York, 1943, p. 1751, and considering the contributions of the three double bonds in pyridine as equal to 3 × 1.73 = 5.19. The close agreement is undoubtedly fortuitous under the circumstances.

Ethyl *p*-Anisoylacetate.—To sodamide prepared from 9.2 g. (0.4 atom) of sodium in 250 ml. of liquid ammonia 30 g. (0.2 mole) of *p*-methoxyacetophenone dissolved in 100 ml. of dry ether was added with vigorous stirring. The excess ammonia was evaporated off and replaced with ether. Under reflux 47.2 g. (0.4 mole) of ethyl carbonate was then added. After stirring the fluid grayish black suspension under reflux for five hours, a semi-solid mass resulted which was hydrolyzed with acetic acid and extracted with ether. After drying and evaporating the solvent, the residue was distilled with some decomposition giving 11.9 g. (26.8%) of clear, viscous oil at 155–158° (0.6–0.7 mm.) (reported,[14] boiling point 180–190° (10–12 mm.) with decomposition, prepared by another method).

The identity of the ester, prepared by this method for the first time, was established by refluxing a small portion in ethanol with hydroxylamine hydrochloride. Long, slender, white needles of 3-(*p*-methoxyphenyl)-isoxazolone-5 were obtained melting at 140–141° (reported,[15] 143°).

Ethyl *β*-(2-Thienyl)-*β*-oxopropionate.—According to the procedure of Levine and Hauser,[12] 0.4 mole of 2-acetothienone was carbethoxylated in the presence of sodamide. A yield of 33.3 g. (84%) of viscous, oily ester distilling at 121–123° (0.4–0.5 mm.) was obtained (reported,[16] 48% yield boiling at 150–153° (5 mm.)).

6-(α-Pyridyl)-2-thiouracil. Procedure A.—The procedure used was substantially that of Anderson, *et al.*[2] Thiourea, 3.8 g. (0.05 mole), and 8.95 g. (0.05 mole) of ethyl picolinoylacetate were added to 0.1 mole of sodium ethoxide in ethanol. Almost immediately a precipitate began to form. After refluxing overnight, the solvent was removed under reduced pressure, the residue taken up in water, filtered, and acidified with acetic acid. The precipitate was filtered off, dried and recrystallized from 200 ml. of glacial acetic acid. Three grams (29%) of hard, well formed crystals with a faint greenish cast was obtained. They melted with slight decomposition at 291–294°. The procedure followed in preparing the other 6-substituted-2-thiouracils was analogous.

2-(γ-Diethylaminopropylmercapto)-4-hydroxy-6-methylpyrimidine. Procedure B.—A suspension of the sodium salt of 6-methyl-2-thiouracil was prepared by digesting 7.1 g. (0.05 mole) of the thiouracil in a solution of 0.05 mole of sodium ethoxide in 50 ml. of ethanol at reflux temperature for two hours. Then 7.5 g. (0.05 mole) of γ-diethylaminopropyl chloride in 25 ml. of ethanol was added, and the mixture was stirred under reflux for six hours. The cooled mixture was filtered free of sodium chloride and the solvent evaporated. On distillation 10.5 g. (82.4%) of a colorless, very viscous oil, almost a glass, was obtained boiling at 183–188° (0.4 mm.). It was very soluble in ethanol, insoluble in water and ligroin, and sparingly soluble in ether. We were not successful in obtaining a crystalline hydrochloride.

The other two compounds prepared by this method (procedure B) were themselves insoluble in ethanol; consequently, the reaction mixture slurry was exhaustively washed with water to remove inorganic substituents and the residue recrystallized to constant melting point (see Table I).

Catalytic Reduction of 2-(*p*-Nitrobenzylmercapto)-4-hydroxy-6-methylpyrimidine and its Next Higher Homolog.—Ten grams (0.036 mole) of the former compound suspended in 200 ml. dioxane with 2–3 g. Raney nickel catalyst was shaken under 4 atm. pressure of hydrogen. The calculated amount of hydrogen for complete reduction of the nitro group was absorbed in five hours, then the uptake of hydrogen ceased. After filtering and removing the solvent under reduced pressure, a hard, red glass softening gradually above 110° was obtained. It was ground to a resinous, yellow powder and dried *in vacuo* at 110° for analysis.

Anal. Calcd. for $C_{12}H_{13}ON_3S$: S, 12.69. Found: S, 10.83.

From a similar treatment of the next higher homolog, the phenethyl derivative, an orange vitreous mass, insoluble in ether and ethanol, was obtained which could not be crystallized. It melted *ca.* 55–70°. This polymeric material also gave a low analysis for sulfur.

Anal. Calcd. for $C_{13}H_{15}ON_3S$: S, 12.27. Found: S, 11.17.

Summary

1. Some new derivatives of 2-thiouracil have been prepared for evaluation as antithyroid agents.

2. Two new *β*-oxo esters have been isolated and improved techniques for the preparation of some others and their precursory starting materials have been described.

3. Catalytic reduction of 2-(*p*-nitrobenzylmercapto)-4-hydroxy-6-methylpyrimidine and its next higher homolog was found to initiate a complex reaction yielding polymeric substances.

Derivatives of Piperazine. XXII. Piperazinium Salts for Utilization in Identification of Organic Acids

BY M. PRIGOT AND C. B. POLLARD

In previous papers[1,2] from this Laboratory certain piperazinium salts were reported for utilization in identification of organic acids. The present paper describes an improved method of preparation, and data concerning thirty-six new piperazinium salts are shown in Table I.

Experimental

The respective acid was dissolved in anhydrous ether or propanol-2 in a Waring blendor. The calculated amount of piperazine was added as 1 *M* piperazine in propanol-2 during vigorous stirring. The precipitate was suction filtered, added to fresh ether or propanol-2, stirred again in a Waring blendor, refiltered and dried in a desiccator over phosphorus pentoxide before physical constants were determined. For purposes of qualitative analysis plate drying is usually sufficient. Acids which were quite insoluble in ether or propanol-2 were dissolved in water before addition of piperazine. This necessitated evaporation on a steam-bath to recover the piperazinium salts.

Melting points are corrected and were determined by use of a bronze block, preheated to within 5° of the m. p.

Neutral equivalents were determined by dissolving the salt in 50% aqueous propanol-2 and titrating with 0.1 *N*

[a] Solution too dark to titrate. [b] Previously prepared by Pollard, Adelson and Hampton, but not reported.

sodium hydroxide using either thymolphthalein or Orange II as indicator.

By the method employed the following acids failed to give salts which are of practical value for qualitative organic analysis: α-bromo-*n*-butyric, anthraquinone-β-sulfonic, barbituric, 2-chloropropionic, 2,5-dichlorobenzenesulfonic, 2,4-dichlorophenoxyacetic, diethylacetic, diphenylacetic, erucic, glycine, *p*-hydroxybenzoic, iodoacetic, itaconic, levulinic, *dl*-methylethylacetic, mucic, 1-naphthol-4-sulfonic, sulfosalicylic, thioglycolic, and trimesic.

Summary

Thirty-six new piperazinium salts which may be utilized for the identification of organic acids are reported.

Twenty organic acids which failed to give suitable derivatives are listed.

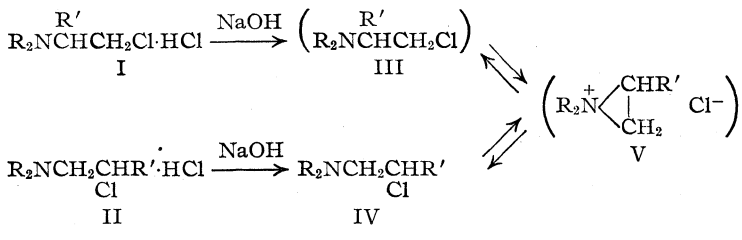
Ring Enlargement by Rearrangement of the 1,2-Aminochloroalkyl Group; Rearrangement of 1-Ethyl-2-chloromethylpyrrolidine to 1-Ethyl-3-chloropiperidine

BY REYNOLD C. FUSON AND CHARLES L. ZIRKLE[1]

Recently it has been found that 1,2-aminochloroalkanes undergo a rearrangement[2] analogous to that of 2-chloroisopropyl sulfides.[3] In all examples thus far studied, the amines liberated from the isomeric 1,2-aminochloroalkane hydrochlorides (I and II) are identical and possess the normal structure (IV).[2b,c,d,4] This rearrangement of



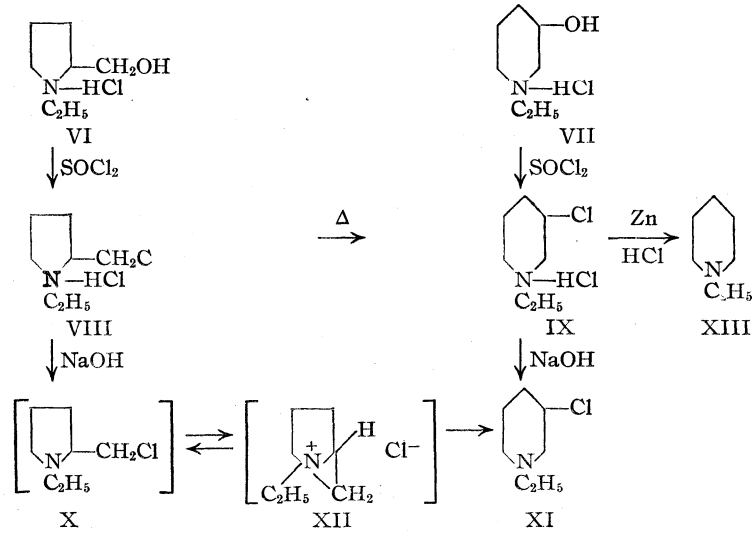
I III V

II IV

chloro amines of structure I is believed to occur through the cyclic imonium chloride intermediate (V). It has been shown that ethyleneimonium salts of this type are formed in other reactions of 2-haloalkylamines.[5]

This behavior of 2-chloroalkylamines suggested the interesting possibility that 1-alkyl-2-chloromethyl cyclic imines—compounds in which the chlorine is in the 2-position to a cyclic tertiary amino group—by a similar rearrangement might undergo ring enlargement, providing a route to 1-alkyl-3-chloro cyclic imines having one more carbon in the ring. We have accomplished such a ring enlargement by rearrangement of 1-ethyl-2-chloromethylpyrrolidine hydrochloride (VIII) to 1-ethyl-3-chloropiperidine (XI).

It was found that when 1-ethyl-2-chloromethylpyrrolidine hydrochloride (VIII), prepared from the corresponding amino alcohol hydrochloride (VI) by treatment with thionyl chloride, was treated with alkali, the free base obtained was not the pyrrolidine derivative (X) but the isomeric 1-ethyl-3-chloropiperidine(XI). Presumably the 1-ethyl-2-chloromethylpyrrolidine (X) underwent rearrangement as rapidly as it was formed, the cyclic imonium salt (XII) being the intermediate. That the chloromethyl pyrrolidine (X) did not rearrange when in the form of its hydrochloride (VIII) was demonstrated by the fact that the picrate formed from the salt was different from that obtained from the free amine. The picrate of the distilled amine was identical with that prepared from the crude base, indicating that no change in the chloro amine occurred during distillation. The chloropiperidine (XI), prepared from 1-ethyl-3-hydroxypiperidine hydrochloride (VII), did not rearrange when liberated from its salt (IX). The free amine after being distilled formed a picrate identical with



that from the original piperidine hydrochloride and that of the free base obtained from the chloromethylpyrrolidine hydrochloride (VIII). For additional proof that the amine isolated from the isomeric chloro amine salts was the piperidine derivative, 1-ethyl-3-chloropiperidine hydrochloride (IX) was converted to 1-ethylpiperidine (XIII) by means of zinc and hydrogen chloride in glacial acetic acid.

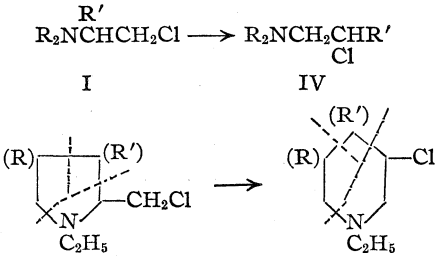
The experiments described above indicate that 1-ethyl-2-chloromethylpyrrolidine is stable in the form of its hydrochloride (VIII). In fact, this salt sublimed without change at temperatures below its melting point. The picrate formed from the sublimed hydrochloride was identical with that obtained from the original chloromethylpyrrolidine hydrochloride. At temperatures above its melting point, however, the pyrrolidine salt rearranged to 1-ethyl-3-chloropiperidine hydrochloride. This property has been found to be general for 1,2-aminochloroalkane hydrochlorides of type I.[2a,b,c,d] Upon rapid heating the pyrrolidine salt (VIII) melted at 165–170°, solidified, and remelted at 193.5–194.0°. When the temperature was raised slowly the isomeric hydrochlorides and a mixture of the two salts had the same melting point (193.5–194.9°), although the picrates prepared from the hydrochlorides differ in melting point.

The direction of rearrangement in this isomeric pair of cyclic chloro imines is that observed in other 1,2-aminochloroalkanes, *i. e.*



However, in some of their reactions, *e. g.*, hydrolysis and alkylation,[2a,b,c,d,e] the 2-chloro-*n*-propylamines (IV, R = CH_3) sometimes yield products containing the isopropylamino group—a change which is the reverse of that found in the isomerization of these chloro amines. Undoubtedly the ease and direction of rearrangement is determined by the steric and polar nature of both the intermediate cyclic imonium ion and the attacking nucleophilic agent. When the latter is chloride ion, the product appears to be that of structure IV exclusively.

Work is now in progress to determine whether other 1-alkyl-2-chloromethyl cyclic imines also undergo this rearrangement.

Experimental

1-Ethyl-2-hydroxymethylpyrrolidine.—This amino alcohol was prepared by the synthesis of Signaigo and Adkins.[6a] Hydrogenation[7] of 1,2-dicarbethoxypyrrole[6b] over Raney nickel in dry methanol at 70° and 1500 lb. pressure gave a 95% yield of 1,2-dicarbethoxypyrrolidine[6a]; b. p. 133–135° (8 mm.) (Signaigo and Adkins reported 133–134° (8 mm.)). The latter (33.6 g., 0.156 mole) in absolute ethanol upon hydrogenation at 250° and 100 atm. in the presence of 10 g. of copper chromite yielded 6.3 g. (31%) of 1-ethyl-2-hydroxymethylpyrrolidine; b. p. 78–79° (17 mm.); $n^{23}D$ 1.4659 (reported: b. p. 82–84° (24 mm.); $n^{25}D$ 1.4662). The hydrochloride, prepared by saturating a dry toluene solution of the amine with hydrogen chloride, separated as an oil which resisted all attempts at recrystallization. The benzoate hydrochloride of the amino alcohol separated as an oil when a mixture of the alcohol and an equimolar amount of benzoyl chloride in dry toluene was heated for an hour on the steam-bath. On standing overnight in the ice-box the oil solidified as waxy needles but all attempts to recrystallize the solid failed. A picrate was formed by adding a concentrated solution of the benzoate hydrochloride to a saturated aqueous solution of picric acid; m. p. 170.5–171.5° after two recrystallizations from acetone.

Anal. Calcd. for $C_{20}H_{22}O_9N_4$: C, 51.95; H, 4.80; N, 12.12. Found: C, 51.68; H, 4.62; N, 12.16.

1-Ethyl-3-hydroxypiperidine.—By the method of Paul,[8] diethyltetrahydrofurfurylamine[8] was converted to 1-ethyl-3-hydroxypiperidine in 43% yield; $n^{23}D$ 1.4744. The benzoate hydrochloride melted at 198–199° (203–204° (cor.)) (Paul reported a boiling point of 97–98° (21 mm.); $n^{23}D$ 1.47427; benzoate hydrochloride, m. p. 204°). A benzoate picrate was prepared as described above for comparison with that of 1-ethyl-2-hydroxymethylpyrrolidine. The yellow crystals recrystallized from acetone melted at 181.5–182.5°.

Anal. Calcd. for $C_{20}H_{22}O_9N_4$: N, 12.12. Found: N, 12.08.

The amino alcohol formed a hydrochloride (VII) which melted at 157–158° after recrystallization from ethyl acetate–ethanol.

Anal. Calcd. for $C_7H_{16}ONCl$: C, 50.75; H, 9.74; N, 8.46. Found: C, 50.93; H, 9.64; N, 8.26.

1-Ethyl-2-chloromethylpyrrolidine Hydrochloride (VIII).—To a flask equipped with a mechanical stirrer and a condenser fitted with a calcium chloride tube was added 4.0 g. (0.031 mole) of 1-ethyl-2-hydroxymethylpyrrolidine in 25 ml. of dry chloroform. The flask was immersed in an ice–salt-bath and the solution saturated with dry hydrogen chloride to form the salt of the amino alcohol (VI). With stirring 4.8 g. (0.040 mole) of thionyl chloride in a few milliliters of chloroform was added dropwise to the cold solution of amine hydrochloride. After all the thionyl chloride was added the mixture was stirred for thirty minutes at room temperature, then refluxed for one hour. The dark crystalline product after removal of solvent was triturated with acetone and collected on a filter. Two recrystallizations of the slightly discolored solid from acetone–ethanol gave 3.2 g. (56%) of the chloro amine hydrochloride. When the bath temperature was raised rapidly (20° per minute), the hydrochloride melted at 165–170°, solidified, and remelted at 193.5–194.0° (rate of heating, two degrees per minute). When the temperature was raised slowly, the sample contracted without melting at 165° and melted at 193.5–194.0°. A mixture melting point with 1-ethyl-3-chloropiperidine hydrochloride (IX) showed no depression. These observations indicate that upon heating the two isomeric salts rearrange to the same compound.

Anal. Calcd. for $C_7H_{15}NCl_2$: C, 45.66; H, 8.21; N, 7.61; Cl, 38.52. Found: C, 45.56; H, 7.86; N, 7.45; Cl, 38.56.

A picrate prepared by adding a concentrated solution of the chloro amine hydrochloride to a saturated aqueous solution of picric acid was recrystallized from ethanol; m. p. 128.5–129.5°.

Anal. Calcd. for $C_{13}H_{17}O_7N_4Cl$: C, 41.44; H, 4.55; N, 14.87; Cl, 9.41. Found: C, 41.59; H, 4.45; N, 14.73; Cl, 9.43.

The pyrrolidine hydrochloride sublimed without change at 90° (2 mm.). The picrate prepared from the sublimed salt was identical with that obtained from the hydrochloride before sublimation.

Evaporation of the acetone with which the crude 1-ethyl-2-chloromethylpyrrolidine hydrochloride was washed

(6) (a) Signaigo and Adkins, THIS JOURNAL, **58**, 709 (1936); (b) **58**, 1122 (1936).

(7) The hydrogenations were performed by Mr. David J. Wallace.

(8) Paul, *Bull. soc. chim.*, **12**, 830 (1945).

yielded a dark water-soluble oil which formed a picrate (1.4 g.) when added to saturated aqueous picric acid solution. After repeated crystallizations from ethanol the picrate (0.4 g.) melted at 163.5–164.5°. The analytical values for this compound are in close agreement with those calculated for the picrate of 1-methyl-2-chloromethylpyrrolidine.

Anal. Calcd. for $C_{12}H_{15}O_7N_4Cl$: C, 39.73; H, 4.14; N, 15.45; Cl, 9.77. Found: C, 39.91; H, 3.99; N, 15.32; Cl, 9.79.

It is possible that the 1-ethyl-2-hydroxymethylpyrrolidine from which the corresponding chloro compound was prepared contained a small amount of 1-methyl-2-hydroxymethylpyrrolidine which would form the 1-methyl chloro compound upon treatment with thionyl chloride. Some of the N-methyl alcohol would be formed along with the N-ethyl alcohol if, upon hydrogenation of 1,2-dicarbethoxypyrrolidine, the 1-carbethoxy group were reduced to a methyl group instead of being removed by hydrogenolysis and replaced by an ethyl group from the ethanol present to form 1-ethyl-2-hydroxymethylpyrrolidine. Contamination of the latter compound by the 1-methyl alcohol would explain the fact that a pure crystalline hydrochloride and benzoate hydrochloride could not be obtained from 1-ethyl-2-hydroxymethylpyrrolidine.

If the unknown chloro amine is 1-methyl-2-chloromethylpyrrolidine, it was thought that the free base probably would rearrange to 1-methyl-3-chloropiperidine. An attempt to demonstrate this gave inconclusive results. The picrate of the unknown amine (0.3 g.) was treated with 20% sodium hydroxide and the free base separated by extraction with several small portions of chloroform. The combined extracts were dried for three hours over anhydrous calcium sulfate, filtered, and saturated with hydrogen chloride. Evaporation of the solvent left a crystalline residue of amine hydrochloride which formed a picrate (0.2 g.) when added to picric acid solution. After recrystallization from ethanol the picrate melted at 148–150°. Four additional crystallizations raised the melting point to 156–159°. A mixture melting point with the original unknown picrate (m. p. 163.5–164.5°) showed no depression. Evidently the picrate of the free base was a mixture, possibly of the unrearranged chloromethylpyrrolidine and 1-methyl-3-chloropiperidine picrates. An insufficient amount of material prevented further investigation of the unknown chloro amine.

1-Ethyl-3-chloropiperidine Hydrochloride (IX).—To a suspension of 5.0 g. (0.030 mole) of 1-ethyl-3-hydroxypiperidine hydrochloride (VII) in 50 ml. of dry toluene was added 3.7 g. (0.031 mole) of thionyl chloride. The mixture was refluxed for three hours during which time the solid disappeared and two layers formed. Removal of the toluene at the water-pump left a dark solid residue which, after recrystallization from ethyl acetate–ethanol (activated carbon), gave 4.8 g. (87%) of slightly discolored crystals. After two additional crystallizations the 1-ethyl-3-chloropiperidine hydrochloride melted at 193.5–194.0°. A mixture of this salt with 1-ethyl-2-chloromethylpyrrolidine hydrochloride showed no depression in melting point. The picrate prepared from the hydrochloride melted at 159–160° after recrystallization from ethanol (Paul[9] reported a melting point of 156–157°).

The Free Amine from 1-Ethyl-2-chloromethylpyrrolidine Hydrochloride.—An ice-cold solution of 1.5 g. of the chloro amine hydrochloride (VIII) in 3 ml. of water was treated with 0.5 g. of sodium hydroxide in 2 ml. of water. The liberated amine was removed by extraction with three 5-ml. portions of chloroform. A small sample of the combined extracts was withdrawn immediately, the solvent evaporated rapidly under an air stream, and the residue added to a saturated aqueous solution of picric acid. The picrate after recrystallization from ethanol melted at 159–160° and showed no depression in melting point when mixed with that obtained from 1-ethyl-3-chloropiperidine hydrochloride, indicating that 1-ethyl-2-chloromethylpyrrolidine, when liberated from its salt, rearranges at room temperature to the piperidine isomer. The remainder of the chloroform solution of the free base was dried overnight over anhydrous calcium sulfate. After removal of the solvent the chloro amine (0.8 g.) distilled at 75–76° (20 mm.); $n^{20}D$ 1.4676 (reported for 1-ethyl-3-chloropiperidine:[9] b. p. 75° (20 mm.); $n^{19.5}D$ 1.46807). The picrate of the distilled amine was identical with that of the crude amine.

The Free Amine from 1-Ethyl-3-chloropiperidine Hydrochloride.—The chloro amine hydrochloride was treated with sodium hydroxide as described above. The isolated base distilled at 74–76° (20 mm.); $n^{20}D$ 1.4678. These constants agree well with those of the free amine from 1-ethyl-2-chloromethyl pyrrolidine hydrochloride. The picrate of the distilled amine was identical with that prepared from 1-ethyl-3-chloropiperidine hydrochloride, indicating that no rearrangement occurred during the liberation and distillation of the chloro amine.

Treatment of 1-Ethyl-3-chloropiperidine Hydrochloride with Zinc and Hydrogen Chloride.—To 1.5 g. of the chloro amine hydrochloride dissolved in glacial acetic acid was added 15 g. of zinc dust. The mixture was saturated with hydrogen chloride and heated on the steam-bath. Every two to three hours the solution was resaturated with hydrogen chloride. After all of the zinc was in solution another 15 g. of the metal was added and the process repeated. The reaction mixture was made strongly basic with sodium hydroxide and steam distilled into hydrochloric acid, the condenser outlet being kept slightly below the surface of the acid in the receiver. After evaporation of the distillate on the steam-bath, the residue of amine hydrochloride was treated with concentrated sodium hydroxide and the liberated base extracted with chloroform. The extract was dried overnight over anhydrous calcium sulfate. Removal of the solvent and distillation of the residue through a narrow 5-cm. Vigreux column yielded 0.4 g. of 1-ethylpiperidine, b. p. 129–130°.[10] About 0.4 g. of high-boiling material remained in the distillation flask. The picrate of the piperidine melted at 167–168°[10] and showed no depression when mixed with an authentic sample of 1-ethylpiperidine picrate.

Summary

1-Ethyl-2-chloromethylpyrrolidine, when liberated from its hydrochloride, undergoes ring enlargement by a rearrangement similar to that observed in other 1,2-aminochloroalkanes, to form 1-ethyl-3-chloropiperidine. The transformation probably occurs through an ethyleneimonium ion intermediate.

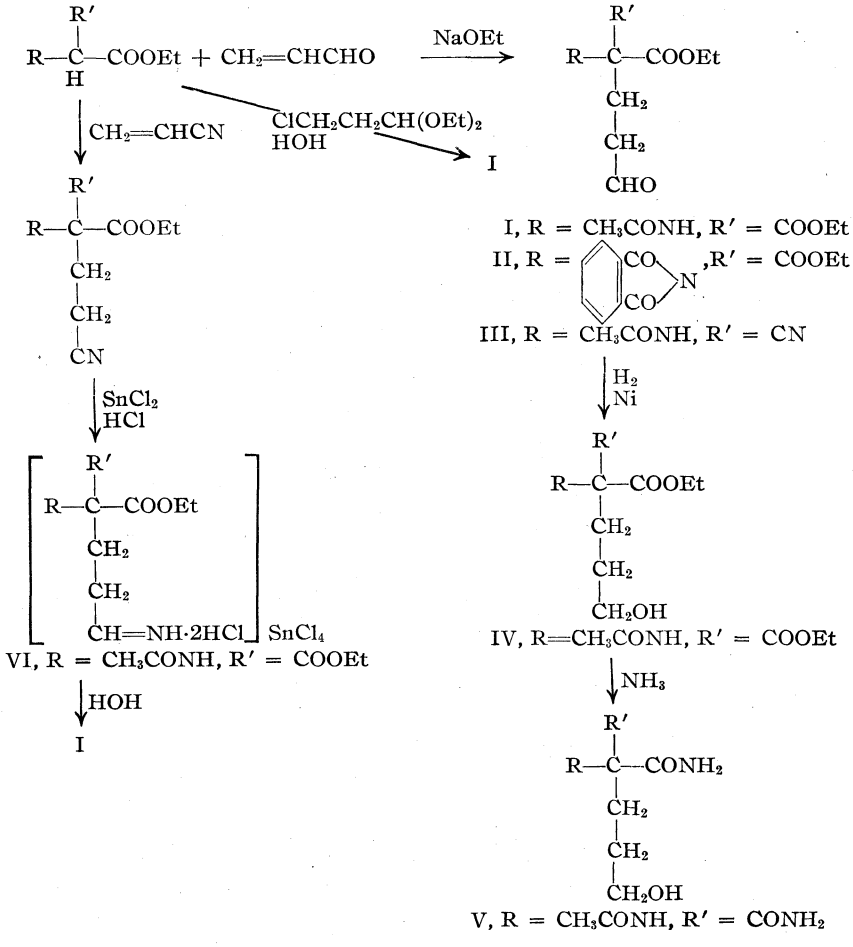
1,4-Addition Reactions. I. The Addition of Acylamidomalonates to Acrolein[1a]

BY OWEN A. MOE AND DONALD T. WARNER

The 1,4-addition reactions between malonate systems and α,β-unsaturated aldehydes have not been reported. Instead, under the conditions employed, a Knoevenagel condensation occurs and the reaction involves a 1,2-addition. However, the latter reaction requires two α-hydrogen atoms for completion (addition followed by loss of water) whereas the former reaction requires only one α-hydrogen atom. Since both reactions, 1,2-addition and 1,4-addition, are reversible, it appeared that a 1,4-addition reaction of acrolein might be realized provided the addend possessed only one, but sufficiently reactive, α-hydrogen atom.



This paper describes the successful 1,4-addition of three such compounds (ethyl acetamidomalonate, ethyl phthalimidomalonate and ethyl acetamidocyanoacetate) to acrolein. The products, obtained in excellent yields, have structures I, II and III, respectively.

(1a) Paper No. 89, Journal Series, Research Laboratories, General Mills, Inc.

The 1,4-addition of ethyl acetamidomalonate to acrolein proceeded smoothly in an alcoholic solution in the presence of catalytic quantities of sodium ethoxide. Because of the exothermic character of the reaction, the acrolein was added at a slow rate to a stirred suspension of ethyl acetamidomalonate. Concentration of the neutralized solution yielded γ-acetamido-γ,γ-dicarbethoxybutyraldehyde I as a straw-colored, viscous oil. The action of phenylhydrazine on either the original reaction mixture or the viscous oil yielded the crystalline phenylhydrazone of compound I in 65–85% yield. The 1,4-addition of ethyl acetamidomalonate to acrolein also proceeded smoothly in the absence of alcohol when benzene was used as the solvent and the phenylhydrazone was obtained in 87% yield directly from the reaction mixture.

The reaction between ethyl phthalimidomalonate and acrolein yielded γ,γ-dicarbethoxy-γ-phthalimidobutyraldehyde II which was characterized as the phenylhydrazone and the 2,4-dinitrophenylhydrazone. Ethyl acetamidocyanoacetate yielded a crystalline adduct (γ-acetamido-γ-carbethoxy-γ-cyanobutyraldehyde) which was characterized as the crystalline 2,4-dinitrophenylhydrazone.

The structure of the aldehydo compound I was proved by two different syntheses. The first method involved the alkylation of ethyl acetamidomalonate with β-chloropropionaldehyde diethylacetal. Hydrolysis of the product with dilute acid gave compound I. In the second synthesis, ethyl α-acetamido-α-carbethoxy-γ-cyanobutyrate[1] was reduced by the action of stannous chloride and hydrogen chloride.[2] The resulting crystalline complex was readily hydrolyzed with warm water to I. As a by-product there resulted a crystalline compound melting at 181–182°. The an-

(1) Albertson and Archer, THIS JOURNAL, **67**, 2043 (1945).

(2) (a) Stephen, *J. Chem. Soc.*, **127**, 1874 (1925); (b) Williams, THIS JOURNAL, **61**, 2248 (1939).

alysis indicated that this compound was ethyl α-acetamido-α-carbethoxy-γ-carbamylbutyrate.

The aldehydo compound I, subjected to hydrogenation in the presence of Raney nickel, gave the crystalline carbinol IV which was characterized as the 3,5-dinitrobenzoate and the *p*-nitrobenzoate. Action of concentrated ammonia upon IV yielded the diamido compound V which in turn yielded a *p*-nitrobenzoate.

Experimental[3]

The 1,4-Addition of Ethyl Acetamidomalonate to Acrolein. A. In Alcohol.—A mixture containing ethyl acetamidomalonate[4] (87.4 g.), sodium (0.1 g.) and absolute ethanol (200 cc.) was chilled in an ice-bath to 3° to produce a thin slurry. Acrolein (25.9 g.) was added dropwise with stirring over a period of seventy-five minutes while the reaction temperature was maintained at 3–7°. A clear, light yellow solution resulted after an additional hour of stirring. The reaction mixture was allowed to stand for an additional ninety minutes at 3° and then the catalyst was neutralized with glacial acetic acid (0.35 g.). The total volume of the reaction mixture was 290 cc. A portion (135 cc.) of the reaction mixture was treated with 4 g. of acetic acid and 22 g. of phenylhydrazine. After warming to 50° the solution was diluted with 7 cc. of water and cooled overnight. The crystalline product was collected by filtration and dried. The phenylhydrazone (44 g.) thus obtained melted at 135–137°. The filtrate was diluted with water and an additional quantity (6.4 g.) of the phenylhydrazone was obtained. After crystallization from aqueous ethanol the phenylhydrazone melted at 140–141°.

Anal. Calcd. for $C_{18}H_{25}O_5N_2$: C, 59.5; H, 6.94; N, 11.58. Found: C, 59.8; H, 7.17; N, 11.41.

B. In Benzene.—Ethyl acetamidomalonate (217 g.) was suspended in benzene (330 cc.) containing a catalytic amount of sodium methoxide (0.5 g.). The resulting reaction mixture was cooled in a water-bath at 19°. Acrolein (68.5 cc.) dissolved in benzene (70 cc.) was added dropwise at a moderate rate. The temperature increased rapidly to 35°. Following the addition of the acrolein the reaction mixture was stirred for an additional two hours and filtered. The clear, yellow filtrate was treated with 24 cc. of glacial acetic acid and 120 g. of phenylhydrazine. After warming to 50° the resulting orange-colored solution was set aside for a period of two days. The crystalline derivative was collected by filtration and washed with 150 cc. of benzene. It was further decolorized by suspension in 250 cc. of benzene, filtered and dried *in vacuo*. The yield of the phenylhydrazone of the aldehydo compound I was 315.1 g. (87%) melting at 140–141°. The crystals were nearly white in color.

Reduction of γ-Acetamido-γ,γ-dicarbethoxybutyraldehyde.—The crude aldehydo compound (46.9 g.) was dissolved in ethanol and Raney nickel catalyst (4.8 g.) was added. The resulting mixture (290 cc.) was hydrogenated for two and one-half hours at a temperature of 85–95° and an initial pressure of 1700 pounds. After cooling, the catalyst was removed by filtration and the filtrate was concentrated *in vacuo*. Benzene was added to the residual oil and the solution was again concentrated. This procedure was repeated three times in order to complete removal of the alcohol. Then ether was added and the carbinol IV crystallized from the ether solution. After drying the crystalline product weighed 14.2 g. and melted at 75–77°. Evaporation of the ethereal filtrate yielded additional quantities of the carbinol IV. Purification by recrystallization from ether increased the melting point to 80–81°.

Anal. Calcd. for $C_{12}H_{21}O_6N$: C, 52.36; H, 7.74; N, 5.09. Found: C, 52.62; H, 8.15; N, 5.30.

The 3,5-dinitrobenzoate and the *p*-nitrobenzoate were prepared in the usual manner and after purification melted at 151–152° and 79–80°, respectively.

Anal. Calcd. for $C_{19}H_{23}O_{11}N_3$: C, 48.6; H, 4.95; N, 8.96. Found: C, 48.86; H, 5.40; N, 9.06. Calcd. for $C_{19}H_{24}O_9N_2$: N, 6.61. Found: N, 6.78.

The carbinol IV, ethyl α-acetamido-α-carbethoxy-δ-hydroxyvalerate, was converted to α-acetamido-α-carbamyl-δ-hydroxyvaleramide by treatment with a concentrated ammonia solution (saturated at 0°). The diamido compound V thus obtained melted at 170–171° after recrystallization from ethanol.

Anal. Calcd. for $C_8H_{15}O_4N_3$: C, 44.22; H, 6.96; N, 19.34. Found: C, 44.15; H, 6.91; N, 19.33.

The *p*-nitrobenzoate of the diamido compound V was prepared in the usual manner and it melted at 242–243° with decomposition.

Anal. Calcd. for $C_{15}H_{18}O_7N_4$: N, 15.30. Found: N, 15.25.

Preparation of γ,γ-Dicarbethoxy-γ-Phthalimidobutyraldehyde.—An alcoholic solution containing 90 cc. of absolute ethanol and 60 mg. of sodium was mixed with 20.4 g. of ethyl phthalimidomalonate, and the resulting reaction mixture was cooled to 5°. Acrolein (4.7 cc.) was added dropwise and the temperature of the reaction mixture increased to 20°. After the addition of the acrolein was complete, the reaction mixture was neutralized by the addition of 0.5 cc. of glacial acetic acid, and a nearly colorless solution resulted. The alcoholic solution of the aldehydo compound II was used directly for the preparation of the phenylhydrazone and the 2,4-dinitrophenylhydrazone which melted at 150–151° and 167–168°, respectively.

Anal. Calcd. for $C_{24}H_{25}O_6N_3$: C, 63.84; H, 5.58. Found: C, 64.08; H, 5.89. Calcd. for $C_{24}H_{23}O_{10}N_5$: C, 53.24; H, 4.29; N, 12.94. Found: C, 53.13; H, 4.12; N, 13.15.

Preparation of γ-Acetamido-γ-carbethoxy-γ-cyanobutyraldehyde.—An alcoholic solution containing 60 cc. of absolute ethanol and 50 mg. of sodium was mixed with 17 g. of ethyl acetamidocyanoacetate and the resulting suspension was cooled in a water-bath. Acrolein (7.5 cc.) was added dropwise, and after the addition was complete the reaction was stirred for two hours and finally neutralized with the requisite quantity of glacial acetic acid. The reaction mixture was filtered, and the filtrate was placed in the refrigerator for a period of twenty-four hours when a copious quantity of needle-like crystals was noted. The crystalline product was collected by filtration and dried. The yield of the crude aldehydo compound III was 15 g. melting at 106–109°. Purification by crystallization from 95% ethanol increased the melting point to 113.5–114.5°.

Anal. Calcd. for $C_{10}H_{14}O_4N_2$: C, 53.56; H, 6.29; N, 12.50. Found: C, 53.10; H, 5.93; N, 12.20.

The 2,4-dinitrophenylhydrazone prepared in the conventional manner melted at 196–197° after purification.

Anal. Calcd. for $C_{16}H_{18}O_7N_6$: C, 47.29; H, 4.46; N, 20.69. Found: C, 47.52; H, 4.44; N, 20.86.

When the above addition reaction was carried out using benzene as the reaction diluent, the aldehydo compound III was obtained in 82% yield and melted at 111–112.5°.

Alkylation of Ethyl Acetamidomalonate with β-Chloropropionaldehyde Diethylacetal.—Ethyl acetamidomalonate (10.9 g.) was added to an alcoholic sodium ethoxide solution containing 1.15 g. of sodium and 100 cc. of absolute ethanol. The above reaction mixture was heated to the reflux temperature and β-chloropropionaldehyde diethylacetal[5] (8.3 g.) was added over a ten-minute period. The reflux temperature was maintained for a period of twenty-four hours. The reaction mixture had developed a light orange color. The precipitated sodium chloride was removed after cooling, and the filtrate was concentrated under reduced pressure. The residual oil was clari-

(3) Micro analyses by Mr. Harold Boyd and Miss Katherine Tellor.

(5) Witzemann, Evans, Hess and Schroeder, "Organic Syntheses," **11**, 26 (1931).

fied by filtration, and the product thus obtained weighed 11.35 g. and was insoluble in water. A portion (5.2 g.) of the above crude diethylacetal of γ-acetamido-γ,γ-dicarbethoxybutyraldehyde was suspended in 15 cc. of water and 3.5 cc. of 1 *N* sulfuric acid was added. The resulting reaction mixture was warmed over a steam-bath for five to six minutes with vigorous swirling. The insoluble acetal hydrolyzed rapidly to yield a clear, light yellow solution. This solution was treated with 0.5 g. of sodium acetate and concentrated *in vacuo* to a volume of 11 cc. The addition of 33 cc. of ethanol caused an immediate precipitate which was removed by filtration and proved to be inorganic. The clear filtrate was mixed with one cc. of acetic acid and 4.8 cc. of phenylhydrazine. The resulting reaction mixture was heated to 55° and after cooling and diluting with water a crystalline product (0.4 g.) was collected by filtration. The filtrate was further diluted with water and yielded an additional crop of crystals (0.53 g.). The crude phenylhydrazone of the aldehydo compound I thus obtained melted at 128–132° and after crystallization from dilute ethanol it melted at 138–140°. The melting point was not depressed when mixed with the phenylhydrazone prepared by the first method.

Reduction of Ethyl α-Acetamido-α-carbethoxy-γ-cyanobutyrate.—The ethyl α-acetamido-α-carbethoxy-γ-cyanobutyrate was prepared in accordance with the directions given by Albertson and Archer.[1]

Anhydrous stannous chloride (41.6 g.) was suspended in anhydrous ether (320 cc.) and anhydrous hydrogen chloride was passed into the reaction mixture until the formation of two layers was noted. The substituted cyanobutyrate (26.8 g.) was dissolved in 125 cc. of chloroform and the resulting solution was added slowly over a ninety-minute period as the reaction mixture was stirred, and dry hydrogen chloride was passed in for four hours with vigorous stirring. The introduction of the hydrogen chloride was then interrupted; however, the stirring was continued overnight. The following day the introduction of hydrogen chloride was continued for an additional period of eighteen hours at which time a few crystals had appeared. The reaction mixture was then permitted to stand at room temperature for a period of five days. After this total reaction time of one week the aldimine complex had precipitated as a white crystalline product. The complex was collected by filtration, washed with ether and dried *in vacuo* (weight, 65 g.). The odor of hydrogen chloride was noted. A portion of the above complex VI (15 g.) was mixed with 100 cc. of water and warmed to 50°. The clear, aqueous solution which resulted was extracted twice with 100 cc. portions of chloroform. The chloroform extracts were combined and dried over anhydrous sodium sulfate. After filtration the chloroform was removed by distillation *in vacuo* and a viscous oil remained which partially crystallized on standing. This residue was dissolved in a small quantity of ethanol, and a few drops of acetic acid were added together with a slight excess of phenylhydrazine. The resulting reaction mixture was warmed on a steam-bath and after cooling and diluting with water a crystalline product was obtained. The crude phenylhydrazone of the aldehydo compound I melted at 133–137°. After crystallization from dilute ethanol it melted at 138–140°.

The above aqueous solution was again extracted with chloroform. After drying, the chloroform was removed under reduced pressure and a crystalline residue remained. This crude product melted at 135–155° and after crystallization from dilute ethanol it melted at 181–182°. The analysis of this product indicated that it was probably ethyl α-acetamido-α-carbethoxy-γ-carbamylbutyrate.

Anal. Calcd. for $C_{12}H_{20}O_6N_2$: C, 49.97; H, 6.99; N, 9.72. Found: C, 49.84; H, 7.07; N, 9.58.

Summary

1. The 1,4-addition of acylamidomalonates such as ethyl acetamidomalonate, ethyl phthalimidomalonate and ethyl acetamidocyanoacetate to acrolein has been reported.

2. The resulting aldehydo compounds have been characterized as the phenylhydrazones.

3. The structure of γ-acetamido-γ,γ-dicarbethoxybutyraldehyde (resulting from the 1,4-addition of ethyl acetamidomalonate to acrolein) has been proved by two independent synthetic routes.

Amino Acids. I. New Syntheses of DL-Tryptophan, DL-Ornithine and DL-Glutamic Acid*

BY DONALD T. WARNER AND OWEN A. MOE

Several syntheses for DL-tryptophan have been reported.[1] Most of these methods employ gramine as the starting material. A different approach was recently disclosed by Hegedus[2] wherein acetoacetic ester was used as the starting material. The present report concerns a new and convenient synthesis of DL-tryptophan employing the phenylhydrazone III of γ-acetamido-γ,γ-dicarbethoxybutyraldehyde I.[3]

The phenylhydrazone III readily underwent cyclization to yield IV, the same product as that obtained by the reaction between gramine and ethyl acetamidomalonate.[1a] The cyclized product IV was converted to DL-tryptophan in the usual way[1a]; the over-all yield based on III was 50%.

Recently, Albertson and Archer[4] published an excellent synthesis of DL-ornithine monohydrochloride in which the cyanoethylation product of ethyl acetamidomalonate was used as an intermediate. The synthesis of DL-ornithine monohydrochloride reported in the present paper involves the phenylhydrazone III as an intermediate. Reduction of III in the presence of Raney nickel gave β-

acetamido-β-carbethoxypiperidone V in 70% yield. This piperidone V is the same product as that obtained by the reduction of ethyl α-acetamido-α-carbethoxy-γ-cyanobutyrate in the presence of Raney nickel. Hydrolysis of V essentially as described by Albertson and Archer[4] yielded DL-ornithine monohydrochloride in nearly quantitative yield.

Glutamic acid has been synthesized by the 1,4-addition of phthalimidomalonic and acetamidomalonic esters to methyl acrylate[5,6] and acrylonitrile.[4] In the present work, oxidation by permanganate of γ-acetamido-γ-carbethoxy-γ-cyanobutyraldehyde yielded γ-acetamido-γ-carbethoxy-γ-cyanobutyric acid VI which was converted to DL-glutamic acid by the action of concentrated hydrochloric acid.

Experimental[7]

Cyclization of III Using Sulfuric Acid as Catalyst.—The phenylhydrazone III (50 g.) was mixed with 300 cc. of water containing 14 cc. of concentrated sulfuric acid. The reaction mixture was heated to the reflux temperature with very vigorous stirring. The phenylhydrazone liquefied at the reflux temperature, and after approximately one hour the suspended liquid had solidified. The reflux temperature was maintained for a period of four and one-half hours. After cooling, the solid reaction product was then mixed with water in a Waring blendor, collected, washed with water and dried *in vacuo*. The yield of product melting at 145–149° was 42.5 g. (approximately 90%). Recrystallization from aqueous ethanol (50–50) gave 35 g. (73%) of product IV melting at 156–157°.

Anal. Calcd. for $C_{18}H_{22}N_2O_5$: C, 62.44; H, 6.40; N, 8.01. Found: C, 62.55; H, 6.51; N, 8.05.

Cyclization of III in absolute ethanol using sulfuric acid as the catalyst gave the cyclized product in 40–50% yield. When the cyclization reaction was carried out in 50 volume per cent. aqueous ethanol the yield of IV was 55–65%.

Ethyl α-acetamido-α-carbethoxy-β-(3-indole)-propionate was also prepared by the reaction between gramine and ethyl acetamidomalonate, as described by Howe, Zambito, Snyder and Tishler.[1c] The resulting product melted at 157–158° and no depression in the mixed melting point was observed with the above described sample.

Cyclization of the Phenylhydrazone III Using Boron Trifluoride[8] as the Catalyst.—To a suspension of the phenylhydrazone III (36.3 g.) in 100 cc. of glacial acetic acid there was added with swirling boron trifluoride etherate (14.2 g.) and the resulting reaction mixture was heated cautiously in an oil-bath. The reflux temperature was maintained for a period of thirty minutes. A copious precipitate of the boron trifluoride–ammonia complex was noted and after cooling was removed by filtration. Water was added to the filtrate to yield a slight turbidity, and the mixture was cooled in the refrigerator overnight. The precipitated product (amorphous in appearance) was collected and dried *in vacuo*. The dry product weighed 13.8 g. (40%) and melted at 137–142°. Recrystallization from 50 volume per cent. aqueous ethanol yielded 8.8 g. (25%) melting at 153–155°.

DL-Tryptophan.—The hydrolysis and decarboxylation of the cyclized product IV to yield DL-tryptophan (m. p. 281–283°) were carried out as described by Snyder and Smith.[1a]

Anal. Calcd. for $C_{11}H_{12}N_2O_2$: C, 64.69; H, 5.92. Found: C, 64.70; H, 6.01.

Preparation of Piperidone V.—The phenylhydrazone III (54.48 g.) was suspended in 350 cc. of 95% ethanol and reduced in the presence of Raney nickel catalyst at 1400 pounds of hydrogen at 100°. After approximately six hours, the reduction was complete. The catalyst was removed by filtration and the filtrate was concentrated *in vacuo*. The residual pasty solid (amine odor) was suspended in 250 ml. of ether. The suspended solid had the appearance of shiny leaflets.

After cooling, the piperidone V was collected by filtration and dried *in vacuo*. The yield of the white crystalline product was 24.1 g. (70%) melting at 136.5–138°. The melting point was not depressed when mixed with the piperidone prepared as described by Albertson and Archer.[4]

DL-Ornithine Monohydrochloride.—The piperidone V was converted to DL-ornithine monohydrochloride (m. p. 218°) by refluxing with concentrated hydrochloric acid as described in the literature.[4] The dipicrate (m. p. 196°) and the dibenzoate (ornithuric acid) (m. p. 186°) of ornithine were prepared.

Permanganate Oxidation of γ-Acetamido-γ-carbethoxy-γ-cyanobutyraldehyde, II.—Crude γ-acetamido-γ-carbethoxy-γ-cyanobutyraldehyde II (22.6 g., m. p. 109–112°) was dissolved in 400 cc. of water. The resulting solution was cooled to 8° and a solution of potassium permanganate (10.6 g. of permanganate in 400 cc. of water) was added in portions. The temperature was maintained at 8–12° and the *p*H at approximately 8. When the oxidation was complete, the reaction mixture

was allowed to stand at room temperature overnight. After removal of the manganese dioxide, the solution was acidified with 10 cc. of concentrated hydrochloric acid. Concentration *in vacuo* to a volume of approximately 100 cc. yielded a turbid emulsion. After saturation with sodium chloride the reaction mixture was extracted with two 100-cc. portions of ethyl acetate. After drying over anhydrous sodium sulfate the ethyl acetate was removed by distillation. The solid residue was macerated with ether, and filtration yielded 15.9 g. of a white solid. Purification by crystallization from ethyl acetate yielded the γ-acetamido-γ-carbethoxy-γ-cyanobutyric acid melting at 154–154.5°.

