α-Piperidyldesoxybenzoin, which had been obtained previously in low yield by Rabe,[10] has now been made by allowing 0.5 mole of desyl chloride to react in ether solution with 1.5 moles of piperidine (twenty-four hours at room temperature). The precipitated piperidine hydrochloride was filtered and the ether evaporated. The crude yellow product was not pure after repeated crystallizations and though nearly colorless it gave low yields of the amino alcohol upon reduction. Purification was effected by washing several times with water, dissolving in 2 l. of 0.5 *N* hydrochloric acid, filtering from an orange-colored residue, extracting by a small amount of benzene, and neutralizing carefully with ammonium hydroxide. It crystallized as white fibrous needles of m. p. 82–83° (Rabe,[10] 82°).

Preparation of Amino Alcohols (IX) by Reduction of the Amino Ketones (Method 1).—A solution of the amino ketone hydrochloride and four equivalents of 3 *N* aluminum isopropoxide in an excess of isopropanol was refluxed until the test for acetone in the distillate became negligible. The excess solvent was distilled under reduced pressure and the residue was treated with an excess of 30% sodium hydroxide, and then with water. The precipitated, crude amino alcohol was filtered, washed, dried and recrystallized. (a) In one case the oily diethylaminopropylamino alcohol was taken up in ether, dried over sodium sulfate and precipitated as the dihydrochloride by ethereal hydrogen chloride; the base was then liberated by means of ammonium hydroxide and was recrystallized. (b) In another case, the oily morpholinyl derivative was precipitated as the hydrochloride from benzene by means of ethereal hydrogen chloride.

The 1,2-Diphenyl-2-piperidylethanols-A and B. (II) Reduction of α-Piperidyldesoxybenzoin.—A solution of 67 g. (0.24 mole) of purified α-piperidyldesoxybenzoin in 400 ml. of 1.8 *N* aluminum isopropoxide was refluxed for 6.5 hours and evaporated to a volume of about 100 ml. under reduced pressure. The viscous residue was hydrolyzed by shaking for one hour with 240 ml. of 4 *N* sodium hydroxide. Extraction with ether, washing, drying over sodium sulfate, and evaporation of the ether, gave a solid which was digested with cold ethanol; yield 59 g.; m. p. 79–81°. Crystallizations from ethanol raised the melting point of this mixture only slightly. It was dissolved in acetone and converted into the hydrochlorides by addition of ethereal hydrogen chloride. Crystallization of this mixture (51 g.) from 95% ethanol gave 20 g. (30%) of pure isomer-A hydrochloride; m. p. 260° (*in vacuo*); it was shown by mixture melting point to be identical with the compound obtained from *trans* stilbene oxide. The mother liquor upon evaporating to crystallization gave 19 g. of solid isomer-B hydrochloride (m. p. 202–203°) which was converted into the base by means of ammonium hydroxide. This base was recrystallized from ethanol; 18 g. (27%); m. p. 101–102°. It was identified by mixture melting point as the same isomer (B) that was obtained from *cis*-stilbene oxide.

Isomer-A ("erythro") methiodide was prepared by the action of methanolic methyl iodide at room temperature (twelve hours).

Isomer-A ("erythro") benzoate was prepared by shaking together 2 g. of the amino alcohol, 2.9 g. of benzoyl chloride and 10 ml. of 20% sodium hydroxide. The viscous oil which separated soon solidified as the temperature rose to 60°. Recrystallization twice from ethanol gave 0.8 g. of m. p. 166.5–167°.

Isomer-B ("threo") benzoate was made by heating a mixture of the isomer-B (base) with a slight excess of benzoyl chloride (65°) for two minutes, adding dilute sodium carbonate, filtering and crystallizing from ethanol; m. p. 143–144°.

Catalytic hydrogenation of the amino ketone hydrochloride in 95% ethanol with platinum oxide catalyst was stopped after one molecule had been absorbed. The

(26) (a) Langenbeck, *C. A.*, **39**, 278 (1945) [*Oel. u. Kohle*, **40**, 206 (1944)]; (b) Schauenstein and Stampfer, *Ber.*, **77**, 19 (1944).

(27) (a) All melting points are "corrected"; (b) microanalyses were performed by Miss Geraldine Alley and Mrs. Joyce Blume Caliga.

products included some unchanged amino ketone, a 30% yield of the amino alcohol, isomer-A, and a large amount of non-basic by-products which were not further investigated.

In a 100:22 by volume mixture of 95% ethanol and concd. hydrochloric acid, reduction did not occur.

The dibenzoyl derivative of 1,2-diphenyl-2,N-benzylaminoethanol was made from the base by the action of pyridine and benzoyl chloride for fifteen minutes at 80–90°.

Preparation of the Amino Alcohols from *cis* and *trans* Stilbene Oxides (Method 2).—A mixture of *cis*[28a] or *trans*[28b] stilbene oxide (XII–XI) and an excess (20% or more) of the appropriate primary or secondary amine, was refluxed for one to eight hours, or, if the boiling point of the amine was above 150°, the reaction temperature was maintained at this point to avoid the decomposition which resulted at higher temperatures. The product was purified in one of the following ways:

(a) If the amine used was water soluble the reaction mixture was taken up in alcohol-free ether. The ether solution was washed with water, dried over sodium sulfate, and treated with ethereal hydrogen chloride to obtain the salt.

(b) If the product crystallized from the reaction mixture upon cooling it was filtered and recrystallized. The hydrochloride could then be obtained in the usual way.

(c) If the amine was water insoluble and the product did not crystallize directly on cooling, the mixture was taken up in ether and the unreacted amine was extracted with 1 *N* hydrochloric acid in which the reaction product was relatively insoluble. The ether solution containing the suspended water-insoluble salt of the reaction product was shaken with 10% sodium carbonate and was dried over sodium sulfate, and the salt was regenerated by addition of ethereal hydrogen chloride.

Reductive amination of benzil with cyclohexylamine (Method 3) was carried out using a mixture of 0.1 g. of platinum oxide (pre-reduced in the solvent), 75 ml. of absolute ethanol, 11 g. (0.1 mole) of cyclohexylamine and 10 g. (0.052 mole) of benzil. These conditions approximated those employed by Manske and Johnson in the synthesis of ephedrine.[11] Hydrogenation at atmospheric pressure was complete in nine hours.

A similar reduction using benzoin instead of benzil gave only *meso* hydrobenzoin, and this in nearly quantitative yield.

Platinum-catalyzed hydrogenation of benzil in the presence of piperidine under the above conditions gave only *meso* hydrobenzoin.

Preparation of the 1,2-Diphenyl-2-aminoethanols[15] from the Stilbene Oxides.—A mixture of 15 g. (0.0765 mole) of *trans*-stilbene oxide (XI), 25 ml. of dioxane and 35 ml. of concentrated ammonium hydroxide was heated in a sealed tube at 120° for ten hours. On cooling, a white solid (isomer-A) separated; 15 g. (92%); m. p. 160–163°. The hydrochloride was obtained by dissolving the pure base in methanol and adding concentrated hydrochloric acid until acid to congo.

The preparation of the diastereoisomer (B) from *cis*-stilbene oxide (XII) was carried out similarly.

Attempts to reduce the N-substituted tertiary ethanolamino ketones (XVIa, b, c), carried out as follows, gave in each case only unchanged material which was recovered in good yield and identified. A mixture of the amino ketone (base) (and the hydrochloride also in the case of XVIa) in 0.7–0.8 *N* aluminum isopropoxide was heated at refluxing for seven to eight hours, and was worked up in the usual way as described above.

2,3-Diphenyl-5,6-dihydro-4-ethyl-1,4-oxazine (XIX).—Two grams of the amino ketone (XVIa) was heated at 120° for fifteen minutes. One drop of concentrated hydrochloric acid was added, and the yellow salt became orange-colored. The temperature was brought to 160° for five minutes. The product crystallized on cooling and was recrystallized from ethanol; yield 1.2 g.; m. p. 88–89°. After recrystallization it melted at 89–90°; a mixture with starting material melted at 75–84°.

Anal. Calcd. for $C_{18}H_{19}NO$: C, 81.47; H, 7.22; N, 5.28. Found: C, 81.42; H, 7.22; N, 5.33.

The hydrochloride was not obtained in crystalline form. When heated with dilute hydrochloric acid the amino ketone was regenerated.

1,2-Diphenyl-3-N-morpholinylpropanone Hydrobromide,[29] $C_6H_5COCH(C_6H_5)CH_2NC_4H_8O$.—A mixture of 30 g. (0.153 mole) of desoxybenzoin, 27 g. of morpholine hydrobromide and 9 g. of paraformaldehyde in 30 ml. of absolute ethanol was refluxed for seven hours. The amino ketone hydrobromide precipitated on cooling and was crystallized from absolute ethanol; 16 g. (28%); m. p. 182–183°.

Anal. Calcd. for $C_{19}H_{21}NO_2 \cdot HBr$: N, 3.72. Found: N, 3.69.

The **hydrochloride** (SN 2589) was made similarly, starting with morpholine hydrochloride, and was crystallized from absolute ethanol; yield 43%; m. p. 176–178°.

Anal. Calcd. for $C_{19}H_{21}NO_2 \cdot HCl$: N, 4.22. Found: N, 4.02.

1,2-Diphenyl-2-hydroxy-3-N-piperidylpropanone (XX) (REL 644).—A solution of 21.2 g. (0.1 mole) of benzoin, 11 g. (0.13 mole) of piperidine, 11 g. (0.13 mole) of 35% formaldehyde in 75 ml. of ethanol was refluxed for seventy hours. (After two hours of heating an additional 5 g. of formaldehyde solution was added.) Cooling, filtering the precipitate and crystallization from ethanol gave 16.8 g. (55%); m. p. 68–69°. Recrystallizations did not raise the melting point.

Anal. Calcd. for $C_{20}H_{23}NO_2$: C, 77.64; H, 7.49; N, 4.53. Found: C, 77.37; H, 7.43; N, 4.50.

The **hydrochloride** was precipitated from acetone by ethereal hydrogen chloride (slow crystallization); m. p. 178–180° (*in vacuo*).

Anal. Calcd. for $C_{20}H_{23}NO_2 \cdot HCl$: C, 69.45; H, 6.99; N, 4.05. Found: C, 69.35; H, 6.84; N, 4.14.

Summary

Seven aliphatic α-secondary amino and the *p*-diethylaminoanilino desoxybenzoins have been made through the Voigt reaction by acid catalyzed condensation of benzoin with the appropriate primary amines. Three tertiary α-(β-hydroxyethylamino)-desoxybenzoins were made by condensing desyl chloride with the appropriate secondary amines.

Reductions of each of eight secondary and tertiary-aminodesoxybenzoins by means of aluminum isopropoxide gave one type (type-A) of amino alcohol except α-piperidyldesoxybenzoin which gave both of the two possible diastereoisomeric amino alcohols.

Six of the type-A amino alcohols including the parent aminohydrin itself, and also the compound obtained by reductive amination of benzil with cyclohexylamine, were obtained by condensation of *trans* stilbene oxide with the appropriate amines and ammonia, and four type-B stereoisomers, including the second isomer obtained in the reduction of α-piperidyldesoxybenzoin, were made similarly from *cis* stilbene oxide. The stereochemical mode of these reactions appears to be consistent.

(28) (a) Prepared according to Taylor and Crawford [*J. Chem. Soc.*, 1130 (1934)]; (b) prepared according to Tiffeneau and Levy [*Bull. soc. chim.*, **39**, 763 (1926)].

(29) *Cf.* piperidyl analog, Mannich and Lammering, *Ber.*, **55**, 3510 (1922).

The configurations of the amino alcohols have tentatively been assigned on the basis of the synthetic relation to the *cis* and *trans* stilbene oxides, assuming consistent *trans* reactions.

Because of the failure of α-(N-ethyl-N-ethanolamino)-desoxybenzoin and two related tertiary-nitrogen analogs to undergo reduction by aluminum isopropoxide, a cyclic structure for this type is suggested. Dehydration of one of these compounds was brought about by heating at 160°, and the reverse reaction was accomplished by the action of acid.

α-(Ethanolamino)-desoxybenzoin, in which the nitrogen is secondary, is reduced by aluminum isopropoxide and appears to be normal in its properties.

Some Fluorinated Derivatives of Propane[1]

BY E. T. MCBEE, ANTHONY TRUCHAN AND R. O. BOLT[2]

This paper is one of a series[3] describing the synthesis of derivatives of fluoroalkanes; it offers an improved synthesis of $CF_3CH_2CF_3$ and describes new chlorofluoropropanes.

Hexachloropropene was subjected to the sequence

$$CCl_3CCl{=}CCl_2 \xrightarrow{SbF_3} CF_3CCl{=}CCl_2{}^{4} \xrightarrow{HF/SbCl_5}$$

$$CF_3CHClCClF_2 \xrightarrow{Zn/C_2H_5OH} CF_3CH{=}CF_2 \xrightarrow{HF} CF_3CH_2CF_3{}^{5}$$

No addition of hydrogen fluoride across the double bond or halide replacement occurred when $CF_3CCl{=}CCl_2$ was heated with anhydrous hydrogen fluoride at 240° in a pressure vessel, but in the presence of antimony(V) halides reaction did occur. Rectification of the product showed that $CF_3CCl{=}CCl_2$, $CF_3CHClCCl_2F$, $CF_3CHClCClF_2$, $CF_3CHClCF_3$, $CF_3CCl_2CCl_2F$ and $CF_3CCl_2CClF_2$ were present in the mixture. Two independent reactions may be viewed as taking place, (a) addition of hydrogen fluoride to the double bond followed by halogen exchange and (b) addition of chlorine (from antimony (V) chlorofluorides) to the double bond followed by halogen exchange. $CF_3CHClCCl_2F$ was formed but it could not be rectified from unreacted $CF_3CCl{=}CCl_2$ because the difference in boiling points is only one degree. For physical constants, $CF_3CHClCCl_2F$ was independently prepared by fluorination of $CF_3CHClCCl_3$, obtained by addition of chlorine to $CF_3CH{=}CCl_2$. The structure of $CF_3CHClCClF_2$ was established by dechlorination to $CF_3CH{=}CF_2$,[4] and dehydrochlorination to $CF_3CCl{=}CF_2$.[3]

The ratio of $CF_3CHClCClF_2$ to $CF_3CHClCF_3$ was controlled by varying the amount of hydrogen fluoride used. The use of a 100% excess of hydrogen fluoride gave high yields of $CF_3CHClCF_3$ with a corresponding decrease in the yield of $CF_3CHClCClF_2$. The amount of $CF_3CCl_2CCl_2F$ and $CF_3CCl_2CClF_2$ varied with the amount of antimony(V) chloride used. Further fluorination of $CF_3CHClCF_3$ with anhydrous hydrogen fluoride and antimony(V) chloride did not take place even at temperatures of 260°. The starting material was recovered.

Bromine was added to $CF_3CH{=}CF_2$ under pressure at 140° to give $CF_3CHBrCBrF_2$. Hydrogen bromide was eliminated readily from the latter compound to give $CF_3CBr{=}CF_2$.

Experimental

Starting Materials and Apparatus.—The $CF_3CCl{=}CCl_2$ used in this work was prepared by the method of Henne and co-workers[4] from hexachloropropene (Hooker Electrochemical Company). J. T. Baker, C. P. antimony(V) chloride and anhydrous hydrogen fluoride (prime commercial grade from Harshaw) were used for the fluorinations.

Fluorination of $CF_3CCl{=}CCl_2$.—A 2-liter, nickel-lined autoclave was assembled, evacuated and then chilled to 0°. $CF_3CCl{=}CCl_2$ (3.25 moles), antimony(V) chloride (0.3 mole) and hydrogen fluoride (18.4 moles) were sucked into the autoclave in the order mentioned through the needle valve. The charged autoclave was heated in a stationary, vertical position for one hundred hours at 250 ± 5°. After cooling to 150°, the contents were released through the needle valve into a recovery train consisting of a gallon bottle three-fourths full of water, drying tower and, finally, a receiver cooled with solid carbon dioxide. No alkali was used in the water scrubber because $CF_3CHClCClF_2$ is easily dehydrochlorinated to $CF_3CCl{=}CF_2$. The organic product was steam distilled, dried and rectified in a suitable column. The products from three similar runs were combined for rectification. Purification of the compounds for chemical analysis and determination of physical properties was accomplished by washing with water, drying and re-rectifying. The recovery of $CF_3CCl{=}CCl_2$ plus an unknown amount of $CF_3CHClCCl_2F$ was 21%. The conversions to $CF_3CHClCF_3$, $CF_3CHClCClF_2$, $CF_3CCl_2CClF_2$ and $CF_3CCl_2CCl_2F$ were 16%, 50%, 2% and 2%, respectively.

$CF_3CHClCF_3$	14.5–15.0	4	1.5415	....	61.1	61.4	19.1	20.6	186	183

In another experiment, a 2-liter, monel lined autoclave was charged with $CF_3CCl{=}CCl_2$ (3.3 moles) and anhydrous hydrogen fluoride (12 moles) and heated at 240° for sixty-seven hours. A pressure of 1225 lb./sq. in. was observed. The product was isolated in the usual manner and rectified. Five-hundred and sixty-six grams of the starting material, $CF_3CCl{=}CCl_2$, was recovered, indicating that substantially no fluorination had occurred.

Synthesis of $CF_3CH{=}CF_2$ and $CF_3CH_2CF_3$.—A 5-liter, 3-necked flask was fitted with a dropping funnel, a mercury sealed stirrer and a reflux condenser through which ice water was circulated. A receiver cooled by solid carbon dioxide was connected in series with the condenser. The flask was charged with zinc dust (7 moles) and absolute ethanol (1500 ml.). This mixture was heated to the temperature of refluxing alcohol and $CF_3CHClCClF_2$ (5.8 moles) was added dropwise to the zinc–alcohol suspension over a period of six hours. Upon rectification of the product, 655 g. $CF_3CH{=}CF_2$ (5.0 moles) and 122 g. $CF_3CHClCClF_2$ (0.6 mole) were obtained representing a conversion of 86% and a yield of 96%. $CF_3CH{=}CF_2$ was converted to $CF_3CH_2CF_3$ by addition of hydrogen fluoride.[5]

Synthesis of $CF_3CHClCCl_3$.—A Carius tube was charged with $CF_3CH{=}CCl_2$ (0.4 mole), liquid chlorine (0.75 mole) and antimony(V) chloride (0.04 mole) and the mixture heated at 140° for twenty-four hours. The product was washed with aqueous alkali, dried and purified by rectification. Fifty grams of $CF_3CHClCCl_3$ (0.21 mole) was obtained representing a yield and conversion of 53%.

Synthesis of $CF_3CHClCCl_2F$.—A mixture of $CF_3CHClCCl_3$ (0.18 mole), antimony(III) fluoride (0.13 mole) and antimony(V) chloride (0.06 mole) was refluxed for one hour. The product was steam distilled and purified by rectification. Twenty-three grams (0.10 mole) of $CF_3CHClCCl_2F$ was obtained representing a yield and conversion of 56%.

Synthesis of $CF_3CHBrCBrF_2$.—Two Carius tubes were charged with $CF_3CH{=}CF_2$ (0.7 mole) and bromine (0.72 mole) and heated at 140° for twenty-four hours. The products were combined, washed free of bromine with aqueous Na_2SO_3, dried and rectified. There was obtained 42 g. of $CF_3CBr{=}CF_2$, b. p. 24.7–25.0°, 216 g. of $CF_3CHBrCBrF_2$, b. p. 88.0°, d^{23}_4 2.1637, $n^{25}D$ 1.3780. Dehydrobromination of $CF_3CHBrCBrF_2$ during washing caused the formation of $CF_3CBr{=}CF_2$.

Acknowledgment.—The authors express their thanks to Mallinckrodt Chemical Works and to the Ethyl Corporation for making this work possible by their financial assistance.

Summary

A new series of reactions for the preparation of $CF_3CH_2CF_3$ is described. The fluorination of $CF_3CCl{=}CCl_2$ with anhydrous hydrogen fluoride and antimony(V) chloride gave $CF_3CHClCCl_2F$, $CF_3CHClCClF_2$, $CF_3CHClCF_3$, $CF_3CCl_2CCl_2F$ and $CF_3CCl_2CClF_2$. Several new compounds are reported.

Studies in Steroid Metabolism. IV. The Characterization of Carbonyl and Other Functional Groups in Steroids by Infrared Spectrometry[1]

BY R. NORMAN JONES, V. Z. WILLIAMS, M. J. WHALEN AND KONRAD DOBRINER

Many organic compounds can be identified by the direct comparison of their ultraviolet, visible or infrared absorption spectra with the spectra of known substances measured under comparable experimental conditions. Such a procedure is strictly empirical and involves no premises as to the nature of the processes concerned in the absorption of the radiation. However, much more insight into the molecular structure of the compound can be derived from the spectrometric measurements if the location and the intensities of the absorption bands can be related to specific molecular structure. In the case of a new compound it is only through such correlations that information about the molecular structure can be derived from the spectrometric measurements.

The high specificity of the infrared absorption spectra of organic compounds has recently become generally appreciated,[2,3] and infrared spectrometry is now applied quite extensively for the qualitative and quantitative analysis of organic compounds. Thus infrared spectrometry was used as an aid in the establishment of the identity of synthetic folic acid with that isolated from natural sources,[4] and the application of infrared spectrometry to the analysis of the steroid constituents of human urine has been described in an

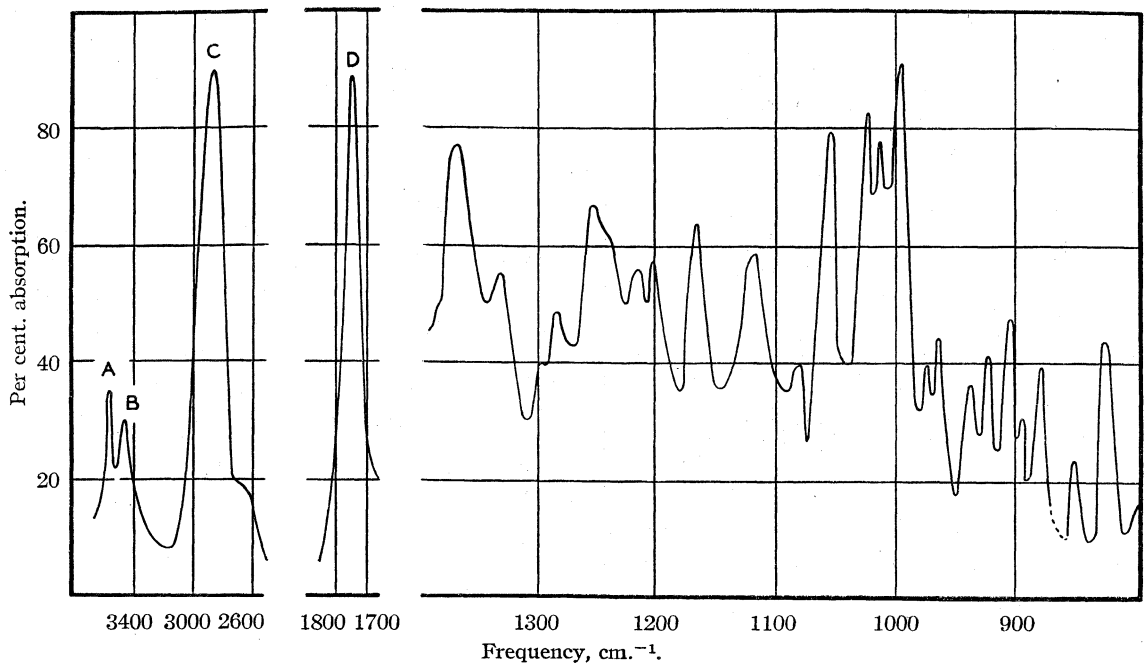

Fig. 1.—Infrared absorption spectrum of androsterone in carbon disulfide solution: A, O–H stretching motion of hydroxyl group; B, carbonyl overtone band; C, C–H stretching maxima; D, C=O stretching maximum of carbonyl group.

earlier paper of this series.[5] In such investigations the spectrometric curves have been used in an empirical manner as "molecular fingerprints."

The dependence of the infrared absorption spectrum on the molecular structure has been investigated very thoroughly for simple symmetrical molecules which are susceptible to mathematical treatment[6] and numerous studies of more complex molecules have been made by many observers following up the pioneer work of Coblenz.[7] In spite of this, comparatively little use has yet been made of infrared absorption data in the elucidation of molecular structure, although the possibilities of the method have been demonstrated by recent work on the structure of the penicillins.[8]

Infrared Absorption Spectra of Steroids.—In this paper an attempt is made to correlate the position of certain infrared absorption bands with the presence of specific molecular groupings in steroids. The infrared spectrum of a typical steroid, androsterone, is shown in Fig. 1. For the purposes of subsequent discussion it is convenient to consider this spectrum in two parts; a high frequency region from 4000 to about 1200 cm.$^{-1}$, and a lower frequency region extending down from 1200 cm.$^{-1}$ to the lower limit of measurement.

In the lower frequency region all steroids exhibit very complex absorption. This part of the spectrum is exceedingly sensitive to minor changes in chemical structure or steric configuration and has been utilized principally for empirical identification purposes.[5]

In the higher frequency region a smaller number of bands is observed. These are associated with hydrogen motions, or the stretching vibrations of doubly or triply bonded atoms from the second row of the periodic table. Such motions usually give rise to absorption bands in specific frequency ranges since they are little subject to perturbing interactions. For example, in the spectrum in Fig. 1, the band at 1742 cm.$^{-1}$ can be correlated with the stretching vibration of the carbon-oxygen bond of the carbonyl group. It is this higher region of the spectrum which offers the most encouraging prospect of yielding information concerning molecular structure.

The investigation described here was carried out in an endeavor to supplement the chemical methods available for the elucidation of the structure of new steroids isolated from biological material. In such compounds interest is centered mainly on the carbonyl group, the hydroxyl group and the double bond. Information is desired as to the presence or absence of these functional groups in the molecule, and if present it is important to locate their position in the ring system or on the side chain. It has been shown by Lecomte[9] and

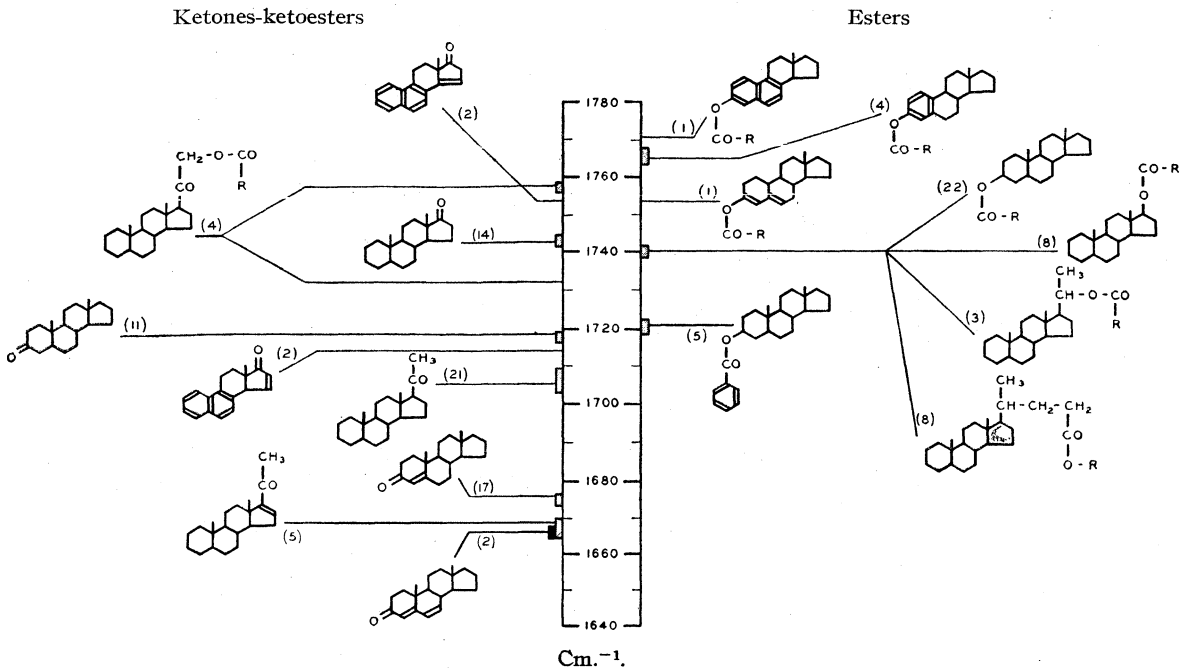

Fig. 2.—Diagram illustrating the relation between the frequency at the maximum of the carbon–oxygen stretching vibration and the location of the carbonyl group in steroid molecules (solvent carbon disulfide). The figures in parentheses indicate the number of individual compounds on which the frequency assignment is based.

others[3] that in certain types of organic compounds all of these groups may give rise to characteristic infrared absorption bands, and Furchgott, Rosenkrantz and Shorr[10,11,12] have demonstrated the presence of these absorption bands in the spectra of certain crystalline steroids.

The Carbonyl Group.—The carbon–oxygen stretching vibration of the carbonyl group may occur between 1550 and 2150 cm.$^{-1}$ and it has been observed in the spectra of ketones, aldehydes, carboxylic esters, acids, and ions, acid anhydrides, lactones and amides. The range of frequencies encompassed by this band varies somewhat for the different types of carbonyl groups.[3]

A comparison has been made of the infrared absorption spectra of carbon disulfide solutions of some one hundred and thirty steroids, and the positions of the maxima in the region between 1660 and 1780 cm.$^{-1}$ are listed for the monocarbonyl compounds in Table I, and for di- and polycarbonyl compounds in Table II. It is to be noted that an absorption band is seen only in the spectra of those steroids which contain a carbonyl group, so that the appearance of a strong band in this region of the spectrum of an unknown steroid is indicative of the presence of a carbonyl group in the molecule.

The carboxylic esters included in Tables I and II are mainly the acetates or propionates of steroid alcohols, although a few methyl esters of bile acid derivatives and some benzoates are also included. These esters give rise to a single absorption maximum between 1719 and 1771 cm.$^{-1}$. The position of the carbonyl maximum in the ketosteroids may be between 1666 and 1754 cm.$^{-1}$ so that it is not always possible to distinguish with certainty between a ketosteroid and a steroid ester from measurements in this region of the spectrum as some overlap in the band positions can occur.[13a]

A more precise consideration of the position of this carbonyl absorption band shows it to be closely dependent on the molecular environment of the carbonyl group in the molecule. The monoketosteroids and mono-steroid esters in Table I are grouped according to the position of the substituent, and the characteristic frequency positions derived from this analysis are summarized diagrammatically in Fig. 2.

For a given position of substitution, the carbonyl stretching vibration occurs at a sharply defined frequency. The frequencies of the maxima in steroids containing more than one carbonyl group are listed in a similar manner in Table II, and here, with certain exceptions to be considered later, the two carbonyl groups do not appear to exert any significant interaction effects, and the bands occur at the same positions as in the monocarbonyl compounds. The four ketonic positions of main significance in the steroid hormones are at carbon atoms 3, 11, 17 and 20 (I). In eleven steroids containing a non-conjugated ketonic carbonyl group at position 3 there is a maximum at

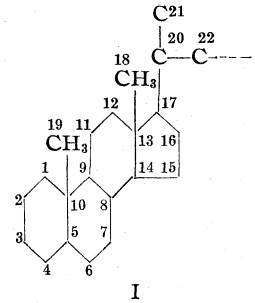
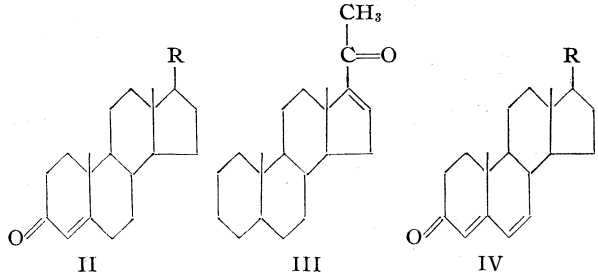
[a] See footnotes to Table I. [b] "m. e." is abbreviation for "methyl ester." [c] Measurements made on a suspension of crystalline material in a saturated solution in carbon disulfide. [d] Inflection only.

1717–1719 cm.$^{-1}$. Twenty-one ketosteroids with a non-conjugated carbonyl group at position 20 have a maximum at 1706–1710 cm.$^{-1}$, while in fourteen non-conjugated 17-ketosteroids the maximum is at 1742–1745 cm.$^{-1}$.

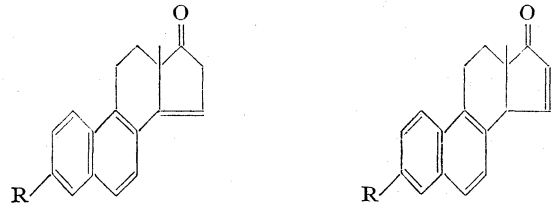


I

The introduction of a double bond in the α,β-position to the ketonic carbonyl group shifts the maximum by about 40 cm.$^{-1}$ to lower frequencies. In seventeen Δ^4-3-ketosteroids (II) there is a band at 1674–1677 cm.$^{-1}$ while in five Δ^{16}-20-ketosteroids (III) the maximum occurs at 1666–1670 cm.$^{-1}$. Two compounds containing the $\Delta^{4,6}$-diene-one-3 system (IV) also possess a maximum at 1666–1669 cm.$^{-1}$. Data on the effect of ethylenic unsaturation in ring D on the 17-carbonyl group is at present limited to the four synthetic equilenin derivatives V–VIII.[13] It is curious to note that in V and VI the introduction of the $\beta\gamma$- double bond shifts the position of the



II III IV



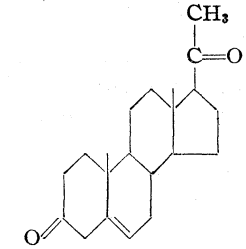
V (R = —H)
VI (R = OCH_3)

VII (R = —H)
VIII (R = —OCH_3)

carbonyl maximum about 10 cm.$^{-1}$ to higher frequencies from its position in the 17-ketosteroids in which ring D is saturated. A change in the force constants in the carbon–oxygen bond may be brought about by the shortening of the bond between carbon atoms 14 and 15 in the unsaturated compound with a resultant strain effect on the valence angles at carbon atom 17.[14]

Few data are yet available concerning the location of the carbonyl band in steroids containing a ketone group at positions other than 3, 17 or 20. The effects of carbonyl groups at 11 and 12, which are of considerable interest in connection with the adrenocortical steroids will form the subject of a separate publication.

In the non-conjugated 3,17-diketosteroids two maxima occur at 1745 and 1719 cm.$^{-1}$, positions normal to the corresponding monocarbonyl compounds. The same is true also of the 3,20-diketones which have two maxima at 1719 and 1710 cm.$^{-1}$. In the latter case the separation between the maxima is about the limit of resolution possible under the experimental conditions employed.[15]



IX

The carbonyl group of the non-conjugated carboxylic ester tends to be less sensitive than the ketonic carbonyl group to the position of substitution in the sterol ring system, and the acetates and propionates of 3-, 17- and 20-hydroxysteroids all absorb at 1739–1742 cm.$^{-1}$. The methyl esters of cholanic acid derivatives also absorb at the same position. This lies quite close to the position of the maximum in non-conjugated 17-ketosteroids so that it is not possible to distinguish 17-ketosteroids from certain steroid esters by this criterion alone. However, the acetate esters possess a strong band near 1240 cm.$^{-1}$ (see Table III) which is lacking from the spectra of ketosteroids, so that a supplementary examination of the absorption in the region near 1240 cm.$^{-1}$ permits a

(13) Johnson, Petersen and Gutsche, THIS JOURNAL, **69**, 2942 (1947).

(14) The possibility that this shift to higher frequency results from effects of the aromatic system in rings A and B cannot be excluded on the basis of this evidence. However, the interpretation given above seems most probable when the data on the band positions in the acetates of estrone, equilin and equilenin are also taken into consideration. These three compounds all possess a band at 1742 cm.$^{-1}$ which can be attributed most reasonably to the unperturbed 17-ketosteroid absorption. These compounds contain a second band at 1764–1771 cm.$^{-1}$ which is attributed to the phenolic acetate group. In estradiol diacetate two maxima are observed at 1767 and 1742 cm.$^{-1}$ indicating clearly that the carbonyl of the phenolic ester absorbs at a position different from that of the simple carbinol ester.

(15) Better resolution of these absorption maxima might be achieved by the use of higher dispersion, as may result from the substitution of a calcium fluoride prism or a grating in place of the sodium chloride prism used in these measurements. Measurements of the band intensity for standard conditions of concentration and sample thickness, or determination of the band width at half the maximum intensity may also yield more information about the nature of the absorbing group, and make possible a distinction between absorption caused by one or two carbonyl groups at the same frequency.

distinction to be made between a 17-ketosteroid and a steroid acetate ester. Some significance may be attached to the observation that in compounds containing the partial structure XI this maximum is displaced by 10–12 cm.$^{-1}$ to lower frequencies as indicated by the last four compounds in Table III.

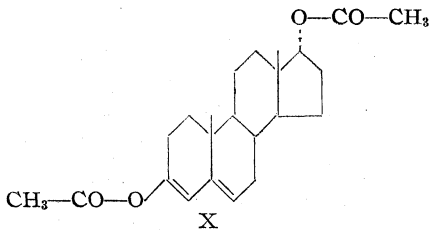
[a] See footnotes to Table I.

Where the esterified hydroxyl group is phenolic in character, as in the 3-acetates of compounds in the estrone and equilenin series, the carbonyl ester absorption maximum is shifted to higher frequencies (Fig. 2). This is true also when the esterified hydroxyl group is associated with a conjugated system as in the enol ester X. It is interesting to observe that this type of attachment of the ester carbonyl group to an ethylenic double bond through the oxygen atom, shifts the carbonyl maximum in the opposite direction from that brought about by direct conjugation with the carbonyl bond, as is seen in the steroid benzoates and the conjugated ketosteroids (Fig. 2).

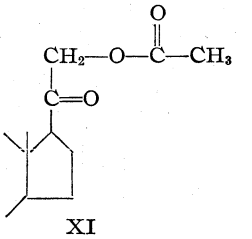


X

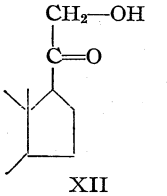
The above observations are all based on measurements in carbon disulfide solution. The positions of the carbonyl stretching maxima have been determined also in a few cases using chloroform as solvent, and the results are listed in Tables I and II. In chloroform the band maxima tend to be displaced to lower frequencies; the effect is least (0–5 cm.$^{-1}$) for non-conjugated 20-ketosteroids, somewhat greater for carboxylic esters and 17-ketosteroids (7–10 cm.$^{-1}$) and greatest for conjugated 3-ketosteroids (12–20 cm.$^{-1}$).

Interaction Effects.—In dicarbonyl compounds it might be anticipated that some interactions involving the vibrations of the two carbonyl groups would be encountered and result in the displacement of the bands from the positions observed in comparable monocarbonyl compounds.

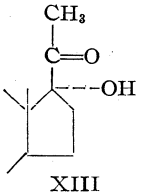
As has been shown above, such interactions have not been detected between carbonyl groups at positions 3 and 17 and 3 and 20. An example of such a displacement is seen in the spectra of the 21-acetoxy-20-ketosteroids which contain the partial structure XI. Such compounds would be expected to possess a band at 1706–1710 cm.$^{-1}$ for the 20-ketone group and at 1739–1742 cm.$^{-1}$ for the acetate ester. Actually all of the four such compounds examined possess bands at 1732 cm.$^{-1}$ and 1756–1758 cm.$^{-1}$. Four compounds containing the partial structures XII or XIII on the contrary show the normal 20-ketosteroid band at 1706–1710 cm.$^{-1}$ from which it may be argued that the displacements associated with structure XI involve carbonyl group interactions, and are not due merely to steric or other non-specific effects of the large oxygen atoms adjacent to the 20-ketone.



XI



XII



XIII

Other evidence of the influence of the molecular environment on the frequency of the carbon–oxygen stretching vibration in cyclic compounds has been reported in the literature. Biquard[16] has measured the position of the analogous band in the Raman spectra of a series of mono- and dicyclic ketones and noted quite similar displacements of the band positions. Thus in the Raman spectrum of cyclopentanone there is a band at $\Delta\nu$ = 1744 cm.$^{-1}$ which is displaced to $\Delta\nu$ = 1714 cm.$^{-1}$ in cyclohexanone. Furchgott, Rosenkrantz and Shorr[12] have reported that in the crystalline state non-conjugated 3-ketosteroids absorb at 1739 cm.$^{-1}$, 17-ketosteroids at 1738–1740 cm.$^{-1}$ and 20-ketosteroids at 1703–1715 cm.$^{-1}$ and that a 17-ketosteroid could not be distinguished from a 3-ketosteroid. This latter observation is contrary to our experience, based on measurements in solu-

(16) Biquard, *Bull. soc. chim. France*, **7**, 894 (1940); **8**, 55, 725 (1941).

tion. Measurements made on solutions would also appear preferable for the purposes of structural identification since the spread of the absorption maximum for a given substituent position seems to be less than for crystalline films or powder suspensions.

In addition to the carbon–oxygen stretching vibration, discussed above, the ketosteroids containing a double bond in the $\alpha\beta$-position to the carbonyl group possess another strong absorption band between 1580 and 1615 cm.$^{-1}$. Both carbon disulfide and carbon tetrachloride absorb appreciably in this region but satisfactory measurements can be made in chloroform solution as has been shown recently by Blout, Fields and Karplus.[17] Measurements on a few unsaturated ketosteroids in this region are summarized in Table IV. These are in agreement with the observation of Furchgott, Rosenkrantz and Shorr[12] who have suggested that the Δ^4-3-ketosteroid and the Δ^{16}-20-ketosteroid systems might be distinguished on the basis of the difference in the position of this band in the two types of $\alpha\beta$-unsaturated compounds.

Carbonyl Harmonic Band.—In addition to the fundamental carbonyl stretching vibration discussed above, another weak absorption band attributed to the carbonyl group occurs between 3300 and 3475 cm.$^{-1}$. This is an overtone of the fundamental carbon–oxygen stretching vibration. It should occur at twice the frequency of the main carbonyl maximum or at a frequency slightly lower than this. The position of this band in the spectrum of androsterone is indicated as B in Fig. 1. This carbonyl harmonic is not likely to be of appreciable value in the elucidation of sterol structure, since it is much weaker than the fundamental band. However its occurrence should be noted, since in certain instances it may be confused with the hydrogen–oxygen stretching vibration of the hydroxyl group (*vide infra*).

The Non-Conjugated Double Bond.—The presence or absence of a non-conjugated ethylenic double bond in a steroid cannot always be determined with certainty by infrared measurements. Several investigators[3,17,18] have shown that in many organic compounds there is an absorption band near 1650 cm.$^{-1}$ associated with a longitudinal vibration of the carbon–carbon double bond. It is difficult to observe this band in the spectra of carbon disulfide solutions since the solvent absorbs appreciably in this region. In only a few instances of solutions in carbon tetrachloride or in crystalline films and suspensions has this band been seen in the spectra of unsaturated steroids. It may be seen more readily in chloroform solutions, but when present it is of low intensity and its detection is rendered more difficult by the fact that atmospheric water vapor produces considerable background absorption in this region of the spectrum. Its detection would be facilitated by the use of a double beam instrument.

At higher frequencies, near 3000 cm.$^{-1}$ there is a group of strong bands associated with the stretching vibration of the carbon–hydrogen bond. Several observers have reported[19] that when the C–H bond forms part of an unsaturated system, this band occurs at a frequency greater than 3000 cm.$^{-1}$ whereas in a saturated group it is normally below 3000 cm.$^{-1}$. In all steroids there are strong bands in the region between 3000 and 2800 cm.$^{-1}$ due to the —C—H vibrations of the ring and side chain aliphatic system. In carbon disulfide solutions of several unsaturated steroids, a band or inflection is seen also on the high frequency side of this band group. A particularly favorable example is illustrated in curves A and B of Fig. 3,

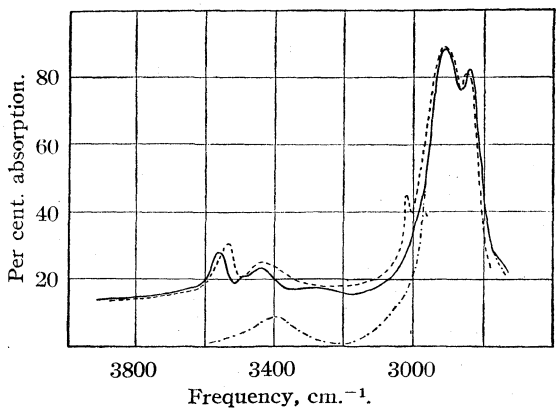

Fig. 3.—Infrared absorption spectra in carbon disulfide solution: A, —, etiocholanol-3α-one-17 (XIV); B, – – –, Δ^{11}-etiocholenol-3α-one-17 (XV); C, ·—·—, etiocholanol-3α-one-17-acetate.

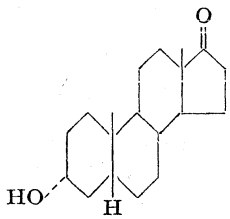
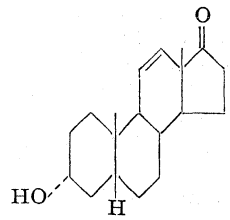
where the spectrum of etiocholanol-3α-one-17 (XIV) is compared with that of the unsaturated derivative with a double bond at the 11,12 position (XV).



XIV



XV

In column A of Table V the positions of this band in the spectra of some 47 steroids in carbon disulfide solution are recorded. Among these compounds are nineteen containing the =C—H group and a band or inflection near 3020 cm.$^{-1}$ is observed in the spectra of fourteen of them. No band was detected in this neighborhood in the spectra of any of the saturated steroids included in this survey. In these compounds the band attributed to the =C—H group is weak and as in many cases it occurs on the rising slope of the —C—H band group, the frequency at the maximum cannot be determined with much certainty. In many cases it fails to appear unless the concentration of the solution is increased considerably above the 10 mg. per ml. which is adequate for the determination of the remainder of the spectrum in a 1 mm. cell. In some instances the concentration cannot be increased sufficiently because of the low solubility of the steroid and this may account

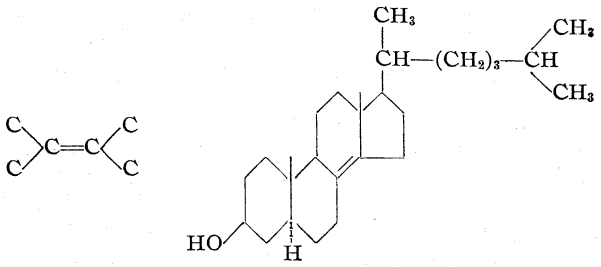
[a] See footnotes to Table I. [b] b = broad band; s = sharp band; a = band absent; — = spectrum not measured; n. o. = spectrum measured but band not observed; ins. = compound insoluble in carbon disulfide.

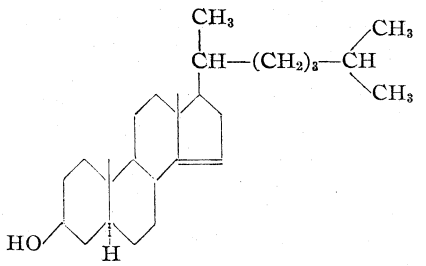
for the failure to detect this band in certain of the compounds in Table V. In column B of Table V similar data are listed for crystalline films or suspensions of these steroids. The possibility of introducing a thicker sample layer into the radiation beam in the form of a crystalline film or suspension in a "Nujol" mull favors the use of films rather than solutions for the investigation of this particular band.

In a molecule containing the partial structure XVI in which there are no hydrogen atoms attached to the unsaturated carbon atoms, this band would not be expected to appear. An example is given in Fig. 4 where the spectra of Δ$^{8:14}$-cholestenol-3β (XVII) and Δ^{14}-cholestenol-3β (XVIII) are compared over the region between 2500 and 4000 cm.$^{-1}$. The absence of the band near 3000 cm.$^{-1}$ from the spectrum of XVII is clearly in evidence.

The Conjugated Diene Systems.—The number of compounds containing this system which have been measured is comparatively small. Absorption associated with the conjugated diene group occurs between 1580 and 1620 cm.$^{-1}$ and the steroids must be examined as crystalline films,



XVI XVII



XVIII

powder suspensions, or in chloroform solution. In view of the fact that a system of conjugated ethylenic bonds can be detected and characterized with facility by ultraviolet spectrometry[20,21] the identification of this group from infrared measurements is of comparatively small importance. The same is true also of the aromatic systems present in the estrogens.

The Hydroxyl Group.—The longitudinal vibration of the hydrogen–oxygen bond of the hydroxyl group is responsible for an absorption band at the high frequency end of the spectrum. The position of this band may vary considerably with the experimental conditions under which the measurements are made, thus it may shift as a result of change in solvent or change in concentration, and may appear quite different (usually broadened, intensified and displaced to lower frequencies) when examined in a crystalline state.

Some data on the frequencies of the hydroxyl band in carbon disulfide solutions and in films of a number of steroids are listed in columns C and D of Table V. Displacement of the absorption band to lower frequency with increase in intensity and band width is associated with a lowering of the strength of the oxygen–hydrogen bond occasioned by inter- or intra-molecular hydrogen bonding. Where the hydroxyl group is not subject to such effects a maximum is observed near 3600 cm.$^{-1}$, a condition most favored in dilute solution.

It has not proved possible to associate the exact frequency of this absorption maximum with the position of the hydroxyl group in the steroid molecule. However, the presence or absence of a hydroxyl group in a steroid can be determined with certainty by examination of this region of the spectrum. This is illustrated in curves A and C of Fig. 3 where the spectra of etiocholanol-3α-one-17 and that of its acetate are compared. Twenty-five of the compounds included in Table V contain a hydroxyl group. When examined as crystalline films, most of these showed absorption bands of varied width between 3200 and 3500 cm.$^{-1}$. In carbon disulfide or carbon tetrachloride solution they showed a much weaker narrow absorption band between 3575 and 3610 cm.$^{-1}$. The two hydroxy steroids which failed to exhibit hydroxyl absorption in solution were poorly soluble and it is most probable that in these cases insufficient of the solute was present in the radiation path for the band to be manifested. Under conditions where association takes place, the spectrum of a compound containing a single hydroxyl group may exhibit two or more broad bands between 3200 and 3500 cm.$^{-1}$ and the relative intensities of these maxima may vary with the conditions of sample treatment. This behavior is suggestive of the presence of two or more types of hydrogen bonding or different modes of packing of the hydroxyl group in two or more crystalline forms.

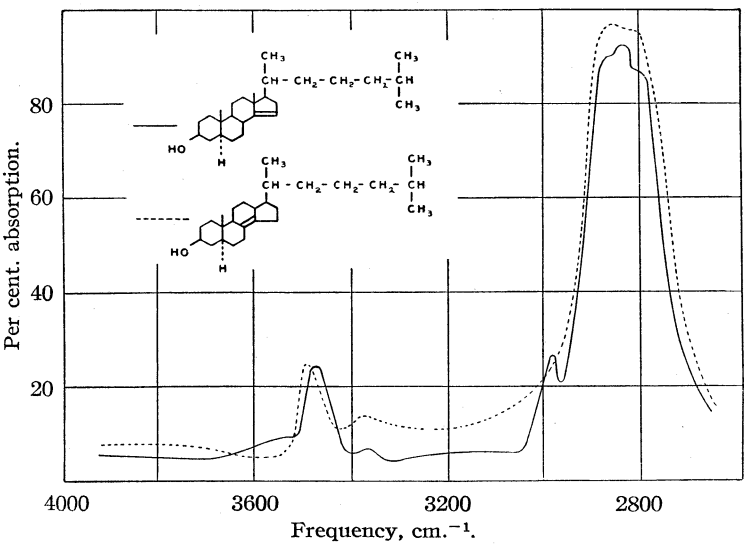


Fig. 4.—Infrared absorption spectra in carbon disulfide solution: —, Δ^{14}-cholestenol-3β; – – – – –, $\Delta^{8,14}$-cholestenol-3β.

General Discussion

While the absorption associated with the carbonyl group is influenced by the molecular environment in such a manner as to permit of the close correlation of absorption frequency with molecular structure, this would appear not to be the case with regard to absorption associated with the double bond and hydroxyl group. The analytical treatment developed in this paper has been

(20) Woodward, THIS JOURNAL, **64**, 72 (1942).
(21) Booker, Evans and Gillam, *J. Chem. Soc.*, 1453 (1940).

concerned almost exclusively with the high frequency region of the infrared spectrum, but it must be kept in mind that structural variations such as the introduction of a double bond also give rise to very large changes in the appearance of the absorption curves at frequencies less than 1200 cm.$^{-1}$. Similar modifications are produced also by stereochemical inversions; studies in the higher frequency region have given no indication of spectral variations which can be related to the stereochemical structure, and this is an important factor in the elucidation of steroid structure. It is reasonable to assume that the variations in the spectra in the lower frequency region should also be subject to regulation and correlatable with specific differences in molecular structure, and it is probably in this region that spectral features relatable to specific stereochemical configurations will be observed. Furchgott, Rosenkrantz and Shorr[10,11,12] have drawn attention to this and pointed out certain relationships, between the stereochemical configurations at positions 3 and 5 and absorption in the neighborhood 1000 cm.$^{-1}$. While we also have noted that absorption near 1000 cm.$^{-1}$ is highly susceptible to structural and stereochemical changes involving the 3 and 5 positions, we have as yet been unable to establish any specific correlations between structure and spectra in this region which are of general application.

Experimental

The data given in this work were obtained at the Sloan–Kettering Institute and at the Stamford Research Laboratories of the American Cyanamid Co. using Perkin–Elmer instruments with either galvanometer or electronic systems of automatic recording; both sodium chloride and lithium fluoride prisms were employed.

Because of the correlations for the carbonyl groups, the region between 1660 and 1780 cm.$^{-1}$ was subjected to special study at the Sloan–Kettering Institute. The positions of the absorption maxima in the carbonyl region were obtained directly by measurement of the displacement of the bands from the water vapor absorption bands at 1830 and 1637 cm.$^{-1}$ which appeared on every curve and were used as external standards of frequency. The estimated accuracy of the frequency measurements in this region is ± 3 cm.$^{-1}$. Most of the measurements were made in a cell of approximately 1 mm. thickness, although a 3 mm. cell was also used in certain instances. The solutions were made up to an initial concentration of 10 mg. per ml. and then diluted so as to obtain an absorption of about 50–75% in the region of the maximum. Under these conditions no appreciable error in the position of the maximum is caused by the slope of the background radiation over the width of the band.

Acknowledgments.—The authors wish to express their indebtedness to the several investigators, listed individually in a footnote to Table I, whose collaboration in supplying many of the compounds made these studies possible. The help of L. D. Marinelli, Sloan-Kettering Institute, with certain problems of instrumentation and the technical assistance of P. Humphries is gratefully acknowledged. This investigation was aided by grants from the American Cancer Society (on recommendation of the Committee on Growth of the National Research Council), Ayerst, McKenna and Harrison, Ltd., the Jane Coffin Childs Memorial Fund for Medical Research, the Commonwealth Fund, the Anna Fuller Fund, the Lillia Babbitt Hyde Foundation, International Cellucotton Products Company, the Albert and Mary Lasker Foundation, the Adele R. Levy Fund, the National Cancer Institute of the National Institute of Health, U. S. Public Health Service, the New York Foundation, and the Sidney Rheinstein Fund.

Summary

A comparative study has been made of the infrared absorption spectra of one hundred and thirty steroids in solution in carbon disulfide, or chloroform. Particular attention has been given to the region between 1660 and 1780 cm.$^{-1}$ where prominent absorption bands occur which are associated with the presence of carbonyl groups in the molecule. The exact location of the maxima of these bands can be employed to locate the position of the carbonyl group in ketosteroids and to distinguish conjugated from non-conjugated ketosteroids. Absorption bands in other regions of the spectrum associated with the presence of ethylenic double bonds and hydroxyl groups have been similarly investigated.

The Solubility of Tetraethylammonium Iodide in Benzene–Ethylene Dichloride Mixtures

BY ARTHUR A. VERNON AND JOHN L. SHEARD[1a]

Introduction

As part of the program to study solubility effects in solvents of low dielectric constant, it was decided to determine the effect of dielectric constant on the solubility of tetraethylammonium iodide. Investigation has shown that in solvents of dielectric constant higher than ten the single ion concentration is high enough so that within certain limits a common-ion effect can be observed. To study the effect in liquids with lower dielectric constant, the system benzene–ethylene dichloride is useful: data for this have been published by Vernon, Wyman and Avery.[1] Tetraethylammonium iodide was selected for the solute since it has a reasonable solubility in ethylene dichloride.

Experimental

Materials.—C. P. thiophene-free benzene, after standing for several days over anhydrous calcium chloride, was distilled from activated alumina, the first and last fifth portions being discarded. The refractive index was 1.4978 at 25.2°; the "International Critical Tables" value is 1.49779 at 25.2°.

Ethylene dichloride was dried over anhydrous calcium chloride to an index of refraction of 1.4422 at 25.2° as compared with the "International Critical Tables" value of 1.44225 at 25.2°.

Tetraethylammonium iodide was prepared by mixing equimolar quantities of ethyl iodide (Merck) and triethylamine (Eastman Kodak Co.) and allowing to stand overnight. The crude product was dried, washed with petroleum ether, dissolved in boiling 95% ethyl alcohol, and treated with alcoholic potassium hydroxide until pink to phenolphthalein. The mixture was then cooled in an ice-bath, the solid filtered off and recrystallized twice from 95% ethyl alcohol. Finally, the pure product was dried in a vacuum desiccator. Since decomposition of the pure solid occurred at 280°, no melting point could be obtained; the analysis of the material for iodine gave 49.61% as compared with the theoretical iodine per cent. of 49.63.

Procedure.—Excess solute was added to 600 cc. of a benzene–ethylene dichloride mixture in a bottle with a ground glass cap which was wired on and coated with paraffin. The bottles were rotated in a water-bath at 35° for twenty-four hours and then at 25 ± 0.02° long enough to establish equilibrium. For the 93.5% ethylene dichloride, rotation at 25° for one hundred and twenty hours gave essentially the same solubility as rotation for twenty-four hours at 35° followed by seventy-two hours at 25°.

After the required rotation time, the bottles and a calibrated 500-cc. volumetric flask were supported in the water-bath at 25 ± 0.02°. The solution, after settling, was forced out by dry air through a glass wool filter into a volumetric flask. Then the solution was poured into a beaker and the flask was washed out with 95% ethyl alcohol, the wash solution being added to the benzene–ethylene dichloride solution. Silver iodide was precipitated by adding excess silver nitrate solution, stirred for five minutes, allowed to settle four hours in the dark, filtered into a Gooch crucible, and dried at 120° to constant weight. This method applied to known amounts of solute was shown to be consistently accurate to within 1.9%.

Results

The solubility results given in Table I are the averages of two or more determinations as shown.

TABLE I

SOLUBILITY OF TETRAETHYLAMMONIUM IODIDE IN ETHYLENE DICHLORIDE–BENZENE MIXTURES AT 25°

Ethylene dichloride, %	Dielectric constant	No. of detns.	Moles per liter of iodide × 10^4
35.5	3.85	4	0.865 ± 0.009
48.0	4.55	3	2.18 ± .02
56.6	5.20	6	3.80 ± .04
68.0	6.07	5	8.51 ± .08
80.0	7.26	2	18.06 ± .14
85.0	8.01	2	30.6 ± .3
93.5	9.02	4	55.6 ± .3
100.0	10.36	5	91.9 ± .2

The average deviation of the individual determinations from the mean is no greater than 1.05% for any solvent mixture. Figure 1 shows a plot of the log of solubility against the log of the dielectric constant.

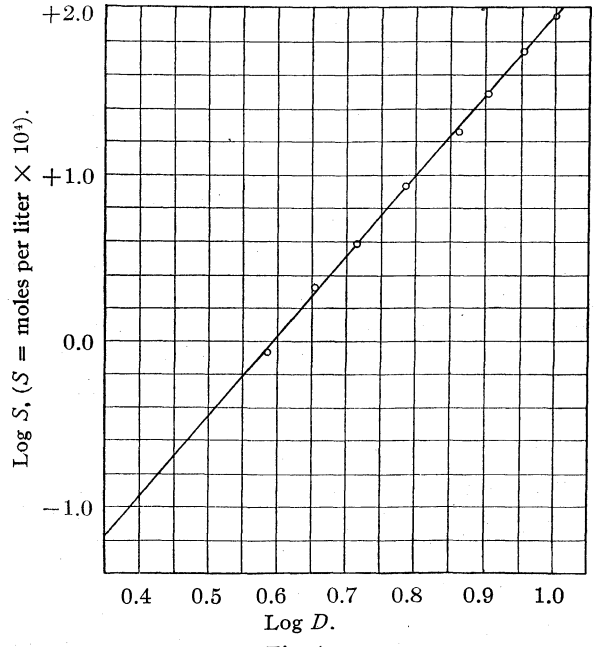

Fig. 1.

Discussion

Tucker and Kraus[2] studied the conductivity of tetraethylammonium picrate in ethylene dichloride at 25° and found that triple ion formation became important at $3.4 \times 10^{-4} N$. Luder, Kraus, Kraus and Fuoss[3] found this effect to be significant

(1a) Present address: University of Minnesota, Minneapolis, Minnesota.

at 1×10^{-5} N for tetrabutylammonium perchlorate in benzene at 25°. For tetraethylammonium iodide the triple ion formation should take place at a lower concentration than for the above reported salts since such an effect increases with decrease in ion size. The solubilities here reported are of the order of 10^{-2} N in pure ethylene dichloride and 10^{-4} N in 35.5% ethylene chloride. Therefore, it seems likely that multiple ion formation exists in all the solutions studied; straight line extrapolation to pure benzene is justified if such conditions continue to exist down to a dielectric constant of 2.274. Extrapolation of Fig. 1 gives a solubility of 6.918×10^{-6} mole per liter for the solubility of tetraethylammonium iodide in benzene at 25°. At this solubility, triple ions may reasonably be expected to exist. Further evidence of ion association would be obtainable from studies of the effect of a common ion upon the solubilities reported in this paper. It is planned to study this as well as the solubility relation in solvents of higher dielectric constant.

Ricci and Davis[4] proposed an empirical equation to relate solubility to dielectric constant of the solvent which showed that a plot of log S against log D should be a straight line with a slope of three. This equation assumed that the Debye–Hückel limiting law applied and that the activity coefficient of an electrolyte at saturation is a constant independent of the dielectric constant of the solvent medium. They further showed that approximate equality of activity coefficients could be expected between solvent dielectric constants of 80 and 40. This, together with the evidence of triple ion formation, seems to indicate that a slope of 3 should not be expected with our data. The explanation of the slope of 5 of Fig. 1 will have to wait until more data are available.

The dielectric constant of benzene is 2.274 and $\log D = 0.3568$. By extrapolation of Fig. 1, assuming a straight line relation, a value of log S of -1.160 is obtained. This gives 6.918×10^{-6} mole per liter for the solubility of tetraethylammonium iodide in benzene at 25°.

(4) Ricci and Davis, THIS JOURNAL, **62**, 407 (1940).

Summary

The solubility of tetraethylammonium iodide in pure ethylene dichloride and ethylene dichloride–benzene mixtures has been determined. A plot of log S *versus* log D follows closely a straight line with a slope of 5 in contrast to the value of 3 found in solvents with higher dielectric constant.

Equilibrium Studies on N-Chloro Compounds. I. The Ionization Constant of N-Chloro-*p*-toluenesulfonamide[1]

BY J. CARRELL MORRIS, J. ALFREDO SALAZAR[2] AND MARGARET A. WINEMAN

The N-chloro compounds, those substances in which it may be considered that one or more chlorine atoms in the +1 oxidation state are bound to nitrogen, are of considerable interest because of the widespread use of a number of them as disinfecting agents. In many cases it is believed that their efficiencies as disinfecting agents are related to the magnitudes of their hydrolytic and other equilibrium reactions in water solution, but quantitative data on the equilibria with which disinfection results might be compared are available for only one or two isolated systems. The present series of papers is therefore concerned with the quantitative evaluation of equilibrium relationships for water solutions of certain important N-chloro compounds and with the use of the equilibrium constants so determined for predicting the disinfectant power of solutions of the N-chloro compounds under various conditions.

The system selected for primary study was that in which the substances Dichloramine-T, and Chloramine-T are participants. These two substances are, respectively, N,N-dichloro-*p*-toluenesulfonamide (I) and sodium N-chloro-*p*-toluenesulfonamide, the latter being the sodium salt of N-chloro-*p*-toluenesulfonamide (II). A number of equilibria are established in solutions of these materials, which can be described most conveniently in terms of the following processes:

I. The hydrolysis equilibrium for Dichloramine-T

$$\underset{(I)}{C_7H_7SO_2NCl_2} + H_2O = \underset{(II)}{C_7H_7SO_2NHCl} + HOCl \quad (1)$$

for which the equilibrium constant equation is[3]

$$K_h = \frac{(HOCl)(C_7H_7SO_2NHCl)}{(C_7H_7SO_2NCl_2)} \quad (1a)$$

II. The exchange or disproportionation reaction

$$2\underset{(II)}{C_7H_7SO_2NHCl} = \underset{(I)}{C_7H_7SO_2NCl_2} + C_7H_7SO_2NH_2 \quad (2)$$

(1) This work was carried out under a research contract with the Office of the Quartermaster General, U. S. Army.

(2) Now with the West Virginia State Department of Health, Charleston, W. Va.

(3) In all of the equations of this paper parentheses, except when they are used just to set off mathematical terms, indicate molar activities of the substances concerned and square brackets indicate molar concentrations. For non-ionic substances the two are assumed to be the same within the experimental accuracy of the determinations.

with the equilibrium constant equation

$$K_d = \frac{(C_7H_7SO_2NCl_2)(C_7H_7SO_2NH_2)}{(C_7H_7SO_2NHCl)^2} \quad (2a)$$

III. The ionization of the hypochlorous acid produced in equation (1)

$$HOCl = H^+ + OCl^- \quad (3)$$

for which

$$K_1 = \frac{(H^+)(OCl^-)}{(HOCl)} \quad (3a)$$

IV. The ionization of N-chloro-*p*-toluenesulfonamide

$$C_7H_7SO_2NHCl = H^+ + C_7H_7SO_2NCl^- \quad (4)$$

giving an ionization constant

$$K_2 = \frac{(H^+)(C_7H_7SO_2NCl^-)}{(C_7H_7SO_2NHCl)} \quad (4a)$$

A fifth reaction, the acid ionization of $C_7H_7SO_2NH_2$ occurs under some conditions, and must eventually be included for a complete depiction of the system. However, preliminary studies indicate that the ionization constant is so small, perhaps 10^{-10}, that this reaction is a measurable factor only above *p*H 9. Other possible pertinent reactions, such as the hydrolysis of $C_7H_7SO_2NHCl$, need not be included, for they can be obtained by appropriate combination of the listed reactions.

The first two of these equilibria have been studied quantitatively by Soper.[4] By measuring the apparent solubility of Dichloramine-T[5] in 0.001 M H_2SO_4, by itself and in the presence of a known large excess of hypochlorous acid to repress the hydrolysis, he was able to calculate a value of 8.0×10^{-7} for K_h. The disproportionation constant, K_d, was evaluated, with the aid of the value for K_h, by measuring the apparent solubility of Dichloramine-T in 0.001 M sulfuric acid solutions containing known added amounts of *p*-toluenesulfonamide to displace reaction (2) to the left. These latter measurements have been repeated in connection with the present research and results in good agreement with the values given by Soper have been obtained. A combined average of the two sets of data yields $K_d = 6.1 \times 10^{-2}$.

The ionization constant for hypochlorous acid has been the subject of a number of studies which give as a probable best value $K_1 = 3.3 \times 10^{-8}$ at 25°.[6] The magnitude of this value is such that the ionization of hypochlorous acid did not occur to a measurable extent under the conditions of the present study, but it is concerned in the application of the results to disinfecting problems.

Although the compound $C_7H_7SO_2NHCl$ has not been isolated, its existence was demonstrated in Soper's studies and it is known that it must be a fairly strong acid because its sodium salt, Chloramine-T, gives only slightly basic solutions in water. However, no quantitative studies of the ionization constant have been reported. The simultaneous occurrence of the other listed equilibria and particularly of the disproportionation equilibrium introduces complicating factors into the standard procedures for determining ionization constants. In the present study these difficulties have been taken care of by appropriate mathematical treatment and the ionization constant has been determined in two ways: by measurement of the apparent solubility of Dichloramine-T in solutions buffered to *p*H 4.5 and containing known added amounts of *p*-toluenesulfonamide, and by potentiometric titration of solutions of Chloramine-T with standard hydrochloric acid.

Experimental

Reagents.—Purified Chloramine-T, furnished by the Monsanto Chemical Company, was recrystallized from distilled water under such conditions that only about 25% yield was obtained. The product was filtered with suction through a sintered-glass funnel and was dried at room temperature in a vacuum desiccator. The resulting product was the trihydrate, $NaC_7H_7SO_2NCl \cdot 3H_2O$, and was found to contain 12.56% Cl, the theoretical value being 12.58%.

Dichloramine-T was prepared by passing gaseous chlorine into water solutions of purified Chloramine-T and filtering out the precipitated Dichloramine-T with suction through a sintered-glass funnel. The material thus obtained was resuspended in a dilute chlorine solution (about 5 p. p. m.) agitated overnight and refiltered; this process was repeated two or three times to ensure complete removal of incompletely chlorinated products. After the final filtration the moist product was used for the solubility studies without drying.

The *p*-toluenesulfonamide was an Eastman Kodak Co. product, which was recrystallized from glacial acetic acid, filtered with suction through a sintered-glass funnel, washed several times with small quantities of cold water to remove adherent acetic acid and then dried in a vacuum desiccator over sulfuric acid. The recrystallized compound had a melting point of 137.0–137.5°.

Solubility Studies.—Samples of Dichloramine-T weighing 1–2 g. (several times the amount required for saturation) were placed in 500-ml. glass-stoppered Pyrex bottles and the bottles were then filled approximately three-quarters full with conductivity water. To these solutions were then added the desired amounts of *p*-toluenesulfonamide and either sufficient sulfuric acid to make the solutions 0.001 M in that reagent or a sufficient quantity of an equimolar solution of acetic acid and sodium acetate to give about 0.05 M concentration of each substance. The bottles were then stoppered and placed in a rotating frame in a constant-temperature water-bath held at 25.0 ± 0.2°. The rotation of the frame caused the bottles to be inverted about four times a minute. Samples were taken from the bottles at six to eight hour intervals by pressure filtration through a microfilter stick and were analyzed for their concentrations of oxidizing chlorine. The shaking and sampling procedures were continued until constant values for the apparent solubility of the Dichloramine-T were obtained. Constancy within the precision of the analytical determinations was generally obtained after about twenty-four hours of shaking and was maintained for at least forty-eight hours longer. Analyses for oxidizing chlorine were conducted by adding excess potassium iodide to the sample and titrating with 0.01 N sodium thiosulfate.

(4) Soper, *J. Chem. Soc.*, **125**, 1899 (1924).

(5) The "apparent solubility of Dichloramine-T" is evaluated by determining that oxidizing chlorine in solutions in equilibrium with solid Dichloramine-T which is attributable to dissolved Dichloramine-T itself or which, existing in other forms, has been produced from Dichloramine-T by any of the previously listed reactions.

(6) See, for example, Ingham and Morrison, *J. Chem. Soc.*, 1200 (1933), and Hagisawa, *Bull. Inst. Phys. Chem. Research (Tokyo)*, **19**, 1220 (1940). A complete summary of the data on this ionization constant is given in Final Report, Contract OEMcmr-251, Disinfection of Water and Related Substances, Dec. 31, 1945.

Titration Studies.—For these determinations accurately weighed samples of recrystallized Chloramine-T were dissolved in conductivity water to make solutions ranging in concentration from 0.01 to 0.08 *M*. The solutions were then titrated potentiometrically with 0.5 *N* hydrochloric acid, the *p*H after each addition being measured by means of a Beckman Model G *p*H meter equipped with glass and saturated calomel electrodes. The meter and electrodes were calibrated before and after each titration against solutions of potassium acid phthalate and of phosphate buffer mixture prepared from Bureau of Standards salts according to their directions. Since these calibrations checked within 0.02 *p*H unit, it is believed that *p*H measurements during the course of the titration were accurate to a similar figure. The amounts of hydrochloric acid added were measured with a calibrated 10-ml. Exax buret, so that volumes could be measured with a precision of 0.01 ml. The necessity for refilling the buret for volume readings greater than 10 ml. made the measurement of the larger volumes less precise, but this did not affect the experimental results since the factor limiting the accuracy of the results for all volume measurements greater than a few ml. was the determination of the *p*H.

Because of the slight solubility of Dichloramine-T in water, precipitation of this substance occurred during the titrations, the first permanent precipitate appearing after the addition of 1–2 ml. of hydrochloric acid. When additional amounts of hydrochloric acid were added to solutions containing the precipitate, particularly in those instances in which only a small amount of precipitate was present, the *p*H showed an initial decrease greater than expected and a following slow increase for a period as long as ten minutes before stabilization resulted. The total amount of this shift was generally about 0.1 *p*H unit. It is believed to have been caused by a temporary supersaturation of the solution with Dichloramine-T upon the addition of the hydrochloric acid followed by a slow precipitation to equilibrium saturation conditions. As the amount of precipitate in the solution increased, the time for stabilization decreased until at the equivalence point it was complete in less than a minute. In the range in which this phenomenon was exhibited *p*H readings were not recorded until equilibrium conditions had been attained and the *p*H readings were constant for several minutes.

An example of the curves obtained showing the typical features of the titrations is shown in Fig. 1. Section A of the curve shows the region in which the solution was not yet saturated with Dichloramine-T and was therefore clear. At the point corresponding to the addition of 1 ml. of hydrochloric acid a break in the curve is noted, coincident with the appearance of a precipitate of Dichloramine-T. The next three points, shown as section B, presumably correspond to a region of supersaturation with Dichloramine-T in which the supersaturation was being relieved so slowly that no drift in the *p*H values was observed. At the point corresponding to the addition of 2 ml. of hydrochloric acid a second break occurs, this being the first point for which the previously discussed shift in *p*H with time was observed. For the region beyond this, section C, the recorded points represent the *p*H readings obtained after stable conditions in the solution were attained and are assumed to correspond to an equilibrium saturation state for the Dichloramine-T present.

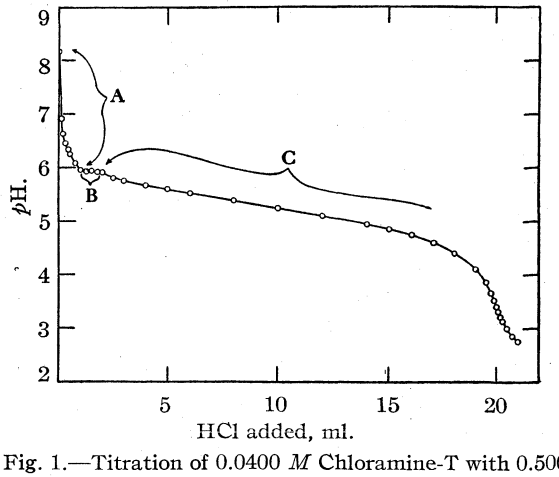

Fig. 1.—Titration of 0.0400 *M* Chloramine-T with 0.500 *M* HCl. Volume of solution 250 ml.: A, region with no precipitate, solution unsaturated with Dichloramine-T; B, region of supersaturation with Dichloramine-T; C, region with precipitate of Dichloramine-T in equilibrium with saturated solution.

The most concentrated solution titrated, 0.08 *M*, showed a fourth section just before the equivalence point. It was possible to calculate that in this region a large enough quantity of *p*-toluenesulfonamide had been produced to exceed its solubility, so that in this range both Dichloramine-T and *p*-toluenesulfonamide were being precipitated by the addition of further hydrochloric acid. This section was not used for any of the calculations.

Theory and Results

Solubility Studies.—In sufficiently acid solutions (0.002 *N*) of Dichloramine-T only the equilibria represented by reactions (1) and (2) are analytically significant, for the ionization of the weakly acidic compounds, hypochlorous acid and $C_7H_7SO_2NHCl$ is substantially completely repressed. Under these conditions the equivalents of oxidizing or "titratable" chlorine per liter, T_a, in the solution can be represented by the equation

$$T_a = 2[HOCl] + 2[C_7H_7SO_2NHCl] + 4[C_7H_7SO_2NCl_2] \quad (5)$$

When the concentration of titratable chlorine in acid solutions in equilibrium with an excess of solid Dichloramine-T, to which various amounts of *p*-toluenesulfonamide have been added, is measured, T_a is found to increase with increase in the concentration of added *p*-toluenesulfonamide because of the displacement of reaction (2) to the left. The accompanying decrease in the Dichloramine-T concentration is compensated for by additional solution of solid Dichloramine-T. On the assumption that the activity of the dissolved Dichloramine-T and hence its true solubility is constant regardless of the presence of the other dissolved substances and with a knowledge of the hydrolysis constant, K_h, it is possible to evaluate the disproportionation constant, K_d, from the increase in the titratable chlorine of the saturated solutions with increase of added *p*-toluenesulfonamide. This is the procedure which was followed by Soper.[4]

If the acidity at which these studies are carried out is changed to a *p*H of 4 to 5, the titratable chlorine level in the solution is further measurably increased over that obtained for the same concentration of added *p*-toluenesulfonamide in the more acid solutions because of the ionization of $C_7H_7SO_2NHCl$, which displaces reaction (2) even more to the left. At *p*H values less than 5 the ionization of hypochlorous acid is still not a factor. For solutions at *p*H 4 to 5 the equation for the

equivalents of oxidizing chlorine in the saturated solutions becomes

$$T_b = 2[HOCl] + 2[C_7H_7SO_2NHCl] + 2[C_7H_7SO_2NCl^-] + 4[C_7H_7SO_2NCl_2] \quad (6)$$

Since the concentration of hypochlorous acid is negligibly small for solutions in which the added *p*-toluenesulfonamide is 0.001 *M* or greater, and since the concentration of dissolved $C_7H_7SO_2NCl_2$ may be considered to be constant, equations (5) and (6) may be reduced to the forms

$$T_a = T_2 + 2[C_7H_7SO_2NHCl] \quad (7)$$

$$T_b = T_2 + 2[C_7H_7SO_2NHCl] + 2[C_7H_7SO_2NCl^-] \quad (8)$$

where T_2 is the saturation concentration of $C_7H_7SO_2NCl_2$ in equivalents per liter, determined by Soper to be 0.310×10^{-3}. Now if equations (7) and (8) be taken to apply to solutions to which the same number of moles, N, of *p*-toluenesulfonamide have been added per liter of solution, then the expressions for K_d for the two conditions may be written

$$K_d = \frac{(C_7H_7SO_2NHCl)^2}{(C_7H_7SO_2NCl_2)(C_7H_7SO_2NH_2)} = \frac{(T_a - T_2)^2}{T_2\left(N - \frac{T_a - T_2}{4}\right)} = \frac{(T_b - T_2 - 2[C_7H_7SO_2NCl^-])^2}{T_2\left(N - \frac{T_b - T_2}{4}\right)}$$

the second term in the denominator of each expression being derived from the stoichiometry of reaction (2). Solution of these expressions for the concentration of $C_7H_7SO_2NCl^-$ yields the equation

$$[C_7H_7SO_2NCl^-] = \frac{T_b - T_2}{2}\left(1 - \frac{T_a - T_2}{T_b - T_2}\sqrt{\frac{4N - T_b + T_2}{4N - T_a + T_2}}\right) \quad (9)$$

The ionization constant for $C_7H_7SO_2NHCl$ expressed in terms of the concentration of $C_7H_7SO_2NCl^-$ and the measured properties of the saturated buffer solutions is given by the following expression derived from equations (4a) and (8)

$$K_2 = \frac{(H^+)[C_7H_7SO_2NCl^-]f}{\frac{1}{2}(T_b - T_2 - 2[C_7H_7SO_2NCl^-])}$$

where f is the activity coefficient of the $C_7H_7SO_2NCl^-$ in the buffer solution. Substitution of equation (9) and simplification lead to the equation

$$K_2/f = (H^+)\left(\frac{T_b - T_2}{T_a - T_2}\sqrt{\frac{4N - T_a + T_2}{4N - T_b + T_2}} - 1\right) \quad (10)$$

Data obtained in the solubility studies and values of the term, K_2/f, calculated from them by means of equation (10) are shown in Table I. The ionic strength in these experiments, made up of the buffer ions and the ions produced in the reactions, was about 0.06.

Titration Studies.—If to a solution of $NaC_7H_7SO_2NCl$ of molar concentration B, is added a quantity of hydrochloric acid equivalent to a molar concentration A, both terms including a correction for the diluting effect of the added hydrochloric acid, then a simple application of equation (4) would indicate that the concentration of $C_7H_7SO_2NHCl$ formed is $A - [H^+]$, and that the remaining concentration of $C_7H_7SO_2NCl^-$ is $B - A + [H^+]$, where $[H^+]$ is the measured concentration of hydrogen ions in the solution after the addition of the acid. Then by substitution of these quantities in the ionization constant equation, the constant might be calculated. Actually, because the $C_7H_7SO_2NHCl$ formed undergoes further reaction according to equation (2), this procedure overestimates the concentration of that substance and gives an apparent ionization constant considerably smaller than the true one. Two sets of calculations are necessary to correct for this additional reaction, one for the early part of the titration in which the solution is not saturated with respect to Dichloramine-T formed by reaction (2) and one for the later part in which the precipitation of Dichloramine-T has caused a further shift of reaction (2) to the right.

15.00	8.70	16.90	4.48	3.82

Average, excluding first value, 3.85

A. Region with no Precipitate of Dichloramine-T.—The term $A - (H^+)$ still represents the concentration of added acid which has reacted and so $B - A + [H^+]$ is still equal to the remaining concentration of $C_7H_7SO_2NCl^-$. However, $A - [H^+]$ is equal to the sum of the concentrations of the $C_7H_7SO_2NHCl$ and its subsequent reaction products. This may be expressed by the equation

$$A - [H^+] = [C_7H_7SO_2NHCl] + 2[C_7H_7SO_2NCl_2] \quad (11)$$

Since the concentrations of $C_7H_7SO_2NCl_2$ and $C_7H_7SO_2NH_2$ formed by reaction (2) are equal, the equilibrium constant for the reaction may be written in the form

$$K_d = \frac{[C_7H_7SO_2NCl_2]^2}{[C_7H_7SO_2NHCl]^2} \quad (12)$$

from which

$$[C_7H_7SO_2NCl_2] = \sqrt{K_d}[C_7H_7SO_2NHCl] \quad (13)$$

Substitution in equation (11) and solution for the concentration of $C_7H_7SO_2NHCl$ gives

$$[C_7H_7SO_2NHCl] = \frac{A - [H^+]}{1 + 2\sqrt{K_d}} \quad (14)$$

This and the expression for the concentration of $C_7H_7SO_2NCl^-$, $B - A + [H^+]$, substituted in the ionization equation (4a) yield

$$K_2 = (1 + 2\sqrt{K_d}) \frac{(H^+)(B - A + [H^+])f}{A - [H^+]} \quad (15)$$

which, upon substitution of the value 0.061 for K_d, reduces to

$$K_2/f = 1.494 \frac{(H^+)(B - A + [H^+])}{A - [H^+]} \quad (16)$$

B. Region of Saturation with Dichloramine-T.—As soon as Dichloramine-T begins to precipitate, equations (11) and (12) are no longer true in terms of the dissolved Dichloramine-T concentration. However, the $C_7H_7SO_2NCl_2$ term in equation (11) may be replaced by $C_7H_7SO_2NH_2$, since this latter substance remains in solution, to give the modified equation

$$A - [H^+] = [C_7H_7SO_2NHCl] + 2[C_7H_7SO_2NH_2] \quad (17)$$

Also, since the concentration of dissolved $C_7H_7SO_2NCl_2$ can now be considered constant at its molar solubility value, S, the disproportionation equation takes the form

$$K_d = \frac{[C_7H_7SO_2NH_2]S}{[C_7H_7SO_2NHCl]^2} \quad (18)$$

Solution of equations (17) and (18) for the concentration of $C_7H_7SO_2NHCl$ gives

$$[C_7H_7SO_2NHCl] = \frac{S}{4K_d}\left[\left(\frac{8K_d(A - [H^+])}{S} + 1\right)^{1/2} - 1\right] \quad (19)$$

Substitution of this expression and of $B - A + [H^+]$ for $[C_7H_7SO_2NCl^-]$ in the ionization constant equation (4a) gives

$$K_2/f = \frac{4K_d}{S} \frac{(H^+)(B - A + [H^+])}{\left(\frac{8K_d}{S}(A - [H^+]) + 1\right)^{1/2} - 1} \quad (20)$$

Upon substitution of the numerical values, $K_d = 0.061$ and $S = 0.775 \times 10^{-4}$, equation (20) reduces to

$$K_2/f = \frac{3150(H^+)(B - A + [H^+])}{(6300(A - [H^+]) + 1)^{1/2} - 1} \quad (21)$$

A typical example of the results obtained is shown in Table II, which gives the data obtained for a titration of 0.02 M Chloramine-T with 0.5 M hydrochloric acid, together with the ionization constants calculated from the data by means of equations (16) and (21) for the regions to which each is applicable. Table III presents a summary of the average ionization constants determined from this and the other titrations which were carried out. It is apparent from Table II that the calculated values of K_2/f showed a good constancy during the course of a titration and that satisfactory agreement between the constants for the region without precipitation and that with precipitation was obtained. The values calculated for the period before the beginning of precipitation are probably less reliable because of the greater errors involved in the measurement of the small amounts of acid added and also because the presence of very small amounts of acid or basic impurity in the Chloramine-T would have had a much more pronounced effect on the data in this region than in the later stages of the titration. On the other hand, because of the possible uncertainty as to the attainment of a constant equilibrium saturation concentration of Dichloramine-T during the latter part of the titrations, it is reassuring to have the values obtained for the initial additions of HCl check the later ones so well.

[a] This term also represents the ionic strength, μ, at which the titration was carried out.

lated from the *p*H measurements by the equation $p\mathrm{H} = -\log(\mathrm{H}^+)$ to hydrogen ion concentrations. The activity coefficients used for this purpose were taken from the chart of individual ion activities given by Chapin and Steiner.[7] The application of these corrections or the exact value of the activity coefficient used for them made very little difference over the greater part of the titration, but by including them it was possible to calculate consistent values for the ionization constant up to and even past the equivalence point.

In Fig. 2 a plot of the negative logarithms of K_2/f, pK_2' values, obtained in the various experiments against the square roots of the ionic strengths at which the experiments were conducted is shown, the circles having been drawn with radii corresponding to an error of 0.02 unit in *p*H measurement. The extrapolation line drawn through the points has a slope of 0.5, corresponding to that given by the simple Debye–Hückel expression in the form $pK_2 = pK_2' - 0.5\sqrt{\mu}$.

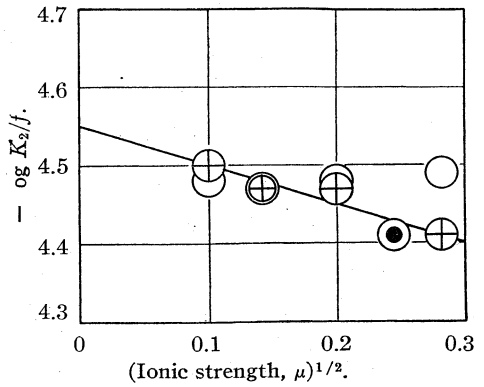

Fig. 2.—Variation of experimental ionization constants for $C_7H_7SO_2NHCl$ with ionic strength: O, titration values for solutions unsaturated with Dichloramine-T; ⊕, titration values for solutions containing precipitate of Dichloramine-T; ◉, value from solubility studies. Line corresponds to equation $-\log f = 0.5\sqrt{\mu}$.