Anal. Calcd. for $C_{10}H_{14}O_5N_2$: C, 49.99; H, 5.87; N, 11.66; neut. equiv., 240. Found: C, 49.68; H, 6.06; N, 11.55; neut. equiv., 241.7.

DL-Glutamic Acid.—The γ-acetamido-γ-carbethoxy-γ-cyanobutyric acid (5 g.) was mixed with 25 cc. of concentrated hydrochloric acid. The resulting reaction mixture was refluxed for a period of sixteen hours and then concentrated *in vacuo*. The residual solid was dissolved in 12 cc. of water. After filtration the filtrate was neutralized by addition of 10% aqueous sodium hydroxide solution to a *p*H of 3.2. When cooled, the resulting solution yielded a crystalline product (2.3 g.) which melted at 193–194° with decomposition after drying *in vacuo*. The melting point was not depressed when mixed with an authentic sample. The N-benzoyl derivative was prepared and it melted at 156–157.5°.

Summary

1. New syntheses of DL-tryptophan, DL-ornithine and DL-glutamic acid have been reported.

2. These amino acids result from the aldehydo intermediates prepared by the 1,4-addition of acylamidomalonates to acrolein.

Some Free Radical Reactions of Hydrogen Chloride

BY JOHN H. RALEY, FREDERICK F. RUST AND WILLIAM E. VAUGHAN

Although the chain addition of hydrogen bromide to ethylenic linkages is readily brought about by peroxides (the well known Kharasch "peroxide effect")[1] or actinic radiation,[2] it has been generally recognized that the analogous reaction with hydrogen chloride is much less likely. In fact, at the time the present study was begun, there was no report of a free radical hydrogen chloride–olefin combination.[3]

In this paper the vapor phase addition of hydrogen chloride to ethylene, as initiated by ultraviolet light or di-*t*-butyl peroxide, is described. Evidence for the corresponding, but much slower, reaction with propylene, is presented. Hydrogen chloride sensitizes the vapor phase decomposition of di-*t*-alkyl peroxides. This reaction, apparently a chain process involving chlorine atoms, is related to the photochlorination of di-*t*-butyl peroxide which is also described.

Experimental

Photochemical Experiments.—The cell was a fused quartz cylinder (22 mm. o.d. × 150 mm.) provided with plane windows. The body of the cell was wrapped with metal foil and jacketed by an aluminum pipe which was heated electrically. A thermocouple imbedded in the foil gave an approximate measure of the reaction temperature.

The light source was a hydrogen discharge tube of the Kistiakowsky type[4] (Hanovia Mfg. Co.) operated from a 2.5-kw. transformer. Since mercury vapor (from the vacuum line) could be present in the cell, radiation absorbable by this element was excluded to prevent the occurrence of mercury-sensitized reactions. The filter was a quartz cylinder dimensionally identical with the cell, containing carbon dioxide saturated with mercury vapor at room temperature. Ethylene absorbs appreciably only below the quartz region[5] but continuous absorption by hydrogen chloride begins at about 2500 Å. and increases rapidly below 2200 Å.[6]

The pressure change was measured with a quartz spiral manometer[7] sealed to the cell. After irradiation, the cell contents were transferred directly to a bulb by means of a Toepler pump, measured, and subsequently analyzed mass spectrometrically.

Experiments with Di-*t*-alkyl Peroxides.—The closed system apparatus used has been described in an earlier communication.[8] For certain experiments the 500-cc. reaction vessel was packed with 2-mm. Pyrex rods to effect an increase in the surface:volume ratio from 0.61 to 7.0 cm.$^{-1}$.

After reaction, the vessel contents were condensed with Dry Ice–acetone and the volatile products, excepting a portion of the dissolved ethyl chloride, pumped into a sample bulb for mass spectrometric analysis. The cold trap contents were dissolved in water containing a little isopropyl alcohol and aliquots taken for carbonyl[9] and chloride ion (Volhard) determinations.

Larger scale runs with a flow type apparatus provided material for product identification. This apparatus also has been described previously.[10] Because of the complexity of the effluent, particularly when the peroxide content of the feed was high, product yields could be determined only very roughly. However, isobutylene chlorohydrin was isolated (in *ca.* 10% yield) from the products of both the di-*t*-butyl peroxide–hydrogen chloride and di-*t*-butyl peroxide–hydrogen chloride–ethylene re-

(9) This procedure, based on reaction with hydroxylamine hydrochloride, is a modification of the method of Marasco (*Ind. Eng. Chem.*, **18**, 701 (1926)), and is described in "Methyl Ethyl Ketone, Its Uses and Data on Its Properties," Shell Chemical Co., San Francisco, Calif., 1938, p. 45.

(10) Rust, Seubold and Vaughan, THIS JOURNAL, **70**, 95 (1948).

actions (b. p. 126.6–126.7°, $n^{20}D$ 1.4375, acidimetric equivalent weight, 114; literature or theoretical values for $(CH_3)_2COHCH_2Cl$, respectively, 126.6–128.8°, 1.4388, and 108.5). The product from the di-*t*-butyl peroxide–hydrogen chloride–propylene reaction contained small amounts of both *n*- and isopropyl chlorides, as shown by infrared absorption analysis.

Materials.—The various gases used in the static apparatus were taken from commercial cylinders (stated purity more than 99% except hydrogen chloride (97.5%)), redistilled under high vacuum (collection of middle one-third), out-gassed, and stored in glass bulbs. For the flow experiments no purification was made. Di-*t*-butyl and di-*t*-amyl peroxides were purified in the manner described previously.[8]

Photochlorination of Di-*t*-butyl Peroxide.—Chlorine (2.0 moles) was bubbled through a sintered glass plate into di-*t*-butyl peroxide (3.0 moles) at a rate which maintained the temperature at 30-40°. A 500-watt projection lamp adjacent to the Pyrex reaction flask served as the source of radiation. The product was water-washed, dried, and fractionated under reduced pressure. The monochloride (b. p. 55° (20 mm.), f. p. −31°, $n^{20}D$ 1.4211, Cl, 19.7% (theory, 19.62%)) was obtained in 42.5% yield based on input chlorine. The dichloride fraction, probably consisting of three possible isomers, boiled at 55-70° at 4-5 mm.; $n^{20}D$ 1.4454, Cl, 33.3% (theory, 32.96%).

Photo-addition of Hydrogen Chloride to Ethylene.—The effect of radiation from the hydrogen lamp on hydrogen chloride–ethylene mixtures at two temperatures is illustrated in Fig. 1. It will be noted that there is no appreciable "dark" reaction. Ethyl chloride is the only significant product detected mass spectrometrically, and the composition after illumination agrees, within the analytical error, with that calculated from the pressure decrease on the assumption that only the addition reaction occurs. For example, at 26° the composition by analysis was 13 ± 1% C_2H_5Cl and 41 ± 2% C_2H_4, while that calculated was 14.5% C_2H_5Cl and 42.2% C_2H_4. The hydrogen and ethane contents were both 0.1% or less.

Since light absorption by hydrogen chloride leads to the production of chlorine and hydrogen atoms, the probable path of the reaction is

$$HCl + h\nu \longrightarrow H + Cl \quad (1)$$

$$Cl + C_2H_4 \longrightarrow CH_2ClCH_2 \quad (2)$$

$$CH_2ClCH_2 + HCl \longrightarrow CH_2ClCH_3 + Cl \quad (3)$$

Addition reactions such as

$$CH_2ClCH_2 + C_2H_4 \longrightarrow CH_2Cl(CH_2)_2CH_2 \quad (4)$$

are apparently much slower than (3) under the present conditions since higher molecular weight products were not detected.

The hydrogen atoms could also initiate a chain, *viz.*

$$H + HCl \longrightarrow H_2 + Cl, \text{ or} \quad (5)$$

$$H + C_2H_4 \longrightarrow CH_3CH_2 \quad (6)$$

$$CH_3CH_2 + HCl \longrightarrow C_2H_6 + Cl \quad (7)$$

and, from the yields of hydrogen and ethane the chain length is estimated to be at least 30 at room temperature.

In keeping with the characteristics of a chain process, the reaction is inhibited by oxygen and a number of other substances (Fig. 2). The pro-

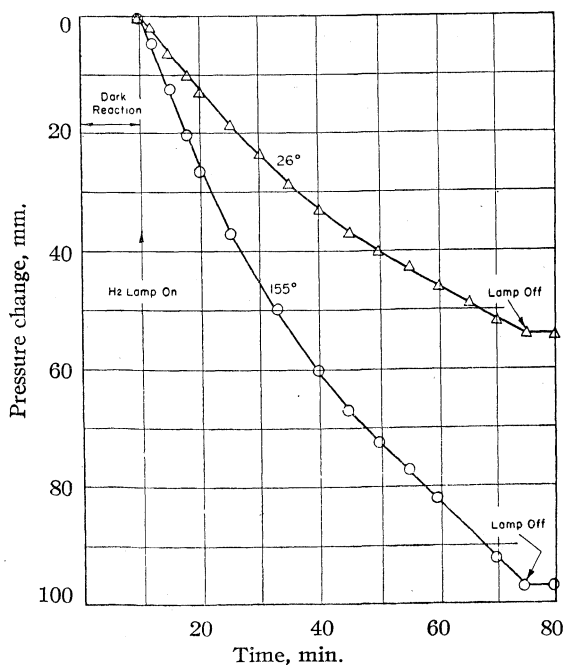

Fig. 1.—Photo-addition of hydrogen chloride to ethylene: (0.0116 mole/liter HCl, 0.0113 mole/liter C_2H_4).

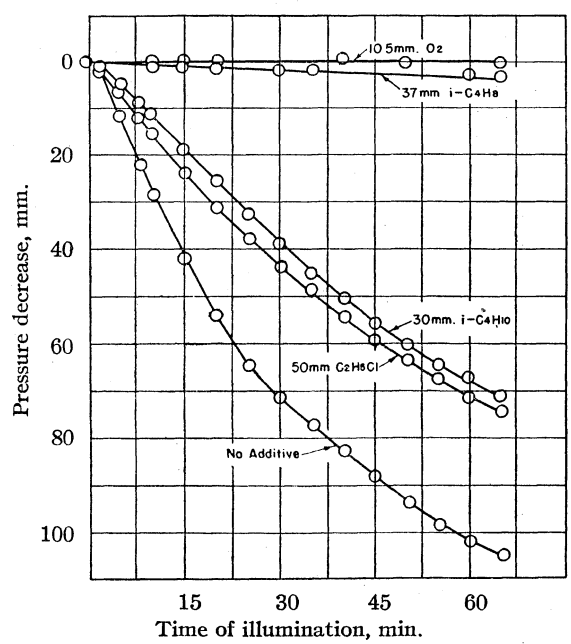

Fig. 2.—Effect of additives on the photochemical hydrogen chloride–ethylene reaction: temperature, 155°; HCl 309 mm.; C_2H_4, 300 mm.

nounced effect of small oxygen concentrations is attributed to the relatively rapid reaction

$$CH_2ClCH_2\cdot + O_2 \longrightarrow CH_2ClCH_2O_2\cdot \quad (8)$$

the peroxy radical being incapable of continuing the chain. Retardation by isobutylene is probably due to the reactions

$$Cl + (CH_3)_2C{=}CH_2 \longrightarrow (CH_3)_2\dot{C}CH_2Cl \quad (9)$$

$$\longrightarrow \dot{C}H_2C(CH_3){=}CH_2 + HCl \quad (10)$$

wherein, respectively, a tertiary or allylic radical, less able to abstract hydrogen from hydrogen chloride is produced. In the presence of isobutylene only a trace of ethyl chloride formed, the chief product being C_4 chloride(s). With isobutane as the additive, chlorine atom attack at the tertiary carbon–hydrogen bond is the most likely mode of interference. Since ethyl chloride is also a retardant, the reaction must be self-inhibiting. In this case the effect is apparently due to the formation of the $CH_3\dot{C}HCl$ radical which is less capable of metathetical reaction with hydrogen chloride than its isomer, $CH_2Cl\dot{C}H_2$. This difference in reactivity might be expected from the results of studies on the thermal chlorination of ethyl chloride.[11]

Peroxide-catalyzed Addition of Hydrogen Chloride to Olefins.—The reaction with ethylene, as initiated by a small amount of di-*t*-butyl peroxide, is illustrated in Fig. 3. A complete product analysis has not been made but ethyl chloride was identified again as a major component. A small amount of methane was also produced. In view of the known decomposition of di-*t*-butyl peroxide to *t*-butoxy and methyl radicals,[8,12] the initiation steps are probably

$$(CH_3)_3COOC(CH_3)_3 \longrightarrow 2(CH_3)_3CO\cdot \quad (13)$$

$$(CH_3)_3CO\cdot + HCl \longrightarrow (CH_3)_3COH + Cl \quad (14)$$

$$(CH_3)_3CO\cdot \longrightarrow (CH_3)_2CO + CH_3 \quad (15)$$

$$CH_3 + HCl \longrightarrow CH_4 + Cl \quad (16)$$

The reaction has been carried out at 140–185° in both types of apparatus.

The analogous reaction with propylene is much slower. For example, at 155° a mixture of 200 mm. propylene, 200 mm. hydrogen chloride, and 13 mm. di-*t*-butyl peroxide undergoes a pressure decrease of only 10 mm. in sixty minutes. The hydrogen transfer step involving a secondary radical

$$CH_3\dot{C}HCH_2Cl + HCl \longrightarrow CH_3CH_2CH_2Cl + Cl \quad (17)$$

would be more endothermic than the corresponding process in the ethylene reaction, (3). Furthermore, allyl radical formation could occur by

$$Cl + CH_3CH{=}CH_2 \longrightarrow HCl + \dot{C}H_2C\dot{H}CH_2, \text{ or} \quad (18)$$

$$CH_3\dot{C}HCH_2Cl + CH_3CH{=}CH_2 \longrightarrow$$

$$CH_3CH_2CH_2Cl + \dot{C}H_2C\dot{H}CH_2 \quad (19)$$

Di-*t*-alkyl Peroxide–Hydrogen Chloride Reaction.—In addition to a simple dissociation into two *t*-alkoxy radicals, di-*t*-alkyl peroxides in the presence of a minor amount of hydrogen chloride undergo a sensitized decomposition (Fig. 4).

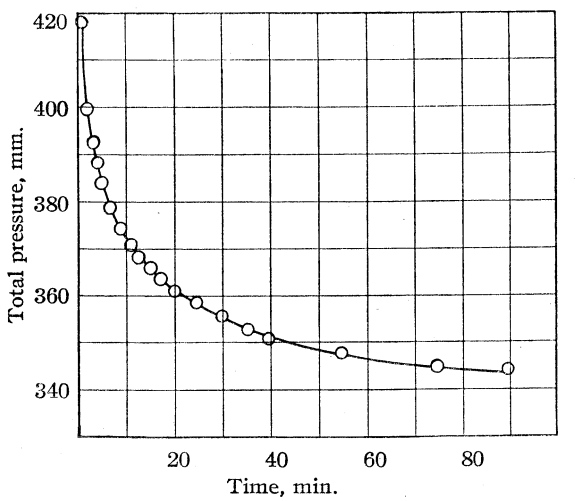

Fig. 3.—Di-*t*-butyl peroxide—catalyzed addition of hydrogen chloride to ethylene: 200.7 mm. HCl, 200.3 mm. C_2H_4, 10.5 mm. peroxide, 6.4 mm. nitrogen, temperature 154.7°.

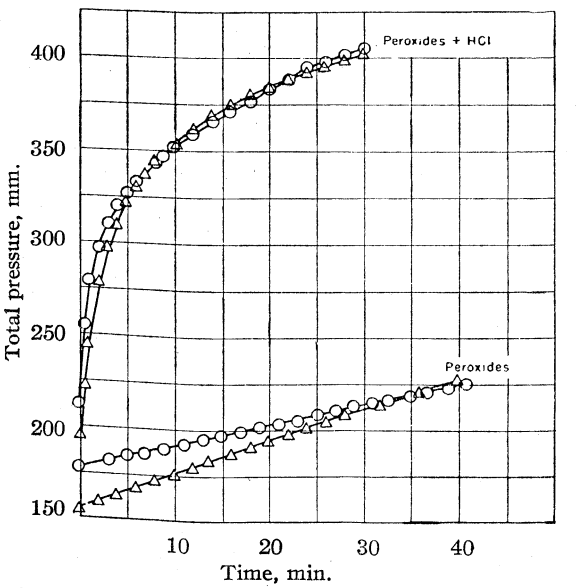

Fig. 4.—Effect of hydrogen chloride on di-*t*-alkyl peroxides: O, di-*t*-butyl peroxide (139.7(8)°) 173.4 mm. peroxide, 180 mm. peroxide + 27.6 mm. HCl; △, di-*t*-amyl peroxide (136.7(4)°) 149.2 mm. peroxide, 160 mm. peroxide + 30.8 mm. HCl.

(11) From the data of Rust and Vaughan (*J. Org. Chem.*, **6**, 479 (1941)), reaction (11) is known to be faster than (12):

$$Cl + CH_3CH_2Cl \longrightarrow HCl + CH_3\dot{C}HCl \quad (11)$$

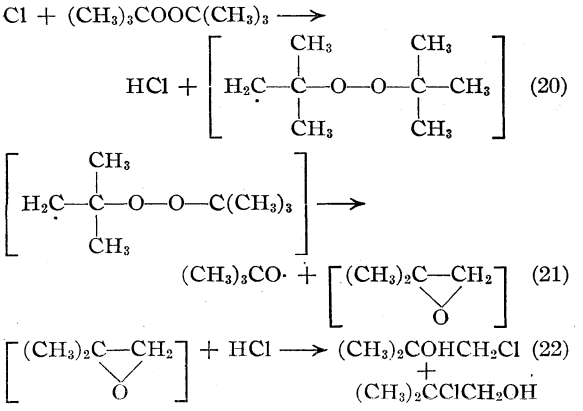
$$Cl + CH_3CH_2Cl \longrightarrow HCl + CH_2Cl\dot{C}H_2 \quad (12)$$

Therefore, the reverse of (11) might be expected to be slower than the reverse of (12).

(12) Milas and Surgenor, THIS JOURNAL, **68**, 205 (1946).

The major hydrocarbon product contains only half as many carbon atoms as that produced in the unsensitized reaction, and substantially less than two molecules of ketone are produced from each peroxide molecule decomposed. Additional products that appear in the case of di-*t*-butyl peroxide include isobutylene chlorohydrin and *t*-butyl chloride. This sensitized reaction is essentially homogeneous since the rate of pressure increase is unaffected by the presence of Pyrex rod packing. Furthermore, various compounds readily attacked by free radicals or atoms (ethylene, propylene, isobutane, etc.) have a retarding influence. These observations indicate a chain, the mechanism for which is postulated to be:

Steps (13) to (16) followed by



Evidence for the step involving chlorine atom attack on the peroxide comes from experiments on the photochlorination of the peroxide described elsewhere in this paper. The production of monochloride, $ClCH_2(CH_3)_2COOC(CH_3)_3$, by a photo reaction must certainly involve (20). Because of the lower temperature and the presence of molecular chlorine, however, the resultant radical does not decompose but instead forms the chloride. It is interesting to note the differing reactivities of chlorine atoms and methyl radicals toward the peroxide. In the vapor phase the latter apparently do not readily abstract hydrogen atoms from the peroxide since the thermal decomposition of this compound is not a chain reaction.[8] Although isobutylene oxide has not been isolated, the chlorohydrin, (22), is a recognized derivative.

The preponderance of ethane over methane observed in the sensitized decomposition of di-*t*-amyl peroxide is in agreement with earlier observations that *t*-amyloxy radicals yield acetone and ethyl radicals.[8,13] A partial product analysis for both peroxides is given in Table I. Carbonyl and methane yields are nearly equivalent for the di-*t*-butyl compound, as are the carbonyl and (methane + ethane) yields for the amyl analog. Products characteristic of the combination of two alkyl radicals (*i. e.*, butane from ethyl radicals) are unimportant. These data illustrate the predominance of (16) and the analogous ethyl radical reaction over other processes involving alkyl radicals. This is particularly interesting inasmuch as (16) is almost energetically neutral while the ethyl-hydrogen chloride reaction is somewhat endothermic. It is clear that (15) is more important than (14) although the exact ratio of these two reactions cannot be determined without knowledge of either the amount of alcohol produced or the fraction of input peroxide decomposed.

TABLE I

HYDROGEN CHLORIDE–DI-*t*-ALKYL PEROXIDE REACTIONS

Reaction time, 31 minutes

Produced, mm.	Di-*t*-butyl peroxide 139.8°	Di-*t*-amyl peroxide 136.7°
Carbonyl	114	135
CH_4	110	6.5
Ethane	...	124
Butane	...	1
Input, mm.		
Peroxide	180	160
HCl	28	31

Under comparable conditions hydrogen bromide has little effect on the decomposition of di-*t*-butyl peroxide. Although hydrogen bromide reacts readily with methyl radicals to produce methane, the resultant bromine atoms apparently are less capable of attacking the peroxide to continue the chain. This is in agreement with the observation that photobromination of the peroxide is more difficult than photochlorination.

Summary

The vapor phase addition of hydrogen chloride to ethylene can be initiated photochemically or by di-*t*-butyl peroxide. A free radical, chain mechanism is proposed and the influence of added inhibitors is interpreted in terms of this mechanism. Propylene reacts much more slowly.

Hydrogen chloride sensitizes the vapor phase decompositions of di-*t*-butyl and di-*t*-amyl peroxides. A chain mechanism involving chlorine atom attack on the peroxide is suggested for these reactions. The latter step is demonstrated by the photochlorination of di-*t*-butyl peroxide.

Coördination Compounds of Mercury. I

BY THOMAS D. O'BRIEN

Mercury exhibits a coördination number of 3 in such groups as $HgCl_3^-$ and a coördination number of 4 in $[Hg(CN)_4]^{-2}$ and $[HgCl_4]^{-2}$. Whereas this same type of ion exists for zinc and cadmium, the latter two elements also exhibit a coördination number of 6. The present study was undertaken to attempt to determine whether mercury also has a stable coördination number of 6.

There are several reports[1] of compound formation between ethylenediamine (en = ethylenediamine) and mercuric chloride, but the results are generally qualitative and usually contradictory. Sinha and Ray[2] report the preparation of Hg $py_6(ClO_4)_2$ in which the mercury seems to be 6-coordinate.

Experimental

The ethylenediamine was dehydrated according to the method of Putnam and Kobe[3] and the fraction boiling at 117° collected.

en $(HgCl_2)_2$.—Ten milliliters of a solution containing 3.0 g. (0.05 mole) of ethylenediamine was slowly added with stirring to 200 ml. of a solution containing 27.16 g. (0.1 mole) of mercuric chloride. After standing for two hours the precipitate was filtered and washed with water. The precipitate was then treated with a solution containing 0.2 mole of hydrochloric acid and allowed to stand, with intermittent stirring, for one hour. The very small amount of undissolved residue was filtered and to the clear filtrate was added a solution containing 0.1 mole of ethylenediamine. After standing two hours the precipitate was filtered and the above procedure repeated. The final precipitate was washed with successive portions of water, methanol, acetone and ether and then dried at 100° for two minutes. Prolonged heating at 100° causes decomposition.

Anal. Calcd. for en $(HgCl_2)_2$.: Hg, 66.5; Cl, 23.5. Found: Hg, 66.0; Cl, 23.3.

en $HgCl_2$.—Same procedure followed as described above except a 1:1 molar ratio of base to salt used.

Anal. Calcd. for en $HgCl_2$: Hg, 60.5; Cl, 21.4. Found: Hg, 60.2; Cl, 21.4.

The white precipitate of en $HgCl_2$ was dissolved in aqueous ethylenediamine and the solution was allowed to evaporate slowly at room temperature. The crystals that formed were washed with ether and dried to constant weight at 100°.

Anal. Calcd.: Cl, 21.4. Found: Cl, 21.3.

Hg en$_2$ SO_4 and [Hg en$_2$ $(H_2O)_2$]SO_4.—Mercuric sulfate was dissolved in excess ethylenediamine and the solution was allowed to evaporate slowly in a covered Petri dish. The large crystals that formed were removed, washed once with anhydrous ether and blotted well between layers of filter paper.

Anal. Calcd. [Hg en$_2$ $(H_2O)_2$]SO_4: Hg, 44.3; SO_4, 21.2. Found: Hg, 44.5; SO_4, 21.3.

The above compound is efflorescent, slowly losing water to the atmosphere at room temperature. When heated at 100° to constant weight (ten to twelve hours) or when dried over concentrated sulfuric acid the theoretical amount of water (7.98%) is lost, and stable [Hg en$_2$]-SO_4 results. Prolonged heating of this compound causes a slow decomposition.

Anal. Calcd. Hg en$_2$ SO_4: Hg, 48.2; SO_4, 23.0. Found: Hg, 48.2; SO_4, 23.3.

(en 2H)$_2$$HgCl_6$.—Some en $HgCl_2$ was dissolved in the smallest volume of *N* hydrochloric acid solution. To the clear solution was added an equal volume of concentrated hydrochloric acid. The crystals which formed were filtered and then redissolved in the smallest volume of water. Concentrated hydrochloric acid was again added and the crystals which formed were again filtered, redissolved and reprecipitated. After the final filtration the precipitate was washed with methanol, then acetone, and finally ether, then dried in an oven for three minutes at 100°. Longer drying causes no decomposition.

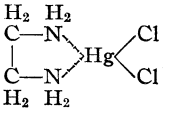
Anal. Calcd. (en 2H)$_2$$HgCl_6$: Hg, 37.3; Cl, 39.6; N, 10.42. Found: Hg, 37.2; Cl, 39.6; N, 10.44.

Cryoscopic Measurements.—The conventional freezing point lowering apparatus was used with a Beckman thermometer. When 0.238 g. of (en 2H)$_2$$HgCl_6$ was dissolved in 46.2 g. of water a freezing point lowering of 0.121° was observed. When 0.416 g. of the salt was dissolved in 45.6 g. of water a freezing point depression of 0.210° was observed.

Refractive Index.—To 100.00 cc. of a 0.1 *M* solution of mercuric chloride there was added 0.90 g. (0.015 mole) of ethylenediamine. The solution was shaken at intervals while digesting for one hour. A small portion of this was filtered and the refractive index of the clear filtrate determined on a Bausch and Lomb refractometer. The above procedure was repeated with separate solutions using increasing amounts of ethylenediamine. The refractive index values of portions of the mixtures were determined after standing for twenty-four hours, and five days, with no change in value. All values are averages of at least six different readings.

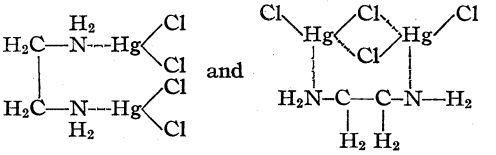
Discussion of Results

Results of the present study show that both en $HgCl_2$ (I) and en $(HgCl_2)_2$ (II) exist. A possible structure of (I) is shown in which the mercury is



(I)

4-coördinate. Two immediately apparent possible structures for (II) are:



(IIa) (IIb)

The mercury has a coördination number of three, in IIa and the mercury is 4-coördinate in IIb, the chloride bridges being analogous to those in the polymeric halides of aluminum and gold.

(1) (a) Schering, German Patent 12,095 (1901); (b) Siemssen, *Chem. Ztg.*, **36**, 214 (1912); (c) Ray and Dhar, *Trans. Chem. Soc.*, **103**, 3 (1913); (d) Tranke and Loewe, *Ber.*, **47**, 1908 (1914).

(2) Sinha and Ray, *J. Indian Chem. Soc.*, **20**, 32 (1943).

(3) Putnam and Kobe, *Trans. Electrochem. Soc.*, **74**, 610 (1938).

Both (I) and (II) are soluble in an excess of ethylenediamine. All attempts to isolate the soluble complex failed, because any solid substance separated from the solution evolved ethylenediamine to give (I). With the analogous sulfate, however, crystalline bis(aquo)bis(ethylenediamine)mercury(II) sulfate was isolated. This compound decomposed slowly at room temperature, and rapidly at 100°, to give the stable Hg en_2 SO_4.

The simple possibilities for the soluble ethylenediamine mercury chloride salt are (1) [Hg en_2 Cl_2,] (2) [Hg en_2 $(H_2O)_2$]Cl_2, and (3) [Hg en_3]Cl_2 (III), with the last one being favored because of the break in the refractive index curve (Fig. 1) at a 3:1 ratio of ethylenediamine to mercuric chloride. The break at the 1:2 ratio probably corresponds to the complete formation of (I). As more ethylenediamine is added it reacts completely with insoluble (I) to form equally insoluble (II), causing no change in the refractive index, which is the value for the pure solvent (for water, n_{28} 1.3321). The refractive index of the corresponding sulfate could not be determined because of the formation of insoluble basic salts when mercuric sulfate is put in water.

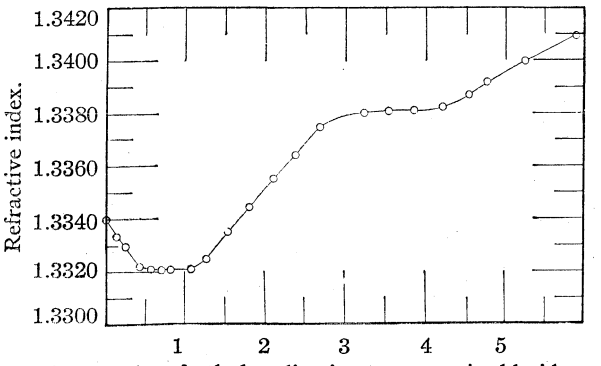


Fig. 1.—Change of refractive index of solution of ethylenediamine and mercuric chloride as concentration of ethylenediamine is increased.

Treatment of (I), (II) or (III) with an excess of concentrated hydrochloric acid produces a white crystalline substance, only slightly soluble in an excess of hydrochloric acid but easily soluble in water. The formula (en 2H)$_2$[$HgCl_6$] (IV) is assigned to the compound in accordance with the analogous copper salt.[4] Cryoscopic measurements indicate that when dissolved in water, (IV) completely dissociates into 2(en 2H+), 4 Cl^- and $HgCl_2$ (only very slightly dissociated). Using 1.86 as the freezing point constant of water, the two observed lowerings of 0.121° and 0.120° correspond to 6.8 and 6.7 particles, respectively, per mole of salt.

Any highly soluble chloride will cause the precipitation of (IV). Saturated solutions of copper, lithium, and cadmium chlorides when added to an aqueous solution of (IV) cause precipitation of the bis(ethylenediamine)hexachloromercury salt and not the metal hexachloromercury salt.

That the mercury to chloride bonds are more ionic than covalent is further supported by the non-availability of possible bonding orbitals for six coördination. Kimball[5] gives the following possibilities: d^2sp^3, d^4sp, d^5p, d^3p^3, d^3sp^2, d^5s and d^4p^2. As the 5d orbitals in mercury are filled, and as it is extremely doubtful if the 6d orbitals are available for covalent bonding, it appears as if the Hg–Cl bonds must be largely ionic in character.

Summary

1. The existence of Hg en Cl_2 and en$(HgCl_2)_2$ has been demonstrated.

2. The results indicate that mercury probably has a coördination number of 6 in the compound (en 2H)$_2$[$HgCl_6$] and that the [Hg en_2 $(H_2O)_2$]$^{+2}$, ion probably exists in solution, wherein the mercury is also 6-coördinate.

3. The new compounds Hg en_2 SO_4 and Hg en_2 $(H_2O)_2SO_4$ have been prepared.

The Isomerization of Cyclohexane and Methylcyclopentane in the Presence of Aluminum Halides. II. Equilibrium and Side Reactions

BY D. P. STEVENSON AND JANE H. MORGAN

Introduction

In the preceding paper with the same title, there were presented the results of a set of experiments designed to elucidate the nature of the catalysis of the interconversion of cyclohexane and methylcyclopentane. In the course of this work considerable data were acquired on the equilibrium constant of the isomerization reaction, as well as on the nature and relative rates of the side reactions which accompany the isomerization reaction. The equilibrium between cyclohexane and methylcyclopentane has been the subject of several previous investigations.[1] The results of the previous investigators are concordant with and confirmed by the present work. Despite the apparent duplication, it seems worth while to record our results in view of the very different and probably more reliable analytical methods at our disposal. In the equilibrium studies particular attention was devoted to the possible presence of the various cyclobutanes and cyclopropanes, isomeric with cyclohexane and methylcyclopentane, which have been reported to be formed by the action of moist aluminum bromide on cyclohexane.[2]

Paraffins, C_7 and C_8 naphthenes, and bicyclanes have been identified among the products of the side reactions accompanying the interconversion of cyclohexane and methylcyclopentane catalyzed by aluminum halides. It was of particular interest to determine whether or not cyclopentane accompanies the formation of the higher naphthenes as might be expected by analogy with formation of isobutane and hexanes in side reactions accompanying the interconversion of iso- and normal pentane.

Experimental

The experiments were carried out by the methods described in the preceding paper, using the materials therein described, with the exceptions noted below.

Purified aluminum bromide, ground to a fine powder in a dry box (dried by spreading Dry Ice on the bottom), was used after exposure to atmospheric moisture to assure catalytic activity. Cyclopentane was prepared by hydrogenation of carefully purified cyclopentadiene. The crude cyclopentane was fractionated in a high efficiency column and residual traces of cyclopentadiene and cyclopentene were removed by percolation through activated silica gel (Davco, 28–200 mesh) and shaking with a small portion of moist aluminum chloride. After the aluminum chloride treatment, the cyclopentane was subjected to a trap (room temperature) to trap (liquid nitrogen) vacuum distillation. The mass and infrared spectra of the final cyclopentane showed the presence of no detectable impurity.

In a number of the experiments the reaction product was separated from the catalyst by a high vacuum distillation. The reaction tube was opened with the contents chilled with liquid oxygen and connected to the vacuum system by means of a short length of rubber tubing. After evacuation, the pump was cut off from the manifold, and the liquid oxygen was transferred to a weighed trap affixed to the manifold by means of a standard taper joint. The reaction tube was permitted to warm slowly to room temperature. The distillation was stopped approximately five minutes after the reaction tube attained room temperature. The product so collected is defined as the volatile product.

The traps were constructed with a stopcock so that the samples could be stored while awaiting analysis without danger of loss of volatile components. The stopcocks were of the pressure type and were lubricated with a hydrocarbon insoluble grease compounded of mannitol, starch and anhydrous glycerol. A section of tubing packed with ascarite was interposed between the reaction tube and collecting trap to remove hydrogen halide and entrained catalyst.

The products of all experiments were examined with the mass spectrometer in order to determine the extent of the side reactions and the applicability of the infrared spectrophotometric method for determining methyl cyclopentane and cyclohexane. The products of the experiments in which the side reaction was excessive were subjected to analytical distillation to give three fractions, (1) boiling below 65°, (2) boiling from 65 to 85°, and (3) boiling above 85°. These fractions were analyzed with the mass spectrometer.

The results of the experiments on the cyclohexane–methylcyclopentane reaction at 27, 59 and 100°, are summarized in Tables I, II, and IIIa, and IIIb, respectively. The experiments with cyclopentane at 100° are described in Table IV.

In all the experiments on the reaction of the C_6 naphthenes with aluminum bromide the reacting system remained a clear, colorless solution. In the 60° experiments, the aluminum chloride retained its white, granular appearance. The aluminum chloride–C_6 naphthene system at 100° rapidly changed from a liquid–solid system to one of two liquid phases. The more dense phase acquired a very faint yellow color. Upon cooling to room temperature the more dense phase became very viscous, and white crystals precipitated from it very slowly. When the 100° reaction tubes were opened, the unfrozen film of the denser phase at the top of the tube became bright red very quickly and then slowly darkened until it became black. The non-volatile residues from the vacuum separation of the product of the 100° experiments were hydrolyzed in the cold (0°) with 6 *N* sodium hydroxide solution. From the resultant mixture a dark yellow to brown, viscous oil was recovered. The depth of color increased with time. This oil as first recovered was soluble in isoöctane, but from the isooctane solutions a brown, resinous substance slowly precipitated on standing in contact with air. It was found that a colorless oil could be recovered from the deeply colored oil by means of a high vacuum (10^{-4} mm.) distillation from a trap at room temperature to one at liquid nitrogen temperature.

The formation of two liquid phases from the solid–liquid system aluminum chloride–aromatic has been often described. However, the more dense phase formed when paraffins, olefins, or aromatics are the hydrocarbon components of the system is very deeply colored (orange to

deep brown), so that the formation of a colorless aluminum chloride–hydrocarbon complex from the C_6 cyclanes is unexpected. In this regard it must be noted that the aluminum bromide–cyclopentane solutions at 100° give rise to two liquid phases and the more dense phase has a deep brown color.

Discussion

In discussing the methylcyclopentane–cyclohexane equilibrium, two related subjects must be considered along with the ratio of the pair of isomers. These are (1) the possibility of cyclopropane and cyclobutane isomers of C_6H_{12} being present in the system, but undetected due to inadequacy of the analytical methods, and (2) the effect of side reactions on the apparent equilibrium ratio.

It has been reported[2] that dimethylcyclobutanes were found in a low boiling fraction resulting from the action of moist aluminum bromide on cyclohexane at a temperature less than 100°. There

are sound thermodynamic reasons for doubting the identification. From the strain energies suggested by Golmov,[3] the heat of isomerization of a cyclopentane to a cyclobutane or cyclopropane isomer may be calculated to be 31.5 ± 3 kcal./mole. If one takes as a very liberal estimate the corresponding entropy of isomerization to be 20 e.u. (cyclohexane → methylcyclopentane, ΔS° = 8.5 e.u.), the free energy of isomerization at 400°K. is found to be of the order of 20 to 25 kcal./mole. Such a free energy corresponds to an equilibrium ratio of the cyclopropane or cyclobutane isomer to the cyclopentane of less than 10^{-4}, *i.e.*, less than 0.01%.

(3) Golmov, *J. Gen. Chem. USSR*, **11**, No. 5–6, 405 (1940). Strain energies per CH_2 group, C_3 ring 11.4, C_4 ring 8.5, C_5 ring 0.5, C_6 and higher rings 0.0 kcal./mole.

It is unlikely that direct mass spectrometric or infrared spectrophotometric analysis would be capable of detecting less than 1% of the cyclopropane and cyclobutane isomers of C_6H_{12} in a mixture of cyclohexane and methylcyclopentane plus small quantities (<2%) hexanes and other paraffins and naphthenes, even if the spectra of the twelve isomers were available. Although the spectra of the C_6H_{12}, cyclopropanes, and cyclobutanes have not been measured, it may be predicted that their mass and infrared spectra are such that the two analytical methods will err in the same direction, namely, that the methylcyclopentane will be overestimated and the cyclohexane underestimated in proportion to the quantity of the other isomers in the system. From the estimate of the probable equilibrium concentration of these extra isomers it appears that the analytical error from this source should be negligibly small.

The experiments with cyclopentane were undertaken in part because there is good reason to believe that the presence of methylcyclobutane and the cyclopropane isomers of C_5H_{10} can be detected by means of the mass spectrometer, even though the mass spectra have not been measured. By analogy with the mass spectra of the C_6 and C_7 naphthenes[4] that have been measured, it may be concluded that the relative intensity of the ion $C_4H_7^+$ in the mass spectra of the C_5H_{10} cyclopropanes and methylcyclobutane should be much greater than the relative intensity of this ion in the mass spectrum of cyclopentane. Thus the evaluation of the relative intensity of this ion, $C_4H_7^+$, should provide a sensitive indication of the presence of isomers of cyclopentane.

After correction for the pentane and butane contribution to the mass spectrum of the low boiling (<45°) fraction of the product of experiment 28, Table IV, the residual intensity of the ion, $C_4H_7^+$, relative to that of the ion, $C_5H_{10}^+$, agreed with that characteristic of pure cyclopentane to better than 1%. This fact, combined with the known low boiling points of the isomers of cyclopentane, a conservative assumption concerning the relative intensity, $C_4H_7^+/C_5H_{10}^+$, in that mass spectra of the isomers of cyclopentane, and the analytical data given in the footnote to Table IV, lead to 0.006% as an upper limit to the concentration of isomers of cyclopentane in the product of experiment 28.

The agreement between the calculated and experimental estimates of the upper limit to the concentration of C_3 and C_4 cyclanes which may exist in such systems as those considered in this paper, may be taken as reasonable grounds for ignoring possible effects of such isomers on the accuracy of the determination of the methylcyclopentane–cyclohexane ratios.

(4) The substances which have been studied include methylcyclopentane, cyclohexane, methylcyclohexane, ethylcyclopentane, four of the five dimethylcyclopentanes and a mixture of dimethylcyclohexanes (hydrogenated commercial xylene).

The effect of irreversible side reactions on the apparent equilibrium ratio of a pair of reversibly interconvertible substances has been considered by Bates.[5] His equation (8) for the limiting ($t = \infty$) ratio of B/A for the reacting system (1)

(1a) $A \underset{kb_1}{\overset{ka_1}{\rightleftharpoons}} B$, K eq $= \frac{B}{A} = \frac{ka_1}{kb_1}$

(1b) $A \xrightarrow{ka_2}$ Products

(1c) $B \xrightarrow{kb_2}$ Products

may be transformed to the form

$$(2) \qquad \left(\frac{B}{A}\right)_{t=\infty} = \frac{K_{eq}}{2}\left[\theta + \sqrt{\theta^2 + \frac{4}{K_{eq}}}\right]$$

where $\theta = 1 - 1/K_{eq} + (ka_2 - kb_2)/ka_1$. The term $(ka_2 - kb_2)/ka_1$, of the parameter θ, is particularly convenient for estimating the effect of the irreversible side reactions on the apparent equilibrium ratio, $(B/A)_{t=\infty}$. It has been found useful to prepare a graph of $(B/A)_{t=\infty}$ a function of $(ka_2 - kb_2)/ka_1$, for various values of K_{eq}.

Bates has pointed out that if $ka_2 = 0$ and $kb_2 = 0$, his equation (8) reduces to $(B/A)_{t=\infty} = K_{eq}$. However, the much less stringent condition, $ka_2 = kb_2$, is also a sufficient condition for the equality of the apparent equilibrium ratio, $(B/A)_{t=\infty}$, and the true equilibrium constant for the reversible reaction. In fact, examination of our equation (2) reveals that the important condition, necessary for the equality of $(B/A)_{t=\infty}$ and K_{eq} is that the ratio of the difference between the rates of the irreversible side reactions to the rate of the forward step of the reversible reaction be small compared with $1 - (1/Ke)$.

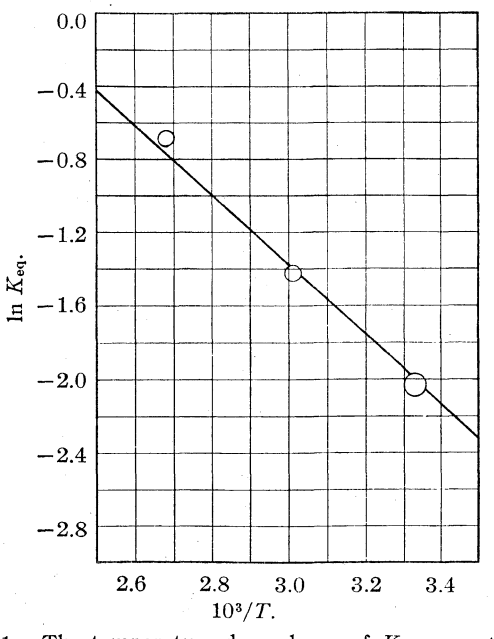

Fig. 1.—The temperature dependence of K_{eq} = methylcyclopentane/cyclohexane.

(5) Bates, THIS JOURNAL, **68**, 511 (1946).

For the experiments described in Tables I, II, and IIIa, it is apparent that the extent of the irreversible side reactions accompanying the C_6H_{12} isomerization must have had a negligible effect on the ratio of methylcyclopentane to cyclohexane. However, this is not the case for the experiments of Table IIIb. If it is assumed that the kinetics of the reactions of cyclohexane and methylcyclopentane may be represented by the differential equations corresponding to equations (1a), (1b), and (1c), experiments 26 and 27 (Table IIIb) lead to $ka_2 = 0.025$ hr.$^{-1}$, while experiments 24 and 25 give $ka_2 + kb_2 = 0.015$ hr.$^{-1}$. Experiments 18 and 19 in the presence to $^1/_{16}$ the quantity of catalyst present in experiments 24 through 26 indicate ka_1 $\left(\text{CH} \xrightarrow{ka_1} \text{MCP}\right)$ to be of the order of 0.1 hr.$^{-1}$. Thus for experiments 24 through 26 $(ka_2 - kb_2)/ka_1 < 0.02/16 \times 0.1 \cong 0.013$, and $\theta - 1 + 1/Ke_2 < 0.01$, and the ratio of MCP/CH must differ from the equilibrium ratio by less than 0.5% as a result of the side reactions.

In view of the foregoing discussion, it is reasonable to assume that the MCP/CH ratios given in Tables I, II, and IIIa may be taken to be equal to the equilibrium constant for the reaction

Cyclohexane (liquid) $\rightleftharpoons$ Methylcyclopentane (liquid)

The three values of this equilibrium constant are shown on the usual ln K *vs.* $1/T$ plot in Fig. 1. The radii of the circles representing the experimental points are equal to the mean deviations of the individual determinations of the MCP/CH ratio from the averages shown in the tables referred to. The straight line shown on the graph, represented by the equation $\ln K = 4.31 - 1890/T$, is a least squares fit of published values of the equilibrium constant.[1] Our values of the equilibrium constant at 27 and 59° agree within their experimental error with the previous determinations. However, our value for the equilibrium constant at 100° is definitely higher than that indicated by previous determinations. A least squares treatment of our data yields the equation

$$\ln K = 4.814 - 2059/T$$

The heats of combustion of cyclohexane and methylcyclopentane have been measured by Moore and Parks,[6] from which one obtains $\Delta H_{298.1} = 3{,}930 \pm 35$ cal./mole. Aston[7] gives $S^\circ_{298.1}$ (liq. CH) = 48.73 e.u., and Ruehrwein and Huffman[8] found $S^\circ_{298.1}$ (liq. CH) = 48.84 e.u. Douslin and Huffman[9] have recently redetermined the entropy of methylcyclopentane and give $S^\circ_{298.1}$ (MCP liq.) = 59.22 e.u. From the data of these authors one then finds

(6) Moore and Parks, *ibid.*, **61**, 2561 (1939).
(7) Aston, Szasz and Fink, *ibid.*, **65**, 1135 (1943).
(8) Ruehrwein and Huffman, *ibid.*, **65**, 1620 (1943).
(9) Douslin and Huffman, *ibid.*, **68**, 173 (1946).

CH (liq.) = MCP (liq.) $\Delta H^\circ_{298.1} = 3{,}930 \pm 35$ cal./mole
$\Delta S^\circ_{298.1} = 10.44 \pm 0.3$ e. u.
$\Delta C^\circ_{p\,298.1} = 0.6$ cal./mole °K.

The values of ΔH°_{298} and ΔS°_{298} obtained from the equilibrium data are compared with the thermochemical and third law values in Table V.

TABLE V

THE HEAT AND ENTROPY OF THE REACTION CYCLOHEXANE (LIQUID) ⇄ METHYLCYCLOPENTANE (LIQUID) 25°

	Thermal[a]	Equil.[b]	Equil.[c]
$\Delta H^\circ_{298.1}$	3,930 ± 35	3,735	4,015 ± 550
$\Delta S^\circ_{298.1}$	10.44 ± 0.3	8.49	9.50 ± 1.1

[a] See text. [b] $\ln K = 4.31 - 1890/T$, from previous investigations. [c] $\ln K = 4.814 - 2059/T$, this investigation.

The values of ΔH and ΔS from the equilibrium data have been corrected from an average temperature of 65° to 25° by use of the value of ΔC_p for the reaction quoted above ($\Delta C_p = 0.6$). The values deduced from our data are in considerably better agreement with the thermal data than are those resulting from the averaging over-all previous work.

The assignment of the formula $C_{12}H_{22}$ to the primary high molecular weight product is based on previous identification of dicyclohexyl and dimethyl dicyclopentyl among the reaction products[10] and our observation of an ion of molecular weight 166 in the mass spectra of the products of a number of our experiments.

In view of the rapid coloration upon exposure to air of the non-volatile catalyst complex formed in the reactions at 100°, it seems likely that unsaturated hydrocarbons are present in the catalyst complex. That the "polymer" can act as a hydrogen donor is indicated by the observation that the total quantity of paraffins formed in experiments no. 26 and 27 exceeds one-half of the $C_{12}H_{12}$ lost as heavy ends.

Our inability to detect cyclopentane in the product of any of the experiments with cyclohexane and methylcyclopentane indicates that reactions between naphthenes, analogous to the well-known paraffin dismutation reactions, are slow.

The results of the experiments with cyclopentane (Table IV) show this substance is not inert to the action of the aluminum halides,[11] although it is considerably less reactive than the C_6 naphthenes. It was definitely surprising to find evidence (mass spectra) for the presence of $C_{12}H_{22}$ (dicyclohexyl, dimethyl dicyclopentyl, etc.) but none for the $C_{10}H_{18}$ (dicyclopentyl). However, the observation that the catalyst complex formed in the cyclopentane reaction is highly colored and similar in appearance to that formed by the action of aluminum halides on paraffins, while the catalyst complex formed from the C_6 naphthene is colorless (in absence of air) indicates that the reactions of the cyclopentane are in important respects different from those of the C_6 naphthenes.

In experiment no. 28 (Table IV) the cyclopentane used was not treated with moist aluminum chloride prior to use. Analyses indicated the sample to contain *ca.* 0.2% cyclopentadiene (ultraviolet) and *ca.* 0.1% cyclopentene (mass spectrometer). The much greater extent of reaction in this experiment than in the other experiments with cyclopentane which had been treated to remove last traces of unsaturates indicates that unsaturates are promoters of catalytic activity in aluminum bromide for reactions of cyclanes. Pines and Wackher[12] have shown that olefins are promoters of isomerization activity in the aluminum halides toward the butanes. Thus there is further evidence of the similarity between the catalysis of alkane and cyclane reactions in the presence of aluminum halides (see the preceding paper).

Summary

The equilibrium constant of the reaction

cyclohexane (liq.) ⇄ methylcyclopentane (liq.)

has been measured at 27, 59 and 100°. It is represented by $\ln K = 4.814 - 2059/T$, which corresponds to $\Delta H^\circ_{298.1} = 4015 \pm 550$ cal./mole and $\Delta S^\circ_{298.1} = 9.50 \pm 1.1$ e.u. in good agreement with thermochemical and cryogenic measurements.

Among the products of side reactions accompanying the equilibration in the presence of moist aluminum halides, there have been identified by mass spectrometric analysis, propane, butane, pentane, hexane, C_7, C_8, and C_9 naphthenes and C_{12} binaphthenes. No evidence could be found for the formation of cyclopentane or C_7 or higher alkanes.

Arguments against the formation of C_5 or C_6 cyclopropanes and cyclobutanes from cyclopentane or methylcyclopentane and cyclohexane are presented, and partial experimental confirmation of the arguments is reported.

It has been found that butane, pentane, hexane, C_6, C_7, and C_8 naphthenes and C_{12} binaphthene are formed by the action of moist aluminum bromide on cyclopentane at 100°.

Nucleophilic Substitution in the Benzene Ring. I. Rates of Reactions of *p*-Substituted Bromobenzenes with Piperidine

BY J. F. BUNNETT AND ARNOLD LEVITT[1]

It has long been known that an ortho- or para-nitro group strongly activates the condensation of a halobenzene with a nucleophilic reagent such as the hydroxide ion, an alkoxide ion, a mercaptide ion, or an amine. Several other groups, such as carboxyl, nitroso, cyano, sulfonyl, acyl and carbalkoxyl groups, have similar ortho–para activating effects.

This activation has been extensively studied, and for various reactions there are available comparisons[2] of the relative activating effects of pairs of groups. From these comparisons it is plain that nitro is more strongly activating than the other important activating groups, but there isn't available any comparison of the relative activating effects of the several groups in a single sort of reaction under constant conditions.

In this paper we report rate constants for the reactions of some *p*-substituted bromobenzenes with piperidine in benzene at 99°. The rate constants found are recorded in Table I. The order of activation in this reaction we have thus found to be: $NO_2 \gg CH_3SO_2 > CN > CH_3CO$.

TABLE I

REACTIONS WITH PIPERIDINE

	k (liters moles^{-1} sec.$^{-1}$)
p-Bromonitrobenzene	64.5×10^{-7}
p-Bromophenyl methyl sulfone	3.40×10^{-7}
p-Bromobenzonitrile	1.98×10^{-7}
p-Bromoacetophenone	0.86×10^{-7}
p-Chloronitrobenzene	11.4×10^{-7}

The determination on *p*-chloronitrobenzene was made with the object of comparing the rate constant found for it with those to be determined for *p*-chlorobenzophenone and *p*-chlorobenzotrifluoride. Samples of the two latter compounds were available in the laboratory; both of them, however, proved to have an order of reactivity too low to allow determination of rate constants in the time available. In about three and one-half days, 3.4% of the chlorine of *p*-chlorobenzophenone was liberated as chloride ion; the corresponding figure for *p*-chlorobenzotrifluoride was 1.2%.

We have also studied the reactions of *p*-nitrobromobenzene and of *p*-bromophenyl methyl sulfone with sodium methoxide in methanol at 99°. Rate constants for these reactions are listed in Table II.

These values, along with those in Table I, show very clearly that the relative activating effects of groups in nucleophilic substitution reactions are influenced by the nature of the nucleophilic reagent and by the nature of the solvent. In the reaction with sodium methoxide the nitro compound reacts twenty-eight times as fast as the sulfone, while in the reaction with piperidine it reacts only nineteen times as fast.

TABLE II

REACTIONS WITH SODIUM METHOXIDE

	k (liters moles^{-1} sec.$^{-1}$)
p-Bromonitrobenzene	78.5×10^{-5}
p-Bromophenyl methyl sulfone	2.84×10^{-5}

Experimental

In the cases of *p*-nitrobromobenzene, *p*-bromoacetophenone and *p*-chloronitrobenzene, the commercial product was recrystallized to a satisfactory melting point. Commercial piperidine was redistilled, and middle fractions were used in this work. A highly purified sample of *p*-chlorobenzotrifluoride was generously furnished by Dr. A. F. Scott.

***p*-Bromobenzonitrile.**—To a solution of 20 g. of *p*-bromobenzamide in 120 ml. of tetrachloroethane, 32 g. of phosphorus pentachloride was added and the mixture was refluxed for several hours during which hydrogen chloride was evolved. The mixture was poured over ice, and the organic layer separated and steam-distilled. After removal of the tetrachloroethane, the distillate containing the nitrile was collected and filtered. The nitrile was recrystallized from petroleum ether; m. p. 110–112°[3]; yield, 7.4 g. (41%).

***p*-Bromophenyl Methyl Sulfone.**—The method of Oxley, Partridge, Robson and Short[4] was followed. From 50 g. of *p*-bromobenzenesulfonyl chloride, 16 g. (35%) of *p*-bromophenyl methyl sulfone, m. p. 102–103°,[5] were obtained.

***p*-Chlorobenzophenone.**—A sample, m. p. 74–75°,[6] was generously supplied to us by Mr. Herbert Hergert who prepared it by the method of Gomberg and Cone.[7]

Kinetic Measurements. A. Reactions with Piperidine.—For the study of a particular compound, four or five sealed Pyrex tubes with identical contents were prepared. Within each tube were 20 ml. of a thiophene-free benzene solution about 1.5 molar in piperidine and about 0.05 molar in the halogen compound. All four or five tubes were placed in the thermostat[8] at once; a drop in temperature ensued, and when the temperature had returned to 99°, one of the tubes was removed and cooled to 0°. The other tubes were

(5) Bourgeois and Abraham, *Rec. trav. chim.*, **30**, 407 (1911), *C. A.*, **6**, 623 (1912), reported m. p. of *p*-bromophenyl methyl sulfone 102–103°.

(6) Kollarits and Merz, "Beilstein," 4th ed., Vol. VII, p. 419, reported m. p. of *p*-chlorobenzophenone 75.5–76°.

(7) Gomberg and Cone, *Ber.*, **39**, 3278 (1906).

(8) A thermostat of the type described in Ostwald–Luther, "Physiko-chemischer Messungen," 5th ed., Leipzig, 1931, p. 121, was used, with water the boiling liquid. The bath temperature was 99 ± 0.5°.

removed at subsequent recorded times. The contents of the tubes were extracted with water and halide ion in the water extracts was determined by the Volhard method.

The percentage of reaction in the last tube removed varied from 75.3% (forty hours reaction time) in the case of *p*-nitrobromobenzene, to 7.0% (137.62 hours reaction time) in the case of *p*-bromoacetophenone.

Rate constants were determined from the equation[9]

$$kt = \frac{2.303}{b - 2a} \log_{10} \frac{(b - 2x)}{(a - x)} + C$$

where b is initial concentration of piperidine, a is initial concentration of the halogen compound, and x is concentration of the piperidinium halide product at time t (first tube removed from bath at $t = 0$). This mathematical expression is valid for the chemical equation

$$RX + 2C_5H_{10}NH \longrightarrow RNC_5H_{10} + C_5H_{10}NH_2X$$

When values of the term $2.303/(b - 2a) \log_{10} [(b - 2x)/(a - x)]$ were plotted against t, the points in every case fell virtually on a straight line.[10] Values of the slope were calculated by the Method of Zero Sum.[11]

B. Reactions with Sodium Methoxide.—The technique was generally the same as used for the reactions with piperidine. The same thermostat was used with temperature again 99 ± 0.5°. Each tube contained 0.00200 mole of the halogen compound (added as a solid) and 0.00200 mole of sodium methoxide in a total volume of 19.28 ml. When a tube was opened, its contents were added to 100 ml. of 50% methanol and unconsumed base was determined by titration with standard hydrochloric acid to the methyl red end-point. For one tube of each compound, this titration was followed by a conductimetric titration of halide ion, and it was observed that bromide liberated was equal to methoxide consumed in the case of the nitro and sulfone compounds.

Rate constants were calculated from the expression

$$1/(a - x) = kt + C$$

applicable to second order reactions in which the initial concentrations of both reactants are equal. Values of k were found by the Method of Zero Sum.[11]

Acknowledgment.—The authors are grateful for generous financial support by the Research Corporation which greatly aided the progress of this work.

Summary

1. Rate constants for the reactions of some *p*-substituted bromobenzenes with piperidine at 99° have been determined; comparison of them shows that for this reaction four groups stand in the following order of activating influence: $NO_2 \gg CH_3SO_2 > CN > CH_3CO$.

2. Rate constants for the reactions of *p*-bromonitrobenzene and of *p*-bromophenyl methyl sulfone with methanolic sodium methoxide at 99° have been determined.

3. The rate constant for the reaction of *p*-chloronitrobenzene with piperidine at 99° has been determined; *p*-chlorobenzotrifluoride and *p*-chlorobenzophenone reacted too slowly with piperidine to allow kinetic study of the reactions.

Polysaccharide Aryl Carbamates[2]

BY IVAN A. WOLFF AND CARL E. RIST

Although aromatic isocyanates are regularly used for the characterization of a variety of alcohols, the reactions of these reagents with carbohydrates have not been extensively investigated. Carbanilates of several common sugars,[3] sugar alcohols,[4] glucosides,[5] and the 1-N-α-naphthyl carbamate of 2,3,4,5,6-0-pentamethyl-(*levo*)-sorbitol[6] have been prepared. Recently carbamate derivatives of cellulose and of partially esterified or etherified cellulose have been reported.[7]

This paper reports the preparation and some properties of the esters of corn starch, corn amylose and amylopectin with phenyl isocyanate and with α-naphthyl isocyanate. Tricarbanilates of waxy (glutinous) corn starch, white potato amy-

lose and amylopectin, glycogen, corn torrefaction dextrin, dextran from *Leuconostoc mesenteroides*,[8] corn β-amylase limit dextrin[9] and Schardinger β-dextrin[10] were also prepared. The tricarbanilate esters were different from the aliphatic esters previously studied in that they could be prepared from starch granules which had no pretreatment. Their optical rotations were negative in pyridine and were related to the degree of branching of the polysaccharide used. Starch tricarbanilate could be separated into its linear and non-linear components by the selective solvent action of ethyl acetate.

Corn starch granules reacted rapidly with phenyl isocyanate at 100° in the presence of pyridine to give a trisubstituted product. Esterification was substantially complete after two hours, but a reaction period of twenty-four hours gave products whose solutions in organic solvents showed greater clarity. The yield of trisubstituted derivatives was quantitative. Waxy corn starch, the corn and white potato starch components, Schardinger β-dextrin and the β-amylase limit dextrin reacted in a similar fashion. Dextran was converted to its triester in the pyridine-phenyl isocyanate medium, although the material was never completely in solution. Corn torrefaction dextrin was quite resistant to carbanilation. After twenty-four hours at 100° only 3.67% nitrogen had been introduced. The dextrin was rendered more reactive by solution in water and reprecipitation in ethanol.

Trisubstitution occurred readily when α-naphthyl isocyanate reacted with corn amylose, amylopectin or previously pasted and dried starch. Reaction with starch granules was, however, slower than in the case of phenyl isocyanate. In the presence of an excess of α-naphthyl isocyanate over that needed for trisubstitution, only two groups per anhydroglucose unit were introduced in twenty-four hours at 100°.

All of the esters were white amorphous solids which fused over a considerable temperature range of 220–300° (see Table I). The Schardinger β-dextrin tricarbanilate melted at 214–215°.

In contrast with the high positive optical rotations of corn starch and its aliphatic esters and ethers the tricarbanilates of the whole starch, corn amylose, and amylopectin had a levorotation in pyridine (see Table I). Even more striking was the 20° difference in the rotations of the amylose and the amylopectin derivatives. Since it is now believed that corn amylose is linear while amylopectin is branched, this rotational difference indicated that correlation might be expected between the structure of a 1,4-linked anhydroglucose polymer and the optical rotation of its tricarbanilate

[b] Taken in capillary tubes. The first figure is the sintering point. Then the melting range is given.

in pyridine. This expectation was borne out in the series of compounds listed in Table I. The potato amylose and amylopectin derivatives had rotations equal to those of the corn starch fractions. Waxy corn starch tricarbanilate had the same rotation as the amylopectin derivative to which it is closely related in structure.[11] Glycogen and corn β-amylase limit dextrin, which are thought to be approximately equally branched[12] and more so than amylopectin, gave derivatives with nearly the same rotations, but less negative than those of amylopectin. Using similar reasoning it would appear that the water-soluble corn torrefaction dextrin, prepared in the absence of catalyst, was more highly branched than amylopectin, but less so than glycogen. The rotation of the Schardinger β-dextrin carbanilate was not directly comparable to the rotations of the higher molecular weight polysaccharides.

Since the dextran tricarbanilate was sufficiently soluble only in morpholine for reading its optical rotation, the rotations of the other derivatives in morpholine were measured for comparison. The accuracy of these last-mentioned rotations was low because of their very small value. An outstanding difference could be noted, however (Table I), between the rotations of the predominantly 1,4-linked polysaccharide derivatives taken as a group and the large dextrorotation of the dextran carbanilate which contained an abundance of 1,6-linkages.[13] This phenomenon is being investigated as a possible test for the presence of different types of glycoside linkages in polysaccharides.

The optical rotations of the tri-α-naphthyl carbamates of the starch, amylose and amylopec-

tin of corn were +40, +50 and +36°, respectively. These positive values were unexpected in view of the negative rotations of the corresponding phenyl derivatives. The spread between the amylose and amylopectin α-naphthylcarbamates, while not as great as between their carbanilates, was substantially more than in the case of the aliphatic acid triesters.

The tri-α-naphthylcarbamates were not completely soluble in any organic solvent tested. They were partially soluble in pyridine, dioxane and morpholine. All of the higher molecular weight tricarbanilates were most soluble in pyridine and morpholine, less so in acetone, ethyl acetate, 1,4-dioxane and cold diethyl Cellosolve, and insoluble in other common organic solvents. The torrefaction dextrin and Schardinger β-dextrin carbanilates were readily soluble in most of the solvents tested. The tricarbanilates were often more soluble in cold than in warm solvents. This was shown most strikingly by the corn amylose derivative, which was completely soluble in diethyl Cellosolve at room temperature, but precipitated immediately on slight warming. Cooling of the mixture caused prompt re-solution.

Fractionation of corn starch tricarbanilate into the corresponding amylose and amylopectin derivatives has been accomplished by the selective solvent action of ethyl acetate. The soluble portion of the ester, constituting from one-sixth to one-quarter of the original material, had a rotation that indicated it to be the amylose ester, from 65 to 80% pure. After removal of the carbanilino groups, the reconstituted fractions were titrated potentiometrically with iodine.[14] The soluble fraction sorbed from 139 to 158 mg. of iodine per gram while the insoluble portion sorbed 19 mg. per gram, thus substantiating the analyses on the basis of optical rotation. This is the first known instance of successful solvent fractionation of a starch ester into its linear and non-linear components.

The close agreement between the optical rotation data and the fraction purities obtained in the potentiometric iodine titration suggested the possible use of the former as an analytical tool in determining the amylose–amylopectin ratio in a mixture. The successful operation of this procedure on a fairly pure amylose sample and on a material of rather low amylose content (whole starch) has been demonstrated above. The principle has also been applied to a synthetic sample composed of a mixture of equal parts by weight of corn amylose tricarbanilate and amylopectin tricarbanilate. The rotation of this mixture was −72.0° (pyridine, $C = 1$) indicating an amylose content of 49%. This procedure might advantageously be applied in cases where only very small amounts of material are at hand since the weight of sample is more than tripled by reaction with phenyl isocyanate.

Further studies on the reactions of carbohydrate materials with mono- and polyfunctional isocyanates are in progress.

Experimental

Materials.—The corn starch used was a high-grade commercial product. The white potato and waxy corn starches were extracted from their natural source in the pilot plant of this Laboratory. Amylose and amylopectin were separated by the butanol precipitation procedure,[15] and the amylose was recrystallized until the iodine sorption was 190 mg./g. or higher.[14] β-Amylase limit dextrin was prepared from an aqueous solution of corn amylopectin by allowing wheat β-amylase to react with it for eighteen hours.[9] The dextrin was isolated by precipitation with ethanol. Dextran from *Leuconostoc mesenteroides* was a water-soluble product of high viscosity prepared by allowing the organism to act for twenty-four hours on a 10% sucrose solution.[8] Corn torrefaction dextrin was prepared by heating corn starch in the absence of a catalyst for six hours at 185°. The product was completely water-soluble. It was pretreated by homogenization of an 8% aqueous solution in a Waring Blendor, filtration, and then isolation of the dextrin by precipitation in ethanol. Schardinger β-dextrin was kindly furnished to us by Dr. T. J. Schoch. Glycogen, phenyl isocyanate, and α-naphthyl isocyanate were Eastman Kodak Co. white label chemicals, used without further purification. Commercial pyridine having a 2° boiling range was dried over solid sodium hydroxide and distilled before use.

General Methods of Preparing the Tricarbanilate Esters.—The reactions of corn starch, waxy corn starch, corn and potato amylose and amylopectin, corn torrefaction dextrin, and corn β-amylase limit dextrin with phenyl isocyanate were carried out as in the following typical preparation. Nitrogen analyses on the products agreed with the calculated value for a tricarbanilate (calcd. for $C_{27}H_{25}N_3O_8$: N, 8.09) within ±0.1%.

Ten grams (0.055 mole) of waxy corn starch (moisture 10.76%) was suspended in 150 ml. of dry pyridine. Distillation through a 6-inch Vigreux column was carried out with stirring until 75 ml. had distilled. The amount distilled was then replaced with dry pyridine. Forty grams of phenyl isocyanate (0.34 mole) was added, and reaction was carried out for twenty-four hours at 100°. The clear, light yellow, viscous mass was precipitated in ethanol, washed three times with ethanol, and then dried, giving 28.9 g. of product (theoretical yield for the tricarbanilate 28.6 g.).

The course of the reaction of corn starch granules with phenyl isocyanate is shown in the following data:

Reaction time	% N in ester
14 min.	3.37
28 min.	5.54
57 min.	7.36
1 hr. 49 min.	7.82
4 hr. 32 min.	8.03

After fifteen minutes the reaction mixture was very viscous. No gross changes in viscosity occurred after this time.

Dextran tricarbanilate was prepared as above, but a reaction period of forty-eight hours was used. The reaction mixture in this case was light tan and somewhat viscous, but was not free of solid material at any time during the period of reaction.

Glycogen tricarbanilate was prepared by reaction of glycogen with phenyl isocyanate for twenty-four hours. After that time the mixture was filtered through a coarse Pyrex fritted glass funnel and the residue, which was estimated at approximately 10% of the starting material, was discarded. This was probably largely impurities in the glycogen. The filtrate was poured into ethanol, where-

(15) Schoch, *ibid.*, **64**, 2957 (1942).

upon the glycogen tricarbanilate formed a very fine precipitate. This ester was washed twice with ethanol, once with water, and then dried.

In the preparation of Schardinger β-dextrin tricarbanilate a reaction period of six hours at 100° was used. The esterification mixture was poured into four volumes of absolute ethanol, giving a clear solution, which was then poured into an equal volume of water. Eighty-three per cent. of the theoretical amount of crude tricarbanilate, m. p. 162–175°, precipitated. The crude product was soluble in hot isopropyl alcohol and reprecipitated (as round, non-crystalline particles) on cooling. Two reprecipitations gave pure Schardinger β-dextrin tricarbanilate, melting at 214–215°.

Anal. Calcd. for $C_{189}H_{175}O_{56}N_{21}$: N, 8.09. Found: N, 8.02.

Preparation of α-Naphthylcarbamates.—Corn starch (5.6 g., air-dried) was dried azeotropically with pyridine and reacted for twenty-four hours at 100°, in 100 ml. of pyridine, with 28 g. of α-naphthyl isocyanate. The tan, opaque reaction mixture was poured into ethanol, giving 16.1 g. of α-naphthyl carbamate, containing 5.61% N; calcd. for the triester 6.28% N.

A 7% cornstarch paste was stirred in a Waring Blendor for fifteen minutes, and the starch was then precipitated in ethanol, washed with ethanol, and dried. This pretreated starch, when treated with α-naphthyl isocyanate as above, gave starch tri-α-naphthylcarbamate.

Anal. Calcd. for $C_{39}H_{31}N_3O_8$: N, 6.28. Found: N, 6.29.

Corn amylose and amylopectin tri-α-naphthylcarbamates were prepared in a fashion similar to that for the starch derivative.

Optical Rotations.—All optical rotations were taken at 1% concentration. When an ester was incompletely dispersed in the solvent or when the solution was too turbid to see through in the saccharimeter, the mixture was homogenized in a Waring Blendor. These blended solutions always showed improved clarity. Their concentrations were determined by evaporating 10-ml. aliquots to dryness.

Fractionation of Corn Starch Tricarbanilate.—Five grams of the tricarbanilate prepared from pretreated corn starch was stirred at room temperature for twenty-four hours with 150 ml. of ethyl acetate. The mixture was then centrifuged and the soluble and insoluble portions were individually precipitated with 50% ethanol, washed with water, and dried. The soluble fraction weighed 1.0 g., $[\alpha]^{25}D$ −78.5° (pyridine, C = 1). The insoluble fraction weighed 3.4 g., $[\alpha]^{25}D$ −66.0° (pyridine, C = 1).

Two grams of the ethyl acetate-insoluble fraction and 0.54 g. of the soluble fraction were refluxed for twelve hours in 100 ml. and 50 ml., respectively, of 1.2 *N* sodium methoxide in absolute methanol. The regenerated fractions were washed twice with absolute ethanol, once in ethanol containing a small amount of glacial acetic acid, once with 90% ethanol, twice more with absolute ethanol, and then were dried. The iodine sorption of the regenerated fractions was 19 mg./g. and 158 mg./g., respectively.

In another similar fractionation, 1.3 g. of soluble tricarbanilate was obtained, $[\alpha]^{25}D$ −75.0° (pyridine, C = 1). The recovered amylose from this material sorbed 139 mg. of iodine per gram.

A similar separation was effected with the tricarbanilate prepared from non-pretreated starch.

The use of trade names in this paper does not necessarily constitute endorsement of these products nor of the manufacturers thereof.

Acknowledgment.—We are indebted to B. K. Zoss and P. R. Watson for carrying out portions of the experimental work, to M. Austin and C. Wilham for certain of the polysaccharide raw materials, and to M. Wiele for the nitrogen analyses reported in this paper.

Summary

1. Tricarbanilates have been prepared of corn starch, corn amylose and amylopectin, potato amylose and amylopectin, waxy corn starch, dextran, glycogen, β-amylase limit dextrin, corn torrefaction dextrin and Schardinger β-dextrin.

2. Tri-α-naphthylcarbamates of corn starch, amylose and amylopectin were also prepared.

3. The melting characteristics, solubility behavior and optical rotations of these derivatives were given.

4. In contrast with the usual aliphatic acid anhydrides, phenyl isocyanate reacted in the presence of pyridine with non-pretreated starch granules to give a fully esterified product.

5. The wide variation of up to 20° between the specific rotations of the tricarbanilates of branched and unbranched polysaccharides suggests a means of differentiation of polysaccharides of different structural types.

6. The fractionation of starch tricarbanilate by the selective solvent action of ethyl acetate into the component amylose and amylopectin esters was successfully accomplished.

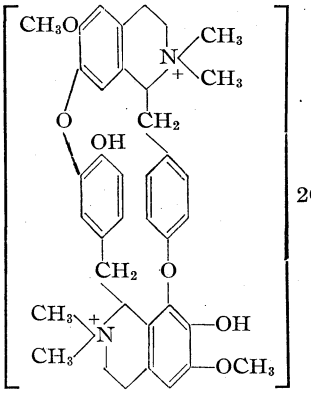
Curariform Activity and Chemical Structure. II. Synthesis in the Benzyltetrahydroisoquinoline Series[1]

BY L. E. CRAIG AND D. S. TARBELL

One of the most effective of the curare alkaloids in causing paralysis of the peripheral nervous system (curariform paralysis) is *d*-tubocurarine chloride. This naturally occurring alkaloid was shown by King[2] to be of the bisbenzyltetrahydroisoquinoline type and to have structure I.



I

The present paper reports the syntheses of and the results of preliminary pharmacological tests on certain compounds analogous to half of the *d*-tubocurarine chloride molecule, that is, quaternary salts of benzyltetrahydroisoquinoline derivatives.

Numerous syntheses of laudanosine (II) have been reported in the literature. Pyman[3] treated tetrahydropapaverine with methyl iodide and obtained laudanosine hydroiodide in 5% yield, along with 21% of tetrahydropapaverine hydroiodide and 19% of laudanosine methiodide. Pictet and Finkelstein[4] prepared the methiodide of 3,4-dihydropapaverine, obtained from homoveratroylhomoveratrylamine by the Bischler–Napieralski reaction, converted it to the methochloride by stirring with silver chloride, and reduced the methochloride chemically with tin and hydrochloric acid. They obtained a 7% yield, based on the starting amide.

Several chemical reductions of N-methyl quaternary salts of papaverine have been reported,[5] in yields of 50–80%, but relatively long reaction periods were required and the necessary decomposition of the tin or zinc complex salts at the end of the reduction made the isolation of the product very inconvenient.

We have found that tetrahydropapaverine can be methylated to laudanosine very conveniently, and in excellent yield (89%), by the reductive methylation procedure,[6] using anhydrous formaldehyde in absolute alcohol, with Raney nickel and hydrogen under mild conditions.

N-Methyllaudanosinium iodide (III) and the previously unreported N-benzyllaudanosinium bromide (IV) were prepared by conventional methods.

The tetrahydropapaverine required for this synthesis was prepared by the hydrogenation of both papaverine and 3,4-dihydropapaverine, in the presence of Raney nickel, giving yields (greater than 80%) greatly improved over those reported in the literature.[7] A further advantage is that the 3,4-dihydropapaverine, which is very unstable, need not be isolated and purified after its formation by ring-closure of homoveratroylhomoveratrylamine, but may be hydrogenated in the crude form after transferring to the appropriate solvent.

(III) R = —OCH_3, R_1 = CH_3
(IV) R = —OCH_3, R_1 = —$CH_2C_6H_5$
(VIII) R = —H, R_1 = —CH_3

A literature survey[8] on the types of compounds exhibiting curariform activity disclosed that certain compounds possessing a tertiary or quaternary nitrogen common to two saturated ring systems show marked curariform activity. Treatment of tetrahydropapaverine with formaldehyde gave such a compound, 2,3,10,11-tetramethoxy-5,6,13,13a-tetrahydro-8-dibenzo(a,g)quinolizine[9] (V), which was converted to the quaternary methiodide (VI) by treatment with methyl iodide.

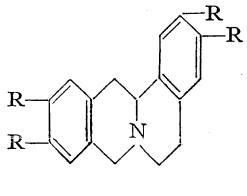
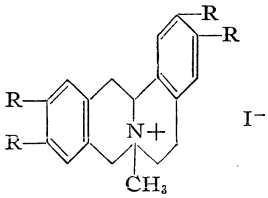
(9) This compound has appeared in the literature under the following names: norcoralydine, tetrahydropalmatine, and 2,3,11,12-tetramethoxyberbine. The "Ring Index" name has been used in this paper for clarity.



(V) R = —OCH_3
(IX) R = —H



(VI) R = —OCH_3
(X) R = —H

The corresponding compounds without methoxyl groups were also prepared. 1-Benzyl-1,2,3,4-tetrahydroisoquinoline was prepared by catalytic hydrogenation (Raney nickel) of the 1-benzyl-3,4-dihydroisoquinoline formed in the Bischler–Napieralski synthesis. Here again the 3,4-dihydroisoquinoline was not isolated. Only chemical reductions have previously been reported.[10] The reductive methylation of the tetrahydroisoquinoline with formaldehyde gave 1-benzyl-2-methyl-1,2,3,4-tetrahydroisoquinoline (VII) in 66% yield. (VII) was converted into the quaternary methiodide (VIII).

Attempts to prepare 5,6,13,13a-tetrahydro-8-dibenzo(a,g)-quinolizine (IX) by treatment of 1-benzyl-1,2,3,4-tetrahydroisoquinoline with formaldehyde under both acidic and basic conditions were unsuccessful, but it was obtained by the method of Leithe[11] and converted to the quaternary methiodide (X).

Compounds III, IV, VI and VIII exhibited curare-like activity in mice, the two most effective, VI and VIII, being 1/70th to 1/75th as active as *d*-tubocurarine chloride. All four of the compounds showed vasodepression in dogs. Compounds V and X were convulsant poisons.[12]

Experimental[13]

Tetrahydropapaverine. A.—Ten grams of papaverine[14] in 250 cc. of ethanol was shaken with 1 g. of Raney nickel for four hours at 150° under hydrogen at 150 atm. The catalyst was removed by filtration and the filtrate reduced in volume to about 100 cc. An excess of dry hydrogen chloride gas was bubbled through the solution and ether added to precipitate the tetrahydropapaverine hydrochloride. Ten grams (89%) was obtained, m. p. 216–218°. The picrate after recrystallization from ethanol melted at 161–162°.[15]

B.—A 10-g. sample of homoveratroylhomoveratrylamine, prepared from the hydrazide of β-(3,4-dimethoxyphenyl)-propionic acid and homoveratric acid by the method of Schöpf and Salzer,[16] was treated with phosphorus oxychloride in thiophene-free benzene according to the method of Kindler and Peschke,[7b] all operations being carried out under an atmosphere of nitrogen rather than carbon dioxide. The chloroform extract of the dihydroisoquinoline was evaporated to dryness, and the residue taken up in 75 cc. of ethanol. The solution was shaken for five hours at about 70° under hydrogen at 3.5 atm. in the presence of about 0.5 g. of Raney nickel. After removing the catalyst by filtration, the solution was reduced in volume to about 50 cc. and an excess of dry hydrogen chloride gas introduced. The tetrahydropapaverine hydrochloride was recrystallized from ethanol–ether, 8.7 g. (79%) of very light tan needles being obtained, m. p. 216°. The picrate melted at 161–162°.[15]

Laudanosine (II).—A 2-g. sample of tetrahydropapaverine hydrochloride was converted to the free base and dissolved in 50 cc. of absolute ethanol. An excess of anhydrous formaldehyde was introduced into the solution by passing a stream of dry nitrogen over dry paraformaldehyde, heated in a flask immersed in an oil-bath at 180–190°, and then into the cooled solution. About 0.5 g. of Raney nickel was added, and the solution shaken at room temperature for three and one-half hours under hydrogen at a pressure of 2.5 atm. The catalyst was removed by filtration, the ethanol solution reduced in volume to about 25 cc., and an excess of dry hydrogen chloride introduced. On adding ether, an oil separated and slowly crystallized. The product was dissolved in water and the cooled solution made basic with dilute alkali. The white amorphous solid (1.7 g., 89%, m. p. 111–113°) melted at 114–115° after recrystallization from dilute ethanol. The picrate was obtained as yellow needles from ethanol, m. p. 173–175°.[17]

N-Methyllaudanosinium Iodide (III).—This product was obtained in 69% yield by refluxing a dry benzene solution (50 cc.) of 3 g. of laudanosine and 1.5 cc. of methyl iodide for three hours, m. p. 212–214° without further purification. A small sample recrystallized from ethanol–ether with charcoal treatment melted at 214–215°.[18] This product was shown by mixed melting point to be identical with a product obtained in 15% yield from the treatment of tetrahydropapaverine with methyl iodide.

Anal. Calcd. for $C_{22}H_{30}INO_4$: C, 52.91; H, 6.10. Found: C, 52.98; H, 6.09.

N-Benzyllaudanosinium Bromide (IV).—This product was obtained in essentially quantitative yield by refluxing a benzene solution (25 cc.) of 1.2 g. of laudanosine and 0.5 cc. of benzyl bromide for six hours. After recrystallization from absolute ethanol, tiny needles were obtained, m. p. 157–165° with decomposition. No attempt was made to separate the diastereoisomers.

Anal. Calcd. for $C_{28}H_{34}BrNO_4$: C, 63.63; H, 6.49. Found: C, 63.50; H, 6.10. These analytical values were obtained after several analyses in which carbon percentages were consistently low.

2,3,10,11-Tetramethoxy-5,6,13,13a-tetrahydro-8-dibenzo(a,g)quinolizine (V).[19]—Five grams of tetrahydropapaverine hydrochloride in 40 cc. of water was heated on a steam-bath while 10 cc. of 35% formaldehyde was added in small portions over a period of thirty minutes. Heating was continued for an additional thirty minutes. After concentrating the solution and cooling, 5.2 g. of the crude hydrochloride was obtained. The product was dissolved in a small amount of water and the free base liberated by the addition of an excess of dilute alkali, giving 3.8 g. (83%), m. p. 158–159°.

Anal. Calcd. for $C_{21}H_{25}NO_4$: C, 70.96; H, 7.09. Found: C, 70.98; H, 6.93.

The hydrochloride, prepared by passing dry hydrogen chloride gas through an ether solution, melted at 234–237° with decomposition.[20]

7-Methyl-2,3,10,11-tetramethoxy-5,6,13,13a-tetrahydro-8-dibenzo(a,g)quinolizinium Iodide (VI).—This quaternary salt was obtained in essentially quantitative yield by refluxing a solution of 2 g. of 2,3,10,11-tetramethoxy-5,6,13,13a-tetrahydro-8-dibenzo(a,g)quinolizine and 1 cc. of methyl iodide in 50 cc. of benzene for three and one-half hours. The tiny white needles which precipitated melted at 244–249°.[21] No attempt was made to separate the diastereoisomers.

Anal. Calcd. for $C_{22}H_{28}INO_4$: C, 53.12; H, 5.67. Found: C, 52.75; H, 5.71.

1-Benzyl-1,2,3,4-tetrahydroisoquinoline.—A 20-g. sample of N-(β-phenylethyl)-phenylacetamide[22] was converted to 1-benzyl-3,4-dihydroisoquinoline by treatment with phosphorus pentoxide in boiling tetralin according to the procedure of Späth, Berger and Kuntara.[23] The light yellow oil (10 g., 54%) was dissolved in 75 cc. of ethanol, 1 g. of Raney nickel added, and the solution shaken for three hours at 70° under hydrogen at 3.5 atm. The catalyst was removed by filtration and the filtrate concentrated to about 40 cc. An excess of dry hydrogen chloride gas was introduced and ether added to facilitate precipitation. The 8.8 g. of colorless crystals obtained represent a 75% yield in the hydrogenation. A small sample after recrystallization from ethanol–ether melted at 172–173°.[24]

1-Benzyl-2-methyl-1,2,3,4-tetrahydroisoquinoline (VII).—The free base from 3.3 g. of 1-benzyl-1,2,3,4-tetrahydroisoquinoline hydrochloride was dissolved in 75 cc. of absolute ethanol and an excess of anhydrous formaldehyde introduced as above. About 0.5 g. of Raney nickel was added and the solution shaken for three hours at room temperature under hydrogen at 3.3 atm. The catalyst was removed by filtration and the ethanol removed by distillation, leaving 2.3 g. (66%) of very light yellow oil. The picrate was obtained as tiny yellow needles from ethanol, m. p. 166.5–167°.[25]

(21) Osada, *J. Pharm. Soc.*, No. 547, 711 (1927), reported a m. p. of 245°. Haworth, Koepfli and Perkin, *J. Chem. Soc.*, 2263 (1927), reported a m. p. of 266° for the β-isomer, 230° for the α-isomer. Robinson and Sugasawa, *ibid.*, 789 (1932), reported a m. p. of 215°.

(22) Prepared by the method of Decker, *Ann.*, **395**, 282 (1912).

(23) Späth, Berger and Kuntara, *Ber.*, **63**, 134 (1930).

(24) Leithe (ref. 10a) reported a m. p. of 173°.

(25) Forsyth, Kelly and Pymán (ref. 10b) reported a m. p. of 165–167°.

1-Benzyl-2,2-dimethyl-1,2,3,4-tetrahydroisoquinolinium Iodide (VIII).—A dry benzene solution (50 cc.) of 2.2 g. of 1-benzyl-2-methyl-1,2,2,4-tetrahydroisoquinoline and 2 cc. of methyl iodide was refluxed for three hours on a steam-bath. The light tan powder obtained on filtering the cooled reaction mixture amounted to 2.9 g. (83%). After recrystallization from absolute ethanol, 2.5 g. (72%) of tiny colorless needles were obtained, m. p. 242°.[26]

5,6,13,13a-Tetrahydro-8-dibenzo[a,g]quinolizine (IX).—Attempts to prepare 5,6,13,13a-tetrahydro-8-dibenzo-[a,g]quinolizine by treatment of 1-benzyl-1,2,3,4-tetrahydroisoquinoline with formaldehyde in the presence of hydrochloric acid, or of sodium bicarbonate, were unsuccessful. It was prepared in 38% yield by the method of Leithe,[11] m. p. of the free base 84–85°, m. p. of the hydrochloride 231–232°.

7-Methyl-5,6,13,13a-tetrahydro-8-dibenzo[a,g]quinolizinium Iodide (X).—A dry solution of 0.6 g. of 5,6,13,-13a-tetrahydro-8-dibenzo[a,g]quinolizine and 2 cc. of methyl iodide in 50 cc. of dry benzene was refluxed for four hours. The light tan precipitate which formed was collected by filtration and dried. The 0.8 g. of product after recrystallization from ethanol–ether with charcoal treatment gave 0.7 g. (73%) of very light tan powder, m. p. 198–202°.[27] No attempt was made to separate the diastereoisomers.

Anal. Calcd. for $C_{18}H_{20}IN$: C, 57.30; H, 5.34. Found: C, 57.64; H, 5.36.

Summary

1-Benzyltetrahydroisoquinolines have been synthesized by improved methods. Quaternary salts of these compounds exhibited curare-like activity, the most effective being 1/75th as active as *d*-tubocurarine chloride.

(26) Leithe (ref. 10a) reported a m. p. of 242°. Freund and Bode, *Ber.*, **42**, 1763 (1909), reported a m. p. of 239–242°.

(27) Chakravarti, Haworth and Perkin, *J. Chem. Soc.*, 2275 (1927), reported a m. p. of 230–232° for the β-isomer, 212° for the α-isomer.

Synthesis of Some Iodo-sugar Derivatives[1]

BY ALBERT L. RAYMOND AND ELMER F. SCHROEDER

The use of iodinated organic compounds as X-ray contrast agents in urography has become well established in recent years. However, the administration of such compounds by the intravenous route is attended by an element of danger because of occasional side effects. In a search for other suitable contrast agents of lower toxicity, a number of water soluble iodo-sugar derivatives have been prepared and subjected to preliminary tests. These include 6-iodo-6-desoxy-D-galactose (I), 6-iodo-6-desoxy-α-methyl-D-glucopyranoside (II), 6-iodo-6-desoxy-β-methyl-D-glucopyranoside (III) and 6-iodo-6-desoxy-1,4-sorbitan (IV).

The introduction of the iodine atom into the sugar residues was accomplished by the well-known procedure of Oldham and Rutherford[1a] by heating the corresponding 6-*p*-toluenesulfonyl (tosyl) derivative, suitably stabilized by substituent groups, with sodium iodide in acetone solution. Thus, 6-iodo-6-desoxy-D-galactose was obtained by the following series of reactions: 1,2,3,4-diisopropylidene-D-galactose[2] → 6-tosyl-1,2,3,4-diisopropylidene-D-galactose[3] → 6-iodo-6-desoxy-1,2,3,4-diisopropylidene-D-galactose[4] → 6-iodo-6-desoxy-D-galactose. The final step in this series was carried out by hydrolysis of the diisopropyli-

dene derivative in 50% acetic acid. The iodogalactose was readily obtained in crystalline form by treatment with absolute ethanol, from which it separated in rectangular plates containing one molecule of ethanol. The anhydrous form resulted on recrystallization of the alcoholate from an acetic acid–methyl ethyl ketone mixture. It melted at 114–116° and rotated $[\alpha]^{25}D$ + 75.3° (three minutes) in water, decreasing to a constant $[\alpha]^{25}D$ + 66.9° in about five hours. The anhydrous form readily gave crystalline alcoholates also with methanol and 2-propanol. On treatment with phenylhydrazine, an insoluble phenylhydrazone was precipitated at room temperature.

6-Iodo-6-desoxy-α-methyl-D-glucopyranoside was recently prepared by Zief and Hockett[5] by deacetylation of 6-iodo-6-desoxy-2,3,4-triacetyl-α-methyl-D-glucopyranoside with hot aqueous–alcoholic hydrogen chloride. We obtained the same compound simply by treating α-methyl-D-glucopyranoside in pyridine with one mole of tosyl chloride, and after removal of the pyridine, heating the sirupy reaction product with sodium iodide in acetone solution. From the resulting digest, the iodo-glucoside was isolated directly in about 22% yield. Alternatively, the crude product from the iodide digestion may be converted by acetylation into 6-iodo-6-desoxy-2,3,4-triacetyl-α-methyl-D-glucopyranoside, which can then be catalytically deacetylated by means of sodium methoxide in methanol solution.[6] The fact that this deacetylation can be smoothly and practically quantitatively accomplished by no more than about 0.01 mole equivalent of sodium methoxide is rather surprising in view of the presence of the halogen atom. The 6-iodo-6-desoxy-α-methyl-D-glucopyranoside obtained by either procedure, after recrystallization from ethanol, melted at 146–147°, and rotated $[\alpha]^{25}D$ + 101.5° in water.

6-Iodo-6-desoxy-β-methyl-D-glucopyranoside was obtained in similar manner, by treatment of β-methyl-D-glucopyranoside hemihydrate with 1.5 mole equivalents of tosyl chloride in pyridine. However, in this case, when the sirupy tosylation product was heated with sodium iodide in acetone, the iodo-glucoside, which itself is easily soluble in warm acetone, separated from the hot reaction mixture presumably as an insoluble complex with sodium *p*-toluenesulfonate. This complex is probably analogous to those described by Watters, Hockett and Hudson[7] of certain β-methyl glycosides with potassium acetate. Treatment of the complex with an acetylating mixture yielded 6-iodo-6-desoxy-2,3,4-triacetyl-β-methyl-D-glucopyranoside, which on deacetylation with sodium methoxide gave the desired 6-iodo-6-desoxy-β-methyl-D-glucopyranoside in an over-all yield of 53%. The product separated from alcohol as needles melting at 157–158° and rotating $[\alpha]^{25}D$ −17° in water.

The synthesis of 6-iodo-6-desoxy-1,4-sorbitan, and several of its derivatives, is represented schematically. On treatment of 1,4-sorbitan (V) with tosyl chloride at low temperature, a 53% yield of 6-tosyl-1,4-sorbitan (VI) was obtained. This was condensed with benzaldehyde in the presence of hydrochloric acid or zinc chloride to give an excellent yield of 6-tosyl-2(3),5-benzylidene-1,4-sorbitan (VII), melting at 129.5–130.5° and rotating $[\alpha]^{25}D$ + 8.9° in water. As an alternative procedure, 1,4-sorbitan was condensed with benzaldehyde using zinc chloride as catalyst to give 2(3),5-benzylidene-1,4-sorbitan (VIII), melting at 154.5–155.5° and rotating $[\alpha]^{25}D$ + 17.7° in methanol,[8] which with tosyl chloride was converted almost quantitatively into 6-tosyl-2(3),5-benzylidene-1,4-sorbitan (VII) identical with the product obtained by benzalation of 6-tosyl-1,4-sorbitan. Treatment of the tosyl derivative with sodium iodide yielded 6-iodo-6-desoxy-2(3),5-benzylidene-1,4-sorbitan (IX) which was readily hydrolyzed by heating for ten minutes at 100° in aqueous–alcoholic 0.1 *N* sulfuric acid to give an 85% yield of 6-iodo-6-desoxy-1,4-sorbitan (IV), melting at 108–109° and rotating $[\alpha]^{25}D$ − 11.9° in water.

The assignment of the tosyl group, and consequently of the iodine atom, to the 6 position in these compounds follows from the Oldham–Rutherford rule[1a] that only tosyl groups attached to primary alcohol groups are readily replaceable by iodine on treatment with sodium iodide. The location of the benzylidene group has not been completely established. However, that one of the linkages is attached to position 5 is highly probable in view of the observation that, while 6-tosyl-1,4-sorbitan (VI) on treatment with sodium iodide decomposes with liberation of iodine, its benzylidene derivative (VII) reacts smoothly without evidence of decomposition. In our experience,[9] when 6-tosyl derivatives, having an unprotected secondary hydroxyl group in the adja-

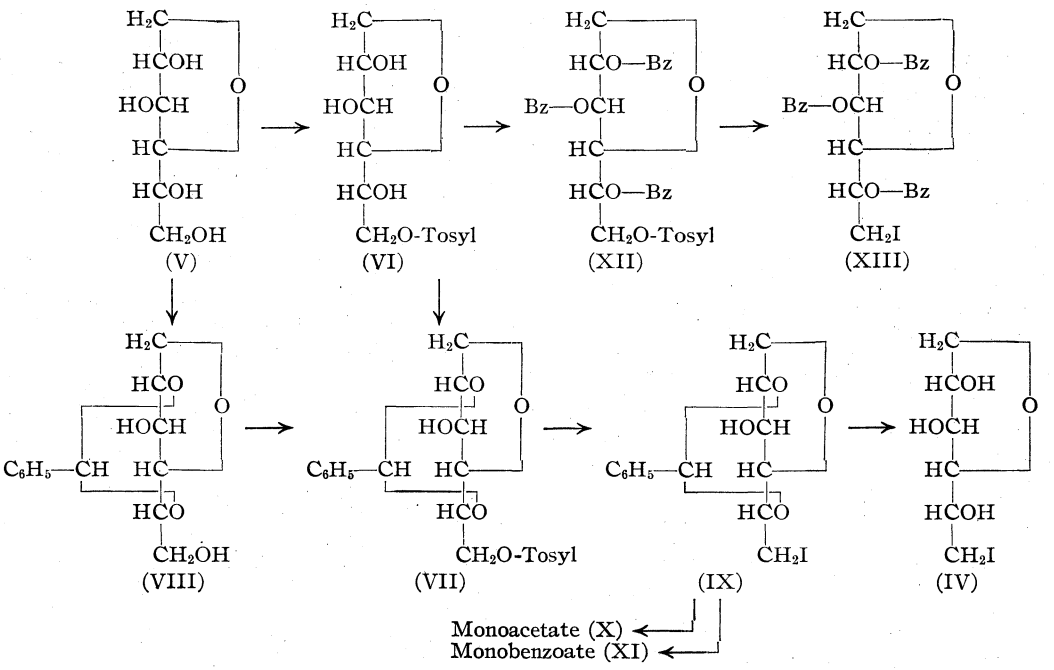
(7) Watters, Hockett and Hudson, THIS JOURNAL, **56**, 2199 (1934).

(8) Soltzberg, Goepp and Freudenberg, *ibid.*, **68**, 919 (1946), recently reported the preparation in small yield of two additional monobenzylidene-1,4-sorbitans by refluxing sorbitan with benzaldehyde without catalyst. That neither of these is identical with the product obtained by us is indicated by the reported constants (m. p. 136–140°, $[\alpha]D$ +33.72° in methanol for the first and m. p. 121–122° for the second).

(9) Unpublished results. See also Bell, Friedmann and Williamson, *J. Chem. Soc.*, 252 (1937).



cent 5 position, are heated with sodium iodide there is a greater or less tendency for liberation of free iodine to occur. This is not evident when the 5 position is blocked, either by a substituent group or, as in the case of the 6-tosyl-α- and β-methyl-D-glucopyranosides, by the presence of a pyranoid ring structure.

Several additional derivatives of 1,4-sorbitan were prepared during the course of this work. 6-Iodo-6-desoxy-2(3),5-benzylidene-1,4-sorbitan (IX) gave a monoacetate (X) and a monobenzoate (XI). On treatment of crystalline 6-tosyl-1,4-sorbitan (VI) with excess benzoyl chloride, there was obtained 6-tosyl-2,3,5-tribenzoyl-1,4-sorbitan (XII) melting 106–107° and rotating $[\alpha]^{25}D$ +47.2° in chloroform,[10] converted by sodium iodide into 6-iodo-6-desoxy-2,3,5-tribenzoyl-1,4-sorbitan (XIII). The latter could not be debenzoylated without simultaneous loss of iodine.

The iodo-sugar derivatives (I-IV) are readily soluble in water to give colorless solutions. Thus 6-iodo-6-desoxy-D-galactose (I) and 6-iodo-6-desoxy-1,4-sorbitan (IV) dissolve at room temperature in their own weight of water. The two 6-iodomethyl-D-glucopyranosides are less soluble, dissolving in about two parts of water at 50°, but partially crystallizing out again on cooling. The β-form separates from water in needles, while the α-form produces rods frequently several centimeters long.