The value of pK_2 determined from the extrapolation is 4.55 ± 0.02. This leads to a value for K_2, the activity ionization constant of $C_7H_7SO_2NHCl$, of $2.8 \pm 0.2 \times 10^{-5}$.

Summary

The ionization constant for N-chloro-*p*-toluenesulfonamide has been determined by potentiometric titration of solutions of Chloramine-T with acid and by measurement of the solubility of Dichloramine-T in solutions at *p*H 4.5 containing added quantities of *p*-toluenesulfonamide. Suitable mathematical equations have been developed to overcome the complications caused by the simultaneous occurrence of other equilibrium processes along with the ionization equilibrium.

The value obtained for the activity ionization constant of $C_7H_7SO_2NHCl$ at 25° is $K_2 = 2.8 \pm 0.2 \times 10^{-5}$, corresponding to $pK_2 = 4.55 \pm 0.002$.

Salts of an Aquoammonomolybdic Acid[1,2]

BY GEORGE W. WATT AND DARWIN D. DAVIES

In 1906, Rosenheim and Jacobsohn[3] prepared molybdenum(VI) oxide 3-ammonate by the interaction of the oxide and liquid ammonia. They considered the compound to be the diammonium salt of "imidomolybdic acid" and attempted to convert it to a lead(II) salt by reaction with lead(II) iodide in liquid ammonia at 108–109°, but their results were inconclusive.

In terms of Franklin's nitrogen system of compounds,[4] molybdenum(VI) oxide 3-ammonate may be looked upon as a salt of a mixed aquoammonomolybdic acid. As such, this acid salt should be unreactive toward liquid ammonia solutions of ammonium salts (acids in liquid ammonia), but in the same medium should react, for example, with potassium amide (a base in liquid ammonia) to form a tripotassium salt which in turn should be convertible by metathesis to other

metal salts. These properties have been demonstrated by the work described below.

The formation of the yellow tripotassium salt by the reaction,

$$(NH_4)_2(HMoO_3N) + 3KNH_2 \longrightarrow K_3(MoO_3N) + 5NH_3$$

goes to completion only very slowly even in the presence of a large excess of potassium amide. A red-brown dipotassium salt appears to be formed as an intermediate. Conversion by metathesis to the silver salt, $Ag_3(MoO_3N)$, or the lead salt, $Pb_3(MoO_3N)_2$, is more rapid and apparently quantitative.

Experimental

Materials.—With the exceptions noted below, all chemicals employed were of analytical reagent grade and of purity demonstrated by analyses prior to use.

Molybdenum(VI) Oxide.—A Schering–Kahlbaum product was dried for six hours at 110°, stored *in vacuo* over concentrated sulfuric acid, and used without further purification.

Anal. Calcd. for MoO_3: Mo, 66.65. Found: Mo, 66.60.

This oxide was also prepared by partial evaporation of a solution of sodium molybdate in concentrated nitric acid.

Anal. Calcd. for MoO_3: Mo, 66.65. Found: Mo, 66.35.

Experimental Methods.—Unless otherwise specified, all reactions in liquid ammonia employed the familiar faraday tube technique[5,6] and were effected at or near 25°. It is important here only to recognize that these techniques permit one to conduct reactions out of contact with the atmosphere under strictly anhydrous conditions and to form, purify, and isolate ammonia-insoluble reaction products.

Diammonium Aquoammonomolybdate.—Molybdenum(VI) oxide (0.6842 g.) was treated with about 15 ml. of liquid ammonia and agitated frequently over a period of one hour. The insoluble product was washed five times with liquid ammonia. Following evaporation of the solvent, the tube was evacuated by means of an oil pump for a period of two hours, filled with dry nitrogen and samples of the white crystalline solid (d^{25}_4 4.04) were removed for analysis.

Anal. Calcd. for $MoO_3 \cdot 3NH_3$: Mo, 49.98; N, 21.87. Found: Mo, 49.78; N, 21.65.

This compound loses ammonia slowly when exposed to the atmosphere and is rapidly and completely deammonated when heated to 110°.

Attempts to demonstrate the presence of ammonium ions in terms of hydrogen liberated upon treatment with liquid ammonia solutions of potassium led to results that were inconclusive.

Treatment of Diammonium Aquoammonomolybdate with Ammonium Salts.—To the diammonium salt produced (as above) from 0.2918 g. of molybdenum(VI) oxide and about 10 ml. of liquid ammonia was added an eight-fold excess (2.3738 g.) of ammonium chloride dissolved in liquid ammonia. After frequent agitation at 25° over a period of eighteen hours, the white solid was washed and removed for analysis in the manner indicated above.

Anal. Calcd. for $MoO_3 \cdot 3NH_3$: Mo, 49.98; N, 21.87. Found: Mo, 49.80; N, 21.75.

Substantially identical results were obtained using an excess of ammonium nitrate at 25° and ammonium chloride or ammonium nitrate at 100°. The experiments at 100° employed a modified Faraday tube[7] so constructed that it could be heated in an autoclave identical with that described by Bergstrom.[8]

Tripotassium Aquoammonomolybdate.—Preliminary experiments showed that the reaction between diammonium aquoammonomolybdate and potassium amide in liquid ammonia at 25° is slow and leads initially to mixtures of products. Accordingly, known weights of molybdenum(VI) oxide and potassium were placed in separate legs of a faraday tube, ammonia was condensed in the tube and the oxide and potassium were converted, respectively, to diammonium aquoammonomolybdate and potassium amide. The amide solution was then added to the suspension of the ammonium salt and the reaction mixture agitated intermittently prior to decantation of the supernatant solution and washing of the insoluble product preparatory to opening the tube for analysis. In a series of experiments of this type, the reaction ratio and time of contact were varied in an effort to obtain a product of reproducible composition. The resulting data are given in Table I. The tripotassium salt (d^{25}_4 4.59) hydrolyzes slowly upon exposure to the atmosphere. When treated with water, the salt hydrolyzes rapidly and yields an alkaline solution containing molybdate ion.

TABLE I

PREPARATION OF TRIPOTASSIUM AQUOAMMONOMOLYBDATE

MoO_3, g.	K g.	K equiv.	Time, hr.	Insoluble product[a,b] Color	Mo, %	N, %
0.6317	0.5878	3.42	0.5	Red-brown	39.12	6.15
.3986	.3575	3.60	0.5	Red-brown	38.48	5.77
.5172	.4671	3.32	2.0	Slate-gray	34.50	5.32
.8590	.9402	4.07	12	Yellow	34.79	5.25
.5620	.9313	6.10	12[c]	Yellow	34.71	5.22

[a] Calcd. for K_2HMoO_3N: Mo, 40.46; N, 5.90. [b] Calcd. for K_3MoO_3N: Mo, 34.86; N, 5.09. [c] Reaction times as long as twenty-six hours (using four to six equivalents of potassium amide) were employed without substantial change in the character of the results.

Silver(I) Aquoammonomolybdate.—The tripotassium aquoammonomolybdate equivalent to 0.7160 g. of molybdenum(VI) oxide was prepared and purified as described above. Thereafter, it was agitated (in the faraday tube in which the tripotassium salt was prepared) with a liquid ammonia solution containing excess silver(I) nitrate (3.1612 g.) until there was no further evidence of reaction (*ca.* one hour). Excess silver(I) nitrate and by-product potassium nitrate were separated from the black insoluble solid product by repeated washing with liquid ammonia.

Anal. Calcd. for Ag_3MoO_3N: Ag, 67.20; Mo, 19.95; N, 2.91. Found: Ag, 67.03; Mo, 19.73; N, 3.18.

This salt (d^{25}_4 7.64) underwent no change in appearance or composition during exposure to the atmosphere for twenty-four hours.

Lead(II) Aquoammonomolybdate.—In an entirely analogous manner, the lead salt was formed by the reaction between a liquid ammonia solution containing excess lead(II) iodide (2.4200 g.) in the potassium salt derived from 0.4877 g. of molybdenum(VI) oxide. The purified product was a light brown ammonia-insoluble solid (d^{25}_4 6.93) which is stable under ordinary atmospheric conditions.

Anal. Calcd. for $Pb_3Mo_2O_6N_2$: Pb, 66.25; Mo, 20.24; N, 2.86. Found: Pb, 65.98; Mo, 20.39; N, 2.82.

X-Ray Diffraction Data.—By the powder technique, X-ray diffraction patterns (Cu K_α radiation) were obtained for the diammonium, tripotassium, and trisilver salts. The interplanar spacings (d) in ångström units and the relative intensities (I/I_0) of the lines are given in Table II. The pattern for the lead salt (twenty-four hour exposure) showed only one line (d = 2.010).

The same result was obtained using a sample of the lead salt that had been maintained for three hours at 300° (without change in composition) in an atmosphere of dry oxygen-free nitrogen.

Summary

1. The existence of a compound of molybdenum(VI) oxide and ammonia in a 1:3 mole ratio has been confirmed and the compound has been interpreted as the diammonium salt of an aquoammonomolybdic acid.

2. This salt has been shown to be unaffected by treatment with liquid ammonia solutions of ammonium chloride or ammonium nitrate at 25 and 100°.

3. By the use of excess potassium amide in liquid ammonia solution and long time of reaction, the diammonium acid salt has been converted to a yellow tripotassium salt.

4. By metathesis with solutions of silver(I) nitrate and lead(II) iodide in liquid ammonia, the tripotassium salt has been converted to the corresponding silver(I) and lead(II) salts.

X-Ray Diffraction Studies of Systems Involved in the Preparation of Alkaline Earth Sulfide and Selenide Phosphors[1]

BY WILLIAM PRIMAK[2a] HERMAN KAUFMAN AND ROLAND WARD

The methods of preparation and some of the properties of the alkaline earth sulfide and selenide infrared phosphors have recently been described.[2,3] It has been shown[4] that in most cases their formation involves a complex interaction between solid phases and a fused salt, or flux, during which the composition of the phases alters. It is important to know the solubility limits of the different base materials which are used in the preparation of phosphors. A knowledge of the ways in which solid solutions may be formed is also useful. This paper presents the results of a study of the intersolubility of some alkaline earth sulfides, selenides and oxides by means of X-ray analysis. The excellent back-reflection powder pictures given by the alkaline earth sulfides, selenides and oxides, all of which have the sodium chloride lattice, have permitted the determination of the lattice constant of these phases with high precision. Our results indicate that the simple Vegard law is applicable over a wide range of composition of mixed sulfides and selenides so that changes in composition of the base material can be determined from the lattice constant measurement.

Experimental

Procedure.—A symmetrical back-reflection focussing powder camera of 6 cm. radius was used for most of the pictures. Several were taken with a Philip's Straumanis type powder camera of 5.72 cm. radius, and these are indicated in footnotes. To obtain a precision lattice constant, the lattice constants computed from the back-reflection lines were plotted against the square of the sine of the Bragg angle and extrapolated to Bragg angle 90°.[5] The error in extrapolation was about $^1/_{10,000}$, but the reproducibility in different samples of supposedly pure material was not better than $^1/_{3000}$. Some of the chemical work did not warrant obtaining lattice constants of such precision. In these cases, lattice constants were computed from a single back-reflection line spacing. They were probably good to $^1/_{500}$.

Preparation of Materials.—All chemicals used were purified as for the preparation of phosphors.[6] Strontium and calcium sulfide were prepared by reducing the sulfates with ammonia, hydrogen or hydrogen sulfide at 850–1050°. They were then treated with hydrogen sulfide at a temperature of 1000°. Strontium selenide was prepared by the reduction of the selenite with ammonia at about 850°. Several preparations of sulfides and selenides were made by the reaction of sulfur or selenium on

the carbonates. These are specifically referred to. Magnesium sulfide was prepared by the action of hydrogen sulfide on magnesium chloride.[7] Strontium and calcium oxides were prepared by treating the carbonates with hydrogen at about 1000° and then with oxygen at the same temperature.

Fluxing Procedures.—Samples were prepared in two ways: (1) 10 to 15 g. of material was molded under a force of 10 tons to form a 7/8 inch diameter cylindrical block, which was then fired on a molded plate of magnesium oxide placed in a platinum boat; (2) 2 to 5 g. of material was placed into a small platinum boat and fired. In both cases the firing was performed by placing the boat into a quartz tube in which a purified nitrogen atmosphere was maintained, and the quartz tube was inserted for the desired length of time into the furnace maintained at a temperature of 1000–1100°.

Lattice Constants for Base Materials.—Precision lattice constants were determined for several different preparations of a number of alkaline earth oxides, sulfides, and selenides. They are given in Table I.

TABLE I

PRECISION LATTICE CONSTANTS

CaO		None			4.7990
CaO	10	LiF	1	30	4.799

[a] Phillip's Straumanis camera was used. [b] Calculated from the lattice constants given for strontium sulfide, strontium selenide and calcium sulfide, using Vegard's law. [c] Strontium oxide, unfluxed, gave diffuse lines which were attributed to poor crystallinity. When fluxed with sodium chloride or strontium chloride, a slight improvement was observed, but with lithium fluoride, rather sharp lines were obtained.

It is seen from these results that the flux does not affect the lattice constant within the limits of experimental error.

Solid Solutions of Strontium and Calcium Sulfides.—This system was previously investigated by Rumpf and Travnicek.[8] They used mixtures of strontium and calcium sulfides and sulfates prepared by the reaction of sulfur with a mixture of carbonates at high temperatures and observed large apparent deviations from Vegard's law, which they could not explain satisfactorily. For the work described here, practically pure sulfides were used. Two mixtures of strontium sulfide and calcium sulfide were prepared by grinding the constituents together in a ball mill. The one contained 75 mole per cent. strontium sulfide, the other 50 mole per cent. strontium sulfide. Several fluxes were used: (a) lithium fluoride; (b) mixtures of lithium fluoride, calcium fluoride, and strontium fluoride with the molar ratio of strontium to calcium ions the same as that of the respective sulfide mixtures. Lithium fluoride constituted one-third the weight of the mixture to give a mixture that was completely molten at the temperature of fluxing. (c) Mixtures of strontium fluoride, calcium fluoride and strontium sulfate with the molar ratio of strontium to calcium ions the same as that of the respective sulfide mixtures. The composition chosen was close to the line of two-fold saturation in the liquidus of the reciprocal salt system.[4]

The results obtained with these mixtures are given in Table II.

TABLE II

LATTICE CONSTANTS FOR FLUXED MIXTURES OF CALCIUM SULFIDE AND STRONTIUM SULFIDE

Base composition (mole% SrS)	Flux composition (Grams of flux for 10 g. sulfide) LiF	CaF_2	SrF_2	$SrSO_4$	Lattice constant ("a" in Å.)
75	1.5				5.9375
75	0.5	0.172	0.828		5.936
75		.205	.330	0.965	9.535
75	Calculated from the lattice constants given in Table I for SrS and CaS, using Vegard's law				5.927
50	1.5				5.853
50	0.5	0.384	0.616		5.854
50		.447		1.053	5.868
50	Calculated from the lattice constants given in Table I for SrS and CaS, using Vegard's law				5.846

These results show that complete solid solution of the two sulfides results on fluxing; and also that using a flux containing calcium and strontium ions in the same molar ratio as in the sulfide does not change the composition of such solid solutions. One would not expect any better agreement than is found above, because of the difficulty experienced in compounding solids quantitatively.

If having the same molar cation ratio in base and flux is the equilibrium condition for ion exchange between base and flux, it should be possible to reach this condition starting with a base containing the one cation and a flux containing the other. Accordingly, calcium sulfide was fluxed with a flux containing strontium fluoride; and strontium sulfide was fluxed with a flux containing calcium fluoride. The lattice constants given by these samples are given in Table III.

TABLE III

ION EXCHANGE BETWEEN BASE AND FLUX

Original base (10 g.)	Original flux (g.) LiF	SrF_2	CaF_2	"a," Å.	Mole per cent. SrS Found[a]	Calculated[b]
SrS	0.50		1.00	5.974	89.6	86.8
CaS	0.50	1.00		5.699	4.6	5.4

[a] Calculated from the lattice constant using Vegard's law. [b] Calculated from the composition, assuming ion exchange continues until the cation ratio is the same in flux and base.

Although complete transposition apparently did not occur in the time of fluxing, it is clearly established that cation exchange does take place. In applying this information to the study of phosphors, it could be assumed that cation exchange results in equal concentrations of these ions in base and flux.

The lattice constants obtained for calcium sulfide, strontium sulfide, and their solid solutions are plotted in Fig. 1 as a function of the composition. Contrary to the results obtained by Rumpf, which are plotted in the same figure for comparison, it is seen that our results obey Vegard's law very closely.

Conditions for the Formation of Solid Solutions.—In the above experiments, solid solutions were obtained by heating a mixture of sulfides with a flux. An attempt was made to obtain a solid solution by the reduction with hydrogen sulfide, of an intimate mixture of calcium and strontium sulfate. With a mixture containing 57 mole per cent. calcium sulfate, the product gave the patterns of the individual sulfides. When fluxed with lithium fluoride this mixture gave a lattice constant of 5.83 Å., corresponding to a composition of 56 mole per cent. calcium sulfide.

Quite different results were obtained when solid solutions of calcium and strontium carbonates were converted to sulfides. Three $(Ca,Sr)CO_3$ precipitates were prepared by adding a solution containing appropriate concentrations of Ca^{+2} and Sr^{+2} to a hot ammonium carbonate solution. They contained 81.7, 59.7 and 32.8 mole per cent. of calcium. Upon conversion to the sulfide by heating in hydrogen sulfide at 1000° the lattice constants of the solid solutions indicated 81.2, 57.7 and 31.0 mole per cent. of calcium, respectively, and on fluxing these products with lithium fluoride 80.5, 57.7 and 30.2 mole per cent. of calcium, respectively. The conversion to sulfide by heating with sulfur at 1000° gave somewhat similar results. The product from the mixture containing the highest percentage of calcium gave a very diffuse pattern before fluxing, and after fluxing a well-defined pattern corresponding to 73.8 mole per cent. calcium. The others yielded sulfides with calcium content 57.7 and 30.4 mole per cent. before fluxing and 59.0 and 30.8 mole per cent. after fluxing. The agreement is reasonably good considering that in the conversion of carbonate to sulfide with sulfur a considerable proportion of sulfate is formed.

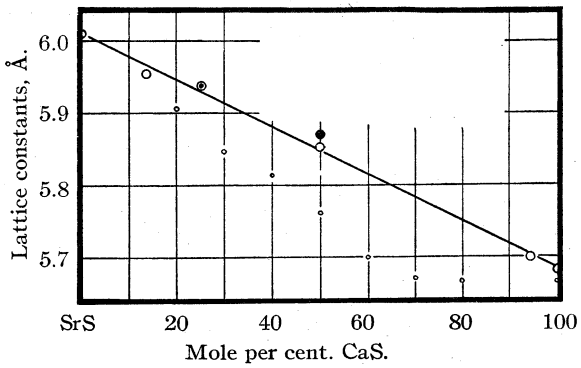

Fig. 1.—Lattice constants (Si,Ca)S: O, LiF fluxes, ●, $SO_4^=$ fluxes; ○, Rumpf.

Thus solid solutions of sulfides form when a mixture that is itself a solid solution is converted to sulfide. When the starting material is not a solid solution, appreciable solid solution is not obtained. This indicates a low rate of diffusion for these ions at 1000°.

These conclusions serve to explain some of the results previously obtained with mixtures of strontium selenite and other salts.[4] One of these systems ($SrSeO_3$–$CaSeO_3$) gave a lattice constant on reduction which differed widely from that predicted from the expected (Ca,Sr)Se solid solution. This experiment was repeated using a larger proportion (39 mole per cent.) of calcium selenite. The pattern of the selenide phase from the reduced mixture could barely be distinguished from the background but a strong set of lines corresponding to calcium oxide was present. Upon fluxing the mixture with lithium fluoride a distinct pattern of selenide phase appeared with lattice constant corresponding to about 14 mole per cent. calcium. The calcium oxide pattern was unaltered by the fluxing. It would appear, therefore, that the hydrolysis which always occurs when calcium selenite is reduced does not lead to the formation of strontium oxide or to a strontium–calcium oxide solution upon reduction of the mixture of strontium and calcium selenites.

The intersolubility of calcium and strontium oxides was accordingly tested by fluxing (a) a mixture of calcium oxide, strontium fluoride, and lithium fluoride in the proportions of 100:15:5, and (b) a similar mixture composed of strontium oxide, calcium fluoride, and lithium fluoride. From the powder picture of the former, a lattice constant 4.8020 Å. was computed. In the powder picture of the latter were found two sets of lines: from those that corresponded to a strontium oxide phase, the lattice constant 5.1312 Å. was computed; and from those that corresponded to a calcium oxide phase, the lattice constant 4.806 Å. It is obvious that ion exchange between base and flux had occurred in experiment b. The intersolubility of strontium and calcium oxides is apparently quite limited. According to Vegard's law, these results correspond to approximately 2.5

mole per cent. calcium oxide in strontium oxide, and 1 mole per cent. strontium oxide in calcium oxide.

The pronounced effect of oxide upon the luminescent properties of phosphors[9] suggested that solid solution with the sulfide or selenide might occur. The lattice constants obtained by fluxing strontium oxide and sulfide and oxide and selenide mixtures are shown in Table IV. It can be seen that the amount of oxide which disssolves in either selenide or sulfide is quite small and lies almost within the limits of determination by X-ray diffraction.

TABLE IV

LATTICE CONSTANTS OF MIXTURES CONTAINING OXIDE

Composition by weight Base	Flux	Fluxing time, hours	Lattice constant Å. SrO	Other base
SrSe 5, SrO 5	LiF 1	30	5.145	6.230
SrSe 100, SrO 0, 1, 2, 4[a]	SrF_2 7.5, $SrSO_4$ 7.5	0.75		6.232
SrS 2, SrO 1	LiF 0.3	30	5.140	6.0050
SrS 100, SrO 3	LiF 9	1.5		6.0075
SrS 100, SrO 10	LiF 9	1.5		6.0070
SrS 100, SrO 2	$SrCl_2$ 12	1.5		6.0065

[a] Phillip's Straumanis camera used.

The intersolubility of magnesium sulfide with calcium and strontium sulfides was also tested by the same procedures. The lattice constants for these mixtures are listed in Table V and should be compared with the values for the pure sulfides given in Table I. There is very little intersolubility in the MgS–SrS systems but with the CaS–MgS system about 11 weight per cent. magnesium sulfide dissolves in the calcium sulfide and about 15 weight per cent. of calcium sulfide in the magnesium sulfide lattice. This is perhaps a greater intersolubility than one would expect with a difference in cationic radii of some 50 per cent.

TABLE V

LATTICE CONSTANTS OF MIXTURES CONTAINING MAGNESIUM SULFIDE

Composition by weight Base	Flux	Fluxing time, hours	Lattice constant, Å. MgS	Other base
MgS 5, SrS 10	LiF 2.2	3	5.194	6.0058
SrS 10	LiF 0.5, MgF_2 1	3		6.0062

MgS 1, CaS 5	NaCl 1.2	1		5.614
MgS 5, CaS 1	NaCl 1.2	1	5.251	

Acknowledgments.—The authors wish to thank Professor Fankuchen for his advice and Mr. Milton Schneider for his assistance in taking some powder diagrams. We are also indebted to Miss Hilda Texin and Messrs. Richard Hall and Kenneth Stripp for some of the samples used.

Summary

Precision lattice constants were determined for magnesium, calcium and strontium sulfides, strontium selenide, calcium and magnesium oxides. The extent of solid solution among these compounds and some of the methods for forming solid solutions were studied.

Complete intersolubility exists among calcium sulfide, strontium sulfide and strontium selenide. Magnesium and calcium sulfides are intersoluble to a limited extent. Solid solution formation among the other pairs appears to be negligible.

Melting Points of Iron Oxides on Silica; Phase Equilibria in the System Fe–Si–O as a Function of Gas Composition and Temperature

BY L. S. DARKEN

The phase relations in the ternary system Fe–O–Si are of considerable interest to the steel industry, particularly in two respects: (1) the oxidation (scaling) of silicon steels produces in some cases a subscale and in other cases a so-called "silicon skin" (mainly metallic Fe + SiO_2). Since the primary requisite for scaling is the production of a gradient of the partial pressure of oxygen in the vicinity of the surface scaled, it is believed that a knowledge of the stability of the different oxides under various partial pressures of oxygen will aid in interpreting the observed phenomena. (2) The behavior of refractories is influenced in some cases by the form of iron oxide contained therein or deposited thereon. This is particularly so in blast furnace brick, in which metallic iron is thought to act as a catalyst for the deposition of carbon which in extreme cases disintegrates the brick. It has been observed that brick fired at high temperatures are less susceptible to this form of attack. It seems reasonable that higher temperatures effect fusion of the iron oxides forming silicates, etc., which are less easily reduced and less catalytic. The present investigation demonstrates that the temperature of fusion of iron oxides in contact with silica is a rather sensitive function of gas composition (varying from 1120 to 1447°), hence that fusion may be accomplished in some

cases by control of the gas atmosphere without changing the temperature.

Experimental Procedure and Data.—A number of the univariant equilibria in the oxide region of the ternary system Fe–Si–O are identical with those of the binary system Fe–O which have been investigated previously. Others may be estimated with sufficient precision from available data, though there are but few data on the influence of gas composition on the melting temperature of the oxides. The present experimental investigation was intended partially to fill this gap by determination of the relation between gas composition and temperature for the two univariant equilibria: silica, magnetite, melt, gas; and silica, fayalite, melt, gas.

In each experiment a silica rod (about 1 mm. diam., 5 cm. long) was coated with Fe_2O_3 by dipping it in an aqueous suspension of the latter. After the coated rod had dried, it was placed on a platinum suspension and hung in the gradient of a platinum-wound tubular furnace, which was controlled in the manner described previously,[1] the winding of the furnace acting as one arm of a bridge circuit which was automatically balanced. The desired atmosphere, usually delivered by a gas mixer, was introduced into the furnace (at atmospheric pressure) through the mercury seal at the bottom of the tube. The rate of flow of gas was about 50 cc. per minute, which is ample to avoid appreciable thermal separation of the gases. The time at temperature varied from fifteen minutes in some of the preliminary experiments to eighteen hours. If the temperature and gas composition were suitably chosen, the sample exhibited on removal a fairly sharp demarcation between the opaque fused region and the region in which no fusion had occurred. This transition is best seen by the naked eye using the sky as a background. In questionable cases, the demarcation was developed by immersing the rod in warm 6 *N* hydrochloric acid for a few minutes; the acid removed essentially all the iron from the unfused region, but had little effect on the fused portion. To determine the temperature, the position of the demarcation line was carefully measured and a thermocouple was inserted at the corresponding position in the furnace. If the temperature gradient in this region was too steep to yield the desired precision, the furnace temperature was readjusted so that on repetition of the experiment the transition occurred nearer the center of the furnace in a region of smaller temperature gradient.

After this temperature adjustment had been made, so that the transition in a given atmosphere occurred in a region where the gradient was about 10° per cm., the specimen was held at the determined position for different lengths of time to be sure that the observed demarcation line corresponded to equilibrium between the phases involved. Fusion of course proceeded from the hotter zone to the cooler. It was found that, within the limits of experimental measurement, motion of the boundary line between fused and unfused portions ceased after about one-half hour; however, the sharpness of the boundary line usually increased appreciably on longer treatment. For this reason, as well as to be sure of equilibration, all specimens were treated for sixteen hours. In each case a preliminary measurement was made, usually at the end of one hour, but at the lower temperatures, at a somewhat longer time. In all cases, the position of the demarcation line was the same at the end of sixteen hours as at the time of the previous preliminary measurement. The experimental data are recorded in Table I, and are presented graphically in Fig. 1 along with curves representing other equilibria subsequently discussed.

Since it is reasonable to expect a slight difference in equilibrium temperature depending on whether the solid silica phase is vitreous or crystalline, several determinations were made using a vitreous silica rod whose surface had been transformed to cristobalite. This conversion was accomplished by heating the rod at about 1500° for an hour; the success of this treatment was easily recognized by the shattering of the surface accompanying the high–low inversion of cristobalite (200–275°) as the specimen was cooled. From the data assembled by Mosesman and Pitzer[2] it is clear that the free energy difference between vitreous silica and any of the crystalline forms is greater, in the range covered, than the free energy difference between any two crystalline forms. Hence it is of negligible importance from the viewpoint of the present investigation that cristobalite was used, in spite of the fact that tridymite is the stable crystalline form in the temperature range investigated. Since the metastability of the vitreous form is greater at lower temperatures, it is evident that the observed temperature of the four phase equilibria would be most greatly influenced by the form of silica at the lower temperatures. For this reason, cristobalite was used in the case of all three measurements of the equilibrium between fayalite, silica, liquid and gas. Cristo-

TABLE I

MELTING POINT OF IRON OXIDES IN CONTACT WITH SILICA AND VARIOUS ATMOSPHERES AT ONE ATMOSPHERE TOTAL PRESSURE

Atmosphere	Form of silica	Temperature, °C.
(the univariant equilibrium; silica, magnetite, melt, gas)		
Oxygen[a]	Vitreous	1447
Air	Vitreous	1442
1/4% O_2 in CO_2	Vitreous	1411
CO_2, CO; CO_2/CO = 308	Vitreous	1369
CO_2, CO; CO_2/CO = 79.2	Vitreous	1279
CO_2, CO; CO_2/CO = 52.8	Vitreous	1230
CO_2, CO; CO_2/CO = 26.0	Cristobalite	1159
CO_2, CO; CO_2/CO = 20.8	Vitreous	1131
(the univariant equilibrium; silica, fayalite, melt, gas)		
CO_2, CO; CO_2/CO = 14.1	Cristobalite	1120
CO_2, CO; CO_2/CO = 11.2	Cristobalite	1129
CO_2, CO; CO_2/CO = 4.02	Cristobalite	1139

[a] Actually the phases in equilibrium at this point are silica, hematite, melt and gas as may be seen from Fig. 1. It is, however, very nearly identical with quintuple point 1.

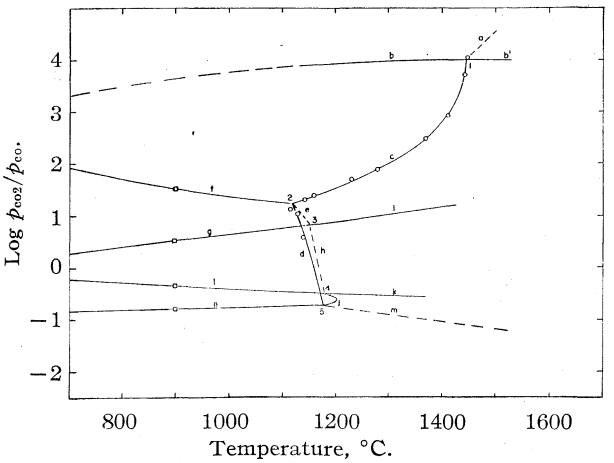

Fig. 1.—Relations between gas composition and temperature for the univariant equilibria of the system Fe–Si–O.

(1) Darken and Gurry, THIS JOURNAL, **67**, 1398 (1945).

(2) Mosesman and Pitzer, *ibid.*, **63**, 2348 (1941).

balite was also used in the case of one sample in the series determining the equilibrium between magnetite, silica, liquid, gas. Since this point falls on the same smooth curve as that for the points representing equilibrium with vitreous silica it is concluded that the influence of the form of silica is smaller than the experimental error, which is estimated to be about 5°.

Although the system investigated comprises four elements (iron, oxygen, silica, carbon) the solubility of carbon (or carbon monoxide or carbon dioxide) in the condensed phases is negligibly small in the region investigated; hence, the system may be regarded as a three component one. It is convenient, however, to give the pressure in terms of the ratio of carbon dioxide to carbon monoxide in the gas phase rather than in terms of the partial pressure of oxygen; it is clear that these are interconvertible by means of the equilibrium constant for the homogeneous gaseous reaction $CO + {}^1/_2O_2 = CO_2$. Values of this constant, calculated from the tabulated values of $(F^0 - E_0^0)/T$ for CO,[3] O_2,[4] and CO_2,[5] using the value of ΔE_0^0 given by Rossini,[6] were given by Darken and Gurry.[2] The uncertainty of this equilibrium constant is negligibly small compared to other errors involved in construction of the diagram.

Construction of the Remainder of the Diagram.—In order to construct the diagram (Fig. 1) showing the equilibrium ratio of carbon dioxide to carbon monoxide in the presence of various stable phases and at various temperatures the general procedure was as follows. The known invariant points (five phase equilibria) and the known univariant curves (four phase equilibria) or points thereon were plotted. A number of these are identical with the invariant curves of the binary system iron–oxygen. In general for a ternary system five univariant curves intersect at an invariant point; however, one of these univariant curves represents the small effect of pressure on the completely condensed system (no gas phase present), and does not appear in the representation chosen since the total pressure is essentially one atmosphere. Hence the construction consisted mainly of interconnecting the univariant curves to accord with this condition, using directly determined data together with indirect data related thermodynamically to the diagram.

There are five invariant points occurring in the region considered; at these points the following phases are in equilibrium (the numbers correspond to those in Fig. 1).

(1) hematite, magnetite, silica, melt, gas
(2) magnetite, fayalite, silica, melt, gas
(3) magnetite, wüstite, fayalite, melt, gas
(4) wüstite, fayalite, metal, melt, gas
(5) fayalite, metal, silica, melt, gas

Of the various stable phases listed, hematite (Fe_2O_3), fayalite ($2FeO{\cdot}SiO_2$), silica (SiO_2), and metal (Fe) are essentially of fixed composition; magnetite (Fe_3O_4) and wüstite ("FeO") are binary compounds containing no appreciable amount of silica, although the ratio of iron to oxygen is variable; the melt contains all three components in variable amounts.

(6) F. D. Rossini, *J. Research Nat. Bur. Standards*, **22**, 407 (1939).

There are fifteen univariant curves derived from these five invariant points. In addition to the gas phase the following phases are present along the univariant curves shown in Fig. 1.

(a) hematite, silica, melt
(b) hematite, magnetite, silica
(b′) hematite, magnetite, melt
(c) magnetite, silica, melt
(d) fayalite, silica, melt
(e) magnetite, fayalite, melt
(f) magnetite, fayalite, silica
(g) magnetite, wüstite, fayalite
(h) wüstite, fayalite, melt
(i) magnetite, wüstite, melt
(j) metal, fayalite, melt
(k) wüstite, metal, melt
(l) wüstite, fayalite, metal
(m) metal, silica, melt
(n) metal, fayalite, silica

Of these fifteen equilibria b, b′, g, i, k, and l are essentially identical with those of the binary system iron–oxygen determined in part by Darken and Gurry.[1,7] Equilibrium c and part of d was determined by the present investigation. Invariant points 1 and 2 are thus established by the intersection of b and c and of c and d, respectively. The temperature of invariant point 4 was determined by Bowen and Schairer[8] as 1175°; its position is thus fixed by this temperature and the fact that it lies on the curves *l* and *k*.

The equilibria of this system at 900° have been investigated by Schenck, Franz and Laymann,[9] whose data on the various univariant equilibria are thermodynamically consistent and in good agreement with the data of Darken and Gurry on the binary system iron–oxygen. At this temperature the ratio p_{CO_2}/p_{CO} is 0.163 for equilibrium n, and is 34.5 for equilibrium f.[10] Curve f is thus reasonably well established by this point at 900° and quintuple point 2 at 1118°. It was constructed under the assumption that $\log p_{CO_2}/p_{CO}$ is linear with $1/T$. Curve n is determined by the point at 900° and a calculated point[11]

(7) Darken and Gurry, THIS JOURNAL, **68**, 798 (1946).
(8) Bowen and Schairer, *Am. J. Sci.*, **24**, 177 (1932).
(9) Schenck, Franz and Laymann, *Z. anorg. allgem. chem.*, **206**, 126 (1932).
(10) The thermodynamic consistency of these values may be demonstrated in the following manner. The chemical reaction corresponding to equilibria f, g, l and n may be written

(f) $3(2FeO{\cdot}SiO_2) + 2CO_2 = 2Fe_3O_4 + 3SiO_2 + 2CO$
(g) $3FeO$ (in wüstite) $+ CO_2 = Fe_3O_4 + CO$
(l) $Fe + CO_2 = FeO$ (in wüstite) $+ CO$
(n) $2Fe + SiO_2 + 2CO_2 = 2FeO{\cdot}SiO_2 + 2CO$

It will be noticed that these four equations are not independent but that any one may be expressed in terms of the others—for example (f) = 6(l) + 2(g) − 3(n). The following relation must then hold between the thermodynamic equilibrium constants: $K_f = K_l^6 K_g^2 / K_n^3$. The values of K_l and K_g (including the activity of (FeO) were taken from Darken and Gurry[1] and that for K_n from Schenck, *et al.*[9] The calculated value for the ratio p_{CO_2}/p_{CO} corresponding to (f) is 34.7 in agreement with the observed value[9] 34.5.

(11) At 1100° the logs of the ratio p_{CO_2}/p_{CO} are 1.28, 0.785 and −0.450, for the equilibria f, g and l, respectively. The log of the ratio of the activity of FeO in wüstite equilibrated with iron to the activity of FeO in wüstite equilibrated with magnetite is 0.124. Hence for equilibrium n at 1100°:

$$\log \frac{CO_2}{CO} = \frac{-1.28}{3} - 0.450 + \frac{0.785}{3} - 0.124 = -0.74$$

at 1100° where p_{CO_2}/p_{CO} is found to be 0.182.

Quintuple point 5 is established as the point on curve n at 1180°, the temperature determined by Bowen and Schairer.[8]

Curve j is constructed connecting quintuple points 4 and 5; it passes through a maximum at 1208°, the melting point of pure fayalite as determined by Bowen and Schairer.

Curve m, radiating from quintuple point 5, is estimated roughly in the following manner: Iron melts in contact with its molten oxide at about 1525°, at which temperature $\log p_{CO_2}/p_{CO} = -0.68$; it is estimated that the activity of ferrous oxide in the oxide phase in equilibrium with iron is depressed by saturation with silica to about one-third,[12] thus at 1525° on curve m the value of $\log p_{CO_2}/p_{CO}$ is $-0.68 - \log 3 = -1.16$. The remainder of the curve is determined approximately by these two points.

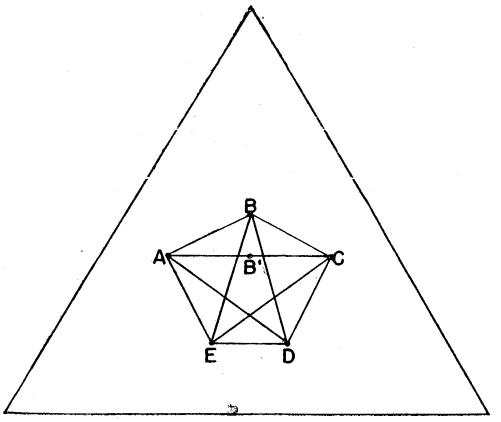
Estimation of Position of Quintuple Point 3.—Of the five quintuple points occurring in the region covered by Fig. 1 four have already been considered and their positions established; the position of quintuple point 3 remains to be determined. Of the fifteen univariant equilibrium curves only three remain to be considered. Curve a is of little interest since the corresponding equilibrium can exist only at pressures above one atmosphere; its general direction is indicated by a dotted line in the diagram. The positions of curves e and h, which connect quintuple point 3 to quintuple points 2 and 4, respectively, are undetermined since there are no available experimental data on either of these curves; also the position of quintuple point 3 is undetermined except that it must be on the curves g, i. Thus from the direct data available, the only facts known concerning curves e and h are that they start from quintuple points 2 and 4, respectively, and terminate at a common point on the curves g, i which is quintuple point 3.

Some insight into possible constructions of these curves is gained by consideration of a theorem relating the order of curves about a quintuple point to the isothermal (triangular) composition diagram. This theorem is due in part to Roozeboom, Schreinemakers and Smits. An original derivation for the general case was given by Morey and Williamson.[13] Since a quintuple point represents the equilibrium of five phases each of a definite composition, the representation of this point on a composition diagram consists of five points, each of which represents the composition of one of the five phases present. The five univariant equilibria derived from the quintuple point correspond to the five possible combinations of four of the five phases. Thus at quintuple point 3, the five phases are magnetite, wüstite, fayalite, melt and gas. It will be noted that the five univariant equilibria correspond to the absence from the five phases present at the quintuple point of wüstite, melt, magnetite, fayalite and gas, respectively. The theorem states that if the points representing the composition of any three phases are colinear on the composition diagram, the two pressure–temperature curves representing the two univariant equilibrium involving these three phases are identical, that is, one is the extension of the other. At quintuple point 3 it is obvious that the compositions of magnetite, wüstite and gas (oxygen) are colinear on the triangular composition diagram; (they all lie on the Fe-O edge of the triangle) hence the curves g and i in Fig. 1 are extensions one of the other, as already anticipated from the consideration that the equilibrium of wüstite, magnetite and gas is not influenced by a third substance which is not appreciably soluble in any of these three phases.

The theorem gives further information as to the more general case in which three points are not colinear. This extended part of the theorem may best be visualized by imagining that five pins are stuck in the composition diagram at the five points corresponding to the compositions of the five phases present at the quintuple point. These pins are then each connected to each of the other four by elastic strings as in Fig. 2a. This particular set of compositions A, B, C, D, E, may be regarded as derived from any one of a variety of sets of compositions (imaginary quintuple points) in which colinearity of three points does occur—for example, the set A, B′, C, D, E. The theorem states in effect that if the pin at B with its attached elastic strings may be moved to B′ without any of the interconnecting lines (elastic strings) crossing any of the points (or *vice versa*) then the two univariant curves corresponding to the equilibria ABCD and ABCE are adjacent at the quintuple point on the pressure–temperature diagram, *i. e.*, no other univariant curve lies between them at their intersection. In the present example B may be so moved to B′ colinear with A and C but may not be so moved as to be colinear with any other two of the five points. The same type of operation may be performed with each of the other points (A, C, D and E). Thus the order of all the univariant curves around a quintuple point may be established provided that the composition of the five phases is known. It is also necessary to establish the stable direction of each univariant curve since each curve is continuous through the quintuple point but represents a stable equilibrium in one direction and a metastable equilibrium in the other. Returning to the illustration, this matter is determined as follows: if the two points E and D lie on the same side of the line AB′C then the two univariant curves for equilibria ABCD

(12) This is based on the data of Körber and Oelsen [*Mitt. Kaiser-Wilhelm Inst. Eisenforsch Dusseldorf*, **15**, 271 (1933)] that at steel making temperatures the equilibrium oxygen content of iron under an iron-oxide slag saturated with silica is about 1/3 the oxygen content of iron under an iron oxide slag.

(13) Morey and Williamson, THIS JOURNAL, **40**, 59 (1918). Further discussion and applications are given by G. W. Morey in "Commentary on the Scientific Writings of J. Willard Gibbs," Yale University Press, New Haven, Conn., 1936.



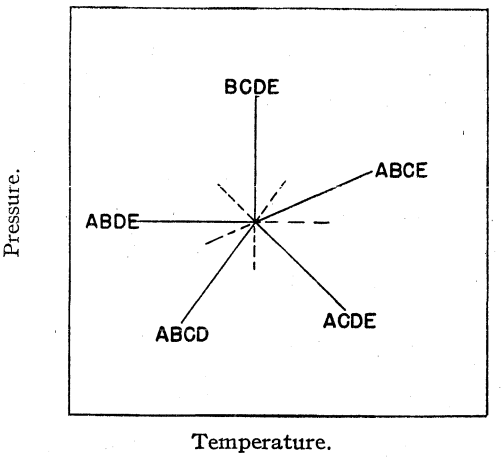


Fig. 2.—Schematic representation of the relation between *a* the composition of the five phases in equilibrium at the quintuple point and *b* the order of the univariant equilibrium curves about the quintuple point.

and ABCE are adjacent stable to metastable (*i. e.*, the stable portion of each, designated by a full line, is adjacent to the metastable portion of the other, designated by a dashed line). If E and D happened to lie on opposite sides of AB'C then these two univariant curves would be adjacent stable to stable. Application of this theorem to the postulated compositions shown in Fig. 2a leads to the order of univariant curves in the pressure temperature diagram as shown in Fig. 2b. Obviously the theorem is equally valid if the logarithm of the pressure is used as ordinate instead of the pressure itself.

Application of this theorem to quintuple point 4 in Fig. 1, using the composition data of Bowen and Schairer, leads to the conclusion that curve h radiates upward from this point and slightly to the left; this follows from the fact that the composition of the melt is very nearly colinear with that of wüstite and fayalite but is slightly higher in oxygen. It is assumed that the curvature of h is small. Quintuple point 3 is thus very roughly estimated as the point at 1150° lying on the curve g,i. The diagram is completed by constructing the short curve e connecting quintuple points 2 and 3.

Temperature Maxima and Minima of the Univariant Curves.—In the case of a univariant equilibrium in a ternary system involving three condensed (solid or liquid) phases and a gaseous phase it is rather unusual to find that all the condensed phases have fixed compositions independent of temperature. It is this variation of composition of the phases with temperature which introduces the most serious complexities into the treatment of such systems. Of the various equilibria here considered only two (f and n) of the truly ternary equilibria, *i. e.*, equilibria in which all components participate, as distinguished from equilibria which may be represented as binary since the third component is inert, consist exclusively of phases of reasonably fixed composition. Thus, equilibrium f may be represented by the chemical equation

$$3(2FeO\cdot SiO_2) + O_2 = 2Fe_3O_4 + 3SiO_2$$

The equilibrium constant may be written

$$K_f = \frac{a^2_{Fe_3O_4} a^3_{SiO_2}}{a_{2FeO\cdot SiO_2} a_{O_2}}$$

Since the solid phases involved are all of fixed composition, or very nearly so, the activities may be set equal to unity. The activity of oxygen is equal to its partial pressure in the gas phase and hence $K_f = 1/p_{O_2}$. The change of K_f and hence of $1/p_{O_2}$ is given by the simple equation: $d \ln K_f/d(1/T) = -\Delta H_f/R$. The treatment of this is relatively simple and leads to the well known linear relation between $\log K$ and $1/T$ if the heat of reaction (ΔH) is essentially independent of temperature. The use of carbon dioxide–carbon monoxide mixtures as the gas phase introduces no further complexities since the ratio CO_2/CO may be regarded as simply a measure of $p_{O_2}^{1/2}$ through the homogeneous gas equilibrium involving carbon monoxide, carbon dioxide, and oxygen. Hence for this equilibrium the plot of $\log p_{CO_2}/p_{CO}$ *versus* $1/T$ exhibits only the slight curvature occasioned by the difference in heat capacities. The use of temperature instead of $1/T$ as ordinate in Fig. 1 does not lead to any serious distortion of the relationship but simply produces a mild curvature.

A very different situation prevails, however, in the equilibria involving the molten oxide phase (curves a, c, d, e, h and j). In each of these cases it is impossible to write a chemical equation with integral or even constant coefficients to represent the reaction. The relation between $\log p_{O_2}^{1/2}$ (or $\log p_{CO_2}/p_{CO}$) and temperature is a function not only of the heats of reaction but also of the variable composition of the liquid phase. In general, these curves cannot be estimated even approximately by assuming $\log p_{O_2}^{1/2}$ to be linear with $1/T$; for example, curve j passes through a maximum temperature. The occurrence of such a temperature maximum (or minimum) may be

predicted, if the compositions are known, by aid of the theorem that at such a maximum (or minimum or stationary value) the composition of the three condensed phases is represented by three colinear points on the composition diagram[14]: The converse of this theorem is also true. Thus, at the maximum temperature of curve j the compositions of metal, fayalite and melt are colinear; the melt may be considered as molten fayalite from which some iron has been removed. It will be observed that the experimentally determined curve c is obviously approaching a maximum at its high temperature end. It does not actually pass through a maximum since it ends at quintuple point 1 first. It may, however, be inferred from the steep vertical rise of curve *c* near quintuple point 1 that the composition of the liquid oxide at this quintuple point is nearly colinear with the compositions of magnetite and silica; *i. e.*, this melt may be regarded approximately as composed of Fe_3O_4 and SiO_2.

Equilibria in Special Cases.—Although Fig. 1 shows the various possible univariant equilibria curves in the region under consideration, it is not possible to decide from this diagram alone what equilibria are pertinent for a given composition. In other words, the regions between the curves in this figure do not correspond to a unique set of phases. In general, the diagram may be applied to a specific case only if some composition data are available. In case a large amount of silica is present, the pertinent equilibria (taken from Fig. 1) are shown in Fig. 3. The stable phases, in addition to the gas, in the various fields are designated in this diagram. This diagram may be taken as a guide to the various iron oxide phases that may be present in contact with silica brick under different conditions of temperature and gas composition.

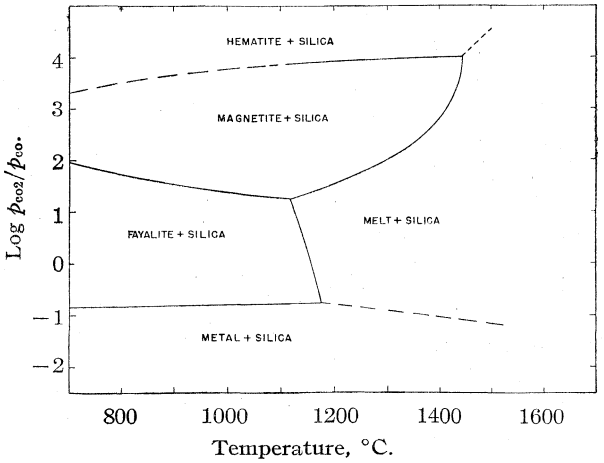

Fig. 3.—Stable phases of the system Fe–Si–O in the presence of solid silica.

(14) This theorem is similar to that of Morey and Williamson, used previously; a proof is given in the appendix. A less explicit derivation was given by Gibbs.

If the ratio of total silicon to total iron is low, as in the case of a silicon steel and the oxides formed therefrom, the stable phases under various conditions of temperature and gas composition are as shown in Fig. 4. The temperature of complete melting is not shown in either Fig. 3 or Fig. 4, since this temperature is a continuous function of composition and may not be readily expressed on this type of diagram. In the region on the right of the diagrams, designated as corresponding to melt plus a solid phase, the relative proportions of the two phases depend on the composition as does the temperature of complete melting corresponding to the complete disappearance of the solid phase.

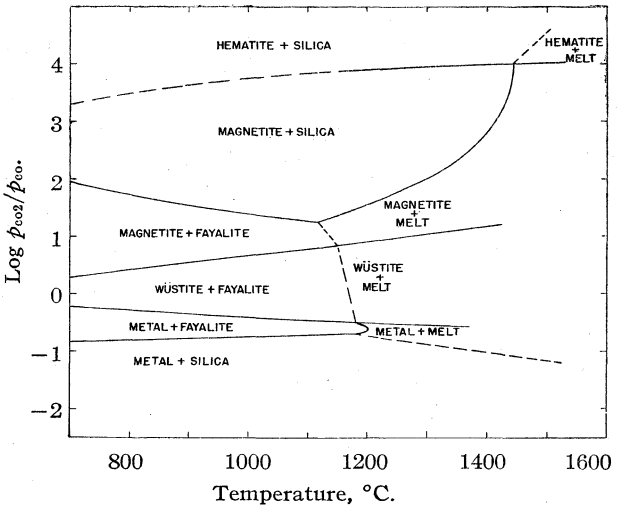

Fig. 4.—Stable phases of the system Fe–Si–O at low amounts of silicon.

The Migration of Silica During the Scaling of Steel.—It has been observed that the presence of a relatively small amount of silica or siliceous material on an iron or steel surface which is heated in an oxidizing atmosphere causes the scale to be more adherent to the metal than is the case in the absence of silica. The siliceous scale forms a very irregular boundary with the metal and is thus anchored so that it does not separate cleanly from the metal when bent, quenched or subjected to impact. The most peculiar part of the behavior is that the silica does not grow out appreciably with the scale, but remains principally near the scale–metal interface and spreads laterally so that the adherent zone increases with time of scaling. Clearly this phenomenon is very undesirable at any stage in the heat treatment of steel since it may occasion surface defects in the finished product.

In an elementary sense some insight is given by the consideration that silica forms a compound with ferrous though not with ferric oxide. It would be expected to migrate toward the region where it can form the most stable compound, which in this case is the scale–metal interface

where the composition of the iron oxide is nearest that corresponding to the formula FeO. This same line of reasoning may be developed in a quantitative manner by consideration of the activity of silica in the metal and various scale layers. At constant temperature silica will tend to move in such manner as to lower its free energy and hence its activity. The activity of silica differs appreciably from unity only when the silica is present in compound form, *i. e.*, combined as fayalite. From the equilibria (f) and (n)[9] it is found that at 900° in the presence of metallic iron and fayalite the activity of silica is given by the expression

$$a_{SiO_2} = 0.0268(p_{CO}/p_{CO_2})^2$$

and in the presence of magnetite and fayalite

$$a_{SiO_2} = 0.094(p_{CO_2}/p_{CO})^{2/3}$$

In the presence of wüstite and fayalite the activity of silica is inversely proportional to the square of that of ferrous oxide; a_{FeO} was taken from Darken and Gurry.[1] The variation of the activity of silica thus calculated with the degree of oxidation is shown in Fig. 5. The lowest activity is seen to be at the scale–metal interface, thus accounting for the observation that silica tends to move to and remain at this interface.

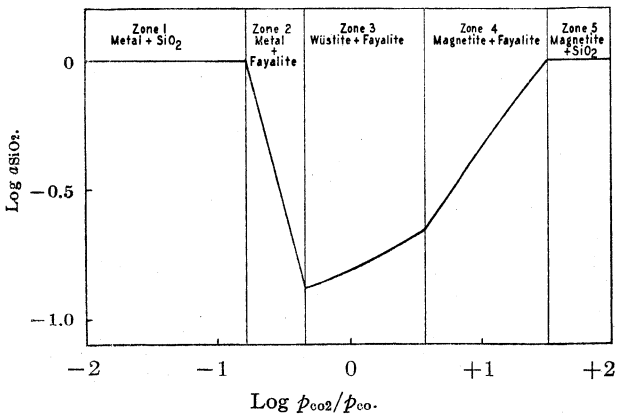

Fig. 5.—Activity of silica in iron and iron oxide systems at 900°.

Appendix

Proof of Theorem.—If a univariant equilibrium in a ternary system has a maximum (or minimum) temperature on a pressure temperature plot, then at this temperature the compositions of the three condensed phases, one of variable and two of fixed composition, are colinear. By the fundamental theorem of partial differentiation the total derivatives of the activities (at constant total pressure), of each of the three components may be written as follows

$$(1)\quad \frac{d\ln a_1}{d(1/T)} = \left(\frac{\partial \ln a_1}{\partial(1/T)}\right)_{N_2,N_3} + \left(\frac{\partial \ln a_2}{\partial N_2}\right)_{N_3,T}\frac{dN_2}{d(1/T)} + \left(\frac{\partial \ln a_1}{\partial N_3}\right)_{N_2,T}\frac{dN_3}{d(1/T)}$$

$$(2)\quad \frac{d\ln a_2}{d(1/T)} = \left(\frac{\partial \ln a_2}{\partial(1/T)}\right)_{N_2,N_3} + \left(\frac{\partial \ln a_2}{\partial N_2}\right)_{N_3,T}\frac{dN_2}{d(1/T)} + \left(\frac{\partial \ln a_2}{\partial N_3}\right)_{N_2,T}\frac{dN_3}{d(1/T)}$$

$$(3)\quad \frac{d\ln a_3}{d(1/T)} = \left(\frac{\partial \ln a_3}{\partial(1/T)}\right)_{N_2,N_3} + \left(\frac{\partial \ln a_2}{\partial N_2}\right)_{N_3,T}\frac{dN_2}{d(1/T)} + \left(\frac{\partial \ln a_3}{\partial N_3}\right)_{N_2,T}\frac{dN_3}{d(1/T)}$$

The a's refer to activities and the N's to mole fractions. If these three equations are multiplied by N_1, N_2 and N_3, respectively, and added, then all terms on the right-hand side except the first of each equation disappear by virtue of the Gibbs–Duhem relationship.

$$(4)\quad \frac{N_1 d\ln a_1 + N_2 d\ln a_2 + N_3 d\ln a_3}{d(1/T)} = N_1\left(\frac{\partial \ln a_1}{\partial(1/T)}\right)_{N_2,N_3} + N_2\left(\frac{\partial \ln a_2}{\partial(1/T)}\right)_{N_2,N_3} + N_3\left(\frac{\partial \ln a_3}{\partial(1/T)}\right)_{N_2,N_3}$$

If the liquid phase is in equilibrium with two solid phases of fixed composition and a gaseous phase, then the two solid phases may arbitrarily be selected as components (designated components 1 and 2). The standard state for these components is selected as the solid and hence the activity of each is unity and its total derivative is zero. Then

$$(5)\quad N_3\frac{d\ln a_3}{d(1/T)} = N_1\left(\frac{\partial \ln a_1}{\partial(1/T)}\right)_{N_2,N_3} + N_2\left(\frac{\partial \ln a_2}{\partial(1/T)}\right)_{N_2,N_3} + N_3\left(\frac{\partial \ln a_3}{\partial(1/T)}\right)_{N_2,N_3}$$

If component 3 be selected as a gaseous component (oxygen in the present case) then $p_{O_2}^{1/2}$ may be written for a_3; further the partial derivatives on the right multiplied by R are equal to the partial molal heats of solution $\overline{H}_1$, $\overline{H}_2$, $\overline{H}_3$, ($\overline{H}_1$ and $\overline{H}_2$ being heats of melting).

$$(6)\quad R\frac{d\ln p_{O_2}^{1/2}}{d(1/T)} = \frac{N_1}{N_3}\overline{H}_1 + \frac{N_2}{N_3}\overline{H}_2 + \overline{H}_3$$

In terms of the ratio p_{CO_2}/p_{CO}

$$(7)\quad R\frac{d\ln (p_{CO_2}/p_{CO})}{d(1/T)} = \frac{N_1}{N_3}\overline{H}_1 + \frac{N_2}{N_3}\overline{H}_2 + \overline{H}_3'$$

where $\overline{H}_3'$ is equal to the change of the heat content of oxygen on transfer from the gas phase to the liquid. Since N_3 occurs in the denominator it follows that whenever $N_3 = 0$ the expression becomes infinitely great. But by the choice of components, the equality of N_3 to zero is synonymous with the colinearity (on the composition triangle) of melt, component 1, and component 2. Hence whenever the composition of the melt is colinear with the composition of the two solid phases in equilibrium with it, it follows that the plot of log p_{CO_2}/p_{CO} (or log p_{O_2}) *vs.* $1/T$ (or *vs.* temperature) is vertical. Conversely, since the heats of solution are never infinite, any vertical portion of the plot corresponds to colinearity of the three phases on the composition diagram. A general proof of this theorem was given by Gibbs.[15]

Summary

The melting point of iron oxides in contact with silica has been determined as a function of the partial pressure of oxygen or the ratio of carbon dioxide to carbon monoxide in the gas phase. With the aid of these and other available data, a large part of the diagram showing the stable phases under various conditions of temperature and gas composition has been constructed for the ternary system iron–silicon–oxygen. The data have been used to interpret the migration of silica through iron oxide to the scale–metal interface during the scaling of steel.

The Reactions of Diborane with Hydrocarbons[1]

BY DALLAS T. HURD

A number of experiments have been conducted to delineate the character of the complex reactions that occur between hydrocarbons and diborane at elevated temperatures. In these experiments the effect of the highly reactive diborane on the reaction products has been minimized by using only small amounts of diborane with relatively large amounts of hydrocarbon. Under these conditions several different reactions have been observed:

1. The addition of diborane to olefins occurs with saturation of the double bonds and the formation of trialkyls of boron.
2. Substitution on the benzene ring occurs with the formation of phenyl boron compounds.
3. Diborane reacts with paraffins to form polymeric reaction products containing boron, carbon, and hydrogen. Breakdown and synthesis of hydrocarbon chains effected by the diborane obscures the nature of the reaction.

Experimental

The general technique employed in studying the addition and substitution reactions was to seal mixtures of diborane with various hydrocarbons in heavy-walled Pyrex tubes. The tubes were frozen in liquid nitrogen and evacuated before sealing. The tubes then were encased in protecting tubes of steel pipe and either heated in an oven or allowed to stand at room temperature. After the time allotted for the reaction had elapsed the tubes were immersed in liquid nitrogen to freeze their contents, their tops were cracked off under a blanket of dry nitrogen, and the reaction products together with any unchanged materials were removed from the tubes, generally by distillation on a vacuum chain.

A. Reactions with Olefins. 1. Isobutylene.—The reaction of isobutylene with diborane was studied with mixtures containing from two to ten per cent. by weight of diborane. Within this range of composition no significant differences in the results were observed. Most of the reactions were conducted by heating the tubes at 100° for twenty-four hours but it also was noticed that the addition reaction took place at room temperature although somewhat more slowly. Since no pressure of noncondensable gas developed in the tubes during these reactions it was presumed that the addition of diborane to the olefin was rapid and almost quantitative. Otherwise the pyrolysis of unreacted diborane at the elevated temperature would develop a pressure of hydrogen that would become apparent when the tubes were opened.

Distillation of excess isobutylene from a reaction mixture left a clear colorless oil of low volatility. Upon exposure of this oil to the air it quickly became warm from spontaneous oxidation. Inflammation was observed if a few drops were placed on a filter paper or in a watch glass.

Fractionation of a fresh sample of the oil under a nitrogen atmosphere in a distillation column of approximately twenty plates separated the sample into two fractions of almost equal volume, one boiling at 181.5° and the other at 188.5°. The boiling point calculated from reduced pressure data for tri-*t*-butylboron is 182°[2] and the reported boiling point of tri-isobutylboron is 188°.[3] Each fraction was shaken individually in a separatory funnel with aqueous sodium hydroxide and air until the oil had been oxidized completely and had been dissolved as the sodium salt of the corresponding butylboric acid. The solutions were concentrated by boiling and, after cooling, were neutralized by the addition of hydrochloric acid. This caused the precipitation of the white crystalline butylboric acids. A determination was made of the melting points of the isomeric acids thus isolated and the values obtained checked very closely with those reported in the literature (*t*-butylboric acid, m. p. 113–114°; reported m. p. 113°[2]; isobutylboric acid, m. p. 112–113°; reported m. p. 112°[3]). Although these two butylboric acid isomers have melting points lying within one degree of each other it was clear that the original reaction product comprised a mixture of isomeric tributylboron compounds since oxidation of an unfractionated sample of the oil and isolation of the mixed butylboric acids by the technique described above yielded a crystalline white solid with no sharply defined melting point melting over the range from 80–90°.

2. Ethylene.—Ethylene containing two per cent. by weight of diborane was heated at 100° for four days. The tube then was opened and the unreacted ethylene was removed by distillation on the vacuum chain. A small amount of clear liquid remained in the tube. This liquid inflamed immediately upon exposure to air. Since the liquid had an appreciable volatility it could be analyzed most conveniently on the mass spectrometer. Strong maxima in the pattern indicated large amounts of triethylboron. Examination of a vapor sample taken during the last stages of the removal of ethylene from the sample revealed no volatile ethyldiborane compounds.[4]

B. Reaction with Benzene.—Pure benzene was heated with five per cent. by weight of diborane in sealed tubes or in a stainless steel bomb for twelve hours at 100°. During the course of the reaction it was observed that the benzene gradually developed a dark yellow color. Upon opening the tubes after freezing the contents in liquid nitrogen it

(3) E. Krause and R. Nitsche, *ibid.*, **54**, 2784 (1921).

(4) These analyses were performed by Dr. Francis J. Norton.

was noticed that a large pressure of non-condensable gas, presumably hydrogen, had developed. The benzene solution of the reaction products was removed from the tubes in a nitrogen atmosphere.

Evaporation of the unreacted benzene from a sample of the solution left a soft solid material. This solid partially dissolved in water with the evolution of gas to give a milky solution. When this solution was made alkaline with sodium hydroxide and boiled it eventually became clear. After cooling the solution it was neutralized, extracted with ether, and the ether extract was evaporated to yield a white crystalline solid, m. p. 214° (reported m. p. for phenylboric acid 216°[5]). The identity of this compound as phenylboric acid was verified by specific chemical tests for this material, *i. e.*, by the precipitation of white phenylmercuric chloride (m. p. 251°) with mercuric chloride from a very dilute solution, by the thermal dehydration of the acid to its cyclic anhydride (m. p. 190°), and by the slow deposition of a silver mirror from ammoniacal silver nitrate solution.[6]

This experiment established that a substitution reaction occurred between benzene and diborane with the formation of phenylboron compounds.

An examination of the yellow benzene solution removed from the reaction tubes was made with the aid of the mass spectrometer. Samples were concentrated to varying degrees by removing benzene on a vacuum distillation system and analyses were made of the residual solutions. It was found, surprisingly enough, that diborane continued to be given off by the solutions even when most of the benzene had been removed and the samples were highly concentrated. The mass spectrographic analyses showed no evidence of any volatile phenylborane compounds, *i. e.*, phenylboron hydrides. These were indicated indirectly however since the benzene volatilized *in vacuo* from the samples gave upon shaking with water, solutions which responded to the very sensitive mercuric chloride test for phenylboric acid (not shown by benzene or diborane alone).

The residue after complete removal of the benzene was found to be of quite high molecular weight. No mass numbers between 130 and 220 appeared on the mass spectrometer. It was possible to isolate a material crystallizing in long prismatic needles from this residue by sublimation *in vacuo* at 100°. This material, believed to be triphenylboron, reacted rapidly with air to form a substance readily soluble in dilute sodium hydroxide. After neutralization of this solution it was possible to extract phenylboric acid (m. p. 215°) which in turn was verified by the specific tests for this compound as mentioned previously.

C. Reactions with Paraffins.—Methane was heated with six per cent. by weight of diborane for seventy-three hours at 180° in a stainless steel bomb. At the end of this time the bomb was frozen in liquid nitrogen and the non-condensable gas was pumped off. Volatilization of the unreacted methane left a small amount of less volatile liquid residue and a solid material containing both boron and carbon. Mass spectrographic analysis of the liquid portion of the reaction product revealed the presence of ethane, propane and butane, in addition to some mass numbers considered explainable as volatile methylboron compounds. Solution of the solid reaction product in water produced a large evolution of gas. The presence of boron bonded carbon in this material could be demonstrated by qualitative analysis.

Thirty-five grams of *n*-pentane and 1.5 g. of diborane were heated in the bomb for sixty-five hours at 180°. The bomb then was cooled in liquid nitrogen to freeze the contents, the non-condensable gas was bled off, and the bomb was evacuated. The bomb then was allowed to warm up slightly and the most volatile fraction of the reaction product was distilled off in the vacuum chain. This volatile material was fractionated further and the components were analyzed in the mass spectrometer. The material comprised roughly 40% methane, 40% ethane, and smaller amounts of other hydrocarbons including pentane.[7] After the bomb had warmed up to room temperature the residual pressure of volatile material was vented and the contents of the bomb were removed. Filtration separated a clear liquid from 3.5 g. of a light yellow powder of unknown composition containing boron bonded carbon. The liquid material was distilled and, with the exception of a very small amount of higher boiling material, the whole amount of liquid boiled at 36° or under.

Diborane and butane reacted only slightly at 100° in twenty-four hours although considerable polymerization of the diborane to decaborane occurred. Analysis of the very small amount of solid residue left after removal of the excess butane revealed only 3% of carbon, the balance being boron and hydrogen. A mixture of butane and five per cent. by weight of diborane heated at 200° for twenty-four hours reacted to yield a light tan powder containing 66% carbon. No analyses were made of the liquid fractions. Large pressures of hydrogen were built up in the tubes during these reactions.

The above experiments show that some substitution to form boron–carbon bonds does occur with diborane and paraffin hydrocarbons although the reactions involving breakdown and synthesis of paraffin chains under the influence of the diborane may be of major importance.

Discussion

There is a considerable amount of evidence on record to show that diborane may take part in many reactions in its monomeric form, that is as borine (BH_3).[8] It seems reasonable, therefore, although not necessary, to assume that in the addition and substitution reactions which diborane undergoes with hydrocarbons the active agent is the BH_3 molecule.

The borine molecule has, like the boron halides and the alkylborons, a strong tendency to accept and coördinate electrons. Thus by a mechanism similar to that proposed for the boron trifluoride activation of olefins a borine molecule could coordinate to one carbon of a carbon–carbon double bond to form temporarily a complex negative ion. Migration of a negative hydride ion (H^-) from the complex ion to the other carbon, positively charged by the withdrawal of electrons from the double bond, would result in a neutral molecule, RBH_2. This process then could be repeated with the remaining hydrogens attached to the boron atom to form eventually a molecule of trialkylboron, R_3B. Alternatively, the newly formed alkylborine molecule (RBH_2) could undergo disproportionation with similar molecules into trialkylboron and borine, a process known to occur readily with the alkyl derivatives of diborane.

Since breakdown of paraffin chains into smaller molecules does occur to a considerable degree under the influence of diborane (such an effect is observed with other strong acceptor molecules such as boron trifluoride and aluminum chloride) the addition or substitution of borine on the hydro-

(7) The author wishes to think Dr. Paul Zemany for these analyses.

(8) For example, diborane dissociates into monomeric borine in its reaction with carbon monoxide to form borine carbonyl. See A. Stock, "The Hydrides of Boron and Silicon," Cornell University Press, Ithaca, N. Y., 1933.

carbon fragments could only result in a complicated mixture of compounds. The observed synthesis of paraffin hydrocarbons from methane and the formation of polymeric solids indicates the complexity of these reactions. It is suggested that in the reaction of diborane with olefins or aromatic hydrocarbons this effect will make isolation of the primary reaction products difficult or impossible if the reaction conditions are severe or if relatively large amounts of diborane are used.

The behavior of the reaction products from benzene and diborane suggests that the intermediate phenyldiboranes, if they are formed, are quite unstable and resemble chlorodiborane rather than the alkyldiboranes. Thus monophenyldiborane may exist at room temperature only in equilibrium with both diborane and triphenylboron. This behavior might be predicted in view of the electronegative character of the phenyl group.

This work has been directed toward outlining the general types of reactions that diborane and hydrocarbons may undergo. It is not unreasonable to assume that under different conditions reaction products other than those observed by the author may be obtained. For example, at lower reaction temperatures it may be possible to isolate intermediate alkylation products of diborane.

Summary

The reactions of diborane with hydrocarbons have been investigated at elevated temperatures using low concentrations of diborane. Under these conditions:

1. The addition of diborane to olefins results in the formation of trialkylborons.
2. A substitution reaction occurs with benzene to form phenylboron compounds.
3. The reactions of diborane with paraffins are complex and involve paraffin chain breakdown and paraffin chain synthesis as well as the formation of boron–carbon bonds.

Spontaneous Ignition of Nickel Carbonyl Vapor. The Ignition of *n*-Butane[1]

BY ELMER J. BADIN, PAUL C. HUNTER AND ROBERT N. PEASE

Earlier papers[2] from this Laboratory have described the spontaneous ignition of zinc dimethyl and of boron triethyl vapors in oxygen, and the oxidation of *n*-butane induced thereby. Similar experiments with nickel tetracarbonyl are here reported.

The apparatus for these experiments was of conventional design.[2] It need only be mentioned that a clean, dry reaction bulb (6.5 cm. diameter) was used for each experiment, and that the bulb was thermostatted at 20°. Nickel carbonyl was obtained through the Matheson Company and fractionated in a nitrogen atmosphere before use (b. p. 43.5°). Oxygen and air were dried before using.

Precise measurements of explosion limits were prevented by the occurrence of long and variable induction periods (up to at least 1000 sec.). Thus, out of 6 experiments on 30 mole % nickel carbonyl in oxygen at 110 to 120 mm. total pressure, explosion occurred almost immediately on admitting the oxygen in two cases; after 30 and 325 seconds in two cases; while there was no explosion in 1000 seconds for two other trials. In another set of 12 experiments on 10% nickel carbonyl in dry air between 150 and 200 mm. total pressure, successes and failures (over 1000 seconds) were spread rather uniformly over the whole pressure range.

The reason for this irreproducible behavior is not clear. In some experiments with long induction periods, a film would form slowly at some point on the surface of the bulb. This could indicate dissociation of the carbonyl, since Mittasch's equilibrium data[3] indicate considerable dissociation at equilibrium even at 20° and 180 mm. A free nickel surface would seem to be ideal as a point from which inflammation could spread. Nevertheless, the formation of a white fog in the body of the gas always immediately preceded explosion, as if the initiating reaction were homogeneous. In this connection it is of interest that Berthelot[4] reported explosions of dry nickel carbonyl–oxygen mixtures at room temperature only if the mixture were abruptly expanded in a buret over mercury, or if the buret were shaken violently. This might suggest ionization due to friction between the mercury and the glass container. Though our mixtures were quiescent at the time of explosion, it is conceivable that an extraneous disturbance is involved. The behavior, however, might be still due to indeterminate differences or non-uniformity in the clean Pyrex surfaces used.

In Table I are reported the lowest pressures at which explosion was observed within 1000 seconds. Minimum values were quite low and only moderately different for oxygen as compared to air,

except for mixtures with excess of carbonyl (40%). They are substantially below those reported by Garratt and Thompson[5] and by Bawn[6] at higher temperatures (40–60° 100–45 mm. nickel carbonyl) when oxygen was admitted slowly to the nickel carbonyl vapor. According to these authors, the induction period is still considerable even at the higher temperatures.

TABLE I

LOWEST OBSERVED EXPLOSION PRESSURES OF $Ni(CO)_4$ IN OXYGEN OR AIR AT 20°

Clean Pyrex bulb, 6.5 cm. diameter. Induction periods up to 1000 seconds

$Ni(CO)_4$, mole %	Total press., mm.	Part. press., $Ni(CO)_4$
In oxygen (Stoich. 28.5 mole % $Ni(CO)_4$)		
10	115	12
30	115	35
40	150	60
In air (Stoich. 7.8 mole % $Ni(CO)_4$)		
10	145	15
20	160	32
40	280	112

A summary of analytical data may be added. After explosion, the gas was found to be mainly carbon dioxide (CO_2/CO = 4 to 40). Solid residues varied in composition from 60 to 81.7% Ni (NiO, 79.7% Ni).

Although we are not in a position to suggest a detailed mechanism for nickel carbonyl oxidation, it is tempting to correlate the induction period with a preliminary dissociation of the carbonyl[5]

$$Ni(CO)_4 \rightleftarrows Ni(CO)_3 + CO$$

followed by addition of oxygen

$$Ni(CO)_3 + O_2 \longrightarrow Ni(CO)_3 \cdot O_2$$

This would be in contrast to the behavior of the metal alkyls[2] whose unsaturated nature seems to permit direct addition of oxygen with negligible induction periods.

It was also found that nickel carbonyl would cause the explosion of *n*-butane–oxygen mixtures at 20°. There were long induction periods, and occasional violent explosions. For example, a mixture of 36 mm. of nickel carbonyl, 24 mm. of *n*-butane, and 140 mm. of oxygen exploded after 550 seconds, shattering the reaction bulb. With somewhat less nickel carbonyl it was possible to preserve the exploded mixtures for analysis, but the temperature had to be raised to 40° in order to obtain explosion in a reasonable time. Analytical data for carbon dioxide, hydrogen and oxygen are reported in Table II, as partial pressures. Olefins and paraffins were found to be present only in negligible amounts. Deficits in the material balance represent nickel compounds, water and other condensable products. The large amounts of carbon monoxide and hydrogen formed from rich mixtures are of interest, and leave no question that the hydrocarbon reacted.

TABLE II

PRODUCTS FROM THE EXPLOSION OF *n*-BUTANE–OXYGEN MIXTURES INDUCED BY NICKEL CARBONYL

Clean Pyrex bulb, 6.5 cm. diameter. Explosion at 40°, pressures measured at 20°. Initial pressure 200 mm.

Partial pressures, mm.							
Initial			Final				Final[a] press., mm.
$Ni(CO)_4$	*n*-C_4H_{10}	O_2	CO_2	CO	H_2	O_2	
25	0	175	86	2	0	122	210
25	10	165	131	2	2	41	176
25	18	157	147	17	9	9	182
25	25	150	103	81	45	10	239
25	35	140	62	158	102	7	329
25	45	130	26	223	173	9	431

[a] Corrected for vapor pressure of water, except in first experiment.

Summary

1. Nickel carbonyl vapor explodes in air or oxygen at 20° and partial pressures as low as 15 mm. Explosion is preceded by a long and variable induction period.

2. The existence of an explosion limit and induction period suggests a chain process. The exact mechanism of initiation is not known.

3. Addition of nickel carbonyl to a *n*-butane–oxygen mixture causes the latter to react at 20–40°.

Inhibition of Lactic Acid Bacteria by Analogs of Pantothenic Acid[1]

BY WILLIAM DRELL[2] AND MAX S. DUNN

The synthesis of the sodium salt of N-(α,γ-dihydroxy-β,β-dimethylvaleryl)-β-alanine (Fig. 1, $R_1 = CH_3$, $R_2 = H$), hereafter referred to as ω-methylpantothenic acid, was reported recently.[3]

The study of ω-methylpantothenic acid was undertaken to determine the effect of R_1 substituents on the activity of pantothenic acid toward lactic acid bacteria. Although most analogs of pantothenic acid possess little or no activity, two are partially active as growth promoters. Thus, N-(α-hydroxy-β,β-dimethylolbutyryl)-β-alanine[4] (Fig. 1, $R_1 = H$, $R_2 = OH$) and N-(α-hydroxy-β-methyl-β-methylolvaleryl)-β-alanine[5] (Fig. 1, $R_1 = H$, $R_2 = CH_3$) exhibit growth activity which is significant but less than that of pantothenic acid. Compounds which inhibit competitively or non-competitively the growth of microörganisms include salicylol-β-alanine,[6] mandelyl-β-alanine,[6] analogs of pantothenic acid lacking the α-hydroxy group[7,8] and analogs with different modifications of the β-alanine moiety.[9]

There was no adequate basis on which to predict the type of activity of ω-methylpantothenic acid, although the competitive inhibition exhibited is somewhat analogous to that shown by the methyl homolog (ethionine) of methionine,[10,11] the methyl homolog (β-aminobutyric acid) of β-alanine[12] and the 2-*n*-butylpyrimidine analog of thiamine.[13] However, the lower homologs of thiamine retain growth activity.[13] That ω-methylpantothenic acid is inactive as a growth promoter for *Lactobacillus casei*[5] was not known until the present experiments were completed.

Since pantoyltaurine inhibits the growth of microörganisms,[14] it was considered desirable to test this and other analogs of pantothenic acid and ω-methylpantothenic acid. Pantoyltaurine, pantoylglycine, pantoyl-DL-α-amino-*n*-butyric acid,

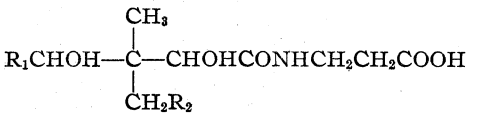

Fig. 1

pantoyl-DL-α-aminoisobutyric acid, pantoyl-DL-α-amino-α-ethyl-*n*-butyric acid, panto-DL-norvaline, ω-methylpantoyl-L-leucine and ω-methylpantoyltaurine were prepared by fusing the *dl*-pantolactones with the sodium salts of these amino acids or by refluxing the lactones and amino acid salts in methanol and precipitating the products with ether. It was found that ω-methylpantoyltaurine inhibited some lactic acid bacteria but that the other analogs were essentially inactive toward *Lactobacillus arabinosus* 17-5. That the α-amino acid analogs were inactive is in agreement with the observations on related α-amino acids reported by earlier workers.[7,15] While this work was in progress, it has been reported that pantoylglycine is inactive toward *Leuconostoc mesenteroides*[16] and that pantoylglycine and related analogs act as antivitamins for *Streptobacterium plantarum*.[17]

Experimental

α,α-Dimethyl-β-hydroxybutyraldehyde.—The method employed is essentially that of Lilienfeld and Tauss.[18] To a cold solution of 102 g. (2.31 moles) of acetaldehyde were added 166 g. (2.31 moles) of isobutyraldehyde and 200 ml. of a saturated aqueous solution of potassium carbonate. The mixture was stirred continuously and maintained below 30°. At the end of an hour the temperature began to rise rapidly and after two hours the reaction appeared to be complete. The viscous mixture was extracted with three 100-ml. portions of ether. The ether solution was washed with *N* acetic acid and saturated sodium bicarbonate solution and dried over sodium sulfate. The ether was removed and the fraction which distilled at 74–76° under 15 mm. (88–90°(22 mm.))[18] was collected in 30% yield.

α-Hydroxy-β,β-dimethyl-γ-valerolactone.—The method employed is essentially that of Stiller, *et al.*[19] To 74.5 g. (0.64 mole) of freshly distilled α,α-dimethyl-β-hydroxybutyraldehyde was added 200 ml. (20% excess) of sodium bisulfite solution. The mixture was stirred and heated on the steam-bath but a small amount of viscous material remained undissolved. The mixture was cooled to 5° and an aqueous solution of potassium cyanide (equivalent to the bisulfite) was added in small portions with stirring while maintaining the mixture between 5 and 10°. Stirring was continued for an hour at 10° and for an additional hour at room temperature. The aqueous and oily (cyanohydrin) layers were separated and the aqueous layer was extracted with three 75-ml. portions of ether. The combined solution of cyanohydrin and ether extracts was added

with stirring to 250 ml. of concentrated hydrochloric acid maintained below 15°. The resulting solution was allowed to stand overnight at room temperature, the ether was removed and the acid solution was refluxed for three hours. The acid was neutralized to *p*H 7 and extracted 12 times with ether. The ether solution was evaporated to a volume of one liter and dried over sodium sulfate. The ether was removed and the fraction which distilled at 94–96° under 2 mm. (120–122° (9 mm.))[5] was collected. The yield was 58.5 g. (63%).[20] The lactone was crystallized by dissolving the sirup in dry ether, adding petroleum ether to the point of cloudiness and cooling the solution below 0°. Two recrystallizations from an ether–petroleum ether mixture gave white needles, m. p. 60–60.5°.

Anal. Calcd., for $C_7H_{12}O_3$: C, 58.31; H, 8.39. Found: C, 58.57; H, 8.54.

3,5-Dinitrobenzoate of ω-Methylpantolactone.—This derivative was prepared from approximately equivalent quantities of ω-methylpantolactone and freshly prepared 3,5-dinitrobenzoyl chloride in freshly distilled dry pyridine by the procedure of Stiller, *et al.*[21] After two recrystallizations from ethanol the compound melted at 123–124°.

Anal. Calcd. for $C_{14}H_{14}O_8N_2$: C, 49.71; H, 4.17; N, 8.28. Found: C, 49.83; H, 4.30; N, 8.61.

Sodium Salt of ω-Methylpantothenic Acid.—The sodium salt of β-alanine was prepared by adding an equivalent of base to the amino acid, evaporating the solution to dryness, and powdering the solid. A mixture of 1.58 g. of freshly distilled ω-methylpantolactone and 1.11 g. of the sodium salt of β-alanine was maintained for two hours at 110–120° with occasional stirring. The product was dissolved in 100 ml. of absolute isopropanol, the solution was cooled and the small quantity of white solid which settled was separated.

To about half the isopropanol solution was added 250 ml. of absolute ether. The resulting suspension was filtered and the precipitate was washed with ether and dried for five days at room temperature *in vacuo* over phosphorus pentoxide; yield, 1.3 g. This product contained isopropanol of crystallization.

Anal. Calcd. for $C_{10}H_{18}O_5NNa \cdot C_3H_8O$: N, 4.44. Found: N, 4.43, 4.46.

Two samples (160 and 190 mg.) of this product heated for three weeks at 70° *in vacuo* over phosphorus pentoxide changed from a pure-white to a light-tan color and attained nearly constant weight (loss <1 mg. in four days). The products appeared to be anhydrous and nearly pure.

Anal. Calcd. for $C_{10}H_{18}O_5NNa$: N, 5.49. Found: N, 5.45 (sample 1), 5.43 (sample 2).

It is of interest that Levy, *et al.*,[22] obtained calcium pantothenate with isopropanol of crystallization which could not be removed by drying *in vacuo* at 100°.

The remainder of the isopropanol solution was evaporated to about 15 ml. and preserved at 0°. The almost solid cake of precipitate which formed after two weeks was filtered and the precipitate was washed first with cold isopropanol and then with ether. The product was dried at room temperature *in vacuo* over phosphorus pentoxide. Yield of product, m.p. 160–161.5°, was 0.9 g. It was less hygroscopic and easier to handle than the sodium salts prepared in other ways. It has been observed that crystalline sodium *d*-pantothenate behaves similarly.[23]

Anal. Calcd. for $C_{10}H_{18}O_5NNa$: C, 47.05; H, 7.11; N, 5.49; Na, 9.01. Found: C, 47.65; H, 7.28; N, 5.48, 5.50; Na, 9.02.

Products obtained by fusion of the lactone and the sodium salt of β-alanine were dissolved in water and used directly in determining inhibitory effects of the analog. These materials were from 70 to 85% condensed according to Van Slyke amino nitrogen determinations.

Sodium Salts of Pantoyltaurine and ω-Methylpantoyltaurine.—These salts were prepared in crude form by fusing equivalent quantities of the lactone and the dry sodium salt of taurine for five hours at 110–120°.[14] According to amino nitrogen analyses, 55 to 85% condensation occurred. The compounds were purified by dissolving the fused products in absolute ethanol, filtering to remove the unreacted amino acid salts, precipitating the analogs with ether, and drying the products *in vacuo* over phosphorus pentoxide.

Anal. Calcd. for $C_8H_{16}O_6NSNa$ (pantoyltaurine): N, 5.05; Na, 8.30. Found: N, 5.12; Na, 8.36. Calcd. for $C_9H_{18}O_6NSNa$ (ω-methylpantoyltaurine): N, 4.81. Found: N, 4.59.

Some of the fusion products were used without purification since the presence of the uncondensed components was found to have relatively little effect on the response of the microörganisms.

Sodium Salt of ω-Methylpantoyl-L-leucine.—The analog was prepared by fusing equivalent amounts of ω-methyl pantolactone and the dry sodium salt of L-leucine for two hours at 110°. Amino nitrogen determinations before and after acid hydrolysis indicated 64% condensation. The product was used without further purification.

Sodium Salts of the α-Amino Acid Analogs of Pantothenic Acid.—These analogs were prepared[7] by refluxing equivalent quantities of *dl*-pantolactone and the amino acid salts in absolute methanol for two hours, filtering the solutions, and precipitating the compounds with ether. The nitrogen (Kjeldahl) of the products, dried *in vacuo* over phosphorus pentoxide, is shown below:

Analog (sodium salt) Name	Formula	Nitrogen, % Calcd.	Found	% Condensation
Pantoylglycine	$C_8H_{14}O_5NNa$	6.16	6.58, 6.61	85
Pantoyl-DL-α-aminobutyric acid	$C_{10}H_{18}O_5NNa$	5.49	5.58, 5.62	98
Pantoyl-DL-α-aminoisobutyric acid	$C_{10}H_{18}O_5NNa$	5.49	5.62, 5.68	97
Pantoyl-DL-norvaline	$C_{11}H_{20}O_5NNa$	5.20	6.40	77
Pantoyl-DL-α-amino-*d*-ethylbutyric acid	$C_{12}H_{22}O_5NNa$	4.95	6.46, 6.41	65

Testing Procedure.—The methods commonly employed in the authors' laboratory were used to determine the microbiological activity of the present compounds. The basal medium was Medium B given in Table I of a previous paper[24] modified in that amino acids, ammonium chloride and pantothenic acid were omitted and the following supplements were added per liter of diluted medium: casein hydrolysate,[25] 7.5 g. (solids); natural asparagine, 100 mg.; L-tryptophan, 50 mg.; L-cysteine hydrochloride, 200 mg.; and xanthine, 12 mg. Four-inch test tubes containing final 3-ml. volumes of solutions were covered with toweling, sterilized, inoculated with a syringe or automatic pipet, and incubated at 35° for seventy-two hours. The acid produced was titrated with standard approximately 0.04 *N* sodium hydroxide using brom thymol blue as indicator.