These compounds show a wide divergence in the firmness with which the iodine atom is held, as is shown in Table I. These data were obtained by dissolving equivalent amounts of the iodo-sugar derivatives (0.0013 mole) in 25 cc. of water, immersing for exactly thirty minutes in a boiling water-bath, then titrating the hydrogen iodide formed with standard alkali.

TABLE I

STABILITY OF IODO-SUGAR DERIVATIVES AT 100°

Compound	Cc. 0.01 *N* NaOH required	% Decomposition
I	2.20	1.66
II	0.10	0.07
III	0.18	0.13
IV	44.80	33.7

As would be expected, the stabilizing effect of the pyranoid ring is evident. The two iodomethyl-D-glucopyranosides (II and III), having a fixed ring structure, show only negligible decomposition; iodo-D-galactose (I), in which a ring shift is possible in solution, is somewhat less stable, while iodo-sorbitan (IV), having a free hydroxyl group adjacent to the iodine, is by far the least stable. At room temperature, aqueous solutions of the iodo-D-glucosides remain unchanged indefinitely, while solutions of iodo-D-galactose and iodo-sorbitan show evidence of acid liberation within several months and several weeks, respectively.

Pharmacological studies carried out on dogs have shown that 6-iodo-6-desoxy-D-galactose exhibits a fairly low acute toxicity, is concentrated rapidly by the kidneys, and yields satisfactory X-ray pictures of the kidney region. However, in view of the relatively low stability of the carbon–iodine linkage, the application to clinical use must await further study.

(10) After completion of our experimental work on this compound, Hockett, Conley, Yusem and Mason, THIS JOURNAL, **68**, 922 (1946), reported its preparation directly from 1,4-sorbitan without isolation of the intermediate 6-tosyl-1,4-sorbitan. However, the constants reported by these investigators are at considerable variance with those found by us (m. p. 161.5–163.0°, rotation +35.1° in chloroform).

Experimental

1,2,3,4-Diisopropylidene-D-galactose.—Crude diisopropylidene galactose was prepared by a modification of the method of Gruenenberg, Bredt and Freudenberg.[2] The principal changes introduced were in the substitution of sulfuric acid for the phosphoric acid–phosphorus pentoxide catalyst, and in a considerable reduction in the quantity of acetone used.

A mixture consisting of anhydrous D-galactose (200 g.), acetone (2500 cc.), powdered, fused zinc chloride (240 g.), and sulfuric acid (8 cc.), was stirred for four hours at room temperature. The reaction mixture was treated with a solution of 400 g. of sodium carbonate in 700 cc. of water, and vigorously stirred until the supernatant liquid became zinc-free. The precipitated salts were filtered off and washed with acetone. The filtrate, consisting of two liquid phases, was completely freed of acetone by distillation, and the crude diisopropylidene galactose, separating as a light-yellow upper layer, was taken up in ether, washed with water, and dried with sodium sulfate. After removal of the solvent, the yield of crude product was 260 g., or 90% of theory.

6-Tosyl-1,2,3,4-diisopropylidene-D-galactose.—The procedure of Freudenberg and Hixon[2] was somewhat modified for this preparation. A solution of 260 g. (1 mole) of crude diisopropylidene galactose in a mixture of 275 cc. of acetone and 175 cc. of pyridine was cooled in tap water. With stirring, 228 g. (1.2 moles) of tosyl chloride was added in portions over a period of one hour, the temperature being maintained below 45°. After standing overnight, the excess tosyl chloride was decomposed by the addition of 10 cc. of water. The reaction mixture was then poured into 2.5 liters of water, a sirupy product precipitating, which solidified on standing for several hours. This was filtered off, washed with water, and air-dried; yield, 360 g. The product was dissolved in 360 cc. of 2-propanol, and allowed to crystallize overnight at room temperature. After 360 cc. of Skellysolve C were gradually added with stirring, the crystals were filtered off and washed with Skellysolve C. The yield was 275 g. (66%) of product melting at 87–89°; reported,[3] 91–92°. If the product melts much below this point, it must be recrystallized before use in the subsequent reaction with sodium iodide.

6-Iodo-6-desoxy-1,2,3,4-diisopropylidene-D-galactose.—The procedure of Freudenberg and Raschig[4] was somewhat modified for this preparation. A solution of 248 g. (0.6 mole) of 6-tosyl-1,2,3,4-diisopropylidene-D-galactose and 180 g. (1.2 moles) of sodium iodide in 1250 cc. of acetone was heated at 105–110° for thirty-six hours.[11] After removal of the precipitated sodium *p*-toluenesulfonate by filtration and washing with acetone, the filtrate was concentrated under reduced pressure. The residual sirup was stirred with 1 liter of water and a few crystals of sodium thiosulfate to destroy traces of free iodine. After several hours, the product solidified and was washed repeatedly with water. This crude material may be used directly, without drying, in the subsequent hydrolysis. If desired, it may be recrystallized from 250 cc. of methanol; yield, 190 g. (85%), melting at 69–71°; reported, 72°.[4]

6-Iodo-6-desoxy-D-galactose.—6-Iodo-6-desoxy-1,2,3,4-diisopropylidene-D-galactose (275 g.) was dissolved in 800 cc. of glacial acetic acid, immersed in a boiling water-bath, and with frequent shaking, treated with 750 cc. of hot water added in 50-cc. portions over a period of one hour. Heating was continued for one hour longer, at which time hydrolysis was complete as shown by the fact that a 1-cc. test portion remained clear on dilution with 5 cc. of water. In some runs, an additional twenty or thirty minutes of heating was required to complete hydrolysis. The solution was cooled, treated briefly with Darco, and filtered through a layer of Celite. The filtrate was then concentrated to a thin sirup under reduced pressure at a temperature not exceeding 40°. Absolute ethanol (500 cc.) was added, and the solution again concentrated. On redissolving the sirupy residue again in 800 cc. of absolute ethanol, cooling and scratching, a voluminous mass of crystals rapidly separated. After standing in the cold overnight, the product was filtered off, washed with ethanol, and twice recrystallized from 1500 cc. of absolute ethanol. The 6-iodo-6-desoxy-D-galactose prepared in this manner crystallized with one molecule of ethanol. The yield of alcoholate was 196 g., or 78% of the theoretical; rectangular plates, melting at 105–106° (cor.); very soluble in water, moderately soluble in hot alcohol, ethyl acetate and acetone, insoluble in chloroform and benzene. The substance had an initial (three minutes) rotation of $[\alpha]^{25}D$ +84.7° (*c*, 6.08 in water), which decreased to a constant value of +57.6° in five hours. Calculated on the basis of the iodo-galactose content, the latter becomes $[\alpha]^{25}D$ +66.8° (*c*, 5.24), identical with the constant value later obtained for anhydrous iodogalactose itself.

Anal. Calcd. for $C_6H_{11}O_5I \cdot C_2H_5OH$: C, 28.58; H, 5.10; I, 37.76. Found: C, 28.30; H, 4.86; I, 37.75, 38.0.

The alcohol is held quite tenaciously, being only incompletely removed by heating at 61° for seventeen hours (1 mm.). Calcd.: C_2H_5OH, 13.71. Found: C_2H_5OH, 12.2. Attempts to obtain the anhydrous form of the iodo-galactose by recrystallization from ethanol under a variety of conditions of concentration and temperature resulted in recovery of the starting material. The following procedure, however, gave the anhydrous form in good yield. A quantity of 50 g. of the alcoholate was heated for five minutes in a boiling water-bath with 25 cc. of glacial acetic acid. To the hot solution was added 250 cc. of hot, freshly distilled, methyl ethyl ketone. On cooling, anhydrous 6-iodo-6-desoxy-D-galactose separated in the form of needles, which were filtered off and washed with methyl ethyl ketone. The yield was 35 g. of product melting sharply at 113–114° (cor.), and rotating $[\alpha]^{25}D$ +75.3° (three minutes, *c*, 5.68 in water), decreasing to a constant value of +66.9° in about five hours.

Anal. Calcd. for $C_6H_{11}O_5I$: C, 24.84; H, 3.82; I, 43.75. Found: C, 24.78, 24.51; H, 3.82, 3.78; I, 43.87, 43.70.

Phenylhydrazone of 6-Iodo-6-desoxy-D-galactose.—To a solution of 7 g. of phenylhydrazine in 75 cc. of 50% acetic acid were added 3 g. of 6-iodo-6-desoxy-D-galactose. A white precipitate began to form at once. After one hour at room temperature the product was filtered off, washed with water and cold alcohol, and dried; yield 3.8 g.; theory, 3.93 g. After two recrystallizations from 120 cc. of 95% ethanol, the product darkened at 126° and melted with vigorous decomposition at 136–137° (cor.); $[\alpha]^{25}D$ +34.3° (*c*, 5.40 in pyridine), showing no evidence of mutarotation, but developing a marked yellow color in the pyridine solution in thirty minutes; rectangular plates.

Anal. Calcd. for $C_{12}H_{17}O_4N_2I$: N, 7.37; I, 33.42. Found: N, 6.99, 7.01; I, 33.49.

6-Iodo-6-desoxy-α-methyl-D-glucopyranoside.—A solution of 300 g. (1.55 moles) of α-methyl-D-glucopyranoside in 1500 cc. of dry pyridine was cooled in tap water and treated by the portionwise addition of 318 g. (1.67 moles) of tosyl chloride, the temperature being held below 40°. After standing for one hour longer, most of the pyridine was removed by distillation under reduced pressure. The residual sirup was taken up in 300 cc. of warm water, cooled, and neutralized (brom thymol blue) by the addition of 5 *N* sodium hydroxide (360 cc. required). The solution was concentrated to dryness under reduced pressure, and the residual sirup (700 g.) dissolved in 1200 cc. of acetone, some insoluble products being removed by filtration. Sodium iodide (210 g.) was dissolved in the acetone solution, which was transferred to pressure flasks and heated for two hours at 100°. Sodium *p*-toluene-

(11) Freudenberg and Raschig[4] employed a temperature of 125° for thirty-six hours. In our hands, considerable decomposition occurred under these conditions. At 105–110° the reaction is complete in thirty-six hours, as indicated by the practically quantitative yield of sodium *p*-toluene-sulfonate.

sulfonate was removed by filtration, washed with acetone, and the filtrate concentrated to dryness. The sirupy residue was dissolved in 700 cc. of water, extracted several times with dichloromethane and the aqueous phase then concentrated under reduced pressure. When about 500 cc. of distillate had been collected, the desired product began to separate out, and crystallization was complete after standing for twenty-four hours in the cold. The product was filtered off and recrystallized twice from 100 cc. of 95% ethanol; yield, 100 g., 22%.

Anal. Calcd. for $C_7H_{13}O_5I$: C, 27.65; H, 4.31; I, 41.74. Found: C, 27.72, 27.94; H, 4.40, 4.61; I, 41.71, 41.62.

The 6-iodo-6-desoxy-α-methyl-D-glucopyranoside is obtained as long rods melting sharply at 146–147° (cor.) and rotating $[\alpha]^{25}D$ +101.5° (*c*, 5.00 in water). Zief and Hockett[5] found m. p. 136.9–137.4° and $[\alpha]D$ +93.9° in water. The product is readily soluble in water but crystallizes out of concentrated aqueous solution on cooling, easily soluble in warm alcohol and acetone, insoluble in chloroform and benzene.

As an alternative procedure, we found that if, as sometimes occurred, the 6-iodo-glucoside failed to crystallize in the final distillation previously described, the residue could be taken to complete dryness and acetylated by addition of 500 cc. of pyridine and 500 cc. of acetic anhydride. On treatment with much water, 6-iodo-6-desoxy-2,3,4-triacetyl-α-methyl-D-glucopyranoside separated. Recrystallization from 900 cc. of 95% ethanol yielded 165 g. of pure product melting at 149–150°; reported,[12] 150–151°. Deacetylation was conveniently carried out by suspending this material in 375 cc. of methanol, adding 40 cc. of 0.1 *N* sodium methoxide in methanol, and shaking for one hour. On concentrating to dryness, the 6-iodo-6-desoxy-α-methyl-D-glucopyranoside separated as a solid mass and was recrystallized from 125 cc. of 95% ethanol; yield, 100 g.; m. p. 146–147°. A mixed melting point with the product obtained by direct isolation showed no depression.

Preparation of β-Methyl-D-glucopyranoside *via* its Potassium Acetate Complex.—Watters, Hockett and Hudson[7] reported that certain β-methyl-D-glycosides form molecular complexes with potassium acetate, and suggested that this property might be useful in some cases in the separation of the α- and β-isomers. We have found that this method offers a fairly convenient means of preparing β-methyl-D-glucopyranoside in quantity directly from D-glucose.

Anhydrous glucose (500 g.) was added to 1000 g. of methanol containing 3% by weight of hydrogen chloride, previously heated to a boil in a flask fitted with a reflux condenser and a calcium chloride tube. With occasional shaking, the heating was continued for just one hour. The solution was cooled, seeded with α-methyl-D-glucopyranoside, and allowed to stand in the icebox overnight. The α-methyl-glucopyranoside (90 g.) was filtered off and the filtrate neutralized by addition of 80 g. of solid sodium bicarbonate. After removal of the salts, the filtrate was concentrated to a thick sirup under reduced pressure. The sirup was dissolved in 500 cc. of hot absolute ethanol, treated with a hot solution of 200 g. of potassium acetate in one liter of ethanol, and allowed to stand overnight in the cold. The voluminous precipitate consisting mainly of the addition complex between β-methyl-D-glucopyranoside and potassium acetate, was filtered off, washed with ethanol and acetone, and finally dried briefly by heating at 100° under reduced pressure; yield, 200 g.

To decompose the complex, the 200 g. of crude addition complex was dissolved in 600 cc. of hot methanol and treated with a hot solution of 110 g. of D-tartaric acid in 600 cc. of 95% ethanol. After one hour the precipitated potassium acid tartrate was filtered off through Celite, the filtrate concentrated to a thin sirup (230 cc.), seeded, and allowed to stand in the cold to complete crystallization. The β-methyl-D-glucopyranoside separating was recrystallized from 500 cc. of 95% ethanol; yield, 115 g., or 21%, melting at 104–106° (cor.), and rotating $[\alpha]^{25}D$ −32° (*c*, 5.72 in water). The product was obtained as the hemihydrate.[13]

6-Iodo-6-desoxy-β-methyl-D-glucopyranoside.—A solution of 100 g. (0.51 mole) of β-methyl-D-glucopyranoside hemihydrate in 100 cc. of dry pyridine was cooled in running tap water and treated by the dropwise addition of a solution of 146 g. (0.76 mole) of tosyl chloride in 100 cc. of dichloromethane. The addition required about thirty minutes, the temperature being held below 45°. After one hour, the reaction mixture was neutralized by the addition of sodium hydroxide (required, 200 cc. of 5.17 *N* solution), using brom thymol blue as external indicator. The solution was concentrated to dryness under reduced pressure, the temperature being raised to 100° toward the end of the distillation to remove water as completely as possible. The sirupy residue (295 g.), together with 100 g. of sodium iodide, was dissolved in 400 cc. of acetone and heated for two hours at 100° in pressure flasks. The voluminous precipitate was filtered off, washed with acetone and air dried. It weighed 285 g. and consisted of some sodium chloride and sodium *p*-toluenesulfonate, together with a large amount of what is, probably, an insoluble complex between sodium *p*-toluenesulfonate and 6-iodo-6-desoxy-β-methyl-D-glucopyranoside.

To break up the complex[14] the 285 g. of material was covered with 150 cc. of dry pyridine and 150 cc. of acetic anhydride. After standing overnight at room temperature, the mixture was poured into two liters of water. After a short time the precipitated 6-iodo-6-desoxy-2,3,4-triacetyl-β-methyl-D-glucopyranoside was filtered off, washed with water, and recrystallized from 150 cc. of 95% ethanol. The yield was 129 g. (59%) of product melting at 114–115°; reported[15] m. p., 114–115°.

Deacetylation was carried out by suspending the 129 g. of triacetate in 300 cc. of methanol, adding 30 cc. of 0.1 *N* sodium methoxide solution, and shaking occasionally for about one hour. The solution was concentrated to dryness under reduced pressure, the 6-iodo-6-desoxy-β-methyl-D-glucopyranoside separating out near the end of the distillation in practically quantitative yield. It was twice recrystallized from 250 cc. of 95% ethanol, giving 82 g. (90%) of pure product. It separated in the form of long colorless needles melting at 157–158° (cor.) with decomposition, and rotating $[\alpha]^{25}D$ −17° (*c*, 5.00 in water). It is readily soluble in warm water, but crystallizes from a concentrated (40%) aqueous solution on cooling; readily soluble in warm alcohol and acetone, insoluble in chloroform.

Anal. Calcd. for $C_7H_{13}O_5I$: C, 27.65; H, 4.31; I, 41.74. Found: C, 27.99, 27.76; H, 4.49, 4.57; I, 41.67, 41.91.

6-Tosyl-1,4-sorbitan.—A solution of 200 g. (1.22 moles) of 1,4-sorbitan[16] in 800 cc. of pyridine was cooled to −5° and treated during one hour with 232 g. (1.22 moles) of tosyl chloride. After standing for two hours, most of the pyridine was removed by distillation under reduced pressure. The sirupy residue (660 g.) was taken up in 800 cc. of 95% ethanol, cooled to −5°, and neutralized with a cold 4 *N* solution of sodium hydroxide in 50% ethanol, using brom thymol blue as internal indicator (required 322 cc., theory 304). The precipitated sodium chloride was filtered off, and the filtrate concentrated to dryness under reduced pressure, the bath temperature not exceeding 50°. The sirupy residue (520 g.) was dis-

(12) Helferich and Himmen, *Ber.*, **61**, 1825 (1928).

(13) Koenigs and Knorr, *ibid.*, **34**, 957 (1901).

(14) Because of contamination with excess sodium *p*-toluenesulfonate, it was not possible to obtain the complex in sufficient purity for analysis. However evidence for its existence is seen in the fact that although 6-iodo-6-desoxy-β-methyl-D-glucopyranoside itself is readily soluble in warm acetone, it does precipitate from the hot acetone during the course of the sodium iodide reaction.

(15) Compton, THIS JOURNAL, **60**, 395 (1938).

(16) To this monoanhydride of sorbitol, a product of the Atlas Powder Co., has recently been assigned the trivial name Arlitan by Soltzberg, Goepp and Freudenberg.[8]

solved, with vigorous shaking, in 200 cc. of dichloromethane. On addition of 800 cc. more of this solvent, and cooling, the 6-tosyl-1,4-sorbitan crystallized out as a voluminous, pasty mass. A further 700 cc. of dichloromethane was added to aid in the crystallization, and after standing in the cold for several hours, the material was filtered off and air dried (300 g.). After two recrystallizations from an equal weight of warm water, 207 g. (53%) of product were obtained; rods, melting at 110–111° (cor.) and rotating $[\alpha]^{25}D$ −3.2 (*c*, 4.96 in water); readily soluble in alcohol and acetone, insoluble in ether, petroleum ether, or chloroform. The product may also be recrystallized with little loss from about twelve parts of ethylene dichloride.

Anal. Calcd. for $C_{13}H_{18}O_7S$: C, 49.05; H, 5.70; S, 10.07. Found: C, 49.1, 48.9; H, 5.68, 5.71; S, 10.23.

The same product was also obtained directly from D-sorbitol by treating a pyridine solution of the latter with two molecular equivalents of tosyl chloride, and neutralizing the reaction mixture as previously described. The amount of alkali required to reach the brom thymol blue end-point indicated that one of the tosyl groups of the 1,6-ditosyl-sorbitol presumably formed in the tosylation had been hydrolyzed during the neutralization. By working up the mixture as indicated above, 6-tosyl-1,4-sorbitan was isolated in a yield of 15%.

2(3),5-Benzylidene-1,4-sorbitan.—A mixture of 400 cc. of benzaldehyde, 100 g. of 1,4-sorbitan, and 100 g. of powdered fused zinc chloride was stirred for four hours. The temperature rose to 40°, and nearly complete solution occurred in one hour. After standing overnight the reaction mixture was repeatedly washed with water and Skellysolve C. The residual sirup was dissolved in a small amount of ethanol, treated with 100 cc. of toluene and evaporated to dryness under reduced pressure. The semi-solid mass was covered with more toluene and allowed to stand overnight in the cold. The crystalline material was filtered off and recrystallized from twelve parts of ethyl acetate. The product separated as rods, melting at 154.5–155.5° (cor.), and rotating $[\alpha]^{25}D$ +17.7° (*c*, 4.52 in methyl alcohol). The yield was 32 g.; readily soluble in acetone and alcohol, insoluble in ether, chloroform and benzene.

Anal. Calcd. for $C_{13}H_{16}O_5$: C, 61.89; H, 6.39. Found: C, 61.8, 61.9; H, 6.32, 6.22.

6-Tosyl-2(3),5-benzylidene-1,4-sorbitan. A. From 2(3),5-Benzylidene-1,4-sorbitan.—A solution of 10 g. (0.04 mole) of 2(3),5-benzylidene-1,4-sorbitan in 50 cc. of pyridine was cooled to −5°, and treated in small portions with 8.5 g. (0.044 mole) of tosyl chloride. After several hours at room temperature, the excess tosyl chloride was decomposed by addition of 2 cc. of water. On pouring the reaction mixture into 200 cc. of water, the product crystallized out at once; yield of crude product, 14 g., or 87%. After two recrystallizations from 8 parts of methanol, the material was obtained as needles melting at 129.5–130.5° (cor.), and rotating $[\alpha]^{25}D$ +8.9° (*c*, 5.88 in chloroform); insoluble in petroleum ether, readily soluble in acetone, ethyl acetate and chloroform.

Anal. Calcd. for $C_{20}H_{22}O_7S$: C, 59.10; H, 5.46; S, 7.89. Found: C, 59.1, 59.1; H, 5.36, 5.49; S, 8.24.

B. From 6-Tosyl-1,4-sorbitan.—A mixture of 100 g. of 6-tosyl-1,4-sorbitan, 100 cc. of water, 100 cc. of benzaldehyde, and 40 cc. of hydrochloric acid (sp. gr. 1.18) was vigorously stirred at room temperature for three hours. A crystalline precipitate began to form in about an hour. After standing overnight, the supernatant liquid was decanted, and the semi-solid residue shaken with 100 cc. of water and 300 cc. of Skellysolve C. The product was filtered off, suspended for a short time in dilute bicarbonate solution, then again filtered and washed with water and Skellysolve C. The crude yield was 116 g., or 91%. The crude material was dissolved in 1200 cc. of hot methanol in the presence of 2 g. of powdered calcium carbonate, and filtered. On cooling, 104 g. of pure material, melting at 129.5–130.5°, was obtained. A mixed melting point with the product prepared by method A showed no depression.

The same product was prepared in equally high yield, but less conveniently, by stirring a mixture of 100 g. of 6-tosyl-1,4-sorbitan, 400 cc. of benzaldehyde, and 100 g. of zinc chloride for four hours at room temperature, and isolating the product essentially as described previously.

6-Iodo-6-desoxy-2(3),5-benzylidene-1,4-sorbitan.—A solution of 40 g. (0.1 mole) of 6-tosyl-2(3),5-benzylidene-1,4-sorbitan and 30 g. (0.2 mole) of sodium iodide in 250 cc. of acetone was heated for two hours at 100° in a pressure flask. The precipitated sodium *p*-toluenesulfonate was removed by filtration, washed with acetone, and the colorless filtrate evaporated to a sirup under reduced pressure. On addition of water, the product crystallized immediately. After two recrystallizations from 5 parts of 95% ethanol, 28.5 g. (80%) of product was obtained; needles, melting at 147–148° (cor.), and rotating $[\alpha]^{25}D$ +24.8° (*c*, 4.00 in chloroform). The substance is insoluble in water and petroleum ether, moderately soluble in alcohol and benzene, and very soluble in acetone, ether, ethyl acetate and chloroform.

Anal. Calcd. for $C_{13}H_{15}O_4I$: C, 43.11; H, 4.17; I, 35.04. Found: C, 42.8, 43.0; H, 4.02, 4.12; I, 35.10.

It is essential that the tosyl-benzylidene-sorbitan used in the reaction with sodium iodide be quite pure. If it is not, extensive decomposition takes place, benzaldehyde is formed, and little product results.

6-Iodo-6-desoxy-2(3),5-benzylidene-monoacetyl-1,4-sorbitan.—A cold solution of 10 g. of 6-iodo-6-desoxy-2(3),5-benzylidene-1,4-sorbitan in 50 cc. of pyridine was treated with 9 g. of acetic anhydride. After several hours at room temperature, the reaction mixture was poured into ice water, crystallization occurring at once. The colorless product was twice recrystallized from 12 parts of ethanol in needles, melting at 126.5–127.5° (cor.), and rotating $[\alpha]^{25}D$ +40.4° (*c*, 3.16 in chloroform); yield, 10 g.

Anal. Calcd. for $C_{15}H_{17}O_5I$: C, 44.57; H, 4.24; I, 31.40. Found: C, 44.7, 44.4; H, 4.20, 4.31; I, 31.53.

6-Iodo-6-desoxy-2(3),5-benzylidene-monobenzoyl-1,4-sorbitan.—A cold solution of 10 g. of 6-iodo-6-desoxy-2(3),5-benzylidene-1,4-sorbitan in 50 cc. of pyridine was benzoylated with 11 g. of benzoyl chloride. After several hours at room temperature, the reaction mixture was poured into ice water, giving a solid product which was twice recrystallized from 25 parts of 95% ethanol in long colorless rods, melting at 139–141° (cor.), and rotating $[\alpha]^{25}D$ +73.8° (*c*, 4.84 in chloroform); yield, 12 g.

6-Iodo-6-desoxy-1,4-sorbitan.—A mixture of 50 g. of 6-iodo-6-desoxy-2,(3),5-benzylidene-1,4-sorbitan, 150 cc. of 95% ethanol, and 150 cc. of 0.2 *N* sulfuric acid, was immersed, under reflux condenser, in a boiling water-bath for just ten minutes. The homogeneous solution was rapidly cooled and extracted several times with 50-cc. portions of dichloromethane to remove benzaldehyde and unchanged starting material. The aqueous layer was neutralized with barium carbonate, filtered through Celite, and concentrated to dryness under reduced pressure, the bath temperature not exceeding 50°. The iodo-sorbitan crystallized out during the final stages of the distillation. Traces of water were removed by storing the flask containing the product in a desiccator overnight. The material was dissolved in 25 cc. of warm methanol, to which was then added 400 cc. of dichloromethane. On cooling and scratching, crystallization occurred. The product was filtered off and washed with dichloromethane, giving 28 g. of colorless product. An additional 4 g. was obtained by reworking the mother liquors; total yield, 32 g., or 85%. The material was recrystallized in excellent yield by dissolving in 25 cc. of methanol and adding 300 cc. of dichloromethane.

Anal. Calcd. for $C_6H_{11}O_4I$: C, 26.29; H, 4.05; I, 46.31. Found: C, 26.7, 26.1; H, 3.98, 4.07; I, 46.70.

6-Iodo-6-desoxy-1,4-sorbitan crystallizes in the form of 6-sided plates melting at 108–109° (cor.), and rotating $[\alpha]^{25}D$ −11.9° (*c*, 3.36 in water). It has a somewhat bitter taste, and is very soluble in water, alcohol and acetone, moderately soluble in hot ethyl acetate, and insoluble in ether, benzene and chloroform. It is rela-

tively unstable, showing signs of decomposition in several weeks when exposed to light, and in several months in the dark.

6-Tosyl-2,3,5-tribenzoyl-1,4-sorbitan.—To a solution of 10 g. (0.031 mole) of 6-tosyl-1,4-sorbitan in 100 cc. of pyridine, cooled in ice, was added 14.6 g. (0.10 mole) of benzoyl chloride. After standing twenty-four hours at room temperature, the reaction mixture was poured into water. The water layer was decanted from the sirupy product which precipitated. On stirring the sirup with 50 cc. of methanol, rapid crystallization occurred. After two recrystallizations from 10 parts of 95% ethanol, 18 g. (90% of theory) of colorless product was obtained in needles, melting at 106–107° (cor.),[10] and rotating $[\alpha]^{25}D$ +47.2° (*c*, 5.55 in chloroform), readily soluble in acetone, chloroform and benzene and insoluble in petroleum ether and water.

Anal. Calcd. for $C_{34}H_{30}O_{10}S$: C, 64.76; H, 4.80; S, 5.08. Found: C, 65.2, 64.5; H, 4.72, 4.76; S, 5.30.

6-Iodo-6-desoxy-2,3,5-tribenzoyl-1,4-sorbitan.—A solution of 19 g. (0.03 mole) of 6-tosyl-2,3,5-tribenzoyl-1,4-sorbitan and 9 g. (0.06 mole) of sodium iodide in 100 cc. of acetone was heated for one hour at 100° in a pressure flask. The precipitated sodium *p*-toluenesulfonate was filtered off, and the solvent removed from the filtrate. The residue solidified on addition of water, and was twice recrystallized from 600 cc. of 95% ethanol; yield, 15 g., 85%. The substance crystallized in plates melting at 151–153° (cor.) and rotating $[\alpha]^{25}D$ +5.1° (*c*, 2.92 in chloroform), insoluble in petroleum ether, ethyl ether and water and soluble in acetone, chloroform and benzene.

Anal. Calcd. for $C_{27}H_{23}O_7I$: C, 55.30; H, 3.95; I, 21.65. Found: C, 55.9, 55.2; H, 3.87, 3.87; I, 21.34.

Summary

1. A number of water soluble iodo-sugar derivatives have been prepared in order to study their utility as X-ray contrast agents in intravenous urography. These include 6-iodo-6-desoxy-D-galactose, 6-iodo-6-desoxy-α- and β-methyl-D-glucopyranosides, and 6-iodo-6-desoxy-1,4-sorbitan.

2. Several other new derivatives of 1,4-sorbitan have been synthesized.

3. β-Methyl-D-glucopyranoside has been prepared in 21% yield by treatment of glucose with methanolic hydrogen chloride, followed by isolation of the glucoside through its complex with potassium acetate.

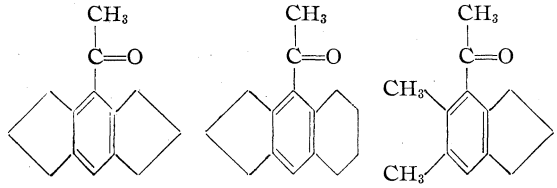
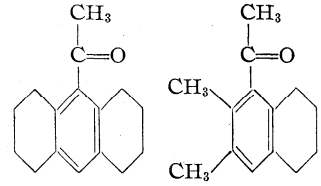
The Steric Effect of Methylene Groups. III

BY RICHARD T. ARNOLD AND PAUL N. CRAIG[1]

In an attempt to determine the relative steric influences of methylene groups in five- and six-membered rings, the following acetophenone derivatives have been prepared and examined.



(I) (II) (III)

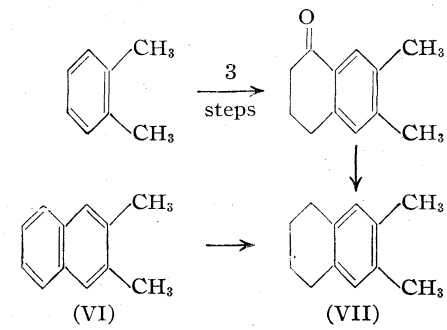


(IV) (V)

As reported earlier,[2] when treated with hypochlorite, acetohydrindacene (I) gives chloroform and 4-hydrindacenecarboxylic acid, whereas 9-acetoöctahydroanthracene (IV) gives a relatively stable trichloro ketone. The amount of methane evolved from methylmagnesium iodide (Zerewitinoff determination) decreases in the order IV > II > I. As a result of these observations and the values of carbonyl Raman frequencies, it was concluded that the steric hindrance around the carbonyl group decreases in the order IV > II > I.[2] Additional confirmatory evidence has now been obtained from observations on compounds III and V.

Of the above five ketones, only II is liquid; the others were readily purified by careful recrystallization. Tetrahydrobenz(f)indane, from which II is derived has now been prepared in a higher state of purity (m. p. 4°) and a sample of II obtained from this purer hydrocarbon has been reexamined.

6,7-Dimethyltetralin (VII) is obtained directly by catalytic reduction of 2,3-dimethylnaphthalene (m. p. 104°) in the presence of Raney nickel. The hydrocarbon so formed is essentially identical with that prepared from pure *o*-xylene.[3]



(VI) (VII)

It would appear that close approach to the cata-

lyst of the benzenoid ring attached to the methyl groups in VI is sterically inhibited.[4]

Table I contains a summary of our observations of the action of methylmagnesium iodide on the ketones I–V.

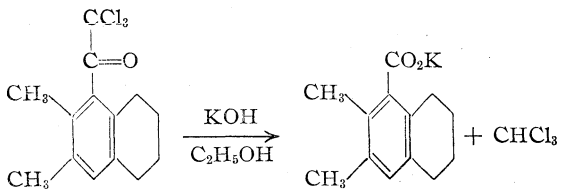
TABLE I

Compound	Action of CH_3MgI % Enolization[a]	% Addition
I	30	70
II	75[b]	25
III	93	9
IV	95	5
V	100	1.5

[a] The per cent. error is approximately ±2. [b] Reported earlier[2] as 62% on a less pure sample.

Ketones IV and V give well-defined trichloro derivatives when treated with sodium hypochlorite solutions. Compounds II and III gave complex mixtures of chlorinated ketones, chloroform and the corresponding aromatic acids.

By comparative studies it has been shown that alcoholic potassium hydroxide is much more effective than sodium hydroxide in bringing about the cleavage of hindered trichloromethyl ketones. Thus, 5-trichloroacetyl-6,7-dimethyltetralin is



relatively easily cleaved with alcoholic potassium hydroxide.

Experimental

6,7-Dimethyltetralin.—2,3-Dimethylnaphthalene (62.4 g.) was dissolved in ethanol (300 cc., 95%) and Raney nickel catalyst (4 g.) was added. Absorption of hydrogen (2 moles) was complete in one hour at 110° and a pressure of 1000 lb./sq. in. After removing the catalyst by filtration, the filtrate was fractionated directly to give 56.4 g. (89%) of 6,7-dimethyltetralin, b. p. 131–133 (20 mm.). Percolation through Alorco chromatographic alumina (80 mesh) gave a material having $n^{25}D$ 1.537.

Oxidation of 6,7-Dimethyltetralin.—A Carius tube was charged with 1.0 g. of the hydrocarbon (obtained from 2,3-dimethylnaphthalene) and nitric acid (15 cc. diluted 3 to 1 with water). This mixture was held at 165° for five hours. The solution was evaporated to dryness on a steam-bath; water (10 cc.) was added and the whole again evaporated to dryness. The residue was dissolved in ether and converted to its tetramethyl ester with diazomethane in the usual manner; m. p. 141–143°. When mixed with an authentic sample of the methyl ester of 1,2,4,5-benzenetetracarboxylic acid there was no depression of melting point.

5-Aceto-6,7-dimethyltetralin.—To 6,7-dimethyltetralin (22 g.) dissolved in carbon bisulfide (150 cc.) was added aluminum chloride (46 g.) at 0°. To this, acetic anhydride (17.3 g.) was added dropwise over a twenty-minute period. After one and three-quarters hours the reaction mixture was poured onto ice and hydrochloric acid. From the organic layer there was obtained the desired ketone; b. p. 150° (1 mm.); m. p. 50–52° (from 28–38° petroleum ether); yield 40%.

Anal. Calcd. for $C_{14}H_{18}O$: C, 83.12; H, 8.97. Found: C, 83.28; H, 9.29.

5-Trichloroacetyl-6,7-dimethyltetralin.—One gram of the above ketone was treated with a solution of potassium hypochlorite prepared from commercial calcium hypochlorite (15 g. H.T.H. grade). After fifteen minutes the crude trichloro ketone was collected on a filter. Two recrystallizations from acetic acid and one from methanol gave a pure product; m. p. 57–58.5°.

Anal. Calcd. for $C_{14}H_{15}OCl_3$: C, 55.03; H, 4.95. Found: C, 55.10; H, 5.21.

6,7-Dimethyltetralin-5-carboxylic Acid.—The above described trichloro ketone (50 mg.) was heated under reflux for twenty minutes with ethanol (20 cc., 95%) and potassium hydroxide (4 pellets). After adding cold water (100 cc.), the solution was extracted with ether. Acidification of the aqueous phase gave the expected acid; m. p. 193–195°.

Anal. Calcd. for $C_{13}H_{16}O_2$: C, 76.44; H, 7.89. Found: C, 76.50; H, 8.13.

3,4-Dimethylphenyl-β-chloroethyl Ketone.—*o*-Xylene (53 g.) was added to a solution containing carbon bisulfide (600 cc.) and aluminum chloride (94 g.) at 0°. To this was added over a period of forty-five minutes, β-chloropropionyl chloride (69 g.) dissolved in carbon bisulfide (100 cc.). Stirring was continued for one hour at 0° and the solution was poured onto ice and hydrochloric acid. The organic layer was washed with dilute sodium hydroxide, dried with sodium sulfate and evaporated to dryness on a steam-bath. Dissolution of the residue in petroleum ether (b. p. 40–75°) gave a solution from which 82.5 g. (90%) of ketone was isolated at low temperature; m. p. 72–72.5°.

Anal. Calcd. for $C_{11}H_{13}OCl$: C, 67.18; H, 6.66. Found: C, 67.05; H, 6.53.

5,6-Dimethylhydrindanone-1.—The above described chloroketone (172 g.) was dissolved in sulfuric acid (1000 cc., sp. gr. 1.84), warmed on a steam-bath for three hours and then poured into 3.5 liters of ice and water. The brown product was recrystallized from petroleum ether (b. p. 60–68°) to give a yellowish-white product; m. p. 61–62°. This consisted of two isomers which were separated by one recrystallization from aqueous ethanol and two recrystallizations from petroleum ether. Only one pure ketone was isolated; m. p. 87–88°; yield 22 g.

Anal. Calcd. for $C_{11}H_{12}O$: C, 82.46; H, 7.55. Found: C, 82.70; H, 7.54.

That this ketone had the assigned structure was established by its oxidation to 1,2,4,5-benzene tetracarboxylic acid.

The oxime of this ketone melted at 181–183°.

Anal. Calcd. for $C_{11}H_{13}ON$: C, 75.39; H, 7.49. Found: C, 75.10; H, 7.65.

5,6-Dimethylhydrindene.—A mixture of 5,6-dimethylhydrindanone-1 (17.0 g.), toluene (120 cc.), acetic acid (60 cc.), concentrated hydrochloric acid (200 cc.) and zinc (50 g. which had been amalgamated) was refluxed continuously for forty-three hours. Distillation of the toluene layer afforded 12 g. (77%) of the expected hydrocarbon, b. p. 115° (25 mm.), $n^{26.5}D$ 1.5314.

Anal. Calcd. for $C_{11}H_{14}$: C, 90.35; H, 9.65. Found: C, 90.14; H, 10.09.

4-Aceto-5,6-dimethylhydrindene.—The above hydrocarbon (8 g.) was acetylated at 0° in carbon bisulfide (200 cc.) with aluminum chloride (16 g.) and acetic anhydride (11.2 g.). The reaction was complete in thirty minutes. After distilling the crude ketone (b. p. 166–167° (25 mm.)) the material solidified. Recrystallization first from aqueous ethanol and then from petroleum ether gave a pure product; m. p. 43°; yield 42%.

Anal. Calcd. for $C_{13}H_{16}O$: C, 82.94; H, 8.57. Found: C, 82.85; H, 8.73.

The oxime of this ketone was prepared from hydroxylamine in pyridine and absolute ethanol; m. p. 133–134°.

Anal. Calcd. for $C_{13}H_{17}ON$: C, 76.81; H, 8.43. Found: C, 75.10; H, 8.65.

5,6-Dimethylhydrindene-4-carboxylic Acid.—The above ketone (35 mg.) was dissolved in methanol and treated with excess potassium hypochlorite at 60–65° for thirty minutes. At this time most of the methanol had evaporated. An ether extract of the solution upon evaporation deposited an oil containing much chlorine (Beilstein test). This oil was dissolved in methanol (15 cc.) to which potassium hydroxide (3 pellets) had been added and the solvent was evaporated on a steam-bath until the volume reached 3 cc. Addition of dilute hydrochloric acid precipitated the carboxylic acid; m. p. 169–170°.

Anal. Calcd. for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42. Found: C, 75.36; H, 7.72.

Tetrahydrobenz[f]indane.—To a mixture containing phosphoric acid (165 g., 85%) and phosphorus pentoxide (165 g.) was added γ-(5-hydrindenyl)-butyric acid (68.5). After being heated at 100–120° for five minutes with good stirring, the solution was poured into water (1000 cc.). The crude product was extracted with benzene and the benzene solution was washed with dilute alkali and dried. Removal of the benzene and distillation in a sausage flask gave a crude ketone which solidified on standing. Two recrystallizations from petroleum ether (b. p. 40–75°) followed by recrystallization from aqueous alcohol gave 28 g. of 6,7-cyclopentene-1-tetralone; m. p. 38–39°.

Clemmensen reduction of this ketone gave pure tetrahydrobenz[f]indane; m. p. +4°. A sample prepared earlier in this Laboratory[5] melted at −3 to −5°.

Acetotetrahydrobenz(f)indane (V).—To tetrahydrobenz[f]indane (8 g., m. p. 4°) dissolved in carbon bisulfide (85 cc.) was added aluminum chloride (21 g.). Stirring was commenced and acetic anhydride (7.1 g.) was added over fifteen minutes. The entire reaction was carried out at 0° for one and three-quarters hours. After decomposition with ice and hydrochloric acid in the usual manner there was obtained a liquid ketone; wt. 6.8 g.; of b. p. 167–170° (1 mm.); $n^{25.5}D$ 1.5610. This material could not be induced to crystallize.

Anal. Calcd. for $C_{15}H_{18}O$: C, 84.07; H, 8.47. Found: C, 84.17; H, 8.44.

Summary

1. Further evidence is presented to prove that the steric effect of methylene groups in five membered rings (*i. e.*, hydrindene) is smaller than that in corresponding six-membered rings (*i. e.*, tetralin).

Tri-α-naphthylboron as a Highly Hindered Reference Acid; a Case of Polymorphism Ascribed to Hindered Rotation[1]

BY HERBERT C. BROWN[2] AND SEI SUJISHI[2,3]

Earlier results[4] have shown that the relative base strengths of ammonia and a given series of primary, secondary, and tertiary amines (NH_3, RNH_2, R_2NH, R_3N) are dependent upon the reference acid used to compare them. Thus the sequence in strength observed with trimethylboron as the reference acid is $NH_3 < CH_3NH_2 < (CH_3)_2NH > (CH_3)_3N$. This sequence is altered to $NH_3 < CH_3NH_2 > (CH_3)_2NH > (CH_3)_3N$, when tri-*t*-butylboron is used as the reference acid. This change in sequence has been ascribed to the increase in the steric requirements of the reference acid.[4b]

According to this interpretation, a reference acid of even greater steric requirements than tri-*t*-butylboron should cause the observed sequence to approach the theoretically possible limit, $NH_3 > CH_3NH_2 > (CH_3)_2NH > (CH_3)_3N$. It was of interest to test this conclusion.

The selection for this purpose of a triarylboron with large steric requirements was dictated by a number of considerations. Tri-*t*-butylboron is a very weak reference acid for the amines under discussion, considerably weaker than trimethylboron itself.[4a] This weakness has been attributed to the large steric requirements of the three tertiary butyl groups. Further increase in the bulk of the alkyl groups would be expected to decrease the stability of the addition compounds with the amines to the point where it would be relatively difficult experimentally to make comparisons. The available evidence strongly suggests that the replacement of alkyl groups by aryl groups markedly increases the acid strength of the boron compounds.

For a number of reasons, tri-α-naphthylboron[5] (hereafter TNB) appeared especially promising in attaining the theoretical limit sequence. It was therefore decided to prepare the addition compounds of ammonia and the three methylamines with TNB and to compare their relative stabilities by a careful study of each system. Since the addition compounds were found to be highly dissociated at temperatures at which neither TNB nor the addition compound were sensibly volatile, the problem reduced itself to measuring and comparing the pressures exerted by the only volatile component of the system—the gaseous base.

$$(\alpha\text{-}C_{10}H_7)_3B{:}NR_3\ (\text{solid}) \rightleftharpoons (\alpha\text{-}C_{10}H_7)_3N\ (\text{solid}) + NR_3\ (\text{gas})$$

The observed pressures vary in the order $NH_3 < CH_3NH_2 < (CH_3)_2NH < (CH_3)_3N$ (*vide post*), and support the conclusion that the theoretical

limit sequence of base strength, $NH_3 > CH_3NH_2 > (CH_3)_2NH > (CH_3)_3N$, is actually under observation. In the course of these studies, some interesting and unusual instances of polymorphism were observed in the behavior of the addition compounds. It is suggested that these phenomena are the result of restricted rotation of the α-naphthyl groups in the addition compounds.

Observations

TNB was prepared by the action of α-naphthylmagnesium bromide on boron trifluoride etherate in benzene–ether solution. The product was isolated in the form of white crystals containing one mole of benzene per mole of TNB. Krause and Nobbe[5] report that TNB separates from benzene solution with two moles of benzene, but repeated experiments support the conclusion that the pure material obtained in the present study contains but one mole of benzene.

After a single recrystallization from benzene, the benzene of crystallization was removed under high vacuum at 150–160°. TNB was thus conveniently obtained in pure form in over-all yields of 50–60%.

The high degree of purity of the product is indicated by the following observations. It melts sharply at 206–207° (vacuum)[6] in contrast to the previously reported value[5] of 203–205°. Moreover, Krause and Nobbe report that the substance, although remarkably stable when compared to other triarylborons, showed significant signs of oxidation after several days of exposure to air; yet samples of TNB prepared by the present procedure show no noticeable change after exposures to laboratory air for more than one year. Finally, ultimate analyses for boron and acidimetric titrations of the compounds with a standard solution of sodium ethoxide in alcohol and phenolphthalein as indicator, yield results which point to purities of better than 99.8%.

$$(\alpha\text{-}C_{10}H_7)_3B + Na^+ OC_2H_5^- = Na^+[(\alpha\text{-}C_{10}H_7)_3B{:}OC_2H_5]^-$$

The titration of TNB with standard solutions of sodium methoxide, ethoxide, and isopropoxide in the corresponding alcohols proceeded very smoothly—the indicator, phenolphthalein, changed color sharply at the equivalence point. However, with sodium *t*-butoxide the end-point was indistinct and the indicator changed color considerably before the true stoichiometric quantity of base had been added. It therefore appears that the large steric requirements of the *t*-butoxide group produce a definite shift of the acid–base equilibrium toward the left.

$$(\alpha\text{-}C_{10}H_7)_3B + {}^-OC(CH_3)_3 \rightleftarrows [(\alpha\text{-}C_{10}H_7)_3B{:}OC(CH_3)_3]^-$$

Krause and Nobbe prepared their addition compounds by adding the base to a saturated solution of the triarylboron in ethyl ether. The addition compounds precipitated and were recovered on the filter. In order to avoid the possibility that the presence of traces of ether in the resulting compounds might affect the observed dissociation pressures, preparation of the substances in the absence of solvents was investigated.

Three methods were examined. In the first, a large excess of the liquified amine was contacted with the boron compound. After reaction was complete, the excess amine was removed under high vacuum. In the second method, the gaseous amine was passed over the solid boron compound. Absorption was very rapid and the reaction could be readily followed by noting the evolution of heat. Both methods yielded products whose composition satisfactorily agreed with the 1:1 compounds previously reported. However, the addition compounds possess a marked affinity for excess amine and it proved difficult to remove such excess amine to obtain samples as analytically pure as the studies required. Recourse was therefore had to the third procedure, which avoided this difficulty. In this method, the addition compounds were synthesized by bringing together carefully matched equivalent samples of the two components in the high vacuum apparatus used to study the dissociation pressures.

The products prepared by each of these three procedures appeared identical as regards analyses, melting points, and dissociation pressures. However, the last procedure proved so much more definite and convenient, that it was finally adopted for all preparations in the present study.

The melting points of the addition compounds showed an unusual behavior not reported by Krause and Nobbe. For example, ammonia–TNB, if heated slowly in a capillary tube, melted at 200–205°. However, if the tube were inserted in a bath at 170–172°, the substance melted, resolidified, and then remelted at the higher temperature. Monomethylamine–TNB likewise showed two melting points—a fugitive one at 150–155°, followed by resolidification, and the permanent one at 190–192°. Dimethylamine–TNB melted only at 193–196°; no other melting point was observed. All attempts to add trimethylamine to TNB by the three procedures described were unsuccessful.

Ammonia–TNB was then synthesized in the apparatus shown in Fig. 7 (attached to the main high vacuum apparatus) and the dissociation pressures measured over a range of temperatures. It

TABLE I

DISSOCIATION PRESSURE OF AMMONIA-TNB

.90	26	.50	4
.98	43	.98	5
1.00	62		

(6) All melting points were taken with capillary tubes of the usual dimensions. These tubes were evacuated and sealed after the samples had been introduced. The temperatures are corrected.

was observed that the pressure of the freshly prepared addition compound varied with the mole fraction of amine. The results of a typical experiment at 40° are summarized in Table I-A. The other amines behaved similarly.