Results

The growth-promoting activity of ω-methylpantothenic acid for *Lactobacillus casei*, *Lactobacillus arabinosus* 17-5, *Lactobacillus fermenti* 36 and *Leuconostoc mesenteroides* P-60 was investigated in the present experiments but the data have been omitted to conserve space. There was no stimula-

(20) A large scale synthesis (9 moles) was carried out without purification of the intermediate aldol in an over-all yield of 38% based on acetaldehyde.

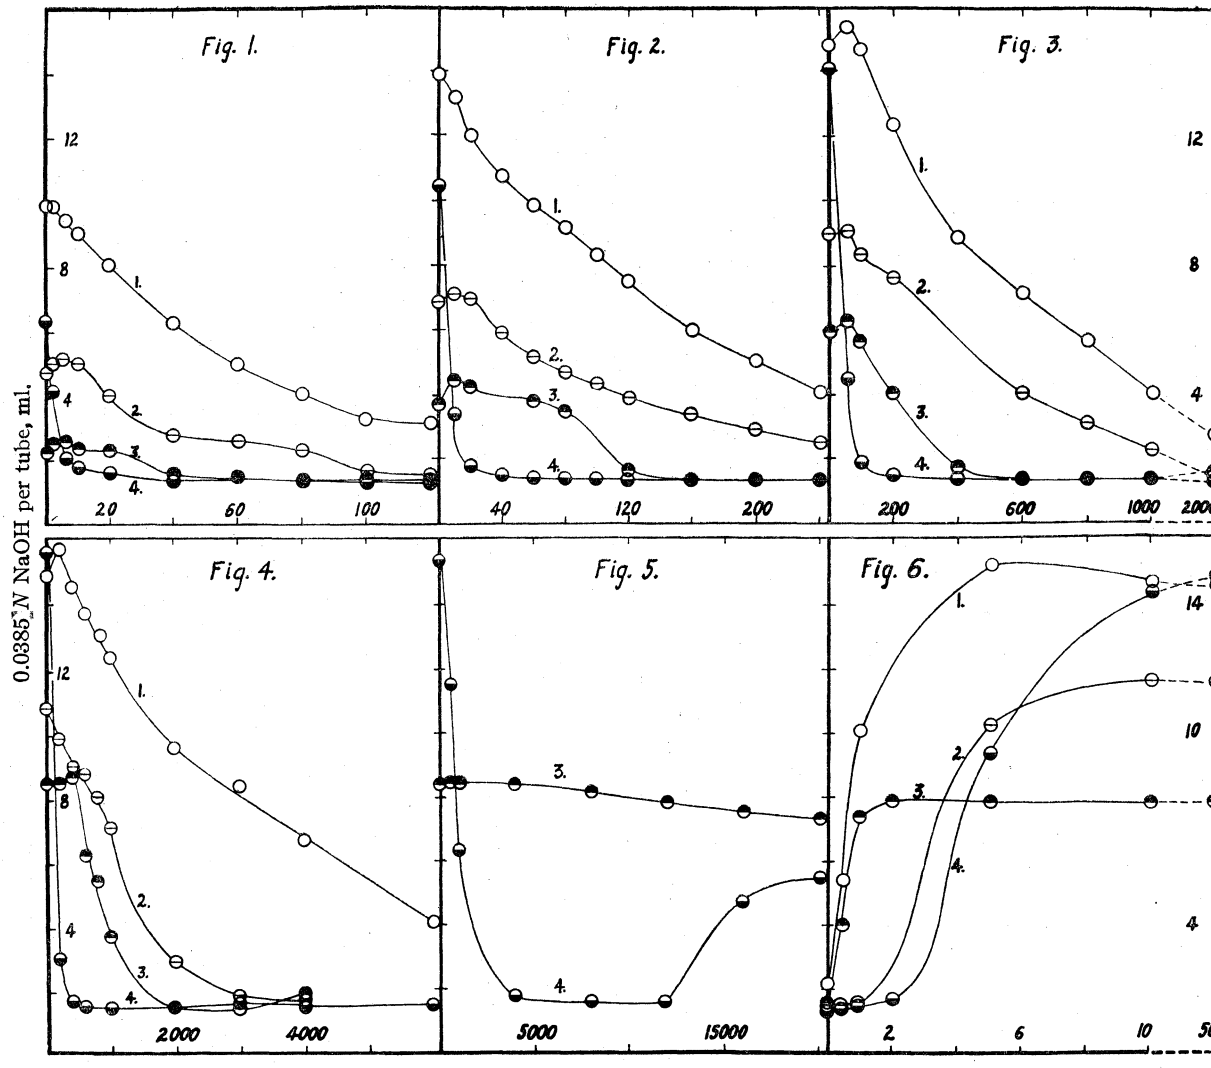

Plate I: Figs. 1–6.—The volumes of base consumed are plotted against γ of sodium ω-methylpantothenate added per tube in the presence of the following amounts of calcium *d*-pantothenate: 0.02γ (Fig. 1), 0.06γ (Fig. 2), 0.2γ (Fig. 3), 0.6γ (Fig. 4), and 2.0γ (Fig. 5). Figure 6 shows the response to increasing concentrations (γ) of pantothenic acid in the presence of 10,000 γ of sodium ω-methylpantothenate. The values at zero γ of pantothenic acid were obtained by extrapolation from other (not shown) data. The responses of four lactic acid bacteria are plotted as: (1) *Lactobacillus arabinosus* 17–5, (2) *Leuconostoc mesenteroides*, P-60, (3) *Lactobacillus fermenti* 36, and (4) *Lactobacillus casei*. Their "blank" titrations were 4.05, 2.33, 1.55 and 1.80 ml., respectively. The uninoculated blank was 1.15 ml. Points are averages of duplicate tubes.

tion at any level (0.01 to 1000 γ per tube) of analog and the "blank" acid production was suppressed. ω-Methylpantoyl-L-leucine was inactive except that at high levels (above 4000 γ) it diminished the blank titration values.

As shown in plate I, ω-methylpantothenic acid repressed the growth of the four lactic acid bacteria. The concentrations of analog required to inhibit the organisms were proportional to the concentrations of pantothenic acid in the medium, and the inhibition was competitive over a wide range in concentrations both of inhibitor and nutrilite. The direct reversal by pantothenic acid of the effects of ω-methylpantothenic acid is shown in Fig. 6, Plate I. Since growth of the organisms was normal in the presence of sufficient pantothenic acid, even at the highest level (20 mg./3 ml.) of inhibitor tested, it appears that ω-methylpantothenic acid is non-toxic for the bacteria investigated.

That the analog is stimulatory for some organisms under certain conditions is indicated by the data in Plate I. Examples of this effect at concentrations below the inhibition range are the stimulation of *L. fermenti* and *L. mesenteroides* (at 0.02, 0.06, and 0.2 γ of pantothenic acid) and *L.*

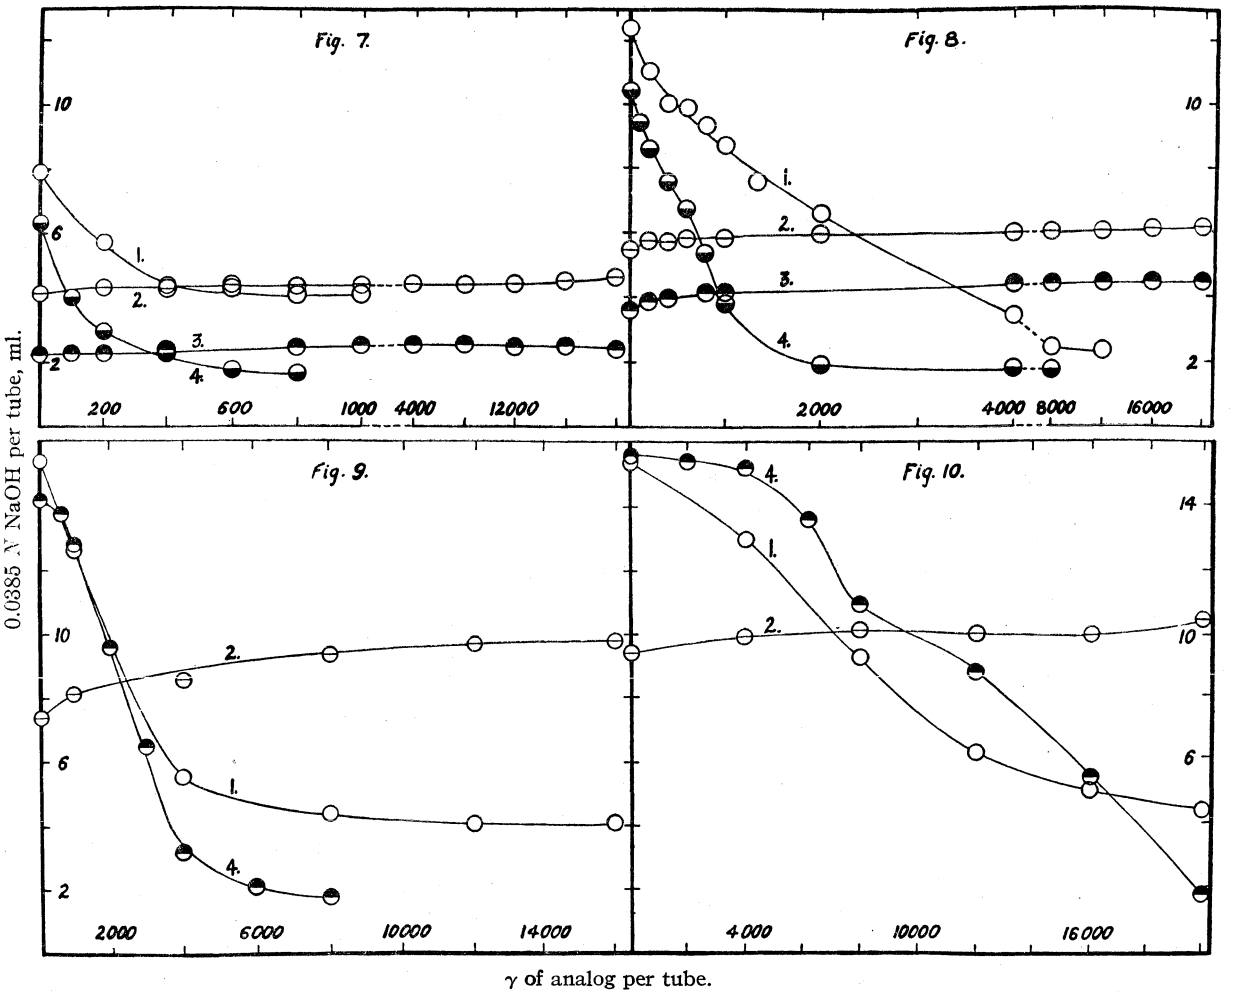

Plate II: Figs. 7–10.—The volumes of base consumed are plotted against γ of the sodium salt of ω-methylpantoyltaurine added per tube in the presence of the following amounts of calcium *d*-pantothenate: 0.02γ (Fig. 7), 00.6γ (Fig. 8), 0.2 γ (Fig. 9), and 0.6 γ (Fig. 10). The lactic acid bacteria are numbered as in Plate I and the blank titration values are the same except for *L. mesenteroides* P-60 (3.70 ml.). The values for *L. mesenteroides* and *L. fermenti* beyond 1000 γ and 8000 γ (Figs. 7 and 8, respectively) were calculated from data obtained in a separate experiment. Points are averages of duplicate tubes.

arabinosus (at 0.2 and 0.6 γ). After complete inhibition has been reached stimulation is observed in the cases of *L. casei* (at 2 γ) and *L. fermenti* (at 0.2 and 0.6 γ). That *L. arabinosus* and *L. fermenti* are not completely inhibited at 0.5 γ of pantothenic acid and 10000 γ of analog (Fig. 6), as would be expected, may be explained by this effect.

ω-Methylpantoyltaurine was found (Plate II) to inhibit the growth of only two of the four lactic acid bacteria. In both cases (*L. casei* and *L. arabinosus*) it was considerably less active than ω-methylpantothenic acid. *L. fermenti* and *L. mesenteroides* were stimulated by the analog, with growth increasing as the level was raised. No inhibition was observed at any concentration tested.

A study of pantoyltaurine under the same conditions was carried out for comparative purposes. It was observed (unpublished work[26]) that both *L. fermenti* and *L. mesenteroides* were stimulated up to high levels (2000–4000 γ) by the inhibitor. Stimulation was maximum at 1000 and 600 γ, respectively, and decreased thereafter as the level was raised leading to inhibition and complete cessation of growth. The degree of stimulation exerted by pantoyltaurine was nearly approached but not exceeded by its homolog.

The activities of the analogs described above are compared in Table I expressed in terms of the antibacterial index[8] (the molar ratio of inhibitor to growth promoter which inhibits completely the growth of the organisms.). It may be noted that the antibacterial indices of the analogs remained essentially constant over a wide range in

(26) Some of the data are summarized in the Thesis by W. Drell submitted in partial fulfillment of the requirements for the Master of Arts in Chemistry, June, 1946.

concentration of pantothenic acid in almost all cases. That the values rose significantly at the highest levels of nutrilite particularly at 2.0 γ with *L. casei* and *L. fermenti* probably was not due to differences in assay conditions.[27]

TABLE I

ANTIBACTERIAL INDICES OF PANTOTHENIC ACID ANALOGS AT VARYING CONCENTRATIONS OF PANTOTHENIC ACID

Analog	Ca *d*-pantothenate γ per tube	Antibacterial index[a] *Lactobacillus casei* 7469[c]	*Lactobacillus rabinosus* 17-5 8014[c]	*Lactobacillus fermenti* 36 9338[c]	*Leuconostoc mesenteroides* P-60 8042[c]
ω-Methylpantothenic acid	0.02	350	3000	1500	3000
	.06	260	3000	1600	3300
	.20	450	3900	1600	3900
	.60	450	5200	2200	3300
	2.0	950		>7500	
ω-Methylpantoyltaurine	0.02	12500	16500	[b]	[b]
	.06	16500	22000	[b]	[b]
	.20	14500	25000		[b]
	.60	16500	22000		[b]
Pantoyltaurine	0.02	13000	4000	150000	300000
	.06	15000	4700	130000	250000
	.20	15000	6200		

[a] Corrected for the per cent. condensation of the *dl*-analogs. [b] Stimulation observed. [c] American Type Culture Collection Number.

The relative concentrations of the analogs required for half-maximum inhibition and for complete inhibition were compared. In the case of ω-methylpantothenic acid, the ratio was approximately two for *L. fermenti* and *L. mesenteroides* and between two and three for *L. arabinosus*. With pantoyltaurine this ratio was about two for all three organisms. ω-Methylpantoyltaurine was required in larger than twofold amounts to achieve complete inhibition with *L. arabinosus*. *L. casei* required threefold or higher concentrations of all analogs.

In view of the results obtained, it was of interest to investigate further the comparative activity of these analogs against a large number of lactic acid bacteria particularly with reference to the mutual influence of the two combined inhibitory groups (ω-methyl and sulfonic acid). The responses of 19 organisms are summarized in Table II. All lactic acid bacteria tested were susceptible to inhibition by ω-methylpantothenic acid. The antibacterial indices ranged from 80 to 13000. Stimulation was observed in those cases (five) where concentrations of analog were sufficiently small to lie below the inhibitory level.

(27) Shive and Snell[28,29] have showed that time of incubation and concentration of inocula modify the responses of organisms to inhibitors of pantothenic acid. An example of the latter effect is illustrated by *L. arabinosus*. When, under otherwise uniform assay conditions, the density of the washed inoculum was increased markedly (from a blank titration value of 4.05 to 6.08 ml. of 0.0385 *N* sodium hydroxide) the antibacterial index of ω-methylpantothenic acid increased from 3000 to 12000. This difference cannot be due to an increase in nutrilite concentration alone. The synthetic ability of *L. arabinosus* (Shankman, Camien, Block, Merrifield and Dunn, *J. Biol. Chem.*, **168**, 23 (1947)) may play a more prominent role under these conditions.

(28) Shive and Snell, *Science*, **102**, 401 (1945).

(29) Shive and Snell, *J. Biol. Chem.*, **160**, 287 (1945).

TABLE II

ACTIVITY OF ANALOGS OF PANTOTHENIC ACID AGAINST LACTIC ACID BACTERIA

Organism	Antibacterial index[a] ω-Methylpantothenic acid	ω-Methylpantoyltaurine	Pantoyltaurine
Leuconostoc citrovorum 8082[b]	80[c]	2400[c]	4200[c,d]
Lactobacillus fermentatus 4006	150	51000[d]	113000

[a] Based on average values of duplicate tubes. Corrected for the per cent. condensation of the *dl*-analogs. [b] American Type Culture Collection Number. [c] The half-maximum point was achieved at a concentration of analog approximately half that required for complete inhibition of growth. [d] Stimulation was observed at concentrations below the inhibitory range. [e] Stimulation only was observed. Levels up to 20,000 γ in the presence of 0.06 γ of calcium *d*-pantothenate were tested. [f] Relatively little effect was observed at levels up to 20,000 γ in the presence of 0.06 γ of calcium *d*-pantothenate. [g] Half-maximum inhibition; growth was not completely repressed at the analog–metabolite molar ratio of 280,000.

Pantoyltaurine inhibited the growth of all but two (*L. pentosus* and *L. brassicae*) of the lactic acid bacteria tested. In most cases the activity was considerably less than that of ω-methylpantothenic acid. Two organisms (*Leuconostoc dextranicum* 8358 and 8359) were more susceptible to the latter than to pantoyltaurine. At levels below the inhibitory range, eight organisms were found to be stimulated and five (*L. fermentatus*, *L. pentoaceticus*, *L. brevis*, *L. pentosus*, and *L. brassicae*) appeared unaffected by pantoyltaurine. The responses of the remaining organisms were not determined in the experiment.

ω-Methylpantoyltaurine was less active than the β-alanine analog against all organisms tested, but in many cases it was more inhibitory than pantoyltaurine. Four organisms (*L. lycopersici*, *L. mesenteroides* 9135, *L. gayoni*, and *L. mannitopoeus*) exhibited stimulation with the analog of the type described previously for *L. fermenti* and *L. mesenteroides* P-60. With these bacteria inhibition was not observed at the levels tested (up to 20 mg. in the presence of 0.06 γ of pantothenic acid). In the cases of *L. pentosus* and *L. brassicae* neither stimulatory nor strong inhibitory effects were noted. At concentrations below the inhibitory level, four lactic acid bacteria were stimulated and one, *L. pentoaceticus*, was not. The responses of the other organisms inhibited by ω-methylpan-

toyltaurine were not determined at these low levels.

The relative concentrations of analogs required for half-maximum and complete inhibition were calculated for these organisms. Of the fourteen bacteria for which data at the half-maximum inhibition level were obtained with ω-methylpantothenic acid, a ratio of two was observed with three organisms. In the case of pantoyltaurine, seven of the sixteen organisms observed were of this type. With ω-methylpantoyltaurine, seven of thirteen organisms showed this behavior. The responses of these bacteria to pantoyltaurine had a high correlation to those obtained with ω-methylpantoyltaurine.

ω-Methylpantoylleucine showed relatively little inhibitory activity against four lactic acid bacteria (those listed in Table I were used) at levels as high as 20,000 γ in the presence of 0.02 γ of pantothenic acid. The uncondensed amino acids, β-alanine, L-leucine and taurine were inactive except for a slight inhibition of *L. casei* and *L. mesenteroides* by leucine (4000 γ) and of *L. arabinosus* by taurine (8000 γ). Somewhat greater inhibition, reversed by the nutrilite, was observed for ω-methylpantolactone in the absence, or at low levels, of pantothenic acid. The behavior of mixtures of the lactone and an amino acid resembled that of the lactone alone.

Discussion

That substitution at the ω-hydroxymethyl group of pantothenic acid leads to compound possessing inhibitory properties has been shown by the results given above and by investigations with other analogs.[30] This is in contrast to substitution at one of the ω-methyl groups whereby significant growth promoting ability is retained. It would seem therefore that methyl substitution in the former case produces a more significant change in the steric configuration, interfering in some manner with the normal functioning of the ω-hydroxy group. The relatively high activity of ω-methylpantothenic acid toward all lactic acid bacteria studied in comparison with the varying effectiveness of inhibitors such as pantoyltaurine and others is noteworthy. Of these β-methylpantothenic acid (N-pantoyl-β-aminobutyric acid)[28] although it shows a somewhat different bacterial spectrum, is the most similar to ω-methylpantothenic acid. The two inhibitors resemble each other further in that both contain methyl groups substituted in positions adjacent to functional groups.[31]

Lipmann and co-workers[32,33] have clearly demonstrated that the pantothenic acid in living organisms is largely bound in the form of a coenzyme. They have shown further that two distinct enzymes, phosphatase and liver enzyme, are required to liberate pantothenic acid for bacterial use, indicating that at least two groups of the growth factor are tied up. The work of Williams[34] has indicated that a point of attachment in the coenzyme is probably at the carboxyl group through an amide linkage, while the activity of phosphatase denotes phosphorylation of a hydroxy group. From the inhibitory activity of ω-methylpantothenic acid it might appear that the ω-hydroxy is the group so concerned. However, it is of interest that methyl substitution at the 2-hydroxyethyl group of thiamine, which is the site of phosphorylation, results in an analog which is entirely active upon the pea root, slightly so upon *Phycomyces blakesleeanus* and inactive upon the rat.[35]

It appears that ω-methylpantothenic acid and pantoyltaurine may interfere with the metabolism of pantothenic acid at different loci either in the same or in different reaction steps. This could account for their greatly different inhibitory activities as well as for the results observed with the hybrid, ω-methylpantoyltaurine. With the latter no synergism was encountered and its observed activity could be correlated in general with the relative inhibitory powers of its two parent compounds. In those cases where ω-methylpantothenic acid was considerably more active than pantoyltaurine, the hybrid was intermediate in strength between the two. If the parent analogs were of approximately equal activity the hybrid was weaker than either. In instances where pantoyltaurine was very weakly inhibitory and (very frequently) stimulatory at concentrations below the range of inhibition, the hybrid was found to exhibit only stimulatory activity. The effect might be one of further weakening in activity, in which case inhibitory effects would be encountered at much higher concentrations of inhibitor than those tested. The hybrid appears to be more sensitive to the variations induced by the sulfonic acid than by the ω-methyl group. In comparing the relative concentrations of inhibitor to produce half-maximum or complete inhibition with these organisms, greater correlation was obtained between pantoyltaurine and ω-methylpantoyltaurine than between the latter and ω-methylpantothenic acid. Against *L. brassicae* and *L. pentosus*, pantoyltaurine and likewise ω-methylpantoyltaurine were almost completely without effect. Further, neither analog was stimulatory at any of the levels tested. This response is similar to that observed with inactive pantoylleucine and ω-methylpantoylleucine.

The stimulation effects observed above have been reported with other inhibitory analogs of

(30) Drell and Dunn, Abstracts of Papers, 112th Meeting, American Chemical Society, 5C (1947).

(31) The inhibition of the growth of yeast by β-amino-*n*-butyric acid[12] presumably through interference in the utilization of β-alanine for the synthesis of pantothenic acid, may be considered a more direct analogy.

pantothenic acid including phenylpantothenone,[36] N-pantoyl-β-aminoisobutyric acid[28,37] and N-pantoylisoserine.[28] The latter two compounds possessed weak growth-promoting properties in the absence of pantothenic acid, and in the presence of the nutrilite were inhibitory, but only to the level at which they had been stimulatory. Higher levels of the analog diminished the inhibitory effect. This type of behavior is comparable to that observed for ω-methylpantothenic acid particularly with *L. casei* at the 2 γ level of pantothenic acid. However, *L. casei* was not stimulated by the inhibitor in the absence of the nutrilite at any level tested.

Investigations of the pantothenic acid requirements and of the responses to ω-methylpantothenic acid for a large number of microorganisms (unpublished experiments) have shown that the analog inhibits only those bacteria which require the preformed nutrilite or are stimulated by it. Similar observations have been reported with other pantothenic acid analogs in cases of reversible inhibitions. It has been suggested[38] that the ineffectiveness of pantoyltaurine and related analogs in inhibiting microörganisms which might utilize pantoic acid or lactone may be due to the availability of these components in solution. This explanation is not tenable for ω-methylpantothenic acid although the possibility of inactivation of the analog through hydrolysis cannot yet be ruled out. However, it appears more likely that, as indicated by McIlwain,[8] pantothenic acid may be produced and utilized by these organisms in a form with which these analogs cannot compete.

Streptococci are susceptible to ω-methylpantothenic acid both *in vitro* and *in vivo*. In preliminary experiments it was found that mice were protected from an 80% fatal infection of a β-hemolytic streptococcus (Group A, type 23, no. 1072)[39] when the inhibitor was incorporated in a characterized diet at a molar analog–pantothenic acid ratio of 200 for four days prior to inoculation. Substituted amides of pantoyltaurine have been prepared which are effective against Group A *Streptococcus hemolyticus in vivo*.[40,41]

In view of the stereochemical specificity of the pantolactone moiety in pantothenic acid required for growth,[19] or in analogs which exhibit inhibitory activity,[14,16,41,42,43] it would be of interest to investigate the relative activities of the resolved isomers of ω-methylpantothenic acid. Presumably, at least one of the four possible isomers will show greater activity than the *dl*-compound.

Summary

ω-Methylpantolactone (α-hydroxy-β,β-dimethyl-γ-valerolactone) has been synthesized and condensed with β-alanine, taurine and L-leucine. It has been found that ω-methylpantothenic acid inhibits the growth of twenty-three strains of lactic acid bacteria which require pantothenic acid. That the inhibitory action is reversed competitively by pantothenic acid over wide ranges in concentrations has been shown with four lactic acid bacteria. The taurine analog has been shown to be less active than the β-alanine derivative, but more inhibitory than that containing L-leucine. The comparative activity of pantoyltaurine has been determined. The contributions of ω-methylpantothenic acid and pantoyltaurine to the activity of ω-methylpantoyltaurine have been discussed.

2-Thenyl Substituted Diamines with Antihistaminic Activity

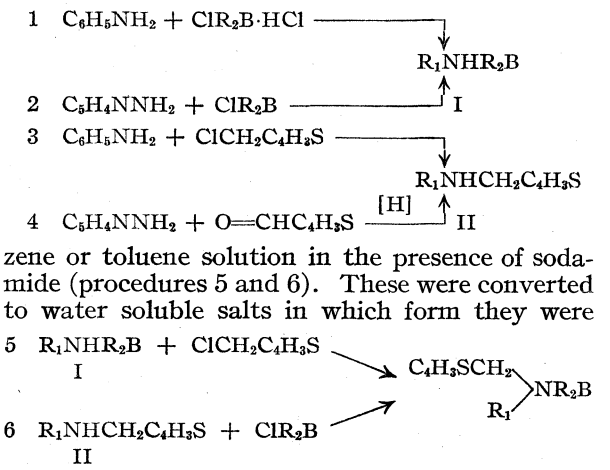
BY FREDERICK LEONARD AND ULRICH V. SOLMSSEN

A number of aminoalkyl ethers and alkylenediamines which exhibit antihistaminic activity have been discovered[1] and several have been adopted for clinical use. Since these substances are not without their undesirable side effects we prepared a series of 2-thenyl substituted alkylenediamines which conform to the general type $C_4H_3SCH_2$(R$_1$)N—R_2B, where R_1 is phenyl or 2-pyridyl, R_2 is a straight or branched alkylene chain containing two or three carbon atoms and B is a dimethylamino or piperidino group.

In a recent note[2] we reported the preparation and pharmacological activity of one of the compounds described herein, N,N-dimethyl-N′-(2-pyridyl)-N′-(2-thenyl)-ethylenediamine,[3] the 2-thienyl analog of Pyribenzamine. Another of our compounds, N,N-dimethyl-N′-phenyl-N′-(2-thenyl)-ethylenediamine, the thiophene analog of Antergan has been described in the chemical literature.[4] However, prior to these publications we had prepared and evaluated it in these laboratories.

The intermediate secondary amines (I) and (II) were prepared by condensing aniline with a dialkylaminoalkyl chloride hydrochloride or 2-thenyl chloride (procedures 1 and 3), and 2-aminopyridine with dialkylaminoalkyl chlorides[1f,5] or 2-thiophenealdehyde followed by reduction[6] (procedures 2 and 4).

The tertiary amines were obtained by the alkylation of the intermediates (I) and (II) in benzene or toluene solution in the presence of sodamide (procedures 5 and 6). These were converted to water soluble salts in which form they were evaluated under the direction of Dr. N. Ercoli in the pharmacological laboratories of this institute.[7] Preliminary results have shown that several of the compounds described here have a range of antihistaminic activity similar to that of preparations now on the market. One of these N,N-dimethyl-N′-phenyl-N′-(2-thenyl)-ethylenediamine is characterized by a very low toxicity and a high order of activity. Viaud[4] found this compound to be inactive while Kyrides, *et al.*,[4] reported an activity which apparently is lower than that found in our laboratories.



All attempts to form either hydrochlorides or drobromides of N^2,N^2-dimethyl-N^1-phenyl-N^1-(2-thenyl)-1,2-propanediamine and N^2,N^2-dimethyl-N^1-(2-pyridyl-(2-pyridyl)-N^1-(2-thenyl)-1,2-propanediamine (amines 3 and 7, respectively) resulted in their decomposition.[8] Analytical data on amine 3 (obtained using both procedures 5 and 6) and its picrate and the picrate of amine 7 agreed with the theory. Since we were able to obtain stable picrates we attempted the formation of water soluble salts of organic acids and found that succinic acid gave stable bisuccinates.

The decomposition of N^2,N^2-dimethyl-N^1-phenyl-N^1-(2-thenyl)-1,2-propanediamine (amine 3)[9] under conditions of hydrochloride formation was observed when the removal of solvents from the

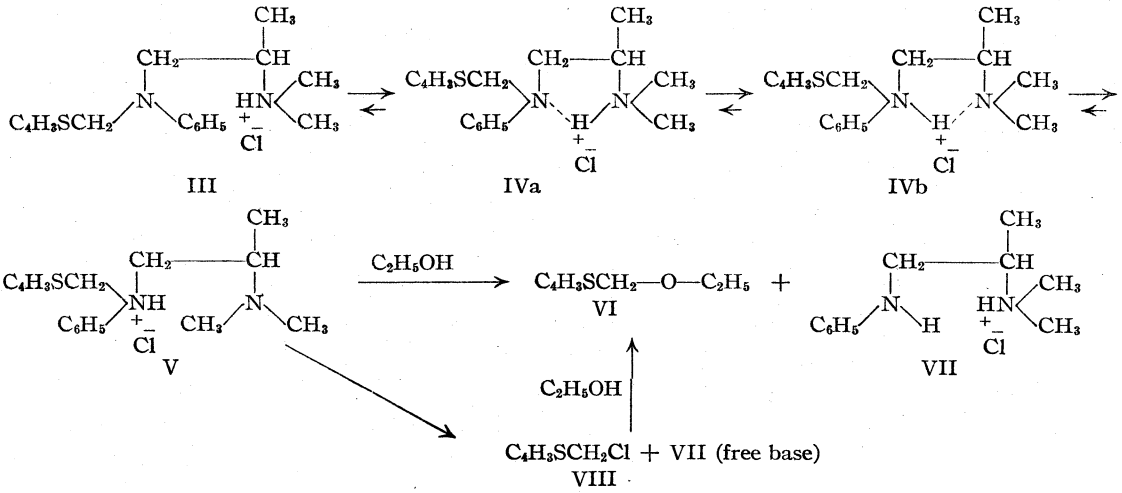
(7) A detailed account of these studies will be published in another journal.

(8) The work of Brode and Hill (THIS JOURNAL, **69**, 724 (1947)) and Schulz, Robb and Sprague (*ibid.*, **69**, 2455 (1947)) on the rearrangement of the isomeric 1,2-dimethylaminopropyl chlorides suggests that the condensation product of any alkylation involving the use of either of these halides would be a mixture of the desired substance and its isomer. We employed one of these halides in our investigation but made no effort to determine the amount of isomer obtained along with the 1,2-propanediamines reported here.

(9) It would seem that N^1,N^1-dimethyl-N^2-phenyl-N^2-(2-thienyl)-1,2-propanediamine may undergo the same type of decomposition as amine 3. The secondary amine (VII), therefore, was probably contaminated with its isomer.

neutralization mixture left a sirup which possessed an unexpected, strong sweet odor. Fractionation of the sirup yielded 2-thenyl ethyl ether (VI), N^2,N^2-dimethyl-N^1-phenyl-1,2-propanediamine (VII) and recovered tertiary amine.

We feel that this decomposition can be accounted for by the formulation[10]



The monohydrochloride (III)[11] which is obtained upon neutralization of amine 3 can be in equilibrium, because of intramolecular hydrogen bonding with the quasi-five-membered ring systems (IVa and IVb) which may open to yield (V). Since the electronegativity of the N^1-atom in amine 3 is small, due to the phenyl substituent, the localization of the proton at this point will further decrease the charge to such a low value that the strongly electropositive 2-thenyl radical will only be weakly bound. (V) will therefore be able to enter into metathetical reactions of the type $A^+B^- + C^+D^- \rightarrow AD + BC$ in much the same manner as esters of toluene sulfonic acids and some of the quaternary ammonium halides. In our case (III) was formed in the presence of ethanol (which was used as a solvent) with which its isomer (V) may have reacted to form 2-thenyl ethyl ether (VI) and N^2,N^2-dimethyl-N^1-phenyl-1,2-propanediamine hydrochloride (VII). The formation of these stable products would then shift the equilibrium of all the intermediate forms to the right. Another route to (VI) and (VII) may involve a decomposition of (V) to 2-thenyl chloride (VIII) and the free base of (VII). Subsequent reaction of (VIII) with ethanol would produce the ether (VI) and cause a shift of the equilibrium to the right as before.

Since all of our straight chain diamine monohydrochlorides are stable compounds it would seem that the instability of the hydrochlorides of amines 3 and 7 can be related to their C-methyl branch. It is conceivable that this substituent crowds the dimethylamino hydrochloride group at least close enough to the N-thenylanilino group for intramolecular hydrogen bonding, rearrangement and subsequent decomposition to occur. The degree of stability of all of these hydrochlorides therefore probably depends directly upon the internitrogen distance in the "horseshoe shaped" rotational configuration. This distance and the stability appear to be at a minimum in the branched chain diamines (III).

The stability of the picrate and bisuccinate salts of bases 3 and 7 may be due to the greater bulk of their anions which are unable to approach closely enough the nitrogen bearing the large phenyl and 2-thenyl groups to form an intermediate corresponding to (V). This would have the effect of keeping the electrical center of the molecule in the neighborhood of the nitrogen bearing the two methyl radicals and result in a stable configuration.

Experimental[12]

2-Thenyl chloride,[13] γ-dimethylaminopropyl chloride[14,15] and hydrochlorides of β-dimethylaminoethyl chloride,[16] β-piperidinoethyl chloride[17] and β-dimethylaminopropyl chloride[15,18] were obtained by methods described in the literature.

Procedure 1: N^2,N^2-Dimethyl-N^1-phenyl-1,2-propanediamine.—A mixture of 37.2 g. (0.40 mole) of aniline, 31.6 g. (0.20 mole) of β-dimethylaminopropyl chloride hydrochloride, 55.2 g. (0.40 mole) of anhydrous potassium carbonate and 100 cc. of dry toluene was stirred and refluxed for seven hours, cooled, water added and the organic

(10) This formulation can be applied equally well to the possible decomposition of the isomeric N^1,N^1-dimethyl-N^2-phenyl-N^2-(2-thenyl)-1,2-propanediamine.

(11) Since the *Kb* of dialkylamines is in general of the order of magnitude of 10^{-4} to 10^{-5} while that of N-alkylanilines is 10^{-10} it is reasonable to assume that the dimethylamino is more basic than the N-(2-thenyl)-anilino group and will be involved in the primary neutralization of the diamine.

[a] Bisuccinate. [b] Prepared by Dr. C. P. Huttrer.

layer separated. The aqueous phase was extracted with ether, the combined organic layers washed with water and dried. Solvents were removed and the residual oil fractionated. The amine was obtained as a yellow oil, b. p. 97–102° (3 mm.), $n^{25}D$ 1.5300; yield 26.1 g. (73.3%). It was characterized by conversion to a monopicrate, m. p. 158–159° after recrystallization from ethanol.

Anal. Calcd. for $C_{17}H_{21}N_5O_7$: C, 50.12; H, 5.20; N, 17.20. Found: C, 49.83; H, 5.44; N, 16.91.

Procedure 2: N²,N²-Dimethyl-N¹-(2-pyridyl)-1,2-propanediamine.—A suspension of 14.16 g. (0.36 mole) of sodamide, 28.2 g. (0.30 mole) of 2-aminopyridine and 250 cc. of dry toluene was stirred and refluxed for two hours. Heating was stopped and a solution of 40.1 g. (0.33 mole) of β-dimethylaminopropyl chloride in 40 cc. of dry toluene added dropwise with stirring. The mixture was refluxed for five hours, cooled, water added, the organic layer separated, washed with water and dried. Fractionation gave 46.4 g. (86.5%) of the secondary amine, b. p. 128–131° (5 mm.), $n^{25}D$ 1.4969. The dipicrate melted at 210°.

Anal. Calcd. for $C_{22}H_{23}N_9O_4$: C, 41.44; H, 3.61; N, 19.78. Found: C, 40.92; H, 3.79; N, 19.78.

Procedure 3: N-(2-Thenyl)-aniline.—Aniline, 93.0 g. (1.0 mole) was dissolved in 150 cc. of dry benzene, 24.5 g. (0.25 mole) of anhydrous potassium carbonate added to the solution, the mixture heated to boiling and a solution of 33.0 g. (0.25 mole) of 2-thenyl chloride in 50 cc. of dry benzene added dropwise with constant stirring. The mixture was stirred and refluxed for four hours, cooled and worked up as in procedure 1. Fractionation at 12 mm. gave 34.0 g. (72.3%) of a product which boiled at 174–177°, solidified to a tan solid, m. p. 37–39°, and yielded a hydrochloride melting from 170–171°.

Anal. Calcd. for $C_{11}H_{12}NSCl$: N, 6.21; Cl, 15.71. Found: N, 6.32; Cl, 15.93.

Procedure 4: 2-(2-Thenylamino)-pyridine.—Freshly distilled 2-thiophenealdehyde,[19] 45.9 g. (0.41 mole) was added to a solution of 37.6 g. (0.40 mole) of 2-aminopyridine in 75 cc. of 95% formic acid. The mixture was refluxed for seventeen hours, diluted with water and neutralized from sodium hydroxide. The precipitate was washed with water and dried, m. p. 73–76°; yield 40.7 g., (53.5%). A sample recrystallized from a toluene–petroleum ether (b. p. 90–110°) mixture, melted at 78–80°.

Anal. Calcd. for $C_{10}H_{10}SN_2$: C, 63.12; H, 5.30; N, 14.73. Found: C, 63.02; H, 5.16; N, 14.57.

Procedure 5: N,N-Dimethyl-N′-phenyl-N′-(2-thenyl)-ethylenediamine Hydrochloride.—A solution of 32.4 g. (0.198 mole) of N,N-dimethyl-N′-phenylethylenediamine[20] in 50 cc. of dry toluene was added to a suspension of 8.5 g. (0.217 mole) of sodamide in 100 cc. of dry toluene. The mixture was stirred and heated at 100° for three hours, heating discontinued and a solution of 28.8 g. (0.217 mole) of 2-thenyl chloride in 30 cc. of dry toluene added dropwise. After refluxing for two hours, the mixture was cooled and worked up in the usual way. Distillation *in vacuo* yielded 36.17 g. (69.8%) of a dark yellow oil, b. p. 183–185° (7 mm.), $n^{25}D$ 1.5902. Hydrochloride formation was generally effected by solution of the amine in ether and treatment of the resulting solution with a slight excess of ethanolic hydrochloric acid with cooling. In a number of instances the salt precipitated at once in crystalline form, in others it oiled out or remained in solution. In these cases it was necessary to remove the solvents *in vacuo* and crystallize the residual sirups. This amine was dissolved in 85 cc. of absolute alcohol and treated with 74.5 cc. (1% excess) of 1.885 *N* alcoholic hydrochloric acid. The monohydrochloride was filtered off, washed with alcohol and ether and dried; yield 35.6 g., m. p. 185–186°. Recrystallized from ethanol the salt melted at 186–187°.

Anal. Calcd. for $C_{15}H_{21}SN_2Cl$: C, 60.69; H, 7.13; Cl, 11.95. Found: C, 60.49; H, 7.11; N, 9.44; Cl, 11.90.

N²,N²-Dimethyl-N¹-(2-pyridyl)-N¹-(2-thenyl)-1,2-propanediamine Bisuccinate.—A stirred suspension of 8.5 g. (0.22 mole) of sodamide and 35 g. (0.20 mole) of N²,N²-dimethyl-N¹-(2-pyridyl)-1,2-propanediamine and 320 cc. of dry toluene was refluxed for two hours, heating stopped and a solution of 2-thenyl chloride in 30 cc. of toluene added dropwise. The mixture was refluxed for two hours, cooled and worked up as before to give the tertiary amine, b. p. 162–169° (1.5 mm.), $n^{25}D$ 1.5755, in 53.2% yield (29.3 g.). The dipicrate, recrystallized from acetone melted at 136–138°.

Anal. Calcd. for $C_{27}H_{27}N_9O_{14}S$: C, 44.20; H, 3.70; N, 17.18; S, 4.37. Found: C, 44.36; H, 3.89; N, 17.23; S, 4.68.

The bisuccinate formed in the same manner as that of the phenyl analog (see procedure 6) melted at 101–102° after recrystallization from ethyl methyl ketone.

Anal. Calcd. for $C_{19}H_{27}O_4SN_3$: C, 57.99; H, 6.92; N, 10.68. Found: C, 57.88; H, 6.93; N, 10.90.

Procedure 6: N²,N²-Dimethyl-N¹-phenyl-N¹-(2-thenyl)-1,2-propanediamine Bisuccinate.—A sodium salt prepared by stirring and refluxing for two hours a mixture of 29.8 g. (0.157 mole) of N-(2-thenyl)-aniline, 6.15 g. (0.157 mole) of sodamide and 240 cc. of dry benzene was treated dropwise with 19.2 g. (0.157 mole) of β-dimethylaminopropyl chloride in 45 cc. of dry benzene. The material was stirred and refluxed for eight hours and the product obtained in the usual way; b. p. 164–171° (3 mm.), $n^{25}D$ 1.5792; yield 34.5 g. (77.0%).

Anal. Calcd. for $C_{16}H_{22}SN_2$: C, 70.02; H, 8.08; N, 10.21; S, 11.68. Found: C, 70.13; H, 8.34; N, 10.09; S, 11.98.

(19) Dunn, Waugh and Dittmer, THIS JOURNAL, 68, 2118 (1946).

(20) Prepared in 81.5% yield by procedure 1. We found b. p. 100–104° (6 mm.), $n^{25}D$ 1.5395. Huttrer, Djerassi, Beears, Mayer and Scholz (ref. 1f) reported b. p. 103–107° (0.2 mm.), $n^{25}D$ 1.5380.

The base gave a monopicrate which melted at 139–140° after recrystallization from benzene.

Anal. Calcd. for $C_{22}H_{25}O_7SN_5$: C, 52.47; H, 5.00; N, 13.91; S, 6.37. Found: C, 52.39; H, 5.26; N, 14.09; S, 6.43.

The bisuccinate was formed by adding 11 cc. of a saturated alcoholic solution of succinic acid to a solution of 2.328 g. of the base in 10 cc. of ether. The mixture was kept at room temperature overnight, concentrated to a sirup *in vacuo* and crystallized under ether. Recrystallized twice from an ethyl methyl ketone–ether mixture, the salt melted at 99–100°.

Anal. Calcd. for $C_{20}H_{28}O_4SN_2$: C, 61.20; H, 7.19; N, 7.14. Found: C, 61.35; H, 7.37; N, 7.15.

Attempted Hydrochloride Formation of Amine 3 and Identification of Decomposition Products.—N^2,N^2-Dimethyl-N^1-phenyl-N^1-(2-thenyl)-1,2-propanediamine, 18.28 g. (0.059 mole) was dissolved in 27 cc. of dry ether, treated with 27.6 cc. of 2.15 *N* ethanolic hydrochloric acid, let stand at room temperature overnight and placed in the refrigerator. After several days the solution was evaporated and the sirupy residue found to have a strong, sweet odor. Water was added to the sirup, the solution made strongly alkaline with sodium hydroxide, the oily layer taken up in ether and the solution dried. After removal of ether the residual oil was fractionated *in vacuo*. Three definite fractions were obtained.

Fraction 1, b. p. 52° (3 mm.), $n^{25}D$ 1.5061, was the sweet smelling component. It was redistilled, b. p. 58.7° (5 mm.). 184–185° (760 mm.), $n^{25}D$ 1.5061 and analyzed.

Anal. Found: C, 58.69; H, 6.79; S, 23.00; N, 0.35.

Disregarding the nitrogen as a trace impurity the analysis indicates an empirical formula of C_7H_8SO or $C_7H_{10}SO$. The analytical and physical data agree reasonably well with that of 2-thenyl ethyl ether,[21] $C_7H_{10}SO$, which has the following constants: b. p. 84–86° (22 mm.), 181–182° (740 mm.), $n^{20}D$ 1.5062, and percentage composition C, 59.12; H, 7.09; S, 22.54.

Fraction 2, b. p. 106–108° (3 mm.), $n^{25}D$ 1.5321, was redistilled (b. p. 111–113° (4 mm.)) with no change in refractive index and gave a monopicrate which melted at 155–156°. This data and the analysis of the base was in good agreement with that of N^2,N^2-dimethyl-N^1-phenyl-1,2-propanediamine (see procedure 1).

Anal. Calcd. for $C_{11}H_{18}N_2$: C, 74.11; H, 10.18; N, 15.72. Found: C, 74.33; H, 10.28; N, 15.56.

Fraction 3, b. p. 163–165° (3 mm.), $n^{25}D$ 1.5800. These constants showed that this fraction was recovered tertiary amine.

Acknowledgment.—The authors wish to express their appreciation to Drs. H. M. Wuest and J. A. King for their interest in this project and to Mr. I. Ehrenthal for his help in a number of the preparations.

Summary

Six new and two previously reported 2-thenyl substituted diamines, $C_4H_3SCH_2(R_1)NR_2B$, have been synthesized in which R_1 is a phenyl or 2-pyridyl radical, R_2 is a straight or branched alkylene chain of two or three carbon atoms and B is a dimethylamino or piperidino group. An interesting decomposition of one of these in the presence of hydrogen halides has been observed, the products identified and a mechanism suggested.

The Resolution of *dl*-Arterenol

BY B. F. TULLAR

Recently the resolution of *dl*-arterenol, α-aminomethyl-3,4-dihydroxybenzyl alcohol, was announced together with a brief description of the physiological characteristics of the active *l*-isomer.[1] The present paper deals with the method of effecting this resolution.

An observation that *dl*-arterenol is almost quantitatively converted to its methyl ether by evaporating *in vacuo* a solution of the hydrochloride in methanol[2] suggested that ether formation might occur during resolution attempts in anhydrous alcohols. Accordingly, aqueous alcohols seemed to offer more promise as resolution solvents.

The presence of water in the resolution mixture afforded an additional advantage since only the *l*-arterenol forms a *hydrated* salt with *d*-tartaric acid. This *l*-arterenol *d*-bitartrate monohydrate possesses greater solubility in aqueous methanol and considerably lower water solubility than does the *non-hydrated* *d*-arterenol *d*-bitartrate, permitting an easy separation of the diastereomers.

The bitartrates were purified by repeated recrystallization from water (*l* isomer) and from 95% methanol (*d* isomer) and converted to the free bases by treatment with ammonium hydroxide. The hydrochlorides were prepared by dissolving the base in isopropanol with slightly more than the calculated amount of concentrated hydrochloric acid and crystallizing by cooling.

d-Arterenol was racemized by heating at 90° for two hours in dilute hydrochloric acid solution with an 83% recovery of the racemic base.

Experimental

Resolution. (a) In Aqueous Methanol.—In a solution of 155 g. of *d*-tartaric acid in 100 ml. of water 169 g. of *dl*-arterenol was dissolved by vigorous stirring. The solution was diluted slowly with methanol to one liter. Crystallization was induced by scratching and after several hours at room temperature there was a nearly solid mass of crystals which was separated and washed with a little 90% methanol. After drying *in vacuo* at

(1) Tainter, Tullar and Luduena, *Science*, **107**, 39–40 (1948).

(2) A similar reaction of epinephrine was described by Öppinger and Vetter, *Med. u. Chemie*, **4**, 343–367 (1942), see *C. A.*, **58**, 5928 (1944). Johnson, *et al.*, THIS JOURNAL, **69**, 2945 (1947), reported alkylation of a hydroxymethylene group under quite similar conditions.

25° the white crystalline *d*-arterenol *d*-bitartrate[3] weighed 110 g., had m. p. 161–163° and $[\alpha]^{23}D$ +31.4° (*C* = 6% water).

***d*-Arterenol *d*-Bitartrate.**—The crystalline fraction was recrystallized twice from 95% methanol. After drying *in vacuo* at 25° the product weighed 58 g. and had m. p. 164–165° (cor.), $[\alpha]^{25}D$ +39.9° (*C* = 1.5% in water). A portion recrystallized from one-half its weight of hot water had the same constants. The solubility of this salt in water is greater than 20% at 25°.

Anal. Calcd. for $C_{12}H_{17}O_8N$: N, 4.40; C, 45.20; H, 5.33. Found: N, 4.30; C, 45.38; H, 5.44.

***l*-Arterenol *d*-Bitartrate Monohydrate.**—The resolution liquor was evaporated to dryness *in vacuo*. The residue was dissolved in 150 ml. of water at 60° and cooled to 2–3° for several hours with occasional stirring and scratching to induce crystallization. The heavy, crystalline precipitate was collected, washed with 95% alcohol and dried *in vacuo* at 25°. The crude salt amounted to 80 g. and had m. p. 90–115°. A portion was converted to base as described below and had $[\alpha]^{25}D$ −20° (*C* = 1.5% in water with 1 equiv. hydrochloric acid).

After three recrystallizations from equal weights of water, drying finally at 50° *in vacuo*, 28 g. of *l*-arterenol *d*-bitartrate monohydrate was obtained with the following constants: m. p. 102–104° (cor.) $[\alpha]^{25}D$ −11° (*C* = 1.6% in water). Recrystallization from 95% ethanol or from water did not change these values. This salt is soluble to more than 20% in water at 25°.

Anal. Calcd. for $C_{12}H_{17}O_8N \cdot H_2O$: H_2O, 5.35; N, 4.15; C, 42.48; H, 5.68. Found: H_2O, 5.34; N, 4.10; C, 42.73; H, 5.65.

(b) **Resolution in Water.**—The same quantities of *dl*-arterenol and *d*-tartaric acid as in (a) were dissolved in 300 ml. of water. By cooling to 3–5° and inducing crystallization by stirring and scratching there was a heavy precipitate after several hours. This was filtered off, washed with 30 ml. of ice-water and with 2 × 100 ml. of 95% alcohol and air-dried. The product weighed 135 g. and had m. p. 88–95°.

Recrystallization by dissolving in 135 ml. of water at 50° and after decolorizing with charcoal cooling to 2–3° for several hours gave 80 g. of nearly pure *l*-arterenol *d*-bitartrate, m. p. 94–98°. After two more such recrystallizations, 43 g. was obtained having m. p. 102–104.5° (cor.) and $[\alpha]^{26}D$ −10.8°.

From the aqueous resolution liquors by concentration and crystallization from aqueous methanol 110 g. of *d*-arterenol *d*-bitartrate having m. p. 161–165° was recovered.

***d*-Arterenol.**—A solution of 10 g. of the *d*-arterenol bitartrate of maximum rotation in 100 ml. of de-ionized water containing a trace of sodium bisulfite was cooled to 10° and treated slowly while stirring with 4 ml. of ammonium hydroxide solution. After fifteen minutes at 10° the microcrystalline precipitate was collected, washed with water, methanol and finally with ether. After drying *in vacuo* at 25° the colorless base weighed 5.2 g. and had m. p. 215–217°, dec., and $[\alpha]^{26}D$ +37.4° (*C* = 5% in water + 1 equiv. hydrochloric acid).

Anal. Calcd. for $C_8H_{11}O_3N$: N, 8.28; C, 56.75; H, 6.54. Found: N, 8.12; C, 56.77; H, 6.47.

***l*-Arterenol.**—*l*-Arterenol *d*-bitartrate monohydrate of maximum rotation was treated exactly as above. The colorless *l*-arterenol base from 10 g. of the salt amounted to 4.9 g. and had m. p. 216.5–218°, dec., and $[\alpha]^{25}D$ −37.3° (*C* = 5% in water with 1 equiv. hydrochloric acid).

Anal. Calcd. for $C_8H_{11}O_3N$: N, 8.28; C, 56.75; H, 6.54. Found: N, 8.21; C, 56.37; H, 6.61.

(3) When equivalent amounts of *l*-malic acid or of N-benzoyl-*l*-threonine were substituted for tartaric acid the corresponding salts of *d*-arterenol separated in about the same yield and degree of purity.

***d*-Arterenol Hydrochloride.**—To 10 ml. of isopropanol and 1.5 ml. of concentrated hydrochloric acid at 25° was added 1.69 g. of *d*-arterenol. The mixture was stirred until a clear solution was formed and then cooled to −10°. After fifteen minutes the crystalline precipitate was collected, washed with ether and dried *in vacuo* at 25°. The colorless *d*-arterenol hydrochloride weighed 1.4 g. and was very readily soluble in water. It had m. p. 146.8–147.4° and $[\alpha]^{27}D$ +39° (*C* = 6% in water). Recrystallization of this hydrochloride did not raise the melting point or rotation. Exposure of solutions of this salt to elevated temperatures (higher than 50°) during crystallization for even a few minutes lowers the melting point and rotation. This is also true of the *l*-arterenol hydrochloride.

Anal. Calcd. for $C_{11}H_{11}O_2N \cdot HCl$: N, 6.80; C, 46.72; H, 5.88. Found: N, 6.75; C, 46.95; H, 5.99.

***l*-Arterenol Hydrochloride.**—*l*-Arterenol was treated as above. One and sixty-nine one hundredths grams yielded 1.3 g. of colorless *l*-arterenol hydrochloride, having m. p. 145.2–146.4° and $[\alpha]^{25}D$ −40° (*C* = 6% in water).

Anal. Calcd. for $C_6H_{11}O_2N \cdot HCl$: N, 6.80; C, 46.72; H, 5.88. Found: N, 6.73; C, 46.98; H, 5.83.

Racemization of *d*-Arterenol.—One hundred and twenty grams of *d*-arterenol was dissolved in one liter of de-ionized water with 100 ml. of concentrated hydrochloric acid at 90°. After two hours at this temperature in a nitrogen atmosphere the solution was cooled to 20°, treated with Darco and filtered. The filtrate was made alkaline with 80 ml. of concentrated ammonium hydroxide at 10° and let stand until precipitation was complete. The base was collected, washed with water, alcohol and ether and dried *in vacuo* at 25°. One hundred grams of *dl*-arterenol was recovered, m. p. 190–191°, $[\alpha]^{22}D$ +0.6° (*C* = 5% in water as the hydrochloride).

***dl*-Arterenol Methyl Ether Hydrochloride,** [β-(3,4-Dihydroxyphenyl)-β-methoxyethylamine hydrochloride]. —One-hundred grams of *dl*-arterenol was suspended in 800 ml. of methanol and hydrogen chloride was passed in with stirring at 10° until a slight excess had dissolved and a clear solution resulted. The solution was concentrated at the water pump at 30–35° to a volume of 300 ml. when heavy crystallization occurred. The precipitate was collected at 0°, washed with cold methanol and ether and dried *in vacuo*, yielding 72 g. of a hydrochloride which was very easily soluble in water and had m. p. 170–171°. A sample of this salt in aqueous solution gave a green coloration with ferric chloride as does arterenol. *dl*-Arterenol hydrochloride has m. p. 141° (dec.).

Anal. Calcd. for $C_9H_{12}O_3N \cdot HCl$: OCH_3, 14.13; N, 6.38. Found: OCH_3, 13.41; N, 6.25.

A portion of the hydrochloride was converted to the free base as described above for *d*-arterenol. The base, which was appreciably soluble in water and methanol, had m. p. 109–112°.

Acknowledgment.—The author is indebted to M. E. Auerbach of these laboratories for determination of physical constants and analyses.

Summary

1. *dl*-Arterenol has been resolved through the acid tartrates.

2. The *d*- and *l*-base and hydrochloride were prepared.

3. *d*-Arterenol was racemized by heating with dilute acid.

RENSSELAER, NEW YORK RECEIVED JANUARY 3, 1948

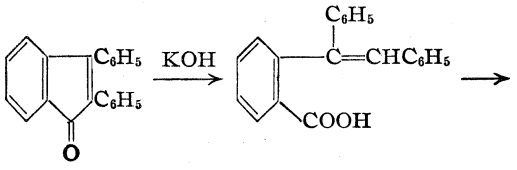
[COMMUNICATION NO. 1176 FROM THE KODAK RESEARCH LABORATORIES]

The Formation of 1,3-Diphenylisobenzofuran from 2,3-Diphenylindone

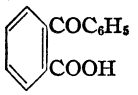
BY C. F. H. ALLEN AND J. A. VANALLAN

In earlier papers[1,2] it has been shown that alcoholic alkaline reagents give two types of reaction with carbonyl bridge compounds, depending on the nature of the substituent groups at the ends of the bridge. When these groups are phenyl, the bridge is cleaved at one end, a carboxylic acid resulting, whereas the presence of methyl groups favors a reduction of the carbonyl to carbinol. It seemed desirable to learn the behavior of a simpler phenylated ketone with the same sort of reagent.

2,3-Diphenylindone (I) was selected for study, since so many of the possible reaction products were at hand from our earlier work. It was previously known that, upon fusion with potassium hydroxide, the ring is cleaved, with consequent formation of *o*-α,β-diphenylvinylbenzoic acid (II).[3]



I II

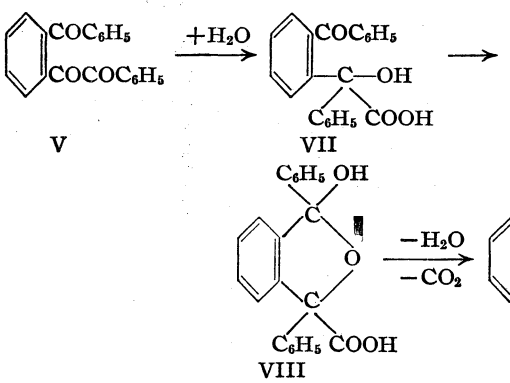


III

We found that cleavage takes place at the same point when a cymene solution of 2,3-diphenylindone is boiled with sodium amide. Under these conditions, however, the unsaturated acid was not isolated; instead, degradation proceeds to *o*-benzoylbenzoic acid (III).

In view of these observations, it was anticipated that alkaline reagents in solvents such as water or alcohol would bring about the same result. Much to our surprise, however, after acidification, the principal reaction product was found to be 1,3-diphenylisobenzofuran (IV). This same furan was also formed in reactions between ethanolic potassium hydroxide and related substances such as *o*-benzoylbenzil (V) and 2,3-diphenylindone epoxide (VI). In the latter case, the yield is small. It is, thus, apparent that not only has there been a different mode of cleavage, but that it has been accompanied by a rearrangement, for in the furan one phenyl group is attached to each carbon atom directly connected to the ring. The route followed cannot be a simple reaction, since the empirical formulas of the indone and isobenzofuran differ by only one carbon atom.

The mechanism of the formation of a diphenylisobenzofuran (IV) from *o*-benzoylbenzil (V) seems obvious. The first step is probably a benzilic acid rearrangement to (VII); this is followed by intramolecular addition, to give the isomeric lactol which is a dihydrofuran (VIII); the last step is the elimination of carbon dioxide and water. The facile elimination of groups from the 1,3-positions of dihydrofurans is well known.[4]



V VII VIII IV

The mechanism of isobenzofuran formation from the epoxide (VI) and alcoholic potassium hydroxide is more complex. A plausible sequence of reactions is as follows: The oxide ring is opened in the presence of the potassium ethoxide, with consequent formation of the glycol ether (IX). The latter, by the reverse of an aldol reaction,[5] forms a benzil (X), which, in the alkaline alcoholic solution, undergoes a benzilic acid rearrangement

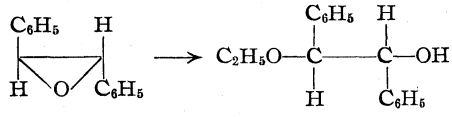
to give (XI); elimination of alcohol closes the dihydrofuran ring (XII), from which formic acid is lost, to give 1,3-diphenylisobenzofuran (IV).[6] An analogy for the ring opening (VI–IX) is furnished by Read and Campbell's observation[7] that *l-trans*-diphenylethylene oxide, on standing in ethanolic solution, gave the monoethyl ether of *l*-isohydrobenzoin.



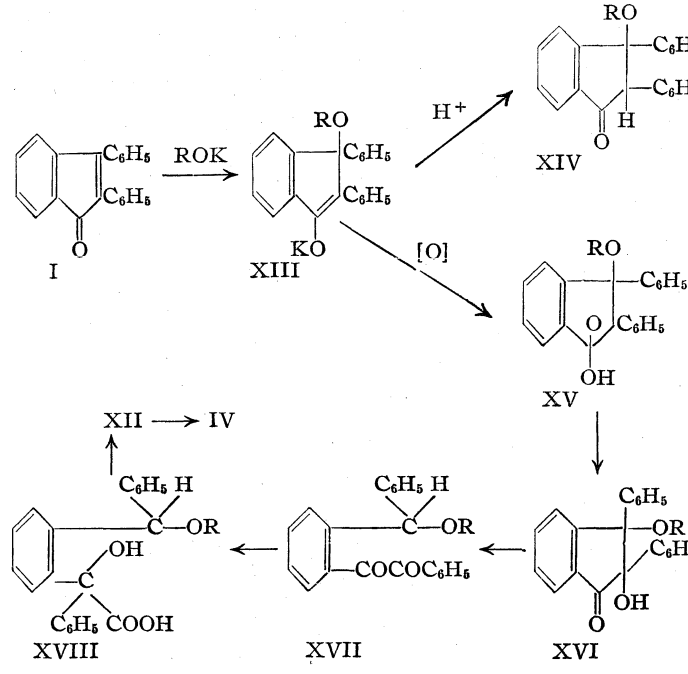
Since 2,3-diphenylindone likewise gives 1,3-diphenylisobenzofuran under the same conditions, it would seem that by some obscure process it must be first converted to either *o*-benzoylbenzil or the epoxide (VI). This indone has been reported to form an epoxide[5] when treated with alkaline hydrogen peroxide in aqueous alcoholic solution, and to form *o*-benzoylbenzil on permanganate oxidation.[8] However, there is no indication of the presence of either in the reaction mixture.

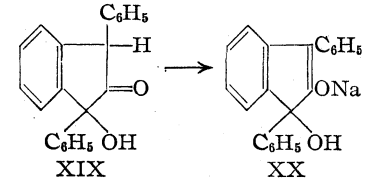
The yield of the isobenzofuran which is isolated from the reaction mixture is 50–55%. Upon concentration, the filtrate deposits two colorless substances. The one obtained in larger amount (25%), upon analysis, gave figures indicating that a molecule of the solvent, isopropyl alcohol, had been added to the indone. The second substance, isolated in a yield of 2–5%, analyzes for a glycol (XXI).

While there are several ways in which an alcohol might be added to the indone (I), it seems highly probable that 1,4-addition of the potassium alkoxide to the conjugated systems of double bonds has occurred, with consequent formation of an enolate (XIII). The free enol would undoubtedly isomerize to the isomeric β-alkoxyketone (XIV), which is the product isolated in 25% yield. This alkoxyketone gives a green color with concentrated sulfuric acid; the alcohol is lost and 2,3-diphenylindone regenerated.

Now it is well known that many enolates undergo spontaneous oxidation to oxanols.[9] In this instance, the oxanol (XV) can be considered as undergoing two successive reactions, each of which is the reverse of an aldol condensation (XV → XVII), to give an ether (XVIII) of a benzilic acid corresponding to (XI); the subsequent ring closure to a dihydroisobenzofuran (XII) and loss of formic acid then proceeds exactly as just outlined. The proposed sequence of reactions, as indicated by formulas XIII–IV, is supported by the observation that when one equivalent of alkoxide is used and the time decreased to one hour, only a very small amount of the isobenzofuran is formed, but the alcohol addition product can be isolated in a good yield.

Dufraisse[10] recently announced that 1,3-diphenylisobenzofuran (IV) resulted when an alkaline solution of 1,3-diphenyl-1-hydroxy-2-indanone (XIX)[11] was treated with air or oxygen (no reaction *in vacuo*); the gas was absorbed very rapidly, which led the authors to assume intermediate formation of an enolate.





In view of our conclusions, it is suggested that his observations can be correctly explained by a similar mechanism, involving oxidation of the metallic enolate (XX) to an oxanol, and so forth, through a dihydrofuran to the isobenzofuran (IV). By an alternative interpretation, the double bond in the enolate could be cleaved by oxidation to give the ketobenzilic acid (VII), with the subsequent steps as already outlined.

The glycol (XXI) is an isomer of one previously described.[5] It exhibits the same halochromism

(6) In footnote 22 [Bissinger, *et al.*, THIS JOURNAL, **69**, 2955 (1947)], it is noted that 3,4-epoxy-1-butene is opened in both possible ways by methanol under alkaline conditions. Other products that are formed from the 2,3-diphenylindone epoxide are retained in the untractable resinous material that is formed; this probably accounts for the low yield of furan.

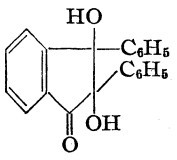
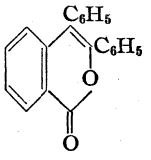
with sulfuric acid, and, like its isomer, is easily converted to the lactone (XXII). It, thus, appears that this is an instance of geometrical isomerism. The new glycol has a much higher melting point and is therefore assigned a *trans* structure. Its origin is not clear, but it probably arises from a *trans* ring opening of a little epoxide formed in the alkaline solution.



XXI

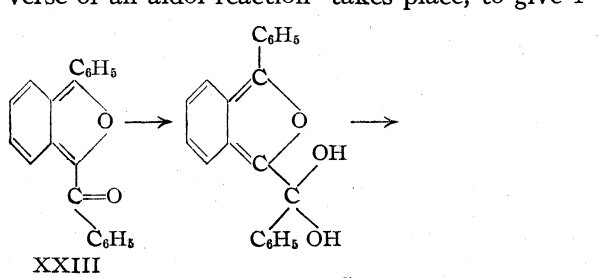


XXII

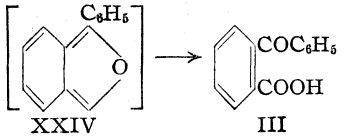
It has been reported[4] that 1,3-diphenylisobenzofuran in alcoholic solution is oxidized by air alone to *o*-dibenzoylbenzene. This observation has been checked and the time required found to be thirty-four hours. Since a high yield is obtained, the reaction makes available this hitherto relatively inaccessible diketone. The furan can be prepared either from 2,3-diphenylindone (I)[12] as described in this paper, or through Adams and Gold's procedure[13] which starts with a diene synthesis.

This remarkably easy oxidation procedure was applied to 1 - phenyl - 3 - benzoylisobenzofuran (XXIII).[5] The same type of reaction took place, and *o*-benzoylbenzil (V) was obtained in high yield.

It seemed that if potassium hydroxide were added to a solution of 1-phenyl-3-benzoylisobenzofuran before aeration the reaction should not stop with formation of the diketone, but should continue, as described earlier in this paper, to 1,3-diphenylisobenzofuran; the latter would, thus, be obtained in a single operation from 1-phenyl-3-benzoylisobenzofuran. However, *o*-benzoylbenzoic (III) and benzoic acids were formed in excellent yield. Two mechanisms could account for such a result. In the first, an equivalent of water adds to the carbonyl group, after which the reverse of an aldol reaction[5] takes place, to give 1-phenylisobenzofuran (XXIV) and benzoic acid. The furan is then oxidized by air, as in the other instances. By the second mechanism, *o*-benzoylbenzil is produced by aerial oxidation, whereupon the 1,2-diketone is cleaved by further alkaline oxidation. This suggestion seems less likely, for 1,2-diketones are cleaved by alkaline peroxides, rather than through aerial oxidation.



XXIII



XXIV III

An apparent exception to the easy oxidation of isobenzofurans has been noted in the case of the 1,3-dibenzoyl derivative.[14] This deep red substance was reported as not being further oxidized. Such a discrepancy, along with the unusual color of the substance, suggests that a reinvestigation is in order.

Experimental

Formation of 1,3-Diphenylisobenzofuran (IV). A. From 2,3-Diphenylindone.—To a solution of 1.6 g. of potassium hydroxide in 75 ml. of isopropyl alcohol was added 4 g. of 2,3-diphenylindone,[12] and the mixture was refluxed for ten hours. The red solid slowly dissolved, giving a brownish solution. After pouring into water, the cooled solution was extracted with ether to remove alkali-insoluble material, treated with Norite, and acidified. The yellow solid was taken up in benzene, the solvent evaporated, and the residue triturated with methanol and recrystallized from alcohol. It melted at 127° and showed no depression when mixed with an authentic sample. The yield was 51%; with ethanol as solvent, the yield dropped to 44%, while it was less than 2% with methanol.

From a similar-sized run, in which one equivalent of sodium isopropoxide was used, and the time reduced to one hour, under 0.1 g. of isobenzofuran was obtained. The oily material is easily separated from 0.2 g. (3%) of the glycol (XXI) but crystallizes very reluctantly. The solid that does separate is a mixture of the alcohol addition product (XIV) (31%) and unchanged starting material (5%).

B. From *o*-Benzoylbenzil.—A mixture of 1.2 g. of *o*-benzoylbenzil[8] and 10 ml. of 10% potassium hydroxide in ethanol was refluxed for one and one-half hours, and worked up as in A. It gave an 85% yield of the 1,3-diphenylisobenzofuran.

C. From the Epoxide (VI).—Following the same procedure, but using 2 g. of the epoxide, resulted in formation of the isobenzofuran in a yield of only 10–11%.

3-Isopropoxy-2,3-diphenylindanone (XIV; R = i-C_3H_7).—The ethereal extract from A (above) was evaporated to dryness and the residue extracted twice with ligroin (b. p. 90–120°). The crude crystals deposited from the ligroin were recrystallized from a mixture of petroleum ether and benzene, when the melting point was 127–128°.

Anal. Calcd. for $C_{24}H_{22}O_2$: C, 84.3; H, 6.4. Found: C, 84.8; H, 5.8.

When 0.2 g. of this ether was added to 2 ml. of concentrated sulfuric acid, it gave a green solution; after a half hour this was poured into water. The bright red crystals were removed and found to be 2,3-diphenylindone by mixed melting point.

2,3-Dihydroxy-2,3-diphenylindanone (XXI).—The residue, insoluble in ligroin, was triturated with benzene, filtered, and recrystallized from benzene. It melted to a red liquid at 233–235° with decomposition; the yield was 4.2%.

Anal. Calcd. for $C_{21}H_{16}O_3$: C, 79.7; H, 5.1. Found: C, 79.4; H, 5.1.

This is the *trans* glycol, corresponding to the *cis* form obtained from the epoxide.[5]

Both the *cis* and *trans* glycols give a red halochromism with concentrated sulfuric acid, which soon changes to

(12) Allen, Gates and VanAllan, "Organic Syntheses," **27**, 30 (1947).

(13) Adams and Gold, THIS JOURNAL, **62**, 56 (1940).

(14) Weiss and Sonnenschein, *Ber.*, **58**, 1043 (1925).

pale yellow. On dilution and appropriate manipulation, the same lactone (XXII) is obtained from both; it was identical with a previously prepared specimen.[5]

Formation of 1-Phenyl-3-benzoylisobenzofuran (XXIII).—The yield of this substance from the glycol (XXI)[5] has been improved (90%) by modifying the procedure as follows: A mixture of 8 g. of the glycol, 0.3 g. of potassium hydroxide, and 50 ml. of alcohol is refluxed for three hours and worked up as usual.

Formation of *o*-Benzoylbenzoic Acid. A. From the Indone.—A mixture of 1.4 g. of 2,3-diphenylindone, 0.39 g. of sodium amide, and 10 ml. of xylene was refluxed for twelve hours. It was then diluted first with alcohol, then with water, and 1 ml. of 40% sodium hydroxide, and the xylene distilled with steam. The residual alkaline solution was treated with Norite and acidified. After some time, *o*-benzoylbenzoic acid separated in a yield of 50%, and was identified by comparison with an authentic specimen.

B. From 1-Phenyl-3-benzoylisobenzofuran (XXIII).—A mixture of 1.5 g. of the furan, 0.5 g. of potassium hydroxide, and 75 ml. of absolute alcohol was heated in a current of oxygen for five hours. The next day the solvent was removed *in vacuo*, the residue taken up in water, treated with Norite, acidified, and extracted with benzene. The acid was caused to crystallize by the addition of ligroin; the yield was 0.98 g. (93%); it was shown to be *o*-benzoylbenzoic acid by mixed melting point.

Oxidation of Isobenzofurans to 1,2-Aroylbenzenes. A. *o*-Dibenzoylbenzene.—A solution of 0.4 g. of 1,3-diphenylisobenzofuran in 15 ml. of benzene was refluxed for thirty-four hours in a slow current of oxygen. When the fluorescence had disappeared, the solvent was evaporated and the residue recrystallized from methanol. The yield of *o*-dibenzoylbenzene was 0.37 g. (86%); m. p. 145–147°. It was identified by comparison with a sample at hand.

B. *o*-Benzoylbenzil (V).—A solution of 1 g. of 1-phenyl-3-benzoylisobenzofuran in 20 ml. of alcohol was refluxed in a current of air for seven hours, the solvent removed, and the residue crystallized from acetic acid. The yellow crystals (0.55 g.) melted at 96°; a mixed melting point with a stock sample was not depressed.

Summary

1,3-Diphenylisobenzofuran is easily obtained by the action of alcoholic potassium hydroxide upon 2,3-diphenylindone, its epoxide, and *o*-benzoylbenzil. Mechanisms are proposed to account for the reactions.

1,3-Disubstituted isobenzofurans are slowly but completely oxidized by air or oxygen, in refluxing alcoholic solutions, to *o*-diaroylbenzenes.

1-Phenyl-3-benzoylisobenzofuran, in an alkaline alcoholic refluxing solution, is oxidized to *o*-benzoylbenzoic acid. This same acid also results when 2,3-diphenylindone is cleaved by sodium amide in boiling xylene.

Morphine Studies. 2-(2′,3′-Dimethoxyphenyl)-2-(β-ethoxyethyl)-cyclohexanone

BY E. C. HORNING, M. G. HORNING AND E. J. PLATT[1]

One of the chief structural characteristics of morphine and many of its derivatives is the presence of a quaternary carbon, identified in the Gulland–Robinson formula as C-13 of the octahydrophenanthrene system. Methods for the synthesis of octahydrophenanthrenes of this kind are quite limited; few such compounds have been made, and attempted applications of known methods to the synthesis of morphine derivatives have not been successful.

It was recognized by Cook[2] that octahydrophenanthrenes could be obtained from 2-arylcyclohexanones by an apparently general method involving a Reformatsky reaction, followed by dehydration, hydrogenation and cyclization. This method was applied by the English workers to 2-phenylcyclohexanone, and we have used it with 2-(2′,3′-dimethoxyphenyl)-cyclohexanone.[3]

We have been interested in the application of Cook's procedure to the synthesis of certain morphine derivatives, and for this purpose it has first been necessary to investigate the preparation of a dimethoxyarylcyclohexanone containing an appropriately substituted carbon in the 2-position. The reactions employed are indicated on the diagram; the starting material was prepared by the sodamide alkylation of 2,3-dimethoxyphenylacetonitrile with δ-chlorovaleronitrile. Continued study of this reaction has led to the inclusion of certain apparently minor modifications which result in consistent yields of 80–83%. The product, 2-(2′,3′-dimethoxyphenyl)-pimelonitrile, is a dinitrile which can undergo cyclization to a six-membered β-iminonitrile, but which can also be alkylated directly by the sodamide method. This situation apparently arises through the structural factors which affect the cyclization. In the case of pimelonitriles, cyclization does not occur so readily as in the case of adiponitriles, and structural modifications may impose added difficulty in the way of the reaction. In the cyclization of α-(2,3-dimethoxyphenyl)-pimelonitrile (I) with sodium,[3] the cyclizing agent will produce a carbanion by removal of the most acidic hydrogen, which in this case is that associated with the phenylacetonitrile system. If a carbanion of this structure is formed, however, cyclization may follow directly only by addition of a completely substituted carbanion carbon to the nitrile group at the other end of the chain. The effective steric hindrance presented toward this addition is a barrier which in similar cases usually is sufficient to prevent cyclization. It is not known whether

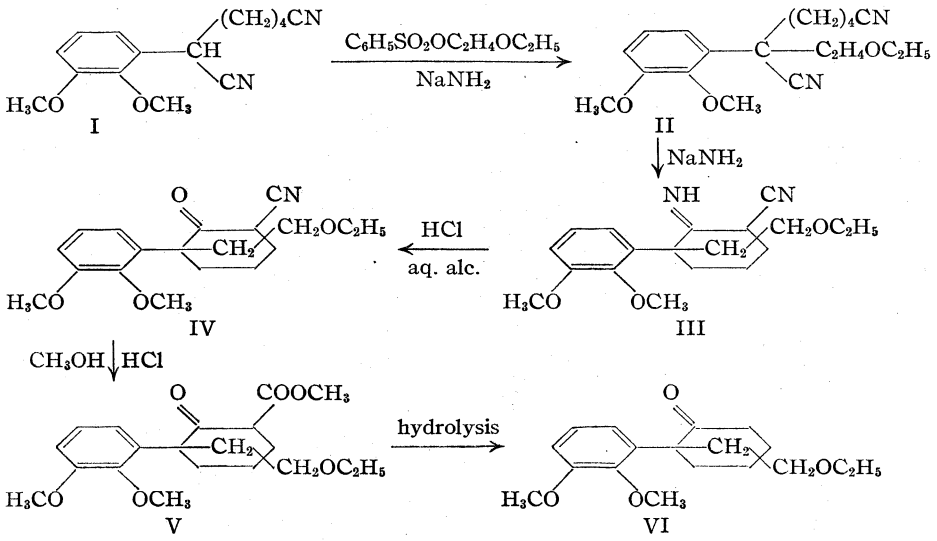
(3) Horning, Horning and Platt, THIS JOURNAL, 69, 2929 (1947).

the cyclization which occurs here takes place in spite of this steric effect, or whether a partial replacement of one of the α-hydrogens at the other end of the chain leads to cyclization in the other direction; this would also be possible, but it would represent a condition not easily arrived at in the presence of the more acidic hydrogen of the phenylacetonitrile system. These effects, which retard cyclization, are fortunately the same effects which are needed to allow alkylation of I in the desired position. With β-ethoxyethyl benzenesulfonate as the alkylating agent, an 80% yield of 2-(2′,3′-dimethoxyphenyl)-2-(β-ethoxyethyl)-pimelonitrile (II) may be obtained.

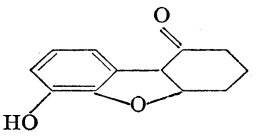


The cyclization of this pimelonitrile (II) can occur in only one fashion, and the structure of the resulting β-iminonitrile is that of III. Sodamide (in boiling benzene) was used as the cyclizing agent; a nitrogen atmosphere must be employed. The iminonitrile was isolated in crystalline form, and was converted into the β-ketonitrile IV in quantitative yield by acid hydrolysis in aqueous ethanol. Treatment of IV with hydrogen chloride in dry methanol gave the β-ketoester V.

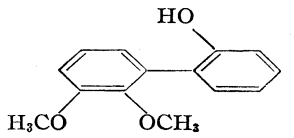
Under appropriate conditions, it might be expected that either III, IV or V would undergo hydrolysis-decarboxylation to yield the desired product, 2-(2′,3′-dimethoxyphenyl)-2-(β-ethoxyethyl)-cyclohexanone (VI). Three methods were investigated; the best proved to lie in the hydrolysis of the β-ketoester (V) with a dilute alcoholic solution of potassium hydroxide, followed by brief heating of the acidified solution to effect decarboxylation. The ketone (VI) was obtained from (V) in 83% yield as a colorless viscous oil.

The removal of the carbomethoxy group of (V) by ester interchange-decarboxylation with ethyl hydrogen adipate, following the general method of Fourneau[4] was also investigated. It was not possible to obtain material of analytical purity by this method, although the reaction apparently proceeded without difficulty. The yield was slightly lower than that obtained by direct hydrolysis-decarboxylation.

The use of a boiling hydrochloric acid–acetic acid mixture for hydrolysis led to an unexpected result. When this hydrolysis method was applied to the iminonitrile (III), with a reflux period of three hours, a crystalline phenolic product was isolated. While demethylation under such circumstances is not unusual, analytical data for the phenol indicated that the β-ethoxyethyl chain was no longer present. The structure of this compound is under investigation; the analytical results correspond to structure VII.



(VII)



(VIII)

The possibility that the product was 2,3-dimethoxy-2′-hydroxybiphenyl (VIII) was excluded both by analysis and by synthesis of (VIII) by dehydrogenation of 2-(2′,3′-dimethoxyphenyl)-cyclohexanone.

Experimental

All melting points are corrected.

α-(2,3-Dimethoxyphenyl)-pimelonitrile (I).—By the introduction of several apparently minor modifications into the procedure described previously,[3] the yield has been raised to 80–83%. After addition of the solvent (toluene), the ammonia was allowed to evaporate, with little or no warming, over several hours. The addition of δ-chlorovaleronitrile was started while the mixture was at room temperature, and was carried out as rapidly as possible. Good stirring and spraying of water on the flask during the addition were necessary to allow continued control of the vigorous exothermic reaction. Under these circumstances, 88.5 g. (0.50 mole) of 2,3-dimethoxyphenylacetonitrile yielded 106.5 g. (83%) of the dinitrile, b. p. 191–199° (0.5–0.7 mm.).

β-Ethoxyethyl Benzenesulfonate.—A mixture of 180 g. of ethylene glycol monoethyl ether, 360 g. of benzenesulfonyl chloride, 200 ml. of water, and 200 ml. of chloroform was stirred in an ice-bath while a solution of 120 g. of sodium hydroxide in 700 ml. of water was added dropwise over one hour. The mixture was then stirred for one hour longer at room temperature. The chloroform layer was separated and washed with 200 ml. of water. After drying over magnesium sulfate the solvent was removed and the residue distilled under reduced pressure. There was obtained 232 g. (50%) of the ester, as a nearly colorless oil, b. p. 136–144° (0.7 mm.).

(4) Fourneau, *Bull. soc. chim.*, [4] **43**, 859 (1928); Stoll, *Helv. Chim. Acta*, **30**, 1401 (1947).

α-(2,3-Dimethoxyphenyl)-α-(β-ethoxyethyl)-pimelonitrile (II).—Sodamide was prepared from 8.85 g. (0.38 mole) of sodium in approximately 350 ml. of ammonia. With the aid of 40 ml. of dry ether, 89.0 g. (0.35 mole) of α-(2,3-dimethoxyphenyl)-pimelonitrile was added with stirring. After ten minutes, 200 ml. of dry benzene was added, and the mixture was allowed to stand until the ammonia had evaporated. There was then added with good stirring, at a rate compatible with the ensuing vigorous reaction, 97.6 g. (0.42 mole) of β-ethoxyethyl benzenesulfonate. The mixture was heated and stirred for two and one-half hours; methanol (30 ml.) and water (150 ml.) were added to the cooled mixture, and the benzene layer was separated. The aqueous layer was extracted with 100 ml. of benzene and two 50-ml. portions of ethyl acetate. The combined extracts were washed with 100-ml. portions of 5% sodium hydroxide solution, water, 5% hydrochloric acid, water, and saturated sodium bicarbonate solution, and dried over magnesium sulfate. The solvents were removed by distillation and the residue distilled under reduced pressure. The product was collected as a light yellow viscous oil at 210–220° (0.5–0.7 mm.); yield 91.2 g. (80%).

Anal. Calcd. for $C_{19}H_{26}O_3N_2$: C, 69.00; H, 7.87. Found: C, 69.00; H, 7.77.

2-(2′,3′-Dimethoxyphenyl)-2-(β-ethoxyethyl)-6-cyanocyclohexanone Imine (III).—Sodamide was prepared from 4.6 g. (0.20 mole) of sodium. There was added to the sodamide-ammonia mixture 59.0 g. (0.18 mole) of α-(2,3-dimethoxyphenyl)-α-(β-ethoxyethyl)-pimelonitrile in 50 ml. of dry ether, and this was stirred for fifteen minutes. After providing a nitrogen atmosphere, 175 ml. of dry benzene was added and the ammonia was evaporated with slight warming. The mixture was heated under reflux for two and one-half hours, cooled, and treated with methanol (15 ml.) and water (100 ml.). The benzene layer was separated, and the aqueous layer washed with 50 ml. of benzene and four 50-ml. portions of ethyl acetate. The combined extracts were washed with 100-ml. portions of 5% sodium hydroxide solution, water, 2% aqueous acetic acid, and saturated sodium bicarbonate solution, and dried over magnesium sulfate. The solvents were removed by distillation; the product was collected at 191–200° (0.2–0.3 mm.) as a very viscous light-yellow oil; yield, 47.3 g. (80%).

The distillate solidified immediately, but was apparently composed of both oil and solid. Trituration with ether–pentane (2:1) gave 32.5 g. of colorless crystalline material; evaporation of the solvents returned an oil which crystallized in part on standing. The nature of the oily product obtained here has not been determined; it may have been unchanged starting material.

Recrystallization from cyclohexane–ethyl acetate provided an analytical sample, m. p. 116–117°.

Anal. Calcd. for $C_{19}H_{26}O_3N_2$: C, 69.09; H, 7.88; N, 8.48. Found: C, 69.24; H, 7.64; N, 8.54.

2-(2′,3′-Dimethoxyphenyl)-2-(β-ethoxyethyl)-6-cyanocyclohexanone.—A mixture of 3.0 g. of the iminonitrile, 45 ml. of ethanol (95%), 9 ml. of concentrated hydrochloric acid, and 9 ml. of water was heated under reflux for one hour. The solution was diluted with 300 ml. of water, and the product was extracted with five 100-ml. portions of ether. The ethereal extract was washed well with water and with two 30-ml. portions of saturated sodium bicarbonate solution, and dried over magnesium sulfate. Evaporation of the ether gave a crystalline residue of crude, slightly discolored ketonitrile; yield, 3.0 g.; m. p. 97–99°.

A small sample was recrystallized from ether–pentane to give a colorless crystalline product, m. p. 98–99°.

Anal. Calcd. for $C_{19}H_{25}O_4N$: C, 68.86; H, 7.60. Found: C, 69.11; H, 7.74.

2-(2′,3′-Dimethoxyphenyl)-2-(β-ethoxyethyl)-6-carbomethoxycyclohexanone (V).—A solution of 2.00 g. of crude ketonitrile in 25 ml. of methanol was saturated with hydrogen chloride, without cooling. After standing at room temperature for twelve hours, the mixture was poured into 300 ml. of water, and the product extracted with four 50-ml. portions of ether. The ether solution was washed with water and with saturated sodium bicarbonate solution, dried over magnesium sulfate, and evaporated to yield 1.68 g. of crude ketoester. This material was used directly for decarboxylation.

Additional purification by evaporative distillation at 110–130° (0.1 mm.) gave the ketoester as a colorless, viscous oil.

Anal. Calcd. for $C_{20}H_{28}O_6$: C, 65.91; H, 7.74. Found: C, 66.49; H, 7.67.