The addition compounds were then synthesized by bringing the two components together with a slight constant deficiency of the base. It was hoped that in this way the observed pressures for the different bases would be made strictly comparable, and, moreover, that the effects of slight errors in the mole ratio of the two components would thereby be minimized. Under these conditions, the pressure of the system became sensibly constant within several minutes,[7] and the plot of log P *vs.* $1/T$ showed the expected linearity (Fig. 1).

New phenomena made their appearance at higher temperatures. The curve showed a definite deviation from linearity, and the observed pressures, particularly in the higher ranges (120° and above) declined noticeably with time. The decrease was very rapid at 140°. In one experiment at this temperature the pressure dropped from a value of 450 mm to 20 mm. within one hour. However, the rate of pressure decrease then diminished, and the pressure at this temperature became constant at a new low value, 10 mm., only after a period of twenty hours.

The behavior of the product obtained in this way was then investigated. A new series of pressure values at elevated temperatures were recorded. These values were much lower than the first series of measurements, they were easily reproducible, and yielded only the second series of pressure measurements, without evidence of any tendency to revert to the original high values.

In contrast to the original material, the dissociation pressures of which were highly dependent on the mole ratio of the components (Table I-A), the dissociation pressures of the heat-treated material were essentially independent of composition (Table I-B).

That these phenomena were not due to some irreversible change in the TNB component was demonstrated by a number of experiments. A sample of the heated compound was maintained at 130°. The gas evolved was pure ammonia; the amount corresponded exactly to the original quantity of ammonia used in the synthesis. The residual solid melted at 205–206° and caused no depression in melting point when mixed with a sample of the original material. Moreover, the product formed by recombining the recovered ammonia and TNB possessed the same characteristic high dissociation pressures as the original preparation and exhibited the same behavior on heating. It may therefore be concluded that the recovered TNB is chemically indistinguishable from the original material.

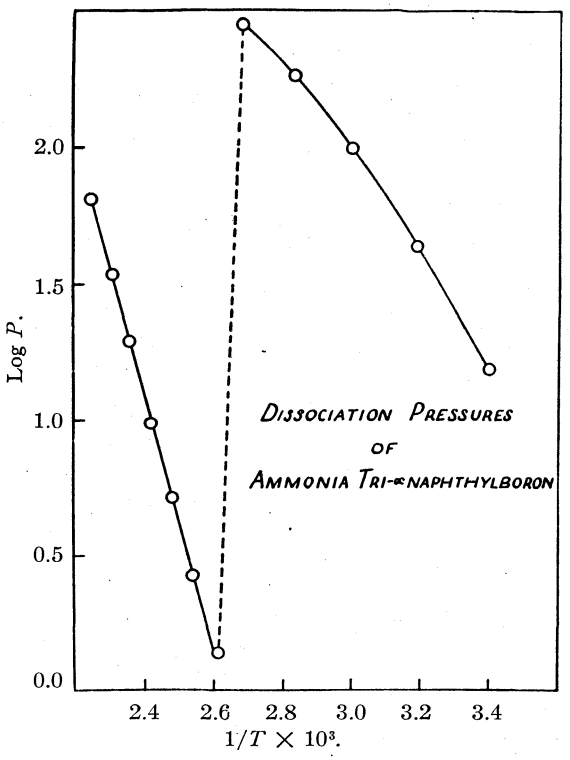

Fig. 1.—Dissociation pressures exhibited by a freshly prepared sample of ammonia-tri-α-naphthylboron as the temperature is raised.

The curves for the log P *vs.* $1/T$ plots of the corresponding monomethylamine and dimethylamine compounds with TNB showed the same general characteristics. The entire curve (*i. e.*, the two sections which describe the behavior of the freshly prepared substance and of the heat-altered product) for the methylamine compound lies above the curve for the ammonia derivative; the curve for dimethylamine is higher still.[8] Trimethylamine did not add to TNB under these conditions.

It was concluded that the observed pressures of the freshly prepared compounds are dependent not only on the mole fraction (particularly so in the region of equimolar ratios), but are also dependent upon time (particularly in the higher temperature ranges.) It was therefore decided that little could be gained by further refining the measurements of the variable pressures exhibited by these materials. Instead, attention was focused on the highly reproducible dissociation pressures exhibited by the addition compounds after prior heat treatment at 100–140°.

(7) Although the pressure of the system apparently reached an equilibrium value within several minutes, it was noted that the observed pressure tended to drift to lower values over periods of several hours duration. Moreover, samples of the addition compound which had been stored at room temperature for several weeks yielded considerably lower values of the dissociation pressure than freshly synthesized samples.

(8) The dissociation pressure curve definitely established the existence of two forms of the dimethylamine derivative. Failure to observe a "fugitive" melting point, as in the case of the other two addition compounds, is believed to be due to a more rapid transformation of the dimethylamine derivative near its melting point into the higher melting form.

TABLE II

DISSOCIATION PRESSURES OF THE HEAT ALTERED FORMS OF THE ADDITION COMPOUNDS OF TNB WITH AMINES

Ammonia, $\log P = -4762/T + 12.525$

Temp., °C.	110	120	130	140	150	160	170
Press., mm.	1.4	2.7	5.3	10.0	20.0	34.5	65.5

Methylamine, $\log P = -4666/T + 12.863$

Temp., °C.	103	110	119	130	140	150
Press., mm.	2.7	5.3	10.7	19.9	39.1	72.1

Dimethylamine, $\log P = -4296/T + 13.71$

Temp., °C.	50	60	70	80	90	100
Press., mm.	4.0	7.4	15.2	34.8	71.3	164

The observed dissociation pressures for the heat-treated products are listed in Table II, and the values are represented graphically in Fig. 2.

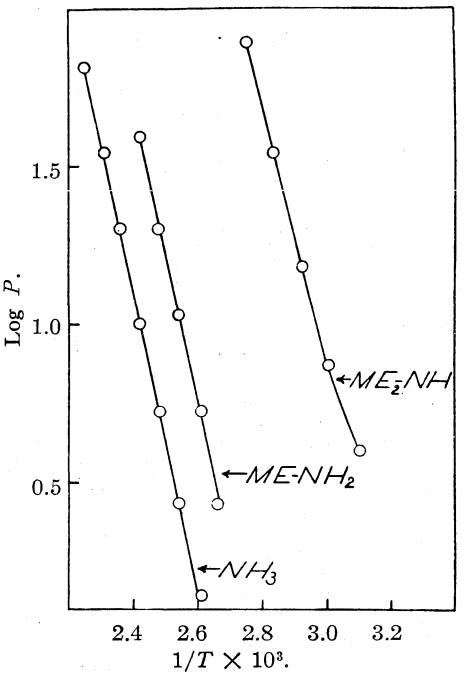

Fig. 2.—Dissociation pressures of the heat-treated ("stable") forms of the addition compounds of tri-α-naphthylboron with ammonia, methylamine and dimethylamine.

Discussion

In this investigation the pressure of the gaseous amine above a mixture of the solid TNB and solid addition compound has been taken as a measure of the stability of the latter.

$$(\alpha\text{-}C_{10}H_7)_3B{:}NR_3\ (\text{solid}) \rightleftharpoons (\alpha\text{-}C_{10}H_7)_3B\ (\text{solid}) + NR_3\ (\text{gas})$$

This interpretation of the data apparently ignores such complications as may be caused by the crystal lattice energies of the solid compounds. Fortunately, there are reasons for believing that the differences between the crystal lattice energies of TNB on the one hand and each of the addition compounds on the other are relatively small and sensibly constant.

First, TNB and the three addition compounds (the heat stable forms) all melt at approximately the same temperatures. This observation suggests that the stabilities of the crystal lattices are of the same order of magnitude. Second, the molecular dimensions of the amines used are quite small compared to the TNB component. It therefore appears probable that the attractive forces between individual molecules of the addition compounds are largely due to the TNB portion of the molecule. This suggests that the difference between the lattice energy of any given addition compound and that of TNB itself should not be large. Finally, the amine component is so small and must be buried so deeply within the relatively huge masses of the three α-naphthyl groups that the attractive forces between individual molecules of the addition compounds should not be markedly affected by the particular amine present. It therefore appears not unreasonable to assume that, in the present instances, the differences in the crystal lattice energies of the individual compounds are relatively small and their effects are relatively minor compared with the effects of F-strain.

If this assumption is valid, it may be concluded that the relative stabilities of the addition compounds decrease in the order, $NH_3 > CH_3NH_2 > (CH_3)_2NH > > (CH_3)_3N$, and the apparent strengths of the four bases decrease in the same order, $NH_3 > CH_3NH_2 > (CH_3)_2NH > (CH_3)_3N$. This is obviously the order predicted by the F-strain hypothesis for a reference acid with an exceedingly high F-strain factor.

There remain to be considered the phenomena observed in the course of preparing the addition compounds and measuring their dissociation pressures. It is suggested that these phenomena are due to the existence of two polymorphic forms of the solid addition compounds. Furthermore, the existence of these polymorphic forms is ascribed to the restricted rotation of the three α-naphthyl groups in the addition compounds about the carbon to boron bonds.

The observations requiring explanation may be briefly summarized as follows:

1. Solid TNB absorbs the gaseous bases with avidity to form only the lower melting, metastable form of the addition compound. For convenience, this substance will be referred to hereafter as the "metastable" form of the addition compound.

2. The metastable form of the addition compound is converted to another form, the "heat-altered" or "stable" form, slowly at room temperature and rapidly above 100°.

3. The dissociation pressures exhibited by the metastable form are much higher than those exhibited by the corresponding stable form.

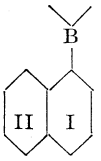
4. The dissociation pressures of the metastable form are strongly dependent upon the relative

mole ratios of the two components; the dissociation pressures of the stable form do not exhibit such dependence.

5. The dissociation pressures of the metastable form are dependent upon the age of the sample and decrease with time, slowly at room temperature and more rapidly at higher temperatures. The corresponding pressures of the stable form are not dependent upon these factors.

6. Removal of the base from either form of the addition compound yields apparently identical samples of TNB.

For the ensuing discussion it will be convenient to distinguish between the two fused rings of the α-naphthyl groups. Accordingly, that ring which is directly attached to the boron atom will be designated by the numeral I; the other by the numeral II.



Presumably, the boron atom in TNB will be similar to the boron atom in trimethylboron[9] with its three bonds coplanar, making equal angles of 120° with each other. For convenience this plane, defined by the three bonds of the boron atom, will be referred to simply as the plane of reference or reference plane of the molecule.

Examination of the Fisher–Hirschfelder model of TNB indicates that the three α-naphthyl groups can be arranged about the central boron atom in two different ways. In one of these arrangements, the three α-naphthyl groups are relatively symmetrically fixed, with the three II-rings all pointing in the same direction away from the reference plane (the "symmetrical" arrangement or form, Fig. 3). In the other possible form, one of the α-naphthyl groups is so fixed that its II-ring is pointed in a direction from the plane of reference opposite to that of the other two α-naphthyl groups (the "unsymmetrical" arrangement or form, Fig. 4).[10]

These two forms would be readily interconvertible were it possible to rotate one of the α-naphthyl rings about the boron-to-carbon bond through the reference plane. However, the model suggests that such a rotation would be difficult and would involve the simultaneous rotation of all three groups at a carefully controlled rate in order to effect the transformation without excessive distortion of the model.

Simplified line drawings of the two postulated forms of TNB are shown in Figs. 5 and 6. In

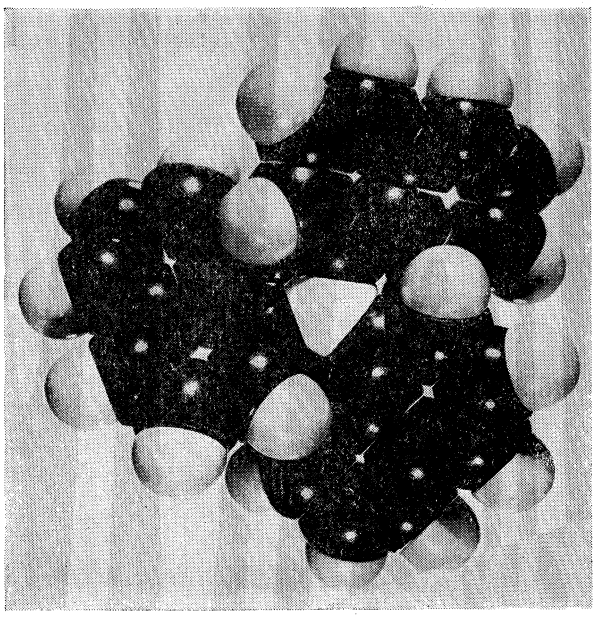


Fig. 3.—Molecular model of tri-α-naphthylboron–symmetrical arrangement.

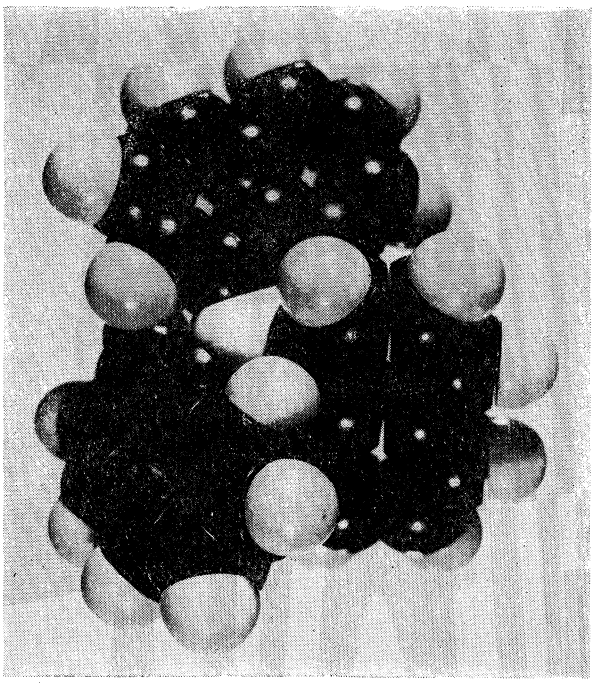

Fig. 4.—Molecular model of tri-α-naphthylboron–unsymmetrical arrangement.

(9) Levy and Brockway, THIS JOURNAL, **59**, 2085 (1947).

(10) It has been suggested already [Lewis, Magel and Lipkin, *ibid.*, **64**, 1774 (1942)] that triphenylmethyl and related compounds exist in two isomeric forms, one in which the three rings face in the same direction, similar to the blades of a propeller, the other containing one ring facing in a direction opposed to the other two. At first sight the isomerism proposed in the present paper may seem to be related to that proposed by G. N. Lewis. However, the latter is independent of the symmetry of the rings involved; the former could only be observed if the rings attached to the central atom were unsymmetrical, as with the α-naphthyl groups of the present investigation. Indeed, the consideration of the molecular models indicates that the large II-ring makes the type of isomerism proposed for triphenylmethyl impossible in the case of TNB.

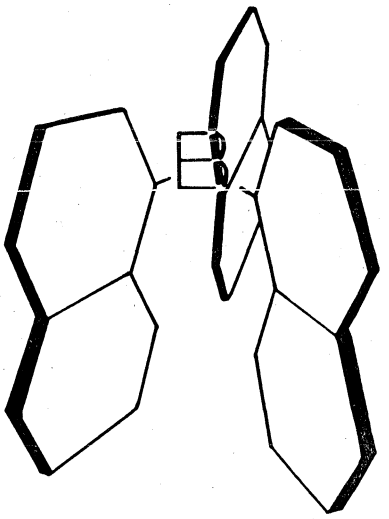

Fig. 5.—Symmetrical arrangement of tri-α-naphthylboron.

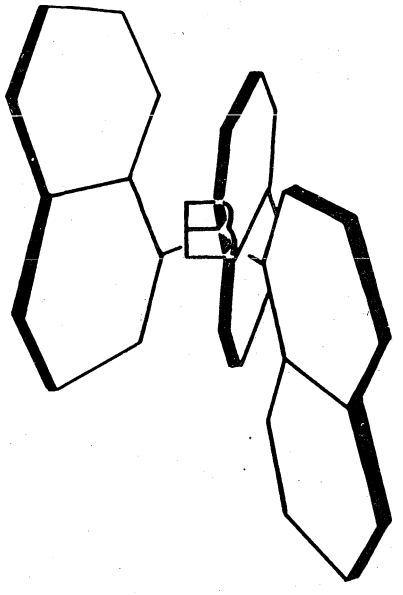

Fig. 6.—Unsymmetrical arrangement of tri-α-naphthylboron.

these figures the three α-naphthyl groups are represented with the plane of each ring lying perpendicular to the plane of reference of the molecule. It is highly probable that the three α-naphthyl groups are tilted to a greater or lesser degree from this idealized position, as indicated in Figs. 3 and 4. However, use of the idealized line drawings will facilitate the discussion without affecting the conclusions.

It is proposed that the unsymmetrical arrangement of TNB (Figs. 4 and 6) is the more stable of the two possible arrangements and that the crystalline TNB prepared in the present study consists of this unsymmetrical form. Addition of an amine to a molecule with this configuration could conceivably occur in two ways. The base could unite with the boron atom by approaching it either from above the reference plane, or from below. However, the latter path is considerably more hindered than the former. In approaching from below, the amine molecule must contend with two *peri* positions blocking the line of approach; from above, there is but one *peri* position in its path. It is therefore postulated that the base adds to the unsymmetrical form of TNB and that the addition occurs from above to give the less strained of the two possible configurations derived from the unsymmetrical form of TNB. It is further suggested that the projection of the one *peri* position of the inverted α-naphthyl group into the region occupied by the amine molecule leads to a condition of considerable strain—strain which is not present in the free TNB molecule. This strain is largely relieved by rotation of the offending α-naphthyl group so that all three *peri* positions lie below the reference plane, on the other side from the attached amine. The resulting addition compound is now configurationally related to the symmetrical arrangement of TNB and theoretically may be considered as being derived from this arrangement (Fig. 5) by addition to the boron atom from above the reference plane.

This hypothesis permits a simple interpretation of the observed phenomena. 1. Addition of the base to TNB yields the metastable or *strained* form of the addition compound.

2. The metastable or *strained* form is converted to the stable or *unstrained* form[11] slowly at room temperature, rapidly at 100°. Conversion requires rotation of one α-naphthyl group and involves an appreciable energy of activation.

3. The dissociation pressures of the metastable form are high because of the strain which results from projection of the *peri* position of the odd α-naphthyl group into the region occupied by the amine molecule. The stable form exhibits much lower dissociation pressures because the offending *peri* position has been moved below the plane of the molecule, away from the added amine. (In other words, the unsymmetrical form of TNB has a higher F-strain factor[4] than the symmetrical form.)

4. Addition of the amine to the unsymmetrical form of TNB is not accompanied by any marked changes in the configuration or in the size of the molecule. Therefore the metastable form of the addition compound and TNB form a series of solid solutions and the dissociation pressures depend on the mole ratio of the two substances. On the other hand, formation of the stable form is accompanied by a marked change in the molecular configuration and the crystal lattice of TNB (the more stable, unsymmetrical form) is no longer able to accommodate the molecules of the addition compound (stable form). Accordingly, solid solution phenomena no longer occur, and the dis-

(11) It probably would be more precise to describe it as "less strained" rather than "unstrained," since there must be considerable F-strain present even in the stable form.

sociation pressures are no longer dependent on mole ratio.

5. Transformation of the metastable form to the stable form, slow at room temperature and rapid at higher temperatures, in effect removes equimolar quantities of the two compounds (amine and TNB) from the reaction mixture. If the amine and TNB are not present in exactly equivalent amounts at the start, the slow transformation of the metastable to the stable form will bring about a gradual change in the mole ratio of "available" TNB and amine. The observed pressure will then show a gradual change with time.[12]

6. Removal by volatilization of the amine from the stable forms of the addition compounds requires elevated temperatures (100–140°) and proceeds relatively slowly. It is probable that the symmetrical form of TNB is the first product of the dissociation, but at the elevated temperatures used it must be rapidly converted into the more stable unsymmetrical form. It is therefore not too surprising that removal of the amine from the metastable form of the addition compound at relatively low temperatures and removal of the amine from the stable form at elevated temperatures yield samples of TNB that appear to be identical.

It should be possible either to isolate or to obtain some definite evidence on the existence of the symmetrical form of TNB by removing the base from the addition compound at relatively low temperatures by chemical means. An investigation of this problem is under way.

There remain to be considered certain discrepancies between the results of the present investigation and those previously reported by Krause and Nobbe.[5] These authors report that TNB is "moderately" soluble in ether. They prepared the compound by the action of α-naphthylmagnesium bromide on boron trifluoride in ether solution. After the reaction was complete, water was added. The ether layer was dried and *concentrated*, then poured into a crystallizing dish where a mass of fine crystalline needles separated. In the present investigation, addition of water to the Grignard reaction mixture caused an immediate precipitate of TNB. In order to avoid such precipitation it was necessary to add large quantities of benzene to the reaction mixture. Experiment revealed that the solubility of TNB thus obtained is relatively small, 1.6 g. per 100 ml. of ether at 25°, and is practically constant over a wide temperature range. In their preparations of triarylborons Krause and Nobbe report that they used one mole of Grignard reagent in a 1-liter reaction flask. Assuming yields similar to those we obtained, a quantity of ether from 3 to 5 liters should have been required to dissolve the product, instead of the concentration of the ether layer reported by the authors.

Krause and Nobbe prepared their amine addition compound by treating a solution of the triarylboron in ether with the base. The addition compounds precipitated immediately and were recovered by filtration. Although they do not report any details on the preparation of ammonia–TNB, presumably the technique was similar to that which they had used for other such compounds reported in their paper. In the present investigation, a saturated solution of TNB in anhydrous ether was treated with an equivalent quantity of ammonia in the same solvent. However, no precipitate was observed. At the end of several hours a small quantity of precipitate was noted, but the quantity was not increased by cooling the solution to the neighborhood of −80°. The precipitate was collected and tested—its dissociation pressures corresponded to the *stable* form of ammonia–TNB. The ether solution was allowed to stand for an additional ten days at room temperature. In the course of this time the quantity of crystalline precipitate continued to grow.

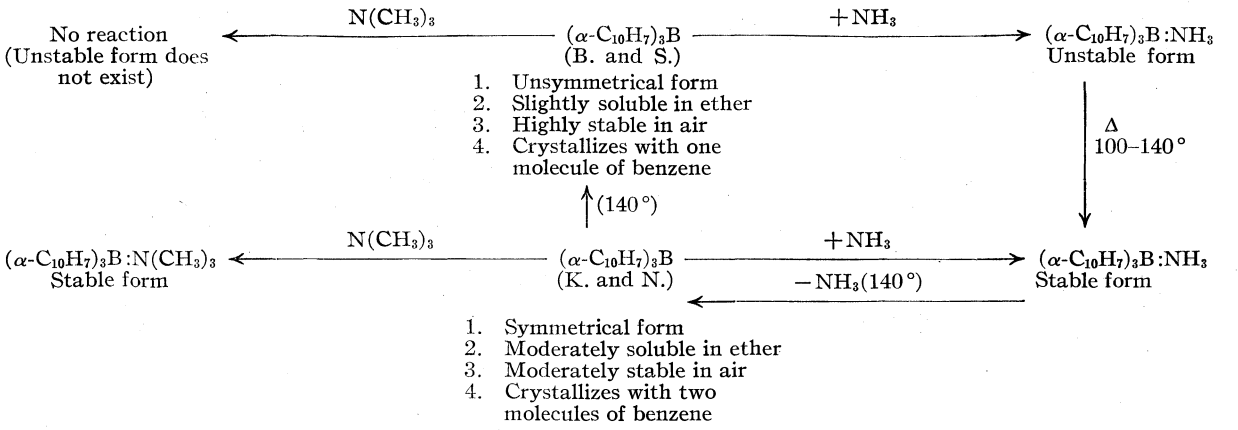
This experiment is of interest not only because of the discrepancy between our observations and those of Krause and Nobbe, but also because it suggests that the formation of the stable form of ammonia–TNB from the metastable form is a relatively slow process, even in solution at room temperature, so that the two forms of the addition compound are true geometrical isomers whose existence does not depend on crystal lattice forces. Further experimental studies along this line are underway.

Krause and Nobbe further report that trimethylamine–TNB precipitates immediately upon bringing the components together in ether solution. Even though they report that the compound is measurably dissociated at room temperature, their ability to make the two components unite is remarkable in view of our numerous failures along this line.

The relative instability toward oxidation of TNB reported by Krause and Nobbe may also be contrasted with the high stability shown by our product. The difference in the number of molecules of benzene of crystallization in the two investigations is also worthy of comment.

There is a possible explanation which could resolve these differences. If the product isolated by Krause and Nobbe were the symmetrical form of TNB, the higher reactivity of their product to-

(12) This point may be clarified by an illustration. Assume that the reaction mixture at the start of the experiment consists of one mole of TNB and 0.5 mole of ammonia. The dissociation pressure exhibited by this mixture at a suitable temperature, 40° for example, would be that of a solid solution of 0.5 mole fraction of TNB and ammonia–TNB (metastable form). If the temperature is maintained at 40°, the metastable form will slowly change over to the stable form. At the point where the change is 50% complete, the reaction mixture will consist of 0.25 mole of ammonia–TNB (stable form), 0.25 mole of ammonia–TNB (metastable form) and 0.5 mole of free TNB. Since the pressure of the stable form is negligible at 40°, the pressure exerted by the mixture would be that of a solid solution of 0.33 mole fraction of the addition compound and 0.67 mole fraction of the free boron component. It is obvious that it should be possible to use the observed dissociation pressure to analyze a given mixture of the two forms and to follow the rate of the transformation.



ward ammonia and trimethylamine could be understood. Moreover, the symmetrical form would presumably be the less stable of the two crystalline forms of TNB, so that its crystal lattice energy would be less than that of the unsymmetrical form and a higher solubility would be anticipated. Differences in the stability toward oxidation and in the number of molecules of benzene of crystallization between their product and ours would then offer no difficulty.

In this case the various interconversions and reactions could be interpreted as shown in the chart.

Several of the proposed transformations are, of course, highly hypothetical and require experimental verification. Experimental studies to resolve the discrepancies and difficulties raised by the present study are now under way.

Experimental Part

Preparation and Purification of Intermediates.—The preparation of ammonia and the methylamines in pure form has been previously described.[4] Other intermediates used were largely Eastman Kodak Company products and were purified by standard methods.

Preparation of TNB.—Because of the discrepancies between the product obtained in the present investigation and that obtained by Krause and Nobbe, the preparation of TNB will be described in detail.[5]

A standard 1-liter 3-necked flask, fitted by standard-taper glass joints to a condenser, gland-sealed stirrer, and dropping funnel, was used. In the flask were placed 24.3 g. (1 g. atom) of magnesium turnings and a crystal of iodine. The flask was flushed out with nitrogen and then gently heated until the iodine had partially sublimed. The flask and its contents were allowed to cool to room temperature and a mixture of 100 ml. of anhydrous ether and 10 ml. of α-bromonaphthalene (b. p. 143° at 14 mm.) was added. Meanwhile 130 ml. of α-bromonaphthalene (making a total of 1 mole) was dissolved in an additional 400 ml. of anhydrous ether. One-half of this solution was then slowly added through the dropping funnel at such a rate as to keep the ether gently refluxing. The reaction mixture became brown during the addition and toward the end of the addition the Grignard reagent began to separate. Benzene, 100 ml., was added to dissolve the Grignard reagent and the remainder of the ether–halide mixture added. A total of three hours was required to add the halide. The reaction mixture was then heated under reflux for a further period of one-half to one hour to ensure completion of the reaction.

The flask was next cooled in ice, the ice-bath removed, and a solution of 32 ml. (0.25 mole) of boron trifluoride–etherate (b. p. 125°) in 150 ml. of benzene was added to the Grignard reagent over a period of approximately one hour. After all of the reagent had been added, the reaction mixture was heated under gentle reflux for an additional hour. The reaction mixture was then forced under nitrogen pressure through a glass tube into a 2-liter flask filled with crushed ice and containing 50 ml. of concentrated hydrochloric acid. The upper organic layer was yellow in color and contained a small quantity of brownish solid suspended near the interface; the lower aqueous layer was greyish-brown in color.

No attempt was made to separate the layers at this stage. The flask was stoppered and put aside overnight to allow time for the crystallization of the benzene addition compound of TNB. The organic layer was then decanted from the aqueous layer and suspended solid. The solid was recovered on a Buchner funnel (without filter paper) by pouring the gelatinous aqueous layer and suspended solid into the funnel under slight suction. The brownish-appearing residue was washed repeatedly with water and then with alcohol. The crude product was dissolved in 300 ml. of refluxing benzene (nitrogen atmosphere) and quickly poured through a prewarmed Buchner funnel (with filter paper) into a 1-l. Erlenmeyer flask. White crystals immediately began to separate from the filtrate. The flask was stoppered and placed in a refrigerator overnight (6–8°).

The next day the bottom and walls of the flask were covered with an adhering crust of white large crystals. The supernatant liquid was poured off and the solid broken up with a stirring rod. The crystals were washed with several small portions of cold benzene and then transferred to a weighed flask and the adherent solvent removed by volatilization under high vacuum to constant weight.

In a typical preparation 63 g. of the pure product, $(\alpha\text{-}C_{10}H_7)_3B\cdot C_6H_6$, was obtained, a yield of 54% based on the boron trifluoride-etherate used.

The benzene of crystallization was removed by heating the flask and its contents to a temperature of 150–160° at pressures of less than one millimeter. After the flask had reached constant weight (weighings were made only after the flask and its contents had reached room temperature to avoid exposure of the hot triarylboron to oxygen), the product weighed 51.8 g. Thus the product lost 11.2 g. compared with 10.5 g. of benzene calculated for the 1:1 compound.

The product was analyzed for boron by treating it with hot concentrated sulfuric acid followed by distillation of the boron as methyl borate and titration as boric acid in the presence of mannitol.[13]

Calcd. for $C_{30}H_{21}B$: B, 2.71. Found: B, 2.75.

Titration of TNB.—G. N. Lewis[14] has frequently pointed out the similarity between the behavior of the "proton" acids and electron acceptors such as the trialkyl- and triarylborons. It was of interest to determine whether

(13) Fowler and Kraus, THIS JOURNAL, **62**, 1143 (1940).

(14) Lewis, *J. Franklin Inst.*, **226**, 293 (1938).

TNB could be analyzed by a standard base similar to more conventional acid analyses.

A standard solution of 0.04644 *M* TNB in benzene was prepared. Ten-ml. aliquots of this solution were titrated with approximately 0.06–0.10 *N* solutions of sodium alkoxide in the corresponding alcohol. Phenolphthalein was used as the indicator. The results are summarized in Table III.

TABLE III

TITRATIONS OF TNB WITH SODIUM ALKOXIDES

Base	Normality	Volume of base used		Volume of base calcd.	End-point
Sodium methoxide	0.1050	4.46	4.49	4.42	Sharp
Sodium ethoxide	.1075	4.31	4.32	4.32	Sharp
Sodium isopropoxide	.0880	5.34	5.29	5.29	Sharp
Sodium *t*-butoxide	.0593	7.68		7.83	Indistinct[a]

[a] End-point taken as very faint pink which persisted.

Solubility of TNB.—The solubilities were determined by placing in a vessel excess solid TNB and 50 ml. of solvent. The mixture was stirred at constant temperature (under nitrogen) for twenty-four hours. The excess solid was permitted to settle and 5 ml. of the supernatant liquid was pipetted out. The solvent was removed under vacuum and the solid determined by weighing. The results indicated a solubility per 100 ml. of solvent at 25° of 1.7 g. in ether, 0.2 g. in alcohol, 6.4 g. in benzene, and 5.0 g. in carbon tetrachloride. At −80° the solubility was 1.4 g. per 100 ml. of ether.

Preparation of Addition Compounds. (a) By Condensation of Excess Amine.—A large excess of the amine was liquefied in a tube immersed in a Dry Ice-bath. Sodium was used to remove traces of moisture. The amine was then permitted to volatilize from the sodium and condense in a second tube containing 2–3 g. of TNB. The liquid amine and suspended solid were allowed to remain in contact for two hours at 20–30° below the boiling point of the amine. At the time the cooling bath was removed and the excess amine permitted to volatilize away as the temperature rose to 25°. In these operations the product was at all times protected from the atmosphere. The last traces of excess amine were removed by pumping the material with a high vacuum pump. Periodic weighings of the product showed asymptotic approach to 1:1 addition over a period of several hours. Composition of the products was verified by Kjeldahl analyses for nitrogen. Ammonia, methylamine and dimethylamine all yielded well-defined addition compounds whose properties have been previously described. Trimethylamine showed no signs of reaction; even at −80° a stream of nitrogen rapidly removed all of the amine from a mixture of the liquid amine and solid TNB.

(b) **Reaction with a Stream of the Gaseous Base.**—In a typical experiment, a stream of ammonia was passed over a sample of 0.9030 g. of TNB contained in a boat. Considerable heat was evolved as the ammonia reached the solid and there was a sharp drop in pressure as the gas was absorbed. The slow stream was continued for one hour. The product gained 0.0401 g. Calculated gain for 1:1 addition is 0.0392 g. The properties of the product obtained in this way were identical with those obtained in the first method. Trimethylamine was not absorbed in a similar experiment involving this base.

(c) **By Reaction of Measured Quantities of the Components in the High Vacuum Apparatus.**—The apparatus shown in Fig. 7, attached to the usual high vacuum line, was used. A weighed quantity of TNB was introduced into the small bulb and the tube sealed. The tube was evacuated through the manometer (with the mercury lowered) and the float valve. A quantity of amine was then measured out as a gas in the high vacuum line and then condensed in the tube with liquid nitrogen. Mercury was then raised into the manometer and the equilibrium pressures developed at room temperature and above were measured on the manometer.

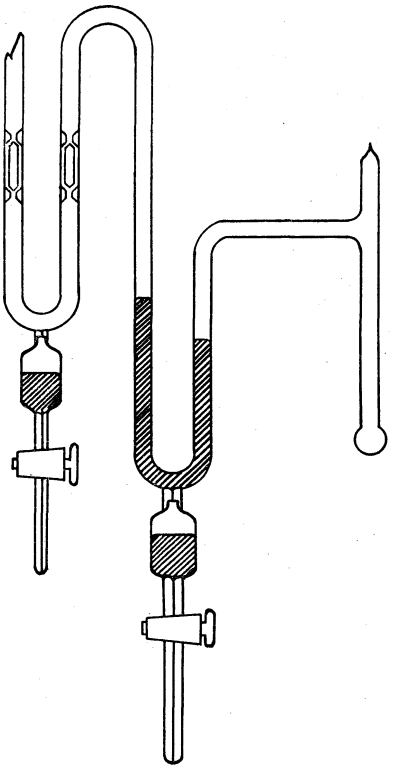


Fig. 7.—Apparatus for following the dissociation pressures of the addition compounds.

There was a remarkable difference in the time required for the equilibrium pressure to be reached. The ammonia derivative reached essentially stationary pressure values in five minutes; the monomethylamine derivative required approximately one hour; the dimethylamine compound required some five to twelve hours for the observed pressure to become sensibly constant. Over a period of some three months trimethylamine showed no signs of being absorbed.

(d) **By Reaction in Ether Solution.**—A solution of 2.04 g. of TNB in 250 ml. of anhydrous ether was mixed with 74.5 ml. of ether containing an equivalent quantity of ammonia. No precipitate was observed. A portion of the solution was cooled to approximately −80°, but no precipitate formed. Overnight a few crystals appeared. These were isolated and introduced into the high vacuum apparatus. They exhibited pressures corresponding to the stable form of ammonia-TNB[15] and analyzed for a 1:1 addition compound.

The solution was permitted to stand at room temperature (protected from the atmosphere) for nearly two weeks. In this time, additional crystals of the same appearance as those already isolated were observed to precipitate, the amount increasing daily. Unless it is assumed that the crystallization is an exceedingly slow process, in contradiction to the observation of Krause and Nobbe,[7] one can only conclude that the crystalline material is the result of a slow change occurring in the dissolved soluble addition compound (presumably the metastable form is isomerizing to the stable form).

Acknowledgment.—This investigation was made possible by Grants No. 710 and 776 from the Penrose Fund of the American Philosophical

(15) The observed pressures, 5.5 mm. at 130°, 16.5 mm. at 150° and 57.0 mm. at 170°, differed slightly from the pressures measured for the addition compound prepared by direct synthesis. The cause of the discrepancy is under investigation.

Society. In addition, the financial assistance afforded by two graduate fellowships supported by the Ethyl Corporation is gratefully acknowledged.

Summary

1. Tri-α-naphthylboron has been prepared and found to possess somewhat different properties from the product previously described in the literature.

2. Addition compounds of tri-α-naphthylboron with ammonia, methylamine and dimethylamine were prepared. Trimethylamine did not combine with tri-α-naphthylboron.

3. The dissociation pressures of the addition compounds indicate a relative stability in the order, $NH_3 > CH_3NH_2 > (CH_3)_2NH > (CH_3)_3N$. This order is the theoretical limit predicted for a reference acid with an exceedingly high F-strain factor.

4. The addition compounds exist in two polymorphic modifications. It is suggested that these modifications result from restricted rotation of the α-naphthyl groups in the addition compounds.

5. The hypothesis is advanced that the discrepancies between the properties of the tri-α-naphthylboron prepared in the present investigation and the tri-α-naphthylboron previously described may be due to the existence of two rotation isomers of the compound.

The Reaction of Hydrazine Hydrate on Nitro-Compounds and a New Route to Synthetic Oestrogens

BY HUANG-MINLON[1]

The reduction of nitrobenzaldehydes by alkaline treatment of the corresponding hydrazones is not successful.[2] The modified Wolff–Kishner reduction[3] has now been found to proceed normally, with the exception that nitro-groups are reduced simultaneously. *p*- or *m*-toluidine can be obtained by this method from *p*- or *m*-nitrobenzaldehyde, respectively, in good yield. The reduction of nitro compounds by hydrazine has been observed,[4] although a sealed tube or an autoclave was usually employed. The reduction by hydrazine of *p*- or *m*-nitrotoluene to the corresponding toluidines required reaction in a sealed tube at 130° for four hours.[5] In the present investigation, the reduction was found to proceed readily in refluxing diethylene glycol. *m*-Nitrotoluene can be reduced to *m*-toluidine in good yield in this way; alkali does not affect the course of the reduction. *p*-Toluidine is obtained from *p*-nitrotoluene in good yield only if alkali is absent; in the presence of alkali a dimeric product, 4,4′-diaminostilbene (I), is also formed. The action of alkali alone on *p*-nitrotoluene is known to yield a mixture of condensation products from which 4,4′-dinitrodibenzyl (II) and 4,4′-dinitrostilbene could be isolated (IV).[6] The initial products of the alkali treatment are believed to be nitroso dimeric compounds.[7] Consequently the formation of 4,4′-diaminostilbene from *p*-nitrotoluene undoubtedly proceeds through a nitro or nitroso dimeric product by reduction. The same diamino product in better yield can also be obtained from *p*-nitrobenzyl chloride by treatment with alkali and hydrazine hydrate.

4,4′-Dinitrostilbene (II) is readily reduced by hydrazine hydrate in the presence of alkali to 4,4′-diaminostilbene (I) (80% yield). If alkali is absent, the double bond is also saturated, and 4,4′-diaminodibenzyl (III) can be obtained in this way in 70% yield. Alkali also affects the reduction of 4,4′-dinitrodibenzyl (IV): Treatment with hydrazine alone yields 4,4′-diaminodibenzyl (III) in almost quantitative yield, whereas treatment with hydrazine and alkali yields 4,4′-diaminostilbene (I) in more than 90% yield. Since neither 4,4′-diaminostilbene (I) nor 4,4′-diaminodibenzyl (III) is affected by treatment with hydrazine, with or without alkali, the electron-attracting *p*-nitro group thus activates the methylene or methine group for the donation or acceptance of hydrogen.

Substitution of sulfonic acid groups in the 2,2′-positions does not alter the reaction (see chart, R = SO_3H).

p-Nitrophenylacetic acid can be converted to a dinitrodicarboxylic acid (m. p. 264–266°) by treatment with alkali in the presence of an oxidizing agent. This acid when treated with hydrazine gives 4,4′-diaminodibenzyl; reduction and decarboxylation both take place.

p-Nitropropylbenzene[8] on heating with hydrazine hydrate and alkali gives *meso* and racemic 4,4′-diamino-α,β-diethyldibenzyl (V) along with *p*-aminopropylbenzene. Both of these isomeric diamino compounds have been used by Carlisle and Crowfoot[9] for X-ray measurements but the methods of preparation have not been mentioned.

Baker[10] prepared these compounds from *p*-propiopropionanilide in several steps.

The *meso* and racemic 4,4′-diamino-α,β-diethyldibenzyls on diazotization followed by heating with water give *meso*-4,4′-dihydroxy-α,β-diethyldibenzyl (VI) (hexestrol)[11] and its racemic isomer (isohexestrol),[12] respectively.

It is remarkable that *p*-nitrotoluene and 4-nitrotoluene-2-sulfonic acid on heating with hydrazine hydrate and alkali give the stilbene derivatives whereas *p*-nitropropylbenzene under the same conditions gives the isomeric dibenzyl derivatives.

Further work is in progress for the conversion of *p*-nitropropylbenzene into the corresponding dimeric nitro product to explore the possibilities of obtaining diethylstilbestrol and hexestrol by using hydrazine hydrate in the presence or absence of alkali, similar to the conversion of the dinitrostilbenes or dinitrodibenzyls into diaminostilbenes and diaminodibenzyls as shown in the chart, followed by diazotization.

I am indebted to Prof. L. F. Fieser for his encouragement in the pursuance of this investigation and to Mary Fieser for help in the preparation of this manuscript.

Experimental[13]

All the compounds were reduced by the following general methods with the variations described in the notes.

A mixture of nitro compounds, diethylene glycol and 85% hydrazine hydrate with or without addition of alkali hydroxide was refluxed for about half an hour and the condenser was then removed to allow the aqueous liquor to evaporate and the temperature of the reaction mixture to rise to about 200°. Refluxing at this temperature was continued until the dark colored solution became nearly colorless or light brown (one to three hours). The reaction mixture was cooled and diluted with water and the separated amino product was filtered or extracted with ether.

Note 1.—In reduction of alkali-sensitive compounds such as nitro aldehydes it is advisable to reflux the solution of starting material in diethylene glycol with hydrazine hydrate for about half an hour and then a concentrated aqueous soution of alkali hydroxide is added slowly through the condenser and after refluxing for about twenty minutes longer the aqueous liquor is evaporated as described above.

Note 2.—In cases where either the starting material or the reduced product is volatile a take-off adapter was used instead of removing the condenser to evaporate aqueous liquor.

Note 3.—In some cases a mixture of nitro compound, diethylene glycol and hydrazine hydrate was allowed to stand for a while and then alkali hydroxide in solid form or dissolved in a small amount of water was added.

Note 4.—In cases where the reduced product is acidic, such as amino sulfonic acids, the cooled and diluted reaction mixture was acidified with warm concentrated hydrochloric acid.

p-Toluidine.—(a) From *p*-nitrobenzaldehyde (Notes 1 and 2): *p*-Nitrobenzaldehyde (7.5 g.) dissolved in 100 cc. of diethylene glycol with addition of 15 cc. of hydrazine hydrate and 11 g. of potassium hydroxide gave 3.79 g. (70.8%) of *p*-toluidine, b. p. 116–117° at 53 mm., m. p. 44–45° not depressed with an authentic sample; acetyl compound, m. p. 148–149°, not depressed with N-acetyl-*p*-toluidine. A reduction made with 6.1 g. of *p*-nitrobenzaldehyde without addition of alkali hydroxide gave only 1.8 g. (41.3%) of *p*-toluidine.

(b) From *p*-nitrotoluene (Note 2): 13.7 g. of *p*-nitrotoluene, 200 cc. of diethylene glycol and 20 cc. of hydrazine hydrate (without addition of alkali) gave 9.55 g. (89.2%) of *p*-toluidine, b. p. 106–107° at 34 mm., m. p. 44–45°. Acetyl compound, m. p. 147–148°, not depressed with N-acetyl *p*-toluidine.

m-Toluidine.—(a) From *m*-nitrobenzaldehyde (Notes 1 and 2): 7.5 g. of *m*-nitrobenzaldehyde, 100 cc. of diethylene glycol, 15 cc. of hydrazine hydrate and 11 g. of potassium hydroxide gave 3.54 g. (66.6%) of *m*-toluidine, b. p. 118–119° at 53 mm., $n^{25}D$ 1.5659; acetyl compound, m. p. 67–68°, not depressed with N-acetyl-*m*-toluidine.

(11) For literature or review of syntheses of hexestrol, see Sisido and Nozaki, *ibid.*, **70**, 778 (1948); Solmssen, *Chem. Rev.*, **37**, 481 (1945).

(12) My thanks are due to Prof. E. C. Dodds, Dr. W. Lawson and Dr. C. W. Sondern for a sample of isohexestrol, to Dr. C. H. Carlisle for a sample of *meso*-4,4′-diamino-α,β-diethyldibenzyl, and to Dr. B. R. Baker for the samples of dipropionyl compounds of *meso* and racemic 4,4′-diamino-α,β-diethyldibenzyl.

(13) The microanalyses were carried out by Shirley Katz of this Laboratory.

(b) From *m*-nitrotoluene (Note 2): The reduction of 13.7 g. of *m*-nitrotoluene with 20 cc. of hydrazine hydrate in 200 cc. of diethylene glycol in absence and in presence of alkali gave 8.26 g. (77.2%) and 8.59 g. (80.3%), respectively, of *m*-toluidine b. p. 107–109° at 34 mm., $n^{25}D$ 1.5658; acetyl compound m. p. and mixed m. p. 67°.

4,4′-Diaminostilbene.—(a) From *p*-nitrotoluene (Note 3): On reduction of 13.7 g. of *p*-nitrotoluene in 200 cc. of diethylene glycol with 20 cc. of hydrazine hydrate and 22 g. of potassium hydroxide and extraction of the reaction product with ether there was obtained 3.1 g. (30%) of crystalline basic product separated from the ethereal solution, m. p. 223–225°. Recrystallization from acetone–alcohol gave pure product (short prisms), m. p. 226–228° not depressed by admixture with 4,4′-diaminostilbene prepared from 4,4′-dinitrostilbene.[14,15]

Anal. Calcd. for $C_{14}H_{14}N_2$: N, 13.32. Found: N, 13.71.

It furnished a dibenzal compound,[14] m. p. and mixed m. p. 253–254°. From the ethereal mother liquor, 3.17 g. of *p*-toluidine was obtained.

(b) From *p*-nitrobenzyl chloride: To a warm solution of 5 g. of *p*-nitrobenzyl chloride in 20 cc. of alcohol a solution of 1.8 g. of potassium hydroxide in 1.5 cc. of water and 8 cc. of alcohol was added dropwise at about 50°. After cooling to room temperature 120 cc. of diethylene glycol, 12 cc. of hydrazine hydrate and 8 g. of potassium hydroxide were added and the reaction mixture was treated as described for the general method. On extraction with ether and evaporation of the ethereal solution there was obtained 2.17 g. (70.5%) of crystalline product, m. p. 212–220°; 227–228° after recrystallization from alcohol, not depressed by admixture with 4,4′-diaminostilbene prepared from *p*-nitrotoluene and from 4,4′-dinitrostilbene.[15] It furnished a dibenzal compound, m. p. 253°.

(c) From 4,4′-dinitrostilbene: The reduction of 1 g. of 4,4′-dinitrostilbene (prepared from *p*-nitrobenzyl chloride[16]) in 40 cc. of diethylene glycol with 2.5 cc. of hydrazine hydrate and 2 g. of potassium hydroxide gave 0.62 g. (80.5%) of 4,4′-diaminostilbene, m. p. 227–228° (228–229° after recrystallization from alcohol) not depressed by admixture with the authentic samples from other sources.

(d) From 4,4′-dinitrodibenzyl: The reduction of 1 g. of 4,4′-dinitrodibenzyl (prepared from dibenzyl by nitration[17]) by the general procedure gave 0.72 g. (93.2%) of 4,4′-diaminostilbene, m. p. 222–224°, and 0.57 g. (74%) of once-recrystallized material, m. p. 228–229° (no depression in mixed m. p. with authentic samples). It gave the dibenzal compound, m. p. and mixed m. p. 252–254°.

4,4′-Diaminodibenzyl.—(a) From 4,4′-dinitrostilbene: On reduction of 2.7 g. of 4,4′-dinitrostilbene in 100 cc. of diethylene glycol with 4 cc. of hydrazine hydrate in absence of alkali there was obtained 1.5 g. (71%) of 4,4′-diaminodibenzyl, m. p. 135–136° (white glistening plates, m. p. 137–138°, recrystallized from dilute alcohol after treatment with charcoal), not depressed by admixture with the authentic sample prepared from 4,4′-dinitrodibenzyl by reduction with tin and hydrochloric acid.[18]

Anal. Calcd. for $C_{14}H_{16}N_2$: N, 13.20. Found: N, 13.41.

(b) From 4,4′-dinitrodibenzyl: The reduction of 1 g. of 4,4′-dinitrodibenzyl in absence of alkali as above gave 0.77 g. (99%) of 4,4′-diaminodibenzyl, m. p. 130–133°. Recrystallization from dilute alcohol (charcoal) gave 0.62 g. (79.5%) of pure product, m. p. 136–137°, not depressed by admixture with an authentic sample.