2-(2′,3′-Dimethoxyphenyl)-2-(β-ethoxyethyl)-cyclohexanone (VI).—A solution was prepared from 1.50 g. of potassium hydroxide, 3 ml. of water, and 27 ml. of absolute ethanol. To this was added 2.00 g. of β-ketoester (V), and the mixture was heated under reflux for three hours. It was acidified by the addition of 5 ml. of concentrated hydrochloric acid in 5 ml. of water, and refluxing was continued for fifteen minutes. The solution was diluted with 200 ml. of water and the product extracted with four 60-ml. portions of ether. The combined extracts were washed with two 30-ml. portions of 5% sodium hydroxide solution, and with 30-ml. portions of water and 2% aqueous acetic acid. After drying, the ether was removed and the residue evaporatively distilled at 110–120° (0.07 mm.) to yield 1.40 g. (83%) of the ketone as a colorless, viscous oil.

Anal. Calcd. for $C_{18}H_{26}O_4$: C, 70.56; H, 8.55. Found: C, 70.69; H, 8.25.

Ester Interchange Method.—A solution of 1.68 g. of crude ketoester (V) in 9.0 ml. of ethyl hydrogen adipate was heated under gentle reflux in an apparatus arranged for sweeping with dry nitrogen. The rate of evolution of carbon dioxide was followed by means of an attached anhydrone–ascarite absorption tube. About forty minutes were required for the collection of 210 mg. (theoretical, 202 mg.) of carbon dioxide.

Hydrolysis of the mixture was carried out by adding 90 ml. of ethanol and a solution of 20 g. of potassium hydroxide in 50 ml. of water. The solution was heated under reflux for two hours, and most of the ethanol was removed by distilling until 90 ml. of distillate was obtained. The residue was diluted with 250 ml. of water and extracted with five 60-ml. portions of ether. The combined ether extracts were washed well with water and with 50 ml. of 2% aqueous acetic acid, and dried over magnesium sulfate. After evaporation of the ether, the remaining oil was evaporatively distilled at 105–110° (0.05 mm.) to provide 0.99 g. of the cyclohexanone as a colorless viscous oil. Material obtained in this way was not of analytical purity (about 0.5% or more from the calcd. values) although it was evidently the same compound as that obtained by hydrolysis-decarboxylation.

Hydrolysis with Hydrochloric Acid–Acetic Acid.—A mixture of 1.00 g. of the iminonitrile (III), 10 ml. of acetic acid, 10 ml. of concentrated hydrochloric acid, and 3 ml. of water was heated under reflux for three hours. After dilution with 100 ml. of water, 30 ml. of saturated sodium bicarbonate solution was added and the mixture was extracted with three 30-ml. portions of ether. The combined ether extracts were washed with saturated sodium bicarbonate solution, and with four 30-ml. portions of Claisen alkali. The combined Claisen solution was diluted with water and treated with 20 ml. of concentrated hydrochloric acid, followed by saturation with carbon dioxide. After chilling, the crystalline phenol was removed by filtration and air dried. The product, 290 mg., was recrystallized twice from ether–ethyl acetate to give a colorless product, m. p. 134–135°.

Anal. Calcd. for $C_{12}H_{12}O_3$: C, 70.56; H, 5.92. Found: C, 70.78; H, 5.71.

In separate experiments, it was established that a noncrystalline fraction, insoluble in sodium bicarbonate solution, which was isolated as a reaction product after a reflux period of twenty minutes, had a composition by analysis indicating that one nitrogen atom had been lost, and that the β-ethoxyethyl chain was largely intact. A

reflux period of six hours resulted in a lowered yield of phenolic product.

2,3-Dimethoxy-2-hydroxybiphenyl.—A mixture of 500 mg. of 2-(2′,3′-dimethoxyphenyl)-cyclohexanone, 5 ml. of triethylbenzene, and 1.0 g. of 5% palladium–charcoal catalyst[5] was heated under reflux for one hour. The warm solution was filtered and the catalyst washed with warm benzene. The organic solution was extracted with one 25-ml. and one 15-ml. portion of Claisen alkali. The Claisen solution was washed with benzene, and the benzene added to the organic solvents. The combined organic solution was extracted with three 15-ml. portions of Claisen alkali, and the combined Claisen solution was washed with 40 ml. of pentane. The alkaline solution was diluted with 100 ml. of water. A 40-ml. portion of concentrated hydrochloric acid was added and neutralization was completed with carbon dioxide (Dry Ice). After chilling, the crystalline product was removed by filtration and air dried. The yield of phenol, m. p. 102–104°, was 225 mg. Recrystallization from cyclohexane gave a colorless sample, m. p. 103–104.5°.

Anal. Calcd. for $C_{14}H_{14}O_3$: C, 73.02; H, 6.13. Found: C, 73.22; H, 6.07.

Chemical Investigation in Guayule. II. The Structure of Partheniol, A Sesquiterpene Alcohol from Guayule

BY A. J. HAAGEN-SMIT AND C. T. O. FONG[1]

In studies conducted in this Laboratory on the constituents of guayule, *Parthenium argentatum, Gray*, it was found that cold alcohol extracted from the plant a cinnamate of an optically active sesquiterpene alcohol previously isolated by Alexander.[2] The yield of the alcohol from the plant was approximately 0.03%. Later, the same ester was obtained by chromatographic adsorption of guayule extracts on silicic acid. Further studies showed that guayule resin obtained from Mexico as a by-product of guayule rubber refining would serve as a convenient source of this alcohol, yielding as much as 0.3% of the desired substance.

The physical constants of this alcohol and its cinnamate are listed below and are compared with those given by Alexander[2] and by Walter.[3]

Parthenyl cinnamate: empirical formula, $C_{24}H_{30}O_2$,[4,2] $C_{24}H_{32}O_2$[3]; m. p. 125–126°[4,2,3]; molecular weight by saponification of ester, 355[4], 354.[3]

Partheniol: empirical formula, $C_{15}H_{24}O$,[4,2] $C_{15}H_{26}O$[3]; m. p. 127–128°,[4,2] 131°[3]; mol. wt. 215,[4] 222[2]; $[\alpha]^{26}D$ 116.5° ($CHCl_3$, *c* 1.29%),[4] $[\alpha]^{24}D$ + 88.7° ($CHCl_3$, *c* 1.566%)[3]; parthenyl *p*-phenylazobenzoate, m. p. 162.5–164°[4]; parthenyl 3,5-dinitrobenzoate, m. p. 143–144°.[4]

Our data for the alcohol are in agreement with those of Alexander and the empirical formula $C_{15}H_{24}O$ for the alcohol was substantiated throughout this work. Also the melting point of partheniol repeatedly recrystallized from different solvents agrees with that of Alexander. The chromatographic separation of the phenylazobenzoate showed only traces of compounds other than the partheniol derivative. The presence of isomeric forms of partheniol might explain the melting point of 131° found by Walter[3] since we have observed that heating partheniol with alcoholic potassium hydroxide resulted in a raise of melting point to 132–132.5°. Similar observations were made in preparing a maleic anhydride addition compound.

Catalytic hydrogenation of the alcohol indicated the presence of two double bonds. The absorption spectrum of partheniol, together with the failure of partheniol to form an adduct with maleic anhydride or to be reduced by sodium in alcohol, indicates that the two double bonds are not conjugated.

The relative ease of dehydration with potassium bisulfate confirms the presence of an alcoholic hydroxyl group and indicates that the hydroxyl group is probably tertiary. The failure of esterification with phthalic anhydride under conditions described by Ruzicka, *et al.*,[5] as well as the failure to form a xanthate indicated that partheniol is a tertiary alcohol.[6]

Dehydration of partheniol with potassium bisulfate resulted in the formation of a mixture of isomeric hydrocarbons, $C_{15}H_{22}$, which we shall call dehydroparthenene.[7] These hydrocarbons contain three double bonds, which physical and chemical methods show are not conjugated.

Dehydrogenation of dehydroparthenene with sulfur gave blue S-guaiazulene which was identified by its 1,3,5-trinitrobenzene addition product, its picrate and its trinitrotoluene addition prod-

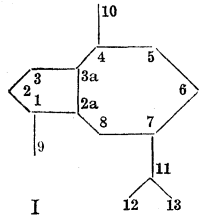
(7) Conforming to sesquiterpene nomenclature: parthenene is $C_{15}H_{24}$.

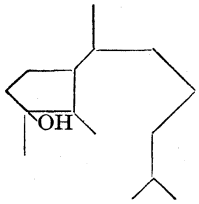
uct. The adsorption spectrum of the S-azulene obtained from partheniol correspond with those reported for S-guaiazulene by Willstaedt[8] and by Plattner.[9] Dehydration of dehydroparthenene with selenium gives a violet azulene. This behavior is similar to that shown by the dehydrogenation of a crystalline sesquiterpene alcohol, guaiol obtained from the wood of *Guaiacum officinale* (family *Zygophyllacae*).[10] These data show that the carbon skeleton of partheniol is that of 1,4 - dimethyl - 7 - isopropyl - decahydrocyclopentacycloheptene (I).



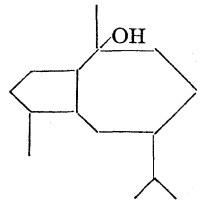
I

Tetrahydropartheniol, $C_{15}H_{28}O$, is formed by hydrogenating both double bonds of partheniol. Dehydration of tetrahydropartheniol with potassium bisulfate gives dihydroparthenene, $C_{15}H_{26}$, a hydrocarbon containing one double bond. In the ozonization of dihydroparthenene formaldehyde was formed, indicating the presence of a methylene group. Since the double bond in this methylene group arose from the removal of the hydroxyl group in tetrahydropartheniol, we may conclude that the hydroxyl group in partheniol is situated on a carbon atom to which a methyl group is attached.

If the hydroxyl group were located at carbon atom 7 or 11 dehydration of tetrahydropartheniol to dihydroparthenene would have given a mixture of isomers yielding acetone and formaldehyde upon ozonization. As no trace of acetone could be detected in the ozonization products, only two structures are possible for tetrahydropartheniol. They are shown in II and III.

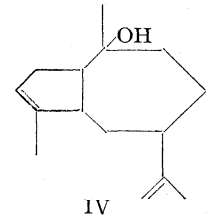


II

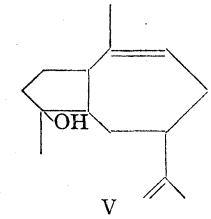


III

The position of the hydroxyl group at carbon atom 1 or carbon atom 4 is confirmed by the results of ozonization experiments on partheniol, since a neutral product, $C_{14}H_{22}O_4$, containing an aldehyde and two methyl ketone groups was obtained. The presence of formaldehyde among the volatile oxidation products demonstrated that one of the double bonds is exocyclic and present in a methylene group. The oxidation of the double bond located in the isopropenyl group explains the formation of formaldehyde and one of the methyl ketone groups. The other double bond has given rise to the aldehyde and second methyl ketone group. This limits the position of the second double bond to one adjoining a methyl group and one not connected with the bridge between the 5 and 7 membered ring. The fourth oxygen in $C_{14}H_{22}O_4$ is present as in the original tertiary hydroxyl group. This leaves out of the numerous possible isomers only the following two structures for partheniol.



IV



V

These structures are in harmony with the absence of conjugation of the double bonds in partheniol and its dehydration product dehydroparthenene. To secure a possible check of the exact position of the hydroxyl group the dicarboxylic acid, which was formed from the ozonization of dihydroparthenene followed by hypobromite oxidation, was treated with acetic anhydride according to Blanc's method.[11]

In the removal of the hydroxyl group from tetrahydropartheniol, a mixture of isomers is formed, which upon ozonization gives rise to a ketone, a diketone and a keto acid (VI or VIII) or keto aldehyde. On hypobromite oxidation of the keto acid, a dicarboxylic acid is formed which would be, in the case of structure II, a substituted glutaric acid (VII), and in the case of structure III, a substituted pimelic acid (IX). With acetic anhydride, ketone formation was not detected, indicating the presence of a glutaric acid derivative rather than a pimelic acid derivative. Also, our

analytical data show that an anhydride rather than a ketone was formed. These facts indicate that the hydroxyl group in partheniol is attached to carbon atom 1, as shown in structure V.

Experimental[12]

Isolation of Partheniol.—Twenty-five gallons of crude resin was extracted three times with five-gallon portions of ether and twice with seven-gallon portions of a 5:2 ether–methanol mixture. After the removal of the solvents from the extract, the ether-soluble portion of the guayule resin was saponified with *N* alcoholic solution of sodium hydroxide for three hours at a bath temperature of 90°. After neutralization and extraction with ether, the residue (about five gallons) was distilled at 0.01 mm. pressure. Approximately two liters of material boiling below 150° collected. Redistillation through a short helix-packed column fitted with a variable take-off still head yielded 1.2 liters of viscous oil boiling at 100–125° at 0.01 mm. pressure. This distillate was then diluted slightly with petroleum ether and inoculated with a few crystals of partheniol. After standing for several days, this solution became a solid mass of partheniol crystals.

These were recrystallized from petroleum ether to constant melting point: 150 g. of purified crystalline partheniol, m. p. 127–128°, was obtained. This melting point stayed constant after recrystallization from petroleum ether, from acetone and from benzene as well as after sublimation.

Anal. Calcd. for $C_{15}H_{24}O$: C, 81.76; H, 10.98. Found: C, 81.77, 81.73; H, 10.92, 10.98.

Attempt at Reduction of Partheniol with Sodium and Alcohol.—Two grams of partheniol in 10 ml. of amyl alcohol was heated in a 40-ml. flask at a bath temperature of 135° for six and one-quarter hours. Sodium (4.5 g.) was gradually added; at periodic intervals, more amyl alcohol was introduced until all the sodium had reacted. The residue was recrystallized twice from low-boiling petroleum ether; the substance melted at 132–132.5°.

Anal. Calcd. for $C_{15}H_{24}O$: C, 81.76; H, 10.98. Found: C, 81.85; H, 11.06.

Reaction of Partheniol with Maleic Anhydride.—The reaction of partheniol with maleic anhydride or ethyl maleate dissolved in benzene and refluxed for ten hours gave no adduct. The recovered partheniol melted at 129.5°, no depression with original partheniol.

Absorption Spectrum of Partheniol.—The absorption spectrum of a solution of 1.76 mg. of partheniol in 100 ml. of absolute alcohol was determined with the Beckman photoelectric spectrophotometer. The spectrum did not show any characteristic maxima or minima within the range of the spectrophotometer.

Parthenyl *p*-Phenylazobenzoate.—To 2 g. of partheniol in 15 ml. of dry pyridine 2.4 g. of *p*-phenylazobenzoyl chloride in 20 ml. of anhydrous benzene was added. The reaction mixture was heated at a bath temperature of 90° for half an hour and worked up in the usual manner. The residue was recrystallized first from a mixture of benzene and petroleum ether, then from acetone.

One gram of this benzoate dissolved in a mixture of 10 ml. of benzene and 50 ml. of petroleum ether (85–100°) was chromatographed on a silicic acid–celite column (2:1) 4.5 cm. × 20 cm., which had been initially washed with 250 ml. of petroleum ether. The column was developed with 400 ml. of petroleum ether (85–100°) and post-washed with 50 ml. of 30–60° petroleum ether. The chromatogram showed two very faint bands near the top. The main zone *ca.* 10 cm. below the top was cut out from the extruded column and was recovered by eluting with ether; after recrystallizing three times from acetone, m. p. 163–164°.

(12) All melting points are corrected; microanalysis by Dr. G. Oppenheimer and G. Swinehart.

Anal. Calcd. for $C_{28}H_{32}O_2N_2$: C, 78.47; H, 7.53; N, 6.54. Found: C, 78.42; H, 7.53; N, 6.66.

Parthenyl 3,5-Dinitrobenzoate.—A solution of approximately 150 mg. of partheniol and an equal amount of 3,5-dinitrobenzyl chloride in a mixture of 2 ml. of dry benzene and 5 ml. of anhydrous pyridine was gently refluxed for 0.75 hour. The reaction mixture was worked up according to Reichstein.[13] The turbid solution was allowed to stand in the refrigerator for several days: the crystals formed were recrystallized from acetone and washed with alcohol, m. p. 143–144°.

Anal. Calcd. for $C_{22}H_{26}N_2O_6$: C, 63.75; H, 6.31; N, 6.76. Found: C, 63.88, 63.97; H, 6.61, 6.51; N, 6.67, 6.90.

Dihydropartheniol.—A 5.04-g. sample of partheniol dissolved in 55 ml. of absolute ethanol was hydrogenated with approximately 2 g. of Raney nickel as catalyst at 25° and 760 mm. pressure.

The rate of hydrogenation was fairly rapid for the first fifteen hours, decreasing rapidly thereafter. The hydrogenation was terminated after the required amount of hydrogen for one double bond was taken up. After the removal of the Raney nickel and the alcohol, the remaining oil was distilled at 92–102° at 0.1 mm.; a total of 3.5 g. of dihydropartheniol was obtained. The dihydropartheniol gave the constants: $n^{26}D$ 1.5035, $d^{23.6}_4$ 0.9614; calcd. MD for $C_{15}H_{26}O$ with one double bond and one hydroxyl group is 68.15; found 68.5; *p*-phenylazobenzoate, m. p. 121.5–122.5°.

Anal. Calcd. for $C_{15}H_{26}O$: C, 81.02; H, 11.79. Found: C, 81.05; H, 11.96.

Dehydroparthenene.—A mixture of 5 g. of partheniol and 3.5 g. of fused potassium acid sulfate was refluxed at a bath temperature of 180–190° for one-half hour. Extraction was carried out with ether and the recovered oil was distilled twice over potassium. In the second distillation at 60–65° and 0.1 mm., 1.1 g. of dehydroparthenone was obtained: $n^{25}D$ 1.15120, $d^{23.6}_4$ 0.9194. Calcd. MD is 65.67 calcd. for three double bonds; found 66.04.

Anal. Calcd. for $C_{15}H_{22}$: C, 89.04; H, 10.96. Found: C, 88.90; H, 11.15.

Dehydrogenation of Dehydroparthenene.—Fifteen grams of crude dehydroparthenene was heated with 4.7 g. of sulfur at a pressure of 30–50 mm. and a bath temperature of 180–185°, for three hours.[14] The blue azulene which was formed was distilled directly from the reaction flask. The fraction obtained at 70–100° and 10–15 mm. was 7 g. The distillate was taken up in petroleum ether and the azulene was extracted with 85% phosphoric acid following the procedure of Ruzicka, *et al.*[15] The crude azulene distilled at 140–150° (bath temperature) and 0.05 mm. The yield based on crude parthenene is 1.7%. The purification was carried out as indicated by Plattner and St. Pfau[16] by converting the azulene to its trinitrobenzene addition compound.

The addition compound was decomposed and the azulene liberated through chromatographic adsorption on an aluminum oxide column. The trinitrobenzene forms a zone at the top of the column while the azulene is less strongly adsorbed. After development with petroleum ether the azulene was eluted with a mixture of 1:1 benzene–petroleum ether. A trinitrobenzene addition product was again prepared and the cycle of the decomposition and the regeneration of the azulene was repeated. The final product was distilled under reduced pressure. Approximately 125 mg. of the purified blue azulene was obtained.

Anal. Calcd. for $C_{15}H_{18}$: C, 90.85; H, 9.15. Found: C, 90.93; H, 9.24.

The addition products of the azulene with picric acid, trinitrobenzene and trinitrotoluene were prepared following the methods of Plattner and St. Pfau.[16]

The melting points found in the literature are: picrate m. p. 120–121°, trinitrobenzene compound 150–151.5° and trinitrotoluene compound 88–89°.[10,17]

Absorption Spectrum of the S-Azulene.—The absorption spectrum of the S-azulene in hexane, with a concentration of 3.62 mg. per 10 ml., was determined with a Beckman photoelectric spectrophotometer using a slit width of 0.02 to 0.3 mm. The spectrum was characterized by three maxima at 603, 659 and 735 mμ and undulations at 557, 582, 630 and 698 mμ.

Reported for S-guaiazulene are strong bands at 604, 663, 736 mμ and weak bands at 557, 581, 633 and 697 mμ.[18,19]

Tetrahydroparthenio l.—32.8 g. of partheniol was hydrogenated at room temperature and at a pressure slightly above atmospheric in 200 ml. of glacial acetic acid with 0.4 g. of platinum dioxide as a catalyst. After removal of the catalyst and the solvent, the hydrogenated product distilled at 70–85° at 0.01 mm.: $n^{25}D$ 1.4820, $d^{25.4}_4$ 0.9342; *MR* calcd., 68.60 for one hydroxyl group; found, 68.47.

Anal. Calcd. for $C_{15}H_{28}O$: C, 80.29; H, 12.58. Found: C, 80.16; H, 12.72.

Dihydroparthenene.—A mixture of 38.5 g. of tetrahydropartheniol and 24 g. of fused powdered potassium bisulfate was heated for forty-five minutes at a bath temperature of about 160°. After washing the ether extract with dilute sodium hydroxide and with water until neutral, the hydrocarbon was distilled twice over potassium. The dihydroparthenene had the following constants: b. p. (0.02 mm.) 59–60°; $n^{25}D$ 1.4880; d^{25}_4 0.9025; *MR* calcd. 66.6 for one double bond; found, 65.9.

Anal. Calcd. for $C_{15}H_{26}$: C, 87.30; H, 12.70. Found: C, 87.31; H, 12.83. Microhydrogenation: Found: uptake 1.0 mole H_2, calcd. for $C_{15}H_{26}$.

Ozonization of Partheniol.—Five grams of partheniol was ozonized in glacial acetic acid. The ozonide was decomposed by hydrogenation in 1:1 acetic acid–ether with a platinum catalyst (Adams). The reaction mixture was cooled in an ice–salt-bath during the first phase of the hydrogenation in order that a secondary reaction of "acid rearrangement" of the ozonide would not occur to any appreciable extent. The hydrogenation was later allowed to proceed at room temperature till the required amount of hydrogen was taken up. A test for formaldehyde on the volatile products with dimedon reagent was positive, while a test for acetone with *p*-nitrophenylhydrazine was negative. From the ozonized products was separated a neutral fraction, by making the solution alkaline and extracting with ether. An acid fraction was obtained by acidifying the alkaline solution and extracting with ether. A qualitative test for methyl ketone in the neutral fraction was positive; a qualitative test for aldehyde with Schiff reagent was also positive.

The amount of acid fraction was negligible. A greater portion of the neutral fraction was not distillable. By distilling at 0.6 mm. and 98–100°, 0.5 g. of the neutral fraction was collected with the following constants: $n^{24}D$ 1.4762; d^{24}_4 1.0624.

Anal. Calcd. for $C_{15}H_{24}O_4$: C, 67.13; H, 9.01; for $C_{14}H_{22}O_4$: C, 66.11; H, 8.72. Found: C, 66.74; H, 8.69. Micro-Zerewitinoff: Found: 0.9 mole act. H and 1.8 moles carbonyl, when calcd. for $C_{14}H_{22}O_4$. Methyl ketone determination. Found: 1.9 moles CH_3CO group, calcd. for $C_{14}H_{22}O_4$.

Quantitative Ozonization of Partheniol and of Dihydroparthenene.—Following the procedure and using the apparatus described by Grignard, Doeuvre and Escourrou,[20,20a] a 1.5-g. sample of partheniol was ozonized in 25 ml. of acetic acid (30% water) at 17° for forty minutes (ozone concn. 1.24 g./hr.). Decomposition of the ozonide was carried out by adding 50 ml. of water and heating at 100° for three hours. A suspension of mercuric oxide in water was then added and the reaction mixture was heated in a boiling water-bath for one hour. The wash-bottles did not contain formaldehyde when tested with dimedon. The amount of carbon dioxide formed by oxidation of the formic acid present was 180 mg. or 60% of the theoretical amount if one exocyclic double bond were present.

Following the same procedure 0.85 g. of dihydroparthenene was ozonized in 25 ml. of acetic acid containing 30% water for forty minutes (O_3 concentration 1.24 g./hr.). The amount of formaldehyde which was precipitated was negligible; the quantity of carbon dioxide after oxidation of the formic acid with mercuric oxide was 111 mg. or 65% of the theoretical if one exocyclic double bond were present. This result was confirmed by ozonizing 0.4 g. of dihydroparthenene in carbon tetrachloride. The ozonide was decomposed by adding 10 ml. of water and heating on a boiling water-bath. A test with dimedon for formaldehyde on the volatile products was positive; a test for acetone with *p*-nitrophenylhydrazine was negative.

Ozonization of Dihydroparthenene and Reduction of Ozonides.—An 18.2-g. sample of dihydroparthenene in 40 ml. of glacial acetic acid was ozonized at about 15° for three hours. To decompose the ozonide, 18 g. of zinc dust suspended in a small amount of water was slowly added; the reaction temperature was kept at 50–70° for approximately one hour. A test for peroxides was made with titanic sulfate and dilute sulfuric acid; no peroxides were found. After the removal of the excess zinc and zinc salts, the acetic acid solution was neutralized with dilute potassium hydroxide and the neutral solution was extracted with ether. An acid fraction was obtained by acidifying the ether-extracted aqueous phase with dilute sulfuric acid and extracting with ether. Fractionation of neutral fraction at 0.125 mm. gave the following fractions: 68–78°, 6.4 g.; 78–93°, 1.4 g.; 93–108°, 2.4 g.; 108–120°, 2.8 g.

Anal. Calcd. Fr. b. p. (0.125 mm.) 68–78°. Found: C, 83.83; H, 12.51. Fr. b. p. (0.125 mm.) 78–93°. Found: C, 77.56; H, 11.36. Fr. b. p. (0.125 mm.) 93–108°. Calcd. for $C_{15}H_{26}O_2$: C, 75.58; H, 11.00. For $C_{14}H_{24}O$: C, 80.71; H, 11.61. Found: C, 75.17; H, 11.37.

Ozonization of Dihydroparthenene and Oxidation of Ozonides.—A 10.5-g. sample of dihydroparthenene was ozonized in 20 ml. of glacial acetic acid for 1.5 hours (1.45 g. O_3/hour). Since a maximum yield in acid fraction was desired, the ozonide was decomposed with a 5–7% solution of hydrogen peroxide, heating in a water-bath for an hour. The excess hydrogen peroxide was removed by heating for half an hour in the presence of a few mg. of platinum black. The mixture was concentrated in order to remove the excess acetic acid. A neutral and acid fraction were obtained by making the concentrate basic and acidic, respectively, and extracting with ether. The total acid fraction obtained was 2.5 g.; the neutral fraction 4.5 g. Distillation of the acid fraction at 0.1 mm. gave the following fractions: 176–190°, 0.65 g.; 190–210°, 0.5 g.

Anal. Fraction b. p. (0.1 mm.,) 176–190°, calcd. for $C_{15}H_{26}O_3$: C, 70.82; H, 10.30; for $C_{14}H_{24}O_4$: C, 65.60; H, 9.44. Found: C, 66.51; H, 9.70.

Oxidation of Acid Fractions with Sodium Hypobromite.—Fraction b. p. (0.1 mm.) 176–190° was treated with

Resin Acids. III. The Isolation of Dextropimaric Acid and a New Pimaric-type[1] Acid, Isodextropimaric Acid

BY GEORGE C. HARRIS AND THOMAS F. SANDERSON

The history of the discovery and isolation of dextropimaric[2] acid parallels that of levopimaric[2] acid by virtue of one property common to both acids, namely, the insolubility of their crystalline sodium salts. In other physical and chemical properties, they are significantly different. Dextropimaric acid is not susceptible to oxidation by air or isomerization by heat or dilute mineral acid, whereas levopimaric acid is relatively sensitive to both changes.

Previous methods of isolation of dextropimaric acid depended on fractional crystallization as its insoluble sodium salt from mixtures of resin acids such as "galipot"[3] or on recrystallization after oxidation of the more susceptible acids.[4] We have obtained a fraction containing dextropimaric acid and related acids by removal of the two-double-bond abietic-type acids by reaction with maleic anhydride after acid isomerization. The unreacted acids were separated from the maleic anhydride adduct by precipitation from aqueous alkaline solution by adjustment of the *p*H to 6.2.[5] Ultraviolet absorption spectra showed the absence of two-double-bond abietic-type acids in this fraction.

Further fractionation of this mixture has not only given relatively large amounts of dextropimaric acid but also yielded a new pimaric-type acid. When this resin acid fraction was dissolved in acetone and treated with butanolamine, an insoluble salt was obtained and recrystallized to constant rotation $[\alpha]^{20}D$ 0°. When the salt was decomposed with mineral acid, the resin acid was obtained which was crystallized first from alcohol and water as thin plates and finally as needles after standing in the mother liquor; $[\alpha]^{24}D$ 0°; m. p. 162–164°; neutral equivalent 302. The yield was 8% of the total oleoresin acids of *Pinus palustris*. The physical constants indicated a new resin acid. The isolation of formaldehyde as its "dimedon" derivative, m. p. 190–191°, on ozonolysis at −60° and of pimanthrene as its trinitrobenzolate,[6] m. p. 158–160°, on dehydrogenation with palladium–carbon catalyst at 330° proved it to be a pimaric-type acid. The homogeneity of the acid was proved by the preparation and purification of the methyl ester, m. p. 61.5–62°, and the butanolamine salt, $[\alpha]^{24}D$ 0°, and the regeneration of the acid with the same physical constants. The ultraviolet absorption spectrum, like that of dextropimaric acid, showed no maximum, indicating the absence of a conjugated double bond system.[7] This new pimaric-type acid has been termed isodextropimaric acid.

Dextropimaric acid was isolated from the acids regenerated from the residual salts, after that of isodextropimaric acid was separated, by crystallization first from acetone and then from glacial acetic acid in 4% yield with rotation, $[\alpha]^{24}D$ + 79°, m. p. 213–215°. The isolation of dextro-

(1) We wish to designate by this term that type of resin acid which yields pimanthrene (1,7-dimethylphenanthrene) upon complete dehydrogenation, and that has the gem configuration of methyl and vinyl groups at C-7. Evidence for this will be shown in a subsequent publication: G. C. Harris and T. F. Sanderson, Resin Acids. IV. THIS JOURNAL, **70**, 2081 (1948). The abietic-type acids are those that yield retene (1-methyl-7-isopropylphenanthrene) upon complete dehydrogenation and have an isopropyl or isopropylidene group at C-7.

(2) These words have purposely been written as one word since the compounds are not stereoisomers as the prefixes *levo-* and *dextro-* would imply.

pimaric acid of high purity from this source supports the supposition that two-double-bond pimaric-type acids were not altered by the action of mineral acid in boiling benzene, the conditions used in the removal of the two-double-bond abietic-type acids.

The separation of both dextropimaric and isodextropimaric acid from wood or gum rosin was possible after observation was made of their very high volatility. It was found that in the course of the fractional distillation of rosin, these acids distilled with the more volatile constituents, the neutral bodies, at 136–200° with 1.0 mm. pressure. The total acids were separated by an alkaline extraction to obtain a mixture of resin and non-resin acids from which the isodextropimaric acid was separated as the insoluble butanolamine salt, and the dextropimaric acid crystallized as in the foregoing mixture of oleoresin acids in about 4 and 2% yield, respectively.

Experimental[8]

Isolation of Resin Acids from Oleoresin.—The procedure for the isolation of the resin acids from oleoresin was described in a previous publication.[9] It is carried out in the same manner with the exception that the temperature can be raised above 50° and dilute hydrochloric acid, *ca.* 10%, can be used in place of boric acid solution.

Separation of the Two-Double Bond Abietic-Type Acids.—A solution of 200 g. of oleoresin acids and 200 g. of maleic anhydride in one liter of dry benzene was saturated with dry hydrogen chloride and refluxed for forty-eight hours. At the end of this time, the benzene was steam distilled and the residue washed twice with hot water to remove the excess maleic anhydride. It was dissolved in a concentrated solution of 67 g. of sodium hydroxide, and, after complete solution, diluted to 6 liters. This solution was titrated to a *p*H of 6.2 with dilute hydrochloric acid and the precipitated resin acids were filtered, dissolved in ether, the ether solution washed free of acid, dried over sodium sulfate, and the ether evaporated. To assure the complete removal of two-double-bond abietic-type acids, the reaction with maleic anhydride was repeated to obtain 48 g. (24% yield) of maleic anhydride–unreactive acids with neutral equivalent of 304. An ultraviolet absorption curve showed the absence of these abietic-type acids.

Isolation of Isodextropimaric Acid.—The resin acids (48 g.) were dissolved in 96 g. of acetone and treated with a solution of 14.7 g. of butanolamine (2-amino-2-methyl-1-propanol, Commercial Solvents, Inc.) in 14.7 g. of acetone. A very vigorous reaction resulted with the simultaneous precipitation of the crystalline salts. In subsequent experiments, methyl acetate was used as the precipitating solvent. The salts were filtered and recrystallized three times from large volumes of methyl acetate to the constant rotation, $[\alpha]^{24}D$ 0°.[10,11] A few drops of amine were added after the salts were dissolved and the solution concentrated to compensate for that lost by evaporation. This was found necessary for complete recovery.

The salts were then suspended in ether and decomposed by shaking with 10% hydrochloric acid. To assure complete decomposition, two fresh portions of acid were used after the salts were in solution. The ether solution containing the resin acid was washed free of mineral acid with water, dried over sodium sulfate, and the ether evaporated. The residue was dissolved in acetone and crystallized from the hot solution by the addition of water to incipient turbidity, first as thin platelets and then, on long standing in the solution, as shiny needles, with rotation $[\alpha]^{24}D$ 0°, melting point 162–164°, and neutral equivalent 302 (theory 302). The yield was 8% (16.0 g.) based on the total oleoresin acids.

Anal. Calcd. for $C_{20}H_{30}O_2$: C, 79.37; H, 10.00. Found: C, 79.48, 79.40; H, 9.90, 9.95.

Preparation of the Methyl Ester of Isodextropimaric Acid.—A 20-g. sample of isodextropimaric acid was dissolved in 100 cc. of ether and the solution treated with an excess of an ether solution of diazomethane. The isolation was carried out in the usual manner to obtain an excellent yield (20 g.) of the ester melting at 61.5–62°.

Anal. Calcd. for $C_{21}H_{32}O_2$: C, 79.69; H, 10.19. Found: C, 79.70, 79.65; H, 10.27, 10.30.

The purity and homogeneity of the acid was established in the following manner. Material with rotation $[\alpha]^{24}D$ 0° and melting point 162–164° was used to prepare the butanolamine salt which was recrystallized three times to constant rotation $[\alpha]^{24}D$ 0°. The resin acid was regenerated in the usual manner with no change in rotation, $[\alpha]^{24}D$ 0°, or melting point, 162–164°. The methyl ester prepared as above was recrystallized to the constant melting point of 61.5–62°. Saponification in alcoholic alkali with subsequent acidification with mineral acid resulted in the isolation of isodextropimaric acid with rotation $[\alpha]^{24}D$ 0° and melting point 162–164°.

Ozonization of Isodextropimaric Acid; Isolation of Formaldehyde.—A 1.0-g. sample of pure isodextropimaric acid, rotation $[\alpha]^{24}D$ 0°, was dissolved in 50 cc. of dry ethyl chloride and treated with 3–5% ozone at −60° for two hours. The solvent was evaporated over water at room temperature and the ozonide decomposed in boiling water in an apparatus so arranged that the escaping gases were passed through an aqueous alcohol solution of "dimedon" (dimethyldihydroresorcinol). Upon standing, needles of the dimedon derivative of formaldehyde precipitated, m. p. 190–191°. A mixed melting point with an authentic sample showed no depression.

Dehydrogenation of Isodextropimaric Acid.—A 1.0-g. sample was mixed with 1.0 g. of 5% palladium–carbon catalyst and heated at 300–330° for four hours using carbon dioxide gas to sweep the gaseous products out of the reaction flask. After cooling, the catalyst was filtered from an ether solution of the reaction product and the ether evaporated. The trinitrobenzolate of pimanthrene, melting point 158–160°, crystallized upon heating the residue with a saturated alcoholic solution of trinitrobenzene.

Isolation of Dextropimaric Acid.—The acetone solution of the residual salts was evaporated to dryness, the residue dissolved in ether, and washed with dilute (10%) aqueous hydrochloric acid to decompose the salts. The ether solution containing the resin acids was washed free of mineral acid and water, dried over sodium sulfate, and the ether evaporated to obtain 32 g. of resin acids. The latter were dissolved in 30 cc. of acetone and cooled to

(8) All melting points are corrected.

(9) G. C. Harris and T. F. Sanderson, THIS JOURNAL, **70**, 338 (1948).

(10) All rotations are of 1% solutions in absolute ethanol.

(11) Same rotation, $[\alpha]^{24}D$ 0°, in chloroform and dry benzene.

−20° to obtain crystals of dextropimaric acid. Recrystallization from glacial acetic acid gave 8.0 g. (4% yield) of pure acid with rotation $[\alpha]^{24}D$ +79°, and melting point 217–219°.

Isolation of the Pimaric Acids from Wood or Gum Rosins.—A 1000-g. charge of wood or gum rosin was distilled fractionally at 1.0-mm. pressure in a 10-plate column and the fraction, 120 g., boiling between 136 and 200° was taken. It was found to be composed of nonacidic material and of resin and nonresin acids. The total acids were separated from the neutral bodies by extraction with a 2% aqueous alkaline solution from an ether solution of the mixture. The alkaline solution was acidified, the resin acids dissolved in ether, and the ether solution washed free of mineral acid, dried, and the ether evaporated.

The total acids (65 g.) were dissolved in 200 cc. of acetone and treated with 20 g. of butanolamine in 20 g. of acetone. The pure salt of isodextropimaric acid, $[\alpha]^{24}D$ 0°, was isolated and decomposed with mineral acid as before to obtain 39 g. (*ca.* 4%) of isodextropimaric acid. The acetone solution of the residual salts was evaporated, the salts decomposed, and dextropimaric acid crystallized as above to obtain 20 g. (2%) of the pure acid with rotation $[\alpha]^{24}D$ +79°, and melting point 217–219°.

Summary

1. A new, pimaric-type resin acid, termed isodextropimaric acid, has been isolated from the oleoresin of *Pinus palustris* and from wood or gum rosin.

2. Dextropimaric acid has also been isolated from these sources.

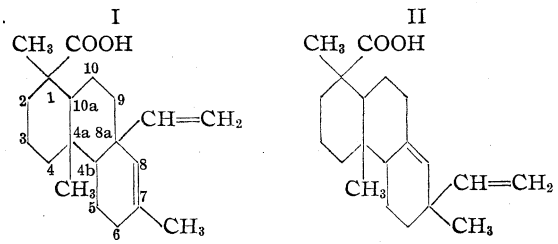
Resin Acids. IV. The Position of the Ring Double Bond in Dextropimaric[1] Acid and the Structure of Isodextropimaric[1] Acid

BY GEORGE C. HARRIS AND THOMAS F. SANDERSON

Ruzicka and Sternbach[2] have recently advanced Formula I and suggested Formula II as possible structures for dextropimaric acid.



Their argument against the latter was the fact that upon dehydrogenation of tetrahydrodextropimaric acid only pimanthrene (1,7-dimethylphenanthrene and no 1-methyl-7-ethylphenanthrene) was obtained. However, Formula II cannot be eliminated on this basis because the latter hydrocarbon may have been formed in such low yield as to escape detection. Experience shows that the isolation of pure hydrocarbons even as their solid derivatives from dehydrogenation mixtures is difficult, and especially so, if they are only minor constituents.

Formula II was proposed and preferred by Fleck and Palkin[3] in explaining the structure of a lactone obtained from dextropimaric acid treated with sulfuric acid at −20 to −30°. Lactonization at 4b position was suggested by the comparable stability of this lactone to that of hydroxytetrahydroabietic acid. If Formula I is assumed for dextropimaric acid, the necessary shift of the double bond to the bridgehead position, 4b,8a, is not possible; whereas if Formula II is assumed, the shift can be brought about by mineral acid so that lactonization of the carboxyl group can occur at C-4b.

Ruzicka and co-workers[4] have shown on the basis of experimental results that the vinyl group must be on a tertiary carbon atom, either 7 or 8a, however, not 4b, and still be compatible with the isoprene rule. Since the endocyclic double bond can be at the 7,8 or 8,8a position, the vinyl group must be on C-8a carbon atom for the former and on C-7 carbon atom for the latter position. The experimental evidence described herein will show the vinyl group to be at C-7 carbon atom, and, hence, the endocyclic double bond at 8,8a position.

Dextropimaric acid, I or II, $[\alpha]^{24}D$ + 75°, melting point 217–219°,[5] was hydrogenated selectively to the dihydro stage in absolute ethanol with 5% palladium–carbon catalyst. The reaction proceeded smoothly to the absorption of 1.0 mole of hydrogen yielding the insoluble dihydro acid, III or VII, in excellent yield.[6] The dihydro acid was ozonized in dilute carbon tetrachloride solution at −20° and the ozonide decomposed in boiling water in the presence of zinc powder to obtain a ketoaldehyde, IV or VIII. If the endocyclic double bond in dextropimaric acid is in 7,8 position, Formula I, a methyl ketone, IV, would be obtained and detected by the liberation of iodo-

(1) These words have purposely been written as one word since the compounds are not stereoisomeric with levopimaric acid as the prefixes *levo-*, *dextro-*, and *isodextro-* would imply.

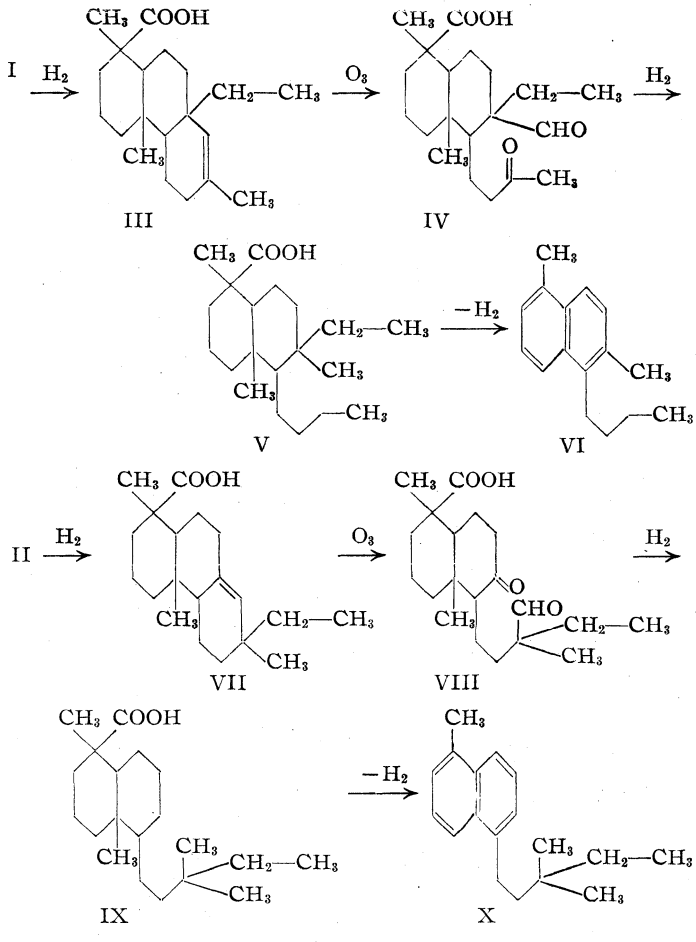
(6) It was also found (reference below) that the crystals formed from rosin hydrogenated in the presence of platinum oxide were those of the dihydrodextropimaric acid. This afforded an abundant source of the material. T. Hasselstrom and B. L. Hampton, *ibid.*, **61**, 967 (1939).

form from a sodium hypoiodite solution of the substance. A negative iodoform test indicated that the endocyclic double bond is at 8,8a position, Formula II, hence a ketoaldehyde of structure VIII.



The latter compound, VIII, was reduced to the hydrocarbon by the Wolff–Kishner method. The non-crystalline product was dehydrogenated, the hydrocarbon isolated, and its trinitrobenzolate prepared and recrystallized to a constant melting point, 113–116°. Analyses for carbon, hydrogen, and nitrogen content and molecular weight determinations, obtained ebullioscopically with acetone as solvent, of the solid derivative showed it to be conclusively the trinitrobenzolate of a C_{18} hydrocarbon. The derivative was decomposed over activated alumina and the hydrocarbon isolated. Carbon and hydrogen analyses and molecular weight determination showed it to be a C_{18} hydrocarbon. Attempts to oxidize the hydrocarbon to the 1,5-dicarboxylic acid with potassium ferricyanide were unsuccessful, possibly because of the long alkyl chain at the 5 position. The ultraviolet absorption curve[7] of the isolated hydrocarbon, Fig. 1, Curve 2, demonstrates absorption that is characteristic of dialkylated naphthalenes, with intense band at 228 mμ, for example, 1,5-dimethylnaphthalene, Fig. 1, Curve 1 (see below). The height of the maxima of the C_{18} hydrocarbon is not so intense as those of the 1,5-dimethylnaphthalene because of the larger molecular weight of the former.

If the vinyl group is on C-8a carbon atom, Formula I, dehydrogenation of V should give a C_{16} hydrocarbon, VI; whereas, if the vinyl group were on C-7 carbon atom, Formula II, dehydrogenation of IX would give a C_{18} hydrocarbon. Since a C_{18} hydrocarbon was isolated, the vinyl group is placed at 7 position and the endocyclic double bond at 8,8a position. Hence Formula II is concluded to be that for dextropimaric acid.

The same series of experiments was carried out with pure isodextropimaric acid, $[\alpha]^{24}D$ 0°, and melting point 162–164°,[5] to obtain the trinitrobenzolate of the same hydrocarbon, X, with melting point 113–116°. A mixed melting point with the corresponding derivative from dextropimaric acid showed no depression, 113–116°. The identity of the two substances was *further* supported by the identity of their X-ray diffraction patterns and identity of their ultraviolet absorption spectra (Fig. 1, Curve 2).

From this, it was concluded that the two acids, isodextropimaric and dextropimaric acid, are dissimilar only with regard to the difference in the configuration of the methyl and vinyl groups about the asymmetric C-7 carbon atom. If this is the case, a similar decomposition product, in which the asymmetry at C-7 carbon atom was destroyed, should be obtained from each acid. Formula IX represents such a compound; how-

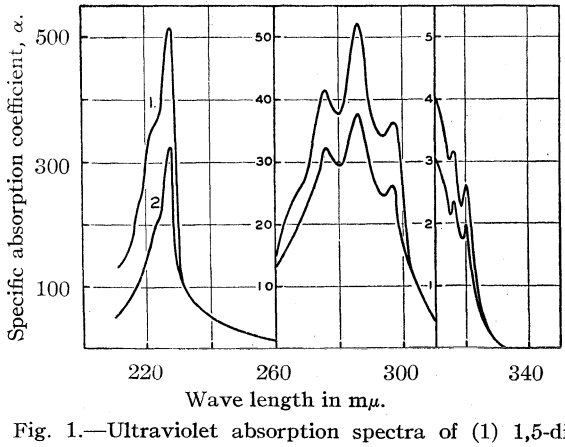


Fig. 1.—Ultraviolet absorption spectra of (1) 1,5-dimethylnaphthalene, and (2) the C_{18} hydrocarbon (X) from both dextropimaric and isodextropimaric acids.

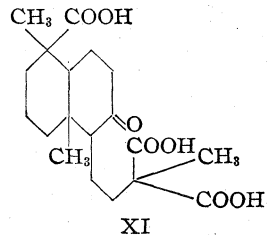
(7) The ultraviolet absorption data were determined by Dr. Evelyn V. Cook of this Laboratory.

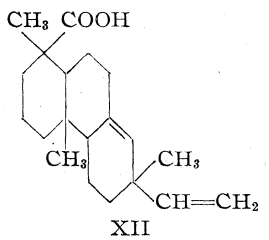
ever, it was not possible to crystallize either it or an acid derivative thereof.

Another approach for eliminating the asymmetry at 7 position is to ozonize the intact acids to obtain a tricarboxylic acid of Formula XI.



XI

This scheme was followed successfully to obtain the crystalline 2,4-dinitrophenylhydrazones and semicarbazones of triacids XI, which were proved to be identical by comparison of X-ray diffraction patterns and mixed melting points that showed no depression as compared with those of the individual derivatives. Therefore, the indication is that isodextropimaric and dextropimaric acids are dissimilar only with respect to the configuration of the methyl and vinyl groups at C-7 carbon atom. If Formula II is assumed for dextropimaric acid, Formula XII is that for isodextropimaric acid.



XII

Further evidence for Formula II as that for dextropimaric acid was obtained by the partial dehydrogenation of the pure acid.

The dehydrogenation was carried out in the usual manner at 300–330° with palladium–carbon catalyst, but the products were isolated by fractionation through a column of silica gel with hexane as solvent. The first product of dehydrogenation was a trisubstituted naphthalene, a C_{18} hydrocarbon (XIII). Its most intense band in the near ultraviolet (Fig. 2) is at 232 mμ, characteristic of trialkylated naphthalenes,[8] a shift of 4 millimicrons from that of dialkylated naphthalenes (Fig. 1). An intense band at 325 mμ, absent in the spectrum of the dialkylated naphthalenes, is also characteristic of the trisubstituted naphthalenes. If Formula I is that for dextropimaric acid, a C_{16} hydrocarbon would be isolated with only one substituent, a methyl group, at C-7. This structure would not be expected to be stable so that further dehydrogenation would give pimanthrene (XV) at once.

The C_{18} hydrocarbon was further dehydrogenated under the same conditions to obtain pimanthrene (XV).

(8) The characteristic absorption maxima of mono- and polyalkylated naphthalenes will be the subject of a future publication.

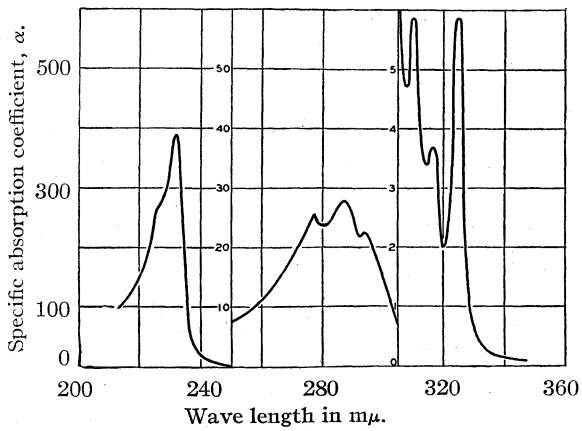


Fig. 2.—Ultraviolet absorption spectrum of C_{18} hydrocarbon (XIII and/or XIV).

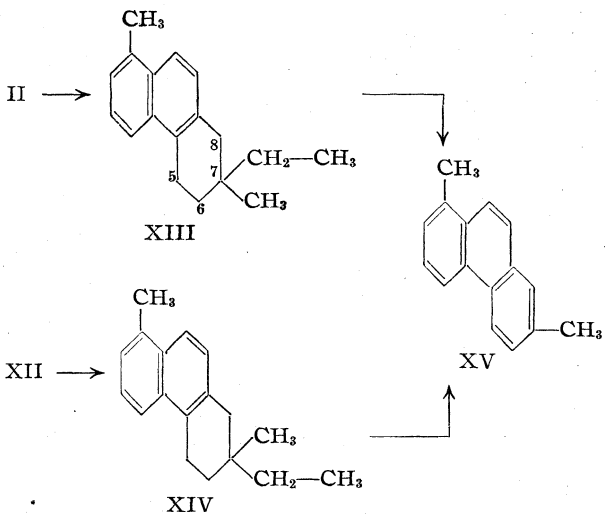

Isodextropimaric acid (XII) was treated in a similar manner to obtain the C_{18} hydrocarbon, XIV, whose trinitrobenzolate had the same melting point as that of hydrocarbon XIII, m. p. 122–123°. Further dehydrogenation of hydrocarbon XIV also gave pimanthrene in good yield. No difference in spatial configuration of the two hydrocarbons (XIII and XIV) was detected by a mixed melting point of their trinitrobenzolates, optical rotation of the pure substances, or X-ray diffraction patterns of the trinitrobenzolates. It, therefore, can be assumed that racemization took place during the dehydrogenation so that hydrocarbons XIII and XIV are identical. Racemization during partial dehydrogenation is further evidence for the asymmetry at C-7. The identity of the hydrocarbon derivatives was substantiated by identical X-ray diffraction patterns. The synthesis of the C_{18} hydrocarbon is now in progress.

The known and new derivatives of the two acids and their melting points are:

		Melting point, °C.
1	Methyl isodextropimarate	61–62
2	Methyl dextropimarate	68–69
3	Dihydroisodextropimaric acid	173–175
4	Dihydrodextropimaric acid	243–245
5	Lactone of 3	109–110
6	Lactone of 4	98–99
7	Methyl ester of 3	75–76[a]
8	Methyl ester of 4	78–79

[a] Mixed melting point with 8 shows a marked depression.

Experimental[9]

Hydrogenation of Dextropimaric Acid (II).—A 5.0-g. sample of dextropimaric acid, $[\alpha]^{24}D$ +75°,[10] melting point 217–219°, was dissolved in 50 cc. of absolute ethanol and the solution agitated in a hydrogen absorption apparatus in the presence of 1.0 g. of 5% palladium–carbon catalyst until 408 cc. (1.0 mole) of hydrogen was absorbed. The reaction was carried out at room temperature and atmospheric pressure and stopped completely after the absorption of 1.0 mole of hydrogen. The catalyst was removed by filtration, and the dihydro acid watered out of the warm alcoholic solution to obtain 4.9 g. of acid (98% yield) with rotation, $[\alpha]^{24}D$ +19°, and melting point 243–245°.

Hydrogenation of Isodextropimaric Acid (XII).—The reaction was carried out in the same manner to obtain the dihydroisodextropimaric acid in the same yield with rotation, $[\alpha]^{24}D$ 0°, and melting point 173–175°.

Anal. Calcd. for $C_{20}H_{32}O_2$: C, 78.88; H, 10.54. Found: C, 78.91, 78.95; H, 10.66, 10.60. Hydrogen absorption calcd. 0.66; found, 0.66.

Ozonization of Dihydrodextropimaric Acid (VII).—A 1.0-g. sample of dihydrodextropimaric acid, $[\alpha]^{24}D$ 0°, was dissolved in 50 cc. of boiling carbon tetrachloride and the solution allowed to cool to room temperature and eventually to −20° in an acetone–Dry Ice-bath. The ozonolysis reaction was carried out for two hours with an oxygen throughput of 20–25 liters per hour using a generator issuing 3–5% ozone. At the end of this time, the solvent was evaporated in vacuum at room temperature, the residue dissolved in a minimum amount of ether, water added, and the suspension boiled for four hours in the presence of 1.0 g. of powdered zinc. The reaction product was isolated in ether, the ether solution washed, dried, and the ether evaporated to obtain 0.80 g. (77% yield) of the ketoaldehyde, VIII, with neutral equivalent 330 (theory 336). It was not possible to crystallize the ketoaldehyde or a derivative thereof.

Anal. Calcd. for $C_{20}H_{32}O_4$: C, 71.38; H, 9.60. Found: C, 70.40, 70.49; H, 9.41, 9.38.

The product gave a negative iodoform test.

Ozonization of Dihydroisodextropimaric Acid.—The results with this acid were almost identical with those of dihydrodextropimaric acid. A non-crystalline substance was obtained giving approximately the same analytical data and a negative iodoform test.

Anal. Calcd. for $C_{20}H_{32}O_4$: C, 71.38; H, 9.60. Found: C, 70.20, 70.43; H, 9.45, 9.50.

Wolff–Kishner Reduction of the Ketoaldehyde, VIII, and of the Corresponding Product from Isodextropimaric Acid.—The disemicarbazones were prepared by dissolving 2 g. of the ketoaldehyde in an alcoholic solution of semicarbazide acetate, adding a few drops of pyridine and allowing the solution to stand for two days. The non-crystallizable derivative was then extracted in ether after the reaction solution was poured into a large volume of water. The ether was evaporated, the residue taken up in 35 cc. of alcohol containing 3.0 g. of sodium metal, and the solution heated at 200° for eight hours under 1800 p. s. i. of nitrogen pressure.

(9) All melting points are corrected.

(10) All rotations are of 1% solutions in absolute ethanol.

The solution was poured into water and acidified with dilute mineral acid, and the organic material was dissolved in ether. The ether solution was washed free of mineral acid, dried, and the ether evaporated. The crude product, IX, 0.9 g. (50% yield) was dehydrogenated.

The corresponding product from isodextropimaric acid was treated in a similar manner to obtain a crude product in the same yield.

Dehydrogenation of the Crude Product IX.—A 2.0-g. sample of the powdered material was mixed intimately with 2.0 g. of 5% palladium–carbon catalyst and heated at 300–325° for four hours under a stream of carbon dioxide gas. At the end of this time, the dehydrogenated product was dissolved in ether and the catalyst filtered. The residue was dissolved in 1 cc. of 95% ethanol and treated with 10 cc. of a saturated solution of trinitrobenzene. Upon concentrating to 5-cc. volume and cooling, light-yellow needles of the trinitrobenzolate of hydrocarbon X precipitated in 35–40% yield. The derivative was recrystallized to a constant melting point of 113–116°.

Anal. Calcd. for $C_{18}H_{24}$ (X) + $C_6H_3N_3O_6$, $C_{24}H_{27}N_3O_6$: C, 63.56; H, 6.00; N, 9.27. Found: C, 63.76, 63.43; H, 5.75, 5.67; N, 9.14, 9.20. Molecular weight Calcd.: 227. Found (ebullioscopic method): 225, 229. Calcd. for $C_{16}H_{20}$ (VI) + $C_6H_3N_3O_6$, $C_{22}H_{23}N_3O_6$: C, 62.11; H, 5.44; N, 9.88. Molecular weight calcd.: 213.

Dehydrogenation of Compound, Corresponding to IX, from Isodextropimaric Acid.—This reaction was carried out in the same manner to obtain a trinitrobenzolate of the hydrocarbon that melted at 113–116°. The identity of the two substances was shown by a comparison of their X-ray diffraction patterns, ultraviolet absorption curves, and a mixed melting point that showed no depression.

Anal. Calcd. for $C_{18}H_{24}$ + $C_6H_3N_3O_6$ or $C_{24}H_{27}N_3O_6$: C, 63.56; H, 6.00; N, 9.27; mol. wt., 227. Found: C, 63.60, 63.40; H, 5.85, 5.65; N, 9.22, 9.17; mol. wt., 227, 230.

Isolation of Hydrocarbon X.—The trinitrobenzolate derivative (2.0 g.) was dissolved in 5 cc. of benzene and placed on a column of alumina (30 × 320 mm.). Upon elution with benzene, the hydrocarbon was washed through the column and the trinitrobenzene remained adsorbed. The benzene was evaporated under vacuum to obtain 1.0 g. (95% yield) of a fluorescent hydrocarbon that could not be made to crystallize.

Anal. Calcd. for $C_{18}H_{24}$: C, 89.92; H, 10.08; mol. wt., 240. Found: C, 89.84, 89.87; H, 10.10, 10.10; mol. wt., 237, 242.

Complete Ozonization of Dextropimaric Acid, II.—A 1.0-g. sample was dissolved in 30 cc. of ethyl chloride and the solution cooled to −60° in an acetone–Dry Ice-bath. The reaction was carried out for two hours with an oxygen throughput of 20–25 liters per hour using a generator issuing 3–5% ozone. At the end of this time, the solvent was evaporated in vacuum, the residue dissolved in a minimum amount of ether, water added, and the suspension boiled for four hours in the presence of 1.0 g. of powdered zinc. Upon isolation in ether, the decomposed ozonide was dissolved in 5% alkali, and 2% hydrogen peroxide solution was added to oxidize the aldehyde to carboxyl groups, XI.

The aqueous solution was acidified and the precipitate dissolved in ether. The ether solution was extracted with bicarbonate solution and the product isolated in ether upon careful acidification of the bicarbonate solution. It could not be made to crystallize, so the data were obtained on the powdered material.

Anal. Calcd. for $C_{19}H_{28}O_7$ (XI): C, 61.82; H, 7.89. Found: C, 62.29, 62.89; H, 8.28, 8.00. Molecular weight, calcd.: 368. Found: 373 (ebullioscopically).

Its 2,4-dinitrophenylhydrazone was prepared in the usual manner, melting point 185–188°. The semicarbazone was also prepared, m. p. 223–225°, and analyzed for nitrogen content. Calcd., 9.9; found, 10.35, 10.12.

Complete Ozonization of Isodextropimaric Acid, XII.—The reaction was carried out in the same manner to obtain

a product of the same nature. Its dinitrophenylhydrazone also melted at 185–188° and its semicarbazone at 223–225°. The identity of the two derivatives with the corresponding ones from dextropimaric acid was shown by mixed melting points that showed no depression and also by the fact that their X-ray diffraction patterns were identical.

Dehydrogenation of Dextropimaric and Isodextropimaric Acids.—A 2.0-g. sample of the pure acid was mixed intimately with 1.0 g. of 5% palladium–carbon catalyst and heated at 300–330° for four hours. The catalyst was filtered from an ether solution of the mixture of hydrocarbons.

Isolation of the Trinitrobenzolate of C_{18} Hydrocarbon (XIII or XIV).—The dehydrogenation product (1.4 g.) was dissolved in 10 cc. of hexane and transferred to a column of silica gel. The chromatogram was developed with hexane and followed with ultraviolet light. The fraction (0.6 g.) taken was that which preceded the blue fluorescence due to pimanthrene.

The same trinitrobenzolate, m. p. 122–123°, was isolated from the corresponding fraction obtained from each of the two resin acids as shown by identical X-ray diffraction patterns and no depression in a mixed melting point. Once their identity was established, they were mixed and analytical data obtained.

Anal. Calcd. for $C_{18}H_{22}$ + $C_6H_3N_3O_6$ (T. N. B.), $C_{24}H_{25}N_3O_6$: C, 63.56; H, 6.00; N, 9.27. Found: C, 64.16, 64.10; H, 5.75, 5.75; N, 9.18, 9.34.

Isolation of Hydrocarbon XIII or XIV.—The procedure is the same as that described for the isolation of hydrocarbon X. The first experiments were done with the pure trinitrobenzolates of the hydrocarbons obtained from each acid. Each was found to have a rotation of 0° in absolute ethanol or benzene.

Anal. Calcd. for $C_{18}H_{22}$: C, 90.65; H, 9.35. Found: C, 90.23, 90.64; H, 9.30, 9.35.

Dehydrogenation of Hydrocarbon XIII or XIV.—The same procedure was used as in the section on the dehydrogenation of the free acids. The trinitrobenzolate of pimanthrene, m. p. 158–160°, was isolated in good yield.

Summary

The positions of the vinyl group and of the endocyclic double bond of dextropimaric acid have been established, hence the structure of the acid completed.

The structure of isodextropimaric acid has been determined and the stereoisomerism of the two acids demonstrated.

Streptomyces Antibiotics. XVI. The Structures of bis-Desoxystreptose, Dihydrodesoxystreptose and Tetraacetyl-bis-desoxystreptobiosamine

BY NORMAN G. BRINK, FREDERICK A. KUEHL, JR., EDWIN H. FLYNN AND KARL FOLKERS

Treatment of ethyl tetraacetylthiostreptobiosaminide diethyl mercaptal,[1,2] I, with Raney nickel catalyst gave tetraacetyl-bis-desoxystreptobiosamine, II, and tetraacetyldesoxystreptobiosamine, III. Acid hydrolysis of tetraacetyl-bis-desoxystreptobiosamine yielded N-methyl-L-glucosamine,[3] IV, and bis-desoxystreptose, a 3,4-dihydroxy-2,3-dimethyltetrahydrofuran,[4] V. Details of these investigations and an account of the analogous degradation of pentaacetyldihydrodesoxystreptobiosamine[5,6] to dihydrodesoxystreptose are described herein.

When a solution of ethyl tetraacetylthiostreptobiosaminide diethyl mercaptal in 70% ethanol was refluxed in the presence of Raney nickel catalyst (not freshly prepared) and the products of the reaction were chromatographed on alumina, two compounds were isolated. The first crystalline fractions from the chromatogram consisted of tetraacetyl-bis-desoxystreptobiosamine, m. p. 159–160°, $[\alpha]^{25}D$ − 85°. The second product melted at 166–167°, $[\alpha]^{25}D$ − 81°, and was isolated from later fractions. It differed by the presence of one additional oxygen atom, and was designated tetraacetyldesoxystreptobiosamine. A mixture of the two compounds did not give a mixed melting-point depression, and the close correspondence of their physical properties added to the difficulties of separation. The bis-desoxy derivative was unchanged by acetylation treatment, but the desoxy derivative on acetylation gave a pentaacetyl derivative, VI, which melted at 111–112°. The pentaacetyldesoxystreptobiosamine was considerably more soluble than either of the tetraacetates. This observation was of value for the purification of tetraacetyl-bis-desoxystreptobiosamine, because after acetylation it could be separated readily from pentaacetyldesoxystreptobiosamine by recrystallization. Crude tetraacetyldesoxystreptobiosamine was purified by repeated chromatography.

The conversion of tetraacetyldesoxystreptobiosamine to pentaacetyldesoxystreptobiosamine indicated that the additional oxygen atom in the desoxy compound was present as a hydroxyl group, and it seemed likely that this group had been introduced by hydrolysis which competed with the hydrogenolysis during the treatment with Raney nickel catalyst. In support of this interpretation was the observation that when the reaction was carried out with Raney nickel catalyst which had been prepared immediately before use,

R = tetraacetyl-N-methyl-L-glucosoaminido

the yield of the bis-desoxy derivative was greatly increased and no appreciable amount of the desoxy derivative could be isolated. Tetraacetyldesoxystreptobiosamine gave a precipitate with 2,4-dinitrophenylhydrazine and reacted with one mole of hydroxylamine, as determined acidimetrically.[7] Treatment of tetraacetyldesoxystreptobiosamine with methanol containing hydrogen chloride, followed by reacetylation, gave crystalline methyl tetraacetyldesoxystreptobiosaminide, VII. These observations establish that the hydroxyl group in tetraacetyldesoxystreptobiosamine is glycosidic, rather than alcoholic, and that this hydroxyl group marks the location of the thioglycosidic ethylmercapto group in the original ethyl thiostreptobiosaminide diethyl mercaptal.

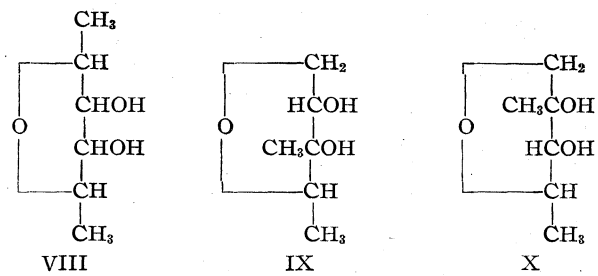
The partial deacetylation of tetraacetyl-bis-desoxystreptobiosamine with methanolic ammonia to N-acetyl-bis-desoxystreptobiosamine has been described.[1] In like manner, N-acetyldesoxystreptobiosamine was prepared from tetraacetyldesoxystreptobiosamine. Kuhn–Roth determinations on both of these N-acetyl derivatives indicated the presence of three C-methyl groups. In each case, the N-acetyl group accounted for one C-methyl group, and another C-methyl group was known to be present in the streptobiosamine skeleton.[5] Hence, an additional C-methyl group had been introduced during the hydrogenolysis reaction.

When the infrared spectrum of a sample of tetraacetyl-bis-desoxystreptobiosamine, which had been purified by reacetylation and recrystallization and carefully dried, was determined at high concentration (*ca.* 50%) in tetrachloroethane solution, a well-defined absorption band at 2.85 μ (–OH region) was observed. Further, in a Zerewitinoff determination, the compound gave one mole of methane. The presence in the bis-desoxy derivative of a free hydroxyl group, resistant to acetylation, was indicated. Tetraacetyl-bis-desoxystreptobiosamine was stable to chromic acid in 90% acetic acid solution. In view of the resistance of this hydroxyl group to acetylation and its stability to chromic acid, it was presumed to be tertiary.

When a solution of pure tetraacetyl-bis-desoxystreptobiosamine in 5% sulfuric acid was refluxed for six hours, and the acid solution then extracted continuously with chloroform, the chloroform extract yielded crystalline bis-desoxystreptose, $C_6H_{12}O_3$. From the sulfuric acid solution after chloroform extraction, N-methyl-L-glucosamine was isolated as the pentaacetyl derivative.

Bis-desoxystreptose melted at 90–91° and was dextrorotatory. Kuhn–Roth determinations showed the presence of two C-methyl groups. No carbonyl group could be detected in the compound. That two of the three oxygen atoms were present as hydroxyl groups was demonstrated by the preparation of a bis-*p*-nitrobenzoate. Bis-desoxystreptose reacted with one mole of periodic acid, from which it followed that the two hydroxyl groups were on adjacent carbon atoms. The periodic acid cleavage product was characterized as a dicarbonyl compound of formula $C_6H_{10}O_3$ by conversion to the crystalline bis-*p*-nitrophenylhydrazone.

Three structures (VIII, IX and X) were to be considered for bis-desoxystreptose. Structure

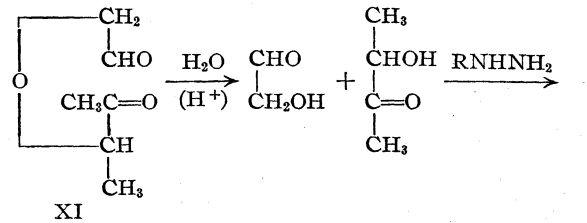


VIII seemed to be unlikely, because it did not contain a tertiary hydroxyl group. In order to decide which of these three structures was correct, the reactions of the periodic acid cleavage product $C_6H_{10}O_3$ were studied.

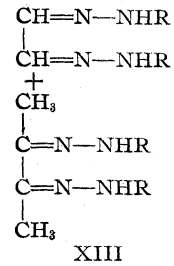
Compounds of structures IX and X on treatment with periodic acid should yield products XI and XII, respectively; and these in turn, being ethers of α-hydroxy carbonyl compounds, should be readily hydrolyzed by acid, as shown. Further, treatment of the acid hydrolysis products with excess hydrazines would be expected to give osazones of biacetyl (XIII) and osazones of pyruvaldehyde (XIV), respectively. A similar degradation of a compound of structure VIII would also

(7) Bryant and Smith, THIS JOURNAL, **57**, 57 (1935).

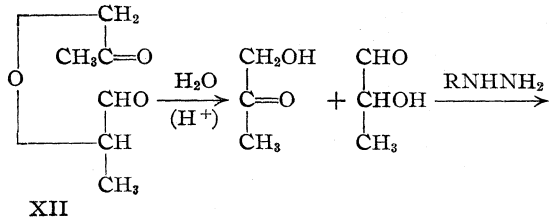
be expected to yield osazones of pyruvaldehyde (XIV).



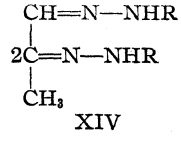
XI



XIII



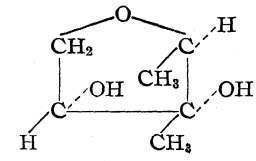
XII



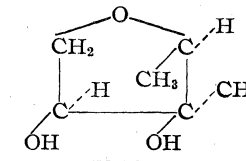
XIV

Bis-desoxystreptose was allowed to react with one mole of periodic acid, the inorganic products were removed, and the solution was warmed briefly on the steam-bath with 50% acetic acid to effect the hydrolysis of the dicarbonyl compound. Portions of the hot solution were then added to solutions of phenylhydrazine, *p*-nitrophenylhydrazine and *p*-bromophenylhydrazine in hot dilute acetic acid. In each case, the corresponding osazone of biacetyl (XIII) was obtained. The products were identified by comparison with authentic specimens and, in the case of the phenyl compound, by oxidation to 5,6-dimethyl-2,3-diphenylosatetrazine.[8] These results show that the structure of bis-desoxystreptose is as represented by formula IX and that the compound is a 3,4-dihydroxy-2,3-dimethyltetrahydrofuran.

The acidity of a dilute boric acid solution was strongly increased by the addition of a slight excess of bis-desoxystreptose. The formation of such an acidic complex with boric acid indicates that the two hydroxyl groups are in the *cis* configuration.[9] The isolation of the phenylosazone of 4-desoxy-L-erythrose from streptobiosamine[10] showed that carbon atom five of the tetrahydrofuran ring of streptose possessed the L-configuration. Bis-desoxystreptose is thus a 3,4-dihydroxy-2,3-dimethyltetrahydrofuran having a configuration XV or XVI.



XV

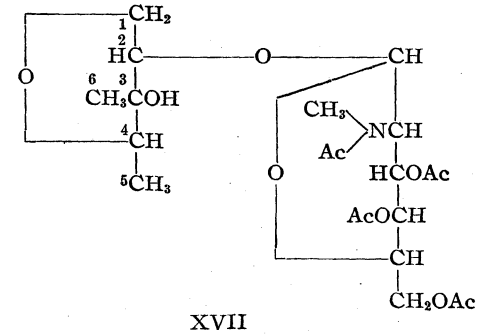


XVI

In tetraacetyl-bis-desoxystreptobiosamine, the presence of a free tertiary hydroxyl group requires that N-methyl-L-glucosamine be attached through the secondary hydroxy group of the bis-desoxystreptose. That the two portions of the disaccharide are linked glycosidically through the aldehydic carbon atom of the methylamino hexose has already been established.[1,2,4]

When N-acetyl-bis-desoxystreptobiosamine was treated with an excess of sodium periodate in aqueous solution, one mole of oxidant was rapidly consumed, the reaction then proceding more slowly. At the time that one mole of periodate had reacted, a potentiometric titration of the reaction solution showed the presence of 0.25 mole of a weak acid, presumably acetic acid formed by partial deacetylation. No formic acid could be detected. In another experiment, N-acetyl-bis-desoxystreptobiosamine was oxidized with exactly one mole of sodium periodate. No formaldehyde could be isolated from the reaction solution. The rapid primary reaction of the disaccharide with one mole of periodate without the formation of either formaldehyde or formic acid is consistent only with a pyranose ring structure for the N-methyl-L-glucosamine moiety.

The structure of tetraacetyl-bis-desoxystreptobiosamine, on the basis of this evidence, is represented by formula XVII.



XVII

Since carbon atom four (structure XVII) has been shown to have the L-configuration,[10] streptose is an L-sugar by definition.

Tetraacetyldesoxystreptobiosamine, on the basis of this evidence, is represented by formula XVIII.[4,11] Since the free hydroxyl group is gly-

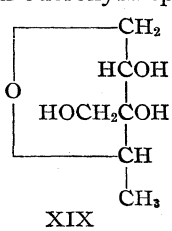
XVIII

cosidic, it must be located either at carbon atom one or four; from the structure of ethyl tetraacetylthiostreptobiosaminide diethyl mercaptal,[11] it is evident that the group is at carbon atom one.

It can be seen that in bis-desoxystreptose the methyl group adjacent to the tertiary hydroxyl group must have been the one formed during the hydrogenolysis reaction. However, it was felt that a direct proof of this, and consequently of the position of the original streptomycin aldehyde group, would be of interest. For this reason, the hydrolysis of pentaacetyldihydrodesoxystreptobiosamine[5,6] was studied.

Pentaacetyldihydrodesoxystreptobiosamine was hydrolyzed with acid under conditions used for the cleavage of tetraacetyl-bis-desoxystreptobiosamine, but in this case the products could not be separated by chloroform extraction. Treatment of the neutralized acid hydrolysate with ion-exchange resins served, however, to remove N-methyl-L-glucosamine, and crystalline dihydrodesoxystreptose, $C_6H_{12}O_4$, was isolated from the eluates. Dihydrodesoxystreptose consumed two moles of periodate with the liberation of one equivalent of an acid. One equivalent of formaldehyde was also formed upon periodate cleavage as demonstrated by the isolation of the dimedone derivative. These results are consistent with the structure XIX of dihydrodesoxystreptose, and support



XIX

the previously assigned position of the linkage of streptidine to streptobiosamine.[11]

Experimental

Tetraacetyl-bis-desoxystreptobiosamine (II) and Tetraacetyldesoxystreptobiosamine (III).—A solution of 10 g. of ethyl thiostreptobiosaminide diethyl mercaptal hydrochloride in 20 ml. of pyridine was cooled in an ice-bath, and 15 ml. of acetic anhydride was added. The mixture was allowed to warm slowly to room temperature and stand overnight. Water was added to decompose the excess acetic anhydride, and the solution was concentrated *in vacuo* to a sirup which was dissolved in chloroform. The chloroform solution was washed with water, 5% sulfuric acid, and twice with water. The chloroform was removed under reduced pressure and 12.6 g. (95%) of crude tetraacetate remained.

A solution of the tetraacetate in 1.4 l. of 70% ethanol was refluxed for one and one-half hours in the presence of 350 g. of Raney nickel catalyst which had been prepared some weeks previously. The nickel was removed by centrifugation and washed repeatedly with portions of hot methanol. The combined supernatant and washings were concentrated under reduced pressure to a volume of about 150 ml. The organic material was removed by extraction with chloroform. The chloroform was distilled *in vacuo* giving 9.3 g. of oily residue. This oil was dissolved in 265 ml. of a 78% benzene–22% petroleum ether mixture, and the solution was poured on a column which was prepared with 91 g. of acid-washed alumina and petroleum ether. The material was eluted by solvents and solvent mixtures of increasing polarity. Details of the chromatographic separation are shown in Table I.

TABLE I

CHROMATOGRAPHIC SEPARATION OF HYDROGENOLYSIS PRODUCTS

Fraction	Solvents	Products,[a] mg.	M. p., °C.
I	78% Benzene–22% petroleum ether (265 ml.)	Oil	
II	100% Benzene (120 ml.)	Oil	
III	80% Benzene–20% chloroform (120 ml.)	Oil	
IV	60% Benzene–40% chloroform (120 ml.)	273	155–159
V	40% Benzene–60% chloroform (120 ml.)	967	158–160
VI	20% Benzene–80% chloroform (120 ml.)	717	161–165
VII	100% Chloroform (120 ml.)	724	162–164
VIII	50% Chloroform–50% acetone (480 ml.)	1460	166–167

[a] Yields and melting points refer to material crystallized from ether and recrystallized from chloroform–ether.

Fractions IV and V consisted of nearly pure tetraacetyl-bis-desoxystreptobiosamine. For final purification, 980 mg. of this material was reacetylated with pyridine and acetic anhydride. The product was worked up in the usual manner and crystallized from a chloroform–ether mixture, giving 846 mg., m. p. 158–160°. Two recrystallizations of this product from chloroform–ether gave pure tetraacetyl-bis-desoxystreptobiosamine, m. p. 159–160°, $[\alpha]^{25}D$ −85° (*c*, 1.0 in chloroform).

Anal. Calcd. for $C_{13}H_{21}NO_7(CH_3CO)_4$: C, 53.04; H, 7.00; N, 2.95; O-acetyl, 27.2. Found: C, 52.98; H, 6.75; N, 2.87; O-acetyl, 27.7.[12]

In a Zerewitinoff determination carried out in anisole solution at room temperature on a sample dried in a weighing pig, 0.94 mole of methane was liberated from tetraacetyl-bis-desoxystreptobiosamine.

In tetrachloroethane solution at ordinary concentration (10–15%), tetraacetyl-bis-desoxystreptobiosamine showed absorption of 5.75 μ (ester) and 6.12 μ (disubstituted amide). However, a very concentrated solution (about 50%) showed a strong absorption band at 2.85 μ (hydroxyl group region).

Fractions VI and VII contained mixtures of tetraacetyl-bis-desoxystreptobiosamine and tetraacetyldesoxystreptobiosamine. These mixtures could not be separated by crystallization methods, but rechromatographing on alumina afforded some further separation.

Fraction VIII appeared to be pure tetraacetyldesoxystreptobiosamine. Its properties could not be changed by recrystallization, nor did repeated chromatography give material of higher melting point. A sample for analysis was recrystallized from ether containing a small amount of chloroform. It melted at 166–167°, and had a specific rotation of $(\alpha)^{25}D$ −81° (*c*, 1.04 in chloroform).

Anal. Calcd. for $C_{13}H_{21}NO_8(CH_3CO)_4$: C, 51.32;

(12) Determined by the method of Kunz and Hudson, THIS JOURNAL, **48**, 1982 (1926).

H, 6.77; N, 2.85; CH_3CO, 35.0. Found: C, 51.29; H, 6.94; N, 2.81; CH_3CO, 33.6.

There was no appreciable lowering of the melting point of a mixture of the two pure products. The desoxy compound (m. p. 166–167°) admixed with the bis-desoxy compound (m. p. 159–160°) melted at 162–165°.

Improved Preparation of Tetraacetyl-bis-desoxystreptobiosamine (II).—The acetylation product of 4.0 g. of ethyl thiostreptobiosaminide diethyl mercaptal hydrochloride was treated with Raney nickel catalyst exactly as described above, except that the catalyst was prepared immediately before use. The reaction products were isolated and chromatographed on alumina as in the previous example. The crystalline fractions were recrystallized separately from chloroform–ether. The lowest melting fraction melted at 153–156°; the highest melting fraction melted at 158–160°. The total weight of the recrystallized fractions was 1.91 g. They were combined and reacetylated, yielding 1.46 g. (33%) of tetraacetyl-bis-desoxystreptobiosamine, m. p. 157–159°.

In subsequent preparations, it was found that the chromatographic analysis of the reduction products could be omitted if freshly prepared Raney nickel catalyst had been used. The total organic material from the reduction was reacetylated and once recrystallized. This consistently afforded essentially pure tetraacetyl-bis-desoxystreptobiosamine in yields of 30–35%.

N-Acetyldesoxystreptobiosamine.—A solution of 212 mg. of tetraacetyldesoxystreptobiosamine in 8 ml. of methanol was cooled in an ice-bath and saturated with anhydrous ammonia. The solution was allowed to warm gradually to room temperature, and after two hours the solvent was removed *in vacuo*. The residue was dissolved in 10 ml. of water and the aqueous solution extracted with three 5-ml. portions of chloroform to remove acetamide. The aqueous solution was concentrated to dryness, the product dissolved in 1 ml. of isopropyl alcohol, and 15 ml. of chloroform added. The resulting gel was warmed gently, giving an oil which crystallized on standing. The product, 122 mg., melted at 224–226°. Pure N-acetyldesoxystreptobiosamine, m. p. 224–225°, was obtained by recrystallization from chloroform–methanol mixtures.

Anal. Calcd. for $C_{13}H_{24}NO_8(CH_3CO)$: C, 49.30; H, 7.45; N, 3.84; CH_3CO, 11.7; C-methyl, 8.2 (2 moles) 12.3 (3 moles). Found: C, 49.34; H, 7.20; N, 4.19; CH_3CO, 10.8; C-methyl, 9.8 (2.4 moles).

Pentaacetyldesoxystreptobiosamine (VI).—One hundred milligrams of tetraacetyldesoxystreptobiosamine was acetylated overnight at room temperature with 1 ml. of acetic anhydride in 5 ml. of pyridine. The solvents were removed *in vacuo* and the residue was dissolved in ether. The solution deposited 40 mg. of needle-like crystals on standing, m. p. 60–63°. Several recrystallizations of the product from ether gave pure pentaacetyldesoxystreptobiosamine, m. p. 111–112°, $[\alpha]^{25}D$ −132° (*c*, 0.62 in chloroform).

Anal. Calcd. for $C_{13}H_{20}NO_8(CH_3CO)_5$: C, 51.78; H, 6.61; N, 2.63; CH_3CO, 40.2. Found: C, 51.90; H, 6.56; N, 2.99; CH_3CO, 36.0.

Methyl Tetraacetyldesoxystreptobiosaminide (VII).—A solution of 200 mg. of tetraacetyldesoxystreptobiosamine in 5 ml. of absolute methanol containing 1% of hydrogen chloride was allowed to stand overnight at room temperature. The solvent was removed *in vacuo* and benzene was added and distilled. The residue was evacuated on the oil pump for two hours and was then dissolved in 3 ml. of pyridine, cooled to 0°, and treated with 2 ml. of acetic anhydride. After standing overnight at room temperature, the acetylation mixture was treated in the usual manner, giving a colorless oil. This oil was dissolved in ether containing a small amount of chloroform. On standing for three hours, the solution deposited crystals; 68 mg., m. p. 152–165°. Recrystallization of the product from a small volume of cold methanol gave 25 mg. of material, m. p. 176–180°. The combined mother liquors were chromatographed on 3 g. of alumina. An additional 36 mg. of crystalline material, m. p. 177–181° and 172–175° (two fractions), was eluted by benzene–chloroform mixtures. The two highest melting fractions were recrystallized from methanol yielding pure methyl tetraacetyldesoxystreptobiosaminide; m. p. 179–180.5°, $[\alpha]^{25}D$ −129° (*c*, 0.925 in chloroform).

Anal. Calcd. for $C_{13}H_{20}NO_7(CH_3O)(CH_3CO)_4$: C, 52.27; H, 6.98; N, 2.77; CH_3O, 6.1. Found: C, 52.21; H, 6.87; N, 2.65; CH_3O, 5.0.

Volumetric Determination of Carbonyl in Tetraacetyldesoxystreptobiosamine.—Sixty-seven milligrams (0.136 millimole) of tetraacetyldesoxystreptobiosamine, m. p. 165–167°, was added to a dilute alcohol solution containing pyridine, brom phenol blue, and an excess of hydroxylamine hydrochloride. After the solution had stood overnight, titration with 0.105 *N* sodium hydroxide in 90% methanol according to the method of Bryant and Smith[7] required 1.27 ml. to match the color of a blank prepared with hydroxylamine hydrochloride, pyridine, and brom phenol blue. This amount corresponded to 0.133 millimole of pyridine hydrochloride formed, or 0.98 mole of carbonyl function in the compound tested.

Treatment of Tetraacetyl-bis-desoxystreptobiosamine with Chromic Acid.—Twenty-seven milligrams of tetraacetyl-bis-desoxystreptobiosamine, m. p. 159–160°, was dissolved in 0.5 ml. of acetic acid and treated with a solution of 14 mg. of chromic anhydride in 0.5 ml. of 80% acetic acid. After two hours at room temperature, no appreciable color change could be detected. The chromic acid was then reduced with methanol. The solution yielded 18 mg. of crystals, m. p. 155–158°. Recrystallization of this material from a chloroform–ether mixture gave pure starting material, m. p. and mixed m. p. 159–160°.

bis-Desoxystreptose (3,4-Dihydroxy-2,3-dimethyltetrahydrofuran) (V).—A solution of 1.52 g. of tetraacetyl-bis-desoxystreptobiosamine in 95 ml. of 5% sulfuric acid was refluxed for six hours. The solution was then extracted continuously with chloroform for six hours. The chloroform solution was shaken with solid sodium bicarbonate, filtered, and the chloroform distilled, leaving a mixture of crystals and red tar. The crystalline material sublimed readily at 50–60° and 10^{-4} mm. pressure. The sublimate was recrystallized from an ether–petroleum ether mixture, giving 98 mg. (22%) of needle-like crystals, m. p. 90–90.5°. After recrystallization of this material from ether–petroleum ether and from ether, the product melted constantly at 90–91°; $[\alpha]^{25}D$ +32° (*c*, 0.975 in chloroform); $[\alpha]^{25}D$ +21° (*c*, 1.02 in water).

Anal. Calcd. for $C_6H_{12}O_3$: C, 54.52; H, 9.16; 2 C-methyl, 22.7; mol. wt., 132. Found: C, 54.63; H, 8.93; C-methyl, 19.4; mol. wt., 141 (ebullioscopic in carbon tetrachloride).

In tetrachloroethane solution, bis-desoxystreptose showed 3 μ (—OH group) absorption in the infrared; no carbonyl absorption could be detected. The compound did not react with a solution of 2,4-dinitrophenylhydrazine hydrochloride, nor was it affected by treatment with hydroxylamine hydrochloride in the presence of pyridine.

The pure bis-desoxystreptose did not reduce Tollens reagent in the cold. Fehling solution was not reduced, even when boiled for several minutes.