(c) From *p*-nitrophenylacetic acid: To a warm solution (40°) of 4.2 g. of *p*-nitrophenylacetic acid in 20 cc. of water containing a few drops of 30% sodium hydroxide solution a mixture of 10 g. of sodium hydroxide in 9 cc. of water and 25 cc. of sodium hypochlorite (5% available chlorine) was added slowly so that the temperature was not over 45°. After addition of the alkaline oxidizing agent, stirring was continued for three to five hours at 45–50°. The clear diluted solution was acidified with dilute hydrochloric acid and the separated yellowish white crystalline product was filtered (4.04 g.), melting at 258–261° (decomposing). After recrystallization from a large volume of acetic acid the melting point could be raised to 261–262° or 264–266°, depending on the rate of heating. Titration of this compound roughly indicated the presence of two carboxyl groups. Without further identification the dibasic acid (1 g.) was heated in 25 cc. of triethylene glycol with 4 cc. of hydrazine hydrate in absence of alkali (general method). Cooling and dilution of the reaction mixture gave 4,4′-diaminodibenzyl melting at 131–132°. On recrystallization from dilute alcohol, there was obtained 0.51 g. (white plates) of pure product, melting and mixed melting point 137–138°.

4,4′-Dinitrostilbene-2,2′-disulfonic Acid.—This was prepared according to Green and Wahl[19] with the following modifications.

To a warm solution (40–45°) of 5 g. of *p*-nitrotoluene-*o*-sulfonic acid[20] (recrystallized from acetone–benzene, m. p. 137–138°) in 30 cc. of diethylene glycol, a mixture of 50 cc. of sodium hypochlorite (5% available chlorine) and a solution of 6 g. of sodium hydroxide in 8 cc. of water was added slowly under stirring (inside temperature 45–55°). After addition stirring was continued and the temperature was kept at 50–55°. After about fifteen minutes the clear solution became turbid and fine yellow needles began to separate. After about twenty minutes the reaction was complete and the sodium hypochlorite was consumed (iodide starch paper). On cooling and filtration there was obtained 4.9 g. of the sodium salt of 4,4′-dinitrostilbene-2,2′-disulfonic acid which was converted to the free acid,[21] m. p. 266° after recrystallization from acetic acid.

Anal. Calcd. for $C_{14}H_{10}O_{10}N_2S_2$: N, 6.51. Found: N, 6.23.

4,4′-Diaminostilbene-2,2′-disulfonic Acid.—(a) From 4,4′-dinitrostilbene-2,2′-disulfonic acid (Note 4): One gram of 4,4′-dinitrostilbene-2,2′-disulfonic acid was treated with hydrazine hydrate and alkali as described in the preparation of 4,4′-diaminostilbene (c) and there was obtained 0.63 g. (73.3%) of diamino product (fine yellowish needles, m. p. over 300°) which appeared to be identical with 4,4′-diaminostilbene-2,2′-disulfonic acid[6,19,22] (prepared from the same starting material by reduction with tin and hydrochloric acid), from its crystal form, high melting point, solubility and decolorization of cold alkaline potassium permanganate solution.

Anal. Calcd. for $C_{14}H_{14}O_6N_2S_2$: N, 7.56. Found: N, 7.47.

(b) From 4,4′-dinitrodibenzyl-2,2′-disulfonic acid (Note 4): One gram of this starting material (prepared from *p*-nitrotoluene-*o*-sulfonic acid[19]) treated with hydrazine hydrate and alkali as above gave 0.58 g. (67.5%) of 4,4′-diaminostilbene-2,2′-disulfonic acid.

Titration: 96.01 mg. consumed 0.1 *N* sodium hydroxide 5.180 cc. Calcd. for $C_{14}H_{14}O_6N_2S_2$: 5.184 cc.

(c) From *p*-nitrotoluene-*o*-sulfonic acid (Note 4): 2.2 g. of this starting material with 20 cc. of diethylene glycol, 2.5 cc. of hydrazine hydrate and 3 g. of potassium hydroxide gave 0.5 g. (27%) of 4,4′-diaminostilbene-2,2′-disulfonic acid.

Titration: 152 mg. consumed 0.1 *N* sodium hydroxide 8.21 cc. Calcd. for $C_{14}H_{14}O_6N_2S_2$: 8.20 cc.

4,4′-Diaminodibenzyl-2,2′-disulfonic Acid.—(a) From 4,4′-dinitrodibenzyl-2,2′-disulfonic acid (Note 4): One gram of this starting material with 25 cc. of diethylene glycol and 4 cc. of hydrazine hydrate gave 0.63 g. (70%) of

4,4′-diaminodibenzyl-2,2′-disulfonic acid (white pointed flat needles) which was found to be identical with an authentic sample prepared from the same starting material by reduction with tin and hydrochloric acid.[23]

Anal. Calcd. for $C_{14}H_{16}O_6N_2S_2$: N, 7.53. Found: N, 7.13. *Titration:* 99.03 mg. consumed 0.1 *N* sodium hydroxide 5.295 cc. Calcd. for $C_{14}H_{16}O_6N_2S_2$: 5.318 cc.

(b) From 4,4′-dinitrostilbene-2,2′-disulfonic acid (Note 4): 2 g. of 4,4′-dinitrostilbene-2,2′-disulfonic acid in 40 cc. of diethylene glycol with 8 cc. of hydrazine hydrate gave 0.8 g. (46.2%) of 4,4′-diaminodibenzyl-2,2′-disulfonic acid (white pointed flat needles).

Titration: 95.80 mg. consumed 0.1 *N* sodium hydroxide 5.12 cc. Calcd. for $C_{14}H_{16}O_6N_2S_2$: 5.14 cc.

4,4′-Diamino-α,β-diethyldibenzyl.—The reduction of 19.8 g. of *p*-nitropropylbenzene with 180 cc. of triethylene glycol, 30 g. of potassium hydroxide and 24 cc. of hydrazine hydrate gave 14 g. of dark oily product which was fractionally distilled.

Fraction I: 3.5 g. boiling at 86–87° at 4 mm., identical with *p*-aminopropylbenzene. It furnished an acetyl compound (plates), m. p. 95–96°.

Anal. Calcd. for $C_{11}H_{15}ON$: C, 74.53; H, 8.53; N, 7.90. Found: C, 74.68; H, 8.49; N, 8.03.

Fraction II: 5.1 g. boiling at 178–188° at 0.3 mm.; it solidified after standing. Recrystallization from a mixture of ether and petroleum ether (70–90°) and then from methanol gave about 2 g. of *meso*-4,4′-diamino-α,β-diethyldibenzyl (rhombic plates), m. p. 141–142°, not depressed by admixture with an authentic sample.[12]

The ether–petroleum ethereal mother liquor obtained above on concentration gave the racemic isomer in leaflets. Recrystallization from ether–petroleum ether gave 1.7 g., m. p. 97–98.5° (one sample recrystallized from methanol melting at 98–99°).

Anal. Calcd. for $C_{18}H_{24}N_2$: C, 80.54; H, 9.01; N, 10.43. Found: (*meso* form) C, 80.68; H, 9.12; N, 10.63; (racemic form) C, 80.50; H, 8.82; N, 10.71.

Both *meso* and racemic isomers furnished the dipropionyl compounds melting at 264–266° (plates) and 217–218° (plates), respectively, mixed with authentic samples[12] (*meso* form m. p. 262–264°; racemic form 207–215°[10]) melted at 263–266° and 210–216°, respectively.

4,4′-Dihydroxy-α,β-diethyldibenzyl.—0.14 g. of *meso*-diamino compound, m. p. 141–142°, was dissolved in dilute sulfuric acid and diazotized with sodium nitrite. After standing at 2–5° about twenty minutes and pouring in portions into 300 cc. of boiling water, the crystalline dihydroxy compound separated on cooling, m. p. 174–178° (0.12 g.). Recrystallization from benzene gave pure product, m. p. 181–182°, not depressed by admixture with an authentic sample of hexestrol.

Diazotization of racemic diamino compound (m. p. 97–98°) under the same conditions as above gave the racemic or isohexestrol which after repeated recrystallization from ether–petroleum ether melted at 128–129°, not depressed by admixture with an authentic sample.[12]

Anal. Calcd. for $C_{18}H_{22}O_2$: C, 79.96; H, 8.20. Found (*meso* form): C, 80.18; H, 8.14. (racemic form): C, 80.04; H, 8.22.

Summary

1. The modified Wolf–Kishner method has been adapted for the reduction of aromatic nitroaldehydes.

2. Nitrotoluenes have been converted to the corresponding dimeric amino products and toluidines by using hydrazine hydrate.

3. Both the 4,4′-dinitrostilbenes and the 4,4′-dinitrodibenzyls have been converted to the diaminostilbenes or diaminodibenzyls by the action of hydrazine hydrate. In all of these cases the presence of alkali was a determining factor with respect to the formation of dimeric products and the persistence or the reduction of the ethylenic linkage.

4. A new synthetic route for the preparation of hexestrol has been described.

Preparation of Acetals or Ketals from Vinyl-type Esters

BY W. J. CROXALL, F. J. GLAVIS AND H. T. NEHER

In the course of an investigation of the addition of alcohols to vinyl compounds, it was observed that when vinyl acetate is added to an excess of alcohol containing a small amount of mercury oxide and boron trifluoride, heat is evolved and an acetal and acetic acid are formed in high yields. Under similar conditions isopropenyl acetate gives a ketal and acetic acid. The over-all course of the reaction is

$$CH_2{=}CHOCOCH_3 + 2ROH \longrightarrow CH_3CH(OR)_2 + CH_3COOH$$

Mixtures of mercuric oxide and the complexes formed from boron trifluoride with alcohols, ethers or carboxylic acids were found to be the most active catalysts. With these, the reaction starts promptly and is so rapid that efficient cooling is required to prevent vigorous or even violent boiling. Mercuric sulfate is a slightly less active catalyst. With mercuric phosphate no appreciable reaction occurs at room temperature, but after the mixture is refluxed for two hours, some hemiacetal acetate is formed. Coffman[1] obtained the 1-acetoxyethyl ether of a glycolic ester when equi-molar quantities of vinyl acetate and the glycolic ester were refluxed in the presence of mercuric phosphate. Mercuric oxide alone is entirely inert as a catalyst at room or elevated temperatures. Boron trifluoride diethyl etherate alone induces no exothermic reaction, but when the reaction mixture is refluxed, acetal is produced in low yield, together with acetic ester, acetaldehyde and water. Presumably, the initial reaction in this case is an alcoholysis[2] after which some of the acetaldehyde undergoes acetal formation

$$CH_2{=}CHOCOCH_3 + ROH \longrightarrow CH_3CHO + CH_3COOR$$
$$CH_3CHO + 2ROH \longrightarrow CH_3CH(OR)_2 + H_2O$$

(1) Coffman, U. S. Patent 2,384,726 (1945).

(2) Herrmann and Deutsch, British Patent 314,646 (1929).

The course of the reaction is believed to be quite different when the mercuric oxide boron trifluoride catalysts are used. No acetaldehyde could be detected when dry reagents were used. When the mole ratio of alcohol to vinyl acetate is less than two, 1-alkoxyethyl acetate occurs as one of the products. This compound is believed to be an intermediate in the reaction. It is suggested that the reaction proceeds as follows

(a) $CH_2{=}CHOCOCH_3 + ROH \longrightarrow CH_3CH(OR)OCOCH_3$

(b) $CH_3CH(OR)OCOCH_3 + ROH \longrightarrow CH_3CH(OR)_2 + CH_3COOH$

The plausibility of reaction (b) was clearly demonstrated when butyl acetal was obtained in 81% yield by the action of 1-butoxyethyl acetate on *n*-butyl alcohol in the presence of mercury oxide and boron trifluoride. The 1-butoxyethyl acetate was prepared from *n*-butyl vinyl ether and acetic acid.[3]

The reaction offers a convenient method for preparing acetals and is especially useful for preparing ketals. It is applicable to primary and secondary alcohols. Ethylene glycol forms the cyclic acetal, 2-methyl-1,3-dioxolane. Tertiary alcohols do not give the acetals but undergo alcoholysis to acetaldehyde and the tertiary alkyl acetates. Phenol undergoes a vigorous reaction with vinyl acetate under the reaction conditions to give acetic acid and alkali soluble polymeric materials. The yields of acetals from primary alcohols are 80–90% as compared to a 38% yield from isopropyl alcohol. The best yields are obtained when the reaction is carried out under anhydrous conditions. In one experiment in which 98% ethanol and undistilled vinyl acetate were used with mercuric sulfate as a catalyst, the yield of acetal was 58%, as compared to 88% when anhydrous reagents were used. Ethyl acetate was isolated in this experiment, indicating that some alcoholysis also occurred. The ketal yields are lower than the yields of the corresponding acetals. Table I lists some of the acetals and ketals prepared by this method.

TABLE I

ACETALS AND KETALS PREPARED

Acetals (of acetaldehyde)	B. p., °C. (mm.)	Yield, %	$n^{20}D$
Methyl	62.5–64	84	1.3665[a]
Ethyl	103–104	88	1.3809[a]
Isopropyl	126.5	38	1.3890[b]

[e] Claisen, *Ber.*, **31**, 1012 (1898). [f] *Anal.* Calcd. for $C_{11}H_{24}O_2$: C, 70.16; H, 12.84. Found: C, 70.01; H, 12.79. [g] Otto, THIS JOURNAL, **59**, 1591 (1937).

The substitution of mercaptans for alcohols in the reaction gave 2-alkylmercaptoethyl acetates instead of mercaptals. The yield was about 75% when mercuric sulfate or mercuric oxide and boron trifluoride etherate was used, as compared to a 99% yield with boron trifluoride etherate alone as the catalyst. A 10% yield of the same product was obtained when the reaction mixture was refluxed without catalyst.

Experimental

Materials.—The alcohols were dried when necessary in the usual manner and carefully fractionated. The vinyl acetate was fractionated and material of b. p. 72.5–73° used. The isopropenyl acetate was obtained from Tennessee Eastman Corporation and material of b. p. 96° used. *n*-Butyl mercaptan was fractionated and material of b. p. 97° used.

Preparation of Acetals and Ketals.—The following preparation of *n*-butyl acetal is representative of the method used. In a one-liter three-necked flask equipped with a mercury-sealed stirrer, thermometer, dropping funnel and reflux condenser, were placed 148 g. (2.0 moles) of *n*-butyl alcohol, 1 g. of red mercuric oxide and 1 ml. of boron trifluoride diethyl etherate. To this was added 86 g. (1.0 mole) of vinyl acetate over a period of ten minutes while maintaining the temperature below 55° by means of an ice-bath. The mixture was allowed to stir for one hour, after which it was poured into a suspension of 56 g. (0.5 mole) of sodium carbonate in 250 ml. of water. The upper oil layer was separated and dried over anhydrous potassium carbonate. The aqueous layer was acidified with concd. hydrochloric acid, extracted with ether, dried over anhydrous sodium sulfate and distilled to give 26 g. of acetic acid, b. p. 116.5–117°, $n^{20}D$ 1.3721.

The oil layer upon distillation through a one-foot glass helices packed column gave 153 g. (88.5%) of *n*-butyl acetal, b. p. 74.5–76° (14 mm.), $n^{20}D$ 1.4080.[4]

When the mercuric oxide was omitted in the above experiment, a small amount (3 g.) of acetaldehyde, 18 g. of *n*-butyl acetate and 50 g. of butyl acetal was obtained. The major portion of the reaction mixture consisted of the starting materials and butyl acetate.

Reaction of *t*-Butyl Alcohol with Vinyl Acetate.—From 296 g. (4 moles) of *t*-butyl alcohol, 2 g. of mercuric oxide, 4 g. of methanol boron trifluoride complex (1:1) and 344 g. (4 moles) of vinyl acetate, there was obtained 5 g. of material trapped in a Dry Ice receiver (b. p. around 0°, decolorized a solution of bromine in carbon tetrachloride; thought to be isobutylene); 76 g., b. p. up to 97°; 69 g. (15%) *t*-butyl acetate, b. p. 97–98°, $n^{24}D$ 1.3875; 70 g. higher boiling material (98–170°), and considerable polymeric residue. Attempts to fractionate the 98–170° cut gave no constant boiling fractions.

Preparation of 1-(*n*-Butoxy)-ethyl Acetate from *n*-Butyl Vinyl Ether.—To 120 g. (2 moles) of acetic acid and one drop of concd. sulfuric acid was added with stirring 208 g. (2 moles) of *n*-butyl vinyl ether. The temperature during the addition was maintained below 45° by cooling. Stirring was continued for one and one-half hours and 0.5 g. of sodium methoxide was added. Distillation gave 265 g. (82.8%) of 1-(*n*-butoxy)-ethyl acetate, b. p. 65° (14 mm.), $n^{20}D$ 1.4025.[5] The saponification equivalent determined for this compound was 158, the calculated value is 160.

Preparation of *n*-Butyl Acetal from 1-(*n*-Butoxy)-ethyl Acetate.—Two moles of *n*-butyl alcohol (148 g.), 3 g. red mercuric oxide and 2 ml. of methanol boron trifluoride

(3) Reppe, "Advances in Acetylene Chemistry," 1940, trans. by R. F. C., Office of Rubber Reserve, July 25, 1945.

(4) Connor, Elving and Steingiser, *Ind. Eng. Chem.*, **40**, 498 (1948).

(5) Hurd and Green, THIS JOURNAL, **63**, 2202 (1941).

(1:1) were placed in a one-liter flask. To this was added with rapid stirring, 320 g. (2 moles) of 1-(*n*-butoxy)-ethyl acetate over a period of fifty-five minutes. The temperature was maintained at 10–20° by means of an ice-bath. Stirring was continued for thirty minutes, the reaction mixture poured into a suspension of 106 g. (1.0 mole) of sodium carbonate in 150 ml. of water, the oil layer separated, dried over anhydrous potassium carbonate and distilled to give 295 g. (85%) of *n*-butyl acetal, b. p. 185–189°, $n^{20}D$ 1.4080.[4]

Preparation of 2-Butylmercaptoethyl Acetate.—Upon mixing 90 g. (1 mole) of *n*-butyl mercaptan, 43 g. (0.5 mole) of vinyl acetate and 0.5 ml. of boron trifluoride etherate, the temperature rose slowly to 62°. The mixture was allowed to stand overnight and 1 g. of sodium methoxide added. Distillation gave 75 g. (99% yield based on vinyl acetate) of 2-butylmercaptoethyl acetate, b. p. 72–75° (2 mm.), $n^{20}D$ 1.4616.

With mercuric sulfate as the catalyst instead of boron trifluoride etherate, the yield of the mercapto-ester was 76%; with no catalyst present the yield of this ester amounted to only 10%.

Summary

1. Acetals are produced in good yield by the reaction of vinyl acetate with primary aliphatic alcohols in the presence of an acidic mercury catalyst.

2. Ketals are produced in a similar manner from isopropenyl acetate.

3. It is suggested that the vinyl acetate and alcohol initially react to form a hemiacetal acetate, which subsequently reacts with alcohol to give an acetal and acetic acid.

Some Diethylisopropoxyhalogenosilanes and their Hydrolysis Products[1]

BY PATRICK A. MCCUSKER AND CHARLES E. GREENE

Although a number of alkoxyfluorosilanes and some alkylalkoxychlorosilanes have been prepared, no alkylalkoxyfluorosilanes have been previously reported. In the course of the preparation of a compound of this type, some previously unreported organosilicon compounds were prepared and some observations made on the hydrolysis of diethylisopropoxyhalogenosilanes.[2]

Direct reaction of excess isopropyl alcohol and diethyldichlorosilane gave yields of only 20% of diethyldiisopropoxysilane while yields of 67% have been reported for the analogous preparation of dimethyldi-*n*-butoxysilane.[3] The lower yield of the isopropoxy compound may be attributed to the greater steric requirements of the isopropoxy group or to the general lower reactivity of the secondary alcohol compared to the primary. A low yield of diethylisopropoxyfluorosilane (22%) was obtained from the reaction of zinc fluoride on diethylisopropoxychlorosilane. This is probably due to a competing reaction in which both the alkoxy and chloro substituents are replaced by fluorine.

An aqueous suspension or a homogeneous solution of 0.04 molar diethylisopropoxyfluorosilane in a methanol–water mixture, maintained a hydrogen ion concentration of less than 10^{-4} mole per liter, as indicated by the basic color given by methyl orange which is unchanged on standing several days. Using phenolphthalein as an indicator, however, the suspension in water could be rapidly titrated to a stoichiometric end-point with 0.1 *N* base. A calculation of the concentration of hydrogen fluoride necessary to produce a hydrogen ion concentration of 10^{-4} mole per liter indicated that the hydrolysis came to equilibrium when less than 0.3% of the fluoride has been hydrolyzed in neutral water. At a somewhat lower hydrogen ion concentration, 10^{-10} mole per liter, hydrolysis proceeded to completion very rapidly.

On the hydrolysis of diethylisopropoxychlorosilane, with an equivalent amount of base, even in the presence of excess isopropyl alcohol, the alkoxy group split off and the cyclic trimer and tetramer were formed in high yield. [Diethyldiisopropoxysilane was found, however, to be stable in excess base.] Justification for the assignment of formulas to the two cyclic compounds is based on the analytical composition, molar refraction and molecular weight determination. The absence of any hydroxyl groups was further shown by the application of the Zerewitinoff reaction.

A marked difference in the action of sodium on the cyclic trimer and the cyclic tetramer was incidentally observed. The trimer on heating with sodium in the temperature range 150 to 245° evidently underwent a polymerization resulting in a marked increase in viscosity. The tetramer, on the other hand, was completely unaffected by long heating with finely divided sodium at 295°.

Experimental

The reaction apparatus used in this work consisted of a 1-liter, 3-necked flask equipped with stirrer and reflux condenser and protected from atmospheric moisture. All products were purified by fractional distillation through a total reflux, partial take-off column, 12 mm. inside diameter and 53″ in height, packed with 1/8″ glass helices. The column was operated at a reflux ratio of ten to one. Carbon and hydrogen analyses were made by Micro-Tech Laboratories, Skokie, Illinois, and hydrolyzable halogen was determined by titration of aqueous mixtures with standard base. Molar refractions were calculated from the bond refraction values of Warrick[4] and molecular

(1) This paper consists of a report of work done under contract with the Technical Command, Chemical Corps, U. S. Army.

(2) The authors wish to thank Dr. Charles C. Price for his helpful interest in this work.

weights were obtained from cryoscopic measurements in benzene.

Diethylisopropoxychlorosilane.[5]—Purified diethyldichlorosilane (1.75 moles) and 500 ml. of benzene were heated to reflux in the reaction flask. During a period of three hours, 1.75 moles of isopropyl alcohol was added dropwise to the refluxing mixture. During the first stages of the reaction a water-insoluble, combustible gas was given off in addition to the hydrogen chloride. The volume of the gas, presumably propylene, was measured and found to represent a loss of about 5 mole %. In a considerable number of preparations this same gas evolution was observed and appeared to be characteristic of the reaction under these conditions. After addition was complete the reaction mixture was fractionated in the 53″ column to give a 72% yield of diethylisopropoxychlorosilane. The properties of the purified compound are as follows: b. p. 155.5° at 750 mm., $n^{20}D$ 1.4123, d^{20}_4 0.9227, MR_D calcd. 49.2, obs. 48.7.

Anal. Calcd. for $C_7H_{17}OSiCl$: C, 46.6; H, 9.5; Cl, 19.6; mol. wt., 180.5. Found: C, 46.7; H, 9.5; Cl, 19.2; mol. wt., 182.

Diethyldiisopropoxysilane.—In the residue from the fractionation of diethylisopropoxychlorosilane there was found in all runs about 10 mole % of the diether. For purposes of characterization further amounts of this compound were prepared by addition of diethyldichlorosilane to excess isopropyl alcohol. Only a small yield (20%) was obtained in this manner. Sufficient product, however, was obtained for characterization. The compound was purified by fractional distillation and had the following properties: b. p. 174° at 750 mm.; $n^{20}D$ 1.4032; d^{20}_4 0.8423; MR_D calcd. 59.6, obs. 59.2.

Anal. Calcd. for $C_{10}H_{24}SiO_2$: C, 58.8; H, 11.8. Found: C, 58.8; H, 11.9.

The compound is a colorless liquid with a mild sweet odor, insoluble and non-reactive in water. Hydrolytic cleavage was found to occur very rapidly in aqueous acid but either slowly or not at all in aqueous base.

Diethylisopropoxyfluorosilane.—Diethylisopropoxychlorosilane (0.58 mole) in 250 ml. of benzene was placed in the reaction flask. Technical grade zinc fluoride (0.33 mole) dried by heating for one hour at 200°, was added slowly with stirring during one hour. The reaction was slow to start but exothermic enough to require cooling. The mixture was stirred for four hours and filtered. Fractional distillation of the filtrate gave the following fractions: Ten grams of diethyldifluorosilane, 12 g. (22% yield) of diethylisopropoxyfluorosilane, 12 g. of unreacted diethylisopropoxychlorosilane and 31 g. of unidentified residue. The purified diethylisopropoxyfluorosilane had the following properties: b. p. 127° at 750 mm., $n^{20}D$ 1.3803, d^{20}_4 0.8745, MR_D calcd. 43.5, obs. 43.5.

Anal. Calcd. for $C_7H_{17}OSiF$: C, 51.2; H, 10.4; F, 11.5. Found: C, 51.1; H, 10.6; F, 11.5.

(5) The authors acknowledge the assistance of Mr. O. C. Kohler in the preparation of this compound.

Cyclic Polysiloxanes.—Hydrolysis of diethylisopropoxychlorosilane was carried out under two sets of conditions. In procedure A, 50 g. (0.9 mole) of potassium hydroxide was added to 500 g. of isopropyl alcohol and the mixture heated until nearly all the solid had dissolved. Diethylisopropoxychlorosilane (0.83 mole) was added dropwise to the cold solution with agitation, while the temperature of the mixture was held below 20°. After addition was complete the potassium chloride was filtered off and the filtrate fractionated. The isopropyl alcohol which came off first gave a strongly acid reaction when dissolved in water indicating that an excess of base may not have been maintained in the reaction mixture. Distillation of the 84 g. of residue remaining after the removal of the alcohol gave 21 g. of hexaethylcyclotrisiloxane (25% yield) and 50 g. (59% yield) of octaethylcyclotetrasiloxane.

In procedure B a 20% aqueous sodium hydroxide solution containing 2.5 moles was placed in the reaction flask and 1 mole of diethylisopropoxychlorosilane added slowly under the surface of the solution with stirring. The temperature of the reaction mixture was held below 20°. The cloudy one-phase liquid was then extracted with three 50-ml. portions of ether and the combined extracts dried with anhydrous sodium sulfate. On distillation a 50-g. fraction of isopropyl alcohol was obtained. The higher boiling fraction yielded 28 g. (27% yield) of hexaethylcyclotrisiloxane, 12 g. (12% yield) of octaethylcyclotetrasiloxane and 29 g. of a high boiling residue.

The properties of the purified cyclic trimer from both procedures were as follow: b. p. 246° at 750 mm., 97° at 2 mm., $n^{20}D$ 1.4305, d^{20}_4 0.9560, MR_D calcd. 83.7, obs. 82.9.

Anal. Calcd. for $C_4H_{10}SiO_3$: C, 47.01; H, 9.86; mol. wt., 306. Found: C, 46.91; H, 10.04; mol. wt., 319.

The purified cyclic tetramer had the following properties: b. p. 295° at 750 mm., 134° at 2 mm.; $n^{20}D$ 1.4340, d^{20}_4 0.9625; MR_D calcd. 111.6, obs. 110.6.

Anal. Calcd. for $C_4H_{10}SiO_4$: C, 47.01; H, 9.86; mol. wt., 409. Found: C, 47.16, H. 9.83; mol. wt., 394.

Summary

1. Diethylisopropoxychlorosilane, diethylisopropoxyfluorosilane and diethyldiisopropoxysilane have been prepared and characterized.

2. The hydrolysis of the fluoro compound has been observed to proceed to only a very slight extent in neutral water but to go rapidly to completion in slightly basic solution.

3. Hydrolysis of diethylisopropoxychlorosilane in excess isopropyl alcohol, containing a nearly equivalent amount of potassium hydroxide, has been found to give high yields of cyclic trimer and tetramer. These cyclic polysiloxanes have been purified and characterized.

NOTRE DAME, IND. RECEIVED FEBRUARY 24, 1948

NOTES

Ribitol Pentaacetate

By W. W. Binkley[1] and M. L. Wolfrom

The acetates of the sugars and sugar alcohols are significant reference compounds especially in certain types of chromatographic techniques.[2] All of the acetates of the pentitols have been described in crystalline form save that of ribitol (synonym, adonitol). We wish to report herein the crystallization of such a derivative of this naturally occurring pentitol.

Experimental

A mixture of 2.00 g. of ribitol, 0.3 to 0.4 g. of freshly fused zinc chloride, and 20 ml. of acetic anhydride was surrounded with an ice- and water-bath and was stirred for sixteen hours. The temperature of the bath was allowed to rise gradually to 25° during this period. The reaction mixture was poured on 30 g. of finely crushed ice, was stirred for thirty minutes, and was adjusted to a *p*H of 6 with sodium bicarbonate. This solution was extracted with four 25-ml. portions of chloroform. Solvent removal from the dried extract yielded crystalline material; yield 4.78 g. Pure material was obtained on recrystallization from diethyl ether; yield 3.87 g., m. p. 51°. A further crop of less pure material (0.33 g.) was obtainable from the mother liquor on the addition of petroleum ether (b. p. 60–65°). The substance crystallized in elongated prisms that were soluble in benzene, chloroform, ethanol and diethyl ether.

Anal. Calcd. for $C_{15}H_{22}O_{10}$: C, 49.72; H, 6.12; CH_3CO, 13.80 ml. of 0.1 *N* NaOH per 100 mg. Found: C, 49.62; H, 6.07; CH_3CO, 13.82 ml.

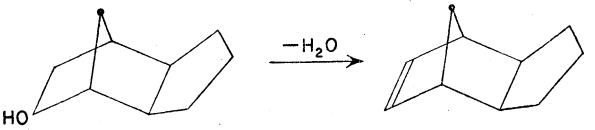
Dihydro-*exo*-dicyclopentadiene

By Herman A. Bruson[1] and Thomas W. Riener[1]

Recently Bartlett and Goldstein[2] showed that the hitherto rare *exo* isomer of dicyclopentadiene can be readily obtained by dehydrohalogenation of iodo-dihydro-*exo*-dicyclopentadiene[3] which may conveniently be prepared by warming ordinary *endo*-dicyclopentadiene with hydriodic acid.[3]

By dehydrating hydroxy-tetrahydro-*exo*-dicyclopentadiene[4] (I) with phosphoric acid we have obtained the corresponding dihydro-*exo*-dicyclopentadiene (II) in which the residual double bond is in the bridge endomethylene ring.



(I) (II)

This completes the series of isomeric dihydrodicyclopentadienes.

Experimental

Dihydro-*exo*-dicyclopentadiene.—A mixture of 15 g. of sirupy 85% phosphoric acid and 198 g. of hydroxytetrahydro-*exo*-dicyclopentadiene[4] which had twice been recrystallized from nitroethane to m. p. 53°, was stirred and heated in an oil-bath under a reflux condenser to which was attached a water separator device. After heating for about one hour at 150–230°, 40 cc. of oily liquid and 20 cc. of water had collected in the separator. The residual oil in the still flask was washed with water and distilled under reduced pressure to yield 40 g. of oil boiling at 80–95° (40 mm.). This was combined with the 40 cc. of oil distillate and the mixture redistilled. A fraction (68 g.) boiling at 89–93° (40 mm.) was thus secured. This was refractionated through an efficient packed column to yield 61 g. of colorless oil b. p. 89–91° (39 mm.) having $n^{25}D$ 1.4993; d^{25}_4 0.9571. It boiled at 182° (768 mm.).

Anal. Calcd. for $C_{10}H_{14}$: C, 89.55; H, 10.44. Found: C, 89.45; H, 10.43.

Addition of Organolithium Compounds to the Azomethine Linkage of γ-Picoline and 6-Methoxyquinoline

By Henry Gilman and H. Smith Broadbent[1]

In connection with some studies on compounds having possible physiological activity, occasion arose to prepare some "anil addition" compounds of γ-picoline and 6-methoxyquinoline.

At −80° *n*-butyllithium was found to be without observable action on γ-picoline in ether solution. Upon carbonation of the reaction mixture, γ-picoline and valeric acid were the only isolable products. At −10°, however, addition to the anil linkage is the predominant reaction yielding first the lithium salt of 2-*n*-butyl-4-methyl-1,2-dihydropyridine (not isolated) which upon acidification and air oxidation gave 2-*n*-butyl-4-methylpyridine.

Addition of α-thienyllithium to 6-methoxyquinoline at the reflux temperature of ether similarly yielded 2-(α-thienyl)-6-methoxyquinoline.

(1) Present address: Department of Chemistry, Brigham Young University, Provo, Utah.

Experimental

2-*n*-Butyl-4-methylpyridine.—Twenty-three grams (0.25 mole) of γ-picoline in 75 ml. of anhydrous ether was added dropwise with stirring to an equivalent amount of 0.94 molar butyllithium in ether, which was maintained at −10° in an ice–salt-bath. A yellow precipitate formed. After one and one-half hours stirring the mixture was carbonated by pouring jet-wise into a slurry of Dry Ice and ether. After the Dry Ice had evaporated, the mixture was extracted with 20% sodium hydroxide solution. On acidifying the alkaline extract only a very small amount of red gum was obtained from which a very small amount (*ca.* 10–20 mg.) of unidentified crystalline material, m. p. 148–150°, separated on cooling. The alkali-insoluble portion was a yellow oil, which was aerated to oxidize the dihydropyridine to the pyridine, dried over barium oxide and distilled. Five grams of the anil addition product was obtained boiling at 200–202° (740 mm.). A Siwoloboff boiling point determination gave reproducible values at 201–202°: $n^{20}D$ 1.4778; sp. gr.$^{27}_{27}$ 0.885.

Anal. Calcd. for $C_{10}H_{15}N$: N, 9.39. Found: N, 9.50.

The picrate was prepared in boiling ethanol giving bright yellow crystals, melting at 88.5–90.5° after two recrystallizations from ethanol.

Anal. Calcd. for $C_{16}H_{18}O_7N_4$: N, 14.8. Found: N, 14.9.

2-(α-Thienyl)-6-methoxyquinoline.—Thiophene, 30.3 g. (0.36 mole) in 100 ml. of anhydrous ether, was metalated with 0.3 mole of butyllithium in the conventional apparatus under a nitrogen atmosphere. Then 34 g. (0.214 mole) of 6-methoxyquinoline in 60 ml. of ether was added dropwise to the stirred α-thienyllithium at such a rate as to maintain reflux. A greenish-white precipitate formed. After stirring the mixture for one hour, it was hydrolyzed carefully with 200 ml. of water.

The ether phase was separated, mixed with 25 ml. of nitrobenzene to oxidize the dihydroquinoline, and distilled. A fraction (nitrobenzene, aniline, thiophene) was collected at 90–105° (18 mm.). Then 26 g. (a 75% recovery) of 6-methoxyquinoline was obtained boiling at 105–114° (18 mm.). (Its identity was checked by preparing its picrate and comparing the picrate prepared from an authentic sample of 6-methoxyquinoline. Both melted at 217–218°, with no depression on mixing.) A final fraction of 3.5 g. (6.8%) boiling 200–210° (18 mm.), was collected and crystallized from a benzene and ligroin mixture; melting point, 137–138.5°.

Anal. Calcd. for $C_{14}H_{11}ONS$: N, 5.81. Found: N, 5.69.

A picrate of the product was prepared and recrystallized from ethanol. The melting point was 190.5–192°.

Anal. Calcd. for $C_{20}H_{14}O_8N_4S$: N, 11.9. Found: N, 11.75.

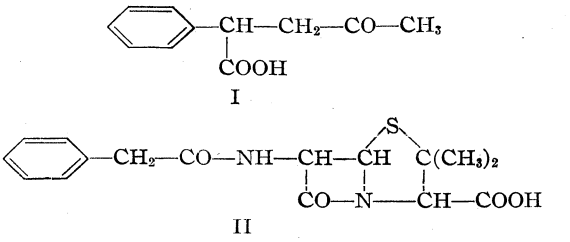
α-Phenyl-levulinic Acid, a Product of the Alkaline Degradation of Penicillin G

BY M. W. GOLDBERG, WILLIAM R. SULLIVAN AND W. E. SCOTT

In the course of studies on the chemistry of penicillin G carried out in 1945, we encountered significant amounts of a degradation product which was readily identified as α-phenyl-levulinic acid (I). It was obtained from penicillin G, along with larger quantities of phenylacetic acid, by treatment with aqueous sodium hydroxide.



I

II

At that time no information was available to us concerning results of degradative studies carried out in other laboratories. Meanwhile, there have appeared several publications on the chemistry of penicillin[1] which discuss in survey form the experimental evidence that led to the general acceptance of formula II for penicillin G. These publications, while mentioning a great number of degradation products obtained from the various penicillins, do not contain any reference to α-phenyl-levulinic acid.

The accepted β-lactam formula for penicillin G (II) does not contain the carbon skeleton of α-phenyl-levulinic acid, and it is not readily apparent to us by what series of reactions this C-11 acid could be formed from it. The β-lactam structure is based upon such a wide variety of evidence that it seems necessary to conclude that our product is an artifact formed somehow by a reductive condensation of certain of the penicillin G degradation products. The mechanism, however, is obscure.

There is no question that the α-phenyl-levulinic acid isolated by us is actually formed from penicillin G. The preparation has been repeated several times during the past two and a half years, using sodium penicillin G of high purity, obtained by different methods from different lots of penicillin. The α-phenyl-levulinic acid has been isolated as such and in the form of its methyl ester and as the *p*-nitrophenylhydrazone, all of which have proved to be identical with authentic synthetic specimens.

Experimental

Isolation of α-Phenyl-levulinic acid.—Crystalline penicillin G sodium salt (2.694 g.), a composite of several pure samples obtained by a chromatographic process, was dissolved in 140 ml. of *N* sodium hydroxide which had been freed of dissolved oxygen by boiling in a stream of nitrogen. The solution was boiled under reflux for one hundred minutes, while nitrogen was passed into the mixture through a capillary. Ammonia was evolved. After cooling, the solution was acidified with sulfuric acid, saturated with sodium chloride, and extracted with ether. Removal of the solvent from the extract left 1.106 g. of a deep purple oil which was sublimed *in vacuo*. The fraction subliming between 75° and 129° (201 mg.) was recrystallized twice from ligroin and gave 54 mg. of an acid melting at 121–124°. This was combined with corresponding fractions from other experiments and recrystallized from *n*-hexane, which raised the melting point to 124–125.5°. The melting point of a mixture with a

(1) Committee on Medical Research, O. S. R. D., *Science*, **102**, 627 (1945); du Vigneaud and co-workers, *ibid.*, **104**, 431 (1946); Editorial Board of Monograph on the Chemistry of Penicillin, *ibid.*, **105**, 653 (1947); **106**, 503 (1947).

sample of synthetic α-phenyl-levulinic acid[2] was not depressed.

Anal. Calcd. for $C_{11}H_{12}O_3$: C, 68.73; H, 6.29; neut. equiv., 192. Found: C, 68.39; H, 6.03; neut. equiv., 183, 186.

The *p*-nitrophenylhydrazone melted at 190.5–191.5° (cor.), and a mixture with a sample prepared from the synthetic acid was not depressed.

Anal. Calcd. for $C_{17}H_{17}O_4N_3$: C, 62.37; H, 5.23; N, 12.84. Found: C, 62.00, 62.10; H, 5.13, 5.04; N, 12.87, 13.22.

Isolation as Methyl α-Phenyl-levulinate.—The material used in this experiment was crystalline penicillin G sodium salt obtained *via* the crystalline triethylamine salt. It was purified by repeated recrystallization from aqueous acetone and dried to constant weight *in vacuo* over phosphorus pentoxide. The preparation was acetone free. The minimum penicillin G content, as determined by the official FDA N-ethylpiperidine method, was 95%, and the potency ratio in the *Bacillus subtilis–Staphylococcus aureus* plate test was 0.98; $[\alpha]^{25}D$ +301° (c = 0.51 in water).

Anal. Calcd. for $C_{16}H_{17}N_2O_4SNa$: C, 53.92; H, 4.81. Found: C, 53.96; H, 5.15.

Nineteen grams (0.0533 mole) of this sodium penicillin G sample was dissolved in 950 cc. of 1 *N* sodium hydroxide previously heated to boiling under nitrogen. The solution was refluxed one hundred minutes under nitrogen, cooled, and extracted with ether. Evaporation of the ether extract left a red-brown residue weighing 0.25 g. The water layer was acidified with dilute sulfuric acid and extracted with ether. The ether layer was evaporated, leaving a semi-crystalline residue of 7.09 g. which was treated with an excess of freshly distilled diazomethane in ether. Removal of the solvent left a liquid residue of 7.50 g. which was distilled at 5 mm. to yield several fractions:

Fraction	Bath temp., °C.	Weight, g.	$n^{22}D$
1	Up to 119	3.80	1.5047
2	119–130	0.09	....
3	130–135	0.14	1.5058
4	135	0.18	1.5054
5	135–165	1.74	Crystalline
Residue		1.46	

The first four fractions consisted of methyl phenylacetate[3] and amounted to 4.21 g. (0.024 mole) or 45%.

Fraction 5 was suspended in petroleum ether and filtered. The crystals weighed 1.47 g. and melted at 66–68°. Recrystallization from *n*-butanol gave 1.18 g. melting at 68–70°, and a mixture with synthetic methyl α-phenyl-levulinate[4] melted at 68–70°.

Anal. Calcd. for $C_{12}H_{14}O_3$: C, 69.88; H, 6.84. Found: C, 69.80; H, 6.67.

The yield (1.47 g.) corresponded to 0.064 mole or 12% of the theoretically possible amount.

Direct Isolation as the *p*-Nitrophenylhydrazone.—The crystalline penicillin G sodium salt used in this experiment was purified in the manner described above. It was, however, derived from an entirely different lot. The minimum penicillin G content, as determined by the N-ethyl-piperidine method, was 94%, and the potency ratio in the *B. subtilis–S. aureus* plate test was 0.99; $[\alpha]^{26}D$ +302° (c = 0.49 in water).

Anal. Calcd. for $C_{16}H_{17}N_2O_4SNa$: C, 53.92; H, 4.81. Found: C, 53.84; H, 5.11.

Ten grams of this penicillin G sodium salt was treated with 500 ml. of boiling *N* sodium hydroxide as above. Concentration of the ether extract of the acidified reaction mixture gave 3.90 g. of a semi-crystalline red mass. A portion (2.90 g., corresponding to 7.436 g. of starting material) was heated to boiling with 100 ml. water and the solution filtered to remove some reddish resin. To the hot filtrate was added a hot solution prepared by heating 0.92 g. of *p*-nitrophenylhydrazine with 18 ml. of glacial acetic acid and 55 ml. of water and filtering. The mixture became cloudy at once, and crystals appeared on heating. After cooling in the ice-box, the product was filtered off and dried. It weighed 0.95 g. and melted at 171–173°. Two recrystallizations from dioxane–water mixtures raised the melting point to 186–188° and a further recrystallization from ethanol brought it up to 188–188.5°.

Anal. Calcd. for $C_{17}H_{17}O_4N_3$: C, 62.37; H, 5.23. Found: C, 62.24; H, 5.58.

A mixture with an authentic sample of the synthetic *p*-nitrophenylhydrazone melted at 187.5–188.5°. Based on crude product, the yield was thus 0.14 mole per mole of penicillin G degraded.

We are indebted to Dr. Al Steyermark for the microanalyses, to Dr. E. G. Wollish for the penicillin G determinations, and to Mr. B. Tabenkin for the microbiological assays.

Aminative Reduction of Ketones

BY L. HASKELBERG

Aminative hydrogenation has been used widely to convert ketones to primary amines

$$>C{=}O \xrightarrow[NH_3]{H_2\ cat.} >CH{-}NH_2$$

This paper reports a number of such conversions using ethanolic ammonia, hydrogen at about atmospheric pressure and Raney nickel. Included in this study are ketones containing an ω-diethylamino group and α,β-unsaturated ketones. The products were isolated by fractionation of the mixture, after removal of the catalyst. In most cases a higher boiling constituent, according to the analysis secondary amine, was isolated also.

For details of the experiments, see Table I.

The following general observations appear pertinent.

β-Phenylisopropylamine has been synthesized by reduction of phenylacetone oxime[1] or by interaction of the ketone itself with ammonium formate.[2] Aminative hydrogenation of phenylacetone at ordinary temperature and pressure appears to be a simpler procedure; it gives a yield of 85%.

Catalytic hydrogenation of benzalacetone and furfuralacetone leads to saturation of the C=C bond and replacement of the carbonyl group by $CHNH_2$. β-Ionone (I), too, absorbed the amount of hydrogen required for these two reactions, leading to a dihydroionylamine. By analogy, one should assign it formula (II); this structure would be in accord with the observation of Kandel[3] that catalytic hydrogenation of β-ionone (I) reduces first the carbonyl group to a secondary hydroxyl and then attacks the (exocyclic) α,β-double bond, leading to (III).

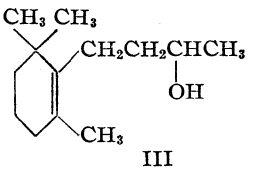
II



III

The amines of the general formula $(C_2H_5)_2N(CH_2)_nCH(NH_2)CH_3$ are usually prepared by reduction of the corresponding ketoximes.[4] It has been found that they can be obtained directly from the ketones by catalytic hydrogenation in presence of ammonia under fairly mild conditions.[5] In the case of 5-diethylamino-2-aminopentane (from 5-diethylamino-2-pentanone), the product was characterized by its known[6] chloroaurate; it is believed that the products obtained from 4-diethylamino-2-butanone and diethylaminoacetone are, analogously, 4-diethylamino-2-aminobutane and 3-diethylamino-2-aminopropane, respectively.

In each of the three cases, a higher-boiling by-product was observed in small quantities, which analyzed for the corresponding secondary amine $[(C_2H_5)_2N(CH_2)_nCH(CH_3)]_2NH$. For $n = 3$, the structure was proved by conversion into 5-diethylamino-2-aminopentane according to Grigorowski, Margolina and Magidsson[7] with 40% yield. Assignment of the analogous structures in the other two cases appears justified.

The Reaction of Benzyl Bromide with Ethyl α-Acetoxyacetoacetate

BY NATHAN GREEN AND F. B. LAFORGE

Dimroth and Schweitzer[1] have described the preparation of ethyl α-acetoxyacetoacetate and state that the sodium derivative reacts with halogen compounds, giving substitution products. The resulting compounds were not further investigated, however.

The present investigation is a study of the reaction of benzyl bromide with the sodium derivative of ethyl α-acetoxyacetoacetate, and of the behavior of the product.

The reaction with benzyl bromide proceeded normally, giving ethyl α-acetoxy-α-benzylaceto-

(1) Dimroth and Schweitzer, *Ber.*, **56**, 1381 (1923).

acetate. An acetyl determination on the product showed two acetyl groups. Attempted ketone cleavage with sodium ethylate, or even with cold dilute aqueous barium hydroxide, removed two acetyl groups and gave β-phenyllactic acid as the end-product. The reaction had therefore proceeded exclusively in the sense of the acid cleavage with simultaneous saponification of the acetoxy group. Attempts at acid hydrolysis were also unsuccessful, where the compound showed great resistance to this treatment.

It is probable that the reaction of halides with α-acetoxyacetoacetates may be generally useful in the preparation of α-hydroxy acids.

Experimental Part

Ethyl α-Acetoxyacetoacetate.[1]—Eighty-four grams of ethyl acetoacetate (0.65 mole) was dissolved in 320 ml. of benzene, and 88 g. of lead tetraacetate (0.6 mole calculated on a 100% basis) was added in several small portions with stirring, the temperature being kept below 35°. The mixture was stirred for one-half hour after the last addition, and then ice-water was added and the layers were separated. The benzene solution was washed with ice water and sodium bicarbonate solution, dried, and distilled from a modified Claisen flask. Forty-one grams (34%) of product was obtained boiling at 125–127° at 17.5 mm., $n^{25}D$ 1.4280.

The compound distills as a pale yellow liquid, which becomes colorless upon standing. It readily reduces Fehling solution in the cold. *Anal.* Calcd. for $C_8H_{12}O_5$: C_2H_5O, 23.9. Found: C_2H_5O, 23.8.

Ethyl α-Acetoxy-α-benzylacetoacetate.—Two and four-tenths grams (0.1 mole) of sodium hydride was placed in a nitrogen-swept flask with 100 ml. of dioxane, and 18.8 g. (0.1 mole) of the acetoxy compound in 40 ml. dioxane was added dropwise to the stirred mixture over a period of thirty minutes. After an additional thirty minutes 17.1 g. (0.1 mole) of benzyl bromide was added slowly, and the mixture was then refluxed for one and a half hours. The reaction mixture was poured into 1 liter of water containing sufficient acetic acid to neutralize the alkali. The heavy oil which separated was extracted twice with ether, and the ethereal solution was washed with water and then with saturated sodium chloride solution. The solution was dried, the solvent removed, and the product distilled from a modified Claisen flask. The yield was 18.6 g. (67%) of product boiling at 118–122° at 0.5 mm., $n^{25}D$ 1.4916.