Bis-*p*-nitrobenzoate of Bis-desoxystreptose.—Sixty milligrams of bis-desoxystreptose, m. p. 89–91°, was converted to the bis-*p*-nitrobenzoate by treatment with a large excess of *p*-nitrobenzoyl chloride in pyridine solution. The crude crystalline product (89 mg.) was recrystallized from ether and then twice from methanol, giving the pure ester, m. p. 141–142°.

Anal. Calcd. for $C_{20}H_{18}N_2O_8$: C, 55.81; H, 4.22; N, 6.51. Found: C, 55.58; H, 4.00; N, 6.72.

Hydrolysis of Tetraacetyl-bis-desoxystreptobiosamine to Pentaacetyl-N-methyl-L-glucosamine and N-Methyl-L-glucosamine Hydrochloride.—The 5% sulfuric acid solution from the hydrolysis of 1.52 g. of tetraacetylbis-

desoxystreptobiosamine, after continuous chloroform extraction to remove the bis-desoxystreptose, was neutralized with barium carbonate and the filtrate concentrated to dryness. A solution of the residue in 10 ml. of concentrated hydrochloric acid was refluxed for two hours, and the hydrolysis mixture was twice extracted with chloroform. The aqueous solution was concentrated to dryness *in vacuo* and the product acetylated. Three recrystallizations of the crude acetylated product from chloroform–ether mixtures gave 707 mg. of pentaacetyl-N-methyl-L-glucosamine,[3] m. p. 160–160.5°. Hydrolysis of the pentaacetyl derivative with 10% hydrochloric acid gave 330 mg. of crude product,[3] m. p. 151–155° (dec.), and recrystallization gave the pure N-methyl-L-glucosamine hydrochloride, m. p. 161–165° (dec.), $[\alpha]^{25}D$ −103° (four minutes) → 88.5° (twelve hours, constant) in aqueous solution (*c*, 0.61).

Periodic Acid Oxidation of Bis-desoxystreptose. bis-*p*-Nitrophenylhydrazone of Oxidation Product $C_6H_{10}O_3$ (Glycolic Aldehyde Ether of Acetoin).—To a solution of 30.3 mg. of bis-desoxystreptose in 2 ml. of dioxane was added 2.19 ml. (1.0 equivalent) of a 0.105 *M* solution of periodic acid in 90% dioxane. A white crystalline precipitate of iodic acid appeared immediately. After one hour at room temperature, the precipitate was removed by centrifugation and washed twice with dioxane. To the combined supernatant and washings was added dropwise 0.1 *N* barium hydroxide until the solution was neutral. The small precipitate was removed and the filtrate concentrated *in vacuo* to a sirup. A solution of the sirup in 1 ml. of 50% acetic acid was added to a solution of 73 mg. of *p*-nitrophenylhydrazine in 1 ml. of 50% acetic acid. An orange crystalline precipitate formed and was centrifuged and washed with warm 50% acetic acid. The crude product, 55 mg., melted at 188–193°. Two recrystallizations of the product from alcohol gave tiny orange needle-like crystals, m. p. 204–206° (dec.).

Anal. Calcd. for $C_{18}H_{20}N_6O_5$: C, 53.99; H, 5.04; N, 20.99. Found: C, 53.95; H, 4.92; N, 21.42.

Hydrolysis of the Oxidation Product $C_6H_{10}O_3$ (Glycolic Aldehyde Ether of Acetoin). Preparation of Phenylosazone of Biacetyl.—The freshly isolated product from the periodic acid cleavage of 37.6 mg. of bis-desoxystreptose was dissolved in 1.5 ml. of 50% acetic acid and the solution was heated in the steam-bath for ten minutes. The solution was then added to a hot solution of 0.15 ml. of phenylhydrazine in 2 ml. of 50% acetic acid, giving a clear light brown solution. A crystalline precipitate began to form after about two minutes at 95–100°. The heating was continued in the steam-bath for one-half hour, after which the hot solution was centrifuged and the precipitate washed with dilute acetic acid, twice with water, and once with ethanol. The product, light tan, feathery needle-like crystals, weighed 28 mg., m. p. 226–237°. Two recrystallizations of this material from ethanol–pyridine (10:1) gave material melting constantly at 247–249°. A mixture of this product and an authentic sample of the phenylosazone of biacetyl[13] (m. p. 246–250°) melted at 246.5–250°.

Anal. Calcd. for $C_{16}H_{18}N_4$: C, 72.15; H, 6.81; N, 21.04. Found: C, 71.65; H, 6.69; N, 21.34.

5,6-Dimethyl-2,3-diphenylosatetrazine.—A solution of 21 mg. of sodium dichromate in 1 ml. of 20% acetic acid was added to 22 mg. of the phenylosazone isolated from the hydrolysis of the dicarbonyl compound $C_6H_{10}O_3$. The suspension was heated at 100° for one hour. The mixture was cooled and the precipitate separated and washed with water and ethanol. Recrystallization of the material from 1 ml. of acetone gave red crystals; 14 mg., m. p. 153–155° (dec.). No depression of melting point was observed when this product was mixed with an authentic sample of 5,6-dimethyl-2,3-diphenylosatetrazine[8] of m. p. 151–155°.

***p*-Bromophenylosazone of Biacetyl.**—The hydrolysis products of the glycolic aldehyde ether of acetoin gave, with excess *p*-bromophenylhydrazine hydrochloride in hot 50% acetic acid solution containing sodium acetate, a crystalline compound which melted, after recrystallization from chloroform, at 210–215° (dec.). Similar treatment of an authentic sample of biacetyl gave crystals of m. p. 212–216° (dec.). A mixture of the "natural" and synthetic products melted at 209–215°.

***p*-Nitrophenylosazone of Biacetyl.**—In a manner similar to that described for the preparation of the phenylosazone, a *p*-nitrophenylosazone of biacetyl was prepared. After two recrystallizations from pyridine, the product melted at 312–316° (dec.), varying somewhat with the rate of heating. Melting points of 316°[14] and 326°[15] are reported for the *p*-nitrophenylosazone of biacetyl.

Anal. Calcd. for $C_{16}H_{16}N_6O_4$: C, 53.93; H, 4.53; N, 23.59. Found: C, 53.82; H, 4.39; N, 23.77.

Bis-desoxystreptose–Boric Acid Complex.—The acidity of an aqueous boric acid solution was greatly increased by the addition of a small molecular excess of the 3,4-dihydroxy-2,3-dimethyltetrahydrofuran. When the solution was titrated with alkali, the general region of binding was at about *p*H 7.5, instead of at about *p*H 9, as is the case with boric acid alone.

Periodate Oxidation of N-Acetyl-bis-desoxystreptobiosamine.—To a solution of 36.3 mg. (0.104 millimole) of N-acetyl-bis-desoxystreptobiosamine in water was added 3.00 ml. of 0.0955 *M* sodium periodate solution, and water was added to make exactly 10 ml. of solution. The course of the reaction was followed by withdrawing 1.00-ml. aliquot portions, adding sodium bicarbonate and potassium iodide, and titrating the iodine with standard arsenite solution. The results are presented in Table II. After one and eight-tenths hours, a portion of the reaction solution was titrated with alkali. There was found to be present 0.25 equivalent of a weak acid (*pK* 4.8), apparently acetic acid, since the *pK* of acetic acid is 4.85, while that of formic acid is 3.8.

TABLE II

TITRATION RESULTS

Time, hours	Periodate consumed, equivalents
0	0
0.10	0.21
0.50	0.53
1.36	1.08
2.25	1.17

A solution of 99.8 mg. (0.286 millimole) of N-acetyl-bis-desoxystreptobiosamine in 3 ml. of 0.07 *M* phosphate buffer (*p*H 7) was treated with 61 mg. (0.286 millimole) of sodium periodate. After one and one-half hours, all of the periodate had been consumed. Water was added to a volume of 15 ml., and 10 ml. of the solution was distilled into 5 ml. of a saturated solution of 2,4-dinitrophenylhydrazine in 2 *N* hydrochloric acid. Centrifugation of the mixture gave 4 mg. of a gummy orange solid. In a control experiment, two-thirds of a solution of 9 mg. of formaldehyde in 15 ml. of very dilute *p*H 7 phosphate buffer was distilled into 2,4-dinitrophenylhydrazine hydrochloride solution, yielding 24 mg. of yellow, crystalline formaldehyde 2,4-dinitrophenylhydrazone.

Dihydrodesoxystreptose (XIX).—Nine-tenths gram of pentaacetyldihydrodesoxystreptobiosamine was dissolved in 75 ml. of 5% sulfuric acid and the solution was refluxed for eight hours. It was then neutralized by stirring with barium carbonate, filtered, and the filtrate (*p*H 8) concentrated *in vacuo* to a volume of 15 ml. This solution was passed over a column of 17 g. of freshly regenerated and washed Amberlite IR-100. The first 10 ml. of eluate was discarded. Washing was continued with water until 65 ml. of eluate had been collected. The eluate was concentrated *in vacuo* to a volume of 12 ml., and passed over a column of 5 g. of Amberlite IR-4B.

(13) Neuberg and Reinfurth, *Biochem. Z.*, **143**, 563 (1923).

(14) Hirsch, *ibid.*, **131**, 184 (1922).

(15) Neuberg and Kobel, *ibid.*, **160**, 255 (1925).

The column was washed with water. In all, 30 ml. of eluate was collected and lyophilized.

The solid product was triturated with boiling chloroform, and the chloroform solution filtered. Concentration of the filtrate to a small volume gave crystals which were filtered and washed with cold chloroform. The yield of crystalline product, m. p. 75–77°, was 35 mg. Recrystallization of the product from chloroform gave pure dihydrodesoxystreptose, m. p. 78–79°.

Anal. Calcd. for $C_6H_{12}O_4$: C, 48.64; H, 8.17. Found: C, 48.53; H, 7.96.

Periodate Oxidation of Dihydrodesoxystreptose.—A solution of 15.2 mg. (0.102 millimole) of dihydrodesoxystreptose and 55.3 mg. (0.259 millimole) of sodium periodate in 10 ml. of water was allowed to stand at room temperature for one hour. Titrations of aliquot portions showed the presence of 0.047 millimole of periodate and of 0.098 millimole of acid, corresponding to a consumption of 2.07 equivalents of periodate with formation of 0.96 equivalent of acid.

In another experiment, 6.7 mg. of dihydrodesoxystreptose in 2 ml. of water containing 14 mg. of sodium bicarbonate was oxidized with 19.3 mg. (2 equivalents) of sodium periodate. After one hour, no periodate could be detected, and a solution of 81 mg. of dimedone in 2 ml. of ethanol was added. The crystalline precipitate which formed rapidly was collected, washed with 50% ethanol and dried. It weighed 11.6 mg. (88%) and melted at 182–189°. One recrystallization of this material from dilute ethanol gave pure dimedone–formaldehyde condensation product, m. p. and mixed m. p. 191–194°.

Acknowledgment.—The authors wish to thank Dr. N. R. Trenner and his associates for the infrared absorption measurements and potentiometric titrations, Dr. J. B. Conn for the molecular weight determination, and Mr. Richard N. Boos and his associates for microanalyses.

Summary

Treatment of ethyl tetraacetylthiostreptobiosaminide diethyl mercaptal with Raney nickel catalyst has given two products, tetraacetyl-bis-desoxystreptobiosamine and tetraacetyldesoxystreptobiosamine.

The additional oxygen atom of the desoxy compound is present as a glycosidic hydroxyl group. Tetraacetyldesoxystreptobiosamine was characterized by the preparation of N-acetyldesoxystreptobiosamine, pentaacetyldesoxystreptobiosamine and methyl tetraacetyldesoxystreptobiosaminide.

Acid hydrolysis of tetraacetyl-bis-desoxystreptobiosamine yielded N-methyl-L-glucosamine and bis-desoxystreptose.

Bis-desoxystreptose has been determined by periodic acid oxidation studies to be a 3,4-dihydroxy-2,3-dimethyltetrahydrofuran. The two hydroxyl groups of bis-desoxystreptose appear to be in a *cis* configuration. The structure of tetraacetyl-bis-desoxystreptobiosamine is given.

Pentaacetyldihydrodesoxystreptobiosamine was hydrolyzed with acid to give dihydrodesoxystreptose. The periodate degradation of dihydrodesoxystreptose to yield formaldehyde and an acid was in agreement with the proposed structure of this product, and offered further evidence for the position of the linkage of streptidine to streptobiosamine.

Alkaloids of *Dichroa Febrifuga* Lour.

BY FREDERICK A. KUEHL, JR., CLAUDE F. SPENCER AND KARL FOLKERS

The tests on extracts of about six hundred plants have shown that several plants possess interesting unknown principles which exibit antimalarial activity.[1] Of those plants containing active principles which were investigated, *Dichroa febrifuga* Lour. was particularly interesting because of the high antimalarial activity of the alkaloidal fraction isolated from it. Extractions were made on dried roots, stems and leaves of the plant obtained from both India and China. Unfortunately, the samples of *Dichroa febrifuga* Lour. from India, the material available when most of this work was done, contained only about one-tenth of the alkaloidal fraction present in the Chinese samples.

A number of extraction procedures was investigated. The best yields of the alkaloidal fraction from the Chinese root material were 0.1 to 0.15%. The yield of alkaloids from stem and leaf material was invariably much lower.

(1) Spencer, Koniuszy, Rogers, Shavel, Easton, Kaczka, Kuehl, Phillips, Walti and Folkers, *Lloydia*, **10**, 145 (1947).

Nothing crystallized directly from the crude alkaloidal fraction. A solution of this material and oxalic acid, however, gave a characteristic crystalline oxalate, which represented more than 75% of the antimalarial activity of the crude fraction. The yield of crude oxalate was 0.05% from the Chinese root sample and 0.005% from the Indian root sample. The recrystallized oxalate, m. p. *ca.* 212–214° (dec.), $(\alpha)^{25}D$ +18° (*c*, 1.5 in water), had a composition which was in agreement with the formula $(C_{16}H_{19}N_3O_3)_2 \cdot C_2H_2O_4$.

When a sample of a recrystallized oxalate was converted to the free base, two different crystalline alkaloids appeared which were not separated satisfactorily by crystallization. Chromatography of the mixture over alumina gave crystalline alkaloid I, m. p. 131–132°, $(\alpha)^{25}D$ +31° (*c*, 1.5 in ethanol), $(\alpha)^{25}D$ +120° (*c*, 0.8 in chloroform) and the properties of this alkaloid were not changed after repeated crystallization. The results of analytical data, potentiometric titration and ebullioscopic molecular weight determination were in-

dicative of the formula $C_{16}H_{19}N_3O_3$ for this alkaloid.

A sample of alkaloid I was chromatographed over a mixture of Norite and filter paper pulp. The specific rotation of all twenty eluates was about the same, but the value was somewhat lower than that of the starting material. After the eluates were allowed to stand for two days, they acquired a yellow color. The combined fractions 1–16 yielded alkaloid I upon crystallization, and the mother liquor yielded alkaloid II, m. p. 140–142°, $(\alpha)^{17}D$ +21° (*c*, 1.4 in ethanol). The composition of alkaloid II was also indicative of the formula $C_{16}H_{19}N_3O_3$.

These results were interpreted as indicating that alkaloid I is unstable under certain conditions and may be converted to some extent into alkaloid II. To test for this reaction or conversion, an alcoholic solution of alkaloid I was refluxed for twleve hours, and it was observed that the specific rotation decreased and approximated that of alkaloid II. In contrast, the specific rotation of alkaloid II was unchanged after this treatment. In the extraction of the plant material, where the alkaloid undoubtedly exists as a salt, alkaloid I was isolated after the root was extracted for three days with hot methanol. It is of interest that despite the instability of alkaloid I in solution, reference samples of the crystalline alkaloid have been on hand for almost three years without evidence of change.

Not only do alkaloids I and II appear to have the same formula $C_{16}H_{19}N_3O_3$, they also have indistinguishable ultraviolet and infrared absorption spectra. The ultraviolet absorption spectrum of alkaloid I in ethanol solution showed maxima at 2250 Å. (*E*% 900), 2650 Å. (*E*% 267), 3020 Å. (*E*% 125), and 3140 Å. (*E*% 101); the spectrum of alkaloid II showed maxima at 2250 Å. (*E*% 895), 2660 Å. (*E*% 246), 3010 Å. (*E*% 109), and 3130 Å. (*E*% 98). The infrared absorption spectra of both compounds showed bands at 6.03, 6.26, 6.45 and 6.78 μ.

We are indebted to Dr. A. O. Seeler and Miss Christine Malanga of the Merck Institute for Thereapeutic Research for the antimalarial tests. The crude alkaloidal fraction at a level of 20 mg./kg. orally showed an activity equivalent to a dose of 40 mg./kg. of quinine for essentially complete suppression of the trophozoite-induced infections of *Plasmodium gallinaceum* in chicks according to the described procedure.[2,3] Alkaloid I at a level of 5 mg./kg. and alkaloid II at a level of 2.5 mg./kg. orally were equivalent to a dose of 40 mg./kg. of quinine. The toxicity of these alkaloids to chicks was rather high since doses only twice the above-mentioned levels were toxic. A communication[4] has appeared which announced the isolation of two alkaloids from *Dichroa febrifuga* Lour. The melting points, compositions, and ultraviolet absorption spectra of these two alkaloids correspond closely with the properties of the two alkaloids which we have isolated. Our supply of alkaloids, as well as plant material, is exhausted and further comparisons are not possible at present. It was also mentioned[4] that isofebrifugine (alkaloid I) was converted to febrifugine (alkaloid II) by heat. Febrifugine showed approximately one hundred times the activity of quinine and isofebrifugine showed relatively slight activity against *P. lophurae* in ducks.

We also found[4] no evidence of the two alkaloids dichroine A and dichroine B which were described[5] as being derived from *Dichroa febrifuga* Lour. (Ch'ang Shan).

Experimental

Crystalline Alkaloidal Oxalate from *Dichroa febrifuga* Lour. from China.—A 2467-g. portion of finely ground root material of *Dichroa febrifuga* Lour., W. M. Clark 18634,[6] was moistened with water and extracted in a Soxhlet with methanol for three days. The methanol extract was evaporated *in vacuo*, and the aqueous solution remaining (*ca.* 800 ml.) was adjusted to *p*H 3 with dilute hydrochloric acid. The aqueous solution was extracted continuously with chloroform for twenty hours to remove impurities, and then the solution was adjusted to *p*H 8 with sodium bicarbonate and the alkaloids were removed by continuous chloroform extraction for twenty hours. The alkaloidal fraction was obtained as a brown residue, 3.78 g. (0.15%), after removal of the chloroform. It was dissolved in 25 ml. of 50% methanol and oxalic acid was added to *p*H 3. The resulting solution was warmed, filtered and concentrated. The gummy residue was dissolved in methanol and treated with acetone, and 1.453 g. (0.052%) of a crystalline oxalate, m. p. 199–201°, was obtained. After recrystallization from 50% methanol, the oxalate melted at 215–218° (dec. temperature somewhat dependent upon the rate of heating), $(\alpha)^{25}D$ +17° (*c*, 1.0 in water).

Extraction of *Dichroa febrifuga* Lour. from India.—An alternative extraction procedure to obtain the alkaloidal fraction was carried out as follows. A 4901-g. portion of ground root of *Dichroa febrifuga* Lour., National Institute of Health (Kaleshan) 18629, was moistened with water, added to *ca.* 15 l. of methanol and then the mixture was boiled for three hours. The extract was removed by filtration and the extraction was repeated two more times with fresh solvent. The combined extract was concentrated *in vacuo* to a volume of *ca.* 2 l. and the solution was adjusted to *p*H 8 and continuously extracted with chloroform. After distillation of the chloroform, the residue weighed 9.845 g. It was dissolved in 150 ml. of chloroform and the solution was extracted with 5–40 ml. portions of 3.5% hydrochloric acid. The aqueous extract was then adjusted to *p*H 8 and continuously extracted with chloroform to give 1.424 g. (0.029%) of the alkaloidal fraction.

Crystalline Alkaloidal Oxalate from *Dichroa febrifuga* Lour. from India.—Two kilograms of ground root material of *Dichroa febrifuga* Lour., Biswas 18637, was extracted in a Soxhlet and the methanol extract was processed in the manner described above. The alkaloidal fraction yielded 98 mg. of crude oxalate, m. p. 195–210°. After two recrystallizations from 50% methanol, the oxalate melted at 213–214° (dec.), $(\alpha)^{25}D$ +18° (*c*, 0.5 in water).

Anal. Calcd. for $(C_{16}H_{19}N_3O_3)_2 \cdot C_2H_2O_4$: C, 58.85; H, 5.83; N, 12.10. Found: C, 58.97; H, 6.06; N, 12.37.

Alkaloids I and II from the Oxalate from a Chinese Sample.—An aqueous solution of 4.38 g. of the oxalate, $(\alpha)^{25}D$ +17° (*c*, 1.0 in water), was treated with sodium bicarbonate to *p*H 8, and extracted continuously for three hours with chloroform. The chloroform extract was concentrated to a residue *in vacuo*. An alcohol solution of this residue deposited 2.74 g. of crystalline alkaloid I, m. p. 131–132° (softening at 127°), $(\alpha)^{25}D$ +33.6° (*c*, 1.7 in alcohol). On standing, the mother liquor deposited crude crystalline alkaloid II, m. p. 135–142°, $(\alpha)^{25}D$ +21° (*c*, 0.9 in ethanol).

Upon recrystallization of the first crop, two distinct fractions were obtained, the first crystallizing immediately in small needles, 1.700 g., m. p. 124–130°, $(\alpha)^{25}D$ +31° (*c*, 1.1 in alcohol), and the second crystallizing in long needles on standing overnight, 0.359 g., m. p. 135–142°, $(\alpha)^{25}D$ +23° (*c*, 0.9 in alcohol).

Separation of Alkaloid I and II by Chromatography.—A solution of 2.487 g. of a mixture of the two alkaloids in 25 ml. of chloroform was passed through a column containing 35 g. of acid-washed alumina. Elution with 800 ml. of chloroform gave 1.604 g. of residue, $(\alpha)^{25}D$ +31° (*c*, 2.6 in ethanol). A second elution with 200 ml. of chloroform containing 5% methanol gave 749 mg. of residue, $(\alpha)^{25}D$ +21° (*c*, 2.0 in ethanol). Finally, elution with 200 ml. of methanol gave 106 mg. of material, $(\alpha)^{25}D$ +20° (*c*, 1.3 in ethanol). The first eluted fraction, after recrystallization from benzene, gave 376 mg. of alkaloid I, m. p. 131–132°, $(\alpha)^{25}D$ +31° (*c*, 1.5 in ethanol). Concentration of the mother liquor yielded a second crop of 0.984 g., m. p. 124–130°. Recrystallization of this second crop gave 0.775 g., m. p. 128–132°, $(\alpha)^{25}D$ +31° (*c*, 1.9 in alcohol). This was combined with the first crop and recrystallized again from benzene, giving 0.829 g., m. p. 131–132°, $(\alpha)^{25}D$ +31° (alcohol), $(\alpha)^{25}D$ +120° (*c*, 0.8 in chloroform). The melting point of this material did not alter after further recrystallization from methanol.

Anal. Calcd. for $C_{16}H_{19}N_3O_3$: C, 63.8; H, 6.4; N, 14.0, mol. wt., 301. Found: C, 63.91; H, 6.50; N, 14.10, eq. wt. (potentiometric titration) 314; mol. wt., 281 (ebullioscopic in benzene).

Chromatography of Alkaloid I.—A solution of 1.6 g. of alkaloid I, $(\alpha)^{25}D$ +33.6° (*c*, 1.7 in ethanol), in 5 ml. of ethanol was diluted with chloroform and the solution was concentrated *in vacuo* to a gum. This gum was dissolved in chloroform and the concentration was repeated to yield an alcohol-free gum. A solution of this gum in 10 ml. of chloroform was poured onto a column composed of 25 g. of Norite and 2 g. of pulverized filter paper. The column was developed with 200 ml. of chloroform and then eluted with chloroform containing 2% ethanol. The data are shown in Table I.

The eluates were allowed to stand for two days, during which time they acquired a yellow color. Fractions 4, 6, 8, 10 and 12 were combined to give 0.435 g. of residue, a total of 1.24 g. in all (78%). Fractions 1 to 16 were combined and concentrated *in vacuo* to a residue, which was dissolved in a small amount of alcohol and decolorized with a little charcoal. Upon cooling, 560 mg. of alkaloid I deposited as colorless needles, m. p. 131–132°, $(\alpha)^{25}D$ +32° (*c*, 1.7 in ethanol). After standing for several days, the mother liquor deposited 170 mg. of alkaloid II. After several recrystallizations, alkaloid II melted at 140–142°, $(\alpha)^{25}D$ +21° (*c*, 1.4 in ethanol).

Anal. Calcd. for $C_{19}H_{16}N_3O_3$: C, 63.80; H, 6.40; N, 14.00. Found: C, 63.42; H, 6.56; N, 14.33.

TABLE I

CHROMATOGRAPHIC DATA ON ALKALOID I

Fraction	Volume, ml.	Weight of residue, mg.	$[\alpha]^{25}D$ (in ethanol)
1	10	11	+29°
2	10	38	
3	10	65	+30°
4	10		
5	10	85	+29°
6	10		
7	10	78	+31°
8	10		
9	10	83	+29°
10	10		
11	10	84	+32°
12	10		
13	20	85	+31°
14	30	57	+32°
15	30	37	+31°
16	50	45	+29°
17	50	41	+27°
18	50	35	+26°
19	50	28	+26°
20	50 (methanol)	29	+23°

Stability Tests in Ethanol.—A solution of 22 mg. of alkaloid I, m. p. 130–132°, $(\alpha)^{25}D$ +32° (*c*, 1.7 in ethanol), in 25 ml. of ethanol was boiled for twelve hours. The solvent was then removed *in vacuo*. The residue showed $(\alpha)^{25}D$ +24° (*c*, 1.5 in ethanol).

A solution of 23 mg. of alkaloid II, m. p. 140–142°, $(\alpha)^{25}D$ +20.5° (*c*, 1.4 in ethanol) in 25 ml. of ethanol was boiled for twelve hours. The residue showed $(\alpha)^{25}D$ +20° (*c*, 1.5 in ethanol).

Preparation of the Oxalate of Alkaloid I.—A mixture of 33 mg. of alkaloid I, m. p. 131–132°, $(\alpha)^{25}D$ +31° (*c*, 1.1 in ethanol) and 14 mg. of oxalic acid was heated in 1 ml. of 50% methanol until the components dissolved. After standing in ice, 19 mg. of the oxalate salt deposited which, when recrystallized from 50% methanol to constant melting point, was obtained as colorless crystals, m. p. 212–213° (dec.), $(\alpha)^{25}D$ +19° (*c*, 0.3 in water).

Acknowledgment.—We wish to express our appreciation to Mr. B. A. Krukoff of the New York Botanical Garden for obtaining certain plant materials, for determining specimens, and for advice on botanical matters. We also wish to thank Dr. N. R. Trenner and his associates for the ultraviolet and infrared analyses, and Mr. Richard Boos and his associates for the microanalyses.

Summary

Two crystalline alkaloids have been isolated from *Dichroa febrifuga* Lour. which show antimalarial activity. These two alkaloids appear to be isomeric, both having the composition $C_{16}H_{19}N_3O_3$.

Poly-condensation of α-Amino Acid Derivatives. III. Poly-lysine[1]

BY EPHRAIM KATCHALSKI, ISAAC GROSSFELD AND MAX FRANKEL

In the previous papers of this series we have described the preparation and properties of some polymers of glycine[2a] and *d,l* alanine.[2b] As an extension of this work the study of the polymerization of poly-functional α-amino acids was undertaken. In the present paper the formation of poly-lysine by the polymerization of a 1-lysine derivative is described.

The following considerations had to be taken into account in the choice of a suitable monomer for polymerization: (a) the ε-amino group of the lysine had to be masked in order to prevent its participation in the polymerization and thus to insure that all the —CONH— bonds in the polymer are derived from the α-amino groups of the monomer. The ε-amino group was masked by Bergmann's method of introducing the carbobenzoxy group; (b) the monomer must consist of a lysine derivative having a pronounced tendency to polymerize. ε-Carbobenzoxylysine itself is comparatively stable owing to its zwitterionic structure, while its methyl ester yields mainly the corresponding diketopiperazine on heating;[3] both these lysine derivatives did not appear therefore to be the proper starting material. A more suitable monomer was eventually found in ε-carbobenzoxy-α-carboxyl-lysine anhydride.[4] It was found that this substance polymerizes on heating with the evolution of carbon dioxide in a manner similar to the polymerization of N-carboxyl anhydrides of other amino acids.[5]

The steps of preparation of poly-lysine from the chosen monomer are summarized in the first part of the scheme: ε-carbobenzoxy-α-carboxyl-1-lysine anhydride (I), yields on heating, under the catalytic action of water, poly-carbobenzoxylysine (II), carbon dioxide being evolved. The carbobenzoxy groups of (II) were removed by phosphonium iodide, and poly-lysine hydriodide (III) obtained.

For each polymerization experiment, the starting material, ε-carbobenzoxy-α-carboxyl-1-lysine anhydride, had to be freshly prepared from α,ε-carbobenzoxy-1-lysine kept in stock. This was necessary, as it was found that while the freshly prepared substance undergoes rapid polymerization at its melting point (100°), the same substance after having been allowed to stand for several weeks did not polymerize even at higher temperatures (160–170°), but decomposed slowly under such conditions. In this connection the observation of Bergmann, Zervas and Ross,[4] may be recalled that the melting point of freshly prepared ε-carbobenzoxy-α-carboxyl-1-lysine anhydride rises on standing several months to above 250°. Our attempts to recover the ε-carbobenzoxy-α-carboxyl-1-lysine anhydride with a melting point of 100° from the preparation having a high melting point by recrystallization were unsuccessful as no solvent for the latter was found.

During search for other precautions to be taken in the polymerization of ε-carbobenzoxy-α-carboxyl-1-lysine anhydride, the following findings were useful: (a) pure α,ε-di-carbobenzoxy-1-lysine, as well as pure carbobenzoxy-glycine, give no amino N values on using Van Slyke's[6] manometric method for amino N determination.

(b) ε-Carbobenzoxy-1-lysine yields practically the theoretical amount (96%) of carboxyl nitrogen in Van Slyke, MacFadyen and Hamilton ninhydrin–CO_2 method[7] when the reaction is carried out at *p*H 2.5.

(c) ε-Carbobenzoxy-α-carboxyl-1-lysine anhydride evolved an amount of carbon dioxide equivalent only to about 50% of its total α-nitrogen when analyzed by the usual ninhydrin–CO_2 method. The samples were boiled, after addition of citrate buffer, *p*H 2.5, for thirty seconds to remove performed carbon dioxide. The solution was chilled and the N-carboxyl determination carried out as usual after addition of ninhydrin.

Finding (a) shows that during the carrying out of the amino nitrogen determinations, no cleavage of the NH-carbobenzoxy bond, leading to the liberation of free NH_2 groups, occurs. It is thus possible to determine the free amino-N in materials containing NH-carbobenzoxy bonds, without fear that additional free amino groups, not present in the original material will be liberated on analysis. Finding (b) permits the determination of ε-carbobenzoxy-lysine in the presence of poly-carbobenzoxy-lysine. Furthermore, in view of (b) and (c), it is clear that high values of carboxyl-N (determined according to the ninhydrin–CO_2 method) indicate the presence of a considerable amount of either or both ε-carbobenzoxy lysine and ε-carbobenzoxy-α-carboxyl lysine anhydride. This conclusion enables us to estimate roughly the amount of "monomer" derivatives in the prepara-

(1) A manuscript under this title was received from these authors on January 21, 1946, for publication in the Journal. It was returned to them on February 21, 1946, for revision and further data.—The Editor.

tions obtained on heating ε-carbobenzoxy-α-carboxyl lysine anhydride, even before removal of the carbenzoxy groups.

In Table I we summarize various analytical data concerning preparations obtained on heating ε-carbobenzoxy-α-carboxyl-lysine anhydride, purified in different ways and using different conditions of polymerization. Table II contains data concerning products derived on reduction of the corresponding preparations described in Table I.

TABLE I

ANALYTICAL DATA ON PREPARATIONS OBTAINED ON HEATING ε-CARBOBENZOXY-α-CARBOXYL-LYSINE ANHYDRIDE UNDER VARIOUS CONDITIONS

	Mg. of element (or group) per 100 mg. preparation					
Prepn.	N	Amino N	Carboxyl N	Total C	H	Remarks
(a)	2.00	1.09	10.7	63.5	6.9	Transparent brittle film, readily soluble in cold glacial acetic acid, insoluble in water
(b)	1.08	0.092	10.7	..	...	
(c)	0.22	0.025	10.8	64.2	6.8	Transparent film soluble in hot glacial acetic acid, insoluble in water
(d)	0.17	0.017	1.3	63.9	7.1	

(a) Obtained from ε-carbobenzoxy-α-carboxyl-1-lysine anhydride recrystallized once from ethyl acetate and petroleum ether and then dried for several days over sulfuric acid. The dried anhydride was left to polymerize in an open vessel at 105° for twenty-four hours.

(b) Obtained from ε-carbobenzoxy-α-carboxyl-1-lysine anhydride recrystallized twice from ethyl acetate and petroleum ether and dried in a 20-mm. vacuum over phosphorus pentoxide for forty-five minutes. Polymerization was carried out in the drying apparatus by raising the temperature to 104°, and maintaining this temperature for several hours.

(c) Obtained from ε-carbobenzoxy-α-carboxyl-1-lysine anhydride recrystallized three times from ethyl acetate and petroleum ether, and introduced immediately after the last recrystallization into a high vacuum apparatus containing phosphorus pentoxide and liquid air trap. The monomer was dried in this apparatus for three hours at 50° and then the temperature raised to 104° for two hours. A high vacuum (10^{-4} mm.) was maintained throughout. The polymeric preparation represents a hard, colorless transparent substance.

(d) The preparation of this product is described in detail under the heading preparation of poly-carbobenzoxy-lysine (*n* average = 32 carbobenzoxy-lysine units).

Table I shows clearly that the purification of the ε-carbobenzoxy-α-carboxyl-lysine anhydride by recrystallization from ethyl acetate and petroleum ether and the thorough drying of freshly prepared monomer leads on heating to prepara-

TABLE II

ANALYTICAL DATA ON PRODUCTS DERIVED FROM THE CORRESPONDING PREPARATIONS DESCRIBED IN TABLE I, ON REDUCTION WITH PHOSPHONIUM IODIDE

Product	Mg. of element (or group) per 10 mg. preparation: Amino, N	Carboxyl, N	Total, N	C	H	I	Remarks	Mg. group per 100 mg. preparate after hydrolysis: Amino, N	Carboxyl, N
(a′)	5.40	1.120	10.8	28.4	5.3	50.8	Soluble in water	..	...

tions with a small percentage of free amino-N and carboxyl-N. In accordance, Table II shows that products obtained on reduction of the preparations prepared by heating purified and thoroughly dried ϵ-carbobenzoxy-α-carboxy-lysine anhydride, contain small amounts of free lysine. Some of the bulk products, (*cf.* b′c′d′, Table II) obtained on reduction of the corresponding polycarbobenzoxylysine preparations, were totally hydrolyzed by boiling with 20% hydrochloric acid for twenty-seven hours. In the hydrolyzate, practically a quantitative yield of lysine was found.

The loss in weight of highly purified and thoroughly dried ϵ-carbobenzoxy-α-carboxyl-1-lysine anhydride during polymerization was measured. It was found that this loss is equivalent to 98–100% of the theoretical amount of carbon dioxide which could evolve on polymerization.

The presence of amino nitrogen in the preparations described in Table I and the fact that the amino N content of these preparations is considerably higher than that of the corresponding carboxyl-N's seems to indicate that water plays a certain role in the carbon dioxide cleavage of ϵ-carbobenzoxy-α-carboxyl-1-lysine anhydride, and its polymerization.

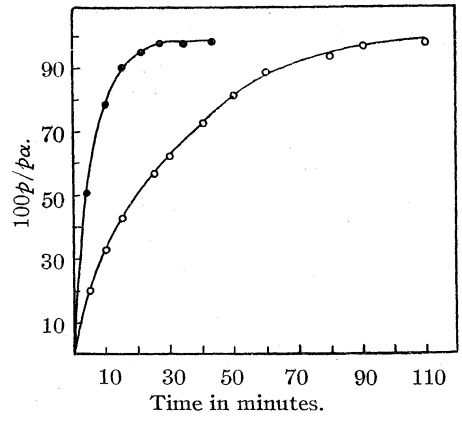

Fig. 1.—Per cent. of theoretical carbon dioxide, evolved on polymerization of ϵ-carbobenzoxy-α-carboxyl-lysine anhydride *versus* time at 102°: ●, monomer kept over water for forty minutes; O, monomer dried over phosphorus pentoxide.

In order to evaluate the role of water in our case, the rate of carbon dioxide evolution of two samples of ϵ-carbobenzoxy-α-carboxyl-1-lysine anhydride containing different amounts of water was measured at 102° (*cf.* Fig. 1).

From these experiments, details of which are given in the experimental part, it became obvious that water acts as a catalyst during the polymerization of ϵ-carbobenzoxy-α-carboxyl-1-lysine anhydride. Catalytic action, but to a smaller extent, was found with methanol. This conclusion is in agreement with the findings of several previous authors,[5] who found that N-carboxyl anhydrides of various amino acids, while relatively stable in dry atmosphere, undergo rapid polymerization when exposed to moist air.

By taking into account the previously discussed precautions, we could obtain poly-carbobenzoxy-lysine polymers and poly-lysines virtually free of monomer and possessing a considerable chain length.

In the following, we describe in some detail the preparation and properties of one such polymer.

ϵ-Carbobenzoxy-α-carboxyl-lysine anhydride recrystallized six times, and dried in high vacuum (10^{-4} mm.) over phosphorus pentoxide at 60° for three hours, in an apparatus equipped with a liquid air trap, yielded on heating to 105° in high vacuum (10^{-4} mm.) for one hour, a transparent glassy hard polycarbobenzoxy-lysine. This polymer is insoluble in water and dissolves in hot glacial acetic acid. It contains free terminal amino groups determinable by Van Slyke's manometric method. Assuming that the above polymer is a mixture of poly-carbobenzoxy-lysine peptides of various chain lengths, an average chain length of 32-lysine units was calculated from the values of free terminal amino-N.

The carbobenzoxy groups of the poly-carbobenzoxylysine (*n* average = 32) were removed by reduction with phosphonium iodide according to the procedure used by Harington and Mead[8]; attempted reductions by the usual catalytic methods were unsatisfactory. Poly-lysine hydriodide (III) thus obtained, is very readily soluble in water, gives positive ninhydrin and biuret reactions, and negative picric acid test. The latter negative test indicated the absence of lysine anhydride in the poly-lysine hydriodide polymer obtained.

By making use of the ninhydrin–carbon dioxide method for determination of free amino acids it was found that (III *n* average = 32) contains a

(8) Harington and Mead, *Biol. Chem. J.*, **29**, 1603 (1935).

very small amount of free lysine (0.2 mg. free lysine per 100 mg. (III)).

Elementary analyses of poly-lysine hydriodide (*n* average = 32) and ratio of amino nitrogen to total nitrogen (found to be 1 to 2) are in agreement with the formula suggested. On hydrolysis, poly-lysine, yields lysine quantitatively.

Independent support for the proposed constitution for poly-lysine hydriodide (*n* average = 32) was obtained by using the procedure worked out by Sanger,[9] who found that 2,4-dinitrofluorobenzene reacts with the free amino groups of α-amino acids, peptides and proteins in the presence of sodium bicarbonate at room temperature with elimination of hydrogen fluoride. The dinitrophenyl-N-bond formed is relatively stable to acid hydrolysis. Thus, in the case of insulin, he was able, after coupling with 2,4-dinitrofluorobenzene and following acid hydrolysis, to isolate and determine quantitatively the 2,4-dinitrophenyl derivatives of those amino acids which in insulin bear the free amino groups.

On coupling poly-lysine hydriodide (*n* average = 32) with 2,4-dinitrofluorobenzene at room temperature, a yellow substance was obtained in almost quantitative yields. The low value of amino N (Van Slyke 0.03%) in the polymer (IV) indicates the blocking of all amino groups by 2,4-dinitrophenyl groups. Dinitrophenyl-poly-lysine (IV) was hydrolyzed in 50% (w/w) sulfuric acid during ten hours. The acid hydrolysate contains the α,ε-di-(2,4-dinitrophenyl)-lysine and ε-dinitrophenyl-lysine. The former is derived from the terminal lysine units of the poly-lysine containing two (α and ε) free amino groups, the latter from the other lysine units containing only one (ε) free amino group.

The α,ε-di-(2,4-dinitrophenyl)-lysine contained in this hydrolyzate was quantitatively extracted with ether, while the ε-2,4-dinitrophenyl-lysine remained in the aqueous acid solution. Both lysine derivatives were purified chromatographically; α,ε-di-(2,4-dinitrophenyl)-lysine by using butanol–chloroform 1% as developing solvent and ε-2,4-dinitrophenyl-lysine by using methyl ethyl ketone–ether (66%) as developing solvent. Water was the stationary phase in both cases. The R values found for α,ε-di-(2,4-dinitrophenyl)-lysine and ε-2,4-dinitrophenyl-lysine obtained from the acid hydrolyzate, were 0.6 and 0.2, respectively, under our conditions. The same values were obtained for the corresponding substances prepared from l-lysine. When each of the 2,4-dinitrophenyl-lysine derivatives, obtained from the polymer hydrolysate, was mixed with the corresponding synthetic substance, and each of the mixtures developed chromatographically by the suitable developing solvent only one yellow band was obtained which in each case showed the characteristic R value.

The quantitative estimations of α,ε-di-(2,4-dinitrophenyl)-lysine and ε-2,4-dinitrophenyl-lysine were carried out colorimetrically according to Sanger. Sanger found that during acid hydrolysis of 2,4-dinitrophenyl derivatives of α-amino acids, partial decomposition occurs. This is taken into account in the evaluation of the amount of the terminal amino acids with free amino groups in the insulin molecule. In order to determine the percentage decomposition of the two dinitrophenyl lysine derivatives, under the hydrolytic conditions applied in the present case, parallel experiments were carried out with the corresponding 2,4-dinitrophenyl-lysine derivatives obtained synthetically. It was found that on boiling with 50% (w/w) sulfuric acid for ten hours, 38% of α,ε-di-(2,4-dinitrophenyl)-lysine and 25% of ε-2,4-dinitrophenyl-lysine were decomposed. After correcting for the decomposition of each of the 2,4-dinitrophenyl-lysine derivatives during hydrolysis of 2,4-dinitrophenyl-poly-lysine, the amounts and ratio between α,ε-di-(2,4-dinitrophenyl)-lysine and ε-2,4-dinitrophenyl-lysine were determined; 4.80 mg. of α,ε-di-(2,4-dinitrophenyl)-lysine, and 98 mg. of ε-2,4-dinitrophenyl-lysine per 100 mg. of 2,4-dinitrophenyl-poly-lysine, were found. The ratio of the two compounds as determined in the hydrolysate was therefore: 31 moles of ε-2,4-dinitrophenyl-lysine per 1 mole of α,ε-di-(2,4-dinitrophenyl)-lysine.

The above data indicate that poly-lysine hydriodide from which the 2,4-dinitrophenyl-poly-lysine was obtained, is built up on the average of 31 lysine units. This conclusion is in satisfactory agreement with the average chain length ascribed to the above poly-lysine hydriodide from the value of the amino-N of the poly-carbobenzoxy-lysine from which it had been derived by reduction.

It must be emphasized, however, that the considerable destruction of both dinitrophenyl-lysine derivatives during hydrolysis on the one hand, and the low amino nitrogen content of poly-carbobenzoxy-lysine on the other, may lead to some uncertainty in the estimation of the average chain length. Nevertheless, the agreement between the two analytical methods justifies, in our opinion, the drawing of a conclusion concerning the order of magnitude of the average chain length of the poly-lysine derivatives synthesized.

From poly-lysine hydriodide (*n* average = 32), the picrate, picrolonate, hydrochloride and benzoyl derivatives were prepared.

An indication for the presence of polymers of various chain lengths was found by carrying out a rough fractionation experiment. Poly-carbobenzoxy-lysine, containing a very small amount of monomeric lysine derivatives, yielded three fractions which differed in terminal amino nitrogen content.

Preliminary enzymatic experiments were carried out with poly-lysine and lysine anhydride. It was found that poly-lysine is split by glycerol

(9) Sanger, *Biochem. J.*, **39**, 507 (1945).

extract of pancreatin as well as by crystalline trypsin. About 50% of the peptide bonds were split. Lysine anhydride is not split by pepsin.

Experimental

Preparation of ϵ-Carbobenzoxy-α-carboxyl-l-lysine Anhydride.—l-Lysine was prepared from the red corpuscles of ox blood according to Rice[10]; from it ϵ-carbobenzoxy-α-carboxyl-lysine anhydride was prepared according to Bergmann, Zervas and Ross.[4] The anhydride was recrystallized several times from ethyl acetate and petroleum ether, and the purified starting material used at once for polymerization experiments. The freshly purified product dissolves readily in ethyl acetate, and its m. p. is 100°.

Estimation of Carbon Dioxide from ϵ-Carbobenzoxy-carboxyl-lysine Anhydride on Heating to 102°.—1.140 g. of twice recrystallized ϵ-carbobenzoxy-α-carboxyl-lysine anhydride dried over phosphorus pentoxide *in vacuo* was kept at 102° for two hours. Carbon dioxide evolution started on melting and a transparent, glassy polymer residue was obtained. The weight of polymer residue was found to be 0.979 g. The weight of carbon dioxide evolved (161 mg.) represents 98.5% of the theoretical.

Rate of Carbon Dioxide Evolution at 102° from ϵ-Carbobenzoxy-α-carboxyl-lysine Anhydride (a) Kept over Phosphorus Pentoxide; (b) Kept over Water.—The rate of carbon dioxide evolution at 102° was measured in an apparatus similar to that described by Hinshelwood.[11] ϵ-Carbobenzoxy-α-carboxyl-lysine anhydride twice recrystallized was dried over phosphorus pentoxide *in vacuo* during two days at room temperature. One sample from the dried preparation was put at once into Hinshelwood's apparatus, the apparatus sealed, and placed in a constant temperature bath at 102°. The rate of carbon dioxide evolution was calculated from the manometric readings of the apparatus.

The second sample of the dried ϵ-carbobenzoxy-α-carboxy-lysine anhydride, weighing 67.85 mg., was put into a desiccator over water for forty minutes. After this period it was found to have gained in weight 0.870 mg. The wet product was put into Hinshelwood's apparatus and the rate of carbon dioxide evolution at 102° measured as above.

A comparison of the rate of carbon dioxide evolution in both cases is given in Fig. 1.

The increase in rate of carbon dioxide evolution in the presence of water may be at least partly explained by the catalytic action of water on the polymerization of ϵ-carbobenzoxy-α-carboxyl-lysine anhydride according to the first step of the general scheme. Nevertheless, it should be borne in mind that water may open the anhydride bond of the N-carboxyl anhydride, and thus lead to carbobenzoxy-lysine with carbon dioxide evolution. Regarding the latter possibility, it should be remarked, that for quantitative transformation of ϵ-carbobenzoxy-α-carboxyl-lysine anhydride into ϵ-carbobenzoxy-lysine, water in an amount of 5.9% of the weight of the anhydride is needed, whereas only 1.3% of water was taken up by ϵ-carbobenzoxy-α-carboxyl-lysine anhydride in our case. The fact that this amount of water is sufficient to shorten the time of cleavage, involving the loss of 95% of the theoretical amount of carbon dioxide in ϵ-carbobenzoxy-α-carboxyl-lysine anhydride, from ninety-five minutes to twenty minutes, justifies the conclusion that water acts under our experimental conditions mainly as polymerization catalyst. This is borne out also by the polymeric properties of the reaction products.

Preparation of Poly-carbobenzoxy-lysine (*n* average = 32 Carbobenzoxy-lysine Units).—The starting ϵ-carbobenzoxy-α-carboxyl-lysine anhydride for the polymerization, was recrystallized six times from ethyl acetate and petroleum ether. The purified product was introduced immediately into a glass vessel connected to an apparatus with phosphorus pentoxide and a liquid air trap and dried in high vacuum (10^{-4} mm.) at 60° for three hours. The temperature was then elevated to 105°; carbon dioxide evolution started at once with the melting of the anhydride. After one hour no further gas evolution was observed; a transparent, glassy hard residue remained in the reaction vessel.

The poly-carbobenzoxy-lysine preparation thus obtained is insoluble in water, ether or toluene. It is soluble in hot glacial acetic acid, and slightly soluble in hot alcohol. Part of the polymer precipitates from its solution in acetic acid on cooling, and from the supernatant solution a further precipitate of polymer may be obtained on adding water.

On heating the mixture of poly-carbobenzoxy-lysine in water with ninhydrin for half an hour, the polymers turn deep blue, while the water remains almost colorless.

The analytical data obtained correspond to a polymer having formula (II) with an average chain length $n = 32$.

Anal. Calcd. for (II) (*n*-average = 32 units): C, 64.0; H, 6.9; N, 10.6; amino N, 0.17. Found: C, 63.9; H, 7.1; N, 10.3; amino N, 0.17. The total nitrogen determinations, in this case as in other analytical data given in this paper, were carried out by the micro Dumas method.

Poly-lysine Hydriodide (*n* average = 32).—One gram of the above poly-carbobenzoxy-lysine (*n* average = 32) was dissolved in 25 ml. of hot glacial acetic acid and the solution kept at 50°, while a stream of dry hydrogen was passed through it; 4 g. of phosphonium iodide was added in portions of about 1 g. during one to one and one-half hours. The reduction of the carbobenzoxy groups was accompanied by a strong evolution of carbon dioxide. During the reduction, the phosphonium iodide dissolved, and a voluminous precipitate formed on the walls of the vessel. At the end of the reaction, the clear liquid was decanted off and the residue washed several times with dry ether and dissolved in 2 ml. of water; to this solution about 5 ml. of absolute alcohol and 70 ml. of ether were added. After standing overnight in the ice box, the supernatant fluid was decanted from the viscous material which had separated out. The latter was then dissolved in several ml. of water, and the solution filtered and evaporated to dryness in a vacuum desiccator over sulfuric acid and sodium hydroxide. The transparent, solid film-like polymer thus obtained was washed several times with ether and dried. It was obtained in almost quantitative yield. Poly-lysine hydriodide was dried in a micro vacuum desiccator over phosphorus pentoxide at 80° before analysis.

Anal. Calcd. for (III) (*n* average = 32): C, 27.7; H, 5.0; N, 10.7; amino N, 5.5; I, 50.2. Found: C, 27.6; H, 5.2; N, 10.7; amino N, 5.3; I, 50.0. The amino N value was obtained after shaking the polymer solution with HNO_2 for five minutes; this value was not altered on further shaking for half an hour.

Poly-lysine hydriodide dissolves very readily in water and its aqueous solution gives a positive ninhydrin reaction and a strong biuret reaction. A negative Abderhalden test was obtained on heating with an alkaline solution of picric acid.

Poly-lysine hydriodide does not dissolve in the usual organic solvents.

Search for Free Lysine in Poly-lysine Hydriodide (*n* average = 32).—The amount of free lysine in the poly-lysine hydriodide described above was determined by the ninhydrin-carbon dioxide method at *p*H 2.5. In 100 mg. of polymer product described in the previous section 0.2 mg. of free lysine was found.

Total Hydrolysis of Poly-lysine Hydriodide (*n* average = 32).—15.9 mg. of dried poly-lysine hydriodide was dissolved in 4 ml. of 20% hydrochloric acid and the solution boiled under reflux for twenty-four hours. The acid hydrolyzate was neutralized with sodium hydroxide and brought to 15 ml.

In 2 ml. of the final solution the amount of carboxyl N was determined by using the ninhydrin–carbon dioxide method[7]; in the other 2 ml., the total free amino N (Van

(10) Rice, *J. Biol. Chem.*, **131**, 1 (1941).

(11) Hinshelwood, *J. Chem. Soc.*, **117**, 156 (1920).

Slyke's manometric method—on shaking half an hour with nitrous acid—was determined. From the data obtained, the total amounts of carboxyl N and amino N in hydrolyzate were calculated. The amount of these groups per 100 mg. starting material are given below.

Anal. Calcd. for hydrolysis of 100 mg. poly-lysine hydriodide (*n* average = 32). Carboxyl-N 5.50 mg.; amino N, 10.60 mg. Found: carboxyl N, 5.4 mg.; amino N, 10.7 mg.; on hydrolysis of 100 mg. of starting material.

The analytical data show that the total amount of amino-N is equal to twice that of carboxyl N and thus indicates the presence of free lysine in the hydrolyzate. Furthermore, it is proved that the starting poly-lysine hydriodide is built up quantitatively of lysine units.

Preparation of 2,4-Dinitrophenyl-poly-lysine.—150 mg. of poly-lysine hydriodide (*n* average = 32) and 3.1 g. of sodium bicarbonate were dissolved in 30 ml. water; 30 ml. of ethanol and 5 ml. of 2,4-dinitrofluorobenzene were then added and the mixture mechanically shaken for two hours. A large excess of 2,4-dinitrofluorobenzene was necessary in order to assure complete coupling of the large number of free amino groups in poly-lysine hydriodide with the 2,4-dinitrophenyl reagent. The yellow precipitate of 2,4-dinitrophenyl-poly-lysine was centrifuged and washed several times with water and ethanol and dried in a vacuum desiccator. 2,4-Dinitrophenyl-poly-lysine is a yellow powder, insoluble in water, alcohol, ether, and glacial acetic acid. It is soluble in concentrated sulfuric acid, and can be precipitated from it by addition of water.

Anal. Calcd. for 2,4-dinitrophenyl-poly-lysine (*n* average = 32): amino N, 0.0; N, 18.9. Found: amino N, 0.03; N, 19.0.

The amino N value found indicates that practically all of the amino groups of poly-lysine reacted with 2,4-dinitrofluorobenzene.

Hydrolysis of 2,4-Dinitrophenyl-poly-lysine; Identification and Estimation of α,ε-Di-(2,4-dinitrophenyl)- and ε-2,4-Dinitrophenyl-lysine Formed.—2,4-Dinitrophenyl-poly-lysine is not hydrolyzed quantitatively in 20% hydrochloric acid even on boiling for extended periods, as clumps of polymer settle to the bottom of the vessel and do not enter into solution. We thus looked for another acid in which the polymer would dissolve more readily before hydrolysis. It was found that total hydrolysis of 2,4-dinitrophenyl-poly-lysine can be carried out in 50% (w/w) sulfuric acid; the following hydrolytic experiment was therefore carried out in this medium.

Twenty mg. of 2,4-dinitrophenyl-poly-lysine was boiled under reflux for ten hours in 20 ml. 50% (w/w) sulfuric acid. After cooling, the solution was extracted five times with ether. The first two ether extracts showed a clear yellow color which could be attributed to the presence of α,ε-di-(2,4-dinitrophenyl)-lysine in the hydrolyzate.

The ether extracts were washed with a small amount of water and the washings returned to the original aqueous solution. The collected ether extracts were reduced to dryness, and passed through an ether column prepared from 2 g. of silica, and again evaporated to dryness, and developed on a 1% butanol–chloroform column. There was a red band that moved rapidly ($R = 1.5$) and a yellow band which moved much more slowly ($R = 0.6$). After repeating the separation between the two bands on a 3 g. of 1% butanol–chloroform column, the red band was decanted and not explored further, as it seemed to represent a breakdown product of hydrolysis. The R of the yellow band was that found for synthetic α,ε-di-(2,4-dinitrophenyl)-lysine prepared from lysine and 2,4-dinitrofluorobenzene. Furthermore, in a parallel hydrolysis experiment, it was found that on mixing the fraction of yellow band with synthetic α,ε-di-(2,4-dinitrophenyl)-lysine, evaporating to dryness and developing with 1% butanol–chloroform one band only with the anticipated R was formed.

The solution of the yellow band is thus identified as the solution of α,ε-di-(2,4-dinitrophenyl)-lysine.

In order to estimate the α,ε-di-(2,4-dinitrophenyl)-lysine formed by the hydrolysis of 2,4-dinitrophenyl-poly-lysine quantitatively, the fraction of yellow band mentioned above was run out, taken to dryness, the residue dissolved in 50 ml. of chloroform and estimated colorimetrically, with a photoelectric absorptiometer after plotting the standard curve of synthetic α,ε-di-(2,4-dinitrophenyl)-lysine in chloroform; 0.596 mg. was found.

The acid solution, after extraction with ether, was diluted to 500 ml. with water, and the sulfuric acid removed quantitatively by means of barium chloride. The precipitate of barium sulfate was filtered off and washed several times with water. The combined filtrate and washings were made up to 1000 ml. A 100-ml. sample from this solution was withdrawn and evaporated to dryness. The residue was passed through a 66% methyl ethyl ketone ether column on silica gel. One yellow band was formed having $R = 0.2$. The same R was obtained when synthetic ε-2,4-dinitrophenyl-lysine prepared according to Sanger was passed through this column, and when the residue from aqueous solution of hydrolyzate, described above, in another hydrolytic experiment, was mixed with synthetic ε-2,4-dinitrophenyl-lysine and the mixture passed through a 66% methyl ethyl ketone ether column. The presence of ε-2,4-dinitrophenyl-lysine in the aqueous solution of hydrolyzate is thus proved.

In order to determine quantitatively the amount of ε-2,4-dinitrophenyl-lysine obtained, the yellow band in the original column was run out, taken to dryness and made up to 50 ml. with *N* hydrochloric acid. The amount of ε-2,4-dinitrophenyl-lysine in this solution was estimated colorimetrically. A total amount of 14.7 mg. of ε-2,4-dinitrophenyl-lysine was found in the 1000 ml. of aqueous solution.

In order to estimate the amount of α,ε-di-(2,4-dinitrophenyl)-lysine and ε-2,4-dinitrophenyl-lysine, decomposing under the conditions prevailing in the hydrolysis of 2,4-dinitrophenyl-poly-lysine, weighed amounts of synthetic α,ε-di-(2,4-dinitrophenyl)-lysine and ε-2,4-dinitrophenyl-lysine were kept in boiling 50% (w/w) sulfuric acid for ten hours. In the first case, the amount of α,ε-di-(2,4-dinitrophenyl)-lysine and in the second case, the amount of ε-2,4-dinitrophenyl-lysine which remained unaffected by the acid were determined as above.

A breakdown of 25% of ε-2,4-dinitrophenyl-lysine and a breakdown of 38% of α,ε-di-(2,4-dinitrophenyl)-lysine were observed under the hydrolytic conditions used.

If the values obtained on the hydrolysis of 2,4-dinitrophenyl-poly-lysine are corrected by the last data for the breakdown of ε-2,4-dinitrophenyl-lysine and α,ε-di-(2,4-dinitrophenyl)-lysine, the following yield from 100 mg. of 2,4-dinitrophenyl-poly-lysine of α,ε-di-(2,4-dinitrophenyl)-lysine and ε-2,4-dinitrophenyl-lysine, are obtained: 4.80 mg. of α,ε-di-(2,4-dinitrophenyl)-lysine and 98.0 mg. of ε-2,4-dinitrophenyl-lysine.

Although as already remarked by Sanger, "the correction may not be strictly valid, as the stability of the derivatives while still condensed in the protein or in peptide split products may not be the same as that found for the derivatives themselves," it seems that at least a good approximation for the real estimation of the two 2,4-dinitrophenyl-lysine derivatives is thus obtained.

It can be seen that 31 moles of ε-2,4-dinitrophenyl-lysine per 1 mole of α,ε-di-(2,4-dinitrophenyl)-lysine was obtained in the hydrolyzate. As pointed out previously, these data are in fair agreement with the suggested structure for poly-lysine hydriodide (*n* average = 32).

Proof for the Practical Absence of α,ε-Di-(2,4-dinitrophenyl)-lysine, in 2,4-Dinitrophenyl-poly-lysine.—In order to prove that the α,ε-di-(2,4-dinitrophenyl)-lysine is derived entirely from the original terminal lysine units of the 2,4-dinitrophenyl polymer, and does not partly originate from the coupling of 2,4-dinitrofluorobenzene with any free lysine monomer in the poly-lysine hydriodide (*n* average = 32), the following experiment was carried out.

A sample of 30 mg. of 2,4-dinitrophenyl-poly-lysine

was dissolved without heating in 10 ml. of concentrated sulfuric acid, 20 ml. of water was slowly added under strong cooling, and the mixture shaken vigorously with ether. No yellow color indicating the presence of α,ϵ-di-(2,4-dinitrophenyl)-lysine appeared in the ether extract.

On the other hand, when a sample of 2,4-dinitrophenyl-poly-lysine dissolved in 50% (w/w) sulfuric acid was boiled for about thirty minutes and the mixture then extracted with ether, the formation of small amounts of α,ϵ-di-(2,4-dinitrophenyl)-lysine due to hydrolysis was apparent from the faint yellow color of the ether extract.

Poly-lysine Picrate.—100 mg. of poly-lysine hydriodide (n average = 32) was dissolved in 2 ml. of hot water, and 2 ml. of hot saturated solution of picric acid added. After standing overnight in the ice box, the yellow picrate was filtered off and washed several times with cold water and ether. Yield was 85% of the theoretical.

The product was thoroughly dried in vacuum desiccator at 100° before analysis.

Anal. Calcd. for poly-lysine picrate (n average = 32): C, 40.5; H, 4.2; N, 19.5. Found: C, 40.1; H, 4.4; N, 19.4.

The picrate is soluble in hot water, slightly soluble in alcohol but insoluble in ether and benzene.

Poly-lysine Picrolonate.—100 mg. of poly-lysine hydriodide (n average = 32) was dissolved in 2 ml. of water, and 5 ml. of hot saturated solution of picrolonic acid in water added. A voluminous precipitate separated at once. After standing overnight in the icebox, the precipitate was filtered and washed several times with water and ether. The material was thoroughly dried in a vacuum desiccator at 100° before analysis.

Anal. Calcd. for polylysine picrolonate (n average = 32): C, 49.0; H, 4.9; N, 21.4. Found: C, 48.6; H, 5.1; N, 21.1.

It is sparingly soluble in water and insoluble in the usual organic solvents.

Benzoyl-poly-lysine.—100 mg. of poly-lysine hydriodide (n average = 32) was dissolved in 2 ml. of water, 400 mg. of sodium bicarbonate added and the mixture cooled to 0°. On further cooling, 0.5 ml. of benzoyl chloride in five portions was added with vigorous shaking. After forty-five minutes, the mixture was acidified to congo red with concentrated hydrochloric acid, and the white precipitate decanted and thoroughly washed with water, alcohol and ether. Benzoyl-poly-lysine was obtained in 80% yield as a white powder. It is soluble in hot glacial acetic acid and concentrated sulfuric acid, but insoluble in ether, alcohol and water. For analysis the polymer was dried in vacuum desiccator at 100°.

Anal. Calcd. for benzoyl poly-lysine (n average = 32): N, 11.86. Found: N, 11.60.

Poly-lysine Hydrochloride.—0.65 ml. of N hydrochloric acid was added to 150 mg. of poly-lysine picrate suspended in 5 ml. of water. The mixture was shaken several times with ether to remove the picric acid liberated. An equal volume of alcohol was then added to the aqueous solution and the mixture dried at room temperature in a vacuum desiccator over sulfuric acid and sodium hydroxide. The remaining hydrochloride was washed several times with dry ether and dried *in vacuo*. The yield was quantitative. The hydrochloride was further dried at 80° *in vacuo* over phosphorus pentoxide before analysis.

Anal. Calcd. for poly-lysine hydrochloride (n average = 32): Cl, 22.3. Found: Cl, 22.0.

Poly-lysine hydrochloride is very soluble in water and gives a strong violet biuret reaction. The ninhydrin reaction is positive, and when heated with an alkaline solution of picric acid, no red coloration is obtained. Polylysine hydrochloride is insoluble in usual organic solvents.

Preliminary Experiment in the Fractionation of a Poly-carbobenzoxy-lysine Preparation.—This experiment was carried out with the material described under Table IC; this preparation contains a very small percentage of carboxyl-N indicating a very small percentage of "monomers." 100 mg. of polymer was dissolved in 5 ml. of hot glacial acetic acid. The solution was allowed to cool and the precipitate (fraction 1) filtered. To the filtrate an equal amount of water was added and the turbid mixture formed allowed to stand overnight in the icebox. The white precipitate (fraction 2) was filtered off and the filtrate concentrated *in vacuo* to dryness (fraction 3). In the three fractions the free amino N (Van Slyke) was determined.

Fraction	Weight of fraction, mg.	Amino N, %
1	18	0.18
2	63	.23
3	19	.30

Discussion

The structure suggested for the polymeric derivatives obtained from ϵ-carbobenzoxy-α-carboxyl-lysine anhydride (*cf.* scheme) calls for proof of the presence of peptide bonds and free α-amino and α-carboxyl terminal groups.

The presence of the assumed –CONH– bonds is indicated by the positive biuret reaction, and proved by the formation of the expected equivalent amounts of α-amino and α-carboxyl groups on hydrolysis of poly-lysine hydriodide. The peptide structure of poly-lysine is also supported by the fact that crystalline trypsin causes cleavage of this polymer. This enzymatic result is in agreement with the findings of Bergmann and Fruton,[12] that a typical trypsin substrate has to contain lysine or arginine residues.

Furthermore, the method of synthesis of poly-lysine and the fact that it yields on hydrolysis lysine quantitatively, leave little doubt that the polymer is built up of lysine residues bound by normal peptide bonds.

The positive ninhydrin reaction in poly-lysine hydriodide and poly-carbobenzoxy-lysine indicates the presence of α-amino groups. The presence of the α-amino end-group in poly-carbobenzoxy-lysine is proved by the Van Slyke manometric amino nitrogen determination, while the presence of the same terminal group in poly-lysine hydriodide is proved by the isolation of α,ϵ-di-(2,4-dinitrophenyl)-lysine from 2,4-dinitrophenyl-poly-lysine. The formation of the terminal groups can be explained by the observed catalytic action of water on the polymerization of ϵ-carbobenzoxy-α-carboxyl-lysine anhydride.

The above facts support our view that the poly-lysine derivatives described in this paper represent mixtures of straight chains of poly-lysine peptides probably of various chain length; nevertheless the presence of high rings in the polymeric mixtures cannot be excluded.

In connection with our previous work on the polycondensation of esters of α-amino acids,[1,2] the absence of diketopiperazine in the product obtained on polymerization of ϵ-carbobenzoxy-α-carboxyl-lysine anhydride is of interest. While

(12) Bergmann and Fruton, "Advances in Enzymology," I, 75 (1941).

the methyl ester of ϵ-carbobenzoxy-lysine yields on heating mainly ϵ,ϵ′-dicarbobenzoxy-lysine anhydride,[3] the corresponding N-carboxyl anhydride yields a polymer without any diketopiperazine. This difference may be connected with the fact that polycondensation of α-amino acid esters proceeds slowly, while the polymerization of the corresponding N-carboxyl anhydrides is rapid. Thus the methyl ester of ϵ-carbobenzoxy-lysine condenses to ϵ,ϵ′-di-carbobenzoxy-lysine anhydride at 105° over a period of several days, while the polymerization of ϵ-carbobenzoxy-α-carboxyl-lysine anhydride is accomplished under the same conditions within an hour.

Summary

ϵ-Carbobenzoxy-α-carboxyl-lysine anhydride (I) when heated to 102–105° evolves carbon dioxide and yields a polymeric preparation to which the structure of poly-carbobenzoxy-lysine (II) is ascribed.

The products of polymerization of (I) obtained under various conditions were studied.

On polymerization of (I) under special precautions, a poly-carbobenzoxy-lysine was obtained with an average chain length of 32-carbobenzoxy-lysine units.

Poly-carbobenzoxy-lysine (II) (*n* average = 32) yields on reduction with phosphonium iodide poly-lysine hydriodide (III) (*n* average = 32).

Poly-lysine hydriodide (*n* average = 32) contains practically no free lysine or lysine anhydride. On hydrolysis it yields lysine quantitatively.

The following derivatives were prepared from (III) (*n* average = 32): picrate, picrolonate, hydrochloride, benzoyl and 2,4-dinitrophenyl-poly-lysine.

The suggested formula for poly-lysine (*n* average = 32) is supported by the analytical data, and by the fact that 2,4-dinitrophenyl-poly-lysine (*n* average = 32) yields the expected amounts of α,ϵ-di-(2,4-dinitrophenyl)-lysine and ϵ-2,4-dinitrophenyl-lysine on hydrolysis.

Independent support for the presence of peptide bonds in (III) is given by its cleavage with crystalline trypsin.

Phosphorylation of Proteins with Phosphoric Acid Containing Excess Phosphorus Pentoxide

BY ROBERT E. FERREL, HAROLD S. OLCOTT AND HEINZ FRAENKEL-CONRAT

When proteins are treated with cold concentrated sulfuric acid, the principal reaction is a transformation of the aliphatic hydroxyl groups to half-esters of sulfuric acid.[2,3] The present study was undertaken in order to determine whether analogous reactions occur when proteins are treated with phosphoric acid containing excess phosphorus pentoxide. Levene and Schormüller[4] had used such a reaction mixture for the preparation of *o*-phosphoric acid esters of serine, hydroxyproline and serine anhydride in small yield, and Plimmer,[5] using the same medium at elevated temperatures, had duplicated their findings and also reported the preparation of *o*-phosphoric acid esters of tyrosine, threonine and isoserine.

In general, the reaction was carried out by permitting a mixture of the material to be treated and the phosphoric acid–phosphorus pentoxide reagent to stand for three days at room temperature in a dry atmosphere (desiccator). The product was isolated by pouring the reaction mixture over cracked ice, neutralizing, and dialyzing, first against ion-free water, then against 10% sodium chloride, and finally against distilled water until free of inorganic phosphates. Recoveries ranged from 70 to 100% based upon nitrogen analyses. The extent of reaction was estimated from the phosphorus-to-nitrogen ratio of the product.

Of the many polar groups in proteins available for reaction, only the aliphatic hydroxyl groups of serine, threonine and hydroxyproline, and to some extent the aromatic hydroxyl group of tyrosine were found to bind phosphorus in a stable manner.[6]

The basic groups and the peptide bonds, however, appear to be responsible for an additional amount of phosphate, retained during dialysis against water but liberated by high salt concentration. Part of the peptide bonds were labile to

(6) This specificity contrasts with the non-specific action of other phosphorylating agents which are known to react with amines, guanidyl compounds, etc., as well as with alcohols and phenols. Mayer and Heidelberger[7] phosphorylated horse-serum albumin in alkaline solution with phosphorus oxychloride. The derivatives contained 2–3% phosphorus, approximately half of which was accounted for by reaction with the amino groups. The reaction of egg albumin under similar conditions was described by Heidelberger, *et al.*[8]

hydrolysis when the lightly bound phosphate was present.

A considerable part of the ester-bound phosphorus was present as metaphosphate.

Reactivity of the Aliphatic Hydroxyl Groups.—That the aliphatic hydroxyl groups of proteins and model polypeptides bind phosphorus is shown in Table I, in which the amount of phosphorus introduced is compared with the β-hydroxyamino acid content. There is, in general, good correlation between the two values, although materials treated ranged in β-hydroxyamino acid content from sericin, which contains 37 equivalents per 10^4 grams (38% serine), to synthetic polypeptides containing none. Further evidence for the reactivity of the hydroxyl groups was the considerable amount of phosphorus bound by polyvinyl alcohol (18%).

TABLE I

COMPARISON OF STABLY-INTRODUCED PHOSPHORUS WITH THE ALIPHATIC HYDROXYAMINO ACID CONTENTS OF PROTEINS AND MODEL SUBSTANCES

	Equivalents per 10^4 g. original material		
	Phosphorus introduced[a]	Sulfate sulfur introduced[b]	Hydroxyamino acids[c]
Sericin	35.8	37.7	37.7
γ-Globulin	14.2	17.3	16.8
Gelatin	15.6	15.2	14.2[d]
Silk fibroin	16.5	16.9	12.8
Isinglass	13.7	13.7	10.2[d]
Bovine serum albumin	9.6[e]	..	10.0
Edestin	9.6[e]	..	9.3
Insulin	8.2	7.9	6.1
Globin	6.0	..	5.2
Gramicidin	6.1	5.9	4.8
Gliadin	7.4	7.9	4.6
Polyglutamic acid	0.2	1.6	..
Polyglutamine	0.3	0.7	..
Nylon	1.2[e]	0.5	..
Tyrosine–formaldehyde polymer	0.4	..	..
Polyglycine	0.8	0.5	..
Crystalline egg albumin	15.5[f]	13.6	10.0
Ovomucoid	16.7[f]	17.5	7.6
Gluten (soluble fraction)[g]	15.8[f]	7.5 (wt. av.)	5.6
Gluten (insoluble fraction)[g]	8.3[f]	..	..

[a] Calculated from the phosphorus-to-nitrogen ratio of the phosphorus derivative and the nitrogen content (dry basis) of the original material. Equivalents phosphorus introduced per 10^4 g. of original material = (% N (orig. material) P/N (derivative) × 100)/14. [b] For comparison, the results of previously reported sulfation experiments with cold concentrated sulfuric acid[2] have been included. [c] These data have been reported previously.[2] The total β-hydroxyamino acid content may be expected to be low by 10% because of the known sensitivity of serine to acid hydrolysis. Also, the method used for their determination yielded recoveries of ammonia corresponding to only about 90% of added serine or threonine. [d] The values 9.5 and 3.4 have been added for the hydroxyproline content of gelatin and isinglass, respectively. [e] In these samples significant amounts (over 10%) of the products were insoluble. Only trace amounts of phosphorus were bound in the insoluble fraction and values given here are for the soluble portion. [f] These derivatives are listed out of the normal order of decreasing hydroxyamino acid content, since they are the proteins known to contain significant amounts of carbohydrate, 26%, 10%, and 3%, respectively, for ovomucoid, gluten, and egg albumin. The role of carbohydrates in the reaction is discussed in the text. [g] Yield, approximately 50% by weight.

The large amounts of phosphorus introduced into gelatin and isinglass were evidence that the hydroxyl group of hydroxyproline was as available for phosphorylation as was that of serine and threonine.

It appears significant in this connection that those proteins that bound amounts of phosphorus in excess of the β-hydroxyamino acids present were generally the same proteins that bound excess sulfate sulfur when treated with concentrated sulfuric acid (Table I).[2] This result may be attributed to the presence of unknown amounts of hydroxyproline, other hydroxyamino acids, or carbohydrate in the proteins. Of these, only the amount of carbohydrate can be determined with any degree of accuracy. The role of carbohydrate is illustrated by ovomucoid (26% carbohydrate), which after phosphorylation was found to contain phosphorus much in excess of the hydroxyl groups present as β-hydroxyamino acids (16.7 equivalents P/10^4 g. as compared to 7.6 equivalents β-hydroxyamino acids).

Other Polar Groups.—The phenolic hydroxyl group appears to react to a limited extent only. Model experiments with tyrosine and *p*-cresol showed that these phenols were phosphorylated to the extent of 38 and 60%, respectively, (as determined colorimetrically with the Folin phenol reagent), after treatment with the phosphoric acid–phosphorus pentoxide reagent. The original chromogenic value was restored by acid hydrolysis. Conversely, a tyrosine–formaldehyde polymer[9] containing free phenolic groups bound only trace amounts of phosphorus. The extent to which the phenolic groups of proteins participate in the reaction was difficult to evaluate. Both insulin and silk fibroin bound phosphorus in excess of their known aliphatic hydroxyl groups. These same proteins had previously been found to bind similarly high amounts of sulfate upon treatment with concentrated sulfuric acid (Table I).[2] In that case, however, model experiments with tyrosine suggested that almost no phenol sulfates were formed with the usual sulfation procedure but only sulfonates, which did not yield sulfate upon hydrolysis. That the extent of phosphorylation of the phenolic groups was small was suggested by colorimetric measurements (Folin) on intact phosphorylated insulin and untreated insulin, which were found to correspond to 8.5 and 9.0% of tyrosine, respectively. The corresponding value for the water-soluble phosphorylated silk fibroin was 6.0% tyrosine, but the fibroin derivative could not

(9) Olcott, in preparation for press.

be compared with the original protein because of the insolubility of the latter.[10]

That the sulfhydryl groups did not react was suggested by the observation that the chromogenic activity (Folin uric acid reagent) of cysteine was not affected when this amino acid was exposed to the phosphorylating mixture. Confirming evidence for the comparative non-reactivity of the sulfhydryl groups was obtained with phosphorylated egg albumin, which, when prepared with special precautions[11] gave a strongly positive sulfhydryl test in the presence of guanidine hydrochloride. Titration indicated that slightly over half of the sulfhydryl groups were still present.

The non-participation of the guanidyl group was indicated with edestin, which contains 9.6 equivalents of guanidyl per 10^4 g. of protein. This protein bound phosphorus only to the extent of its hydroxyl groups (Table I). Further evidence was obtained with methylguanidine sulfate. No phosphorus appeared to be bound by this compound. An attempt was made to use salmine sulfate (approximately 66% arginine) as a further model. Precipitation techniques had to be used for the isolation of these reaction products. Although considerable amounts of phosphorus in excess of its hydroxyl groups were found in reacted salmine, it was possible to show that this excess was due to salt-linked metaphosphoric acid rather than to primary ester linkages (see Experimental).

That the amino group did not participate in the reaction was shown with the tyrosine–formaldehyde polymer (5% free amino nitrogen)[9] which bound almost no phosphate stably (see above). Further evidence was the fact that proteins rich in amino groups bound phosphorus only to the extent of their aliphatic hydroxyl groups, and showed unchanged or slightly increased amino nitrogen values. (Bovine serum albumin gave amino nitrogen values of 7.2 and 8.7% of the total nitrogen, respectively, before and after treatment.)

That the carboxyl group and peptide bond did not contribute to the stable fixation of phosphorus was shown with polyglutamic acid, nylon, polyglutamine and polyglycine. The labile fixation of phosphate by the peptide linkage will be discussed below.

The non-reactivity of the imidazole group was suggested by the fact that globin (approximately 9% histidine) bound phosphorus only to the extent of its hydroxyl groups (Table I).

Evidence that the indole group did not bind phosphorus was obtained with gramicidin which, although it contains almost 40% tryptophan, bound amounts of phosphorus only slightly in excess of its content of hydroxyl groups.

Nature of the Phosphate Bound.—Levene and Schormüller[4] and Plimmer[5] had found that the hydroxyamino acid phosphates prepared by reaction with phosphoric acid–phosphorus pentoxide reagent were acid esters of *o*-phosphoric acid. However, the phosphate bound in proteins and model systems appears to be a mixture of the meta and ortho and possibly other forms. Possibly the low yields obtained by these investigators were due to the presence of similar mixtures in the amino acid reaction products.

The first indication that the phosphate was not entirely in the ortho form was obtained from titration data (Table II). While synthetic monoesters of phosphoric acid and a phosphoprotein obtained from egg yolk[12] required approximately 2 equivalents of alkali for each equivalent of phosphorus present in order to bring a solution from *p*H 2 to *p*H 8, the phosphorylated proteins required only 0.7 to 1 equivalent of alkali under the same conditions.

TABLE II

EQUIVALENTS OF ALKALI REQUIRED TO TITRATE PHOSPHORYLATED PROTEINS AND MODEL SUBSTANCES FROM *p*H 2.0 TO *p*H 8.0[a]

Sample	Equivalents of alkali per equivalent of phosphorus
Phosphorylated polyvinyl alcohol	0.8
Phosphorylated gelatin	1.0[b]
Phosphorylated sericin	0.7[b]
Phosphorylated bovine serum albumin	0.8[b]
Phosvitin[d]	1.9
Sodium pyrophosphate[c]	2.1
Mono ethyl orthophosphoric acid[c]	1.9
Dimethyl orthophosphoric acid[c]	1.0

[a] Titrations were performed in 0.1 *M* potassium chloride. [b] Corrected for the titration of the untreated material over the same range. [c] Commercial preparations. [d] See footnote 12.

These findings were supported by acid group analyses by a dye method.[13] Orthophosphoric monoesters of proteins behave as dibasic acids in fixing 2 dye molecules, as was shown with the naturally occurring phosphoprotein.[12] In the artificial phosphoproteins, however, the acid group increase due to phosphorylation corresponded to only about 70% of the phosphorus, if the latter is

(10) Dispersion of both the phosphorylated and intact silk fibroin (5 mg.) in saturated lithium iodide (0.2 ml.) made a comparison possible by colorimetry immediately after dilution with water; but the accuracy of these analyses was small, since lithium iodide markedly augmented the chromogenic value of the standard tyrosine solution. The results obtained with the known samples were corrected by this apparent excess tyrosine. The tyrosine contents found by this technique were 11.5 and 12.7%, respectively, for phosphorylated and unreacted silk fibroin.

(11) In the first preparation of phosphorylated egg albumin no sulfhydryl groups could be detected. It was suspected that this might be due to the oxidizability of sulfhydryl groups of the denatured protein during prolonged dialysis in neutral solution. In an attempt to eliminate this factor, the reaction was repeated in an atmosphere of carbon dioxide and most of the acid was removed by dialysis without neutralization. The completely insoluble product was washed free of inorganic phosphorus, frozen, and dried from the frozen state *in vacuo* over sodium hydroxide flakes. Ten mg. of phosphorylated protein required 0.3 to 0.4 micromole of *p*-chloromercuribenzoate as compared with 0.7 to 0.8 for unreacted egg albumin for the abolishment of the nitroprusside test.

(12) Phosvitin, a protein containing 10.3% phosphorus; Mecham and Olcott, *Fed. Proc.*, **7**, 173 (1948).

(13) Fraenkel-Conrat and Cooper, *J. Biol. Chem.*, **154**, 239 (1944).

assumed to be present as the dibasic monoester (Table III). Therefore either most of the phosphorus introduced into proteins by this method must be present as the diester, or, more likely, a smaller fraction in an uncharged (presumably the meta ester) form.

TABLE III

APPARENT ORTHOPHOSPHATE CONTENT OF SOME PHOSPHATE DERIVATIVES BY ACID GROUP DETERMINATIONS

Samples	Equivalents per 10^4 g. original material: Acid groups, Derivative	Acid groups, Untreated	Acid groups, Increase	Phosphorus, As ortho	Phosphorus, Total
Phosphorylated bovine-serum albumin	28.8	14.6	14.2	7.1	9.1
Phosphorylated sericin	59.8	15.5	44.3	22.2	32.2
Phosphorylated polyvinyl alcohol	107.0	..	107.0	53.5	127.0
Phosvitin[a]	89.0	5.4	83.6	41.8	39.0

[a] Since phosvitin (footnote 12) is a naturally occurring phosphoprotein, the value of 5.4 acid groups in the untreated material was obtained by a determination on a 90% enzyme-dephosphorylated sample and correcting for the phosphorus still present. The other values for phosvitin are calculated on the basis of this dephosphorylated material.

To support this conclusion by elementary analytical means, polyvinyl alcohol, chosen as a simple model of a polyhydroxy compound, was phosphorylated. Complete analyses were obtained on the product, isolated both as the sodium salt and as the free acid after electrodialysis. The results corresponded to the following empirical formulas (per vinyl unit): $C_2H_{3.40}P_{0.55}Na_{0.379}O_{2.27}$, $C_2H_{3.60}P_{0.485}O_{2.04}$.

The phosphorus content indicated that about half of the vinyl alcohol units had reacted. Since titration data have shown that at *p*H 7.5 (sample neutralized to this *p*H) the ortho fraction is 90% neutralized, *i. e.*, $C_2H_{3.2}PO_4Na_{1.8}$, then the first analysis indicates that about one-fourth of the units contain orthophosphate (or the equivalent of pyrophosphate), one-third contain metaphosphate, and the rest are unreacted. The analysis of the electrodialyzed preparation indicates that about 8% of the hydroxyl groups are orthophosphate esters and about 40% are metaphosphate esters.

Salt-Labile Phosphorus.—The usual method of purifying protein derivatives by extensive dialysis was inadequate for phosphorylated proteins, in that it yielded materials having somewhat variable phosphorus contents, usually much higher than was to be expected from the β-hydroxyamino acid content of the material. In some cases phosphorus was found in model substances having no aliphatic hydroxyl groups (nylon, polyglutamine, polyglycine and tyrosine-formaldehyde polymers). This phosphorus, however, was shown to be only loosely held, since it was readily removed by dialyzing the material for five days against 10% sodium chloride (Table IV).

The results obtained with some model polypeptides (Table IV) suggested that the labile fixation of extra phosphorus might be due to the formation of salt linkages with the basic groups and to an unknown type of linkage at the peptide bond.

TABLE IV

EFFECT OF HIGH SALT CONCENTRATIONS UPON LABILE PHOSPHORUS BOUND BY SOME PROTEINS AND MODEL SYSTEMS[a]

	Equivalents phosphorus/10^4 g. original material: Before salt treatment[b]	After salt treatment[c]
Edestin	68	9.6
Sericin	41	35.8
Bovine-serum albumin	36	9.6
Polyglutamine	58	0.3
Nylon	56	1.2
Polyglycine	20	0.8
Tyrosine–formaldehyde polymer	13	0.4

[a] Dialysis for five days against 10% sodium chloride. [b] These values were not constant but varied markedly with various preparations. [c] Longer dialysis did not change these values significantly.

The participation of the peptide bonds was also suggested by Van Slyke amino nitrogen analyses on samples of phosphorylated bovine serum albumin. A preparation *not* exposed to salt dialysis (containing 36 phosphorus equivalents per 10^4 g.) seemed to contain more amino nitrogen (13.5% of the total nitrogen) than either the salt-dialyzed (8.8%) or the untreated protein (7.2%), even though no loss of nitrogen occurred during either type of dialysis. This finding could be interpreted as indicating that some peptide–phosphate bonds are labile to hydrolysis under the condition of the Van Slyke amino nitrogen analysis. Removal of the phosphate by salt dialysis restores the stability. The situation appears to be analogous to the lability toward dilute acid hydrolysis of proteins that have been exposed to concentrated sulfuric acid for several days.[2] Removal of the labily-bound sulfate by techniques that do not involve exposure to dilute acid avoids the hydrolysis. A plausible interpretation might be that phosphate or sulfate introduced on the peptide bond activates it in some manner so that under certain conditions the peptide bond is split concomitantly with the liberation of the inorganic acid.[14]

Stability of the Phosphate Bond.—A neutral solution of phosphorylated sericin was stable for four months at 4°. The phosphate bond was also stable at *p*H 2.2 and *p*H 11.5 for twenty-four hours at room temperature (23–25°). Exposure of the derivatives to 0.1 *N* hydrochloric acid and 0.1 *N* sodium hydroxide for twenty-four hours resulted

(14) Of interest in this respect is nylon, approximately 20% of which became water-soluble during the phosphorylation. This fraction contained large amounts of labily-bound phosphorus (Table IV). Subsequent salt dialysis not only liberated the phosphorus but split enough of the peptide linkages so that a major portion of the nitrogen was lost through the dialysis membrane.

in the liberation of 5–10% and 20–40%, respectively, of their phosphorus as orthophosphate, while incubation at 40° for twenty-four hours in 1% (0.25 *N*) sodium hydroxide caused the liberation of 60–80% of their total phosphorus as inorganic orthophosphate. Plimmer and Bayliss[15] and Rimington and Kay[16] reported that naturally occurring phosphoproteins were completely dephosphorylated in twenty-four hours at 37° by 0.25 *N* sodium hydroxide. Conversely, Plimmer[5] reported that the hydroxyamino acid phosphate monoesters were completely stable to both *N* hydrochloric acid and *N* sodium hydroxide at 37°.

Gel-Forming Property.—The neutral product of the reaction of wheat gluten with concentrated sulfuric acid possessed the property of absorbing large amounts of cold water rapidly to form gels.[2,3] The insoluble product obtained from wheat gluten and the phosphoric acid–phosphorus pentoxide reagent was also gel-forming but the gels were weaker than those obtainable with sulfuric acid. The hydration capacity[3] (ratio of grams water absorbed per gram gluten product) of the phosphorylated material was about 100 compared to 200–300 for gluten sulfates. Most of the products obtained from other proteins were soluble at neutrality. The insoluble fractions, except for those obtained from wheat gluten, did not form gels.