Anal. Calcd. for $C_{15}H_{18}O_5$: C, 64.73; H, 6.52; C_2H_5O, 16.2; $2CH_3CO$, 30.9. Found: C, 64.02; H, 6.72; C_2H_5O, 16.0; CH_3CO, 26.7.

Hydrolysis of Ethyl α-Acetoxy-α-benzylacetoacetate.—The compound was unchanged by refluxing with water for one hour. Refluxing with glacial acetic acid containing a little concentrated hydrochloric acid also failed to hydrolyze the compound. Although some carbon dioxide was evolved by the process, the starting material was recovered almost quantitatively. The same was true when the compound was refluxed with 20% sulfuric acid. The products of these experiments were identified, by boiling points, refractive indices and ethoxyl analyses, as the original material.

Hydrolysis with Sodium Ethylate.—Five and one-half grams (0.02 mole) of ethyl α-acetoxy-α-benzylacetoacetate was added to 2 g. of sodium dissolved in 35 ml. of ethanol and the solution was refluxed for one hour. Most of the alcohol was removed under diminished pressure, and the residue was acidified to congo red with dilute hydrochloric acid. The solution was then saturated with sodium chloride and extracted several times with ether. On evaporation of the solvent on the steam-bath and subsequently under reduced pressure, 3.3 g. of crystalline material was obtained, which was recrystallized from benzene. The product melted at 95–96°, neutralization equivalent 166, and was identified as β-phenyllactic acid.[2]

Hydrolysis with Barium Hydroxide.—Five and one-half grams of ethyl α-acetoxy-α-benzylacetoacetate was added to 250 ml. of a 2.5% aqueous solution of barium hydroxide, and the suspension was shaken for forty-eight hours. Carbon dioxide was then passed into the solution to remove the excess alkali. After the barium carbonate had been filtered off, most of the water was removed under reduced pressure. On addition of ethanol, 5.8 g. of crude barium salt of β-phenyllactic acid was obtained.

Preparation of 1,2-Dichloropropene-1

BY ERNEST H. HUNTRESS AND F. SANCHEZ-NIEVA[1]

In view of the extent of recent studies of chloro- and polychloro-olefins the paucity of reports on 1,2-dichloropropene is remarkable. This compound should exist in two geometrically stereoisomeric forms. The only record of the lower boiling stereomer is an ancient report[2] claiming its preparation from 1,2,2-trichloropropane by dehydrochlorination with alcoholic potassium hydroxide. A liquid regarded as the higher boiling stereomer was subsequently obtained[3] from α,β,β-trichloro-*n*-butyric acid by solution and heating in aqueous sodium carbonate. None of the cited papers give satisfactory details.

We have developed the preparation of the lower boiling stereomer to give readily 55–58% yields, have established certain needed physical constants, have shown that upon ozonolysis the compound yields formic and acetic acids, and that with methanol it gives an azeotrope. We did not, in this work, study the preparation of the supposed higher boiling stereomer[3] but all attempts to isomerize the lower boiling material were unsuccessful. The configuration of the two stereomers is still undetermined.

1,2-Dichloropropene-1 (*lower boiling stereomer*).—One mole of 1,2,2-trichloropropane (b. p. 123–125° at 762.4 mm., $n^{25}D$ 1.4609, obtained from 2-chloropropene-1 by addition of chlorine) was added dropwise with frequent shaking to a 25% solution of sodium methoxide (1.3–1.5 moles) in methanol kept cold in ice water. After completion of the vigorous reaction the solution was poured into a large volume of water, and the heavy insoluble layer washed, dried and distilled. Because of its much higher boiling point any unreacted trichloropropane was easily separated from the desired dichloropropene (55–58% yield).

Redistillation of the crude product through a ten theoretical plate column gave the lower boiling 1,2-dichloropropene-1, b. p. 76.8–77.0° at 757.0 mm.; d^{25}_4 1.1755, d^{20}_4 1.1818, $n^{25}D$ 1.4451, $n^{20}D$ 1.4471.

This product formed with anhydrous methanol an azeo-

trope, b. p. 56.5–56.8° at 760.5 mm., $n^{25}D$ 1.4030, found by comparison with a plot of $n^{25}D$/% composition for known mixtures to contain 75 weight % of lower boiling 1,2-dichloropropene.

Ozonization of the above 1,2-dichloropropene-1 in carbon tetrachloride solution at −15° followed by treatment with boiling water gave a mixture of hydrochloric, formic and acetic acids. Treatment with silver hydroxide precipitated silver chloride, oxidized the formic to carbonic acid, and thus permitted identification by the Duclaux method of the acetate in the filtrate.

The structure of the 1,2-dichloropropene-1 was confirmed by addition of chlorine at 0° in light from a 200-watt clear glass lamp, giving the saturated 1,1,2,2-tetrachloropropane, b. p. 153–155° at 774 mm., $n^{25}D$ 1.4850.

The Structure of C_3F_6

BY EDMOND G. YOUNG AND WILLIAM S. MURRAY

Studies in this Laboratory involving methods of commercial feasibility for the synthesis of $CF_3CF{=}CF_2$ brought to the fore the question of the proper structure of C_3F_6 as prepared by several methods. In particular, Benning, Downing and Park[1] reported the structure of the C_3F_6 obtained from pyrolysis of "Teflon" tetrafluoroethylene polymer as being a cyclic compound. It is to be noted that Lewis and Naylor[2] report the difficult oxidation of this product to acidic substances which also suggests the cyclic structure.

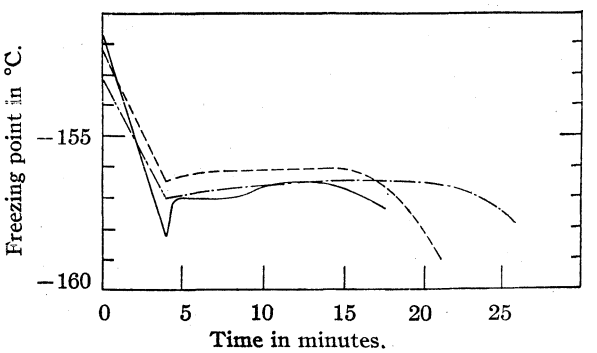

Fig. 1.—C_3F_6 products: ---, pyrolysis product; —·—, dechlorination product; ——, mixed.

It has been the purpose of this work now being reported, to establish the structure of C_3F_6 firmly and to correct any errors which have appeared in the literature.

A sample of C_3F_6 prepared by pyrolysis of tetrafluoroethylene polymer was compared with a sample of C_3F_6 prepared by the dechlorination of $CF_3CFClCF_2Cl$ with zinc and alcohol.[3] The marked similarity of these products is shown in Table I.

TABLE I

Product source	"Teflon" pyrolysis	$CF_3CFClCF_2Cl$ dechlorination
Molecular weight from vapor density	151	153
Boiling point, °C.	− 29.8	− 29.6
Freezing point, °C.	−156.2	−156.5
Mixed freezing point, °C.	156.6	

Not only is the mixed freezing point datum excellent evidence for the identity of these products (see Fig. 1), but also the infrared absorption curves of these two preparations were found to be identical. The curve for C_3F_6 is given in Fig. 2. The maximum at 5.55 microns is a positive indication of the existence of a double bond in the molecule.

Chlorination in light of the two C_3F_6 products (A) from polymer and (B) from $CF_3CFClCF_2Cl$ gave the corresponding dichlorides which were identical to each other and different from the dichloride obtained (C) by chlorination of $H(CF_2)_3$-

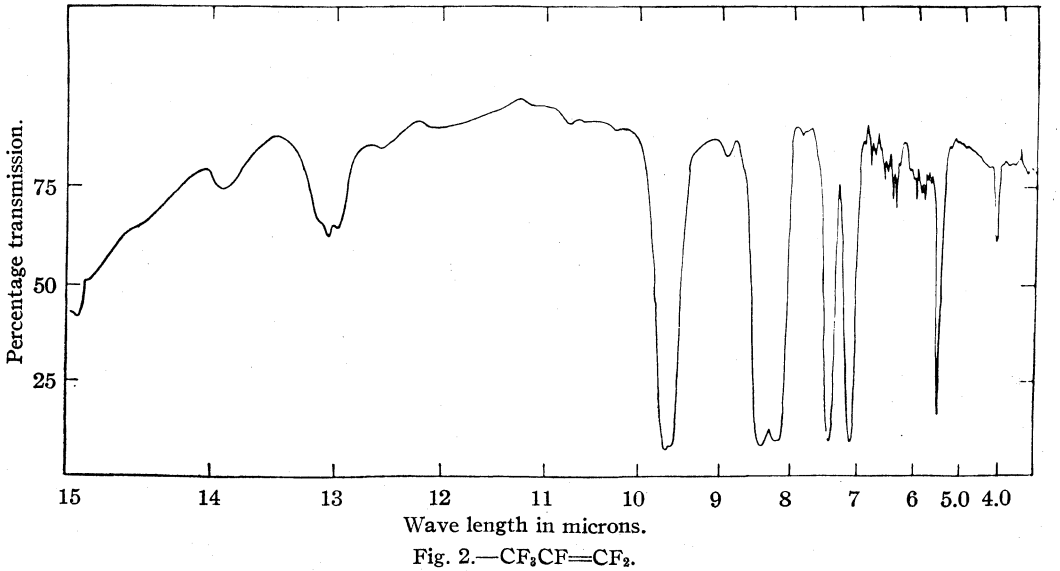

Fig. 2.—$CF_3CF{=}CF_2$.

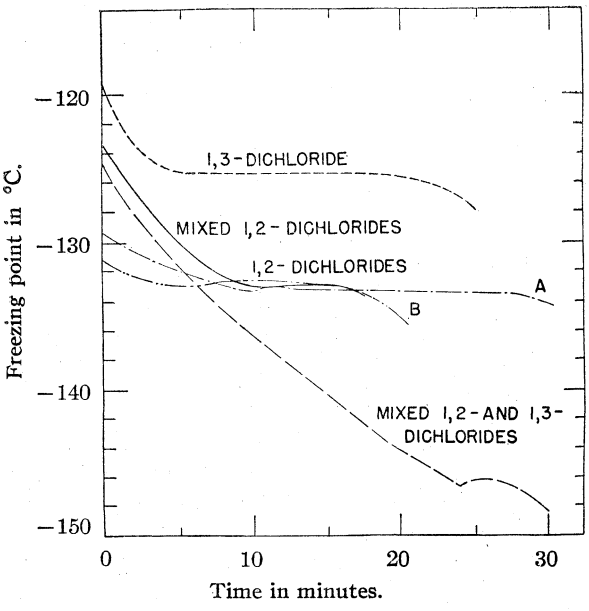

Fig. 3.—$C_3F_6Cl_2$ products.

in Fig. 4 where both A and B are represented by the single solid line.

TABLE II

COMPARISON OF $C_3F_6Cl_2$ PRODUCTS

Product	Molecular weight	Boiling point, °C.	Freezing point, °C.	Mixed freezing point, °C.
A	227.1	34.5	−132.7	−133.0
B	226.1	34.5	−133.3	
C	227.8	35.8	−125.4	−146.5
D	224.8	35.6	−126.3	−126.0

The reactions of the 1,2 and 1,3-dichlorohexafluoropropane with zinc in alcohol likewise differ in the products obtained. Although the 1,2-dichloride gave the original C_3F_6, the 1,3-dichloride gave a C_3F_6HCl which has identical infrared absorption with that of $CF_2HCF_2CF_2Cl$. The statement of Park, *et al.*,[5] that $CF_2ClCF_2CF_2Cl$ reacted with zinc to give a cyclic product must have been based upon the reaction of $CF_3CFClCF_2Cl$ obtained from pyrolysis of tetrafluoroethylene polymer, which at that time was thought to be the

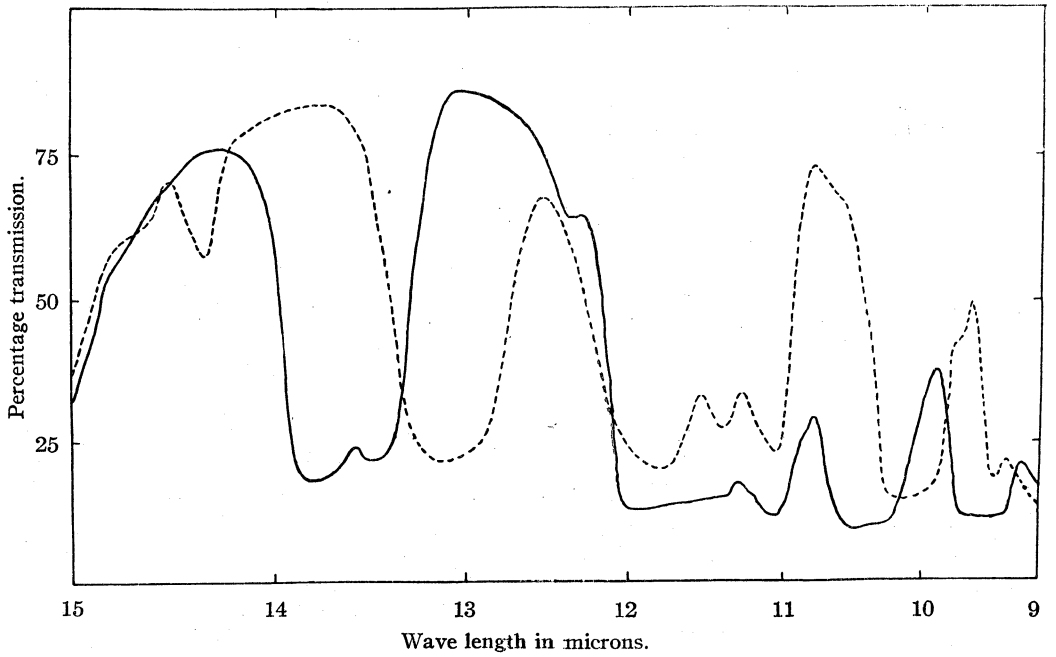

Fig. 4.— ----, 1,3-$C_3F_6Cl_2$; ——, 1,2-$C_3F_6Cl_2$.

Cl[4] and (D) by fluorination of $CFCl_2CF_2CFCl_2$. This is shown by the data given in Table II.

The freezing point curves shown in Fig. 3 not only verify the identity of A and B but also assure that the dichloride from the pyrolysis product of "Teflon" is not the same as the 1,3-dichloride. This is further corroborated by infrared absorption curves of the three $C_3F_6Cl_2$ molecules as shown

(4) Downing, Benning and McHarness, U. S. Patent 2,384,821.

1,3-dichloride, to give $CF_3CF{=}CF_2$ boiling at −30°.

There remains no doubt that C_3F_6 prepared by the pyrolysis of tetrafluoroethylene polymer is $CF_3CF{=}CF_2$ and not $\underline{CF_2CF_2CF_2}$.

On the Molecular Structure of ("Cyclic") C_3F_6

BY WALTER F. EDGELL

In line with our interest in fluorocarbons the Raman spectrum of "cyclic" C_3F_6 was determined early in 1946. The results were not published then because they were at variance with the reported "definite chemical evidence" for the cyclic structure which was later published.[1,2] Recently F. A. M. Buck and R. L. Livingston have made electron diffraction studies on this compound which also could not be interpreted with a ring model.[3] These two independent studies show clearly that this material does not have the cyclopropane structure—a conclusion also reached by other workers.[4]

Experimental Details

The Raman effect was determined in the liquid state using the spectrographic arrangement reported elsewhere.[5] The Raman tube was surrounded by an unsilvered Dewar which was maintained at low temperatures by dry air that had been passed through coils immersed in a Dry Ice–acetone slush and liquid air. The twenty Raman lines found are listed in Table I. The usual weak scattering power of fluorocarbons was observed and two of the lines listed were so weak that it would be better to consider them uncertain at present. This in no way influences the conclusions drawn.

Discussion of Results

The cyclic ring model, $\overline{CF_2CF_2CF_2}$, has the symmetry D_{3h} for which the selection rules and the approximate character of the vibrations, listed in Table II, may be obtained by group theoretical considerations. In contrast to the twenty Raman lines found, this model calls for but ten. To be sure this is about the number of stronger lines observed, but their frequencies do not correspond to the order of magnitude expected of a cyclic fluorocarbon.[5] Most important is the rather strong line at 1790 cm.$^{-1}$ for which no explanation seems possible in terms of this model; also five lines between 1000 and 1400 cm.$^{-1}$ are more than can be reasonably accounted for. A consideration of the C–F stretching vibrations is very significant. Experience has shown that they are found in the region *ca.* 1000 to *ca.* 1400 cm.$^{-1}$.[5–9] This model calls for three such Raman active fundamentals plus two that are infrared active—only one of which would

appear in both spectra. This is in complete disagreement with the data; all five frequencies in this region appear in both the Raman and infrared spectra.

It is clear that "cyclic" C_3F_6 is not hexafluorocyclopropane.

The Raman spectrum indicates a molecule which has either no symmetry or at most one element of symmetry, in which case all 21 fundamental modes of vibration would appear individually in both the Raman and infrared spectra. Molecules containing a double bond have their stretching fundamental at *ca.* 1650 cm.$^{-1}$,[10] which is shifted in polyfluorinated ethylenes to *ca.* 1750 cm.$^{-1}$.[11,12] This corresponds to the Raman line found at 1790 cm.$^{-1}$ and the infrared band at 1798 cm.$^{-1}$. Thus the spectra indicate the structure $CF_3CF{=}CF_2$!

It is difficult to predict the character of the vibrations of this molecule because of the lack of symmetry restrictions and the complexity resulting from the large interactions between the fluorine atoms. An approximate description of them based upon the neglect of coupling between the groups is found in Table I. The correlation between the expected magnitudes[5-12] and the observations is good. No definite assignment of all the frequencies can be made yet. For example, it is not clear why only five lines are found in the region where the six C–F stretching vibrations are expected. Work now under way in this Laboratory on similar molecules should throw light on these matters, however. The correlation of Table I is given solely to show that the spectrum has the proper number of lines in the proper spectral region for such a model.

In order to conclusively demonstrate that "cyclic" C_3F_6 is in reality hexafluoropropylene, the infrared spectrum between 2 and 15μ of an authentic sample of $CF_3CF{=}CF_2$ is included in Table III, column 2. It is identical with that for "cyclic" C_3F_6. This spectrum was obtained and furnished by Mr. D. G. Weiblen of the Central Research Department, Minnesota Mining and Manufacturing Company, using material prepared by Lyle Hals of that laboratory.

It is now clear why the physical properties of $CF_3CF{=}CF_2$[13] are so close to those earlier reported for "cyclic" C_3F_6.

Acknowledgment.—The author is indebted to Dr. A. F. Benning who furnished the infrared spectrum and sample of C_3F_6. Thanks are also due to Mr. D. G. Weiblen for the infrared spectrum of hexafluoropropylene.

The Identification of C_3F_6[1]

BY F. A. M. BUCK AND R. L. LIVINGSTON

The compound C_3F_6, obtained by pyrolysis of polytetrafluoroethylene and by pyrolysis of monochlorodifluoromethane has been reported to be hexafluorocyclopropane[2,3] although some doubt as to its identity has been expressed.[4] Interpretation of electron diffraction photographs of this compound has led us to the conclusion that the compound is not hexafluorocyclopropane but is hexafluoropropene. This conclusion has been reached independently by other workers.[5,6]

The electron diffraction photographs[7] were prepared using an apparatus built by Professor H. J. Yearian of the Purdue Physics Department. The sample of C_3F_6 was kindly supplied by Drs. Young and Benning of the Jackson Laboratory of E. I. du Pont de Nemours and Company. Diffraction maxima were observable on the photographs out to $s = 33$ ($s = 4\pi/\lambda \sin \theta/2$). A radial distribution curve (Fig. 1) was calculated using essentially a method previously described.[8] The five prominent peaks of this curve at 1.32, 2.16,

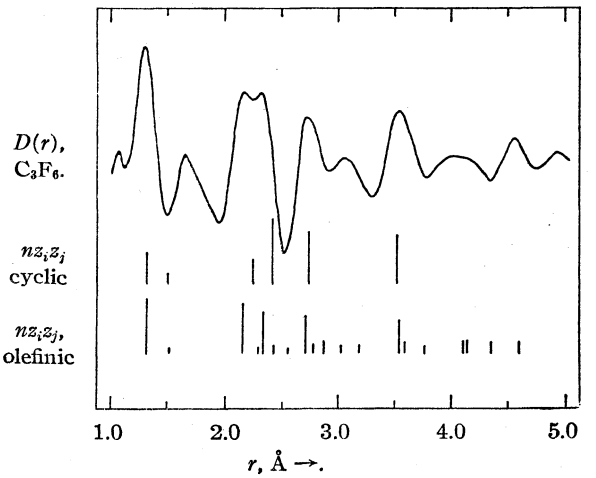

Fig. 1.—Radial distribution curve for C_3F_6. The lines under the curve correspond to bond distances in models of hexafluorocyclopropane and hexafluoropropene; the lengths of the lines indicate the relative weights, nz_iz_j, of the corresponding terms in the simplified intensity function.

2.34, 2.70, and 3.54 Å. are not compatible with any cyclic model having D_{3h} symmetry. The bond distances in one cyclic model are indicated by vertical lines under the radial distribution curve; other cyclic models disagree with the curve to about the same extent or to a greater extent. Also the theoretical intensity curves for cyclic models are incompatible with the observed pattern.

We have succeeded in finding a model for hexafluoropropene which gives very good agreement with the prominent peaks on the radial distribution curve. This agreement is indicated under the curve by vertical lines representing bond distances in this model. In addition the theoretical intensity curve for this model agrees qualitatively with the photographs and the average of the $s_{calcd.}/s_{obs.}$ (for eleven features which may be confidently compared) is 0.999 with an average deviation of 0.006. Further work is necessary in order to determine the accuracy with which the various parameters in the molecule can be evaluated. The identity of the compound, however, seems clearly established.

We wish to thank Professor Yearian for the use of his diffraction apparatus and for many helpful discussions. We are also grateful to E. I. du Pont de Nemours and Company for the free grant fellowship which made this work possible.

Maxima in Vapor Pressure Curves

BY A. E. KORVEZEE AND P. DINGEMANS

Recently N. B. Keevil[1] has given the vapor pressures of aqueous solutions of a number of salts over an extensive temperature range. In case of highly soluble salts, maxima occur in the vapor pressure curves and the author stresses the point that the maxima lie at increasing temperatures with increasing melting point of the salts.

We have found analogous results for a series of salts with lower melting points. Moreover we have derived[2] the approximate expression

$$\frac{1}{T_{max}} = \frac{1}{T_s} + 0.00021.$$

T_s = melting point of the sale (absolute temperature)
T_{max} = absolute temperature of the maximum.

This expression is derived for ideal solutions, but it proves to give also fairly trustworthy results for the temperature of the pressure maxima even for our saturated salt solutions. The relation given is also valid for vapor pressure curves of solutions saturated with respect to two or more salts, in which case T_s = the eutectic temperature of the salt mixture.[3] A number of examples are to be found in our publications.[4]

We have applied our formula to those of Keevil's curves, for which the temperature of the maximum and the melting point of the salt have been directly determined. The results are collected in Table I.

TABLE I

Salt	Melting point, °C.	Temperature of the maximum, °C. measured	calculated
NaCl	804	600	606
NaBr	755	570	573
KCl	770	565	582

From the figures given it is clear that a fairly accurate estimation of the temperature of the maximum in the vapor pressure curve can be derived from melting point data with the aid of our formula.

The Preparation of Allyl Iodide[1]

BY R. L. LETSINGER AND JAMES G. TRAYNHAM

Reported methods for the preparation of allyl iodide involve the reaction of allyl alcohol or glycerol with either hydriodic acid or phosphorus and iodine.[2] We find that preparative quantities of allyl iodide may be obtained very conveniently by the action of sodium iodide on allyl chloride in acetone. This preparation is based on a reaction investigated kinetically by Conant, Kirner and Hussey.[3]

A mixture made of 0.6 mole (45.9 g.) of allyl chloride, 0.75 mole (113 g.) of sodium iodide, and 100 cc. of acetone was warmed on the steam-bath for three hours and then poured into 500 cc. of water. The organic layer was separated, washed with both a dilute sodium bisulfite solution and with water, dried over sodium sulfate, and distilled. The yield of allyl iodide (b. p. 101–102°, d^{22}_4 1.8454, $n^{22}D$ 1.5542) was 63.1 g. (62.6%). When the reflux time was increased to twenty-four hours and 200 cc. of acetone was used as solvent, the yield was increased to 76.7%.

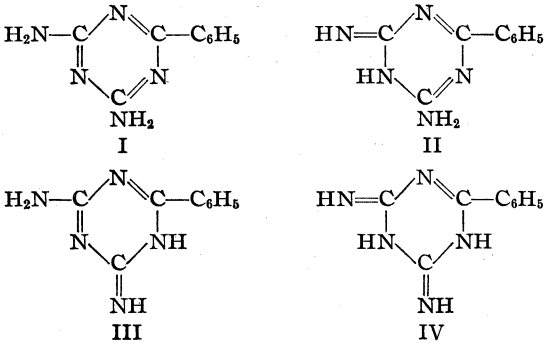
Absorption Spectra of 4,6-Diamino-2-phenyl-1,3,5-triazine

BY FREDERICK C. NACHOD AND EDGAR A. STECK

Although 1,3,5-triazine derivatives have been the subject of many investigations, relatively few

physico-chemical measurements have been made with compounds of this class.[1-7] Of these, only one group of absorption spectra has been reported,[6] referring to cyanuric acid types, as well as at an early date. As a portion of some other investigations, the spectral characteristics of 4,6-diamino-2-phenyl-1,3,5-triazine became of interest. The compound (I) was prepared by the reaction of benzonitrile with dicyandiamide in the presence of piperidine,[8] being an improvement over earlier work.[9,10]

The tautomeric states possible in 4,6-diamino-2-phenyl-1,3,5-triazine are indicated in the structures I–IV. The two mono-imino forms (II and III) are twice as likely of being the more probable



structures of the compound because only one diamino and only one di-imino structure can be formulated (I and IV). This may also account for the fact that only monohydrochlorides are formed in this type.[11,12]

Ultraviolet absorption spectra of 4,6-diamino-2-phenyl-1,3,5-triazone solutions shown in Fig. 1[13] clearly indicate that at *p*H 7 and 13 essentially the same maxima and minima are attained. On passing to *p*H 1, however, a marked batho- and hypochromic shift is to be observed. This indicates that the degree of conjugation is diminished and Table I, which lists the actual values for the maxima obtained, further emphasizes the differences in spectra. The shifting could easily be interpreted as the result of a favoring

of structure (IV) in strongly acidic solution as the preferential form. However, in the crystallization of the hydrochloride, the more probable forms (II) and (III) are predominant. Although the structures (II) and (III) are not equivalent, presumably they do have nearly the same energy content and may be present in a solid solution or hydrogen-bonded condition in the solid state.

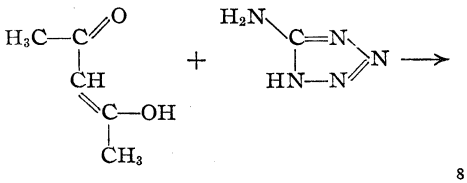
Absorption Spectra of 5,7-Dimethyltetrazolo(a)-pyrimidine

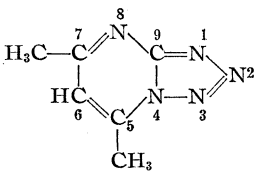
BY FREDERICK C. NACHOD AND EDGAR A. STECK

The interest in the absorption spectral behavior of 5,7-dimethyltetrazolo[a]pyrimidine resulted from certain aspects of related heterocyclic studies. The compound, named 5,7-dimethyl-1,-2,3,4-tetraazaindolizine by Bülow,[1] is now des-

(1) Bülow, *Ber.*, **42**, 4433 (1909).

ignated as above according to the system employed in the "Ring Index."[2] It has not been studied further since its preparation from 5-aminotetrazole and acetylacetone in the presence of piperidine, the method which was also employed in this work.[3]





I

From an examination of the spectra of 5,7-dimethyltetrazolo[a]pyrimidine shown in Fig. 1,[4] a tremendous batho- and hyperchromic shift is to be noted in comparing the spectrum at *p*H 13 with that in neutral and acidic solutions. As the

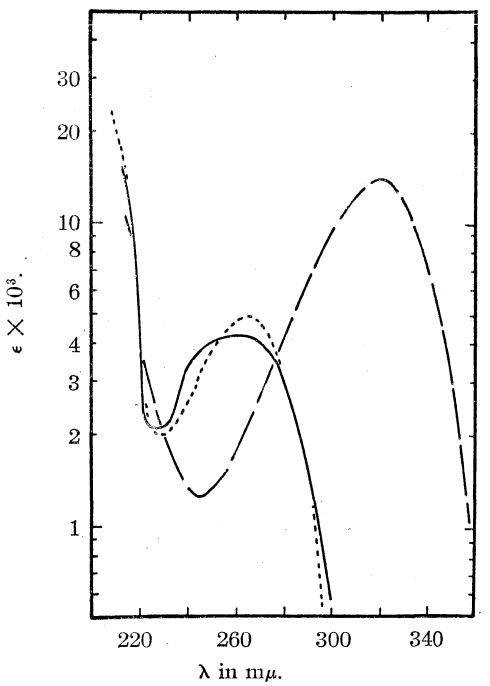


Fig. 1.—Spectra of 5,7-dimethyltetrazolo[a]pyrimidine in — ethanol (95%), ---- 0.01 *N* HCl, — — 0.01 *N* NaOH.

nitrogen atoms do not bear any hydrogen [atoms], a classical picture on the basis of tautomeric shifts cannot be developed. However, if one admits ionic structures,[5] this behavior can apparently be explained satisfactorily. The dipolar ions ("Zwitterions") shown in (II) to (V) contribute to the arrangement of the compound in acid, and, to a somewhat lesser extent, in neutral solution. These considerations would lead one to expect that the resulting spectrum, with respect to the position of the maximum, should be similar to that of a benzenoid ring with a conjugated double bond. Indeed, a measure of similarity to the spectra of styrene,[6] indole,[7] benzotriazole[8] and even benzoxazole[9] is observable. In alkaline medium, however, this polarization tendency, due to the addition of protons in position 1 or 3, disappears and the structure (I) is the only one remaining. Such a spectrum should more closely resemble that of a polyene and shift the absorption maximum toward the visible range. This is borne out by the similarity of the spectrum of 5,7-dimethyltetrazolo[a]pyrimidine in alkali with that of 1,3,5,7-octatetraene which was studied by Kovner[10] and Hausser.[11] Both of the compounds have four conjugated double bonds and a "maximum extinction coefficient" beyond 300 mμ.

Remarks on the Physico-Chemical Mechanism of Muscular Contraction and Relaxation

BY JACOB RISEMAN AND JOHN G. KIRKWOOD

The physico-chemical processes underlying the contraction and relaxation of muscle have been the subject of much speculation. Recently significant analogies between the elastic behavior of muscle and that of rubber and synthetic elastomers have

been investigated by Bull[1] and others. That the structure of striated muscle, and possibly smooth muscle, is much more ordered than those of elastomeric cross-linked high polymers is clearly demonstrated by the studies of Schmitt and his collaborators.[2] Nevertheless, important aspects of structural similarity exist. The basic structural unit of the muscle fibril is considered to be the linear polypeptide chain of the myosin or actomyosin molecule. Like the segments of a polymer network, the long polypeptide chain possesses many internal rotational degrees of freedom which allow it to gain configurational entropy on contraction. Therefore it is probable that the elastic modulus of a structure composed of such elements is in part determined by the dependence of their configurational entropy upon elongation.

The contraction or relaxation of a muscle segment under constant stress is the consequence of a change in the elastic modulus arising from alteration of its structural units. Following certain ideas suggested by the work of K. H. Meyer,[3] we wish to examine the hypothesis that the essential alteration of the structural unit, leading to a change in modulus, is a change in its net electric charge. A structural unit consisting of a long polypeptide chain can gain or lose electric charge in several ways in response to changes in its physico-chemical environment. If the absolute magnitude of the charge, whatever the sign, is increased, electrostatic repulsion between the elementary charges comprising the increment will decrease the elastic modulus by destroying the balance between the external stress and the contractile force arising from configurational entropy. Conversely, if the magnitude of the charge is decreased, the modulus will increase. According to this view, the relaxed state of muscle is an electrically charged state and the contracted state one in which the polypeptide chains are in an uncharged or "isoelectric" condition. We shall presently make some rough estimates of the change in elastic modulus produced by electrostatic repulsion between charges distributed at intervals along a polypeptide chain, after discussing possible mechanisms by which it might gain or lose charge.

Since a polypeptide chain is an ampholyte, it can gain or lose charge in response to a change in the *p*H of its environment. This mechanism was proposed by K. H. Meyer[3] as a basis for the analysis of the energetics of muscular relaxation and contraction. Meyer's proposal was rejected by Weber[4] on grounds which still must be regarded as inconclusive. Adsorption of cations, for example potassium, by actomyosin segments provides a second method of charging, which the work of St. Gyorgi suggests may play a role.[5] Nevertheless, both of these charging mechanisms leave obscure the manner in which the chain of carbohydrate oxidation reactions supplies free energy for the muscular processes.

We are inclined to the view that phosphorylation of the hydroxy amino acid residues of the myosin or actomyosin molecule by adenosine triphosphate provides a charging mechanism in best accord with known facts. From its amino acid analysis, myosin is known to contain a large proportion of hydroxy amino acid residues; serine, 3.9%; and threonine, 4.95%.[6] Myosin is also considered to be one of the enzymes involved in the dephosphorylation of ATP to ADP and inorganic phosphate. Assuming that the first step in the dephosphorylation of ATP consists in the phosphorylation of the $-OH$ groups of the hydroxy amino acid residues of the myosin molecule, we conclude that at a *p*H of 7, the approximate *p*H of the sarcoplasm, each $-H_2PO_4$ group will be approximately singly ionized to $-HPO_4^-$. Thus the phosphorylation process would impart to the neutral sites originally occupied by $-OH$, approximately one unit of negative charge. The extension of the myosin chain and that of the structure of which it is the unit, resulting from electrostatic repulsion between the negatively charged $-HPO_4^-$ groups, stores up the free energy, released in the degradation of the high energy phosphate bond of ATP, in the form of negative configurational entropy of extension. Subsequent dephosphorylation of the myosin molecule with release of inorganic phosphate ion to the sarcoplasm would remove negative charge from the molecule and release the stored free energy as mechanical work in contraction of the structure. The coupling between the carbohydrate oxidation process and the mechanical processes of muscle activity is thus clarified by the proposed mechanism. ATP, regenerated in the chain of oxidation reactions, serves as a carrier of free energy released in these reactions to the myosin units of the muscle structure.

In order to examine the quantitative implications of our hypothesis, we will make some rough estimates of the change in elastic modulus E of a flexible linear molecule produced by attaching electric charges of equal magnitude at equal intervals along its length. If the terminal groups of the molecule are separated by a distance L and n charges of the same sign and magnitude e are attached to the chain at points separated by equal numbers of bonds, the random coil model of a flexible linear molecule leads to the following approximate estimate of the increment in elastic modulus ΔE, produced by the charge increment ne

(6) M. L. Anson and J. T. Edsall, "Advances in Protein Chemistry," Vol. I, Academic Press, Inc., New York, N. Y., 1944, p. 310.

$$\Delta E = -\frac{8}{3}\frac{N\rho}{M}\frac{n^2e^2}{D_eL}$$

where D_e is an effective dielectric constant, N is Avogadro's number, M the molecular weight of the linear molecular unit of the structure and ρ is the density of the structure, regarded as a three-dimensional network with L the average distance between net points. Since electrostatic interactions between the charges of neighboring chain segments are neglected and other gross approximations have been employed in its derivation, Eq. (1) is intended to provide no more than an estimate of the order of magnitude of ΔE.

The elastic modulus of muscle[1] is of the order of magnitude 10^5 dynes/sq. cm. In order to produce a change of this order of magnitude by charging the structural units, we estimate from Eq. (1) a magnitude of n of the order of 100, with the rough assignments of value $\rho = 1$, $M = 10^6$, $L = 10^4$A, $D_e = 100$ to the other parameters. The values of L and M are those determined for the myosin or actomyosin molecule in solution, and D_e is assumed to be of the order of magnitude of the dielectric constant of water. The estimated number of charges would require phosphorylation sites situated at intervals of 100 Å. along the myosin or actomyosin molecule. This value is not inconsistent with the hydroxy amino acid content of myosin.

The observation of Needham[7] that the flow birefringence of myosin solutions is diminished by the addition of ATP seems at first to be in contradiction with our hypothesis. However, it seems that the effect was observed under conditions leading to the dissociation of actomyosin into actin and myosin, according to St. Gyorgi.[5]

We have deliberately avoided placing undue emphasis on hypothetical structural details of muscle and on the detailed analogy between the elastic properties of muscle and elastomers. The essential qualitative aspects of our suggestions, (a) change in the elastic modulus of the structure due to alteration of the electric charge of the structural unit, considered to be a polypeptide chain rich in hydroxy amino acid residues; (b) charging of the structural unit through phosphorylation of the hydroxyl groups by ATP, are to a large extent independent of assumed structural details.

Purification of N-Hydroxymethylphthalimide through a Molecular Compound with Pyridine

BY EUCLID J. SAKELLARIOS

In connection with the synthesis of N-alkylated phthalimides, we have prepared N-hydroxymethylphthalimide. This compound was first prepared by Sachs[1] by the hydrolysis of N-bromomethylphthalimide. It was later prepared by Sachs[2] from formaldehyde and phthalimide in sealed tubes and by Buc[3] from the same reactants at atmospheric pressure. The melting points reported by these authors were 141–142°, 139–140° and 137–141°, respectively. Buc also reported that the melting point is not improved by crystallization from ethanol.

We attempted to eliminate the impurities by adding about 1 g. of fuller's earth per 100 ml. of solution in Buc's procedure. This yielded a product melting at 144–145° which was, however, still not pure.

A product of high purity melting at 149.5° was finally obtained through an unstable, previously unreported complex formed from N-hydroxymethylphthalimide and one mole of pyridine.

Chloro-, bromo- and iodomethylphthalimides were prepared from the pure compound and the appropriate halogen acid. In all cases the products had higher melting points than those previously reported.

Procedure.—A solution obtained by warming 17.7 g. of N-hydroxymethylphthalimide[3] in 30 ml. of pure pyridine was filtered, if necessary, and left to crystallize. If crystallization did not occur, seed crystals were obtained by placing a few drops of the solution in a desiccator over sulfuric acid. As soon as the first crystals appeared, they were added to the solution. The new compound crystallized in long, bright needles which after cooling in an ice-bath were filtered with suction.

To determine the pyridine the crystals were dried briefly on a porous plate over calcium chloride. A weighed sample was then dried in vacuum over sulfuric acid. The crystals gradually lost their brightness and came to constant weight after twenty-four hours.

Anal. Calcd. for $C_6H_7O_3N \cdot C_5H_5N$: pyridine, 30.58. Found: pyridine, 30.68.

The residue melts at 148.5–149°. One crystallization from acetone brings the m. p. to 149.5°.

Anal. Calcd. for $C_6H_7O_3N$: N, 7.91. Found: N, 7.88.

The halogenomethylphthalimides were prepared essentially according to Gabriel,[4] heating at 50° for one hour after the crystals separated. The crystals were filtered, washed with the appropriate acid and then dried over sulfuric acid and potassium hydroxide. The results obtained are summarized in the table.

Some Diacid Salts of Aminoguanidine and Methyl Aminoguanidine[1]

BY JOHN J. PITHA,[2] HARRY HUGHES, JR., AND G. B. L. SMITH[3]

There are some references in the literature to diacid salts of aminoguanidine. Lieber and Smith[4] mention aminoguanidinium dinitrate and aminoguanidinium dichloride, but give no details of the preparation. In another article, Thiele[5] also mentions the preparation of aminoguanidinium dinitrate. In this same article, Thiele also mentions the preparation of neutral aminoguanidine sulfate as well as diaminoguanidine sulfate. This present article reports a generalized method for the preparation of these and other diacid salts of aminoguanidine. This procedure is also applied in the preparation of a diacid salt α-methyl-γ-aminoguanidine. The melting points of the salts prepared are included.

Experimental

Aminoguanidinium bisulfate (0.1 mole) was dissolved in 100 ml. of hot water and to this was added a solution containing 0.1 mole of the barium salt of the acid corresponding to the diacid salt in preparation. To the above mixture was added a considerable excess of the corresponding concentrated acid. After one hour digestion on a hot plate, the barium sulfate was separated by filtration and the filtrate was evaporated on a steam-bath until crystallization started. The solution was then cooled and the crystals separated by filtration, dried *in vacuo*, and analyzed.

The methylaminoguanidine was prepared from methyl nitroguanidine by the method of Lieber and Smith.[6] Methylaminoguanidine bicarbonate was prepared by treating the methylaminoguanidine acetate obtained in the above reaction with potassium bicarbonate and carbon dioxide in isopropyl alcohol at a temperature of $-10°$. A 99% yield was obtained and the melting point of the bicarbonate was observed to be 151.5–152°.

To 6 g. of methylaminoguanidine bicarbonate (0.04 mole) in 60 g. of isopropyl alcohol was added 32 g. (0.32 mole) of 37% hydrochloric acid. The solution was treated with carbon black and filtered. After cooling to $-18°$, needle-like crystals separated out in clusters. These crystals were removed by filtration, washed with cold solvent, dried *in vacuo* for eighteen hours and analyzed. This material proved to be α-methyl-γ-aminoguanidinium dichloride.

Table I lists the diacid salts of aminoguanidine and α-methyl-γ-aminoguanidine prepared, their analyses and their melting points.

From these experiments it seems that aminoguanidine and α-methyl-γ-aminoguanidine will accept two protons in strongly acid solutions. Further work is in progress to gain more knowledge of the ionic species that exist in water solutions of these salts.

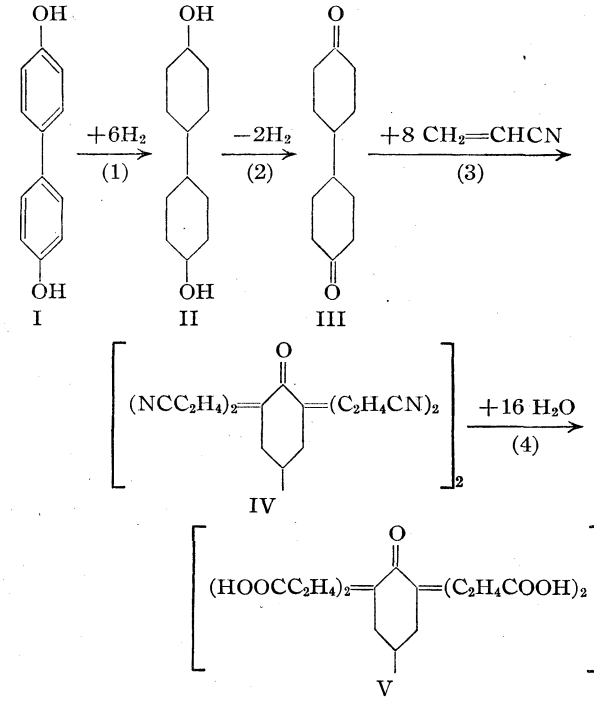
Synthesis of an Octabasic Carboxylic Acid

BY J. R. SCHAEFGEN AND P. J. FLORY

Dicyclohexanoneoctapropionic acid (V) has been prepared for use as the multifunctional reactant in the synthesis of octachain polymers.[1] This acid is of interest because, so far as we are aware, it is the first example of a stable octabasic carboxylic acid.[2] It has been synthesized from *p,p'*-diphenol (I) by the following series of reactions.



The over-all yield was about 6%. Complicating side reactions occurring in steps (1) and (2) are largely responsible for the low yield. Compounds III, IV and V are new.

(1) J. R. Schaefgen and P. J. Flory, THIS JOURNAL, **70**, 2709 (1948).

(2) Beilstein, "Handbuch der organischen Chemie," IV ed., Vol. IX, 1st Suppl., Julius Springer, Berlin, 1932, p. 446, lists diphenyloctacarboxylic acid—(2,4,5,2',4',5,'x,x) which, however, loses carbon dioxide and water when heated to 110°.

Experimental

4,4'-Diketodicyclohexyl (III).—Crude 4,4'-dihydroxydicyclohexyl (II), prepared from *p,p'*-diphenol (I) by high pressure hydrogenation over Raney nickel catalyst by the method of Adkins,[3] was converted to (III) as follows. A mixture of 50 g. of (II), 50 ml. of diphenyl ether, and 13 g. of copper chromite catalyst was heated for three hours at 260–270°. During this time 70% of the theoretical quantity of hydrogen necessary for complete conversion to the diketone (III) was evolved. The reaction mixture was cooled and dissolved in chloroform. The solution was filtered to remove catalyst, and the filtrate was distilled. The fraction boiling from 144–170° (1 mm.) (which solidified on cooling) contained the product. Several crystallizations from mixtures of acetone and *n*-hexane gave a 16.5% yield of diketone (III); m. p. 116.5–118°.[4] The purest material melted from 118–119°.

Anal.[5] Calcd. for $C_{12}H_{18}O_2$: C, 74.18; H, 9.33. Found: C, 74.62; H, 9.53.

The diketone formed a dioxime; m. p. *ca.* 290° (copper block). The dioxime was practically insoluble in all ordinary organic solvents.

Anal. Calcd. for $C_{12}H_{20}O_2N_2$: C, 64.26; H, 8.98. Found: C, 64.82; H, 9.60.

bis-[3,3,5,5-Tetra-(β-cyanoethyl)-4-ketocyclohexyl] (IV).—To a solution of 18.4 g. of 4,4'-diketodicyclohexyl (III) in 80 ml. of dioxane containing 1.3 ml. of Triton B (38% aqueous solution of trimethylbenzylammonium hydroxide) there was added dropwise 41.5 g. of acrylonitrile (3% excess). The reaction mixture was vigorously stirred and maintained at room temperature by use of a water-bath during the addition. Yellow crystals were deposited as the reaction proceeded. After stirring overnight, the mixture was diluted with water and filtered, and the precipitated product was washed with acetone. Two or three crystallizations from formamide–nitromethane mixtures (*ca.* 80–20) gave 39 g. (66%) of white crystalline "octanitrile" (IV); m. p. 280–287°.

Anal. Calcd. for $C_{36}H_{42}O_2N_8$: C, 69.86; H, 6.83; N, 18.11. Found: C, 69.86; H, 7.16; N, 18.05.

bis-[3,3,5,5-Tetra-(β-carboxyethyl)-4-ketocyclohexyl] (V) (Dicyclohexanoneoctapropionic Acid).—A suspension of 6.83 g. of the "octanitrile" (IV) in 35 ml. of 85% aqueous phosphoric acid was heated for forty-eight hours on the steam-bath. Suspended matter dissolved as the hydrolysis proceeded, after which the clear solution gradually changed to a semi-solid mass. When hydrolysis was substantially complete, the reaction mixture was diluted with water, cooled and filtered. The precipitate was dissolved in alkali and the solution filtered. The filtrate on acidification gave fine white needles of the desired acid which, after recrystallization from water, weighed 5.82 g. (66% yield). Further purification consisting of (1) treating the acid with activated charcoal, (2) boiling in dilute hydrochloric acid solution (to hydrolyze any remaining nitrile groups) and (3) crystallizing from water followed by drying at 110° under reduced pressure was found necessary to secure a pure product; m. p. 274–277°, neutral equivalent 96.6, calcd. 96.3. On standing for several months in a desiccator, the melting point rose to 286–288°, probably due to a change in crystalline form.

Anal. Calcd. for $C_{36}H_{50}O_{18}$: C, 56.08; H, 6.54. Found: C, 56.05; H, 6.47.

Preparation of Triethylacetonitrile and Triethylacetic Acid

BY CONRAD SCHUERCH, JR.,[1,2] AND ERNEST H. HUNTRESS

Synthetic methods for the preparation of tertiary aliphatic acids or their simple relatives have not been correlated in the prior literature. They include, however, alkylation of aliphatic nitriles with alkyl bromides or chlorides in presence of sodamide,[3] and the carbonation of RMgX compounds.[4]

For tertiary acids above dimethylethylacetic, carbonation of the appropriate RMgX compounds is not generally utilizable since the Grignard reagents prepared from higher halides usually react abnormally, yielding mixtures of alkanes and alkenes. Furthermore, the required carbinols are not commercially available and simple distillation is somewhat inadequate for removal of residual traces of the carbinols from their chlorides.

Our experience (Table I) in attempting to prepare tertiary acids by carbonation of tertiary-alkyl magnesium chlorides with either gaseous or solid carbon dioxide indicates that the yields of acids become progressively more unsatisfactory. The reactions were run on Grignards derived from 200–300 g. of alkyl chloride using the usual precautions[4d]; yields are not necessarily optimal.

tonitrile. Even when the alkylation was not carried out under pressure but merely at the boiling point of ethyl bromide where the principal reaction is dialkylation leading to diethylacetonitrile, the yield of triethylacetonitrile was sufficiently high to serve as a convenient preparative method.

In the course of our study of this procedure we also examined the behavior of acetonitrile (1 mole) with ethyl bromide (excess) and sodamide (2–2.5 moles); acetonitrile with diethyl sulfate in benzene (no alkylation); alkylation of a mixture of acetonitrile with diethylacetonitrile; and the behavior of *n*-butyronitrile with ethyl bromide (excess) in presence of sodamide (2 moles). The best conditions for the preparation of triethylacetonitrile at ordinary pressure are concisely summarized below.