Specificity.—The observation that the phosphorylation procedure described here is even more specific for the hydroxyl groups of proteins than is sulfation with sulfuric acid suggested that the reagent might be useful for studying the role of the hydroxyl group in biologically-active proteins.[17] However, the reaction conditions are more drastic, with the result that more hydrolysis and denaturation occur. In contrast to sulfated insulin, which retains the biological potency of the untreated protein,[18] a phosphorylated insulin sample had decreased activity.[19]

Experimental

Materials.—Wheat gluten, gelatin, nylon molding powder and crystalline bovine serum albumin were commercial products. Crystalline egg albumin was prepared by the method of Kekwick and Cannan.[20] Sericin was prepared by the method of Rutherford and Harris.[21] The silk fibroin preparation was that portion of the raw silk remaining after four successive treatments with hot water. The sample of gliadin was obtained from D. K. Mecham of this Laboratory, who prepared it by fractional precipitation with alkali from dilute acid solution. Polyglutamic acid was obtained from a culture of a particular strain of *Bacillus brevis* by the method of Bovarnick.[22] The polyamide was synthesized from the peptide and has been characterized previously.[23] Protamine (salmine) sulfate and insulin were kindly furnished by the Eli Lilly Company, isinglass by the Connaught Laboratories, gramicidin by the Wallerstein Company, and edestin by D. M. Greenberg of the University of California. The tyrosine–formaldehyde polymer used was obtained by heating tyrosine with formaldehyde in acid solution.[9] The product contained approximately 5% amino nitrogen, 6.7% total nitrogen.

Phosphorylation Procedure.—Preliminary experiments showed that the following method introduced maximal amounts of phosphorus into proteins: The reagent was prepared by quickly weighing 75 g. of phosphorus pentoxide into a beaker containing 100 g. of 85% orthophosphoric acid and heating the mixture with stirring to dissolve. Ten grams of the cooled reagent was weighed into a small beaker[24] and 100 mg. of finely ground protein was dusted in with stirring to obtain a smooth dispersion. The beaker was then placed in a desiccator over phosphorus pentoxide to react for three days at room temperature.[25] The reaction mixture was stirred several times during the first twenty-four hours to disperse any lumps formed. After seventy-two hours, the viscous reaction mixture was diluted by adding finely crushed ice with vigorous stirring. The diluted mixture was then poured over more cracked ice and neutralized (*p*H 7.5–8.0) with 10 *N* sodium hydroxide, with stirring to prevent local overheating. More ice was added as needed to maintain the temperature at 5–10°. The neutralized mixture was transferred to dialysis tubing and dialyzed against running demineralized water[26] overnight and then against successive changes of distilled water until the dialysate had the same conductivity as distilled water. Some preparations were analyzed at this stage. Others were next concentrated to small volume by placing the dialyzing bags in a stream of warm air, and then dialyzing for five days against 10% sodium chloride solutions to remove all labile phosphorus. The solutions were dialyzed free of salts with distilled water, centrifuged to remove any insoluble material, frozen, and dried *in vacuo* from the frozen state. Soluble portions were either lyophilized or stored in the refrigerator after addition of a few drops of toluene to prevent bacterial action. The extent of reaction was estimated from phosphorus-to-nitrogen ratios.

Analytical Methods.—Nitrogen was determined by the Kjeldahl procedure. Total phosphorus was determined by the Allen[27] method. Inorganic orthophosphate was determined by the method of Lowry and Lopez.[28] Amino nitrogen was determined by the ninhydrin method of Harding and Maclean,[29] and by the Van Slyke manometric procedure (fifteen minutes).[30]

(24) It was found advisable to use freshly prepared acid mixtures each time to prevent solidification during reaction. The composition of such mixtures has recently been elucidated, Bell, cited by Audrieth and Hill, *J. Chem. Ed.*, **25**, 80 (1948). A commercial phosphoric acid preparation containing 83–84% total phosphorus pentoxide is available under the name "phospholeum." The products obtained with this reagent were mostly insoluble (about 70%). The insoluble fractions contained very little phosphorus. The soluble fractions contained amounts of phosphorus similar to those obtained with the reagent prepared as described above (78% phosphorus pentoxide).

(25) Lower percentages of phosphorus pentoxide caused less phosphorus to be bound. Elevated temperatures could not be used to shorten the reaction time because of extensive protein degradation and losses on dialysis. The use of even traces of organic solvents as extenders and aids to dispersion of the protein led to lower phosphorus contents.

(26) Tap water could not be used, since insoluble calcium and magnesium phosphates were formed and most of the protein was rendered insoluble, complicating further purification and analysis.

Tyrosine was determined colorimetrically by Herriott's modification[31] of the Folin method. Total acid groups were determined by a dye technique.[13] Cysteine was determined with the Folin uric acid reagent,[32] protein-SH groups were determined with *p*-chloromercuribenzoate[33] using nitroprusside as an external indicator.

Treatment of Low-Molecular-Weight Materials.—Several amino acids and other materials with molecular sizes too small to permit separation by dialysis were used as model systems. In general, they were handled in one of two ways: by colorimetric analyses performed on the complete, diluted reaction mixture or by measurements on the material isolated by precipitation techniques. Specific methods are cited below.

Phenols.—The reactivity of the aromatic hydroxyl group of tyrosine and *p*-cresol was ascertained as follows: 100 mg. each of tyrosine and *p*-cresol were treated for three days at room temperature with 10 g. of the phosphorylating reagent. Parallel controls (100 mg. each) were treated with 85% *o*-phosphoric acid. The reaction products were diluted with cracked ice and ice water and, in the case of tyrosine, were neutralized by the addition of the necessary amount of sodium hydroxide as calculated by titration of an aliquot to neutrality with brom thymol blue as an indicator. Tyrosine crystallized from the control solution. The diluted *p*-cresol reaction mixture had oily droplets present, hence alkali was cautiously added until these droplets were in solution. An aliquot was then titrated to neutrality and the main solution adjusted with the calculated amount of alkali. Colorimetric measurements on these solutions showed that the chromogenic values for phosphorylated tyrosine and *p*-cresol were reduced by 38 and 60%, respectively, while that for the *p*-cresol control (treated with 85% phosphoric acid) was not affected. Hydrolysis in 6 *N* hydrochloric acid at 120–125° for eighteen hours regenerated the full chromogenic activity.

Cysteine.—To ascertain whether the sulfhydryl group was phosphorylated, the amino acid cysteine was treated as follows: 100 mg. of cysteine hydrochloride was introduced into 10 g. of the phosphoric acid–phosphorus pentoxide reagent and 100 mg. was introduced into 10 g. of 85% orthophosphoric acid and run parallel as a control. The samples were allowed to react for three days at room temperature in a desiccator and then diluted with cracked ice and brought to a volume of 100 ml. with water. Nitrogen and cysteine determinations on aliquots of these solutions showed that the sulfhydryl group had not reacted.

Salmine Sulfate.—500 mg. of salmine sulfate was treated for three days with the regular phosphorylating mixture. Since it could not be dialyzed, the reaction mixture was poured into cold acetone. The water-insoluble precipitate was repeatedly dissolved in *M* sodium chloride and reprecipitated as an oil by addition of distilled water until there was no free phosphate in the supernatant fluid. The final material contained considerable quantities of phosphorus in excess of its hydroxyl groups (30.4 equivalents as compared to 4.3 equivalents per 10^4 g.), not present as free orthophosphate. However, indications were obtained that the phosphorus was present in a labile form, possibly as a salt of a metaphosphoric acid. That this explanation is a plausible one was shown with the ortho- and metaphosphoric acid salts of protamine. These were prepared by quantitatively removing the sulfate from solutions of protamine sulfate with the calculated equivalent amount of barium hydroxide and neutralizing the resulting free base with ortho- or metaphosphoric acids. The resultant orthophosphate salt showed solubility characteristics different from those of the treated material and all of its phosphorus could be determined as inorganic orthophosphate. Conversely, the meta salt had the same solubility characteristics and the same phosphorus content as the phosphorylated material, and its phosphorus could not be determined as inorganic orthophosphate.

(31) Herriott, *J. Gen. Physiol.*, **19**, 283 (1935).

(32) Anson, *ibid.*, **24**, 399 (1940).

(33) Hellermann, Chinard and Dietz, *J. Biol. Chem.*, **147**, 443 (1943).

In the light of these findings it was necessary to ascertain that the metaphosphate ion was quantitatively removed from typical proteins by our technique of dialysis against salt solution. To this end the meta salt of bovine serum albumin was prepared by acidifying a solution of the protein to *p*H 3.0 with dilute metaphosphoric acid and separating the precipitate. The 3.3% phosphorus originally present was completely removed by salt dialysis.

Methylguanidine Sulfate.—A 500-mg. sample of methylguanidine sulfate was treated in the usual manner and isolated by diluting the reaction product with approximately 4 volumes of cold acetone and pouring this diluted mixture into sufficient saturated barium hydroxide solution to keep the final mixture alkaline to brom thymol blue. The precipitate was separated and washed three times by centrifugation. Carbon dioxide was bubbled through the combined supernatants to remove excess barium. The suspension was then filtered and concentrated to a small volume. The extent of reaction was measured by nitrogen, total phosphorus, and inorganic orthophosphate determinations. No bound phosphorus was present.

Serine and Threonine.—Although the isolation in low yields of the orthophosphate esters of serine and threonine has been reported,[4,5] repeated attempts to obtain such preparations in a pure state, either by the methods previously described or by variations in the techniques of phosphorylation and isolation were unsatisfactory.

Titration Method.—The following titration method was used for the estimation of the amount of orthophosphoric acid monoester present in the phosphorylated proteins: A sample of the phosphorylated protein of suitable size to contain approximately 100 mg. original protein (calculated from nitrogen content) was placed in a 100-ml. beaker and water was added to give a volume of 18 ml. To prevent salt concentration changes from materially affecting the results, 2 ml. of *M* potassium chloride was added to make the solution 0.1 *M* with respect to salt. It was then adjusted with *N* hydrochloric acid to *p*H 2.0 as measured with a line-operated continuous-indicating *p*H meter. 0.1 *N* sodium hydroxide was then added in 0.20-ml. portions from a 5-ml. buret (graduated in 0.02 ml.) and the *p*H recorded after each addition. A titration blank was made in the same manner on an equal sample (based on nitrogen) of the untreated protein. Titration curves were prepared by plotting the equivalents of sodium hydroxide required per gram of original material against *p*H. The amount of alkali required to titrate from *p*H 2.0 to *p*H 8.0, as determined from the curve and corrected for the titration blank value, was used to determine the molar ratio of sodium consumed to phosphorus present. This value can be used then as an approximate measure of the amount of phosphorus present in the sample in the form of *o*-phosphoric acid monoester (for orthophosphate monoesters the theoretical value is 2.0). Sodium-to-phosphorus ratios for our preparations varied from 0.7 to 1.0 (Table II).

Stability.—A solution of phosphorylated sericin was stored for four months at 4° with toluene present to prevent bacterial action. It was then dialyzed against three changes of distilled water. The phosphorus-to-nitrogen was the same as that of the original derivative.

Stability at *p*H 2.2 and 11.5 was determined by adding 5 ml. of *p*H 2.2 citrate and *p*H 11.5 phosphate buffers[13] to 5-ml. samples of phosphorylated protein solutions and dialyzing the solutions against 100 ml. of the respective buffers for twenty-four hours at room temperature. The samples were then dialyzed against 10% sodium chloride for five days and finally against distilled water until the conductivity of the dialysate was equal to that of distilled water. Phosphorus-to-nitrogen ratios of the products permitted an estimate of the stability of the phosphate bonds.

Inorganic orthophosphate determinations were used to measure the extent of liberation of phosphorus in samples exposed to 0.1 *N* or stronger acid and alkali, since these conditions caused marked protein degradation leading to low nitrogen recoveries upon dialysis. Solutions of the

materials to be treated were introduced into 50-ml. Erlenmeyer flasks, and an equal volume of 0.2 *N* hydrochloric acid, 0.2 *N* sodium hydroxide, or 2% sodium hydroxide were added. The flasks were stoppered and held for twenty-four hours at room temperature in the case of the 0.1 *N* acid and alkali and at 40° in the case of the 1% sodium hydroxide. The samples were then neutralized with an equivalent amount of alkali or acid, and inorganic orthophosphate determinations were made on aliquots of the solutions.

The data obtained included only a part of the inorganic metaphosphate that may have been liberated. Control experiments with sodium metaphosphate indicated that 0.1 *N* sodium hydroxide and hydrochloric acid hydrolyzed only 11 and 22%, respectively, to orthophosphate at 23° in twenty-four hours; 28% was converted by 1% sodium hydroxide at 40° in the same length of time.

Summary

Proteins reacted with phosphoric acid containing excess phosphorus pentoxide (78% total phosphorus pentoxide) for three days at room temperature. After neutralization and dialysis, the products contained considerable amounts of phosphorus, much of which could be removed by dialysis against 10% sodium chloride solution. The remaining stably-bound phosphate was found to be present as esters of ortho- and metaphosphoric acids on the hydroxyl groups of the serine, threonine, and hydroxyproline residues. Possibly part of the phenolic hydroxyl groups, but probably no other type of protein group, participate in the stable fixation of phosphate.

The stability of the protein phosphate bonds in neutral and dilute acid and alkaline solutions has been determined.

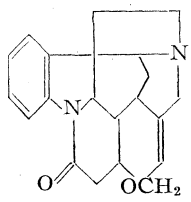
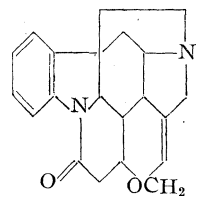
The Structure of Strychnine. Formulation of the *Neo* Bases

BY R. B. WOODWARD AND WARREN J. BREHM

Some years ago we were led to the view that strychnine was best represented by the expression[1] (I), rather than that (II) generally accepted at that time.[2] We considered *i.e.*: (i) that (I) was preferable on biogenetic grounds[3]; (ii) that (I) contains the skeletons of the main products of the drastic degradation of strychnine, *viz.*, tryptamine,[4] carbazole[5] and in particular, β-collidine,[4b,6] while the last could be formed from (II) only by rearrangement; (iii) that in any event little direct evidence was available concerning the mode of attachment of N^b to the carbazole ring.

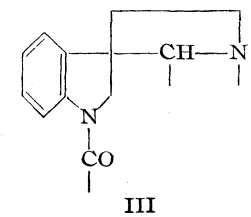


I



II

Since we have recently been able to provide evidence that the part structure (III) is present in the strychnine molecule,[7] only one major barrier



III

has remained in the way of the final acceptance of the expression (I) for strychnine. It will be clear that many of the reactions of the alkaloid will be as readily interpretable on the basis of (I) as of (II).[8] On the other hand, the acceptance of (I) has definite consequences in respect to the formulation of the *neo* series of strychnine derivatives, and the previous knowledge of the reactions of the *neo* bases has indicated strongly that these consequences did not obtain. In this communication, we describe experiments which provide conclusive proof in favor of particular expressions for relevant portions of the molecules of the *neo* bases, and show that the expressions derived are those to be expected if strychnine be formulated as (I).

The first of the *neo* bases, methoxymethyldihydro*neo*strychnidine, $C_{21}H_{24}ON(NCH_3)(OCH_3)$, was formed when strychnidine methosulfate was treated with methyl alcoholic potassium hydrox-

(1) This structure was proposed and discussed at length in the lectures by the senior author on the Chemistry of Natural Products during the summer term of 1944. It was discussed with Sir Robert Robinson in August of 1945, and since that time, investigations have been proceeding independently in the Oxford and Harvard Laboratories with the objective of final clarification of the structural situation. Professor Robinson has very generously kept us informed from time to time of the more important results of his program through private communications, and we in turn have let him know of ours.

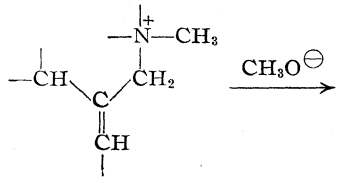
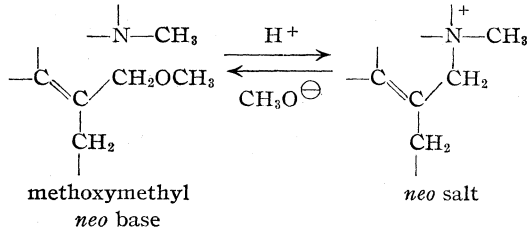
(8) A review of the enormous literature on the subject is outside the scope of this paper. An outline of the main facts is given in Henry's "Plant Alkaloids" (Blakiston's Son, 1939) and an excellent and very complete review by Professor H. L. Holmes will appear in the first volume of the forthcoming series of monographs on alkaloids, to be published by the Academic Press under the general editorship of Dr. R. H. F. Manske.

ide.[9] On boiling with dilute acids, the methoxy group of the new base was lost, and a new quaternary salt, isomeric with the original strychnidinium derivative, was formed.[9,10] The chloride of the new series, methyl *neo*strychnidinium chloride, lost methyl chloride on pyrolysis with the formation of *neo*strychnidine, an isomer of strychnidine.[9,10] Further, the methyl *neo*strychnidinium salts, on treatment with methyl alcoholic potassium hydroxide, were reconverted to the same methoxymethyldihydro*neo*strychnidine from which they were formed.[9,10] Subsequently, exactly parallel transformations were effected in the strychnine series,[11] and the important observations were made that *neo*strychnidine[10] and *neo*strychnine[11] could be reduced catalytically to dihydro derivatives identical with those obtained by the hydrogenation, respectively, of strychnidine and strychnine.[12]

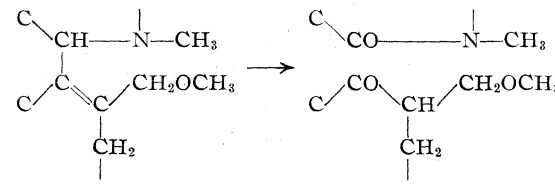
From these observations, it was clear that in the formation of the *neo* bases, no rearrangement of the carbon skeleton had occurred, and that the double bond of the normal series had migrated to a new position. Further, the cleavage of the quaternary salts of both series, as well as the ready reconstitution of the quaternary salts of the *neo* series, was explicable if the double bond present were assumed to be in the β,γ (*i. e.*, allylic) position with respect to the quaternary nitrogen atom, and the fundamental changes outlined above were formulated in this sense





Support for this view was found in the relatively sluggish cyclization (to quaternary salts) of those methoxymethyl derivatives in which the double bond had been saturated.[13]

The validity of this scheme was challenged by facts which emerged from the further study of methoxymethyldihydro*neo*strychnine. It was found that the latter was converted by perbenzoic acid in excellent yield, with addition of two oxygen atoms, to a *neutral* oxidation product (named methoxymethyl*chano*dihydrostrychnone) containing a carbonyl group. It was clear that the new substance contained the group $-N^b-CO-$, and its formation was assumed to involve the change[13,14]:



When methoxymethyl*chano*dihydrostrychnone was reduced by the Clemmensen method, the oxygen atom of its carbonyl function appeared to be replaced by two hydrogen atoms, and a new substance, methoxymethyl*chano*dihydrostrychnane, was formed, which on Kuhn–Roth oxidation gave one mole of acetic acid.[15] This fact was explained by assuming that the new methylene group ($C-CH_2-C$) appeared as acetic acid during the Kuhn–Roth procedure; the assumption was hardly tenable in view of the fact that no such change had been observed even in more likely cases.[16] The simple inference from the above facts was that methoxymethyl*chano*dihydrostrychnone contained an aldehyde group (thus, $-\overset{|}{C}-CHO \longrightarrow -\overset{|}{C}-CH_3$), and although negative evidence was brought forward against that view,[13] no really convincing formulation of the substance was advanced; the recent demonstration[17] that the double bond in the *neo* series is adjacent to N^b served only further to compound the difficulty of the matter.

We turn now to a consideration of the structure of the *neo* bases in the light of the new strychnine

(11) Achmatowicz, Clemo and Perkin, *ibid.*, 767 (1932).
(12) *Neo* bases have been prepared by other methods, of less structural interest, but of more preparative value. Kotake and Yokohama (*Sci. Papers Inst. Phys. Chem. Res. Tokyo*, **31**, 321 (1937)) isomerized strychnine to *neo*strychnine by heating with selenium. Recently Robinson and Chakravarti (*J. Chem. Soc.*, 78 (1947)) have confirmed Kotake's observation, and have shown that the strychnos alkaloids are smoothly converted to the corresponding *neo* isomers when heated in xylene in the presence of Raney nickel. This elegant method makes the *neo* bases readily accessible in quantity for the first time.

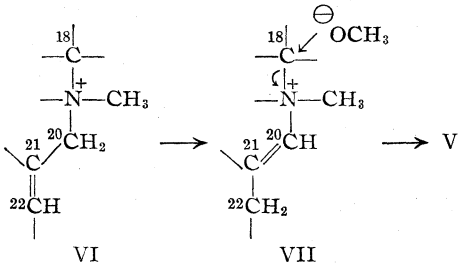
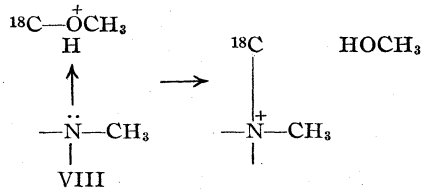
formula (I). It may be deduced at once that only one likely position is available for the double bond in the *neo* series if (I) be accepted.[18] Steric considerations prohibit the placement of unsaturation at Δ^{14-21}, Δ^{13-14}, Δ^{14-15}, or Δ^{15-16}, and no reasonable path is available for the migration of a double bond from Δ^{21-22} to Δ^{8-13} or Δ^{17-18}. Only Δ^{20-21} remains, and on the basis of (I), *neo*strychnine must be represented as (IV).

If *neo*strychnine be (IV), the views outlined above in connection with the formation of the methoxymethyl derivatives must be abandoned. An alternate scheme is available in the following terms: (i) the double bond of the methyl strychninium salt (VI) migrates into juxtaposition with the quaternary nitrogen atom[19] (*cf.* VII); (ii)



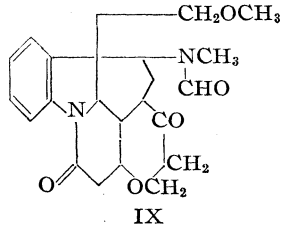
VI VII

the double bond in the new position facilitates[20] a direct bimolecular cleavage reaction (S_N2) involving attack by methoxide ion at C.18 (VII, arrows) to give (V).[21] The greater ease of reconstitution of quaternary salts from the unsaturated, as compared with the saturated methoxymethyl derivatives must be attributed to the lowering of the basicity of N^b in the former by the adjacent double bond. Thus the attack of N^b on C.18, with release of methyl alcohol (VIII, arrows) will be more or less facile as a smaller or greater proportion of the molecules contain a proton attached to N^b.



VIII

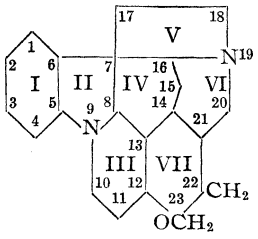
Ample analogy is now available[22] for the cleavage $-\overset{|}{N}-\overset{|}{C}=\overset{|}{C}- \longrightarrow -\overset{|}{N}-\overset{|}{C}O\ O\overset{|}{C}-$ by perbenzoic acid, and if (V) be methoxymethyldihydro*neo*strychnine, the expression (IX) must be accepted for methoxymethyl*chano*dihydrostrychnone. The facts hitherto available could only with the greatest difficulty be so construed as to commend this



IX

view. On the one hand it was necessary to assume that a formamide system survived boiling for twenty-eight hours with concentrated hydrochloric acid[15] (in the Clemmensen reduction of the strychnone), as well as heating for four hours with concentrated methyl alcoholic barium hydroxide[13]

(18) The following numbering of the strychnine skeleton is used in the sequel, and we should like to propose that it be adopted generally. Following general practice contiguous rings are numbered consecutively; the particular choice adopted has the distinct menmonic advantage that the designations of rings, V, VI and VII are identical with the respective ring sizes. The atoms have then been numbered consecutively, beginning with ring I, *etc.*



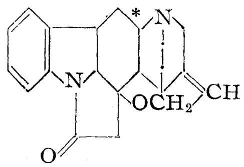
(19) The change is formally analogous in some respects to the well-known shift $-\overset{|}{C}=\overset{|}{C}-\overset{|}{C}H-\overset{|}{C}O \longrightarrow -\overset{|}{C}H-\overset{|}{C}=\overset{|}{C}-\overset{|}{C}O,$ since the carbon atom of —CO bears a considerable formal charge. On the other hand, the first order conjugation effects present in the carbonyl system cannot be operative in the case described above, since $\equiv N^+$ is saturated. However, it may not be doubted that the positive charge in $-\overset{|}{C}=\overset{|}{C}-\overset{|}{C}H-\overset{+}{N}\equiv$ will facilitate the first step in the process, *viz.*, proton release from C*; the operation of the same effect is seen in the very ready elimination of hydrogen bromide from $BrCH_2CH_2N^+(CH_3)_3$ (Renshaw, THIS JOURNAL, **34**, 1618 (1912); Schmidt and Bode, *Ann.*, **267**, 311 (1892)).

(20) No relevant information is available for analogous simple unsaturated systems. However, it is abundantly clear that in the case in which a phenyl group replaces the C.20–C.21 double bond of (VII), cleavage analogous to that outlined above takes place with particular ease (von Braun and Seemann, *Ber.*, **55**, 3820 (1922); *cf. Ann. Rep. Chem. Soc.*, 103 (1920) for collected references to v. Braun's results). Cases strikingly analogous to that discussed above were studied by Vorländer and Spreckels (*Ber.*, **52**, 309 (1919)), who showed that the change $C_6H_5N^+R_3 + {}^-OEt \longrightarrow C_6H_5NR_2 + ROEt$ was readily brought about when the quaternary salt was heated with sodium ethoxide in ethanol for a few hours. Further, the ease of these reactions has a sound basis in theory, in that the breaking of the C—N bond will be facilitated as the environment of the nitrogen atom is such that the latter more readily accepts the released electron pair. The low basicity of nitrogen atoms attached to double bonds, and the ultraviolet absorption characteristics of such systems (*cf.* Bowden, Braude, Jones and Weedon, *J. Chem. Soc.*, 50 (1946)) are attributable to the same effect, which has its origin in the resonance $-\overset{|}{C}=\overset{|}{C}-\overset{|}{N}- \longleftrightarrow -\overset{|}{C}-\overset{|}{C}=\overset{|}{N}-$

(21) There is no direct evidence bearing on the point of attachment of the methoxyl group. It seems probable that a bimolecular substitution reaction of the type outlined above would take place most readily at C.18, which is primary, and possibly otherwise less hindered, than the alternative position (C.16). In any event, the point has no special relevance in connection with the demonstration which follows.

(22) Witkop, private communication. Dr. Witkop has made available to us a proof copy of a communication by himself and Fiedler which was submitted in 1946 for publication in the *Annalen;* we have been unable to determine whether it has appeared. In it the very smooth oxidation of a series of indole derivatives to *o*-acylaminophenyl ketones by perbenzoic acid is described.

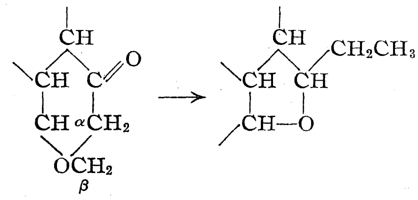
(in the transformation of methoxymethyl*chano*-dihydrostrychnane to the corresponding strychnanic acid, *by cleavage of the* N^a *lactam link*). On the other hand, the presence of the group $-\overset{|}{\underset{|}{C}}-CH_3$ in the Clemmensen reduction product of the strychnone suggested that the carbonyl group of the latter was present as $-\overset{|}{\underset{|}{C}}-CHO$. The obvious inference from these facts was that the *neo* bases contained $-\overset{|b}{N}-\underset{\underset{C}{|}}{C}=CH-C$ and indeed, these, taken with other considerations, led recently to the proposal of a strychnine formula (X) which permitted this feature[23] (double bond at * in the *neo* series).



X

We have now subjected these substances to further study. Methoxymethyl*chano*dihydrostrychnone was converted by ethyl mercaptan in the presence of hydrochloric and acetic acids to the corresponding mercaptal $\left(-\overset{|}{C}=O \longrightarrow -\overset{|}{C}(SEt)_2\right)$. Removal of the mercapto groups by treatment in alcohol with Raney nickel $\left(-\overset{|}{C}(SEt)_2 \longrightarrow -\overset{|}{C}H_2\right)$ gave a substance, $C_{23}H_{30}O_4N_2$, m. p. 136–139°, different from, but isomeric with methoxymethyl*chano*dihydrostrychnane (m. p. 163°). *The new compound contained no* $-\overset{|}{\underset{|}{C}}-CH_3$ *group.*

It is now clear that methoxymethyl*chano*dihydrostrychnone contains the group $C-\overset{C}{\overset{|}{C}}=O$, and that the formation of methoxymethyl*chano*dihydrostrychnane[24] must be accompanied by rear-



XI XII

rangement. It is not difficult to envisage the nature of this change. Thus, in the part structure (XI), present in the strychnone, the opportunity exists for: (i) reductive cleavage of the ether linkage in the reactive β-position to a carbonyl group (this change may well proceed through β-elimination, followed by reduction of the resultant α,β-unsaturated carbonyl system); (ii) reduction of $-\overset{|}{C}=O$ to $-\overset{|}{C}HOH$; (iii) ether formation involving the two hydroxyl groups formed in (i) and (ii). The strychnane, then, contains the part structure (XII), and the presence of $-\overset{|}{\underset{|}{C}}-CH_3$ no longer constitutes a problem.

We turned next to an examination of the nature of the amide function in methoxymethyl*chano*dihydrostrychnone. Since this compound undergoes deep-seated changes in the presence of acid or base, it seemed unlikely that the isolation or characterization of simple hydrolysis products would be possible. (We attribute these changes to the presence of the labile system $-COCH_2CH_2O-$, which can readily suffer elimination, with the formation of the very reactive grouping $-COCH=CH_2$). Consequently, we studied the behavior with hydrolytic reagents of (*a*) methoxymethyl*chano*dihydrostrychnane, (*b*) desoxomethoxymethyl*chano*dihydrostrychnone, m. p. 136–139°, from the Raney nickel desulfurization (see above), and (*c*) a dihydroderivative $\left(-\overset{|}{C}=O \longrightarrow -\overset{|}{C}HOH\right)$ m. p. 225–226°, obtained by the catalytic hydrogenation of the strychnone. As might have been expected from earlier work with the strychnane, none of these substances liberated formic acid even on prolonged treatment with concentrated bases. On the other hand, *each of them readily gave exactly one mole of formic acid on hydrolysis with 2N sulfuric acid.* After hydrolysis of methoxymethyl*chano*dihydrostrychnane ($C_{23}H_{30}$-

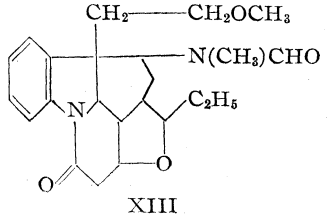
(23) Robinson, *Nature*, **159**, 263 (1947). The supporting evidence involved the formation from the *neo* bases of oxidation products containing one additional oxygen atom by the action of bromine and water. The products are basic, and contain a carbonyl group; the change was assumed to be $-\overset{|}{N}-\underset{|}{C}=CH-C \longrightarrow -\overset{|}{N}-\underset{|}{C}H-CO-C$. In a still more recent note, Robinson and Chakravarti (*Nature*, **160**, 18 (1947)) indicate that the substances are aldehydes, and that a rearrangement accompanies their formation. The opinion is further expressed that while the new evidence does not exclude the structure (X) (presumably in view of the possibility $-\overset{|}{N}-\underset{\underset{C}{|}}{C}=CH-C \longrightarrow -\overset{|}{N}-\overset{C}{\overset{|}{\underset{\underset{C}{|}}{C}}}-CHO$), it removes the necessity for its proposal in so far as the oxidation reaction is concerned (since $-\overset{|}{N}-CH=\overset{|}{C}-$ is transformable with rearrangement to $-\overset{|}{N}\ \ OHC-\overset{|}{C}-$). In these circumstances, Robinson and Chakravarti, as "the best hypothesis to guide future work," revert to the expression (I), which for some years has been under consideration independently in the Harvard and in the Oxford laboratories.

(24) Actually the new substance, m. p. 136–139°, now properly deserves this name, but the adoption of the change would create unnecessary confusion. Consequently, we propose the designation desoxomethoxymethyl*chano*dihydrostrychnone for the new isomer.

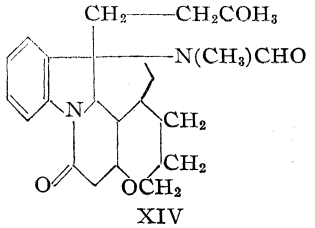
O_4N_2), the corresponding base, $C_{22}H_{30}O_3N$, m. p. 86–86.5° was isolated. In view of the special circumstances *vis-a-vis* the stability of $-\overset{|b}{N}-CO$ in these substances, it was necessary to eliminate the possibility that the formic acid owed its origin to an acid-catalyzed rearrangement (*e. g.*, of an α-hydroxy (*or* alkoxy) amide). This was done by formylating the above base, m. p. 85–86°, through treatment with anhydrous formic acid and acetic anhydride. The formylation product was identical in all respects with methoxymethyl*chano*dihydrostrychnane.

These facts are explicable only if in all of these compounds the presence of the group $-\overset{|b}{N}-CHO$ be accepted. The marked resistance to alkaline cleavage must be attributed to steric hindrance of the approach of hydroxide ion (models indicate the plausibility of this view), while the stability under the strongly acid conditions of the Clemmensen reduction is probably a consequence of the relatively low activity of water in highly acid and concentrated salt (in this case zinc chloride) solutions.[25]

Taken all together our new observations provide conclusive proof of the presence of $-\overset{|b}{N}-CH=\overset{C}{\overset{|}{C}}-C$ in the *neo* bases; we may now assign with confidence the structures (IV), (V), (IX), (XIII) and (XIV),[21] respectively, to *neo*strychnine, methoxymethyldihydro*neo*strychnine, methoxymethyl*chano*dihydrostrychnone, methoxymethyl*chano*dihydrostrychnane and desoxomethoxymethyl*chano*dihydrostrychnone. Since these are precisely the expressions required by the structure (I) for



XIII

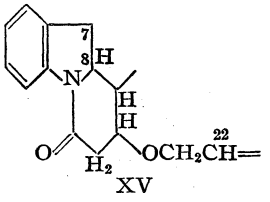


XIV

strychnine, it is clear that the last major barrier in the way of the acceptance of (I) has collapsed.

(25) In any event, the slowing down of amide hydrolysis as the acid concentration is increased beyond a certain point appears to be a general phenomenon. *Cf.* Hammett, "Physical Organic Chemistry," p. 365 (McGraw-Hill Book Co., Inc., 1940). Further it should be mentioned that the formamide link of the strychnane is not completely stable under the above conditions, since we have been able to isolate some of the base $C_{22}H_{30}O_3N_2$ from Clemmensen reduction reaction-mixtures.

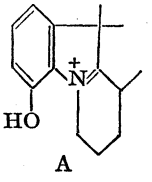
It is therefore now pertinent to examine the general situation in order to determine whether the formula (I) represents a necessary as well as a sufficient solution to the structural problem. We take as the basis for the structural discussion the expression (XV), which follows from (i) the presence in strychnine of an *o*-substituted N-acylaniline system[8]; (ii) Robinson's deduction, from the Leuchs degradations, of the nature of ring III and of the presence of the chain $-OCH_2CH=$ at C.12[26]; (iii) the presence of a dihydroindole sys-



XV

tem, suggested by a number of independent lines of evidence,[8] and definitely confirmed by our recent elucidation of the changes accompanying the formation of strychnone.[7] We now examine evidence which necessitates the elaboration of three independent chains of atoms, each of which originates at N^b and terminates at some atom of (XV): (*a*) the nature of the changes involved in the formation of strychnone requires[7] that in strychnine the β position of the dihydroindole ring be linked by a methine bridge to N^b; (*b*) the formation of tryptamine by the alkaline degradation of strychnine necessitates a chain of two carbon atoms between C.7 and N^b. *We make the reasonable assumption that this chain bears four hydrogen atoms*[27]; (*c*) the results of the present

(26) Robinson, *Proc. Roy. Soc.* (*London*), **130**, 431 (1931). The original demonstration did not include the placing of a hydrogen atom at C.8 but, subsequently, Briggs, Openshaw and Robinson (ref. 17, footnote, p. 903) deduced the presence of this feature through the formulation of one of the colorless benzal derivatives of the (*iso*) strychnine series as an (11-) benzyl α-pyridone. Further, the formation of strychnone (ref. 7) requires a hydrogen atom either at C.7 or C.8, and the lack of reactivity toward bromine of diketonucidine (ref. 2) provides evidence against C.7. We reach a similar conclusion through a consideration of certain changes in the vomicine series (part formulation of the salts of the catalytic hydrogenation products from desoxyvomicidine, isovomicidine and dihydrodesoxyvomicidine (Wieland and Huisgen, *Ann.*, **556**, 161, 166 (1944)) as (A)–note



A

that the typical color reactions of the *o*-aminophenol system are not given by these bases with oxidizing agents in weakly acid solution!).

17 18

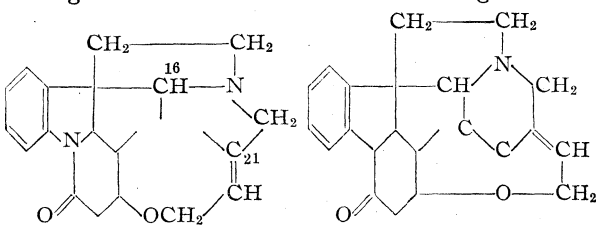
(27) The presence of such a chain ($-CH_2CH_2-$) has been accepted generally (*cf.* ref. 8). No conclusive direct proof of that feature is available but it may be considered unlikely that tryptamine (ref. 4) would be a product of degradative processes involving the scission of carbon-carbon bonds to these positions. The presence of $=CH_2$ in dimethyl*dess*trychnidine D (Achmatowicz and Dybowski, *J. Chem. Soc.*, 1483 (1938)) has also been put forward

18 |b

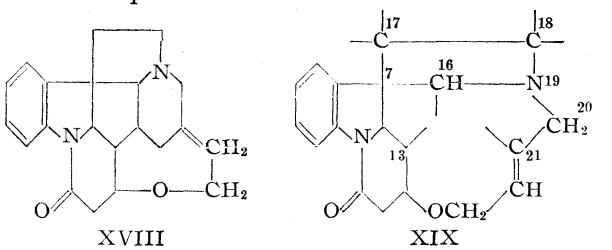
as evidence in support of the presence of $-CH_2-N-$ in strychnine.

paper demonstrate that strychnine contains  , and it is further clear that in order to account for the formation of strychninonic acid, one of the starred carbon atoms must be identical with C.22 (see XV).[28]

These considerations extend the development of the partial structure of strychnine to (XVI). Now Prelog's recent demonstration[29] that ring VI is six-membered, from which a certain amount of ambiguity is removed by our new results,[30] necessitates the incorporation of the two carbon atoms lacking from XVI in a chain bridging C.16 and C.21. The resulting expression (XVII) can be elaborated in only two ways, *viz.*, to (I) or to XVIII, and the latter is excluded in view of the formation from N-methyl*chano*pseudostrychnine of a dibenzal derivative[31] and by the failure of strychninonic acid to be attacked by bromine at the position α to the carbonyl group.[32] It is now clear that (I) provides a unique solution to the structural problem.



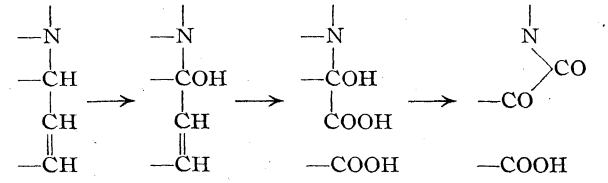
XVI XVII



XVIII XIX

On the other hand, it is necessary to examine the consequences of rejecting the one assumption[27] in the above demonstration for which unambiguous experimental evidence is not available. In that event the structural argument is more complicated, but in our opinion is equally conclusive. Thus, if the four hydrogen atoms at C.17 and C.18 be omitted, it is first possible to show that  cannot be co-extensive with either of the chains of (*a*) or (*c*), above, since: (i) if C.16 were identical with either C.17 or C.18, pseudostrychnine must be a (potential) cyclopropanone or α-iminoketone, and these possibilities may safely be discarded; (ii) C.20 cannot be identical with C.18, since the latter must be contained in a five-membered ring, and it has been shown earlier that C.20 cannot be so situated.[29,30] These considerations lead to the part structure (XIX). Now the chain  must be part of a six-(or seven)-membered ring[29,30]; this ring cannot be constructed from the chain 21-20-19-16-7-17, nor by the interpolation of a bridge containing one or both of the carbon atoms lacking from (XIX) between C.21 and C.17, since in that event the formation and properties of strychninonic acid (and to a greater extent, the formation of the lactam of cunine carboxylic acid[33]) would be inexplicable.[34] Precisely the same circumstances bar construction of the necessary ring by the union of C.13 and C.21. Finally, the ring cannot be constructed by bridging C.21 and C.18 by a chain of two carbon atoms, since in that event, N-methyl*chano*pseudostrychnine could not form a dibenzal derivative,[31] and the stable (and consequently five- or six-membered) N^b-lactam ring of strychnone[7] could not be accounted for. The only remaining possibility, *viz.*, the interpolation of two carbon atoms, to one of which two hydrogen atoms must be attached,[31] between C.16 and

(28) We have presented the situation in the above terms for this reason: Robinson (ref. 26) postulated the presence of the system  (identical with that derived above) on the basis of interpretations of (*a*) the methoxylating cleavage of strychninium salts, and (*b*) the formation of strychninonic acid. It will be clear from the earlier sections of this paper that the considerations involved in (*a*) must now be rejected, but the alternative now adopted yields the same part structure. Beyond that, in our opinion the interpretation of the formation of strychninonic acid has not hitherto been free of ambiguity. Thus, the scheme



is *a priori* in no wise less satisfactory than that originally proposed by Robinson (the concomitant formation of dihydrostrychninonic acid can also be encompassed). The results of the present work, however, permit the unequivocal rejection of the alternative scheme.

(29) Prelog and Szpilfogel, *Helv. Chim. Acta*, **28**, 1669 (1946).

(30) Thus, the work of the Swiss workers indicated that *strychninonic acid* contains a six (or seven) membered ring. The considerations advanced in ref. 28 indicate that hitherto the possibility was definitely present that a five-membered ring in strychnine itself might be transformed into a six-membered ring in strychninonic acid.

(31) Blount and Robinson, *J. Chem. Soc.*, 2305 (1932).

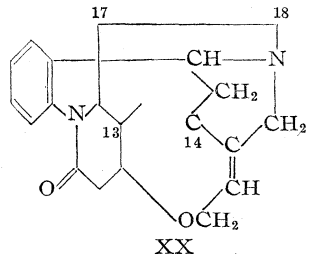
(32) Leuchs, *Ber.*, **72**, 1588 (1939); *cf.* also Robinson, ref. 2, and Leuchs and Grunow, *Ber.*, **72**, 679 (1939). The phenomenon is explicable on the basis of (I) through the steric blocking of enolization, which necessitates a double bond at C.14–C.21. It is worthy of note that pseudostrychnine does not form anhydro salts () for a similar reason (Δ^{16-19} impossible).

(33) Holmes, Openshaw and Robinson, *J. Chem. Soc.*, 908 (1946).

(34) Since the amide link is stabilized by the resonance

amides do not form at the bridgeheads of bicyclic systems which prohibit double bonds to the bridgehead atoms; further, were such an amide obtainable by indirect means, it would be expected to open very readily and *irreversibly* to the corresponding amino acid. The situation is discussed in detail by one of us (R. B. W.) in Chapter XV of the forthcoming monograph on the chemistry of penicillin (Princeton University Press).

C.21, leads to (XX). Now bonds between C.14 and C.17 or C.18 are excluded by considerations already advanced.[34] Only three possibilities remain; of these, the first is I, and those obtained by linking C.13 to C.17 or to C.18 are excluded by the fact that strychninonic acid is not attacked by bromine at the position α to the carbonyl group,[32] and by the failure of pseudostrychnine to form anhydro salts.[35]



XX

We conclude that the structure (I) for strychnine is established.

Experimental

Methylstrychnine.—The method[36] employing strychnine and dimethyl sulfate in the absence of a solvent was found to be superior to the alternate method involving preliminary isolation of pure crystalline strychnine methosulfate.[37]

Methoxymethyldihydro*neo*strychnine (V).—Since, in our hands, both the yield and purity of product were similar whether methylstrychnine was treated with methanolic sodium methoxide or with sodium amalgam in methanol,[11] we favor the former method because of its greater simplicity.

In an early preparative attempt, before any material with the reported melting point of 143° had been obtained, there was isolated a white crystalline substance of m. p. 115–117°. Subsequent to the successful preparation of material with the higher melting point, this material was recrystallized and gave material, m. p. 139–141°, identical with the higher melting sample obtained directly from the reaction-mixture. Hence this is apparently a case of polymorphism.

Methoxymethyl*chano*dihydrostrychnone (IX).—This compound was prepared[14] in almost quantitative yield by treating a boiling ethereal solution of methoxymethyldihydro*neo*strychnine (V) with perbenzoic acid in ether. Ten recrystallizations from ethyl acetate–ether and acetone–ether were required to obtain a sample melting at 189–191°. This is in accord with the observations of the original workers. However, material melting at about 160° (after two recrystallizations from benzene–ligroin) was found to be suitable for use in subsequent reactions.

When (IX) was heated with concentrated sulfuric acid, carbon monoxide was detected in the evolved gases by the production of black metallic palladium from a neutral palladous chloride solution. Under the same conditions the gases from strychnine itself caused no reduction. *Anal.* Calcd. for $C_{23}H_{28}O_5N_2$: mol. wt., 412.5. Found (method of isothermal distillation):[38] 433.

Methoxymethyl*chano*dihydrostrychnone Semicarbazone.—Methoxymethyl*chano*dihydrostrychnone (IX) (2.0 g.), dissolved in the minimum amount of hot water (steam-bath), was treated with an aqueous solution of 2.0 g. of semicarbazide hydrochloride followed by 3.0 g. of anhydrous sodium acetate. After heating for one hour the solution was concentrated *in vacuo;* a yellowish gum precipitated. After a week crystals appeared, 0.65 g., m. p. 238–242°. After recrystallization from methanol the white needles melted at 242–244° (dec.). *Anal.* Calcd. for $C_{24}H_{31}O_5N_5$: C, 61.30; H, 6.60; N, 14.90. Found: C, 61.33; H, 6.70; N, 14.40.

Methoxymethyl*chano*dihydrostrychnol.—Methoxymethyl*chano*dihydrostrychnone (IX) (0.995 g.) was dissolved in 75 cc. of ethanol and was stirred with 0.04 g. of pre-reduced Adams catalyst in an atmosphere of hydrogen. In twenty-four hours only 13.5 cc. of hydrogen was absorbed. After addition of 0.25 g. of pre-reduced catalyst 42.7 cc. of hydrogen was consumed in eleven hours, followed by 6.2 cc. in four hours (theoretical consumption, 54 cc.). The solution was filtered through charcoal and concentrated *in vacuo*. When the concentrated solution was diluted with ether, crystallization occurred; 0.67 g. of white crystals, m. p. 223–226°. After two recrystallizations from ethanol–ether, 0.41 g. of short white needles, m. p. 225.5–226.5°, were obtained. *Anal.* Calcd. for $C_{23}H_{30}O_5N_2$: C, 66.64; H, 7.30; N, 6.76. Found: C, 66.37; H, 7.30; N, 6.73.

When a repetition of this preparation was attempted on a larger scale using a more concentrated ethanolic solution, a larger excess of hydrogen was consumed and only an amorphous product was obtained. This would not crystallize under the conditions described above even with seeding. Similarly, none of the eluted fractions from a chromatographic adsorption of this material could be made to crystallize.

Methoxymethyl*chano*dihydrostrychnone Diethylmercaptal.—Methoxymethyl*chano*dihydrostrychnone (IX) (4.12 g.), dissolved in 30 cc. of glacial acetic acid and 0.3 cc. of concentrated hydrochloric acid and cooled in ice, was treated with 4.4 g. of ethyl mercaptan. After standing in the refrigerator for three days the volatile materials were removed *in vacuo*. The yellowish oily residue crystallized to a pasty mass on standing. After crystallization from ethanol there was 2.6 g., m. p. 177–181°. After recrystallizations from benzene–ligroin, carbon tetrachloride and ethanol the white prisms melted at 183–184.5°. *Anal.* Calcd. for $C_{27}H_{38}O_4N_2S_2$: C, 62.51; H, 7.38; N, 5.40; S, 12.36. Found: C, 61.83; H, 7.64; N, 5.21; S, 12.35.

Desoxomethoxymethyl*chano*dihydrostrychnone (XIV).—About 5 g. of Raney nickel, suspended in 50 cc. of ethanol, was added to a boiling solution of 0.25 g. of methoxymethyl*chano*dihydrostrychnone diethylmercaptal in 50 cc. of ethanol. The reaction-mixture was boiled for thirty minutes and the nickel was filtered off and washed with fresh ethanol. When the solvent had been removed in an air stream on the steam-bath the residue weighed 0.13 g. This was dissolved in benzene and the solution diluted with ligroin. On standing, rosettes of crystals appeared, 100 mg., m. p. 140–143°. The melting point of a mixture with methoxymethyl*chano*dihydrostrychnane (XIII) was 129–131°. After recrystallizations from benzene–ligroin the white prisms melted at 136–139°. *Anal.* Calcd. for $C_{23}H_{30}O_4N_2$: C, 69.32; H, 7.59; N, 7.03; C—CH_3, 0.0. Found: C, 69.73; H, 7.73; N, 6.73; C—CH_3, 0.12.

Methoxymethyl*chano*dihydrostrychnane (XIII).—This material was prepared as reported[15] by the Clemmensen reduction of methoxymethyl*chano*dihydrostrychnone (IX). By strict adherence to the published procedure the reported yield was never obtained although the preparation was repeated many times (from 10 g. of IX yields were 0.2–0.9 g. instead of 3.5 g.). Better yields were obtained when the period of heating was shortened to five hours or when mechanical stirring of the reaction mixture was employed (1.0 and 1.9 g., respectively). However, in these cases, the reported difficulty in purification was observed. This had not been previously encountered in the reactions which gave lower yields. *Anal.* Calcd. for $C_{23}H_{30}O_4N_2$: C—CH_3, 6.8. Found: C—CH_3, 6.1, 6.0.

The acidic mother liquor from the Clemmensen reduction of 6.0 g. of methoxymethyl*chano*dihydrostrychnone

Compound	Amount	Volume (in cc.) of 0.0137 *N* alkali consumed: 1st fraction	2nd fraction	Total	No. of N—CHO groups
N-Formylpenicillamine	0.0737 mmole. (13.0 mg.)	3.56	1.18	4.85 (4 fractions)	0.91
Methoxymethyl*chano*dihydrostrychnane (XIII)	0.0397 mmole. (15.8 mg.)	0.14[a]	..	....	..
Desoxomethoxymethyl*chano*dihydrostrychnone (XIV)	0.0482 mmole. (19.2 mg.)	0.14	0.14	0.79 (5 fractions)	0.22
Methoxymethyl*chano*dihydrostrychnol	0.0487 mmole. (20.2 mg.)	0.27	0.38	3.05 (9 fractions)	0.86
Desoxomethoxymethyl*chano*dihydrostrychnone (XIV)	0.0461 mmole. (18.4 mg.)	0.25[b]	0.34	2.39 (7 fractions)	0.71

[a] Here the amount of base consumed by the first fraction was so small that extra acid was added, and the solution refluxed for a while so as to bring about acidic hydrolysis of the amide linkage. [b] In this determination the hydrolysis mixture was refluxed overnight before acidification and distillation.

Compound	Amount	Volume (in cc.) of 0.0137 *N* alkali consumed: 1st fraction	2nd fraction	Total	No. of N—CHO groups
Desoxomethoxymethyl*chano*dihydrostrychnone (XIV)	0.0446 mmole. (18.0 mg.)	1.53	0.65	3.23 (4 fractions)	0.99
Methoxymethyl*chano*dihydrostrychnane (XIII)	0.0479 mmole. (19.1 mg.)	2.07	0.85	3.45 (6 fractions)	0.99
Methoxymethyl*chano*dihydrostrychnol	0.0397 mmole. (15.8 mg.)	1.91	0.86	3.06 (4 fractions)	1.03
Methoxymethyl*chano*dihydrostrychnone (IX)	0.0514 mmole. (21.2 mg.)	1.73	0.95	3.08 (4 fractions)[a]	0.56

[a] In this determination 0.00937 *N* alkali was used.

(IX) (after extraction of the desired product (XIII) with chloroform) was poured into excess concentrated ammonium hydroxide and extracted continuously with 300 cc. of ether. On evaporation the ether solution was found to contain 2.4 g. of orange-brown oil. In benzene solution this was chromatographed over alumina. Fractional elution with various solvents gave: (1) benzene, 0.67 g.; (2) benzene–ether (1:1), 0.37 g.; (3) ether, 0.20 g.; (4) methanol–ether (1:1), 1.09 g.; (5) methanol, 0.06 g.; (6) methanol–water (1:1), 0.10 g. None of these eluates was crystalline. On treating ethanolic solutions of fractions 2, 3 and 4 with an ethanolic solution of picric acid there was obtained a crystalline picrate, 0.55 g.; after recrystallizations from benzene and ethanol, 0.14 g., m. p. 174–177°. This showed no depression on mixed melting point determination with the picrate of desformylmethoxymethyl*chano*dihydrostrychnane (see below).

Desformylmethoxymethyl*chano*dihydrostrychnane.—Methoxymethyl*chano*dihydrostrychnane (XIII) (0.25 g.) was refluxed for five hours with 15 cc. of 3 *N* sulfuric acid. After cooling, the solution was extracted with chloroform to remove any unchanged starting material. The aqueous solution was made basic with 10 cc. of concentrated ammonium hydroxide, causing the precipitation of a whitish oil. This was extracted with chloroform. The second chloroform extract was dried over sodium sulfate and evaporated to dryness. The residual red oil was boiled with ligroin (b. p. 70–90°). After concentrating the ligroin solution crystallization was induced by cooling in Dry Ice and scratching the sides of the vessel with a glass rod. However, this material was still gummy, and it was found better to remove all the ligroin, dissolve the oil in ethanol and treat the solution with picric acid in ethanol. This gave 0.11 g. of picrate, m. p. 172.5–174°. After recrystallizations from benzene and ethanol the bright yellow wooly needles melted at 176–178°. *Anal.* Calcd. for $C_{28}H_{33}O_{10}N_5$: C, 56.09; H, 5.55; N, 11.68. Found: C, 55.91; H, 5.86; N, 11.92.

The picrate was suspended in benzene and extracted with dilute ammonium hydroxide. The benzene solution on evaporation gave 60 mg. of colorless oil. This was crystallized from ligroin, 50 mg., m. p. 84.8–86°. After recrystallization from ligroin the white needles melted at 86.0–86.6°. *Anal.* Calcd. for $C_{22}H_{30}O_3N_2$: C, 71.32; H, 8.16; N, 7.56. Found: C, 70.80; H, 8.08; N, 7.66.

When 40 mg. of this base was warmed with 2 cc. of 2 *N* perchloric acid, a crystalline perchlorate precipitated on cooling, 40 mg., m. p. 195–201°. After recrystallization from absolute ethanol, the white needles melted at 244.5–245.5°. *Anal.* Calcd. for $C_{22}H_{31}O_7N_2Cl$: C, 56.10; H, 6.64; N, 5.95; Cl, 7.53. Found: C, 56.58; H, 6.86; N, 6.05; Cl, 7.29.

Formylation of Desformylmethoxymethyl*chano*dihydrostrychnane.—Desformylmethoxymethyl*chano*dihydrostrychnane (40 mg., m. p. 83–84°) was dissolved in 10 cc. of anhydrous formic acid[39] and 4 cc. of acetic anhydride. After refluxing for fourteen hours the volatile materials were removed *in vacuo*, and the residue was dissolved in benzene. The benzene solution was twice extracted with dilute hydrochloric acid and then with water. After drying over sodium sulfate the benzene was evaporated leaving a tan-colored oily residue, 10 mg. This was dissolved in a little benzene, treated with charcoal, filtered and diluted with petroleum ether (b. p. 30–60°). On standing the cloudy solution deposited rosette-shaped clumps of crystals, m. p. 160–161.5° after washing with fresh petroleum ether. A sample, mixed with some methoxymethyl*chano*dihydrostrychnane of m. p. 163–164.5°, had a melting point of 161–162°.

An earlier attempt to effect this reaction omitting the use of acetic anhydride resulted in the isolation only of unchanged starting material.

N-Formyl Determinations.—About 20 mg. of the compound to be analyzed was refluxed for one hour with 2 cc. of reagent grade methanol, 1 cc. of 5 *N* sodium hydroxide and 2 cc. of water. The mixture was diluted with 5 cc. of water and the methanol distilled off. After acidification with 1 cc. of 33% sulfuric acid distillation was continued, and the volatile acid in the distillate determined by titration with standard alkali. The distillate was collected in 20-cc. fractions, water being added to the reaction-mixture at intervals to maintain its volume. These fractions were titrated separately, and the process continued until there was detected only a small constant

(39) Lorin, *Bull. soc. chim.*, [2] **5**, 10 (1866).

quantity of volatile acid consistent with that obtained from a blank determination.

The small volume of acid in the first fraction, and the constancy of the amount in successive fractions of distillate, led to the conclusion that hydrolysis of the amide linkage was occurring at the same time as the acid produced was being distilled.

When acidic hydrolysis was employed the sample was refluxed for two hours with 2 *N* sulfuric acid before distillation was started. Here again the collection of fractions of distillate was continued until they contained constant amounts of volatile acid of the same size as was found in a blank determination.

Summary

It has been shown that the *neo* bases derived from the strychnos alkaloids contain the part structure  . This demonstration resolves previous difficulties in the way of the acceptance of the structure (I) for strychnine. The general situation has now advanced to the point at which it is conclusive in favor of the expression (I), and the structure of the major strychnos alkaloids is regarded as established.

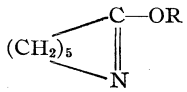
Chemical Reactions of Caprolactam

BY RICHARD E. BENSON AND THEODORE L. CAIRNS

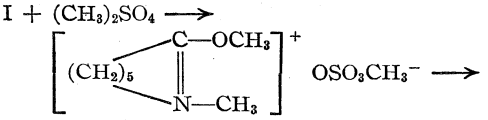
This paper reports the results of a general investigation of the chemistry of caprolactam with emphasis on the O-alkyl imino ethers and their reactions, and on nitrogen-substituted derivatives obtainable by alkylation and acylation. The general reactivity of caprolactam parallels that of related open-chain amides but several unusual transformations were observed and some discrepancies in the literature were clarified.

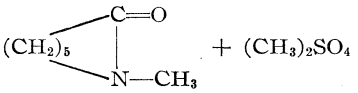
The preparation of O-methylcaprolactim (I) was accomplished by the direct action of dimethyl sulfate on caprolactam in benzene solution.[1a] Dur-



I, R = CH_3
II, R = C_2H_5

ing this preparative work, it was noticed that the proportion of N-methylcaprolactam formed along with the O-methylcaprolactim increased as the scale of the preparation was increased and that, in particular, the amount of N-methyl derivative formed was very much greater when all the dimethyl sulfate was added at once compared with the amount formed when a gradual addition over a long period of time was used. These observations lead to the hypothesis that dimethyl sulfate reacts with I to convert it to N-methylcaprolactam as shown in the equation





That this may actually be the case is demonstrated by the fact that treatment of O-methylcaprolactim in benzene solution with 0.1 mole equivalent of dimethyl sulfate brought about its conversion to N-methylcaprolactam in 80% yield. In addition, the action of excess dimethyl sulfate on the lactam gave the N-methyl derivative in 70% yield. The report[2] that the interaction of dimethyl sulfate and caprolactam leads only to the N-methyl derivative may well be accounted for by the assumption that a slight excess of the alkylating agent was used. O-Ethylcaprolactim (II)[1b] was prepared in an analogous fashion. It was found that heating caused rearrangement of both I and II to the corresponding N-alkyl compounds in a manner similar to that reported for open-chain imino ethers.[3]

O-Methylcaprolactim was found to be a water-insoluble basic material that could be converted by the action of boiling water into a mixture of caprolactam and ϵ-aminocaproic acid. Treatment of the imino ether with amines led to the corresponding amidines; these are listed in Table I. In the case of the unsubstituted amidine it was found that the action of ammonia on the imino ether was not a satisfactory preparative method, while the use of ammonium chloride readily yielded the desired amidine as the hydrochloride, in accord with the experience of Knorr[4]

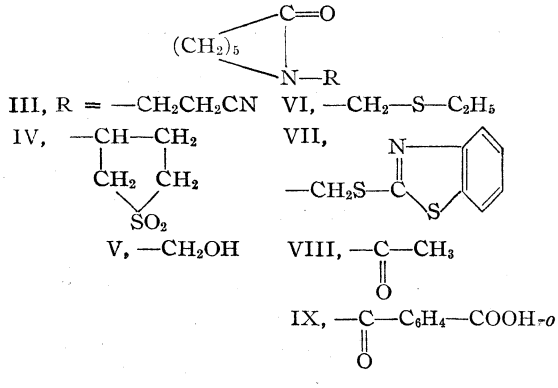
with acetamidine. The hydrogenation of O-methylcaprolactim over Raney nickel, ruthenium oxide, or barium–copper chromite catalyst yielded hexamethylenimine, while the use of platinum gave the amidine derived from interaction of the O-ether and hexamethylenimine.

In addition to N-methyl- and N-ethylcaprolactam, it was found that other nitrogen-substituted derivatives could be prepared from caprolactam by the following types of reactions: (1) addition to active unsaturated compounds, (2) reaction with formaldehyde, and (3) reaction with acid anhydrides. Treatment of caprolactam with acrylonitrile gave the corresponding N-β-cyanoethyl derivative (III),[6] and 2,5-dihydrothiophene-1-dioxide gave an analogous product IV.



The N-methylol derivative V was obtained by the action of formaldehyde on caprolactam. Compound V with mercaptans, such as ethyl mercaptan and 2-mercaptobenzothiazole, yielded the corresponding alkylthiomethyl derivatives VI and VII. Refluxing caprolactam with acetic anhydride formed N-acetylcaprolactam (VIII) as reported by Prochazka.[2] The structure of the product obtained by Prochazka[2] from caprolactam and phthalic anhydride is not clear, but it was apparently regarded as the bisamide from two moles of caprolactam and one mole of the anhydride. Such a formulation is at variance with a German report[7] which states that the compound is the monoamide, N-(*o*-carboxybenzoyl)-caprolactam (IX), and that the bisamide could not be formed. In our work only the monoamide IX was obtained.

Hydrolysis of N-methylcaprolactam with concentrated hydrochloric acid has been reported by Ruzicka[8] to give the expected N-methyl-ϵ-aminocaproic acid, m. p. 130–131°, while the use of 10% sulfuric acid has been reported by Lukes and Smolek[9] to form N-methyl-α-aminocaproic acid, m. p. 66°. We have repeated the work of Lukes and Smolek and obtained a compound melting at 66–67° which has been shown conclusively to be the dihydrate of N-methyl-ϵ-aminocaproic acid and not the α-amino derivative. In view of the fact that the analytical data reported by Lukes and Smolek are correct for the free amino acid and not the dihydrate, it is believed that the water of hydration was lost during drying of their sample for analysis and that they failed to observe the change in melting point which accompanies this dehydration.

Experimental

O-Methylcaprolactim (I).—A modification of the procedure given in the literature[1a] gave increased yields on large runs. To a refluxing, stirred solution of 678 g. (6 moles) of caprolactam[10] in 2 l. of benzene was added 569 ml.

(5) Stolle, *Ber.*, **63B**, 1032 (1930).

(6) This compound is mentioned in Office of Publication Board Report 693 but no experimental details are given.

(7) Office of Publication Board Report 621.

(10) Obtained from Explosives Department, E. I. du Pont de Nemours & Company, Wilmington, Delaware.

(6 moles) of dimethyl sulfate over a period of two and one-half hours. The mixture was refluxed for sixteen hours longer. The cold mixture was made alkaline with excess 50% potassium carbonate, the organic layer was separated, and the product was distilled. There was obtained 517 g. (68% yield) of I, b. p. 65–67° (24 mm.), $n^{25}D$ 1.4610, d^{25}_4 0.9598; lit.[1a,b] b. p. 50–52° (4 mm.), 160°.

Anal. Calcd. for $C_7H_{13}NO$: C, 66.10; H, 10.30; N, 11.01. Found: C, 66.10, 65.86; H, 10.44, 10.31; N, 10.87, 11.04.

There was also obtained 10 g. (1.3% yield) of N-methylcaprolactam, b. p. 133–135° (26 mm.).

O-Ethylcaprolactim (II).—In a manner similar to the preparation of I, O-ethylcaprolactim was prepared in 52% yield, b. p. 81–82° (26 mm.), $n^{25}D$ 1.4564, d^{25}_4 0.9440; lit.,[1b] b. p. 180°.

Anal. Calcd. for $C_8H_{15}NO$: C, 68.04; H, 10.71; N, 9.92. Found: C, 67.71, 67.67; H, 10.63, 10.62; N, 9.40, 9.56.

Hydrolysis of O-Methylcaprolactim.—A mixture of 15 g. of I and 50 ml. of water was refluxed for ten minutes, and the resulting homogeneous solution was then cooled and extracted with ether. Concentration of the ether extract by distillation gave 2 g. (15% yield) of caprolactam m. p. 69–70°, mixed m. p., 69–70°.

Concentration of the water solution gave, after crystallization from ethanol–water, 7 g. (45% yield) of ϵ-aminocaproic acid, m. p. 192–194°, mixed m. p. with authentic ϵ-aminocaproic acid, m. p. 196°. The authentic sample melts at 196.5°.

N-Methylcaprolactam (Method A).—The preparation was similar to that of I except that 0.32 molar excess of the dialkyl sulfate was used per mole of the lactam. There was obtained a 70% yield, b. p. 120° (19 mm.), $n^{25}D$ 1.4818, d^{25}_4 1.0154.

Anal. Calcd. for $C_7H_{13}NO$: N, 11.01. Found: N, 10.92, 11.02.

Ruzicka[8] has prepared this compound, b. p. 120° (15 mm.), by the reaction of N-sodiocaprolactam and dimethyl sulfate, while Prochazka[2] states that only N-methylcaprolactam could be prepared by the action of dimethyl sulfate and caprolactam.

Method B.—By action of dimethyl sulfate on I: A solution of 25.4 g. (0.2 mole) of I, 1.9 ml. (0.02 mole) of dimethyl sulfate and 50 ml. of benzene was refluxed for six hours. The solution was shaken with excess 50% potassium carbonate, the organic layer separated and distilled. There was obtained 20.5 g. of N-methylcaprolactam, b. p. 128° (32 mm.), $n^{25}D$ 1.4812.

Method C.—Thermal rearrangement of I: O-Methylcaprolactim was heated in a steel bomb at 285° for ten hours. Distillation of the product gave a 67% yield of the N-methyl compound, b. p. 110–112° (10 mm.), $n^{25}D$ 1.4833.

N-Ethylcaprolactam.—O-Ethylcaprolactim (25 g.) was heated for two hours at 180–250° in an atmosphere of nitrogen. Distillation gave 23.4 g. (85% yield) of N-ethylcaprolactam, b. p. 97° (5.5 mm.), $n^{25}D$ 1.4777, d^{25}_4 0.9850.

Anal. Calcd. for $C_8H_{15}NO$: C, 68.04; H, 10.71; N, 9.92. Found: C, 68.42, 68.20; H, 10.85, 10.70; N, 9.48, 9.53.

Amidines.—The preparation of several cyclic amidines was achieved by heating I with the appropriate amine. The results are summarized in Table I. A typical example is given below.

A mixture of 25.4 g. (0.2 mole) of I and 24.6 g. (0.2 mole) of *p*-anisidine was heated at 175° for three hours, and the methanol continuously removed by distillation. The resulting 2-(*p*-anisidino)-1-aza-1-cycloheptene was crystallized from hexane-ether to give 36 g. (83% yield) of white needles, m.p. 85–87°. The analytical results are given in Table I.

2-(1′-Azacycloheptyl)-1-aza-1-cycloheptene. Method A.—A solution of 83.3 g. (0.657 mole) of I and 65 g. (0.657 mole) of hexamethylenimine was refluxed for nine hours and then the methanol was removed by distillation. The resulting product was fractionated through a 6″ Vigreux column to give 100 g. (78%) of the amidine, b. p. 165–170° (25–28 mm.), $n^{25}D$ 1.5242; methiodide, m. p. 194.5–196°.

Method B.—A solution of 50 g. (0.394 mole) of I in 125 ml. of absolute ethanol was shaken with platinum oxide catalyst under a hydrogen pressure of 20–30 lb./sq. in. for twenty-four hours. The total pressure drop corresponded to about 0.25 mole of hydrogen. The alcohol was removed by distillation and the product fractionated to give 27.3 g. of I, b. p. 33–35° (1 mm.) and 15.2 g. of the amidine, b. p. 98–105° (1 mm.) (87% yield at 45% conversion of I), $n^{25}D$ 1.5248, d^{25}_4 0.9956.

Anal. Calcd. for $C_{12}H_{22}N_2$: C, 74.17; H, 11.41; N, 14.42. Found: C, 73.77, 73.92; H, 11.29, 11.34; N, 14.18, 14.03.

Methiodide, m. p. 193.5–194.5°: a mixed m. p. of methiodides of the amidine prepared by Methods A and B, m. p. 194–196°.

Anal. Calcd. for $C_{13}H_{25}N_2I$: N, 8.33; I, 37.74. Found: N, 8.99, 8.70; I, 37.67, 37.73.

Hexamethylenimine.—O-Methylcaprolactim was hydrogenated at 150° and 2000–3000 lb./sq. in. hydrogen pressure using barium–copper chromite catalyst to give 70% yield of the imine, b. p. 134–137°, $n^{25}D$ 1.4645, d^{25}_4 0.8806 (literature values,[11] b. p. 138°, $n^{23}D$ 1.4654, d^{25}_4 0.8770). The imine was converted to its picrate, m. p. 144–145°, lit.[11] m. p. 146.5°, and *p*-toluenesulfonamide, m. p. 75–76°, lit.[12] m. p. 76.5°. The hydrogenation of I at 3000 lb./sq. in. using Raney nickel catalyst at 140° gave 49% of the imine, while the use of ruthenium catalyst at 125° gave 31% yield.

N-(β-Cyanoethyl)-caprolactam (III).—To a solution of 113 g. (1.0 mole) of caprolactam in 300 ml. of dioxane and 6 ml. of "Triton" B (trimethylbenzylammonium hydroxide) was added dropwise with stirring 56 g. (1.0 mole) of acrylonitrile over a period of thirty-five minutes with the temperature maintained at 30–35°. Stirring was continued for two hours and the reaction mixture allowed to stand at room temperature for sixty-three hours. The solution was made slightly acid with hydrochloric acid, the dioxane and unreacted acrylonitrile removed by distillation, and the product fractionated through an 8″ Vigreux column to give 108 g. (65% yield) of III, b. p. 153–158° (1.5–1.8 mm.), $n^{25}D$ 1.4903, d^{25}_4 1.074. On standing, the product crystallized to give white needles, m. p. 32–34°, readily soluble in water and most organic solvents.

Anal. Calcd. for $C_9H_{14}N_2O$: C, 65.03; H, 8.49; N, 16.85. Found: C, 64.97, 64.86; H, 8.49, 8.41; N, 17.11, 16.93.

N-(β-Cyanoethyl)-caprolactam was hydrolyzed to 4-azasebacic acid in 40% yield by refluxing with 25% sulfuric acid; m. p. 177–178° from 95% ethanol.

Anal. Calcd. for $C_9H_{17}NO_4$: C, 53.19; H, 8.43; N, 6.89. Found: C, 52.86, 52.93; H, 8.52, 8.56; N, 6.82, 6.77.

N-(1,1-Dioxotetrahydro-3-thienyl)-caprolactam (IV).—A mixture of 56.5 g. (0.5 mole) of caprolactam and 1 g. of potassium hydroxide was heated to 65° and 59 g. (0.5 mole) of 2,5-dihydrothiophene-1-dioxide added in 2-g. portions over a period of thirty minutes with constant stirring. The temperature rose to 70° and the mixture was heated and stirred at 65–75° for seven hours. The product was crystallized from ethanol and then from ethanol–ether to give 19 g. (16.5% yield) of white needles, m. p. 107–108°. An analytical sample melts at 108–109.5°.

Anal. Calcd. for $C_{10}H_{17}NO_3S$: C, 51.92; H, 7.41; N, 6.06; S, 13.86. Found: C, 51.81, 52.06; H, 7.48, 7.59; N, 6.04, 5.92; S, 13.82, 13.78.

N-Methylolcaprolactam (V).[13]—A mixture of 339 g. (3.0 moles) of caprolactam, 135 g. of paraformaldehyde,

(11) Müller and Sauerwald, *Monatsh.*, **48**, 727 (1927).

(12) Müller and Bleier, *ibid.*, **50**, 399 (1928).

(13) Prepared by Dr. Clarence E. Denoon; present address, Rohm & Haas Co., Philadelphia, Pa.

5 g. of sodium hydroxide and 500 ml. of 95% ethanol was stirred and heated at 140–150° for three hours. The mixture was filtered from a small amount of insoluble material and cooled in a Dry Ice–acetone-bath. There was obtained 184 g. of white, microcrystalline solid, V. Concentration of the filtrate yielded an additional 105 g. of V, m. p. 62–64°, total yield 289 g. (67%). Recrystallization from methanol gave an analytical sample, m. p. 65–66°.

Anal. Calcd. for $C_7H_{13}NO_2$: N, 9.78. Found: N, 9.98.

N-(Ethylthiomethyl)-caprolactam (VI).[13]—A mixture of 113 g. (1.0 mole) of caprolactam, 45 g. of paraformaldehyde, 3 g. of sodium hydroxide, and 250 ml. of 95% ethanol was stirred and heated at 40–50° for fourteen hours. The mixture was cooled, 40 ml. of concentrated hydrochloric acid added and the precipitated sodium chloride removed by filtration. To the filtrate was added 93 g. (1.5 moles) of ethyl mercaptan and the resulting mixture allowed to stand overnight. To the mixture was added 100 ml. of ether, the resulting organic layer washed with 5% sodium hydroxide and finally with water. The oil was dried over sodium sulfate and then distilled to give 122 g. (65% yield) of VI, b. p. 138–141° (5–6 mm.), $n^{25}D$ 1.5189, d^{25}_4 1.0689.

Anal. Calcd. for $C_9H_{17}NOS$: S, 17.12. Found: S, 17.30.

N-(Benzothiazolyl-2-thiomethyl)-caprolactam (VII).[13]—A mixture of 113 g. (1.0 mole) of caprolactam and 30 g. of paraformaldehyde was heated at 80–90° for one-half hour. To this hot mixture was added 167 g. (1.0 mole) of 2-mercaptobenzothiazole and the mixture heated at 130–140° for two additional hours. The resulting liquid was poured into 2 l. of 5% sodium carbonate and stirred to give a yellow crystalline mass. The yellow product was ground, extracted again with sodium carbonate and finally with 1500 ml. of 95% ethanol. The ethanol filtrate was decolorized with activated carbon, filtered and cooled to give 150 g. (51% yield) of crystalline solid, m. p. 150–155°. An analytical sample from methanol melts at 157°.

Anal. Calcd. for $C_{14}H_{16}N_2OS_2$: S, 21.93. Found: S, 22.21.

N-Acetylcaprolactam (VIII).—A mixture of 678 g. (6.0 moles) of caprolactam and 670 g. (6.65 moles) of acetic anhydride was refluxed for four hours. After removal of the unreacted anhydride and acetic acid, there was obtained 775 g. (83.5% yield) of N-acetylcaprolactam, b. p. 134–136° (26–27 mm.); $n^{25}D$ 1.4885, d^{25}_4 1.094.

Anal. Calcd. for $C_8H_{13}NO_2$: C, 61.91; H, 8.44; N, 9.03; sapn. eq., 155.2. Found: C, 62.20, 61.90; H, 8.75, 8.70, N, 9.36, 9.06; sapn. eq., 159, 158.

This compound has been prepared previously[2] but physical constants other than b. p. 130–131° (13 mm.) were not given.

N-(*o*-Carboxybenzoyl)-caprolactam (IX).—A mixture of 113 g. (1.0 mole) of caprolactam and 148 g. (1.0 mole) of phthalic anhydride was heated at 180–195° for eighteen hours. The product was distilled through a short column to give 231 g. of IX, b. p. 206–208° (0.20–0.25 mm.), m. p. 104.5–106.5°. Recrystallization from hexane–ethanol gave 210 g. (80% yield) of product, m. p. 105–107°. Further recrystallization from benzene gave m. p. 107.5–108°. The product is soluble in sodium bicarbonate solution.

Anal. Calcd. for $C_{14}H_{15}NO_4$: C, 64.35; H, 5.79; N, 5.36; neut. eq., 261.3. Found: C, 64.38, 64.44; H, 5.94, 5.97; N, 5.51, 5.46; neut. eq., 254.4, 253.6.

Prochazka[2] has reported that the above reaction using one-half mole of the anhydride per mole of lactam yields N-phthaloylcaprolactam, b. p. 279–282° (15 mm.), m. p. 108.5–109°; while a German report[7] states that only N-(*o*-carboxybenzoyl)-caprolactam, b. p. 250° (2–3 mm.), m. p. 109–110°, can be prepared. Since no analytical data were available and the reported physical constants are similar, it was necessary to repeat the reaction to determine the exact structure of the resulting compound. The directions of Prochazka were followed but only unchanged caprolactam and IX were obtained by distillation of the reaction mixture.

N-Methyl-ε-aminocaproic Acid Dihydrate.—A solution of 130 g. of concentrated sulfuric acid, 1170 ml. of water and 130 g. (1.025 mole) of N-methylcaprolactam was refluxed for ten hours. The hot solution was treated with a slight excess of barium hydroxide, filtered to remove the precipitated barium sulfate, the filtrate treated with solid carbon dioxide to remove the barium ions as barium carbonate and the solid removed by filtration. The resulting filtrate was concentrated by distillation to give a sirupy residue that was treated with benzene and heated to remove most of the remaining water. The resulting product was crystallized twice from absolute ethanol–ether to give a white, crystalline solid, m. p. 66–67°. The directions followed were those of Lukes and Smolek[9] who state that the product thus obtained was N-methyl-α-aminocaproic acid, m. p. 66°; however, Ruzicka[8] has stated that the hydrolysis of N-methylcaprolactam with concentrated hydrochloric acid yields N-methyl-ε-aminocaproic acid, m. p. 130–131°.

The product of m. p. 66–67° was identified as N-methyl-ε-aminocaproic acid dihydrate by analysis, dehydration to N-methyl-ε-aminocaproic acid, and ring closure to give N-methylcaprolactam.

Anal. Calcd. for $C_7H_{15}NO_2 \cdot 2H_2O$: C, 46.39; H, 10.57; N, 7.73; neut. eq., 181.23. Found: C, 46.95; 47.00; H, 10.44, 10.74; N, 7.37, 7.58; neut. eq., 180.4, 180.8.

To check the structure of the above compound, a weighed amount of the air-dried material was placed in a drying pistol, evacuated by means of a vacuum pump and heated by boiling alcohol for fifteen hours. The solid did not melt but the crystalline material slowly changed to an amorphous powder. A weighed sample (1.4868 g.) of the compound lost 0.3068 g.; the calculated loss for the dihydrate is 0.2956 g. In addition, the amorphous powder thus obtained melted at 129–131°, lit. m. p. 130–131° for N-methyl-ε-aminocaproic acid.[3]

The air-dried product was heated in a small distilling flask for fifteen minutes and most of the water collected. The temperature was raised and the major portion of the material distilled at 234°, $n^{25}D$ 1.4819. This is in good agreement with the values for N-methylcaprolactam, b. p. 234°, $n^{25}D$ 1.4818.

From the above data it is evident that the product obtained by Lukes and Smolek was the dihydrate of N-methyl-ε-aminocaproic acid rather than N-methyl-α-aminocaproic acid.

Summary

1. The reaction of caprolactam with dimethyl sulfate has yielded O-methylcaprolactim or N-methylcaprolactam depending on the amount of the sulfate used in the reaction. In addition, O-ethyl- and O-methylcaprolactim were rearranged thermally to the corresponding N-substituted derivatives.

2. The condensation of the methyl imino ether with amines yielded the corresponding cyclic amidines.

3. The reaction of caprolactam with active unsaturated compounds, with acid anhydrides and with formaldehyde gave other N-substituted compounds.

4. The hydrolysis of N-methylcaprolactam with 10% sulfuric acid was shown to yield the dihydrate of N-methyl-ε-aminocaproic acid rather than N-methyl-α-aminocaproic acid as previously reported.

The Preparation and Some Reactions of α-(ω-Cyanoethyl)-β-naphthol

BY A. F. HARDMAN

Hoesch[1] discovered that acetonitrile condenses with resorcinol in the presence of zinc chloride and hydrogen chloride to yield a compound which hydrolyzes to 2,4-dihydroxyacetophenone. Later Langley and Adams[2] attempting the same type of condensation with β-chloropropionitrile or acrylonitrile and resorcinol obtained not a ketone, but 2,4-dihydroxyphenylpropionic acid.

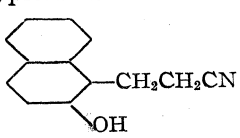
More recently, it was shown that various cyanoethyl aryl ethers are obtained by treating phenols with acrylonitrile in the presence of about 1% of metallic sodium as catalyst. This represents the usual reaction between acrylonitrile and a phenol.

It has now been found that β-naphthol and acrylonitrile in a solvent such as benzene condense in the presence of solid caustic soda. The caustic is used in equal or slightly more than equal molal quantities to the naphthol. Therefore, its function is not merely that of a catalyst. The product first obtained, as a viscous water-soluble layer under the organic solvent, is the sodium salt of α-(ω-cyanoethyl)-β-naphthol, from which the free naphthol is obtained by dissolution in water and acidification. This naphthol (I) is analogous to that obtained by Langley and Adams from resorcinol and acrylonitrile. However, resorcinol, treated with acrylonitrile and caustic under the conditions described, does not react. In fact, this reaction appears to be specific to β-naphthol; other phenols, including α-naphthol, failed to yield satisfactory products.

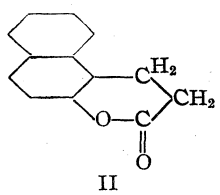
α-(ω-Cyanoethyl)-β-naphthol is readily hydrolyzed to the corresponding propionic acid which on heating forms a lactone (II).

The lactone reacts with ammonia and various amines to yield well-crystallized amides of 2-hydroxynaphthalenepropionic acid, and with alcohols to yield esters of the same acid. The esters cannot be distilled, but revert to lactones and free alcohols on heating.

α-(ω-Cyanoethyl)-β-naphthol also reacts like a typical nitrile to form amidines.



I



II

Experimental[3]

α-(ω-Cyanoethyl)-β-naphthol (1).—A mixture of 29 g. of β-naphthol, 12 g. of acrylonitrile, 50 cc. of benzene and 9 g. of sodium hydroxide pellets was refluxed. The mixture boiled vigorously at first, and the sodium hydroxide mostly went into solution. After about one-half hour the mixture began to separate into two layers. The heating was stopped after two hours, 100 cc. of cold water added and the water solution separated from the benzene, and acidified with acetic acid. The crude precipitate weighed 37 g. and after recrystallization from ethanol yielded white crystals melting at 142°.

Anal. Calcd. for $C_{13}H_{11}ON$: N, 7.1. Found: N, 6.85.

2-Hydroxy-1-naphthalenepropionic Acid.—A solution of 50 g. (I) in 222 g. of 10% aqueous sodium hydroxide was refluxed for eight hours, then cooled and stirred slowly into dilute hydrochloric acid. The crude 2-hydroxy-1-naphthalenepropionic acid melting at 115–117° weighed 54 g. and after recrystallization from benzene, melted at 121°.

Anal. Calcd. for $C_{13}H_{12}O_3$, neutral equivalent, 259. Found: neutral equivalent, 258.

Lactone of 2-Hydroxy-1-naphthalenepropionic Acid (II).—One hundred forty-three grams of crude acid, (m. p. 114–115°) was refluxed in 100 cc. of toluene under a water trap, until no more water collected, about one-half hour. The toluene was removed by distillation and the lactone distilled under 5 mm. pressure, coming over mostly between 210 and 220°. The viscous liquid, which weighed 115 g., crystallized after stirring and seeding. After recrystallization from benzene–petroleum ether, the lactone melted at 69–70°.

2-Hydroxy-1-naphthalenepropionamide.—Dry ammonia was bubbled through a solution of 20 g. of the lactone (II) in 200 cc. benzene. The solution became warm and in a few minutes crystals began to separate. After saturation, the mixture was allowed to stand overnight, then filtered, and the crystals washed with benzene. The yield was 21 g. of fine, white crystals melting with decomposition at 171–172°.

Anal. Calcd. for $C_{13}H_{13}O_2N$: N, 6.52. Found: N, 6.46.

2-Hydroxy-1-naphthalene-N-cyclohexyl-propionamide.—Twenty grams of the lactone (II) was dissolved in 50 cc. of benzene and 10 g. of cyclohexylamine was added. The solution became warm on adding the amine, and in a short time crystals began to separate. After standing overnight, the fine white crystals were filtered off and washed with benzene. The yield was 28 g.; m. p. 172–173°.

Anal. Calcd. for $C_{19}H_{23}O_2N$: N, 4.72. Found: N, 4.81.

Table I below lists a number of other substituted amides which have been prepared by heating the lactone and the amine in an appropriate solvent.

TABLE I

Amine	Amide M. p., °C.	Nitrogen, % Calcd.	Found
Diethylamine	124	5.17	5.26
Monoethanolamine	142–143	5.40	5.14
Ethylenediamine	188	6.14	5.87
Aniline	173–174	4.81	4.48
p-Aminophenol	142–143	4.56	4.32
α-Naphthylamine	205–206	4.11	4.06
β-Naphthylamine	193–194	4.11	3.91
p,p'-Diaminodiphenylmethane	207	4.71	4.68

Methyl 2-Hydroxy-1-naphthalenepropionate.—A solution of 20 g. of the lactone (II) in 50 cc. of methanol to which

(2) Langley and Adams, THIS JOURNAL, **44**, 2326 (1922).

(3) The melting points reported are uncorrected.

a pinch of sodium methylate was added was refluxed for one-half hour. On cooling, 16 g. of the ester precipitated. After recrystallization from methanol, the product melted at 122–123°.

Anal. Calcd. for $C_{14}H_{14}O_3$: sapn. equiv., 244. Found: sapn. equiv., 245.

2-Hydroxy-1-naphthalenepropio-N,N'-diphenylamidine.—One hundred grams of (I) was refluxed with 125 g. of aniline. Ammonia came off rapidly at first, then more and more slowly. After eight hours 86% of the theoretical ammonia had been driven off. The mixture was cooled and stirred into 400 cc. of ethanol and allowed to stand overnight. The product, which was removed by filtration and washed with ethanol weighed 123 g. and melted at 147°. After recrystallization from xylene, it melted at 150–151°.

Anal. Calcd. for $C_{25}H_{22}ON_2$: N, 7.64. Found: N, 7.87.

It has been discovered in preliminary tests that the 2-hydroxy-1-naphthalenepropionic acid is moderately effective as a root growth promoter when applied to chrysanthemum cuttings and is of some value as a spray material to reduce premature apple drop. It is hoped that this publication will stimulate investigation by others in various fields of possible utility.

Acknowledgment. The author is indebted to Miss Marion Treiber for assistance in preparing a number of the amides tabulated above.

Summary

1. A new reaction is described in which α-(ω-cyanoethyl)-β-naphthol is obtained in excellent yield from acrylonitrile and β-naphthol.

2. Derivatives prepared from α-(ω-cyanoethyl)-β-naphthol include 2-hydroxy-1-naphthalenepropionic acid, its methyl ester, various amides and the N,N'-diphenylamidine.

A New Synthesis of Atranol (2,6-Dihydroxy-4-methylbenzaldehyde) and the Corresponding Cinnamic Acid

BY ROGER ADAMS AND JEAN MATHIEU

In experiments designed to prepare products suitable for the synthesis of natural tetrahydrocannabinol,[1] techniques for certain reactions were developed which may be of general interest. A new synthesis of atranol was also discovered. The compounds desired are 2,6-dihydroxy-4-*n*-amylcinnamic acid and its ester. This preliminary work, however, has involved the synthesis of the corresponding 4-methyl derivatives, since orcinol is a much more readily accessible substance than olivetol (3,5-dihydroxy-*n*-amylbenzene).

Orcinol dimethyl ether can be formylated (I) in the position between the methoxyls by treating lithium orcinol dimethyl ether with methylformanilide.[1b] Demethylation of this product was attained only after an exhaustive study of different reagents. Anhydrous aluminum bromide proved successful and a 70% yield of 2,6-dihydroxy-4-methylbenzaldehyde (II) resulted. This product is known as atranol. It was first isolated by degradation of atranorin, a product occurring in various lichens, and its structure was determined by oxidation to *p*-orsellinic acid.[2] It has been synthesized by Pfau in low yields by the introduction of an aldehyde group into ethyl 2,4-dihydroxy-6-methylbenzoate (orcinol carboxylic ester), followed by saponification and decarboxylation.[3] The new method offers a much simpler and more satisfactory procedure. Anhydrous aluminum chloride under similar conditions gives primarily resins, although in very small runs (0.1 g.), a 30% yield of atranol could be isolated. With benzene as a solvent, aluminum chloride causes demethylation of only one methoxyl with formation of 2-hydroxy-6-methoxy-4-methylbenzaldehyde (atranol monomethyl ether). This compound has been described by Asahina,[4] who found it in the pyrolysate of stictinic acid and synthesized it from atranol.

Although atranol dimethyl ether (I) condenses with malonic acid in presence of piperidine with formation of an almost quantitative yield of the corresponding cinnamic acid,[1b] the unmethylated product, atranol(II), did not react similarly under the same conditions. The conversion of substituted aromatic aldehydes to the cinnamic acids by the Knoevenagel reaction has been exhaustively studied. In general the yields are excellent but previous investigators have noted the abnormally low yields of products when *o*- or *p*-hydroxybenzaldehydes were subjected to condensation under conditions entirely suitable to other substituted benzaldehydes.[5] The conditions found most satisfactory for the condensation of salicylaldehyde with malonic acid[5b] were (a) the use of a small amount of pyridine as catalyst resulting in a yield of 51% of 3-carboxycoumarin or (b) heating at 80° followed by twenty-four hours at room temperature in presence of trace amounts of a variety of tertiary bases such as lutidine, quinoline, etc. (methylacridine[1c] proved to be the best) resulting in a 66–77% yield of product. An explanation of the difficulty in the condensation of *o*- and *p*-hydroxybenzaldehydes was suggested by

Vorsatz,[6] who pointed out that at the temperatures usually employed the *o*- and *p*-hydroxycinnamic acids readily decarboxylated with subsequent polymerization of the corresponding styrenes. He was able to overcome this side reaction by keeping the reactants at a relatively low temperature for a period of many days. He also observed that replacing the piperidine by aniline greatly accelerated the reactions. Thus, protocatechuic aldehyde, and 2,3,4-trihydroxybenzaldehyde condensed in better than 80% yield. In this investigation, the usual procedure with atranol and malonic acid failed but that described by Vorsatz using pyridine and aniline proceeded very satisfactorily to give a 75% yield of 3-carboxy-5-hydroxy-7-methylcoumarin (III). Aniline thus appears to be a catalyst of general utility for *o*- and *p*-hydroxybenzaldehyde condensations. Whether the mechanism involves intermediate formation of a Schiff base is now under investigation.

Sastry and Seshadri[7] have described the decarboxylation of 3,8-dicarboxy-5-hydroxy-7-methylcoumarin and report the formation of 8-carboxy-5-hydroxy-7-methylcoumarin. Since the melting point of their product is identical with that of the 3-carboxy derivative obtained in this research and prepared by an unequivocal method, it is probable that in the decarboxylation of the 3,8-dicarboxy derivative the 8-carboxyl group has been lost and that the product reported by Sastry and Seshadri is the 3-isomer.

The decarboxylation of 3-carboxy-5-hydroxy-7-methylcoumarin could not be accomplished with quinoline and copper and only a low yield of impure product resulted when the metal alone was used. It was discovered that aqueous sodium bisulfite was an excellent reagent for this purpose and 75–90% yields of 5-hydroxy-7-methylcoumarin (IV) was readily obtained. Presumably the coumarin is opened and carbon dioxide is lost without transforming the *cis*-cinnamic acid intermediate to the *trans* form. Sodium sulfite could not be used in place of sodium bisulfite.

The 5-hydroxy-7-methylcoumarin was hydrated to the *trans*-2,6-dihydroxy-4-methylcinnamic acid (V) in 65–85% yields by means of aqueous sodium sulfite. In the esterification of the acid produced, difficulties were encountered and only diazomethane gave satisfactory results.

Experimental

2,6-Dimethoxy-4-methylbenzaldehyde (Atranol Dimethyl Ether).—Modifications of Adams and Carlin's method[1b] were introduced to avoid special apparatus and to increase the yield. In a 200-ml. round-bottom flask provided with a dropping funnel, a mechanical stirrer and a reflux condenser fitted with a calcium chloride tube was placed 2.5 g. of lithium hammered to paper thickness under a layer of paraffin oil. The lithium was washed twice with anhydrous ether by decantation and covered with 100 ml. of anhydrous ether. The stirrer was started, 5 g. of *n*-butyl chloride was added all at once and the flask warmed gently to start the reaction. The reflux was maintained by dropwise addition of 15 g. of *n*-butyl chloride. Stirring was continued for about two hours when the lithium disappeared almost completely.

After addition dropwise of 25 g. of orcinol dimethyl ether, the stirrer was stopped and the flask placed in an oil-bath at 50° for eight hours. The oil-bath was removed, the stirrer started and a mixture of 25 g. of N-methylformanilide and 25 ml. of anhydrous ether introduced dropwise. At the end of the addition the mixture was heated for one more hour at 50°.

The product was poured over a mixture of 100 g. of crushed ice and 300 ml. of 3 *N* hydrochloric acid and extracted twice with ether (200 ml., 100 ml., 100 ml.). The combined ether extracts were washed with *N* hydrochloric acid, 10% aqueous sodium bicarbonate, water and dried over anhydrous sodium sulfate.

The ether was distilled and the residue was dissolved in 100 ml. of boiling cyclohexane. On cooling the aldehyde crystallizes in white needles and was filtered, washed twice with a little cyclohexane and finally with petroleum ether (b. p. 60–100°). The product was pure enough for the next step. From the mother liquor, a little more product was obtained but had to be crystallized from cyclohexane to be of acceptable purity. The yield in ten runs was between 12–16 g. (45–55%).

The melting point after crystallization from cyclohexane was 91–92° (Adams and Carlin,[1b] 91–92°).

2,6-Dihydroxy-4-methylbenzaldehyde (Atranol).—To a solution of 5 g. of atranol dimethyl ether in 250 ml. of carbon disulfide in a 500-ml. round-bottom flask fitted with a mechanical stirrer, 22 g. of aluminum bromide (3 moles per mole of aldehyde) in 250 ml. of carbon disulfide was added quickly with stirring. The addition complex precipitated as a red gum. After stirring for one hour the carbon disulfide was decanted into a separatory funnel and 100 g. of crushed ice, 150 ml. of 3 *N* hydrochloric acid and 200 ml. of ether was added to the residual gum in the flask and stirred until it was completely dissolved (one to two hours). The carbon disulfide in the separatory funnel was washed with 50 ml. of 3 *N* hydrochloric acid, the carbon disulfide layer discarded and the acid layer added to the mixture in the flask. The ether layer was removed and the aqueous layer extracted with two 200-ml. portions of ether.

The combined ether solutions were extracted with three 50-ml. portions of *N* aqueous sodium hydroxide. The atranol was precipitated from the alkaline solution by addition of 15 ml. of concentrated hydrochloric acid. The product was filtered, washed with a little water and crystallized from 125 ml. of boiling water (Norit). Yield, (average of twelve runs), 2.9 g. (70%) of slightly yellow product of adequate purity for the next step.

The product can be purified by crystallization from water, or toluene, and sublimation. It forms white crystals which start shrinking at 117° and melt at 123°; Pfau[2] reports m. p. 121° for his synthetic product and m. p. 124° for that obtained by degradation.

Anal. Calcd. for $C_8H_8O_3$: C, 63.15; H, 5.30. Found: C, 63.58; H, 5.40.

It was found that when working with larger runs, the yield was not as satisfactory. The conditions described were the best observed after careful study of many catalysts and solvents, modification of temperature and time.

Aluminum chloride, under similar conditions, gave only resins. In 0.1 g. runs, a yield of 30% could be obtained with this reagent.

2-Hydroxy-6-methoxy-4-methylbenzaldehyde (Atranol Monomethyl Ether).—A solution of 10 g. of atranol dimethyl ether in 200 ml. of benzene and 10 g. of aluminum chloride was placed in a 250-ml. round-bottom flask and stirred mechanically at room temperature. The complex, a dark liquid, formed in about ten minutes and the mixture was then heated for ten minutes at 85° without stirring.

The product was poured onto a mixture of 100 g. of crushed ice and 100 ml. of 3 *N* hydrochloric acid. The precipitate was not filtered but 250 ml. of 3 *N* aqueous sodium hydroxide was added which took it into solution. The alkaline solution was washed with ether, acidified and extracted twice with ether. The combined ether extracts were washed with 10% aqueous sodium bicarbonate, water and dried over anhydrous sodium sulfate. The residue from the ether was distilled under reduced pressure; b. p. 110–112° (1 mm.); yield, 7.4 g. (80%). After purification from toluene, it has a m. p. of 82–83°; Asahina[4] reports a m. p. of 78°.

Anal. Calcd. for $C_9H_{10}O_3$: C, 65.05; H, 6.06. Found: C, 65.64; H, 6.24.

2-Hydroxy-6-methoxy-4-methylbenzaldoxime.—The oxime was prepared in the usual way and purified from ethanol, m. p. 150–151°.

Anal. Calcd. for $C_9H_{11}O_3N$: C, 59.66; H, 6.12. Found: C, 59.72; H, 6.06.

3-Carboxy-5-hydroxy-7-methylcoumarin.—A mixture of 10 g. of atranol, 15 g. of malonic acid (2 moles per mole of aldehyde), 20 ml. of pyridine and 0.4 g. of aniline was heated in an open flask on an oil-bath at 55°. After about four hours, the product crystallized as a yellow mass.

It was heated one more hour and decomposed by trituration with 200 ml. of *N* hydrochloric acid. The product was filtered with suction, dissolved in 200 ml. of *N* hydrochloric acid, and precipitated by addition of 20 ml. of concentrated hydrochloric acid. The yield was 11 g. (75%) of yellowish product of satisfactory purity for the next step. It may be purified by crystallization from acetophenone, m. p. 270–271°.

Anal. Calcd. for $C_{11}H_8O_5$: C, 60.00; H, 3.66. Found: C, 60.00; H, 3.80.

Aniline was the only catalyst used which resulted in a satisfactory yield of the desired product; pyridine, piperidine, pyridine with piperidine, pyridine with methylaniline, ammonia in alcohol, acetic acid and sulfuric acids failed as catalysts.

5-Hydroxy-7-methylcoumarin.—A mixture of 5 g. of 3-carboxy-5-hydroxy-7-methylcoumarin and 60 ml. of a 25% aqueous solution of sodium bisulfite was placed in a 250-ml., round-bottom flask fitted with a mechanical stirrer and a dropping funnel. The flask was warmed with a bare flame until the solution was complete, the mixture stirred for about five minutes and then boiled for about thirty seconds. To the solution 50 ml. of a 50% aqueous solution of potassium hydroxide was then introduced and at the end of the addition the solution was boiled for ten seconds.

The flask was cooled in a freezing mixture, and concentrated hydrochloric acid (about 40 ml.) was added dropwise which resulted in formation of an abundant white precipitate. After one hour in the freezing mixture, the product was filtered with suction, washed twice with water and dried. The yield was 3.0 to 3.5 g. (75–90%). The product was of satisfactory purity for the next step. It may be purified by crystallization from a 50% mixture of dioxane and water. The melting point was 215–216° identical with that reported by Sastry and Seshadri[7] for 8-carboxy-5-hydroxy-7-methylcoumarin. It is believed probable that Sastry and Seshadri had in hand the 3-carboxy derivative.

Anal. Calcd. for $C_{10}H_8O_3$: C, 68.18; H, 4.57. Found: C, 68.67; H, 4.99.

Decarboxylation by means of copper gave only a 10% yield of the same product. The use of quinoline–copper failed completely.

2,6-Dihydroxy-4-methyl-*trans*-cinnamic Acid.—A mixture of 8 g. of 5-hydroxy-7-methylcoumarin and 60 ml. of a 25% aqueous solution of sodium sulfite in a 250-ml. round-bottom flask fitted with a mechanical stirrer and a dropping funnel was heated and stirred. When complete solution had taken place, the mixture was brought to boiling and the flask placed for one hour and a half in an oil-bath at 100° without stirring.

The stirrer was started again and 30 ml. of a 50% aqueous solution of potassium hydroxide was added dropwise after which the mixture was brought to boiling for about fifteen seconds. Upon cooling in a freezing mixture and dropwise addition of concentrated hydrochloric acid (about 30 ml.) an abundant white precipitate formed. The yield was 7 to 8.5 g. (65–85%) of product of satisfactory purity for the next step. The product may be purified by crystallization from glacial acetic acid, m. p. 200° with evolution of carbon dioxide.

Anal. Calcd. for $C_{10}H_{10}O_4$: C, 61.85; H, 5.19. Found: C, 62.10; H, 5.40.

Methyl 2,6-Dihydroxy-4-methyl-*trans*-cinnamate.—A current of diazomethane, prepared by heating a solution of diazomethane in ether, was passed into a stirred solution of 6 g. of 2,6-dihydroxy-4-methyl-*trans*-cinnamic acid in 200 ml. of dried ether. The esterification was followed by dipping blue litmus first in the ether solution and "revealed" by dipping in water (one test per minute). After about twenty minutes the esterification was complete and 100 ml. of a 10% aqueous solution of sodium bicarbonate was added all at once to decompose the excess of diazomethane.

The liquid was placed in a separatory funnel and washed with *N* hydrochloric acid, 10% aqueous sodium bicarbonate, water and dried over anhydrous sodium sulfate. The yield was 6 g. (95%). It was purified by crystallization from 40 ml. of a mixture of water and ethanol (2:1), m. p. 184–185°.

Anal. Calcd. for $C_{11}H_{12}O_4$: C, 63.45; H, 5.81. Found: C, 63.82; H, 5.98.

The usual method of esterification with methanol and sulfuric acid, hydrogen chloride or *p*-toluenesulfonic acid was unsatisfactory. The use of silver oxide and methyl iodide also failed.

Summary

1. The preparation of 2,6-dimethoxy-4-methylbenzaldehyde has been simplified. By demethylation with aluminum bromide, 2,6-dihydroxy-4-methylbenzaldehyde, atranol, is produced.

2. Atranol condenses with malonic acid in presence of pyridine and aniline to give 3-carboxy-5-hydroxy-7-methylcoumarin.

3. Aqueous sodium bisulfite readily causes decarboxylation of 3-carboxy-5-hydroxy-7-methylcoumarin to 5-hydroxy-7-methylcoumarin.

4. For hydration of the coumarin, aqueous sodium sulfite is satisfactory and 2,6-dihydroxy-4-methyl-*trans*-cinnamic acid results. The acid can be esterified with diazomethane.

Hydrogen Transfer. I. Reaction of *p*-Cymene with Olefinic Hydrocarbons in the Presence of Sulfuric Acid and Hydrogen Fluoride Catalysts[1,2]

BY V. N. IPATIEFF, HERMAN PINES AND R. C. OLBERG[2a]

In the course of the study of terpenic hydrocarbons which is being carried out in our laboratory, the reaction of *para*-cymene with dihydrolimonene (1-methyl-4-isopropylcyclohexene) in the presence of either sulfuric acid or hydrogen fluoride at 0° was included. It was noticed that this reaction proceeded abnormally[3] inasmuch as a 60% yield of 1-methyl-4-isopropylcyclohexane was obtained. This could not be attributed to a conjunct polymerization[4] of dihydrolimonene since the product obtained, including the high-boiling fractions, did not contain any olefinic hydrocarbons as determined by means of a potassium permanganate test.[5] It was also noticed that the high-boiling fraction resulting from this reaction had a much higher index of refraction than that expected from a cycloalkylation reaction. This material corresponded, according to elementary analysis, to a tricyclic hydrocarbon of the formula $C_{20}H_{24}$ (I). On the basis of these preliminary results, it was tentatively concluded that *p*-cymene acted as a hydrogen donor and dihydrolimonene as a hydrogen acceptor.

It was difficult to substantiate this conclusion as long as *p*-cymene and dihydrolimonene, having the same skeletal arrangement, were used as reactants. For this reason 3-methylcyclohexene was substituted for dihydrolimonene.

It was found in the reaction of *p*-cymene with 3-methylcyclohexene in the presence of either sulfuric acid or hydrogen fluoride, 62–80% of the methylcyclohexene was converted to methylcyclohexane. The yield of the expected methylcyclohexyl-*p*-cymene was very small, whereas a large amount of the tricyclic hydrocarbon, $C_{20}H_{24}$, was obtained which was identical with compound I. It was also found that for each mole of $C_{20}H_{24}$ produced there was one mole of methylcyclohexane formed.

If, however, *p*-cymene and a branched open chain olefin, such as trimethylethylene, were contacted in the presence of hydrogen fluoride, both an alkylation and a hydrogen transfer reaction occurred; the latter reaction was the predominant one. Isopentane and decanes were found among the reaction products. The presence of decanes is attributed to the dimerization of the trimethylethylene, which through a subsequent hydrogen transfer reaction yields decanes. The major part of *p*-cymene which underwent reaction yielded the hydrocarbon, $C_{20}H_{24}$, identical with the one described above.

In order to determine whether the hydrogen transfer reaction which involves *para*-cymene and an olefinic hydrocarbon is of a general nature, a series of experiments was made using various olefins.

It was found that cyclohexene[6] or straight chain olefin such as 1-octene, react with *p*-cymene in the usual manner yielding the corresponding mono- and disubstituted *p*-cymene; hydrogen transfer reaction did not occur.

The Structure of the $C_{20}H_{24}$ Hydrocarbon (I).—The facts described below and the postulated mechanism of hydrogen transfer reaction suggested that the $C_{20}H_{24}$ hydrocarbon corresponds to 1,3,3,6-tetramethyl-1-*p*-tolylindan (I). In order to establish conclusively the structure of compound (I) 1,3,3,6-tetramethyl-1-*p*-tolylindan was synthesized. The physical constants, nitro derivatives, and ultraviolet absorption spectra of the synthetic sample were compared with the tricyclic hydrocarbon obtained from the hydrogen transfer reaction; the two compounds were identical.[7]

Infrared absorption spectra of the synthetically prepared compound I and that obtained from the hydrogen transfer reaction were taken (Graph I and II). The 1,3,3,6-tetramethyl-1-*p*-tolylindan prepared from the latter reaction solidified on standing, so for that reason the infrared spectrum was taken in a carbon disulfide solution. The spectra of both compounds were found to be basically the same; the synthetic sample seems to be only about 95% pure. Due to the small amount of synthetic sample prepared, no attempt was made to purify it.

Compound I yielded on nitration a tetranitro derivative $C_{20}H_{20}N_4O_8$ melting at 252–253°. A disulfonamide of the hydrocarbon was obtained melting at 227–228°. The tricyclic hydrocarbon yielded on oxidation a dicarboxylic acid, $C_{20}H_{20}O_4$, melting at 294–295°.

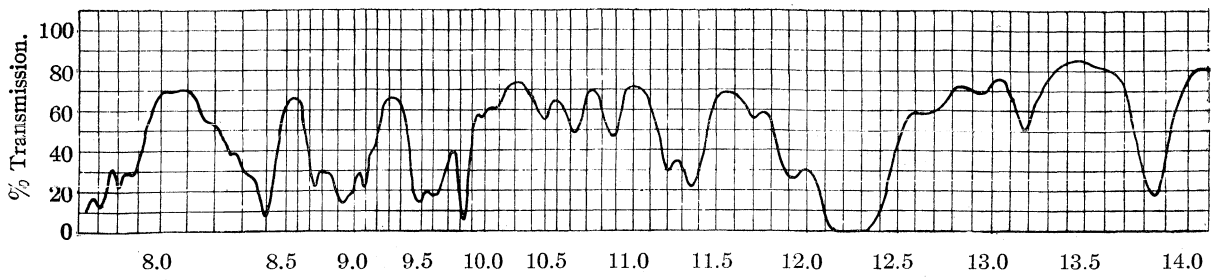
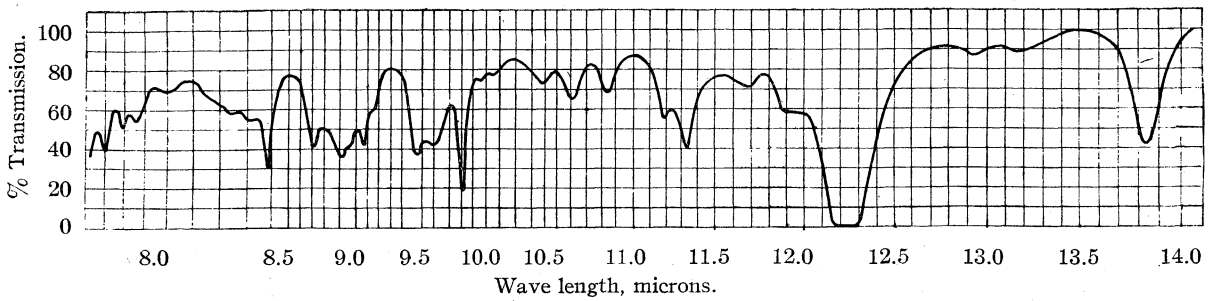
(7) The same tricyclic hydrocarbon, $C_{20}H_{24}$, was reported by N. Puranen (*Ann. Acad. Sci. Fennicae*, **37A**, No. 10, 1–80 (1933); **C**, 1933 II, 856) to be formed by the treatment of *p*-cymene with nitrosylsulfuric acid in sulfuric acid. The melting point of the hydrocarbon and its nitro derivatives agrees with those obtained from the hydrogen transfer reaction. Puranen assigned to this compound the structure of 1,3,3,6-tetramethyl-1-*p*-tolylindan; he did not however prove the structure by either degradative or synthetic means.



Graph I.—1,3,3,6-Tetramethyl-1-*p*-tolylindan; prepared by synthetic means.



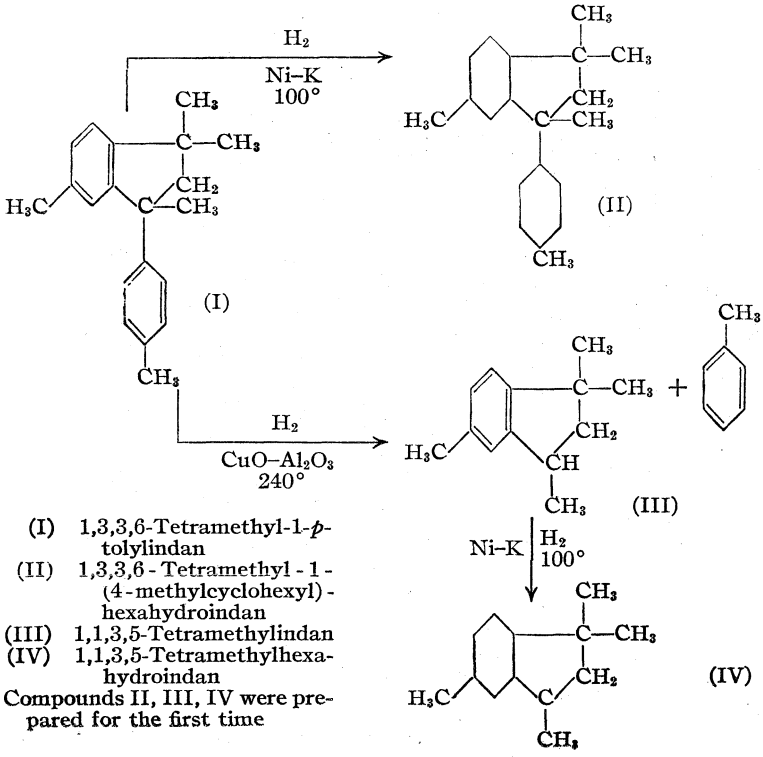
Graph II.—1,3,3,6-Tetramethyl-1-*p*-tolylindan; obtained from a hydrogen transfer reaction.

The $C_{20}H_{24}$ hydrocarbon (I), on hydrogenation in the presence of a nickel–kieselguhr catalyst at 100° and under an initial hydrogen pressure of 100 atmospheres, absorbed six moles of hydrogen per mole of hydrocarbons to yield a compound corresponding to $C_{20}H_{36}$ (II).

The tricyclic hydrocarbon (I) on destructive hydrogenation at 240° under pressure in the presence of a copper oxide–alumina catalyst yielded toluene and a bicyclic aromatic hydrocarbon corresponding to $C_{13}H_{18}$ (III); some of the original tricyclic hydrocarbon was recovered.

The bicyclic hydrocarbon, $C_{13}H_{18}$ (III), obtained from the destructive hydrogenation, was further hydrogenated under pressure at 100° in the presence of a nickel–kieselguhr catalyst. A bicyclic hydrocarbon corresponding to $C_{13}H_{24}$ (IV) was obtained.

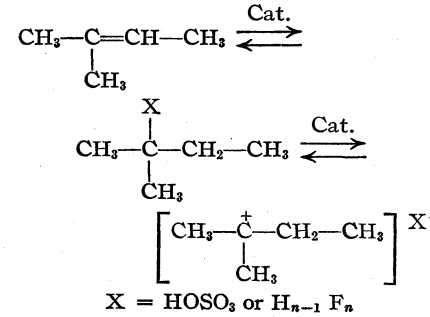
The tricyclic hydrocarbon $C_{20}H_{24}$ (I) did not undergo dehydrogenation when passed over platinized alumina at 300°.



(I) 1,3,3,6-Tetramethyl-1-*p*-tolylindan
(II) 1,3,3,6-Tetramethyl-1-(4-methylcyclohexyl)-hexahydroindan
(III) 1,1,3,5-Tetramethylindan
(IV) 1,1,3,5-Tetramethylhexahydroindan
Compounds II, III, IV were prepared for the first time

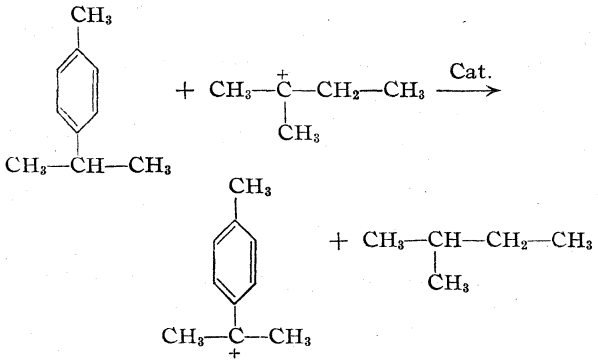
Mechanism of Reaction.—The following mechanism is suggested to explain the hydrogen transfer reaction between trimethylethylene and *p*-cymene:

1. The olefinic hydrocarbons react with the catalyst; a carbonium ion is probably formed.

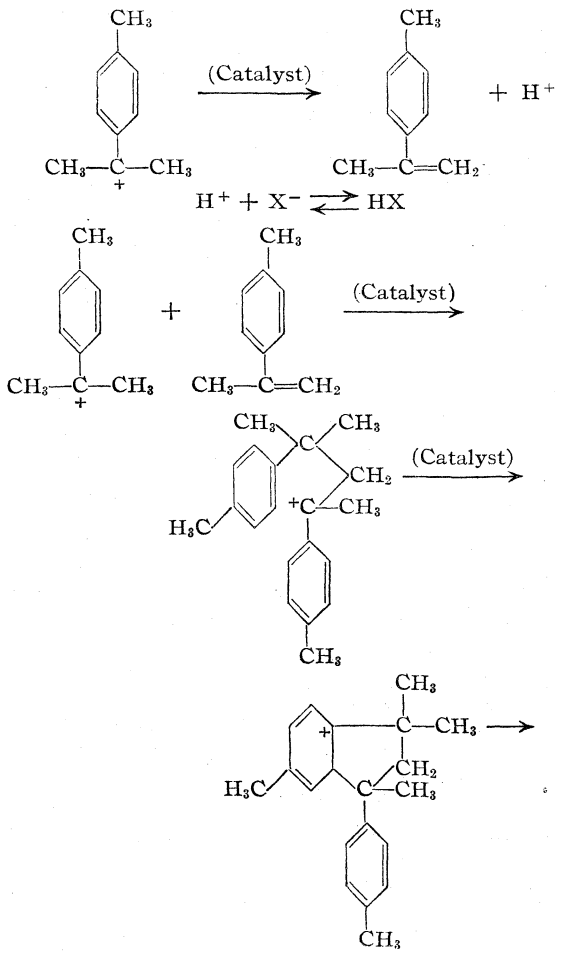


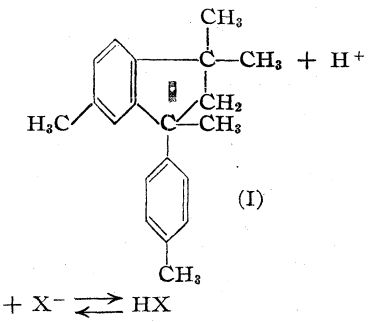
2. In the presence of an alkylating catalyst an exchange reaction

probably occurs similar to the type described by Bartlett, Condon and Schneider.[8]



3. Part of the dimethyl-*p*-tolyl carbonium ion formed may lose a proton to form 1-methyl-4-isopropenylbenzene; the latter on reaction with the dimethyl-*p*-tolylcarbonium ion forms probably 2,4-di-*p*-tolyl-4-methyl-2-pentylcarbonium ion. The latter through an internal addition to the benzene ring and a subsequent loss of a proton yields 1,3,3,6-tetramethyl-1-*p*-tolylindan (I).

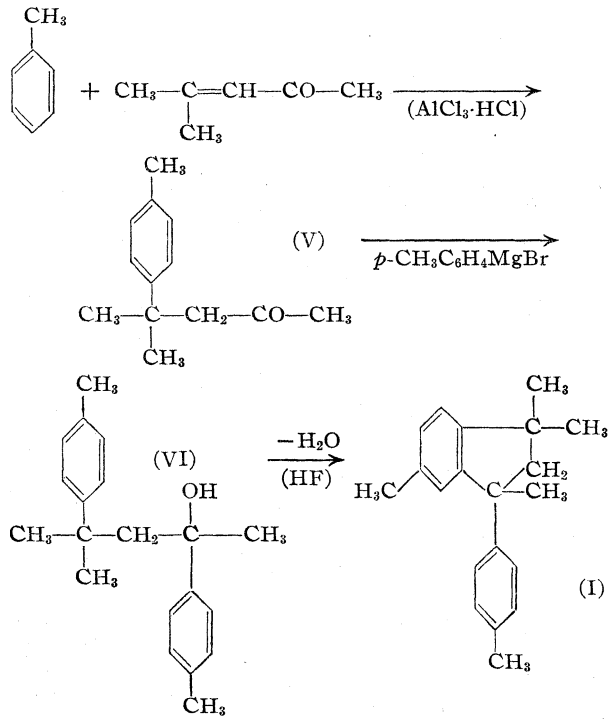




In order to prove that the formation of 1,3,3,6-tetramethyl-1-*p*-tolylindan (I) may proceed through the above indicated mechanism, 1-methyl-4-isopropenylbenzene was prepared and the compound treated with hydrogen fluoride under experimental conditions similar to those required for a hydrogen transfer reaction. The product of the reaction was 1,3,3,6-tetramethyl-1-*p*-tolylindane. This is in agreement with a similar result obtained by Bergmann, Taubadel and Weiss[9] who found that the dimerization of isopropenylbenzene in the presence of acid acting catalysts yields 1,3,3-trimethyl-1-phenylindan.

p-Cymene by itself does not undergo any changes when treated with either hydrogen fluoride or sulfuric acid under the experimental conditions used for the hydrogen transfer reaction.

1,3,3,6-Tetramethyl-1-*p*-tolylindan (I) was synthesized as follows.[9]



The para position of the substituents on the aro-

matic ring was proved by means of oxidation of compound (V) to terephthalic acid.

Experimental Part

The reactions of *p*-cymene with olefins in the presence of catalysts were carried out by the following procedure.

Sulfuric Acid Catalyzed Reaction.—The apparatus consisted of an appropriately sized three-neck flask equipped with a mercury sealed stirrer, reflux condenser and a water-cooled dropping funnel. The flask was surrounded by a cooling bath of ice and water. A thermometer was inserted into the reaction flask.

The sulfuric acid (96%) and one-half of the *p*-cymene were introduced into the flask and cooled at 0°. The olefinic hydrocarbon and the remainder of the *p*-cymene were mixed and added slowly with efficient stirring to the contents of the flask. The rate of addition was controlled so as to maintain the temperature inside the flask between 0° and 7°. After the addition was finished, the stirring was continued for a half hour.

The contents of the flask were poured into a separating funnel and allowed to stand for one to two hours in order to assure a complete separation of the acid and hydrocarbon layers.

The hydrocarbon layer was separated washed with water, with alkali, again with water, dried and distilled.

Hydrogen Fluoride Catalyzed Reaction.—The apparatus consisted of a copper flask provided with a copper stirrer and a dropping funnel. The flask was surrounded by a cooling bath of ice and water. The procedure was the same as that of sulfuric acid.

The contents of the flask were poured into a copper beaker containing ice precooled to about −30°. The hydrocarbon was separated and washed with dilute aqueous potassium hydroxide, followed by a water wash, then dried over calcium chloride and distilled.

The experimental results obtained are given in Table I.

As an example of the methods used for the identification of the reaction product, Experiment 2 is described in detail.

Experiment 2 (*p*-Cymene-methylcyclohexene–Sulfuric Acid).—Distillation of 700 g. of hydrocarbon mixture yielded the following fractions:

Fraction 1, b. p. 101°, $n^{20}D$ 1.4220, 114 g., corresponds to methylcyclohexane, since on dehydrogenation over platinized alumina (Pt 7%) at 260°,[10] it yielded toluene. The latter was identified by means of its dinitro derivative, which melted at 70°.

Fraction 3, b. p. 172–174°, $n^{20}D$ 1.4890, 378 g., consists of unreacted *p*-cymene, as determined by the ultraviolet absorption spectra.

Fraction 6, b. p. 124–126° at 4 mm., $n^{20}D$ 1.5305, d^{20}_4 0.9581, 28 g., corresponds to methylcyclohexyl-*p*-cymene.

Anal. Calcd. for $C_{17}H_{26}$: C, 88.63; H, 11.37. Found: C, 89.40; H, 10.68.

Nitro Derivative.—One ml. of the product was treated with 5 ml. of nitrating mixture composed of 1 vol. 72% nitric acid and 2 vol. 96% sulfuric acid. The nitro compound was crystallized from ethanol. It melted at 152–153°.

Anal. Calcd. for $C_{17}H_{24}N_2O_4$: C, 63.75; H, 7.50; N, 8.75. Calcd. for $C_{16}H_{22}N_2O_4$: C, 62.74; H, 7.19; N, 9.15. Found: C, 62.53; H, 6.91; N, 8.79.

According to elementary analysis, the nitro compound corresponds to isopropyl-(methylcyclohexyl)-dinitrobenzene; it seems that a methyl group in the benzenoid ring was replaced by a nitro group. Such replacement is quite common.[11]

The sulfonamide was prepared by the procedure of Huntress and Autenrieth[12] and crystallized twice from dilute alcohol and twice from benzene–pentane solution. It melted at 187–188°.

Anal. Calcd. for $C_{17}H_{27}NSO_2$: C, 66.02; H, 8.74; N, 4.53. Found: C, 66.22; H, 8.71; N, 4.65.

Fraction 9, b. p. 156° at 4 mm., $n^{20}D$ 1.5580, 128 g., corresponds to 1,3,3,6-tetramethyl-1-*p*-tolylindan.

Anal. Calcd. for $C_{20}H_{24}$: C, 90.85; H, 9.15. Found: C, 91.31; H, 8.96.

The product crystallized out very slowly until it was seeded with (I). It melted at 37.5°.

Nitration.—One gram of the hydrocarbon $C_{20}H_{24}$ was dissolved in 5 ml. of chloroform, cooled to 0°, and to it was added 1.5 ml. of 96% sulfuric acid and 0.5 ml. of 72% nitric acid. A crystalline derivative was obtained, melting at 112–114°. After crystallization from ethanol it melted at 114–115°; it corresponded to 1,3,3,6-tetramethyl-5-nitro-1-(4-methyl-3-nitrophenyl)-indan.

Anal. Calcd. for $C_{20}H_{22}N_2O_4$: C, 67.80; H, 6.21; N, 7.90. Found: C, 68.12; H, 6.02; N, 7.89.

One-half ml. of the product was treated with 5 ml. of a nitrating mixture, composed of 1 vol. 72% nitric acid and 2 vol. 96% sulfuric acid, and heated for a few minutes to 70–80°. The product solidified while still hot; it was poured over ice, filtered and the solid crystallized from a hot ethanol–chloroform mixture. White glistening crystals were obtained, which melted at 251–252°. The nitro compound corresponds to 1,3,3,6-tetramethyl-5,7-dinitro-1-(4-methyl-3,5-dinitrophenyl)-indan. Mixed melting point with a synthetically prepared tetranitro derivative showed no depression.

Anal. Calcd. for $C_{20}H_{20}N_4O_8$: C, 54.05; H, 4.50; N, 12.61. Found: C, 54.20; H, 4.43; N, 12.84.

The sulfonamide crystallized from water–alcohol mixture; it melted at 227–228° and corresponded probably to 1,3,3,6-tetramethyl-1-(4-methyl-3-sulfonamido-phenyl)-5-sulfonamido-indan.

Anal. Calcd. for $C_{20}H_{26}O_4N_2S_2$: C, 56.87; H, 6.16; N, 6.63. Found: C, 57.57; H, 6.34; N, 6.34.

Oxidation.—One gram of the product was heated under reflux with a solution composed of 30 ml. of acetic acid, 30 ml. of water, 5 ml. of 96% sulfuric acid and 7 g. of chromic anhydride. The mixture was heated for six hours. The solution was cooled and diluted with water; a solid precipitated out, which was filtered and washed with water. The solid was dissolved in dilute aqueous sodium hydroxide and extracted with ether to remove any neutral material which might be present. The aqueous solution was then acidified with dilute hydrochloric acid. The organic acid which separated out melted at 294–295°; it corresponds to 1,3,3-trimethyl-1-(4-carboxyphenyl)-6-carboxyindan.

Anal. Calcd. for $C_{20}H_{20}O_4$ (mol. wt. 324): C, 74.08; H, 6.17. Found: C, 73.22; H, 6.78; neutral equivalent of the acid, 160.

Hydrogenation.—Fifteen grams of the hydrocarbon $C_{20}H_{24}$ was hydrogenated at 100° under an initial hydrogen pressure of 120 atmospheres and in the presence of 2.5 g. of a nickel–kieselguhr catalyst. From the pressure drop it was calculated that 6 moles of hydrogen were absorbed per mole of hydrocarbon.

The hydrogenated material distilled at 183° (13 mm., $n^{20}D$ 1.4982, d^{20}_4 0.9248. It corresponds to 1,3,3,6-tetramethyl-1-(4-methylcyclohexyl)-hexahydroindan (Compound II).

Anal. Calcd. for $C_{20}H_{36}$: C, 86.87; H, 13.13. Found: C, 86.70; H, 13.20.

Destructive Hydrogenation.—Twenty-seven grams of fraction 9 was submitted to destructive hydrogenation in the presence of 4 g. of a coprecipitated copper oxide–alumina catalyst (copper oxide 60% by wt.). The reaction was carried out in a 450 cc. capacity rotating autoclave at 270° and at an initial hydrogen pressure of 122 atm. measured at 28°. The time of heating was seven hours; the maximum pressure was 230 atm.; the final pressure measured at 28° was 106 atm.

The gases were collected and analyzed; they consisted of 99.4% of hydrogen. The liquid product was fractionally distilled and the following cuts were collected:

Cut 1, b. p. 108–110°, $n^{20}D$ 1.4940, 3.5 g., consisted of toluene. A dinitrotoluene was prepared melting at 70°.

Cut 3, b. p. 210–212°, $n^{20}D$ 1.5071, 6.5 g., corresponded to 1,1,3,5-tetramethylindan (Compound III).

Anal. Calcd. for $C_{13}H_{18}$: C, 89.66; H, 10.34. Found: C, 89.47; H, 10.50.

Cut 4, b. p. 158° at 4 mm., $n^{20}D$ 1.5545, 12.5 g., corresponded to recovered compound I. It melted at 37.5° and yielded a tetranitro derivative melting at 250° and a sulfonamide melting at 123–124°.

Anal. Calcd. for $C_{13}H_{19}SO_2N$: N, 5.53. Found: N, 5.47.

A larger amount of 1,1,3,5-tetramethylindan was prepared and 17 g. of the hydrocarbon was hydrogenated in the presence of 3 g. of nickel–kieselguhr catalyst at 100° and under an initial hydrogen pressure of 100 atmospheres at 25°. From the drop in hydrogen pressure it was calculated that three moles of hydrogen was absorbed per mole of hydrocarbon. The hydrogenated product distilled at 213–215°, $n^{20}D$ 1.4622. It corresponds to 1,1,3,5-tetramethylhexahydroindan (Compound IV).

Anal. Calcd. for $C_{13}H_{24}$: C, 86.25; H, 13.75. Found: C, 86.77; H, 13.40.

Synthesis of 1,1,3,6-Tetramethyl-1-*p*-tolylindan (I)

4-Methyl-4-*p*-tolyl-2-pentanone (V).—The reaction vessel consisted of a 2-liter three-neck flask containing a mercury sealed stirrer, a dropping funnel and a reflux condenser. Toluene, 108 g. (2 *M*) and 200 g. of carbon disulfide were placed in the reaction flask which was surrounded with ice. To this solution was added 160 g. (1.2 moles) of aluminum chloride; on the addition of the catalyst the solution turned a deep red color. To the contents of the flask 98 g. (1 mole) of mesityl oxide was added over a period of two and one-half hours. After the addition was completed, the stirring was continued for an additional two hours. During all this time a slow stream of hydrogen chloride was bubbled into the liquid. The content of the flask was then poured onto ice. Two layers were formed: the upper (organic) layer was separated, washed with water, followed by sodium carbonate solution and again with water. The product was then steam distilled to remove the excess of toluene and carbon disulfide; the remaining material was separated from the water, dried and distilled under reduced pressure.

The 4-methyl-4-*p*-tolyl-2-pentanone (V) formed, distilled at 160° at 37 mm., $n^{20}D$ 1.5082, d^{20}_4 0.9594; yield, 40%.

Anal. Calcd. for $C_{13}H_{18}O$: C, 82.11; H, 9.47. Found: C, 82.15; H, 9.37.

Semicarbazone, after two crystallizations from 60% ethanol, melted at 190–191°.

Anal. Calcd. for $C_{14}H_{21}ON_3$: N, 17.00. Found: N, 17.40.

Oxidation.—One half gram of the ketone was treated under reflux for three hours with a solution consisting of 3.5 g. of chromic anhydride, 15 ml. of glacial acetic acid, 15 ml. of water and 4 ml. of 96% sulfuric acid. On dilution with water, a solid separated, which was filtered, washed with water and dried. It did not melt at 290°. The solid corresponded to terephthalic acid since the corresponding dimethyl ester melted at 141° and did not show a depression in melting point when mixed with a known sample of dimethyl terephthalate.

4-Methyl-2,4-di-*p*-tolyl-2-pentanol (VI)

p-Tolylmagnesium bromide prepared from 21 g. (0.12 mole) of *p*-bromotoluene and 2.9 g. (0.12 atom) of magnesium was condensed with 19 g. (0.1 mole) of (V). The carbinol VI, 18 g., distilled at 160° (3 mm.); $n^{20}D$ 1.5520.

Anal. Calcd. for $C_{20}H_{26}O$: C, 85.11; H, 9.22. Found: C, 85.10; H, 9.17.

1,1,3,6-Tetramethyl-*p*-tolylindan (I)

Six grams of (VI) was dissolved in 15 g. of methylcyclohexane and the solution was added, with stirring,

to 17 g. of anhydrous hydrogen fluoride at 0°. The content of the copper flask was then poured onto ice. The hydrocarbon layer was separated, washed with potassium hydroxide, water, dried over calcium chloride and distilled. Three grams of (I) was obtained, boiling at 161° (7.5 mm.), $n^{20}D$ 1.5579.

The infrared and ultraviolet absorption spectra were taken.

Two-tenths gram of (I) was nitrated with 5 ml. of nitrating mixture consisting of 2 vol. 96% sulfuric acid and 1 vol. of 72% nitric acid. The nitro compound obtained was crystallized from a solution of ethanol and chloroform. It melted at 251°, and did not depress the melting point of the tetranitro derivative of the $C_{20}H_{24}$ hydrocarbon.

Dimerization of 1-Methyl-4-isopropenylbenzene

A. Dimethyl-*p*-tolyl-carbinol.—The carbinol was prepared from 256 g. (1.5 mole) of *p*-bromotoluene and 81 g. (1.4 mole) of acetone via a Grignard reaction according to the procedure of Sabatier and Marat.[13] The carbinol distilled at 73° (2.5 mm.), $n^{20}D$ 1.5168; yield 66%.

B. 1-Methyl-4-Isopropenylbenzene.—Forty-three grams of the carbinol was passed at 350° during a period of one hour over 40 cc. of activated alumina of a 10–12 mesh size. The hydrocarbon distilled at 82° (21 mm.), $n^{20}D$ 1.5350; yield was over 80%.

C. Polymerization of 1-Methyl-4-isopropenylbenzene.—Eight grams of 1-methyl-4-isopropenylbenzene dissolved in 7 g. of methylcyclohexane was added with agitation to 10 ml. of anhydrous hydrogen fluoride placed in a copper beaker. The mixture was stirred for fifteen minutes and then poured onto 15 g. of ice precooled to −40°. The hydrocarbon layer was separated, diluted with ether, washed with aqueous potassium hydroxide, dried, and distilled. Three grams of a hydrocarbon boiling at 171° (5 mm.) was obtained; $n^{20}D$ 1.5545, melting point 33°. According to ultraviolet analysis it consisted of 1,3,3,6-tetramethyl-1-*p*-tolylindan (Compound I).

Anal. Calcd. for $C_{20}H_{24}$: C, 90.85; H, 9.15. Found: C, 91.03; H, 9.11.

(13) P. Sabatier and M. Murat, *Compt. rend.*, **156**, 184 (1913); *Ann. Chim.*, [9] **4**, 253 (1915).

On nitration with nitrating mixture consisting of 2 vols. of sulfuric acid and 1 vol. of nitric acid it formed a tetranitro derivative, which after two crystallizations from ethanol–chloroform solution melted at 248°, and did not depress the melting point of the tetranitro derivative prepared from a known sample of Compound I.

Acknowledgment.—We are indebted to Mr. Don Strehlau for some of the derivatives, to Mrs. Margaret Ledyard for the elementary analyses and to Dr. W. S. Gallaway of the Universal Oil Products Company for the infrared analyses.

Summary

The reaction of *p*-cymene with trimethylethylene, methylcyclohexene, dihydrolimonene, 1-octene, and cyclohexene in the presence of either sulfuric acid or hydrogen fluoride was investigated.

Hydrogen transfer occurs when *p*-cymene reacts with the first three olefins; the products resulting from such reaction consist of isopentane, methylcyclohexane, and *p*-menthane, respectively, and 1,3,3,6-tetramethyl-1-*p*-tolylindan which is formed in each case.

1,3,3,6-Tetramethyl-1-*p*-tolylindan was synthesized.

A mechanism for the hydrogen transfer reaction is proposed:

The following new compounds and their derivatives were prepared: (a) 4-methyl-4-*p*-tolyl-2-pentanone, (b) 4-methyl-2,4-di-*p*-tolyl-2-pentanol, (c) 1,3,3,6-tetramethyl-1-(4-methylcyclohexyl)-hexahydroindan, (d) 1,1,3,5-tetramethylindan, and (e) 1,1,3,5-tetramethylhexahydroindan.

The Acid Hydrolysis of Egg Albumin. I. Kinetic Studies

BY HENRY B. BULL AND J. WILFRID HAHN

It becomes increasingly clear that a central problem of protein chemistry is the localization of the amino acid residues in the peptide chains, and it is possible that study of the hydrolysis of proteins might shed light on this problem. While the literature on protein hydrolysis is extensive, there are certain features of this reaction which have not been explored. The present paper reports the results of an investigation of the hydrolysis of purified hen's egg albumin at 30°, at 45° and at 60° by hydrochloric acid. The amino nitrogen, the free amino acids, the ammonia, the material insoluble in trichloroacetic acid as well as the heat coagulable material have been determined, and an interpretation of these results is suggested.

Experimental

One volume of a solution of crystalline albumin prepared from fresh chicken eggs by the method of Kekwick and Cannan[1] was added to two volumes of concentrated hydrochloric acid. The flask containing the reaction mixture was securely stoppered and placed in a water-bath at the desired temperature and rotated occasionally. A single, clear, homogeneous phase resulted in a few minutes. At intervals, 20-cc. aliquots were removed and neutralized with powdered sodium bicarbonate, and the turbid solutions resulting made up to 50 cc. with water. Ammonia, free amino acids and amino nitrogen were determined on these dilutions.

Material precipitable by trichloroacetic acid was measured on 5-cc. aliquots of the reaction mixture which were diluted to 50 cc. without neutralization. Five cc. of this dilution was treated with 10 cc. of a 4% trichloroacetic acid solution, and after fifteen minutes filtered and the total nitrogen of the filtrate determined.

The heat coagulable material was determined by adjusting a 5-cc. aliquot of the hydrolyzate to about *p*H 4.5, heating on a boiling water-bath for five minutes, diluting to 50 cc. and filtering. Total nitrogen was run on the filtrate.

(1) Kekwick and Cannan, *Biochem. J.*, **30**, 227 (1936).

On the basis of total nitrogen in egg albumin,[2] the reaction mixture contained 4.25 g. of protein per 100 cc. The hydrochloric acid during the first part of the reaction was 7.95 *N* as determined by titration with standard base.

The ammonia was obtained by a steam distillation in the Pregl micro-Kjeldahl apparatus, using magnesium oxide as the alkalizing agent.

The amino nitrogen was measured in the Van Slyke volumetric apparatus by the Kendrick–Hanke modification,[3] and the reaction time was ten minutes. An ammonia correction was determined by the method of Irving, Fontaine and Samuels[4] and this correction, which amounted to 55% of the ammonia, was applied to the amino nitrogen values.

To calculate the rate of hydrolysis of peptide bonds from the amino nitrogen, it was necessary to assume that the bonds involving proline and hydroxyproline were hydrolyzed at a rate proportional to their amounts[5] in egg albumin.

The free amino acids released were measured by the ninhydrin titrimetric method at *p*H 2.5.[6] Aspartic acid yields carbon dioxide from both its carboxyl groups, and the ninhydrin values are too large by this amount. Following Frost and Heinsen,[7] we have assumed that aspartic acid is liberated at a rate proportional to its relative concentration[8] in the protein, and the ninhydrin values corrected on this basis.

Controls were prepared by neutralizing 13.5 cc. of concentrated hydrochloric acid with sodium bicarbonate and then adding 6.67 cc. of the mother protein solution. Control values have been subtracted from each determination to give the groups actually produced by the hydrolysis.

Results

Tables I, II and III show the quantities of ammonia, amino nitrogen and free amino acids produced by acid hydrolysis at 30°, at 45° and at 60° expressed in milliequivalents per gram of egg albumin. From the average residue weight for egg albumin and on the basis of 4 peptide chains in this protein,[8] there are about 8.89 milliequivalents of peptide bonds in one gram of protein. Percentage hydrolysis was calculated using this value after the proline correction had been applied.

Table IV shows the percentage of the total nitrogen in solution after treatment with trichloroacetic acid by the technique described above. Also shown is the per cent. of the total nitrogen in solution after isoelectric heat coagulation. The agreement between these sets of data is by no means perfect. We are inclined to believe that

Discussion

The liberation of ammonia follows the kinetics of a first order reaction, and the rate constants for this reaction were 0.039, 0.22 and 0.79 mole per hour per mole at 30, at 45 and at 60°, respectively. These rates were proportional to 0.72, 0.72 and 0.71 millimole ammonia per gram of protein at 30, at 45 and at 60°, respectively. The values compare favorably with that reported by Chibnall.[4] The energies of activation were 22,100 calories and 17,700 calories for the temperature ranges 30–45 and 45–60°, respectively.

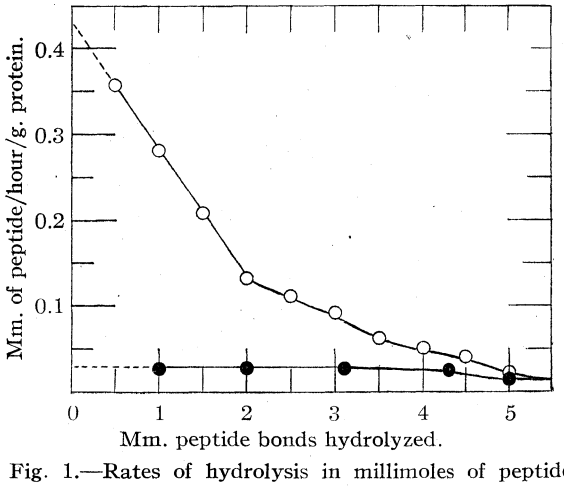

Fig. 1.—Rates of hydrolysis in millimoles of peptide bonds per hour per gram of protein. Open circles represent total peptide bonds and filled circles the liberation of free amino acid, 45° hydrolysis.

For a molecular weight of 45,000 for egg albumin, there are about 400 peptide bonds per molecule and, accordingly, there are potentially a large number of simultaneous reactions to consider. This is a complex problem, and its complete solution must await the future. It is not surprising that none of the measures of reaction velocity, with the exception of the ammonia liberation, follows with exactness any simple kinetic relation, and we do not regard speculation on the order of these reactions as profitable at the present.

The peptide bonds hydrolyzed and the amino acids liberated were plotted against the time of hydrolysis and the rates of rupture of the peptide bonds obtained from the slopes of the curves as a function of the bonds split. Shown in Fig. 1 is a plot of these rates at 45° against the extent of hydrolysis. The rates at 30° and at 60° exhibit the same qualitative behavior as is shown in Fig. 1.

From Figure 1, it appears that there is a fast reaction whose rate is 6 to 7 times greater than the slow reaction which accompanies it, and that the fast reaction is exhausted after a fraction of the peptide bonds have been hydrolyzed.

As a measure of the initial rates of reaction, we have determined the slopes of the tangents drawn from the origin for the various amount–time curves. From these rates we have calculated the ratio of the initial rate of hydrolysis of total peptide bonds and the initial rate of liberation of amino acids to the initial rate of destruction of protein as judged by isoelectric heat coagulation. We have calculated the energies of activation from these initial rates. These results are shown in Table V.

The average ratio of the initial rate of hydrolysis of peptide bonds to initial rate of destruction of protein is 56.5, and the corresponding ratio for the rate of liberation of amino acids is 4.58. When the intact protein is measured by the trichloroacetic acid precipitation, the total peptide ratio is about 70 and the free amino acid ratio is about 6.

Shown in Fig. 2 is a plot of the number of millimoles of peptide bonds hydrolyzed per gram of egg albumin against the fraction of the protein hydrolyzed. It will be noted that the experimental points lie on lines which apparently tend to converge into a single straight line during the first part of the reaction. As the reactions proceed toward completion, the curves swing upward rather sharply. Expressing the slope of the linear portion of the curve in peptide bonds hydrolyzed per gram molecular weight of egg albumin, we find

TABLE V

INITIAL RATES OF HYDROLYSIS IN MILLIMOLES PER HOUR PER GRAM OF PROTEIN, THE RATIO OF INITIAL RATES TO THE INITIAL RATE OF DESTRUCTION OF PROTEIN AND THE ENERGIES OF ACTIVATION

Temp., °C.	Free amino acids			Total peptide			Protein	
	Rate	Ratio to protein	Energy of activation	Rate	Ratio to protein	Energy of activation	Rate	Energy of activation
30	0.0066	4.55		0.074	50.7		0.00146	
45	.0294	4.23	19,100	0.43	61.1	22,500	.00695	20,000
60	.120	4.95	19,700	1.40	57.6	16,700	.0241	17,500

that 55 peptide bonds and 4.3 free amino acids are liberated for each egg albumin molecule destroyed. These values compare favorably with those given in Table V.

As can be seen in Table V the energies of activation for the hydrolysis of peptide bonds, the liberation of free amino acids and the destruction of protein are all of the same order of magnitude, and the conclusion is drawn that the destruction of the protein molecule is initiated by the hydrolysis of a single peptide bond, and the simultaneous activation of two or more peptide bonds is not necessary. It is to be noted that while the energy of activation for the liberation of amino acids is substantially constant over the temperature interval, the energy required for the activation of bonds leading to the destruction of the protein as well as the energy involved in the hydrolysis of total peptide bonds decreases significantly with increasing temperature, reflecting the existence of a complex reaction. Probably of great significance for the problem of hydrolysis of peptide bonds is the resonance energy of this bond. It can be estimated from bond distances that the peptide bond has about 45% double bond character and the activation of this bond, no doubt, blocks the resonance and weakens the bond by the extent of the resonance energy. It should be noted that the hydrolysis of a peptide bond is an exothermic reaction[9] yielding between 2,000 and 4,000 calories per mole. Whether or not the release of this energy would be sufficient to start an energy chain is not known.

In light of the above results and discussion, we suggest that the most reasonable interpretation of the acid hydrolysis of egg albumin is as follows: There exist two classes of peptide bonds in the protein as far as ease of hydrolysis is concerned. About 56 peptide bonds out of the 400 in the protein molecule can be hydrolyzed rapidly. The fragments produced by this initial split of the molecule are then further hydrolyzed, but at much slower rates. The rate at which a peptide bond is split is probably determined by the nature of the amino acid residues next to this bond.

Acknowledgment.—It is a pleasure to acknowledge the generous support afforded this research by Corn Products Refining Company.

Summary

1. The hydrolysis of egg albumin by hydrochloric acid has been studied at 30, at 45 and at 60°.

2. The amino nitrogen, the free amino acids and the ammonia liberated have been determined. The material soluble in trichloroacetic acid as well as the amount which cannot be heat coagulated at the isoelectric point have been measured.

3. The hydrolysis of a protein is not a simple kinetic process. About 56 of the peptide bonds in an egg albumin molecule are rapidly hydrolyzed, but the remaining bonds are hydrolyzed at a much lower rate.

The Acid Hydrolysis of Egg Albumin. II. Molecular Weight Distribution of Peptides

BY HENRY B. BULL AND J. WILFRID HAHN

This paper describes a new method for the estimation of the molecular weight distribution of the products resulting from the partial acid hydrolysis of proteins. The hydrolysate is spread on the surface of an ammonium sulfate solution and compressed. The peptides are forced into the substrate solution. The film is re-expanded, and the average molecular weight of the peptides remaining in the film determined by the application of the gas laws in two dimensions. By successive compressions to higher and higher pressures, it is possible to estimate the molecular weight distribution of the peptides in the hydrolysate. The hydrolysates have been described,[1] and were obtained by the action of 7.95 *N* hydrochloric acid on egg albumin at 30, at 45 and at 60°.

The Method

The general film technique has already been described.[2] The Wilhelmy slides consisted of two thin microscope cover glasses suspended from an arm of a Chain-o-Matic analytical balance and were located at one end of a well paraffined cast aluminum tray which was 65 cm. by 14 cm. One milligram of weight was equivalent to 0.0409 dyne per centimeter film pressure.

The substrate solution was a 5% ammonium sulfate solution which had been treated with activated charcoal and filtered. Glycerol which had been exhaustively extracted with petroleum ether was added to the ammonium sulfate to the extent of 2% by volume. It is not easy to obtain solution surfaces sufficiently free of surface active impurities, and care has to be exercised. Spreading was done with a Blodgett pipet whose delivery volume was 0.0850 cc. From 20 to 30 micrograms is a convenient weight of film for the size of tray used.

One minute after spreading, pressure readings were made as a function of film area up to a pressure of about one dyne per centimeter. The film was then compressed to 5 dynes per centimeter and held at this pressure for five minutes by moving the barrier in as part of the film passed into solution. The film was then re-expanded and a series of pressure readings below one dyne per centimeter was made as a function of the film area. The film was then compressed to 10 dynes per centimeter and held at this pressure for five minutes. The film was re-expanded and the low pressure measurements made. This process was repeated at 15, at 20 and at 25 dynes per centimeter pressure. It was possible to determine the complete molecular weight distribution of an hydrolysate in about an hour and a half.

When the film pressure is multiplied by the film area and this product plotted against the film pressure a straight line results, the equation of which is

$$FA_1 = \alpha_1 F + \beta_1 \qquad (1)$$

At zero film pressure, FA_1 is equal to β_1 and when A_1 is expressed in square meters per milligram, β_1 is equal to NRT which at 25° is equal to $24.6 \times 10^2/M$. The slope is equal to α_1 which is the area occupied by the gaseous film molecules.

Before we can calculate the molecular weight we must know the weight of the film. To find this weight we proceeded in the following manner.

A known weight of intact egg albumin was spread on the surface and compressed to 5 dynes per centimeter, and it was found that 1.11 milligram occupies one square meter at this pressure. An hydrolysate film was compressed to 5 dynes for five minutes. The film was then re-expanded and low pressure readings made. The area of the gaseous film was then determined with the use of equation 1. The relation between the gaseous area and the area at 5 dynes per centimeter for many different films is shown in Fig. 1. Evidently, there is a close relation between these two areas. The average ratio between the gaseous area and the 5 dyne per centimeter area is 1.065. If we assume that the area per milligram of the hydrolysate film at 5 dynes per centimeter is the same as that of the film of intact egg albumin, we can calculate the weight of the hydrolysate film by multiplying the area of the gaseous film by 1.035.

Shown in Fig. 2 is a typical plot of FA_1 against F, and demonstrates the reversibility of the pressure–area relation.

The weight of the Wilhelmy slides tends to increase with time. This increase amounted in some cases to as much as 5 mg. in the course of one and one-half hours and tends to give a non-linear relation when FA_1 is plotted against F, the apparent pressure being too small. It can be determined what weight must be added to the apparent pressures to yield a straight line when FA_1 is plotted against F, and such values have been accepted as valid provided the weight which had to be added was what was to be expected from the apparent increase of the surface tension of the clean surface during the same interval of time.

The return of some of the displaced peptides to the surface after the expansion of the film to low pressures would not invalidate this method, but would render the fractionation of the hydrolysate

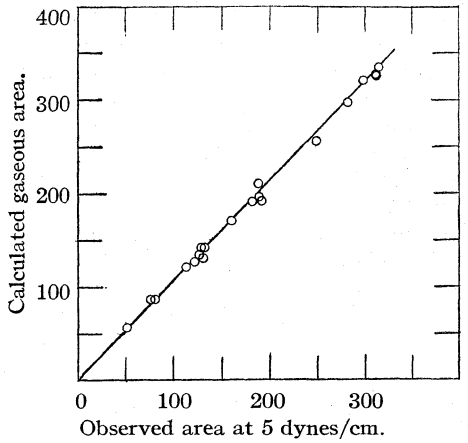

Fig. 1.—Calculated gaseous areas (α_1) in square meters plotted against the observed film area at 5 dynes per centimeter pressure.

inefficient to the extent to which such return occurs. To obtain a measure of this return to the surface the following experiment was done.

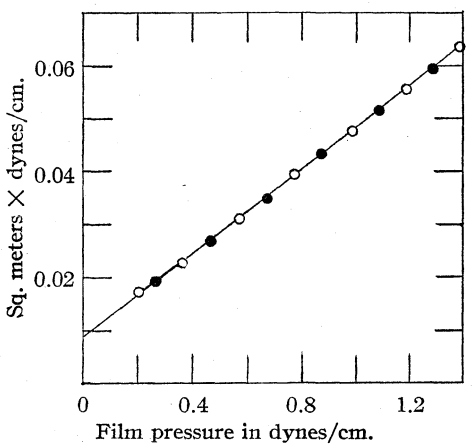

Fig. 2.—FA_1 in dynes per centimeter–square meter plotted against F in dynes per centimeter: open circles compression; filled circles, expansion.

An hydrolysate film was compressed to 25 dynes per centimeter and held at this pressure for five minutes. It was then re-expanded and after a few minutes compressed to 5 dynes per centimeter. This expansion and compression to 5 dynes per centimeter was repeated several times and the results plotted in Fig. 3.

The return of peptides to the film is probably small during a determination of the molecular weight distribution. Judging from the results shown in Fig. 3, roughly 2 to 3% of the displaced peptides would be expected to return to the film during an actual measurement of the molecular weight.

No answer can be given as to the accuracy of the present method because no other method exists for the resolution of peptides on the basis of their molecular weights, and it is not practical to synthesize a series of long chain peptides to calibrate the method. As shown previously,[2] results on the determination of the molecular weight of intact proteins were satisfactory and in accord with the results from accepted methods. As shown in Fig. 4, results from duplicate analyses of the molecular weight distribution of peptides are in reasonable agreement.

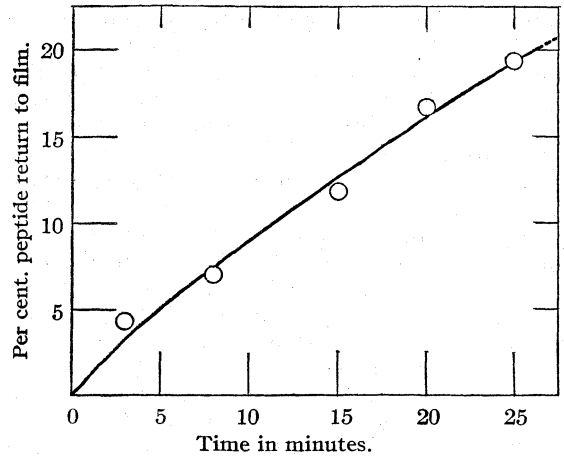

Fig. 3.—Per cent. of return of peptides to the surface as a function of time: 60° hydrolysate with 1.41 millimoles of peptide bond per gram of protein hydrolyzed.

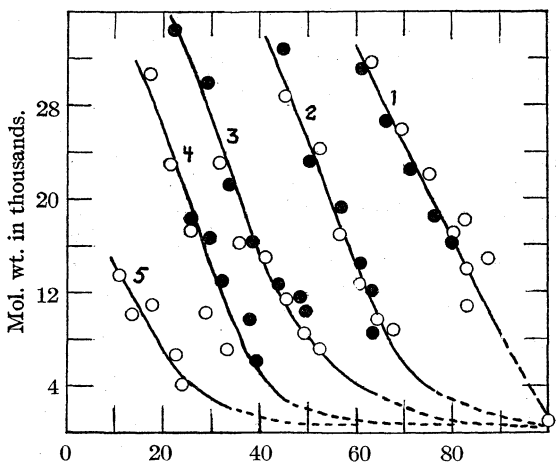

Fig. 4.—Number average molecular weights of peptides remaining in the film plotted against the per cent. of the total hydrolysate remaining in the film. The per cent. of the total peptide bonds hydrolyzed were as follows: Curve 1, 9.9; curve 2, 11.14; curve 3, 15.85; curve 4, 21.45; curve 5, 24.75. Open circles represent one series of measurements, while the filled circles are duplicates; 60° hydrolysates.

Results and Discussion

The partial hydrolysates used have been described[1] and were prepared for spreading by transferring 5 cc. of the hydrolysate resulting from the sodium bicarbonate neutralization to a 250 cc.

volumetric flask. A few drops of concentrated hydrochloric acid were added and after water was added nearly to volume, the flask was warmed to bring all of the hydrolysate into a clear solution. After cooling and making to volume the solutions were ready for spreading.

The primary data resulting from this investigation are very extensive, and it is not practical to report them in detail. It was found that the molecular weight distribution is, within limits of experimental error, the same for 30°, for 45° and for 60° hydrolysates for a given extent of hydrolysis and we are confining our report mainly to results for the 60° hydrolysates.

Shown in Fig. 4 are the number average molecular weights in thousands of the material remaining in the film after being subjected to compression, plotted as a function of the per cent. of the total amount of material in the hydrolysates. The individual curves are identified as representing material from different extents of hydrolysis at 60°. The open circles correspond to one series of measurements and the filled circles to results obtained several weeks later during a second series of measurements. While there is not perfect agreement between the two series, the agreement is reasonably satisfactory.

In order to express the results in Fig. 4 in a more understandable form, we have proceeded in the following manner:

The total number of moles of peptides remaining on the surface at any given compression have been calculated and these values plotted against the weight of the peptides in the film. The slopes of the smooth curves drawn through the points were measured with a Bausch and Lomb Tangent Meter. The reciprocal of these slopes is evidently equal to the molecular weight of the peptides being displaced from the film. These molecular weights were then plotted against the weight percentage of the peptides to give integral weight distributions which are shown in Fig. 5.

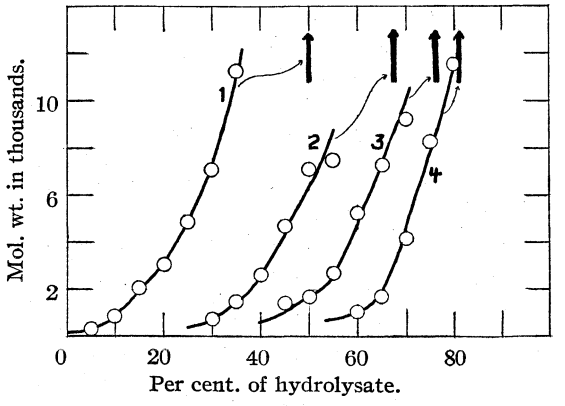

Fig. 5.—Integral molecular weight distribution curves for peptides resulting from the acid hydrolysis at 60°. The number of the curves corresponds to those shown in Fig. 4. Vertical lines at top of figure are the percentages of heat coagulable material at the isoelectric point.

It will be noted from Fig. 5 that the amount of isoelectric heat coagulable material is consistent with the molecular weight distribution of peptides. All curves in Fig. 5 are smooth, and there is no evidence for any appreciable accumulation of a peptide of a particular molecular weight.

A 30°, two hour hydrolysate was subjected to isoelectric heat coagulation. The percentage of peptide bonds hydrolyzed in the soluble peptides was 12.7. The integral distribution curve for these peptides is shown in Fig. 6.

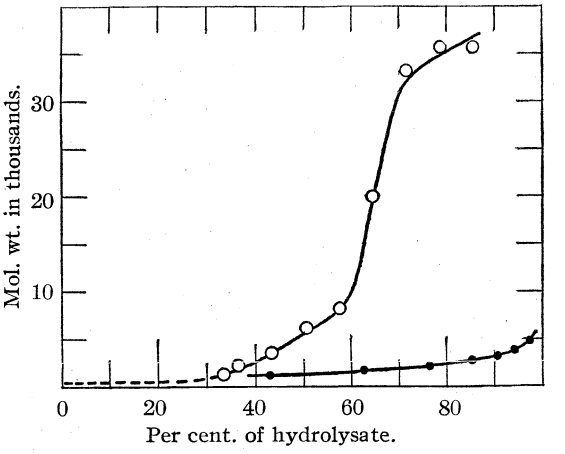

Fig. 6.—Integral molecular weight distribution curve of peptides after removal of isoelectric heat coagulable material: two hour hydrolysate at 30°. Also shown is the distribution of peptides on the basis of random hydrolysis for the same extent of hydrolysis (filled circles).

The molecular weight distribution of the pepides has been calculated for random hydrolysis with the theory of Montroll and Simha.[3] In these calculations the molecular weight of the monomer was assumed to be 111.3[4] and the number of residues to be 400. The fraction hydrolysis was 0.127. Figure 6 shows the results of these calculations, and it is clear that the hydrolysis of peptide bonds in egg albumin is far from being a random process.

Comparing the results shown in Fig. 6 with some of the conclusions drawn in the first paper of this series,[1] we can say the following: The 56 fast hydrolyzing bonds must be rather evenly distributed throughout at least part of the protein molecule, otherwise there would not be such a large fraction of low molecular weight peptides. On the other hand, there is a fairly large amount of peptides with molecular weights between 1,000 and 10,000. There is no way of knowing whether this heavier material is simply an intermediate in the fast reaction or is an end-product of this reaction. It is perhaps significant that there is little material whose molecular weight is between 10,000 and 30,000. This seems to indicate that the initial attack occurs on the ends of the peptide chains rather than in the middle.

(3) Montroll and Simha, *J. Chem. Phys.*, **8**, 721 (1940).
(4) Chibnall, *Proc. Roy. Soc.* (*London*), **B131**, 152 (1942).

In order to obtain the relation between the molecular weight of the peptides forced into the substrate solution and the pressure exerted on the film, the percentages of the hydrolyzed material remaining in the film were plotted against the pressures exerted. The corresponding molecular weights were then interpolated from Figs. 5 and 6. The logarithms of the molecular weight have been plotted against the pressures exerted and are shown in Fig. 7.

The points in Fig. 7 extrapolate at zero pressure to log molecular weight of about 3. This means that peptides whose molecular weight is about 1,000 or less pass spontaneously into the substrate solution and will not form a film.

The techniques described in this paper are being applied to the study of the molecular weight distribution of peptides resulting from the action of enzymes on proteins. These results will be reported in due time.

It is a pleasure to acknowledge the generous assistance granted this research by Corn Products Refining Company.

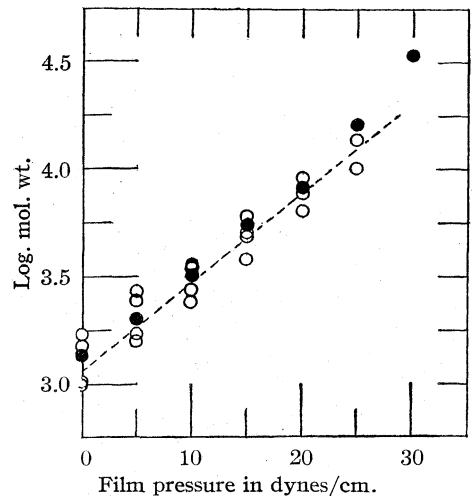

Fig. 7.—Logarithm of molecular weights of displaced peptides plotted against pressure exerted on the film. Open circles are 60° hydrolysates and filled circles two hour hydrolysate at 30° (protein free).

Summary

1. A new method has been described for the determination of the molecular weight distribution of peptides in a partial acid hydrolysate of a protein.

2. An hydrolysate is spread as a monomolecular layer on a 5% ammonium sulfate solution and is compressed to progressively increasing pressures. The logarithm of the molecular weight of the displaced peptides is proportional to the pressure exerted on the film. The molecular weight of the peptides remaining in the film after exposure to a given pressure is determined by the application of the gas laws in two dimensions.

3. The molecular weight distribution of egg albumin hydrolyzed by hydrochloric acid at several degrees of hydrolysis has been reported.

4. It is found that while the molecular weight distribution of peptides departs greatly from that expected for a random hydrolysis, there is no evidence for the accumulation of any considerable amounts of a peptide of a given molecular weight.

Partition Chromatography of Amino Acids with Applied Voltage

BY GOTFRED HAUGAARD[1] AND THOMAS D. KRONER

In the one dimensional partition chromatography developed by Consden, Gordon and Martin[2] it is often very difficult to detect the bands of amino acids whose R_F values lie close together. To overcome this difficulty, two dimensional chromatography employing two solvents was developed by these workers.

In our work, we encountered overlapping of R_F values between the basic, acidic and certain neutral amino acids. We have effected a two dimensional chromatography by the passage of current through paper treated with phosphate buffer at *p*H 6.2.[3] The negatively charged acids—aspartic and glutamic—move toward the anode; the basic acids—lysine and arginine—migrate toward the cathode and the neutral amino acids are unaffected by the voltage gradient at the *p*H close to their isoelectric point.

Experimental

The papers used in the chromatograms were prepared as follows. Whatman no. 1 paper was dipped in *M*/15 phosphate buffer at *p*H 6.2 and the excess fluid was removed by pressing with a photographic roller over a glass plate. The paper strips (570 × 120 mm.) were air dried before use. We have employed aluminum, nickel and platinum as electrodes and have found little difference between them. The nickel ribbon (6.35 × 0.025 mm.) is woven into slits cut into the edges of the paper and the electrodes extend not more than one half the length of the paper. The electrodes may also be attached to the paper by stapling. The mixture of amino acids consisted of two dicarboxylic acids—aspartic and glutamic; two basic acids—lysine and arginine; and six neutral amino acids—serine, glycine, alanine, valine, leucine and proline. The concentration of the individual amino acids in the

(1) Present address: National Dairy Corporation, Oakdale, Long Island, New York.

(3) R. R. Goodall and A. A. Levi, *Nature*, **158**, 675 (1946).

mixture was 0.1 mg. of NH_2-N/ml. and the mixture was applied from a micropipet at the center of the strip. The chromatograms were developed overnight (sixteen to eighteen hours) in a constant temperature room (23°) and phenol was the developing solvent. The potential used in most of the experiments was 100–105 v.

An example of the separation obtained with platinum electrodes and a potential of 105 v. is shown in Fig. 1. The separation of the bands is clear and sharp. It is obvious that little or no differentiation would have been possible without the applied voltage. The identity of the basic and acidic amino acids is substantiated by both the characteristic R_F value and the direction of migration in the electric field.

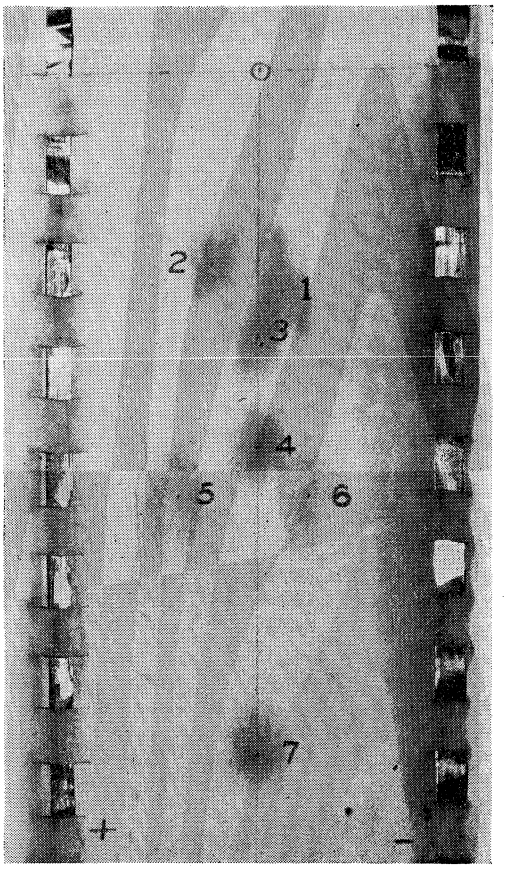

Fig. 1.—Partition chromatography of amino acids with applied voltage: 1, lysine; 2, aspartic acid; 3, serine; 4, glycine; 5, glutamic acid; 6, arginine; 7, alanine. Phenol is the developing solvent. Valine, leucine and proline with greater R_F values than alanine not shown.

In Table I, is shown statistical analysis of R_F values of 26–32 determinations on the ten amino acids. The error on the average values is not tabulated. The error in any of the determined R_F values is less than 0.01. The error in a single determination is found in the table and varies between the limits of ±0.02–0.04.

The R_F values found by us, except in the case of glutamic acid, are for the most part less than those reported by Consden, *et al.* The presence of the salts and the fixed *p*H may account for the lower R_F values.

Discussion

The optimum conditions for this method are (1) a voltage of 100; (2) a run of sixteen to eighteen hours; (3) paper buffered with *M*/15 phosphate at *p*H 6.2; (4) controlled temperature. Chromatograms have been carried out at 50 and 70 v.; the migration rates of the charged acids were a little lower but not as much as expected. The explanation of this phenomenon was found experimentally by measuring the potential gradients across the paper. The largest gradients were close to the electrodes and the potential differences at the interior of the paper were not proportional to the applied voltage. Chromatograms developed for eight hours at 100 v. failed to effect separation of the charged amino acids from the neutral acids. Tailing and spreading of the bands occurred on papers prepared with buffer at one-quarter and one-eighth strength. The optimum has been found to be 6.2.

In several runs, it was noticed that although separation had occurred some of the charged amino acids failed to give the typical color with ninhydrin. In these instances, it was shown by testing the paper with *p*H indicators that a high *p*H and a low *p*H zone extended, respectively, from the cathode and anode toward the midline. This phenomenon was associated with a final current greater than 0.3 milliampere. We believe that excessive electrolysis of the buffer resulted in this marked change in the *p*H of the paper. Careful preparation of the paper is necessary to avoid too great salt concentration.

TABLE I

R_F VALUES OF AMINO ACIDS IN PHENOL[a] ON WHATMAN NO. 1 PAPER BUFFERED WITH *M*/15 PHOSPHATE AT *p*H 6.2, AT 23°

Acid	R_F values	Error on a single measurement[b]
Serine	0.21	±0.02
Glycine	.28	± .04
Alanine	.49	± .04
Valine	.74	± .02
Leucine	.82	± .02
Proline	.86	± .02
Aspartic acid	.16	± .02
Glutamic acid	.32	± .03
Lysine	.17	± .02
Arginine	.32	± .03

[a] Hydrogen cyanide added to the tray. [b] $\sqrt{\Sigma\delta^2/(n-1)}$.

Under the conditions of this study, histidine with an isoelectric point of *p*H 7.6 would not be expected to migrate. This has been found to be true experimentally.

We have observed that tailing of certain acids such as lysine, arginine, histidine, aspartic and glutamic acid has occurred on chromatograms developed on plain paper. Dipping the Whatman no. 1 paper in phosphate buffer at *p*H 6.2 has eliminated this phenomenon, except in the instance of histidine.

Control of temperature should be maintained to prevent (1) distillation of solvent from the paper to the walls of the chamber, (2) disruption of the single phase solvent system; also because temperature has an effect on the constancy of the R_F values.

The authors express thanks to Dr. John T. Edsall for the interest he has taken in this work.

Summary

1. A study of partition chromatography with applied voltage has been presented.
2. R_F values for ten amino acids obtained under the experimental conditions are given.
3. Paper buffered with phosphate at *p*H 6.2 has been used.

The Electrical Conductance of Strontium Chloride and Strontium Bromide in Ethanol–Water Mixtures[1]

BY RICHARD LOUIS BATEMAN AND DWIGHT T. EWING

The earliest investigations of electrical conductance in mixed solvents were those of Lenz,[2] and Stephan.[3] This type of work was extended by other workers and particularly by Jones and coworkers.[4]

In general, these investigations showed that the conductance of electrolytes in mixed solvents decreased as the solvent viscosity and degree of solvation became greater but increased as the dielectric constant of the solvent and temperature became greater. A large part of these early investigations concerned the uni-univalent electrolytes with less attention given to those of higher valence types. No recorded data are given for the conductance behavior of strontium chloride and strontium bromide in ethanol–water mixtures.

The purpose of the present investigation was to determine the influence of concentration, solvent composition and temperature on the conductance behavior of strontium chloride in ethanol–water solutions and to note the influence of viscosity and dielectric constant of the solvent on the conductance of these solutions. For purposes of comparison, a limited amount of work was also done on the conductance of strontium bromide in ethanol–water solutions.

Experimental

Purification of Materials.—J. T. Baker C. P. $SrCl_2 \cdot 6H_2O$ was recrystallized from conductance water once above and once below the transition temperature (61.34°) by the method of Richards and Yngve[5] and oven-dried to constant weight.

J. T. Baker C. P. KCl designated "special crystals" (low in Ca, Mg and NH_4OH ppt.) were twice recrystallized from conductance water. The salt was then partially fused in a platinum crucible and transferred to a closed bottle while still hot.

Ethyl alcohol was purified by distilling 95% alcohol from concentrated sulfuric acid (20 ml. of acid per liter of alcohol) to remove amines. The distillate was then treated with alcoholic lead acetate[6] (3 g. of lead acetate in 5 ml. of water and then 5 g. of KOH in 25 ml. of alcohol) and distilled. Absolute alcohol was then prepared by treating each liter of distillate with fresh calcium oxide (200 g. per liter of alcohol), refluxing and distilling. In these distillations, the first and last portions of distillate were discarded. The water content was determined by density measurement and reference to standard density tables.[7] The alcohol thus obtained was 99.9% absolute and had a specific conductance of 2.0×10^{-7} mho at 25°.

Conductance water was prepared by distilling water containing a little potassium permanganate through a block tin condenser. About 50% of the distillate was allowed to condense and only the middle fraction was retained. At 25° the specific conductance of this water was $1.00\text{–}1.04 \times 10^{-6}$ mho.

Apparatus.—A Leeds and Northrup Kohlrausch slide wire bridge with extension coils, tunable head phones, Curtis coil resistance boxes, adjustable air condensers and Leeds and Northup audiooscillator were used. All parts of the bridge assembly were protected by properly grounded shields. A thermostat bath filled with water was kept constant to within 0.01° during the series of measurements. Temperature measurements were made on a thermometer (No. 23044) that had been certified by the Bureau of Standards (certificate No. 49571). Temperature fluctuations were followed by a Beckmann thermometer. The conductance cells were of the Jones and Bollinger[8] type with the filling tubes widely separated. The electrodes were not platinized.[9] The primary standard solution for cell constants was the 0.01 demal KCl solution of Jones and Bradshaw.[10] Cells having low constants were calibrated using a more dilute solution which had been compared to the standard 0.01 demal KCl in another cell.

Procedure.—The ethanol–water solvents were prepared by the weight method. The electrolytic solutions were prepared in volumetric flasks after attaining thermal equilibrium in the thermostat bath. The conductance cells were rinsed several times with the appropriate solution, brought to thermal equilibrium and the conductance determined. All final readings were taken near the center of the bridge with the air condensers adjusted for the most satisfactory null-point. The cells were selected so that the resistance was ordinarily above 1000 ohms. Duplicate determinations were made from two independently prepared solutions. The conductance of the solvent was determined immediately before the preparation of the elec-

Discussion

Figure 1 shows the influence of concentration on the equivalent conductance of strontium chloride in various ethanol–water mixtures at 25°. The absence of experimental transference data for the ions in these solutions made it unfeasible to evaluate Λ_0 with the aid of the Onsager equation.[11] Curves similar to those in Fig. 1 were drawn on a large scale and the values for Λ_0 were obtained by graphical extrapolation. As one might expect, the values of both Λ_c and Λ_0 decrease as the percentage of ethanol becomes larger.