Triethylacetonitrile.—To a mixture of acetonitrile (61 g., 1.5 moles), ethyl bromide (408 g., 3.75 moles) and dry ether (100 ml.) in a creased 3-liter flask with high-speed stirrer was added a slurry of sodamide (117 g., 3 moles) in dry ether. This addition was effected under slight pressure of nitrogen during a one and one-half-hour period. Although no significant reaction occurred after this period, the mixture was stirred overnight and then cautiously treated with 50 ml. of alcohol, finally with water. After washing the ether solution with dilute sulfuric acid and finally with water, it was dried over magnesium sulfate and fractionally distilled at atmospheric pressure through a one-foot packed column. The products of mono, di and trialkylation were obtained as follows:

n-Butyronitrile	24.1 g.	0.348 mole	$n^{21}D$ 1.3838
Diethylacetonitrile	35.2 g.	0.362 mole	$n^{20}D$ 1.4021
Triethylacetonitrile	28.8 g.	0.23 mole	$n^{20}D$ 1.4219

Fractionation of the intermediate material and residue gave more of all three products.

Triethylacetic Acid.—Triethylacetonitrile (60.3 g.) mixed with 75% sulfuric acid (106 g.) was raised to a temperature of 150° with constant stirring over a period of one-half hour. The temperature was then maintained at 145–150° for twenty-two more minutes after which the contents of the flask were cooled to 50°. Solid sodium nitrite (47 g.) was added from an attached flask during a period of about one hour at 50–60°. After cooling, diluting with water, and extracting with ether, the latter contained both the desired acid and its amide. The former was separated from the latter by extraction of the ether solution with aqueous 6% potassium hydroxide; yield of triethylacetic acid 56.6 g., 81.5%, purified with little loss by distillation under reduced pressure, b. p. 104–105° at 5 mm., f. p. 35.1°; yield of triethylacetamide 11.3 g., 17.6%.

The Reaction of Certain β-Aminomercaptans with Iodine in Ethanol

BY H. R. SNYDER AND ERNEST L. ELIEL

In a recent report[1] on the synthesis of substituted mercaptans the derivatives obtained by reaction of certain β-aminomercaptans with iodine in alcohol were regarded as sulfenyl iodides. Shortly after the appearance of the report Professor Norman Kharasch[2] kindly called to our attention the fact that the properties of the derivatives were not those to be expected of simple sulfenyl iodides and suggested that the substances were the dihydriodides of the disulfides formed by oxidation of the aminomercaptans.

A quantitative study of the reaction of alcoholic iodine with the mercaptan[1] $[C_6H_{12}NCH_2C(CH_3)_2SH]$ obtained from β-pipecoline and isobutylene sulfide now has been made. The iodine consumption averaged 95% of that required for conversion of the mercaptan to the disulfide salt, or only 47.5% of the amount required for conversion to the sulfenyl iodide. The reaction also was carried out on a scale large enough to permit isolation of the product, conversion to the free disulfide by the action of sodium bicarbonate, distillation of the disulfide, and reconversion of the disulfide to the salt by treatment with hydriodic acid; the original salt was regenerated. The derivative previously obtained by the action of iodine on the aminomercaptan $[(C_4H_9)_2NCH_2C(CH_3)_2SH]$ from di-*n*-butylamine and isobutylene sulfide was subjected to the same cycle (except that the free disulfide was not distilled). In this instance also the regenerated substance was identical with the original sample.

It thus appears certain that all the derivatives referred to as sulfenyl iodides in the previous report[1] are dihydriodides of diaminodisulfides having the general formula $[R_2NCH_2C(CH_3)_2S]_2 \cdot 2HI$. The previously recorded analyses of the substances are in good agreement with the theoretical values calculated on the basis of this structure.

Experimental[3]

Reaction of α,α-Dimethyl-β-(β-pipecolino)-ethyl Mercaptan with Iodine in Ethanol.—Samples of about 0.5 g. of the aminomercaptan[1] were dissolved in absolute ethanol and titrated with a standardized solution of iodine (0.1 *N*) in the same solvent. In four titrations the iodine consumption was 0.949, 0.950, 0.950 and 0.954 gram atoms per mole of mercaptan. The end-point was determined by the appearance of the iodine color. The preparative reaction was carried out essentially as described previously; the product (85% yield) melted at 210.5–211.5 (dec.).

Anal. Calcd. for $C_{20}H_{42}N_2S_2I_2$: C, 38.22; H, 6.73. Found: C, 38.02; H, 7.00.

The free disulfide was obtained by the addition of 50 ml. of saturated aqueous sodium bicarbonate solution to a solution of 7 g. of the above salt in 200 ml. of hot water, extraction of the cooled solution with ether, drying of the ether solution with sodium sulfate, removal of the ether, and distillation. The liquid (yield 2.7 g., 64%) boiled at 155–156° (3 mm.); $n^{20}D$ 1.5146; mol. wt. (ebullioscopic in benzene), 328 (calcd., 372.7).

The dihydriodide was regenerated by the addition of 0.6 ml. of hydriodic acid (sp. gr. 1.5) to 0.55 g. of the disulfide in 10 ml. of absolute ethanol. The salt crystallized immediately as a solid melting at 211–212.5° (dec.); recrystallization from ethanol raised the melting point to 212–213° (dec.). A mixture of the recrystallized salt with that prepared from the aminomercaptan and iodine

(3) All melting points are corrected.

melted at 210.5–213° (dec.). The two specimens were identical in appearance under the microscope.

Experiment with the Dihydriodide of Di-[α,α-dimethyl-β-(di-*n*-butylamino)-ethyl] Disulfide.—The oil which separated when 0.15 g. of the product (previously obtained[1] by the action of iodine on the mercaptan) was treated with aqueous sodium bicarbonate was collected in ether. The solution was dried and the solvent was removed and replaced by absolute ethanol. Addition of concentrated hydriodic acid and ether caused the separation of 0.1 g. of the dihydriodide, m. p. 167.5–170.5 (dec.). After two recrystallizations from absolute ethanol and ether the salt melted at 174–176° (dec.) alone or mixed with the original salt of m. p. 173.5–175° (dec.). The two specimens were identical in appearance under the microscope.

Apparent Molar Volume of Sodium in Liquid Ammonia

BY A. J. STOSICK[1] AND ELTON B. HUNT

In a series of communications Ogg[2] has reported the results of experiments with the unusual solutions of alkali metals in liquid ammonia. In one of his communications[2a] he reported that at a concentration of 3×10^{-3} molar, the molar volume of sodium was 700–1000 cc. These values are ten to fifteen times greater than the values reported by Kraus and co-workers[3] for more concentrated solutions. Since the data of Kraus, while indicating an abnormal molar volume, show no trend to larger values with increasing dilution, it seemed worth repeating measurements for dilute solutions. The error in our measurements is relatively large, since we designed our apparatus to accommodate the large effect reported by Ogg. However, our results definitely are not in accord with those of Ogg, but conform to those of Kraus. The experiments consisted in a direct measurement of the increase in volume of liquid ammonia when weighed amounts of sodium were added to form a uniform solution.

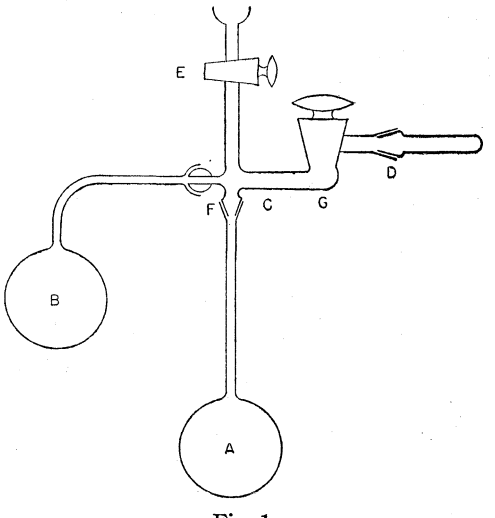

Fig. 1.

The apparatus (Fig. 1) consisted of two 100-cc. bulbs, with bulb A having a calibrated neck which served to measure the increase in volume. The whole unit was connected to a conventional vacuum line via stopcock E and a standard ball joint which permitted shaking the solution.

In the first experiment a freshly cut, massive piece of sodium (27.9 mg. in form of a cube with edge of about 3 mm.) was placed in the side-arm C and the system was quickly evacuated. Next ammonia from a concentrated sodium–ammonia solution contained in a trap on the vacuum line was distilled into bulb A. The stopcock E was then closed. The temperature of A was maintained at $-44.5 \pm 0.2°$ by means of an alcohol-bath in a large clear Dewar flask. After establishing constancy of the meniscus level, about half of the ammonia was distilled into B (previously at room temperature). This enabled the introduction of the sodium (by a magnetic pusher) to be made without splashing or "bumping" and permitted the solution to be stirred by shaking A. The ammonia in B was distilled back to A, B restored to room temperature, and A restored to −44.5°. The meniscus level was noted at intervals to be certain that constancy had been achieved. The observed rise of the meniscus, 3.0 ± 0.2 mm., the weight of the sodium, 27.9 mg., and the flask calibration lead to an apparent molar volume of 59 cc. for sodium, an excess of 36 cc. over 23 cc. for metallic sodium. The concentration of the solution was 1.1×10^{-2} molar. The precise measurements of Kraus indicate an excess volume of 41.0 to 43.5 cc. for concentrated solutions.

In the second experiment the side-arm at C was modified by the addition of an evacuable side chamber D to keep the sodium out of contact with ammonia gas until it was to be placed into solution. The side-arm had a large bore stopcock and an arrangement of magnetic pushers so that the sodium could be moved without touching stopcock grease. A second modification consisted in analyzing for the sodium remaining in A at the end of the experiment by means of a gasometric procedure. At the end of the experiment most of the ammonia was pumped from A, the temperature of A was raised to produce an ammonia pressure slightly over atmospheric. The flask A was detached at the joint F and transferred to a gasometric train where the remaining ammonia was pumped off. Dilute acid was introduced into A, the evolved hydrogen was flushed by means of carbon dioxide into a measuring vessel using concentrated potassium hydroxide as the confining fluid. Blank tests showed that this procedure introduced no gases which potassium hydroxide did not absorb.

In the second experiment the weighed amount of sodium, 5.3 mg., was placed in D and, after evacuation, was isolated by stopcock G. The subsequent steps were similar to the first experiment except for the final analysis for sodium. The temperature of A was maintained at $-42.9 \pm 0.1°$, and no change (±0.2 mm.) was noted in the level of the meniscus. When correction is made for the ammonia gas which entered the evacuated chamber D, the meniscus rise is 0.5 ± 0.2 mm. The analysis for sodium indicated 3.0 mg., which must be taken as a minimum since no allowance was made for solubility loss of hydrogen in the gasometer. These data lead to an apparent molar volume of 52 cc. (5.3 mg. of sodium by weighing) or 92 cc. (3.0 mg. of sodium by analysis). The concentration of the solution was 2.1×10^{-3} molar or 1.2×10^{-3} molar, respectively.

It is clear that these results are not in accord with those of Ogg and conform to those of Kraus. Assuming the solutions to have the same coefficient of expansion as

ammonia itself, it can easily be seen that temperature variations cannot account for the difference from Ogg's result. To agree with his results the elevation of the meniscus would have had to be about ten times the values (3.0 and 0.5 mm.) we observed.

The Preparation of Some Cyclic Acetals

BY M. SULZBACHER, E. BERGMANN AND E. R. PARISER

The present investigation of cyclic acetal derivatives of ethylene glycol (1,3-dioxolanes) was undertaken because of their possible convertibility, by hydrogenolysis, into ethylene glycol monoalkyl ethers,[1] not always available by the usual methods. It was known that aldehydes condense with ethylene glycol without catalyst[2] and that acidic substances accelerate the reaction.[3] It was also known that ketones which cannot easily be acetalated by monohydric alcohols, are capable of such zene in presence of the catalyst.[4,5,6] The time required for the liberation of the theoretically expected quantity of water gives an at least qualitative indication of the reactivity of the carbonyl compounds. From Table I in which our results are briefly summarized, the following conclusions can be drawn: Benzaldehyde has approximately the same reactivity as heptaldehyde. As in many other instances,[7] a 4-methoxy group decreases, while halogen, even in ortho-position, increases the activity of the carbonyl group. Among the ketones, those containing the $-CH_2-CO-CH_2-$ group, are most active, and in the case of cyclohexanone, even an ortho-methyl group does not affect the activity. Bulky radicals, as in the case of pinacolone, acetophenone and benzophenone deactivate the carbonyl group. Methyl isobutyl ketone shows an unexpectedly slow reaction, although it contains the group $-CH_2-CO-CH_2-$. This recalls the inactivity of that ketone in other instances, *e.g.* in the condensation with chloroform.[8] Mesityl oxide behaves in a

catalyzed condensation with glycols; *p*-toluenesulfonic acid has proved to be an efficient catalyst.[4] Without catalyst, the reaction is extremely slow: in the same period in which cyclohexanone, *e.g.*, reacts completely with glycol in presence of the above acid, the reaction proceeds only to an extent of 10% in its absence.

The most convenient method for the preparation of the acetals consists in the azeotropic distillation of the mixture of the components with benmanner similar to that of its hydrogenation product, methyl isobutyl ketone.

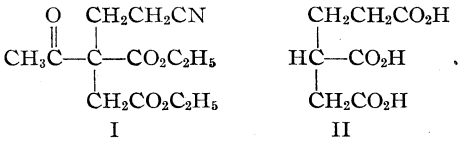
A New Synthesis of Butane-1,2,4-tricarboxylic Acid

BY P. O. TAWNEY AND E. J. PRILL

Butane-1,2,4-tricarboxylic acid (II) has been prepared by various methods.[1] We report herein a new synthesis of this compound.

Diethyl acetosuccinate[2] was treated with acrylonitrile in the presence of a basic catalyst to give a monocyanoethyl derivative (I). The structure of the adduct was demonstrated to be 1-cyano-3-acetyl-3,4-dicarboethoxybutane (I) through conversion to butane-1,2,4-tricarboxylic acid (II) and acetic acid by hydrolysis with concentrated, aqueous potassium hydroxide.



I II

Experimental

1-Cyano-3-acetyl-3,4-dicarboethoxybutane (I).—Potassium hydroxide (1.5 ml. of 50% aqueous solution) was added to a stirred solution of diethyl acetosuccinate[2] (164.8 g., 0.3 mole) and acrylonitrile (18.0 g., 0.34 mole). The temperature of the slightly exothermic reaction was kept at 30–35° by occasional cooling using an ice-bath. After three days at room temperature, the mixture was diluted with 2 vols. of chloroform. The resulting solution was washed successively with saturated sodium bicarbonate solution, dilute sulfuric acid and water. The solvent was removed by distillation at atmospheric pressure and the residue was fractionated at 1 mm.

Fraction I, b. p. 85–120°, 13.0 g. was recovered acetosuccinic ester. Fraction III, b. p. 154–160°, 55.0 g., (87% yield), $n^{20}D$ 1.4556, d^{20}_{20} 1.1186 was the desired 1-cyano-3-acetyl-3,4-dicarboethoxybutane.

Anal. Calcd. for $C_{13}H_{19}O_5N$: C, 58.0; H, 7.07; N, 5.2. Found: C, 58.15; H, 7.05; N, 5.07.

Butane-1,2,4-tricarboxylic Acid (II).—The ester (I) (68.0 g., 0.25 mole) was added in forty-five minutes with stirring to 120 ml. of 58% potassium hydroxide kept at 75–80°. The mixture was stirred for one hour at 75° and one hour at 100°. At the latter temperature ethanol and ammonia was removed by distillation. The solution was then cooled and acidified using 250 ml. of 35% sulfuric acid. The resulting mixture was subjected to continuous extraction with ether for forty-eight hours. After evaporation of the ether, acetic acid and water were removed from the residue by distillation under reduced pressure. The acetic acid was identified as *p*-phenylphenacyl acetate.[3] The crude product (40.5 g.) was crystallized from ethyl acetate to give 29.5 g. (62%) of white crystals, m. p. 120–121°. The reported[1] melting points for butane-1,2,4-tricarboxylic acid vary from 114° to 123–123.5°.

The Preparation of Fluoroacetyl Chloride

BY WILLIAM E. TRUCE

The synthesis of fluoroacetyl chloride was undertaken because of its potential value for directly introducing the group, $-COCH_2F$, into organic molecules. Such applications are being studied at this laboratory.

Experimental

Fluoroacetyl Chloride.—(Caution! Fluoroacetic acid, sodium fluoroacetate and fluoroacetyl chloride are potent poisons. The following reactions should be carried out under a hood.) Two hundred twenty grams (2.27 moles) of sodium fluoroacetate (Monsanto Chemical Co., 90% min. purity) and 530 g. (2.49 moles) of phosphorus pentachloride are mixed in a two-liter, round-bottom flask. The flask is immediately connected to a condenser arranged for downward distillation. The receiver is open to the atmosphere through a drying tube. When the initial reaction subsides, the flask is heated on a steam-bath until no further distillate comes over. The weight of distillate is 154 g. (1.60 moles). This material is redistilled through a 120-cm. helix-packed column. The fraction boiling at 70–71° (755 mm.) is collected. The colorless liquid weighs 123 g. and has $n^{27}D$ 1.3835.

Anal. Calcd. for C_2H_2ClFO: Cl, 36.7; neut. eq., 48.2. Found: Cl, 36.5; neut. eq., 47.9.

After standing for three weeks at room temperature, the compound was redistilled through the 120-cm. helix-packed column. Eighty-three per cent. of the material was recovered as a fraction boiling at 70–71° (755 mm.), signifying that fluorine–chlorine interchange was not great. A forerun, amounting to 6–7%, boiled at 62–70° (755 mm.). Since the column had a large hold-up, the rest of the material was accounted for in this way.

Fluoroacetamide.—This compound was prepared from fluoroacetyl chloride by the procedure used to make trifluoroacetamide.[1] The yield of crude fluoroacetamide is 73%. The product on recrystallization from chloroform melts at 107–108°. Fluoroacetamide has been prepared by other methods and the melting points reported are 104°,[2] 108°[3] and 108°.[4] This material gave no depression in melting point when mixed with an authentic sample of fluoroacetamide.[2]

Anal. Calcd. for C_2H_4FNO: N, 18.18. Found: N, 18.16.

A New Synthesis of O-Substituted Hydroxylamines

BY PRICE TRUITT, LOREN M. LONG AND MARJORIE MATTISON

It has been reported[1] that monochloramine condenses with substances containing the =N—CS—S—Na group.

$$(CH_3)N—CS—S—Na + ClNH_2 \longrightarrow (CH_3)_2N—CS—S—NH_2 + NaCl$$

This suggested the possibility of the analogous reaction of chloroamine with sodium alcoholates to give O-substituted hydroxylamines.

$$RONa + ClNH_2 \longrightarrow RONH_2 + NaCl$$

This method has been applied with the sodium salts of β-phenoxyethanol and benzyl alcohol, giving very poor yields (1 to 5%) of the hydroxylamines. However, similar attempts with isoamyl, cyclohexyl, β-phenylethyl and 4-methoxybenzyl alcohols failed to give the desired products, ammonia (as ammonium chloride) being isolated in each case. This reaction is being studied further, using monochloroamine and various substituted chloroamines.

Experimental

An ether solution of monochloroamine was added to a stirred solution of the alcoholate in benzene, cooled in an ice-salt-bath. A white precipitate appeared at once. The reaction mixture was stirred in the ice-salt-bath for several hours (at room temperature overnight), and refluxed for one hour, cooled and poured into water. The ethereal extract was extracted with 10% hydrochloric acid and the acid layer was concentrated at reduced pressure. When white crystals appeared, the cooled mixture was filtered, the solid product washed with absolute ether and recrystallized from a mixture of absolute ethanol and ether.

One mole of β-phenoxyethanol, 0.25 mole of sodium and 0.081 mole of monochloroamine gave 0.8 g. of O-β-phenoxyethylhydroxylamine hydrochloride melting at 172–174° with decomposition.

Anal. Calcd. for $C_8H_{12}O_2NCl$: N, 7.39; Cl, 18.70. Found: N, 7.57; Cl, 18.56.

One-half mole of benzyl alcohol, 0.25 mole of sodium and 0.155 mole of monochloroamine gave 0.25 g. of O-benzylhydroxylamine hydrochloride melting at 229–235° with decomposition. Behrend[2] reported the melting point of this compound as 229–235°.

Anal. Calcd. for $C_7H_{10}ONCl$: N, 8.78. Found: N, 8.83.

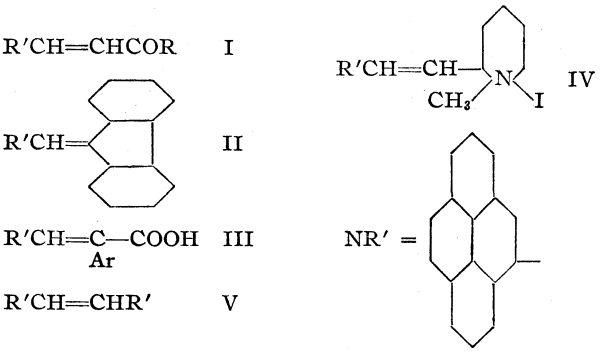
Reactions of Pyrene-3-aldehyde

BY M. WEIZMANN AND E. BOGRACHOV

Pyrene-3-aldehyde reacts readily with the reactive methylene groups in malonic acid[1] and nitromethane.[2] A number of other condensation reactions have been studied, all leading to colored substances characterized by extended conjugated systems. With various methyl ketones (3-pyrenylidene)-compounds of type (I) have been obtained; fluorene gave 9-(3′-pyrenylidene)-fluorene (II) and phenylacetic and α-naphthylacetic acids condensed to form the corresponding α-aryl-β-(3-pyrenyl)-acrylic acids (III). From the methiodides of picoline, lutidine and quinaldine, stilbazole homologs were formed, *e. g.*, α-(3-pyrenyl)-β-(2′-pyridyl)-ethylene methiodide (IV). Another substance which belongs in this group is *sym*-di-(3-pyrenyl)-ethylene (V) available from (polymeric) pyrene-3-thioaldehyde by heating it in boiling ethyl benzoate or naphthalene, with or without Raney nickel.



Experimental

Condensation of Pyrene-3-aldehyde with Methyl Ketones

(a) **Acetone.**—To a solution of 4.6 g. of pyrene-3-aldehyde in 40 cc. of acetone, 1 cc. of a concentrated aqueous solution of sodium hydroxide was added with stirring. The stirring was continued for two hours, and the voluminous precipitate filtered off, washed with alcohol and acetone, and dried. The yellow 3-pyrenylideneacetone (I, R = CH_3) crystallized from acetic acid (or butanol); m. p. 152°. The yield was almost quantitative.

Anal. Calcd. for $C_{20}H_{14}O$: C, 88.9; H, 5.2. Found: C, 88.7; H, 5.1.

The phenylhydrazone, prepared in acetic acid solution, separated after twenty-four hours; the orange-yellow plates were recrystallized from butanol; m. p. 238°.

Anal. Calcd. for $C_{26}H_{20}N_2$: N, 8.0. Found: N, 7.8.

(b) **Pinacolone.**—To a concentrated solution of 4.6 g. of pyrene-3-aldehyde in absolute alcohol, gradually 1 g. of sodium metal, and then 2 g. of pinacolone were added. After a while, the yellow crystals of 3-pyrenylidenepinacolone (I, R = —$C(CH_3)_3$) began to precipitate; after recrystallization from glacial acetic acid, it melted at 155°; yield, 80%.

Anal. Calcd. for $C_{23}H_{20}O$: C, 88.5; H, 6.4. Found: C, 88.6; H, 6.4.

The picrate, prepared in glacial acetic acid solution, formed red leaflets, m. p. 150°.

Anal. Calcd. for $C_{29}H_{23}O_8N_3$; N, 7.8. Found: N, 7.8.

(c) **Acetophenone.**—In the manner described for pinacolone, 2.2 g. of acetophenone gave, in almost quantitative yield, the deep yellow 3-pyrenylideneacetophe-

(2) E. Bograchov, *ibid.*, **66**, 1612 (1944).

none (I, R = C_6H_5). It was recrystallized from glacial acetic acid, xylene or butanol and melted at 158°.

Anal. Calcd. for $C_{25}H_{16}O$: C, 90.4; H, 4.8. Found: C, 90.2; H, 4.8.

The yellow **phenylhydrazone**, recrystallized from xylene, melted at 236°.

Anal. Calcd. for $C_{31}H_{22}N_2$: N, 6.6. Found: N, 7.0.

(d) β-Acetylnaphthalene.—Analogously, 3.4 g. of β-acetylnaphthalene gave an almost quantitative yield of the yellow α-(2-naphthoyl)-β-(3′-pyrenyl)-ethylene (I, R = β-naphthyl). Recrystallization from xylene or glacial acetic acid gave crystals, melting at 184°.

Anal. Calcd. for $C_{29}H_{18}O$: C, 91.1; H, 4.7. Found: C, 90.9; H, 4.6.

The orange-colored **phenylhydrazone** crystallized from xylene, and melted at 246°.

Anal. Calcd. for $C_{35}H_{24}N_2$: N, 5.9. Found: N, 6.2.

9-(3′-Pyrenylidene)-fluorene.—The condensation of 4.6 g. of the aldehyde with 3.3 g. of fluorene was carried out, using sodium ethoxide as catalyst.[3] The yellow-orange fulvene (II) separated spontaneously from the solution, and melted after recrystallization from xylene, butanol or glacial acetic acid at 210°.

Anal. Calcd. for $C_{30}H_{18}$: C, 95.2; H, 4.8. Found: C, 94.9; H, 5.0.

α-Phenyl-β-(3-pyrenyl)-acrylic Acid (III, R = C_6H_5).—One mole each of pyrene-3-aldehyde and sodium phenylacetate was heated in boiling acetic anhydride (1.5 to 2 moles) for two hours. After cooling, the reaction mixture was diluted with water, and the solid residue filtered and washed with alcohol. From glacial acetic acid, the acid was obtained in yellow needles of m. p. 259°; yield, 30%.

Anal. Calcd. for $C_{25}H_{16}O_2$: C, 86.2; H, 4.6. Found: C, 86.5; H, 4.9.

α-(1-Naphthyl)-β-(3′-pyrenyl)-acrylic acid (III, R = 1-naphthyl) was obtained analogously from pyrene-3-aldehyde and sodium 1-naphthylacetate; yellow needles of m. p. 290° (from nitrobenzene).

Anal. Calcd. for $C_{29}H_{18}O_2$: C, 87.4; H, 4.5. Found: C, 87.1; H, 4.7.

α-(3-Pyrenyl)-β-(2′-pyridyl)-ethylene Methiodide (IV).—To a solution of pyrene-3-aldehyde (4 g.) and α-picoline methiodide (4 g.) in a small quantity of absolute alcohol, 10 to 15 drops of piperidine was added at 180°. Heating was continued for thirty minutes; then the red precipitate was filtered, washed with alcohol, dried, and recrystallized from nitrobenzene: m. p. 295°; yield, 65%.

Anal. Calcd. for $C_{24}H_{18}IN$: C, 64.4; H, 4.0; N, 3.1. Found: C, 64.1; H, 4.0; N, 3.3.

α-(3-Pyrenyl)-β-(6′-methyl-pyridyl-2′)-ethylene methiodide was prepared in 70% yield from 2.3 g. of pyrene-3-aldehyde and 4 g. of 2,6-lutidine methiodide, as described above. It was recrystallized from nitrobenzene, and formed red shiny crystals of m. p. 275°.

Anal. Calcd. for $C_{25}H_{20}IN$: N, 3.0. Found: N, 3.1.

α-(3-Pyrenyl)-β-(2′-quinolyl)-ethylene methiodide was formed in 75% yield as a red-violet, insoluble substance from 2.3 g. of pyrene-3-aldehyde and 2.8 g. of quinaldine methiodide; m. p. 285°.

Anal. Calcd. for $C_{28}H_{20}IN$: N, 2.8. Found: N, 2.8.

***sym*-Di-(3-pyrenyl)-ethylene** (V).—(a) 10 g. of pyrene-3-aldehyde was dissolved in 100 ml. of dry benzene. Dry hydrogen chloride and hydrogen sulfide were passed simultaneously through the cold solution. The yellow precipitate was filtered and washed with water, alcohol and ether. It could not be recrystallized, as it decomposed on heating in high-boiling solvents. In its crude state the polymeric pyrene-3-thioaldehyde melted at 260–270°.

(3) Schlenk and Bergmann, *Ann.*, **479**, 56 (1930).

Anal. Calcd. for $(C_{17}H_{10}S)_x$: C, 82.9; H, 4.1. Found: C, 82.5; H, 4.4.

(b) A mixture of 2 g. of the thioaldehyde, 1 g. of Raney nickel and 20 g. of boiling naphthalene was heated for one hour. After removal of the naphthalene *in vacuo*, a brown-red residue was obtained, which was washed with alcohol and recrystallized from ethyl benzoate: m. p. 315°; yield, 75% (calculated on pyrene-3-aldehyde).

Anal. Calcd. for $C_{34}H_{20}$: C, 95.3; H, 4.7. Found: C, 95.1; H, 4.8.

The Di-fluorobibenzyls

The first stage in the pyrolysis of toluene was shown[1] to be the formation of the benzyl radical and a hydrogen atom. The benzyl radicals thus formed subsequently dimerized to bibenzyl.

Recent investigation of the pyrolysis of the fluorotoluenes[2] showed the same type of decomposition. The fluorobenzyl radicals produced in this way dimerized to the corresponding di-fluorobibenzyls, isolated as previously described.[1,2] The melting points, boiling points and the results of analysis of di-fluorobenzyls thus obtained are summarized in the following Table.

All these compounds have a strong smell very similar to that of bibenzyl. Boiling points were determined by the micro-method of Siwoloboff.[3] A correction of +4° was introduced by comparing the boiling point of bibenzyl actually determined in this way (280–281°) with that stated in the literature (284°). Molecular weights were estimated by the Rast method.

We are indebted to Professor M. Stacey of the University of Birmingham for the fluorine analyses.

COMMUNICATIONS TO THE EDITOR

CHAIN ELECTROLYTES[1]

Sir:

We are studying polyelectrolytes in which chain atoms carry ionic charges. Typical is the polyelectrolyte (I) formed by the addition of methyl bromide to the polyester obtained from methyldiethanolamine and succinic anhydride

(I) $HO[CO(CH_2)_2COO(CH_2)_2N^+Me_2(CH_2)_2O]_nH—nBr'$

Theoretical bromide for n infinite is 26.99%; two different preparations gave 22.73 and 23.38%, indicating incomplete addition of methyl bromide. End-group titrations gave molecular weights of 3515 and 2720. The salt hydrolyzes in water but is stable in methanol.

At 1.2 g./100 cc. in methanol, (I) has a reduced viscosity of 0.091. For comparison, polyvinylpyridine with molecular weight 80,000 has an intrinsic viscosity of only 0.15. High viscosities thus seem to be characteristic of polyelectrolytes[2] regardless of the location of the charges.

Conductance curves in methanol are shown in Fig. 1, where concentration is stoichiometric normality of bromide. The marked curvature indicates a high degree of association of counter ions to the polycations. Ordinary electrolytes, such as the addition product (II) of methyl bromide to methyldiethanolamine, are only slightly associated in solvents with high dielectric constant, as shown by the approach to the Onsager limiting slope. In our polysalts, ten positive charges are constrained to remain near each other, regardless of dilution. A bromide ion has a potential energy large compared to kT in the resulting field and therefore at finite concentrations, a certain fraction of bromide ions accompany the polycations. The polycations thus act like droplets of concentrated solution within the liquid, regardless of total dilution. The polycation configuration will, however, depend on dilution: with decreasing total concentration, probability of escape of bromide ions from the field of the polycation will increase, and intramolecular mutual repulsion between unpaired charges on chain nitrogens will then cause the chain to uncoil.

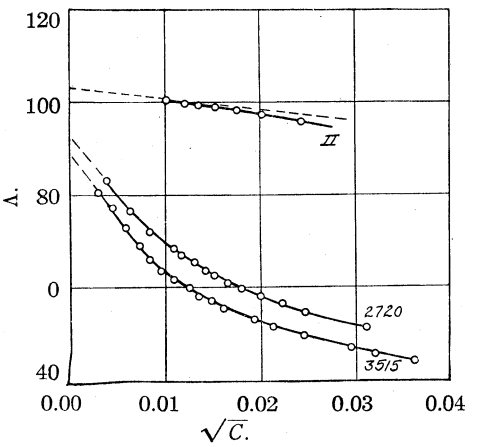

Fig. 1.—Conductance of salts I and II in methanol.

ULTRAVIOLET ABSORPTION BANDS OF IODINE IN AROMATIC HYDROCARBONS

Sir:

In the course of an investigation of the nature of the solvent–solute interaction in solutions of iodine now in progress, new evidence has been found for the presence of addition compounds of iodine and the solvent molecule. We find that the absorption spectrum of the violet-red solution of iodine in benzene shows in addition to the well known absorption maximum at 5000 Å. with a molar extinction coefficient of 1010, an absorption maximum in the ultraviolet region at 2970 Å. having a molar extinction coefficient (based on the iodine concentration) of 9600. This new absorption peak does not appear in solutions of iodine in hexane and carbon tetrachloride which are a pure violet with absorption peaks at 5200 Å. in the visible region. The evidence therefore points to the presence of an iodine–benzene complex. Preliminary measurements show that the height of the absorption peak at 2970 Å. is directly proportional to both the iodine concentration and the benzene concentration, indicating that the addition compound consists of one molecule of iodine bound to one molecule of benzene.

A possible explanation for the presence of such a complex appears to lie in an acid–base interaction in the electron donor–acceptor sense such as we see in the union of I^-, the base, with I_2, the acid, to form I_3^-. Evidence of basic character in benzene is its union with boron trifluoride, boron trichloride and with concentrated sulfuric acid. Additional evidence in support of this hypothesis is to be found in the recent work of Fairbrother,[1] who reports that iodine has an abnormally high dielectric polarization in such solvents as benzene, *p*-xylene, dioxane and di-isobutylene. If this basic character of benzene is also responsible for its union with iodine, then the substitution of methyl groups should increase basic strength and ability to interact with iodine. This is borne

(1) F. Fairbrother, *Nature*, **160**, 87 (1947).

out by the fact that a simple visual examination of iodine solutions of equal concentration in benzene, toluene, *o*-xylene, mesitylene and α-methylnaphthalene shows that the color shifts stepwise in that order ending with a brown solution. Preliminary measurements of the absorption spectra of these iodine solutions show an absorption band in the ultraviolet region similar to that of benzene.

This work is being continued and a complete report of the results will be given in a paper soon to be submitted for publication.

β-PELTATIN, A NEW COMPONENT OF PODOPHYLLIN

Sir:

The fractionation of the drug podophyllin by chromatographic adsorption on alumina has yielded, beside podophyllotoxin and α-peltatin,[1] a new crystalline substance in about 4% yield for which the name β-peltatin is proposed. The new compound possesses about the same high necrotizing activity[2] for mouse sarcoma 37 as α-peltatin.

β-Peltatin crystallizes from alcohol in colorless, transparent prisms, m. p. 231.1–238.0° (shrinks at 225.5°) cor.; $[\alpha]^{20}D$ −115° (*c*, 1.009, absolute alcohol). *Anal.*[3] Calcd. for $C_{22}H_{22}O_8$: C, 63.75; H, 5.35. Found: C, 64.0; H, 5.6. Calcd. for three methoxyl groups: 22.5; found, 22.2. Molecular weight values (Rast) for derivatives of both α- and β-peltatin agree with the formula $C_{22}H_{22}O_8$ and indicate that the peltatins are thus isomeric with podophyllotoxin.[4] α-Peltatin has one less methoxyl group than β-peltatin and podophyllotoxin.

Beside the methoxyl content, α- and β-peltatin differ in their color reactions with sulfuric acid and in the properties of their derivatives. With concentrated sulfuric acid, both peltatins give an immediate yellow color, rapidly turning reddish brown with α-peltatin and green with β-peltatin; the final color with both peltatins is red. A series of derivatives of the peltatins has been prepared and will be reported at a later date.

Structural and biological studies with β-peltatin are in progress.

THE CRYSTALLINE TRIHYDROCHLORIDES OF STREPTOMYCIN AND MANNOSIDOSTREPTOMYCIN

Sir:

The preparation of the crystalline reineckate, sulfate,[1] helianthate,[2] and the calcium chloride double salt[2] of streptomycin and the reineckate of mannosidostreptomycin[3] has been reported. To date, there has been no published information on the crystallization of a simple mineral acid salt of either of these antibiotics. We now wish to report that, starting with relatively pure material, we have obtained the trihydrochlorides of streptomycin and mannosidostreptomycin in the crystalline state from methanol solution.

The streptomycin trihydrochloride crystallizes with two molecules of water of crystallization as monoclinic prisms showing birefringence. The crystalline material was shown to be a single substance by a modification of the Craig countercurrent distribution technique[4] and thus to be free of mannosidostreptomycin. On heating on the hot-stage, the dihydrate decomposes gradually without melting. When the trihydrochloride was dried at 55° *in vacuo*, it had the following analytical composition: C, 34.86; H, 6.36; Cl, 14.25 (Calcd. for $C_{21}H_{39}N_7O_{12}\cdot 3HCl\cdot 2H_2O$: C, 34.54; H, 6.36; Cl, 14.57). After drying at 100° *in vacuo*, the anhydrous material showed $[\alpha]^{26.6}D$ −86.1° (1.0% in water) and the following analytical data were obtained: C, 36.27; H, 6.14; N, 14.29; Cl, 15.69 (Calcd. for $C_{21}H_{39}N_7O_{12}\cdot 3HCl$; C, 36.50; H, 6.13; N, 14.19; Cl, 15.40).

When assayed with *K. pneumoniae* in a broth-dilution test,[5] the trihydrochloride dihydrate had a potency of 820 units/mg. and on this basis the anhydrous material would have an activity of 891 units/mg.[6]

The trihydrochloride of mannosidostreptomycin crystallizes in the form of hexagonal plates which are isotropic. By means of the counter-current distribution method,[4] this material was also shown to be a single entity and to be free of streptomycin.

After drying at 55° *in vacuo*, the trihydrochloride was found to have the following analysis: C, 36.45; H, 6.26; Cl, 12.14 (Calcd. for $C_{27}H_{49}N_7O_{17}\cdot 3HCl\cdot 2H_2O$: C, 36.47; H, 6.35; Cl, 11.96). When dried at 100° *in vacuo*, the anhydrous material showed $[\alpha]^{26.6}D$ −54.1° (1.0% in water)

and gave analytical data: C, 38.25; H, 6.22; N, 11.31; Cl, 12.52 (Calcd. for $C_{27}H_{49}O_7O_{17}\cdot 3HCl$: C, 38.01; H, 6.14; N, 11.49; Cl, 12.47).

When assayed with *K. pneumoniae* in a broth dilution test,[5] the anhydrous mannosidostreptomycin had a potency of *circa* 210 units/mg.[6]

Additional information on the properties and activities of these crystalline hydrochlorides will be published at a later date.

We wish to express our appreciation to Dr. R. Donovick, Mr. R. Blue, and Mr. D. Lapedes for the bio-assays, Mr. F. Russo-Alesi for the countercurrent distributions, and Mr. J. Alicino for the micro-analysis.

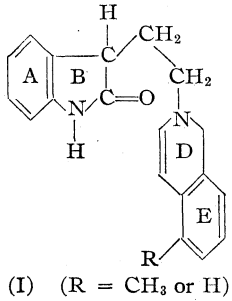
THE SYNTHESIS OF KETOYOBYRINE

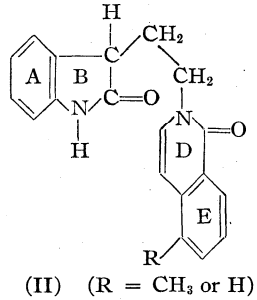
Sir:

For several years we have been investigating the possibility of synthesizing the basic ring structure of yohimbine by ring closure of isoquinolylethyl oxindoles of the type represented by formula (I).[1] The introduction of the double bond in ring D presented numerous difficulties because of the ease with which compounds of the type (I) (as well as the yohimbine molecule itself) suffer cleavage at the nitrogen atom of ring D. Moreover, we have pointed out[1] that 1,2-dihydroisoquinolines like (I) are virtually unknown.

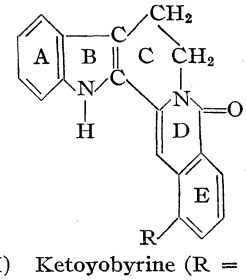
Accordingly, our efforts were later directed toward the preparation and ring closure of compounds of the type represented by formula (II)



(I) (R = CH_3 or H)



(II) (R = CH_3 or H)



(III) Ketoyobyrine (R = CH_3)

where the appropriate double bond of ring D could be introduced without difficulty. Ring closure of such a compound would lead to compounds of the structure (III), which type of structure has recently been proposed for ketoyobyrine, on the basis of an exhaustive study of its chemistry[2a] and likewise on the basis of a comparison of its absorption spectrum with that of rutaecarpine.[2b]

Pending more complete presentation of our various syntheses of the type of structure represented by (III), we wish to record our synthetic confirmation of this proposed structure for ketoyobyrine.

6-Methylhomophthalic acid, m. p. 196°, was prepared from *o*-tolylacetic acid[3] by conversion *via* the Arndt–Eistert reaction into *o*-tolylpropionic acid, which was then treated according to the method of Mercer and Robertson.[4] Condensation with tryptamine yielded N-(β-indolylethyl)-6-methylhomophthalimide, m. p. 228°. Conversion of the latter into the corresponding homophthalamic acid,[5] m. p. of picrate 147°, methylation of the acid with diazomethane, m. p. of methyl ester 222°, dec., followed by ring closure with phosphorus oxychloride, yielded ketoyobyrine, m. p. 316–318°, dec.

Anal. Calcd. for $C_{20}H_{16}ON_2$: C, 79.98; H, 5.37; N, 9.32. Found: C, 79.43; H, 5.55; N, 9.24. Comparisons of the ultraviolet absorption spectrum of synthetic ketoyobyrine with that of the product of natural origin showed the two to be identical. Absorption maxima for synthetic material: at 385, 366 and 340 mμ, log ε 4.40, 4.51 and 4.52, respectively.

THE OZONIZATION OF THE MALEIC ANHYDRIDE ADDUCT OF DEHYDROERGOSTERYL ACETATE

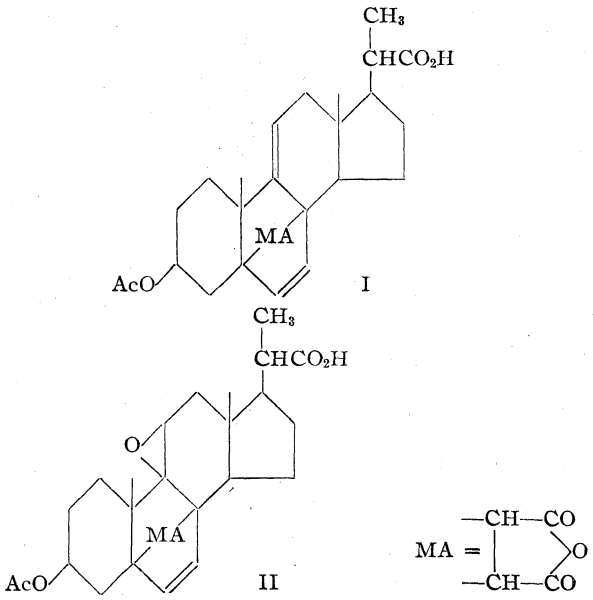
Sir:

A recent publication of Bergmann and Stevens[1] describes the preparation of the maleic anhydride adduct of 3(β)-acetoxy-9,11-oxidobisnor-5,7-choladienic acid (II) by the ozonization of 9,11-oxidoergosteryl acetate–maleic anhydride adduct. For some time previous a study of analogous reactions has been under way in our laboratories and we now wish to report the preparation of the maleic anhydride adduct of 3(β)-acetoxybisnor-5,7,9-cholatrienic acid (I) by the selective ozonization of 9,11-dehydroergosteryl acetate–maleic anhydride adduct (III).

A solution of the dehydroadduct (III) in methylene chloride was treated with two equiva-

(1) Julian, Magnani, Pikl and Karpel, THIS JOURNAL, **70**, 174 (1948).

(1) Bergmann and Stevens, *J. Org. Chem.*, **13**, 10 (1948).



lents of ozone at −30°. The methylene chloride was replaced with glacial acetic acid and the ozonide decomposed with zinc dust. After separation of the zinc, the acetic acid solution was treated with chromic acid in acetic acid at 20° for three hours and the excess chromic acid was decomposed with sodium bisulfite solution. The reaction mixture was poured into water and the precipitate of the bisnor acid (I), m.p. 226–237°, was separated by filtration. For analysis, the acid (I) was crystallized from ether–hexane, m.p. 240–243°. The yield of pure acid (I) was 55% of the theoretical.

Anal. Calcd, for $C_{28}H_{34}O_7$: C, 69.69; H, 7.10; Found: C, 69.73; H, 7.10.

Treatment of the acid (I) with diazomethane in methylene chloride gave the maleic anhydride adduct of methyl 3(β)-acetoxybisnor-5,7,9-cholatrienate (IV), m.p. 246–248°. *Anal.* Calcd. for $C_{29}H_{36}O_7$: C, 70.14; H, 7.31. Found: C, 69.98; H, 7.48. After saponification, methylation with diazomethane, and acetylation with acetic anhydride, the trimethyl ester of the maleic acid adduct of 3(β)-acetoxybisnor-5,7,9-cholatrienic acid (V) was obtained, m.p. 193–195°. *Anal.* Calcd. for $C_{31}H_{42}O_8$: C, 68.61; H, 7.80. Found: C, 68.66; H, 7.65. The trimethyl ester of the maleic acid adduct of 3(β)-acetoxy-9,11-oxidobisnor-5,7-choladienic acid (VI) was prepared by treating the acetoxytrimethyl ester (V) with monoperphthalic acid. It was crystallized from ether, m.p. 208–209.5°. *Anal.* Calcd. for $C_{31}H_{42}O_9$: C, 66.64; H, 7.58. Found: C, 66.76; H, 7.64.

The 9,11-oxido compound was also prepared from the methyl ester of I by perphthalic acid treatment and had a melting point of 263–265° (block), which is in fair agreement with that reported for the methyl ester of II by Bergmann and Stevens.[1]

Details of this work, together with further conversions of compound I, will be published at a later date.

DEGRADATIVE STUDIES ON STREPTOMYCIN

Sir:

Degradation of dihydrostreptomycin with barium hydroxide under conditions which convert streptidine to streptamine[1] yielded an amorphous, antibiotically inactive product containing barium chloride. This substance was acetylated with pyridine and acetic anhydride to a crystalline compound (I), m. p. 261.5–262.5°, $[\alpha]^{23}D$ −84° (*c* 1, water).

Anal. Calcd. for $C_{16}H_{24}O_{12}N_3(CH_3C)(COCH_3)_{10}$: C, 50.92; H, 6.25; N, 4.57; O-acetyl, 7.61 cc. of 0.1 *N* NaOH per 100 mg. CH_3-C, 32.3: mol. wt., 919.9. Found: C, 50.64; H, 6.17; N, 4.47; O-acetyl,[2] 7.37 cc.; CH_3-C,[3] 32.3; mol. wt., 920 (Rast).

Methanolysis of I with subsequent reacetylation yielded hexaacetylstreptamine,[1,4] transition point[1] 250°, m. p. 341–345°, N, 6.61% (calcd. 6.50), and methyl pentaacetyldihydro-α-L-streptobiosamide,[5–8] m. p. 194–195°, unchanged on admixture with a specimen prepared from dihydrostreptomycin trihydrochloride, $[\alpha]^{23}D$ −120° (*c* 0.5, chloroform). I is designated decaacetyldideguanyldihydrostreptomycin. It was found to be readily soluble in methanol, water and hot ethanol, sparingly so in chloroform, ethyl acetate and ethanol, and insoluble in benzene and ethyl ether.

Aqueous solutions of N,N,N-tetraacetyldideguanyldihydrostreptomycin (II), N^1,N^3-diacetylstreptamine (III) and N-acetyldihydro-α-L-streptobiosaminide (IV) were prepared by partial deacetylation of the aforementioned acetyl derivatives with 0.05 *N* sodium hydroxide in water–dioxane. These N-acetates were subjected to oxidation with a large excess of buffered periodate at *p*H 4.9 and 20.0° and showed the following

(10) Bristol Laboratories Research Fellow of the Ohio State University Research Foundation (Project 224).

NEW BOOK

The Chemistry of the Carbon Compounds. BY VICTOR VON RICHTER. Edited by the late Professor Richard Anschütz. Vol. IV. "The Heterocyclic Compounds," By F. Reindel (translated by M. F. Darken) and "Organic Free Radicals" by Ludwig Anschütz (translated by A. J. Mee). Newly translated from the Twelfth German Edition. Elsevier Publishing Co., Inc., 215 Fourth Ave., New York 3, N. Y., 1947. xv + 498 pp. 14.5 × 22.5 cm. Price, $12.00.

This volume is a literal translation of the sections on Heterocyclic Compounds and Free Radicals in the twelfth German edition of this celebrated treatise. The appearance of Volume IV makes the entire twelfth edition available in English. Users will find the new volume to be a concise and, except for the more recent work, a comprehensive guide to the literature of the subjects treated.

REYNOLD C. FUSON