Figure 2 shows the influence of solvent composition on the equivalent conductance of 0.001, 0.005, 0.025 and 0.100 normal solutions of strontium chloride. Increasingly larger percentages of ethanol cause progressively smaller change in the equivalent conductance up to a point of inflection. Beyond this point, the change in equivalent

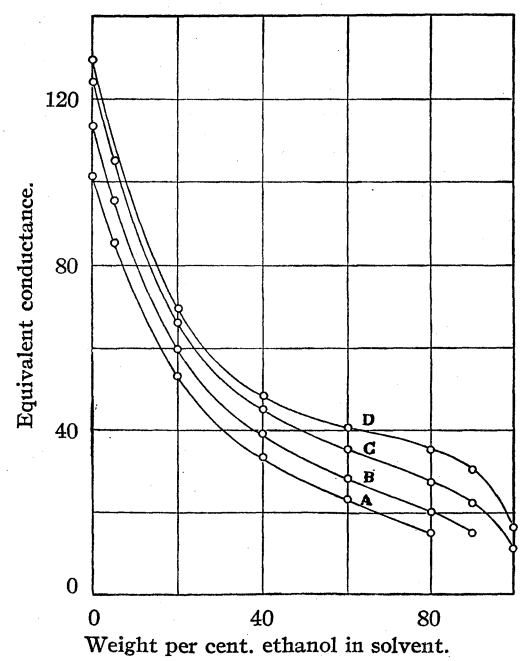

Fig. 2.—Equivalent conductance of strontium chloride in ethanol–water mixtures at 25°: A, 0.1 *N*; B, 0.025 *N*; C, 0.005 *N* and D, 0.001 *N*.

conductance becomes progressively greater as the percentage ethanol increases. An explanation for this might be: in the less alcoholic solutions the change in viscosity is the most significant factor influencing conductance while in the more alcoholic solutions the change in dielectric constant is more significant. Between these two extremes, the two solvent properties are of about equal importance in influencing the conductance. Also, for an electrolytic solution of this type, the ionic "sizes" should vary with solvent composition giving a corresponding influence on conductance. From this, it would follow that Walden's rule[12] ($\Lambda_0\eta$ = constant) should not apply very accurately. The quantity $\Lambda_0\eta/D$ has been applied to electrolytes[13] and in the present case this quantity is more nearly a constant value than $\Lambda_0\eta$. Table IV gives Λ_0, $\Lambda_0\eta$ and $\Lambda_0\eta/D$ for strontium chloride in different ethanol–water mixtures at 25° in which η is the viscosity and D is the dielectric constant of the pure solvents.

TABLE IV

LIMITING CONDUCTANCES OF STRONTIUM CHLORIDE IN ETHANOL–WATER MIXTURES AT 25°

% Ethanol in solvent	Λ_0	η^a poise	D^b	$\Lambda_0\eta$	$\Lambda_0\eta/D$
0	134.5	0.00895	78.5	1.204	0.0153
5	115.0	.01087	75.6	1.250	.0165

80	41.4	.01738	32.8	.719	.0219
90	37.4	.01422	28.1	.532	.0189
99.89	22.1	.01104	24.2	.244	.0101

[a] "International Critical Tables," **5**, 22 (1929). [b] G. Akerlof, THIS JOURNAL, **54**, 4133 (1932).

From Table IV it may be observed that $\Lambda_0\eta/D$ is relatively constant for solutions containing between 20 and 90% ethanol in the solvent.

Figure 3 illustrates, at 25°, the dependence of Λ_0 and $\Lambda_0\eta$ on the composition of the solvent for strontium chloride solutions and gives the values for the viscosities and dielectric constants of the pure solvents.

Figure 4 shows the influence of temperature on the equivalent conductance of 0.01 normal solutions of strontium chloride in four different solvent compositions. In all cases the temperature coefficients are positive and become less as the temperature increases. From tangents to these curves at 25° the information in Table V was obtained.

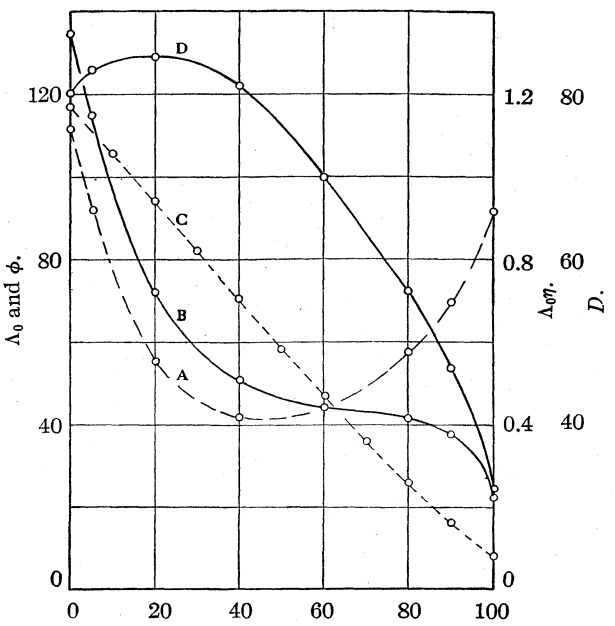

Fig. 3.—Curve A, the fluidity ϕ and curve C, the dielectric constant D of ethanol–water mixtures at 25°: Curve B, the limiting equivalent conductance Λ_0 and curve D, the conductance viscosity product $\Lambda_0\eta$ for strontium chloride at 25°.

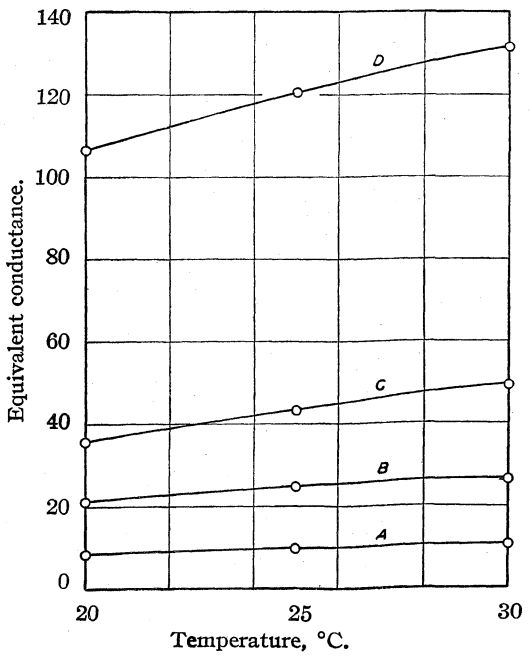

Fig. 4.—Equivalent conductance of 0.01 N strontium chloride in ethanol–water mixtures as a function of temperature: A, 99.89%; B, 80%; C, 40% and D, 0% ethanol in solvent.

For the solvents used in Fig. 4, the temperature coefficients of the dielectric constants are negative and become smaller at the higher temperatures. This would tend to cause the conductance to be less at the higher temperatures and to influence the temperature coefficient of conductance less at the higher temperatures. For these same solvents the temperature coefficients of viscosity are negative and have smaller values at higher temperatures. This would cause an increase of conductance with increasing temperature but the rate of increase should be less at higher temperatures. Even though these two solvent properties work in opposition to each other, they both favor a smaller temperature coefficient at higher temperatures.

Preliminary work on the conductances of magnesium and barium chlorides gave curves of the same general form as those for strontium chloride.

Summary

The conductances of strontium chloride and of strontium bromide in different ethanol–water mixtures have been measured at 25° and the significance of the results discussed.

The conductance of strontium chloride in different ethanol–water mixtures has been measured at 20, 25 and 30° and the temperature coefficients evaluated.

In strongly aqueous solutions the conductances are influenced mostly by the viscosity of the solvent and in the strongly alcoholic solutions mostly by the dielectric constant of the solvent.

Repulsive Forces in Relation to Bond Energies, Distances and Other Properties

BY KENNETH S. PITZER

While the concepts of quantum theory have given a qualitative understanding of most chemical bond phenomena, there are a number of less prominent features that remain puzzling. Many of the ideas in this paper have been held by the writer and very likely by others for some time. However, they were based on conflicting and uncertain data. The immediate reason for this paper is the recent developments in dissociation energy data which makes possible a greatly improved and considerably changed table of bond energies.

Bond Energies.—Gaydon[1] has recently published a very fine compilation of dissociation energies. Furthermore his recommended value of *ca.* 170 kcal. for the heat of sublimation of carbon (to normal ^3P atoms) has been fully confirmed by new thermodynamic measurements of Brewer and Gilles[2] in this Laboratory. The heat of vaporization values of Kelley[3] together with some revisions of these values by Brewer[4] have been employed. These new data supplement the older values of Bichowsky and Rossini[5] upon which Pauling[6] based most of his bond energies. The conventions followed in Tables I and II follow Pauling's system except that the dissociation energies of the nomal $^3\Sigma$ states rather than excited singlet states are taken for O=O, S=S, etc. The energy of dissociation of a molecule completely into atoms is taken as the sum of the energies of all bonds. Thus the C–H bond energy is not the energy change of the reaction of $CH_4 = CH_3 + H$ but rather one fourth of the energy for $CH_4 = C + 4H$. The values are for 0°K. Heat capacities from 0 to 300°K. were estimated where necessary.

In Table I there are listed values for single bonds in elements and for single bonds to hydro-

gen and chlorine. Table II gives values for multiple bond energies and includes the corresponding single bond energy for comparison. Naturally many more values could be included but these will serve as a basis of the discussion to follow.

In some cases the single bond energies for elements must be taken from solids where there may be additional weak bonding of a van der Waals or semi-metallic nature. Such values are inclosed in parentheses.

The first value given for the C–C bond is an average of several hydrocarbons.[7] It would be 77.7 for ethane but approaches 81.0 for higher and branched paraffins. The value from diamond, 85 kcal., is given in parenthesis. The values for N–N and O–O come from hydrazine and hydrogen peroxide on the basis of the values for N–H and O–H from ammonia and steam, respectively. The details for phosphorus will be typical of many other cases. The value for P≡P is from Gaydon.[1] Since the P–P bonds in P_4 are considerably strained, red phosphorus was taken as a basis. Bichowsky and Rossini give 29.1 kcal. for the heat of vaporization to P_2. Brewer gives 42 kcal. Adopting the latter, the heat of dissociation of two gram atoms of red phosphorus to atoms is therefore 42 + 116 = 158 kcal. Since this involves three bonds per two atoms the value for P–P is 53 kcal.

Tetrahedral *vs.* p Orbital Bonding.—The very pronounced drop in bond energy from C–C to N–N must be connected in some way with the appearance of the unshared electron pair on nitrogen. Tetravalent carbon must be based on the $2s2p^3$, ^5S state which is 96.4 kcal. higher in energy[8] than the normal $2s^22p^2$, ^3P state. Thus to the ^5S state the C–C bond energy would be 128 kcal., the C–H bond energy 122.3 kcal., etc. However, according to Bacher and Goudsmidt[9] the $2s2p^4$, ^4P state of nitrogen is 260 kcal. above the normal $2s^22p^3$, ^4S state. The large increase arises because in nitrogen the 2s electron is moved to a half filled 2p orbital whereas in carbon the 2s electron was moved to a vacant 2p orbital. If the trivalent nitrogen atom were to bond with sp^3 hybrid tetrahedral orbitals it would have to be excited $^3/_4$ of the way to the $2s2p^4$ state which would then amount to 65 kcal. extra per bond per atom. On this basis the N–N bond energy becomes 167 kcal. which is well above the value for C–C. However, it would seem more likely that the nitrogen bonding orbitals are mostly p with only a small s component. This avoids the large excitation energy but gives weaker bonds.[6] The less than tetrahedral bond angles in ammonia, etc., tend to confirm this picture. Presumably the normal valence bonding of all the 5th, 6th and 7th group elements is primarily p bonding since the bond angles for PH_3, H_2S, etc. approach the 90° value characteristic of p orbitals.

If the drop in bond energy at nitrogen is caused by the change to p bonds one is confronted by the absence of a corresponding drop from Si–Si to P–P. I believe this is closely related to the weakness of multiple bonds below the first row which will be considered next.

Single and Multiple Bonds.—It has long been recognized that multiple bonds of strength equal or greater than a corresponding number of single bonds occur only with the first row elements oxygen, nitrogen, carbon and possible boron. Only carbon disulfide and a few less clean cut examples show stable multiple bonds between first and second row elements. Multiple bonds with heavier atoms are confined to molecules such as P_2, Se_2, etc., which are of higher energy per atom than single bond structures P_4,S_8 etc.

Figures 1 and 2 indicate crudely the approximate size of various orbitals in nitrogen and phosphorus. The inner shells are given Pauling's "single bond" radii for N^{+5} and P^{+5}, respectively. The outer radius is taken as 0.9 times the van der Waals radius also from Pauling.[6] The value of 0.9 was selected because it was felt the compressional forces within a molecule were rather larger than the intermolecular forces in a molecular crystal. The 2s orbital for nitrogen and the 3s for phosphorus were omitted to avoid confusion. Regions of bonding or attractive exchange overlap are diagonally cross hatched while the principal regions of repulsive exchange overlap are lined horizontally. The overlap of orthogonal orbitals such as $3p_x$ with $3p_z$ will have only a secondary effect. The atoms are shown at the bond distances experimentally observed.

It should be emphasized that orbitals do not have sharp boundaries and that Figs. 1 and 2 are therefore only crude representations. In particular the p orbitals gradually decreased in intensity from a maximum along their principal axis to zero in the plane perpendicular to that axis. They have been cut off at 44° from the axis to separate

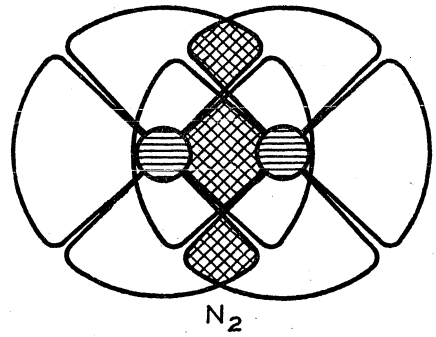

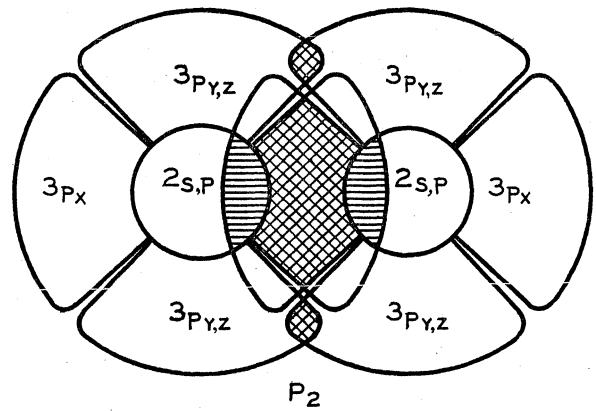

Fig. 2.—Diagrams of relative orbital sizes for N≡N and P≡P bonds.

the p orbitals on the same atom. Also since the intensity decreases both radially and angularly, the outer corners are of particularly low intensity. These corners rounded to remind one of this situation. In spite of their limitations the figures are useful in illustrating qualitative differences between nitrogen and phosphorus.

Repulsive Effects of Inner Shells.—In hydrogen the attractive force of the bonding electrons on the nuclei is balanced by the repulsive force of the two nuclei. However, in P_2 we postulate that the repulsive interactions of the $3p_x$ orbital of one atom with the inner shell of the other constitute a more important repulsive force. Let us call this merely *inner shell* repulsion. In nitrogen the inner shell contains only two electrons as compared to ten in phosphorus. Consequently it is reasonable to suppose that this inner shell repulsive effect is much smaller in nitrogen. These ideas receive support in Fig. 2 in that the N≡N bond distance is so short that the $2p_x$ orbital of one atom extends completely across and beyond the inner shell of the other while in P≡P the $3p_x$ orbital only partially overlaps the inner shell of the other atom. Since other interactions in P_2 are attractive there would appear to be no other reason why the distance should remain relatively longer than in N_2.

The increase in bond energy between the single and triple bonds comes from two principal sources. First, the interaction of the p_y and p_z orbitals changes from repulsive to attractive. Second, the bond distance decreases giving better overlap for all the bonding orbitals. If the p_x-inner shell repulsion keeps the bond distance large, both of these items are small. In the second case the reason is self-evident, and in the first it is because the p_y and p_z overlap is small at large distances. For double bonds the same argument applies but only the p_y interaction is affected.

This inner shell repulsive effect will be general for all atoms below the first row. Consequently it will explain the relative weakness of multiple bonds for all atoms outside the first row. Next let us see if it will help account for other peculiarities.

Pauling[6] suggests that p bonds should have $^3/_4$ of the energy of tetrahedral whereas we find a much smaller value for the ratio of N–N to C–C bond energy. However, Pauling's value may be interpreted as the ratio of the attractive energies of the bonding electrons alone. The net bond energy will be less by the repulsive effects of nonbonding interactions. We see in Fig. 1 that there is a considerable overlap of the $2p_z$ (and $2p_y$) orbitals which is repulsive. A shift to tetrahedral orbitals would decrease this greatly because of the increase from 90° to 109.5° in the angle between orbital axes. Thus one concludes that in the first row elements, single bonds with p orbitals are weaker than with tetrahedral orbitals because of

increased repulsive interactions. Let us call these *valence shell* repulsions.

In heavier elements than the first row, however, we have assumed that the inner shell repulsions are important. Consequently, the valence shell repulsive effect will be less important. There is another factor to be considered here. The character of bonding orbitals may be modified by linear combination with any vacant orbitals, although only those of approximately the same energy can be important. Thus while the 3d orbitals could have only a minor effect for first row elements, the orbitals of second row elements may be considerably modified. The electron density will be concentrated more along the bond axis and will not spread out so far to each side. This change means that the p_y and p_z orbitals which are forming other single bonds perpendicular to the one shown in Fig. 1 will overlap even less than indicated there. Thus the absence of a marked drop in bond energy from Si–Si to P–P is also understandable.

Bond Distances.—While the concept of covalent bond distances as sums of radii is undoubtedly but a first approximation, it has met with considerable success. Schomaker and Stevenson[10] modified this simple concept for partial ionic bonding effects and have found generally improved agreement. The major failure which remained was the series of bonds Si–O, P–O, Si–F and P–F (together with S–O in $SO_4^=$, Cl–O in ClO_4^-, etc.). These bonds are shorter than expected by about 0.10 Å. on the Schomaker and Stevenson formula and by 0.12 to 0.27 Å. on the Pauling and Huggins[11] scale.

Pauling[6] explains these effects as due to multiple bonds using 3d orbitals, but the writer has never regarded this acceptable because it is entirely *ad hoc* and without confirmation from energies and other sources. Also logical extensions of Pauling's structures lead to absurdities such as diatomic argon with the structure: $:\ddot{\underset{\cdot\cdot}{\underset{\cdot\cdot}{A}}} = \ddot{\underset{\cdot\cdot}{\underset{\cdot\cdot}{A}}}:$.

Now it has been postulated in this paper that the N–N and similarly the O–O and F–F distances are determined largely by the valence shell ($2p_y$, $2p_z$) repulsion while the Si–Si, P–P, and S–S distances are determined principally by the repulsive interaction of the inner shell with the $3p_x$ orbital (or the tetrahedral hybrid in silicon). The basic radii are taken as half of the single bond distance with like atoms. However, when a phosphorus atom approaches an oxygen atom, for example, neither of these repulsive effects sets in at the distance calculated from the radii because of this difference in type of predominant repulsion. This is shown clearly in Fig. 3 which depicts P–O on the same basis as Figs. 1 and 2. Thus the upper diagram shows the nuclei at 1.76 Å. as calculated by Pauling and Huggins. The $2p_x$ orbital of oxygen hardly more than touches the inner shell of phosphorus and the p_z (and p_y) orbitals have not overlapped partly because of the difference in atomic size. The $3p_x$ orbital of phosphorus overlaps the inner shell of oxygen but the latter contains only two electrons and was therefore regarded as less important.

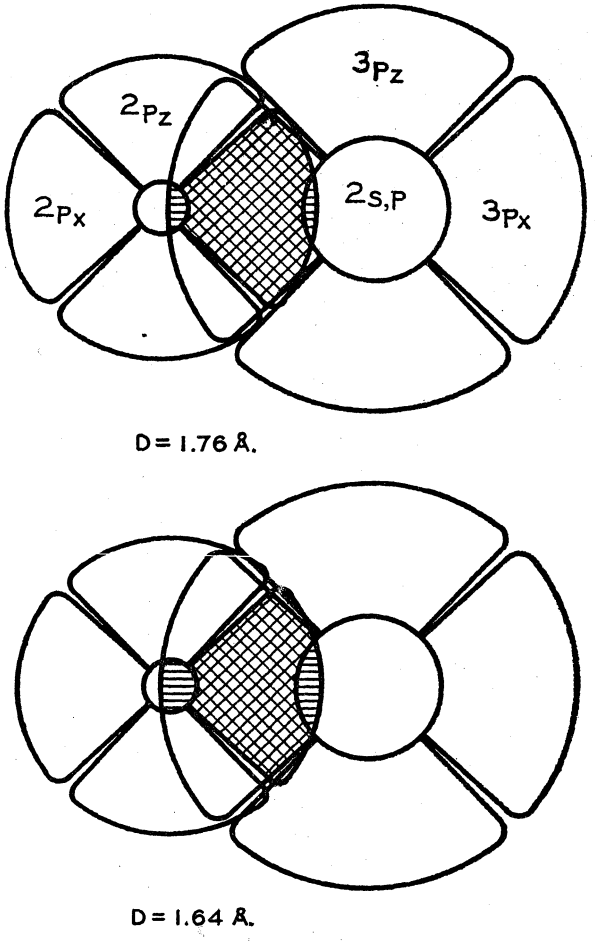

Fig. 3.—Diagrams of the P–O bond at distances indicated.

The lower diagram in Fig. 3 shows the atoms at the distance 1.64 Å. observed in the P_4O_6 gas molecule. Even there the respulsive overlap of various orbitals is moderate. Furthermore the Si–O bond energy is quite normal. On Pauling's electronegativity formula, but using recent data, one calculates 106 kcal. for a single Si–O bond as compared to the observed 103 kcal. Data are not available for the normal P–O bond energy, but the values for Si–F are 159 kcal. calculated for a single bond and 138 kcal. observed. Thus the energies give no indication of multiple bonding.

In molecules such as P_4O_{10} and $PO_4^=$ even shorter bonds arise. While double bonds involving 3d orbitals are more likely in these cases than before, even here a formal charge explanation is equally reasonable. If one maintains the octet for phosphorus in P_4O_{10} then the four oxygens which

(11) L. P. Pauling and M. L. Huggins, *Z. Krist.*, **87**, 205 (1934).

are bonded to only one phosphorus have a net charge of -1 and the phosphorus atoms have a $+1$ charge. At the distance of about 1.6 Å. these charges give an attractive force of 9×10^{-4} dynes. The force constant for a normal P–O single bond is not known but may be expected to be about 4×10^5 dynes/cm. from comparison with other molecules. Thus the electrostatic attractive force may be expected to lower the bond distance by about 0.2 Å. which is roughly that observed.

From these considerations, it is the writer's opinion that in the oxygen and fluorine compounds with second row elements multiple bonding is not significant (in the sense of more than one pair of electrons shared between the two atoms). The short bond distances are explainable in terms of (1) the difference in type of repulsive effect predominating in P–P, etc., from that in O–O, etc., and (2) the large polar effects.

Thus although the 3d orbitals undoubtedly play a part in the detailed nature of the p or sp^3 bonds in second row elements, it appears that they are not available for additional bonds of significant strength.

Barriers to Rotation about Single Bonds.—The very simplest quantum mechanical theory of single bonds indicates no restriction of rotation of the two groups connected by the bond. Thus the experimentally determined barriers of 1 to 4 kcal. per mole must be related to some refinements of the simplest theory. In ethane, if the carbon atom orbitals are strictly sp^3 hybrids, only H–H interactions are affected by rotation and they are too small. However, if the carbon orbitals are concentrated just a little more along the C–H bond directions then these atoms are no longer axially symmetrical. The C–C bond is pulling the two carbons together against the repulsion of these C–H bond electrons. Consequently it is reasonable to assume this repulsion to be larger when the C–H bonds at one end line up with those at the other end and to be less when the C–H bonds are staggered. The stability of the staggered orientation is now well verified. Let us examine the consistency of the magnitude of the rotation restricting barriers listed in Table III with the concepts that the barrier arises from variation in the valence shell repulsion as defined above.

Whereas the axial symmetry of a carbon atom is disturbed by three hydrogens in ethane there are only two hydrogens on the nitrogen of methyl amine and one on the oxygen of methanol. Thus one might expect the barriers to decrease in the ratio 3 to 2 to 1. However, the decrease in bond angle from tetrahedral at the carbon to smaller values for nitrogen and oxygen should increase this repulsive effect. The series ethane, methylamine, methanol and the series propane, dimethylamine, dimethyl ether both show increase from carbon to nitrogen followed by decrease to oxygen in reasonable accord with these ideas.

TABLE III

POTENTIAL BARRIERS RESTRICTING INTERNAL ROTATION (KCAL./MOLE)

CH_3CH_3[12]	2.8		
CH_3NH_2[13]	3.0		
CH_3OH[13]	2.3 ± 1(?)	CH_3SH[14]	1.5
$(CH_3)_2CH_2$[16]	3.4		
$(CH_3)_2NH$[13]	3.5		
$(CH_3)_2O$[13]	3.1	$(CH_3)_2S$[15]	2.0
$(CH_3)_4C$[17]	4.3	$(CH_3)_4Si$[13]	1.3

Unfortunately, barrier values for bonds between two second row elements are now available. They should be small because the valence shell repulsion is largely replaced by the inner shell repulsion discussed above. The situation for bonds between carbon and a second row element should be intermediate and the values in Table III are clearly consistent with this concept.

Bonds to Hydrogen.—Since hydrogen has no further electrons, there should be no electronic repulsion effects of the valence shell type. Consequently the bond energies should show greater regularity. Thus the decrease in bond energy from C–H to N–H is very small compared with that from C–C to N–N or from C–Cl to N–Cl.

Conclusions.—In a single bond between two first row elements the attractive force of the bond itself is balanced principally against the repulsion of the remaining valence shell electrons. Between two second row or heavier elements the repulsion between the bonding orbital and the inner shell becomes more important. The concepts are shown to give qualitative explanation for:

1. The relative absence of stable multiple bonds except with first row elements.
2. The striking drop in bond energy from C–C to N–N.
3. The failure of bond radii to correctly predict the Si–F, P–O and related bond distances.
4. The relative magnitude of barriers to internal rotation about single bonds.

Certain predictions are made.

It does not seem likely that presently feasible quantum mechanical calculations could do more than confirm these qualitative conclusions. However, more quantitative relationships of an empirical nature might be developed.

Summary

A revised table of bond energies is calculated from recent sources.

The concept is introduced of a balance in a

chemical bond between attractive and repulsive forces both of electronic nature. In first row elements the repulsive effects for single bonds arise principally in the valence shell whereas for heavier atoms the inner shells play a predominant role. The ideas are shown to account for several peculiarities in bonding behavior.

Susceptibility Isotherms for Supported Copper Oxide

BY P. W. SELWOOD AND NICK S. DALLAS

The purpose of this work was to examine the structure of supported copper catalysts by use of the magnetic methods previously described.[1] The present paper gives magnetic data on a series of copper–alumina catalyst systems, together with some X-ray and catalytic activity results.

Experimental

Preparation and Analysis of Samples.—Pure γ-alumina of surface area approximately 200 sq. m./g. and magnetic susceptibility -0.2×10^{-6} at $-190°$, was impregnated with copper nitrate solution, then filtered, dried, and ignited at 390° for twenty-four hours. Twelve samples of supported copper oxide were thus made, ranging in concentration from 0.60 to 34.7% copper.

The several samples were analyzed by dissolving them in nitric acid and titrating by the standard iodide–thiosulfate method. One catalyst sample was prepared by multiple impregnation. The copper nitrate impregnating solution was adjusted so as to give a catalyst containing about 1% copper. After ignition this catalyst was reimpregnated and ignited. The process was repeated until the copper concentration reached 5.2%.

Most of the catalyst samples were examined in the reduced condition as well as oxidized. Reduction was carried out in hydrogen at 300° for twelve hours. No change was caused by raising the reduction temperature to 400°.

It is of interest to record that the oxidized catalyst systems were bluish-green in color at all lower concentrations. The reduced catalysts were all jet black.

During the course of these studies it became necessary to prepare some supported silver oxide on alumina. This was obtained by impregnating γ-alumina with dilute silver nitrate solution, followed by drying and ignition at 390°. The sample contained approximately 2% silver. This sample was reduced in hydrogen at 200°. It may be mentioned that the oxidized silver supported on γ-alumina is rapidly changed from white to brown by mere exposure to hydrogen well below room temperature.

The reduced forms of all catalysts were readily reoxidized in air at room temperature. The lower concentrations were handled in the absence of air, although the reduced copper could be stabilized to a fair degree by exposure to carbon dioxide.

Catalytic Measurements.—Comparison of catalysts containing varying proportions of copper was made by mechanically mixing all samples, except the lowest in copper, with γ-alumina so that all samples contained 3.2% copper. The catalytic measurements were not extended below that concentration. The reaction chosen was the dehydrogenation of isopropyl alcohol.

A pelleted catalyst sample containing 0.32 g. of copper in 10 g. of catalyst was placed in the reaction chamber. The catalyst was reduced in hydrogen at 400° for two hours. The temperature was then lowered and held at 225°. Redistilled isopropyl alcohol was fed over the catalyst at the rate of 32 cc. (liquid) per hour. Tests were continued for one hour, and three successive such one hour activity runs were made for each catalyst.

The gaseous product was collected and the volume measured. The liquid product was fractionated in a simple column and a rough analysis was thereby obtained for acetone, unconverted isopropyl alcohol and higher boiling products.

The several catalysts used for the activity tests are conveniently described in the following manner. Catalyst 3.2/10.3 means a sample containing 3.2% of copper but that this was obtained by mechanically mixing appropriate amounts of γ-alumina and a CuO/Al_2O_3 impregnate which contained 10.3% of copper. Four such catalysts were tested. These are thus designated as 3.2/3.2, 3.2/10.3, 3.2/13.3 and 3.2/22.9.

Results

Table I shows the magnetic susceptibility at three temperatures for all the oxidized copper catalyst samples except that prepared by multiple impregnation. Samples containing less than 3% copper are discarded as being too dilute to permit accurate estimation of the susceptibility of the copper. Figure 1 shows the susceptibility isotherms calculated from the data of Table I.

TABLE I

MAGNETIC SUSCEPTIBILITY OF CuO/Al_2O_3 CATALYST SAMPLES

Weight per cent. copper	$\chi \times 10^6$ 25°	$\chi \times 10^6$ −80°	$\chi \times 10^6$ −190°
4.0	0.5 (±0.05)	0.9	2.4
7.2	0.9	1.8	4.4
10.3	1.4	2.5	5.6
11.9	1.3	1.8	3.8
13.3	1.0	1.4	3.1
16.5	0.9	1.2	2.6
22.9	1.0	1.4	2.6
28.4	1.3	1.5	2.6
30.6	1.4	1.7	2.6
34.7	1.7	1.7	2.5

Reduction of the copper in the samples in all cases caused the magnetic susceptibility to drop substantially to zero. The susceptibility isotherms at −180° for oxidized, reduced and reoxidized copper–alumina are compared in Fig. 2.

The magnetic susceptibility of the sample prepared by multiple impregnation was 2.45×10^{-6} at −170°. The susceptibility of the copper in this catalyst, which contained 5.2% copper, was, therefore, 51×10^{-6} at −170°.

(1) This is the third paper on the susceptibility isotherm from this Laboratory. The second paper appeared in THIS JOURNAL, **69**, 2698 (1947). Descriptions of magnetic, X-ray and surface area experimental methods will be found in the earlier papers.

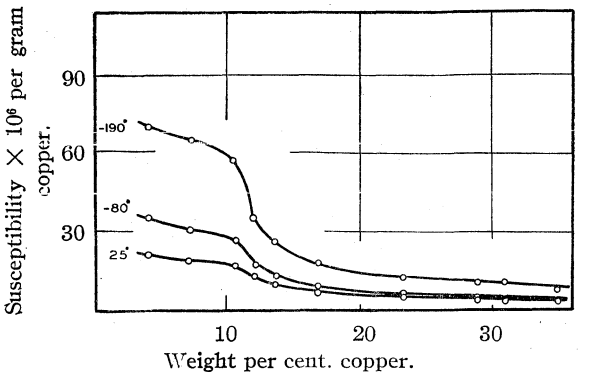

Fig. 1.—Susceptibility isotherms for supported copper oxide on γ-alumina.

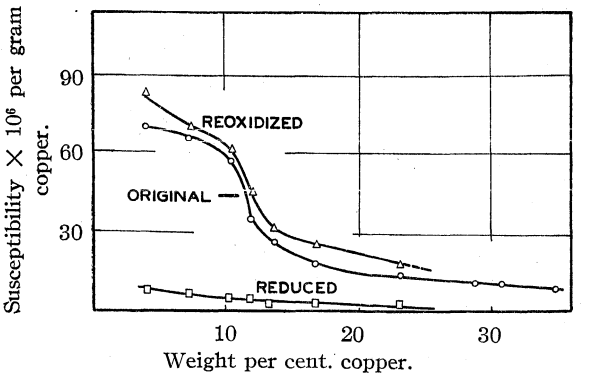

Fig. 2.—Susceptibility isotherms for copper and copper oxide on γ-alumina, all at −190°.

The single sample of supported silver on γ-alumina had a susceptibility of substantially zero both at 25° and at −170°.

The X-ray diffraction results showed clearly the principal lines of cupric oxide at 2.51, 2.30, 1.86, 1.58 and 1.50 Å. down to a concentration of 11.9% copper. But at 10.3% copper no cupric oxide lines, or any lines other than those of γ-alumina, were observed. There is, therefore, a parallelism between the disappearance of the cupric oxide lines and the region of maximum rise of susceptibility in the isotherm.

The results of the catalytic activity tests are summarized in Table II, which gives results for the second of three concordant runs in each case.

TABLE II

RELATIVE CATALYTIC ACTIVITY OF COPPER–ALUMINA CATALYSTS

Catalyst	% Acetone	% High boiling
Pure alumina	None	None
3.2/ 3.2	52	10
3.2/10.3	31	4
3.2/13.3	31	4
3.2/22.9	22	3

In addition, it should be stated that the more dispersed systems gave a relatively smaller volume of higher density gaseous product, and that these systems also lost activity much more rapidly during use than did the less dispersed systems.

Conclusions.—The susceptibility isotherm is generally characterized by a large increase of susceptibility at low concentrations. Copper shows this effect to a greater extent than any other element so far studied. The susceptibility of copper in supported cupric oxide at low concentrations is about twenty times larger than that of copper in massive (unsupported) cupric oxide.

Below about 10% copper the susceptibilities of the several samples accurately follow the Curie–Weiss law, from which it is possible to compute the Weiss constant and the magnetic moment. In this region the Weiss constant is small, but slowly rises, showing the normal effects of decreasing copper–copper distance. At the lower concentrations the magnetic moment is 1.8 Bohr magnetons. This corresponds exactly with the moment predicted from the "spin-only" formula for cupric ion. There is, therefore, no inductive effect of the support on the valence of the copper.

The most striking feature of the susceptibility isotherm for copper is the sharp rise in the neighborhood of 11% copper. The magnetic data, taken in conjunction with the X-ray results, suggest that this is the concentration region below which it is impossible to maintain extensive organization of the copper and oxide ions into unit cells. It might be said that cupric oxide crystallites do not exist below about 11% copper. Nevertheless, the copper can scarcely be considered as atomically dispersed even below 11%. This is shown by the gradual decrease of the Weiss constant and by considerations on the magnetic properties of the reduced copper.

Our general picture of the oxidized copper catalysts is, therefore, not dissimilar to that earlier obtained for the chromia–alumina system. The tendency in such supported systems is shown definitely to be toward inhomogeneity and formation of ionic assemblies, and not toward two-dimensional solid solution except at the greatest dilutions.

Turning now to the results on the reduced copper–alumina systems we are faced with a difficulty. The isotherm for the oxidized form strongly suggests that below 10% copper we are approaching infinite magnetic dilution because the susceptibility is not rising very rapidly. This is in contrast to the case for chromia–alumina.

It is well known that massive copper is slightly diamagnetic, but isolated copper atoms ought to be paramagnetic because they contain an odd number of electrons. It would be anticipated that the higher supported copper concentrations would become diamagnetic on reduction because the massive cupric oxide present is being converted to massive copper metal. But if the cupric ions were atomically dispersed at very low concentrations, then reduction should have no effect on the susceptibility.

Some very careful efforts were made to detect

this effect. But the low susceptibilities and the ubiquitous trace of ferro-magnetic impurity combined to make it difficult to examine this region. We can say, however, that certainly no more than 10% of the copper atoms can be considered as atomically dispersed.

It was hoped that the multiple impregnation catalyst would lead to higher, more readily measureable, susceptibilities and to greater dispersion, but such was not the case. It was also hoped that dispersed silver might yield a more readily observable result. The reason for the choice of silver was that the oxidized form is here diamagnetic. But certainly no large fraction of the supported reduced silver became paramagnetic.

Our conclusion from all these negative results is that the tendency for aggregation is so strong that even when the support must be, of necessity, mostly unoccupied surface, still the supported atoms tend to cling together. It will be noted that the larger size of the reduced atoms may lead to greater exchange interaction as compared with the oxidized forms, even though the ion centers do not appreciably move during the oxidation–reduction cycle.

When reduced supported copper is reoxidized the susceptibility goes as high as or higher than in the original oxidized sample. This shows that no aggregation into crystallites occurs during the oxidation–reduction cycle. In fact the slight increase of susceptibility shown in Fig. 2 may be due to three-dimensional solution of cupric ions in the alumina.

The results on catalytic activity support in a general way this picture of the active surface. The more highly dispersed copper would normally be expected to show greater activity, and such is the case. It is somewhat surprising that no change of activity occurs in the anomalous 11% concentration region. This result must mean that the mere aggregation into definite cupric oxide crystallites has no effect on the activity. There is, of course, the possibility that in the *reduced* form there is no such obvious structural change occurring in this concentration region.

Summary

Susceptibility isotherms are given for copper oxide supported on γ-alumina, for the reduced catalyst, and for related systems. The magnetic data are related to X-ray diffraction studies, and to catalytic activity results on the dehydrogenation of isopropyl alcohol.

Double Fluorides of Potassium or Sodium with Uranium, Thorium or Lanthanum

BY W. H. ZACHARIASEN

This paper summarizes the results of studies of the systems $KF–UF_4$, $KF–ThF_4$, $KF–LaF_3$, $NaF–UF_4$, $NaF–ThF_4$ and $NaF–LaF_3$. The investigations were carried out within the Manhattan Project during 1945.

The systems were studied by means of the X-ray diffraction method. The systematic survey extends over the entire composition range except for a gap between 35 and 65 mole per cent. ThF_4 in the $NaF–ThF_4$ system.

1. The Chemical Preparations.—All chemical preparations were made by the writer. The systematic studies were carried out by determining the phase compositions of solidified melts by means of X-ray diffraction patterns. Thermal analysis data were not taken, however. In the systems involving potassium fluoride precipitates from solutions were also examined.

The dry method preparations were made by melting together the component fluorides in a platinum crucible. The uranium tetrafluoride was from the Harshaw Chemical Company. Dr. Ralph Livingston had prepared the thorium fluoride by treating $ThF_4 \cdot xH_2O$ with HF. The Los Alamos Laboratory supplied the lanthanum fluoride.

The wet way preparations were obtained in the following ways:

1. Solutions of potassium chloride and uranium tetrachloride, of potassium nitrate and thorium or lanthanum nitrate were precipitated with hydrofluoric acid.
2. Solutions of uranium tetrachloride, of thorium nitrate or of lanthanum nitrate were precipitated with a potassium fluoride solution.
3. Solutions of $K_3UO_2F_5$ or of uranyl nitrate and potassium fluoride were reduced with formic acid and direct sunlight whereby precipitates were formed.

2. The Identification of the Phases.—The chemical identity of the various phases was deduced through interpretation of the X-ray diffraction patterns. This unorthodox method of analysis had to be used because the chemical analysts were busy with more important work. Direct chemical analyses of a few single phase preparations were, however, made. These direct analyses were rather unsatisfactory because the alkali content was not determined and because of the customary difficulty in obtaining reliable results for the fluorine percentage.

Because the method is unknown to most chem-

ists it may be useful to discuss in some detail how the chemical formulas of the various phases were determined from the X-ray data.

The method presupposes that the lattice dimensions of the various phases can be deduced from the X-ray diffraction patterns. The observed diffraction intensities can with good approximation be attributed to the heavy atoms since the scattering powers of potassium, sodium and fluorine are small compared to those of uranium, thorium and lanthanum. A small number of degrees of freedom being involved it may accordingly be assumed that intensity considerations have led to a determination of the number and positions of the heavy atoms within the unit cell. The volume of the unit cell, V, and the number of heavy atoms within it, N_X, may thus be regarded as accurately known experimental quantities.

The volume of the unit cell for fluorides of the heavy elements under consideration can with good approximation be attributed to the fluorine atoms alone with the heavy metal atoms fitting into the interstices between the anions. The volume requirement of a fluorine atom may be set at $V_F = 18$ Å.^{3} as shown by the experimental values of Table I.

TABLE I

VOLUME REQUIREMENT OF A FLUORINE ATOM

Compound	UF_3	UF_4	U_2F_9	α-UF_5	β-UF_5	UF_6	LaF_3
V_F	18.1	19.4	16.9	19.0	17.0	19.3	18.2

The mean values for the volume requirement of a sodium or potassium atom as obtained from a number of known crystal structures are $V_K = 21$ Å.^{3} and $V_{Na} = 7$ Å.^{3}.

For the volume of the unit cell we have

$$V = N_A V_A + N_F V_F$$

where N_A and N_F are the number of alkali atoms and the number of fluorine atoms per unit cell, and where V_A is the volume requirement of an alkali atom. The numbers N_A, N_X and N_F are not independent since the valences must be balanced. Making use of this fact it becomes possible to determine the unknown quantities N_A and N_F in terms of the experimentally known quantities V, V_F, V_A and N_X. The result is

I. Systems AF–XF_4

$$N_A = \frac{V - 4N_X V_F}{V_A + V_F} \qquad N_F = \frac{V + 4N_X V_A}{V_A + V_F} \quad (2a)$$

II. Systems AF–XF_3

$$N_A = \frac{V - 3N_X V_F}{V_A + V_F} \qquad N_F = \frac{V + 3N_X V_A}{V_A + V_F} \quad (2b)$$

Since the writer succeeded in determining the lattice dimensions and the number and positions of the heavy atoms in the unit cell for all the observed phases through interpretation of the X-ray diffraction patterns, the chemical formulas of all the compounds could be determined in this novel manner. The results of this method of analysis for the KF–UF_4 and NaF–ThF_4 systems are shown in Tables II and III for purposes of illustration.

TABLE II

IDENTIFICATION OF THE PHASES IN THE KF–UF_4 SYSTEM

Phase no.	V	N_U	N_K	N_F	Deduced formula
1	951 Å.^{3}	12	$2.2 \approx 2$	$50.2 \approx 50$	KU_6F_{25}
2	497	6	$1.7 \approx 2$	$25.7 \approx 26$	KU_3F_{13}
3	697	8	$3.1 \approx 4$	$35.1 \approx 36$	KU_2F_9
4	684	6	$6.5 \approx 6$	$30.5 \approx 30$	KUF_5
5	209	$1.6 \approx 4/3$	$2.4 \approx 8/3$	$8.8 \approx 8$	α-K_2UF_6
6	139	1	$1.7 \approx 2$	$5.7 \approx 6$	β_1-K_2UF_6
7	149	1	$2.0 \approx 2$	$6.0 \approx 6$	β_2-K_2UF_6
8	781	4	$12.6 \approx 12$	$28.6 \approx 28$	α-K_3UF_7
9	1558	8	$25.2 \approx 24$	$57.2 \approx 56$	α'-K_3UF_7

TABLE III

IDENTIFICATION OF THE PHASES IN THE NaF–ThF_4 SYSTEM

Phase no.	V	N_{Th}	N_{Na}	N_F	Deduced formula
1	660 Å.^{3}	8	$3.4 \approx 4$	$35.4 \approx 36$	$NaTh_2F_9$
2	119	1	$1.9 \approx 2$	$5.9 \approx 6$	β_2-Na_2ThF_6
3	241	2	$3.9 \approx 4$	$11.9 \approx 12$	δ-Na_2ThF_6
4	2054	12	$47.6 \approx 48$	$95.6 \approx 96$	Na_4ThF_8

The results from eqs. (2) should correspond to rational stoichiometric ratios and should give values N_K and N_F which are compatible with the observed space group symmetry. As a further check one knows, of course, the gross composition of the melts from which the phases were prepared.

N_X assumes fractional values for the α-phase compounds A_2XF_6 and for the β-phase compounds AXF_4. These phases have disordered crystal structures involving A-atoms and X-atoms in structurally equivalent positions. In these instances $N_A + N_X$, rather than N_X, is experimentally determined from the intensity calculations. Thus $N_A + N_X = 4$ for α-A_2XF_6 and $N_A + N_X = 3$ for β-AXF_4.

When the A-atoms and X-atoms are regarded as structurally equivalent the formulas for α-A_2XF_6 and β-AXF_4 may be written as YF_2 where Y repre-

TABLE IV

RESULTS OF CHEMICAL ANALYSES

Compound	Theoretical	Experimental: Direct method	Experimental: X-ray method
KU_2F_9	U 69.5%	69.6%	70.7%

	K 18.2	..	19.3
β_1-K_2UF_6	U 55.3	59.9	57.7
	F 26.5	24.9	26.2
	K 18.2	..	16.1
β_1-$KLaF_4$	La 54.6	52.6	54.7
	F 29.9	26.7	29.9
	K 15.5	..	15.4

sents the A-atoms as well as the X-atoms. Thus, the α-A_2XF_6 and the β-AXF_4 phases may be regarded as pseudo-difluorides, and the unit cell will contain an integral number of formula weights YF_2. The unit cell of α-A_2XF_6 contains four molecules YF_2 and that of β-AXF_4 three molecules.

The method of analysis is remarkably accurate. This is demonstrated in Table IV where the results of this method are compared with those of the orthodox, direct method of chemical analysis for some of the phases. C. Carter and B. Holt carried out the conventional analyses.

3. The Phase Composition of the Preparations.—Tables V–X show the phase compositions of the preparations made from melts as determined by analysis of the X-ray diffraction patterns. It is seen that the two lanthanum systems are very simple ones while the uranium and thorium systems are exceptionally complex.

The systems involving potassium were also examined by means of samples precipitated from solutions. The precipitates from lanthanum solutions all proved to consist of anhydrous lanthanum fluoride irrespective of the potassium concentration in the solution. However, some of the potassium–uranium and potassium–thorium fluorides can be prepared in the wet way.

KU_2F_9 and KTh_2F_9 are obtained as pure and anhydrous phases by precipitation from solutions containing large excess of uranium or thorium over potassium. Anhydrous KUF_5 and $KThF_5$ are present as pure phases in the precipitates from

solutions containing potassium and uranium or thorium in equal amounts. Single phase precipitates of anhydrous α-K_2UF_6 or α-K_2ThF_6 are obtained from solutions with large excess of potassium over uranium or thorium provided the rate of precipitation is high. Solutions with high potassium concentration yield KUF_5 or $KThF_5$ at low precipitation rates. These are the only double fluorides of potassium and uranium or thorium which the writer has observed in the precipitates.

The various phases which have been found in the systems under consideration are compiled in Table XI. Phases listed in the same horizontal row of the table represent isomorphous compounds.

It seems that only a few of the twenty-seven phases listed in Table XI have been previously described in the literature.

As stated earlier, the writer has succeeded in determining lattice dimensions and the positions of the heavy atoms for all the phases. Complete crystal structures have been found for $NaTh_2F_9$, the α-phase compounds, the β-phase compounds, γ-Na_2UF_6 and Na_3UF_7. These crystal structure determinations will be treated in another paper to appear elsewhere.

Some of the structural constants are listed in Table XII, together with the number of molecules per unit cell, n, and the calculated densities ρ.

4. Other Isomorphous Compounds.—Compounds isomorphous with those listed in Table XI and involving other elements have been observed. These compounds were encountered in incidental preparations submitted to the writer for X-ray diffraction study.

KNp_2F_9 was observed as the only crystalline phase in a sample labeled "Np(V)-fluoride" which had been prepared by T. LaChapelle and L. B. Magnusson. Another sample prepared by the same investigators and labeled "Np(IV)-fluoride" was found to contain KNp_2F_9 as a minor and K_2SiF_6 as the major phase.

KPu_2F_9 was the only crystalline phase in a sample labeled "H-Pu(IV)-fluoride" which H. H. Anderson had prepared.

The compounds $NaPuF_5$, $KPuF_5$, and $RbPuF_5$ were prepared by H. H. Anderson and the correct

formulas deduced by him with the aid of direct chemical analyses. X-Ray diffraction patterns of these preparations showed the compounds to be isomorphous with the corresponding uranium and thorium compounds.

$NaPuF_4$ was found in a sample which was supposed to be plutonium metal. L. Baumbach had prepared this sample.

The isomorphous compounds of neptunium and plutonium are also listed in Table XII.

Miss Anne Plettinger gave valuable aid by taking most of the numerous X-ray diffraction patterns which were required. Mr. W. C. Koehler helped by measuring some of the diffraction patterns. Miss C. Carter and Mr. B. Holt contributed to the work by carrying out direct chemical analyses for some of the phases. The loan of micro-preparations of neptunium and plutonium made by Drs. T. LaChapelle and L. B. Magnusson, H. H. Anderson and L. Baumbach is gratefully acknowledged. The writer is also indebted to Dr. R. Livingston for some pure thorium tetrafluoride.

Abstract

A large number of double fluorides have been found in the systems $KF–UF_4$, $KF–ThF_4$, $KF–LaF_3$, $NaF–UF_4$, $NaF–ThF_4$ and $NaF–LaF_3$. In addition to the terminal compounds the following phases have been observed:

In the $KF–UF_4$ system: KU_6F_{25}, KU_3F_{13}, KU_2F_9, KUF_5, α-K_2UF_6, β_1-K_2UF_6, β_2-K_2UF_6, α-K_3UF_7, and α'-K_3UF_7.

In the $KF–ThF_4$ system: KTh_6F_{25}, KTh_2F_9, $KThF_5$, α-K_2ThF_6, β_1-K_2ThF_6, and K_5ThF_9.

In the $KF–LaF_3$ system: α-$KLaF_4$, β_1-$KLaF_4$.

In the $NaF–UF_4$ system: $NaUF_5$, α-Na_2UF_6, β_2-Na_2UF_6, γ-Na_2UF_6, and Na_3UF_7.

In the $NaF–ThF_4$ system: $NaTh_2F_9$, β_2-Na_2ThF_6, δ-Na_2ThF_6, and Na_4ThF_8.

In the $NaF–LaF_3$ system: β_2-$NaLaF_4$.

Lattice dimensions are given for all the phases. Some results for isomorphous neptunium and plutonium compounds are reported.

A Versatile Technique for X-Ray Single Crystal Structural Analysis Applied to Benzaldehyde 2,4-Dinitrophenylhydrazone and Zinc Salts of Salicylic and Benzoic Acids

BY GEORGE L. CLARK AND HUNG KAO

It is well known among crystal structure analysts that Weissenberg diffraction photographs provide distorted projections of the levels of a reciprocal lattice, from which the true reciprocal lattice, and thence the direct lattice, may be reconstructed after more or less elaborate measurement and interpretation; whereas the comparatively new precession technique devised by Buerger[1] gives X-ray diagrams which are undistorted images of the reciprocal lattice and thus easily interpreted by inspection only. Although the precession method records only a limited part of the reciprocal lattice, especially in case of n-levels and has some other disadvantages, it has some distinct advantages over Weissenberg methods in that it requires a less perfect crystal, shorter time of exposure and above all simpler interpretation. Moreover the precession method makes it possible to precess along two crystal axes without changing a crystal setting if the angle between the two axes is known; thus two reciprocal lattice photographs which will give all three linear constants and two angles can be obtained.

Inasmuch as new Weissenberg and precession cameras designed by Buerger and made by one instrument maker[2] under the same conditions of precision were available, the crystal holders for the two cameras could be interchanged. Thus it seemed possible that a combination usage of the precession and Weissenberg cameras might provide a simpler and more dependable technique than any single method. This paper is a brief report of our first experience in using the precession camera, presented in the hope that it may be helpful in other laboratories, as well as a record of crystallographic information so obtained for benzaldehyde 2,4-dinitrophenylhydrazone, zinc salicylate trihydrate, zinc benzoate and zinc hydrogen benzoate dihydrate.

Notes on the Precession Method

A few remarks concerning our own experience on this method may be useful. The first step in crystal analysis of course is to adjust a crystallographic axis to the precession axis. The techniques are discussed in detail in Buerger's monograph. An improved technique which we have used is the pre-usage of a 57.3 mm. Weissenberg camera. Since the 57.3 mm. Weissenberg camera and the precession camera have an interchangeable adjustable crystal holder, transfer from one to the other is easily accomplished without disturbing the crystal. From the zero-level Weissenberg pattern the possible zones and the angles between them can be determined by simple inspection.

(1) M. J. Buerger, "The Photography of the Reciprocal Lattice," ASXRED Monograph No. 1, 1944.

(2) Charles Supper, Newton Centre, Mass.

One of these zone axes can be located and set parallel to the X-ray beam by several trials on the precession camera. Once it is identified any of the others can be located by turning the crystal through the angle between them followed by readjustment of the crystal. (In the cases of an orthorhombic, a tetragonal crystal or a monoclinic crystal oriented on its b-axis the other axis can be located by simply turning the crystal.) By this method even in the case where the crystal does not possess any well developed faces, it is still possible to locate its axes unambiguously. Moreover the data from the 0-layer line Weissenberg film will provide the best criterion to check whether the correct zone axis is chosen for precession.

Various methods have been discussed in the monograph for the determination of d^* (reciprocal lattice spacing) values for n-level photographs. From the information obtained from a 0-layer Weissenberg film as described above, the value of d^* for one crystallographic axis can be determined easily from the precession photograph along the other axis and *vice versa*. For example, for a monoclinic crystal whose b-axis is parallel to the axis of the crystal holder and whose β-angle is known from the Weissenberg pattern with the crystal rotating along this axis, a precession photograph is made along one axis, say the a-, and then after turning the crystal through $\beta°$ another precession photograph is made along the c-axis. The former will give the d^* value for n-level precession along the latter axis and *vice versa*.

It has been found, in the case of zinc hydrogen benzoate dihydrate, that the value of d^*, derived from precession along the c-axis with Cu Kα radiation, is so small that the annular slit of the layer-line screen will permit more than one level of the reciprocal lattice to register simultaneously, if the layer-line screen is set at the usual distance from the crystal. This will yield patterns with entirely anomalous extinctions. The difficulty can be avoided by selecting the n-level such that the layer-line screen will be as far from the crystal as possible. An alternative way is, of course, to change the X-ray radiation to one with longer wave length (for example Cr Kα radiation).

The Suggested Simple Technique for Single Crystal Structural Analysis

After considerable experience a simple procedure has been adopted by utilizing both the 57.3 mm. Weissenberg camera and precession camera, especially for needle crystals, where the orientation of the crystal along the axis other than needle axis is very difficult, if not impossible, as follows:

(1) Set the crystal on its holder so that the needle axis coincides with the horizontal axis of the crystal holder. Suppose that the needle axis is the b-axis of a monoclinic crystal. Take a rotation pattern from which the approximate value of b can be determined simply by means of a Bernal chart.

(2) Take zero- and first-layer Equi-inclination Weissenberg photographs from which the angle β^* can be accurately measured and a^* and c^* uniquely determined.

(3) Remove the crystal holder from the Weissenberg camera to the precession camera and make a zero-level photograph along one of the other axes, say the a-axis, from which b^*, c^* and α^* are determined by inspection.

(4) Turn the crystal β^* or 180°-β^* and make the zero-level precession photograph along c-axis, and thus determine a^*, b^*, γ^*. Take the n-level precession photographs using the d^* value obtained from (3).

(5) Turn the crystal back to the position (3) and make n-level photographs along a-axis using the d^* found in (4).

By these operations all lattice translations and angles of the reciprocal and hence of the direct lattice can be found. The space group can be determined by examining the extinction data from these two sets of precession photographs. This is usually enough, but additional n-layer line Weissenberg photographs along the b-axis can be made, if necessary.

The Crystal Structure of Benzaldehyde- 2,4-Dinitrophenylhydrazone

This compound was chosen as a logical extension of the work in the laboratory on the X-ray diffraction and crystallography of the 2,4-dinitrophenylhydrazones of aldehydes and ketones.[3]

The benzaldehyde derivative was prepared by the method of Shriner and Fuson.[4] Orange crystals with sharp melting point 233–4° were obtained after four recrystallizations from ethyl acetate. No polymorphism was observed in crystallization from other solvents such as glacial acetic acid. Well-defined crystals were easily obtained. The density of the crystal determined by flotation in a solution of silver nitrate was 1.54. The "ideal" density calculated from X-ray data was 1.569.

X-Ray Data.—The results obtained by using the above procedure for single crystal analysis and that obtained by the Weissenberg method are summarized as follows for comparison:

		From Precession	From Weissenberg
(1) Unit cell constants	α	90°	90°
	β	92.7° ± 0.2°	92.8° ± 0.2°
number of molecules per unit cell		4	4
a (A. U.)		12.8 ± 0.1	13.1 ± 0.1
b		6.78 ± 0.01	6.79 ± 0.01
c		14.26 ± 0.02	14.20 ± 0.05
(2) Space-group		$P2_1/c$	$P2_1/c$
Extinctions (from both):		$h0l$ appears only when $l = 2n$	
		$0k0$ appears only when $k = 2n$

The Crystal Structure of Zinc Salicylate Trihydrate

Because of some interest in zinc salts of salicylic (*o*-hydroxybenzoic) and benzoic acids and their complexes with boric acid as antiseptics, a determination of structure may have added significance. Zinc salicylate trihydrate is formed by mixing equal volumes of 2-molar sodium salicylate and 1-molar zinc sulfate solutions at room temperature. A white powder rapidly separates which may be recrystallized to fine single crystals. It has been claimed that the crystals are needles, but only in the first stage of crystallization was this found to be true since the crystals lost their acicular shape during growth. The composition of the crystal as zinc salicylate trihydrate, $Zn(C_7H_5O_3)_2 \cdot 3H_2O$, is verified by its powder pattern, and by chemical analysis.

For this crystal a procedure similar to that just described was used. From the Weissenberg data the following results are obtained:

$\beta = 94°$
$a = 15.40 \pm 0.02$ A. U.
$b = 5.36 \pm 0.01$ A. U.
$c = 9.18 = 0.01$ A. U.

Extinctions: hkl appears only when $h + k = 2n$
$h0l$, $h = 2n$; $0k0$, $k = 2n$
Space group C2/m, C2, or Cm

From zero, first and second layer fine precession photographs around all three axes, the following data are obtained

$\beta = 93.8° \pm 0.2°$
$a = 15.40 \pm 0.02$ A. U.
$b = 5.37 \pm 0.01$ A. U.
$c = 9.18 \pm 0.01$ A. U.

Extinctions and space group as above.

The measured density is 1.64 from which about 2 molecules per unit cell are found. The ideal density for $n = 2$ is 1.653 g./ml.

The Crystal Structure of Zinc Benzoate

These crystals were prepared by double recrystallization from a pure commercial material, or from the product obtained by treating zinc carbonate with benzoic acid followed by slow evaporation of the solvent. Chemical analysis indicated pure anhydrous $Zn(C_6H_5COO)_2$, with a measured density of 1.54 by flotation in chloroform and carbon tetrachloride. Both equi-inclination Weissenberg and precession patterns gave concordant data as follows:

Monoclinic $\beta = 94° 26'$
$a = 10.67 \pm 0.02$ A. U.
$b = 12.94 \pm 0.02$ A. U.
$c = 19.22 \pm 0.02$ A. U.

Systematic extinctions: hkl all appear
$h0l$ appears only when $l = 2n$
$0k0$ appears only when $k = 2n$
Space group $P2_1/c$

Number of molecules per unit cell 8. The "ideal" density calculated 1.546 g./ml.

The Crystal Structure of Zinc Hydrogen Benzoate Dihydrate

The compound was prepared either by adding zinc chloride to an aqueous solution containing sodium benzoate and benzoic acid or by the reaction of benzoic acid with zinc carbonate in aqueous solution. It was also obtained, as observed in this work, by the addition of benzoic acid to zinc borate which was suspended in hot water; from such solutions benzoic acid first settled out, then long colorless needles of $ZnH_2(C_6H_5COO)_4 \cdot 2H_2O$ crystallized out (for zinc found 11.17%; calculated 11.13%). The compound is soluble in ether and alcohol and slightly soluble in benzene. The crystals have about the same density as pure chloroform at 32°, 1.47 g./ml.

The usual series of equi-inclination Weissenberg and precession patterns in 0, 1 and 2-levels were made yielding the following data:

Orthorhombic, with shortest translations

$a = 5.20 \pm 0.02$ A. U.
$b = 25.4 \pm 0.02$ A. U.
$c = 40.0 \pm 0.5$ A. U.

Compounds	Crystal habits	Crystal system	Cell constants	Space group	n	"Ideal" density
Benzaldehyde 2,4-dinitrophenylhydrazone	Orange plates	Monoclinic	a 12.8 ± 0.1 A. U. b 6.79 ± 0.01 c 14.23 ± 0.02 β 92.8° ± 0.2°	$P2_1/c$	4	1.569
Zinc salicylate trihydrate	Colorless plates	Monoclinic	a 15.4 ± 0.02 b 5.36 ± 0.01 c 9.18 ± 0.01 β 94.0° ± 0.2°	C2/m or C2 or Cm	2	1.653
Zinc benzoate	Colorless plates	Monoclinic	a 10.67 ± 0.02 b 12.94 ± 0.02 c 19.22 ± 0.02 β 94.4° ± 0.2°	$P2_1/c$	8	1.546
Zinc hydrogen benzoate dihydrate	White needles	Orthorhombic	a 5.20 ± 0.02 b 25.4 ± 0.2 c 40.0 ± 0.5	F d d	8	1.47

Systematic extinctions:

hkl appears only when all odd or all even
0kl appears only with $k = 2n$ and $l = 2n$
h0l appears only with $h = 2n$, $l = 2n$ and $h + l = 4n$
hk0 appears only with $h = 2n$, $k = 2n$ and $h + k = 4n$
Space group: F d d

The number of molecules per unit cell is 8 and the "ideal" density of the crystal is 1.478 g./ml. The compound is unusually interesting because of the very small *a* spacing in comparison with *b* and *c*, probably indicating very flat molecules lying extended in the *bc* plane, also probably with hydrogen bonding. Hence this offers an excellent opportunity for a two-dimensional Fourier analysis of electron densities which is now being carried out.

Summary

1. A new simple procedure for single crystal analysis by the combination of the equi-inclination Weissenberg and the Buerger precession methods has been investigated and its application has been illustrated with practical problems. This new procedure provides a simple solution for needle crystals the orientation of which, along the crystallographic axes other than needle axis, is extraordinarily difficult.

2. Determinations were made of crystal habits, densities, lattice constants and probable space-groups of four compounds, for which no previous X-ray and crystallographical data are available, as tabulated on the preceding page.

Heat Contents at High Temperatures of Vanadium Dichloride and Vanadium Trichloride[1]

BY E. G. KING[2]

In continuation of a program of study of the thermodynamic properties of vanadium compounds, high-temperature heat contents of vanadium dichloride and vanadium trichloride were measured. No previous similar values exist for these substances, but low temperature heat capacity and entropy data have been reported by Shomate.[3]

Materials

The samples used in this work were portions of the materials prepared for previous low temperature heat capacity measurements, and the methods of preparation and the analyses were described by Shomate.[3] Before the present measurements were begun, both compounds were given a preliminary heating in vacuum, the dichloride to 850° and the trichloride to 150°.

Measurements and Results

The high temperature heat content measurements were made by the "dropping" method with previously described[4,5] apparatus. Frequent calibrations of the furnace thermocouple at the gold point were made by the method described by Southard.[4]

The samples were contained in platinum–rhodium alloy capsules. Two capsules were employed for the dichloride, containing, respectively, 8.9608 and 8.6643 g. (corrected to vacuum) of sample. These capsules were sealed by platinum welding after replacing air in the pore space by helium. One capsule, containing 7.4429 g. (corrected to vacuum) of sample was used for the trichloride. It was sealed by gold soldering, after the pore space was filled with helium. Corrections for the capsules were made by means of separate measurements of the platinum–rhodium alloy and the known heat contents of gold and platinum. These corrections amounted to 25% of the total measured heats for the dichloride and 28% for the trichloride.

The experimental results, expressed in defined calories[6] (1 cal. = 4.1833 int. joules), are in Table

I. Molal weights accord with the 1947 International Atomic Weights.

Measurements of the dichloride could not be extended beyond 1272°K. because of swelling of the capsule from vapor pressure of the substance. Pressure of tetrachloride from the disproportionation reaction of the trichloride precluded obtaining results above 902°K. for the latter substance.

The heat content curves are shown in Fig. 1. No anomalous behavior of either substance was observed.

Smooth curve values of the heat contents and entropy increments calculated from them are in Table II. The average deviation of experimental points from the smooth curves is 0.15% for the dichloride and 0.3% for the trichloride.

1200	17,220	26.13		
1300	19,270	27.77		

Heat content equations, representing the data, were derived by the method of Shomate,[7] use being made of his values[3] of the heat capacities at 298.16°K. The average deviations from smooth values and temperature ranges of validity are given in parentheses. Corresponding molal heat capacity equations also are listed.

For VCl_2

$$H_T - H_{298.16} = 17.25T + 1.36 \times 10^{-3}T^2 + 0.71 \times 10^5T^{-1} - 5502$$

(298–1200°K.; 0.3%)

$$C_p = 17.25 + 2.72 \times 10^{-3}T - 0.71 \times 10^5T^{-2}$$

(7) Shomate, THIS JOURNAL, **66**, 928 (1944).

For VCl_3

$$H_T - H_{298.16} = 22.99T + 1.96 \times 10^{-3}T^2 + 1.68 \times 10^5T^{-1} - 7592$$

(298–900°K.; 0.2%)

$$C_p = 22.99 + 3.92 \times 10^{-3}T - 1.68 \times 10^5T^{-2}$$

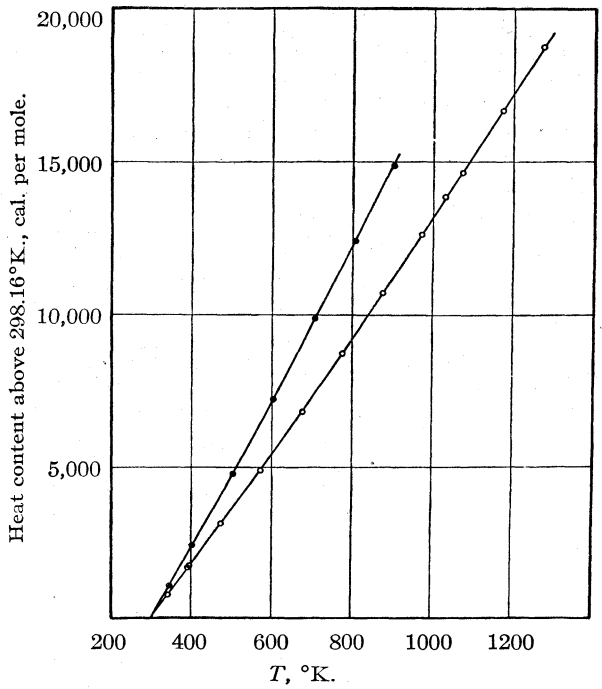

Fig. 1.—High temperature heat content of vanadium chlorides: upper curve, VCl_3; lower curve, VCl_2.

Summary

High-temperature heat contents of vanadium dichloride and vanadium trichloride were measured from 298.16°K. to 1272°K. and 902°K., respectively.

Tables of heat contents and entropy increments above 298.16°K. are assembled and heat content and heat capacity equations are derived.

A Hydrofluoric Acid Solution Calorimeter and the Determination of the Heats of Formation of Mg_2SiO_4, $MgSiO_3$, and $CaSiO_3$[1]

BY D. R. TORGESON[2] AND TH. G. SAHAMA[3]

Heats of formation of most silicates are not amenable to determination by either combustion or ordinary solution calorimetry. However, many silicates can be studied with a hydrofluoric acid solution calorimeter, operating near 75°. This paper describes a calorimeter of this type and presents values of the heats of formation of magnesium orthosilicate, magnesium metasilicate and calcium metasilicate.

Materials

The materials employed were artificial magnesium metasilicate (clinoenstatite), natural calcium metasilicate (wollastonite), a series of 6 natural solid solutions in the Mg_2SiO_4–Fe_2SiO_4 system with a wide range of magnesium: iron ratios, artificial ferrous orthosilicate (fayalite), natural quartz, artificial magnesium hydroxide, and artificial calcium oxide.

The magnesium metasilicate and ferrous orthosilicate were the materials used in previous measurements by Kelley.[4,5] The former contained 92.0% $MgSiO_3$, 5.6% Mg_2SiO_4, and 2.4% uncombined SiO_2. The latter was virtually 100% pure.

The calcium metasilicate was that described by Southard.[6] It contained about 0.6% impurities.

The quartz was the purest available grade. It was crushed, screened through 325-mesh, washed with hot hydrochloric acid for several days, water-elutriated to eliminate the coarser particles, and finally dried. Analyses indicated at least 99.9% silica content.

Magnesium hydroxide was prepared from reagent-grade magnesium oxide in a manner similar to that used by Taylor and Wells.[7] In this instance, the washed oxide was calcined at 900° and then hydrated with steam at 150 lb. per sq. in. pressure. The wet hydrate was dried in vacuum at 120°. Analysis showed 0.1% carbon dioxide content (equivalent to 0.19% $MgCO_3$) and 99.78% magnesium hydroxide.

Calcium oxide was prepared by calcining special reagent grade calcium carbonate at 1150°. Analysis of the product showed 99.98% calcium oxide.

The Mg_2SiO_4–Fe_2SiO_4 samples are described in Table I, using the classification proposed by Deer and Wager.[8] Before chemical analysis, the samples were purified by hand sorting, table classification, magnetic separation, and gravity separation with Clerici solution (aqueous solution of thallium formate and thallium malonate). Final products were examined microscopically.

Apparatus and Method

The calorimetric assembly is shown in Fig. 1. As it is expected that several researches employing this equipment will be published, a brief description is warranted.

The calorimeter, V, is a cylindrical platinum vessel, 10 cm. diam. and 12.5 cm. high, filled with hydrofluoric acid to the level indicated at Y. Chimneys, V and W, provide for admission of the stirrer, X, and for insertion of samples. A cylindrical well, K, 2.2 cm. diameter, extending from 1.3 cm. above the bottom to 2.5 cm. above the top, houses the resistance thermometer and calibrating heater coils.

The resistance thermometer, L, and heater, N, are wound on the hollow copper cylinder, M, which has closed ends. This cylinder has 0.1-mm. wall thickness except at the ends where projecting flanges were left to anchor the coils and provide thermal contact with K. The resistance thermometer consists of B. & S. No. 40, single silk-covered and enameled copper wire and has 104.7 ohms resistance at 73.7°, the sensitivity being 308 μV. per degree. (As both calibration and reaction heats are measured in terms of μv., actual conversion to degrees never is necessary.) The heater is a 100-ohm coil of B. & S. No. 34, double-silk-covered manganin wire. Paraffin was used to fill the annular space between cylinder M and the walls of K. The top of K is closed by the cork, I, to which radiation shield, J, is attached.

Lead wires, A, from the resistance thermometer and

heater coils are protected from acid vapors by the bakelite tube B, which ends in the vapor seal E containing heavy silicon grease.

The calorimeter is supported by the bakelite ringstand, O, which also supports the thin, gold-plated copper surrounding shield, F.

The outer container, G, is of heavy, gold-plated brass. It is attached to the top, D, by means of a bolted flanged joint, the seal being made by a tygon gasket. The top has three chimneys in line with the calorimeter chimneys and well. Chimneys R and C, for admission of the stirrer and the lead wire protection tube, are shown in Fig. 1. A third chimney, not in the plane of the drawing, admitted samples.

The stirrer, X, is pure platinum. Attachment to the drive mechanism is made through the teflon assembly Q-T which also houses two sets of ball bearings. The lower part of T serves as a closure for calorimeter chimney V.

The entire assembly is immersed in an oil-bath to the level indicated at U. The oil bath is thermostatically controlled at 73.7 ± 0.1°.

Readings of resistance thermometer e. m. f. and calibrating heater current are made with a White 100,000 μ v. range double potentiometer. This instrument also serves in fixing and maintaining constant the resistance thermometer current which is 900.000 ± 0.002 μ amp. Energy input times for calibrations are measured with a stopwatch, calibrated against a standard chronometer of the Astronomy Department of the University of California. The resistance of the manganin heater coil is determined at operating temperature by direct comparison with a 100-ohm standard resistance.

All samples are contained in gelatin capsules, sizes O and OO being the most convenient. These are dropped from room temperature through chimney W into the calorimeter at operating temperature. Platinum weights are enclosed with the samples to assure immediate sinking of capsule and contents.

In each heat of reaction measurement, 856.0 g. of 20.1% (by weight) hydrofluoric acid was used. Amounts of reacting materials were in stoichiometric proportion: 0.6750 g. of quartz, 1.1281 g. of magnesium metasilicate, 2.2900 g. of ferrous orthosilicate, 0.6556 g. of magnesium hydroxide, 1.3053 g. of calcium metasilicate, 0.6303 g. of calcium oxide, 1.6482 g. of sample A, 1.6510 g. of sample B, 1.6649 g. of sample C, 1.8931 g. of sample D, 1.9061 g. of sample E, and 2.2482 g. of sample F (all corrected to vacuum).

Reagent grade hydrofluoric acid was employed. This was obtained in case lots consisting of 25 one-pound plastic bottles of approximately 48% acid. The case lots were sampled for uniformity and analyzed in transparent bakelite containers by titration against standard alkali. Each 856.0 g. batch of 20.1% acid was made up separately by weight, correction being made to vacuum.

The time required for complete reaction and attainment of final steady state conditions after dropping a sample into the calorimeter ranged from ten to thirty minutes, depending upon the substance. The temperature rise varied from 120.70 μv. for magnesium hydroxide to 400.64 μv. for olivine A.

All heat-of-reaction values are adjusted to correspond with the process, Reactant (solid, 25°) → Product (73.7°). This was accomplished by measuring the temperature of the gelatin capsule and contents just before dropping into the calorimeter and making the minor correction resulting from deviation of room temperature from 25°. Although reaction with the hydrofluoric acid occurs at 73.7°, this method of adjustment leads to values of heats of formation at 25°.

Measured heats of reaction were corrected for the sensible heat and heat of solution of the gelatin capsules. For the process, gelatin (solid, 25°) → gelatin (in solution, 73.7°), six measurements gave, respectively, 22.06, 22.15, 22.80, 22.79, 22.85, and 22.63 cal. per g., the mean being 22.63 ± 0.22 cal. per g. The gelatin correction ranged from 1 to 2%, depending upon the substance. Correction, from 0.2 to 1%, also was made for the sensible heat in the platinum sinkers, using $H_{73.7} - H_{25.0} = 1.70$ cal. per g. The magnitude of the corrections for impurities will be considered later.

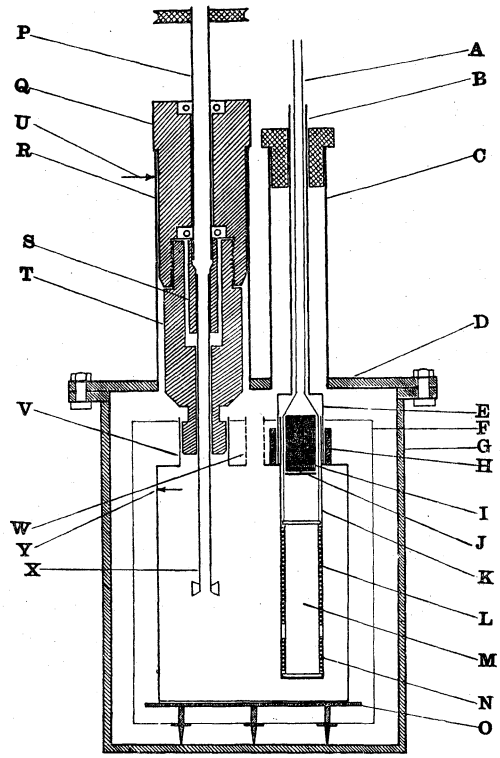

Fig. 1.—Hydrofluoric acid solution calorimeter.

An electrical calibration was made either just before or just after each heat-of-reaction measurement, in terms of the defined calorie (1 cal. = 4.1833 int. joules).[13] The maximum spread in calibration values during the course of this work was 0.2%.

Measurements and Results

Each of the heats of formation is obtained as a resultant of the measurement of the heats of several reactions for which skeleton equations are given in Tables II, III, and V. The method of ascribing uncertainties to the individual reaction heat values and their resultant follows Rossini and Deming.[14]

Heat of Formation of $MgSiO_3$.—Table II summarizes the data for obtaining the heat of formation of magnesium metasilicate from the component oxides. In this and subsequent tables various symbols are employed: c = crystals, l = liquid, p = precipitate, and sol. = in solution.

Six determinations of the heat of reaction (1) were made, the results being −29,901, −29,102, −29,069, −29,095, −29,060 and −29,111 cal. per mole. The mean is −29,090 ± 20. These results include a net correction of 35 cal. for the 0.19% magnesium carbonate impurity. By net correction is meant the difference between the actual reported value and what would have been reported if the impurity had been neglected. It

TABLE II

HEAT OF FORMATION OF $MgSiO_3$ (CLINOENSTATITE) (CAL. PER MOLE)

Reaction	ΔH	Uncertainty
(1) $Mg(OH)_2$ (c, 25°) + 2HF (sol., 73.7°) → MgF_2 (p, 73.7°) + $2H_2O$ (sol., 73.7°)	−29,090	20
(2) SiO_2 (c, 25°) + 6HF (sol., 73.7°) → H_2SiF_6 (sol., 73.7°) + $2H_2O$ (sol., 73.7°)	−33,000	20
(3) $MgSiO_3$ (c, 25°) + 8HF (sol., 73.7°) → MgF_2 (p, 73.7°) + H_2SiF_6 (sol., 73.7°) + $3H_2O$ (sol., 73.7°)	−63,060	140
(4) MgO (c, 25°) + H_2O (l, 25°) → $Mg(OH)_2$ (c, 25°)	− 8,850	25
(5) H_2O (l, 25°) → H_2O (sol., 73.7°)	810	5
(6) MgO (c, 25°) + SiO_2 (c, 25°) → $MgSiO_3$ (c, 25°)	− 8,690	150

$\Delta H_6 = \Delta H_1 + \Delta H_2 - \Delta H_3 + \Delta H_4 - \Delta H_5$

should be noted that to make the final solution from reaction (1) equivalent in H_2SiF_6 content to those of reactions (2) and (3), the magnesium hydroxide reacted with a solution in which had already been dissolved the stoichiometrical amount of silica.

Seven determinations of the heat of reaction (2) gave −33,003, −33,033, −32,981, −32,983, −33,003, −33,008, and −33,019 cal. per mole, the mean being −33,000 ± 20. These values include a net correction of 40 cal. for adsorbed water, which was determined to be about 0.1%.

For reaction (3), seven values of the heat were measured. The results are −62,869, −63,195, −63,059, −63,299, −63,232, −62,893, and −62,899 cal. per mole. The mean is −63,060 ± 140. The net correction included for impurities, magnesium orthosilicate and uncombined silica, is 90 cal.

The heat of reaction (4), the hydration of magnesium oxide, was not determinable in the hydrofluoric acid calorimeter because of slowness of reaction of the oxide. Recourse was taken to the ordinary solvents calorimeter described by Southard[15] and Young[16] and used by Shomate and Huffman[17] in their determination of the heat of formation of magnesium oxide.

Six determinations of the heat of solution of magnesium hydroxide in 1.000 *N* hydrochloric acid were conducted under conditions virtually identical with those of Shomate and Huffman for the oxide and with equivalent stoichiometrical amounts of materials. The results were −26,948, −26,957, −26,953, −26,942, −26,948, and −26,968 cal. per mole. The mean, −26,950 ± 10, is $\Delta H_{298.16}$ for the reaction

$$Mg(OH)_2(c) + 2H^+ = Mg^{++} + 2H_2O(l)$$

(15) Southard, *Ind. Eng. Chem.*, **32**, 442 (1940).
(16) Young, THIS JOURNAL, **67**, 257 (1945).
(17) Shomate and Huffman, *ibid.*, **65**, 1625 (1943).

Corrections included in these results are 10 cal. for the heat of dilution by the two moles of water formed in the reaction and 35 cal. net correction for the magnesium carbonate impurity. Shomate and Huffman obtained $\Delta H_{298.16} = -35{,}799 \pm 21$ cal. per mole for the reaction

$$MgO(c) + 2H^+ = Mg^{++} + H_2O(l)$$

Combination of these values leads to $\Delta H_{298.16} = -8{,}850 \pm 25$ cal. per mole for the reaction

$$Mg(OH)_2(c) = MgO(c) + H_2O(l)$$

which is reaction (4) of Table II.

Four determinations of the heat of reaction (5) were made, obtaining 816, 815, 811 and 807, with a mean of 810 ± 5 cal. per mole. Because of the low heat, these determinations were made with 8 to 12 times the stoichiometrical amount of water, to realize a higher over-all accuracy. To be specific, amounts of water ranging from 1.597 g. to 2.418 g. were dissolved in 856.0 g. of 20.1% hydrofluoric acid to which had already been added amounts of magnesium hydroxide and silica corresponding to those employed in reactions (1) and (2).

The summation, $\Delta H_6 = \Delta H_1 + \Delta H_2 - \Delta H_3 + \Delta H_4 - \Delta H_5$, gives $\Delta H_{298.16} = -8{,}690 \pm 150$ as the heat of formation of magnesium metasilicate from magnesium oxide and quartz.

Heat of Formation of Mg_2SiO_4.—Data for obtaining the heat of formation of magnesium orthosilicate are summarized in Table III.

TABLE III

HEAT OF FORMATION OF Mg_2SiO_4 (FORSTERITE) (CAL. PER MOLE)

Reaction	ΔH	Uncertainty
(7) $2Mg(OH)_2$ (c, 25°) + 4HF (sol., 73.7°) → $2MgF_2$ (p, 73.7°) + $4H_2O$ (sol., 73.7°)	−58,180	40
(8) SiO_2 (c, 25°) + 6HF (sol., 73.7°) → H_2SiF_6 (sol., 73.7°) + $2H_2O$ (sol., 73.7°)	−33,000	20
(9) Mg_2SiO_4 (c, 25°) + 10HF (sol., 73.7°) → $2MgF_2$ (p, 73.7°) + H_2SiF_6 (sol., 73.7°) + $4H_2O$ (sol., 73.7°)	−95,380	200
(10) $2MgO$ (c, 25°) + $2H_2O$ (l, 25°) → $2Mg(OH)_2$ (c, 25°)	−17,700	50
(11) $2H_2O$ (l, 25°) → $2H_2O$ (sol., 73.7°)	1,620	10
(12) $2MgO$ (c, 25°) + SiO_2 (c, 25°) = Mg_2SiO_4 (c, 25°)	−15,120	210

$\Delta H_{12} = \Delta H_7 + \Delta H_8 - \Delta H_9 + \Delta H_{10} - \Delta H_{11}$

Heats of reactions (8), (10), and (11) were discussed previously as heats of reactions (2), (4) and (5), respectively. Reaction (7) is the same as reaction (1) except that twice the amount of magnesium hydroxide is concerned. However, it was determined quantitatively that no measurable difference in molal heat of reaction resulted from

TABLE IV

HEATS OF REACTION OF Fe_2SiO_4 AND Mg_2SiO_4–Fe_2SiO_4 SOLID SOLUTIONS WITH 20.1% HYDROFLUORIC ACID

Sample	Number of detns.	Composition, mole % Mg_2SiO_4	Composition, mole % Fe_2SiO_4	Net correction for impurities	ΔH, cal./mole Meas.	Calcd.	Diff.
A	4	90.6	9.4	100	−94,250 ± 160	−94,060	−190
B	4	90.2	9.8	70	−93,590 ± 80	−94,000	410
C	5	88.2	11.8	160	−93,930 ± 140	−93,720	−210
D	4	56.0	44.0	590	−89,070 ± 100	−89,200	130
E	4	54.2	45.8	470	−88,820 ± 160	−88,940	120
F	4	5.9	94.1	750	−82,080 ± 160	−82,160	80
Fe_2SiO_4	6	0.0	100.0	0	−81,330 ± 50	−81,330	0

the use of 1.3112 g. rather than 0.6556 g. of magnesium hydroxide with 856.0 g. of hydrofluoric acid. Consequently, the heat of reaction (7) is just twice that of reaction (1).

The heat of reaction (9) was obtained by extrapolation of results for the Mg_2SiO_4–Fe_2SiO_4 solid solutions. This was necessary because a suitable sample of pure magnesium orthosilicate was not available. Table IV summarizes the heat of reaction data for the six solid solutions and for pure ferrous orthosilicate. Corrections were made for the principal impurities, the net correction being shown in column (5) and the resulting adjusted molal composition in columns (3) and (4).

The mean measured values in column (6) are represented by

$$\Delta H = -81{,}330 - 140.5\, X_{Mg}$$

in which X_{Mg} is the molal % of magnesium orthosilicate. Values calculated from the equation are in column (7). Extrapolation to 100% magnesium orthosilicate leads to $\Delta H = -95{,}380 \pm 200$ cal. per mole, which is the value adopted for the heat of reaction (9).

The summation, $\Delta H_{12} = \Delta H_7 + \Delta H_8 - \Delta H_9 + \Delta H_{10} - \Delta H_{11}$, gives $\Delta H_{298.16} = -15{,}120 \pm 210$ as the heat of formation of magnesium orthosilicate from magnesium oxide and quartz.

Heat of Formation of $CaSiO_3$.—Data for obtaining the heat of formation of calcium metasilicate are summarized in Table V.

TABLE V

HEAT OF FORMATION OF $CaSiO_3$ (WOLLASTONITE) (CAL. PER MOLE)

Reaction	ΔH	Uncertainty
(13) CaO (c, 25°) + 2HF (sol., 73.7°) → CaF_2 (p, 73.7°) + H_2O (sol., 73.7°)	−54,960	20
(14) SiO_2 (c, 25°) + 6HF (sol., 73.7°) → H_2SiF_6 (sol., 73.7°) + $2H_2O$ (sol., 73.7°)	−33,000	20
(15) $CaSiO_3$ (c, 25°) + 8HF (sol., 73.7°) → CaF_2 (p, 73.7°) + H_2SiF_6 (sol., 73.7°) + $3H_2O$ (sol., 73.7°)	−66,710	120
(16) CaO (c, 25°) + SiO_2 (c, 25°) → $CaSiO_3$ (c, 25°)	−21,250	130

$\Delta H_{16} = \Delta H_{13} + \Delta H_{14} - \Delta H_{15}$

Six determinations of the heat of reaction (13) gave −54,973, −54,974, −54,937, −54,965, −54,963, and −54,959 cal. per mole, the mean being −54,960 ± 20.

The heat of reaction (14) was discussed previously as the heat of reaction (2). Six measurements were made of the heat of reaction (15). The results are −66,711, −66,785, −66,795, −66,705, −66,605, and −66,681 cal. per mole. The mean is −66,710 ± 120. In this instance the calculated uncertainty has been doubled, an estimated allowance for neglect of impurities.

The summation, $\Delta H_{16} = \Delta H_{13} + \Delta H_{14} - \Delta H_{15}$, gives $\Delta H_{298.16} = -21{,}250 \pm 130$ as the heat of formation of calcium metasilicate from calcium oxide and quartz.

Discussion

The only previous data with which comparison can be made are for wollastonite. Bichowsky and Rossini[18] list a heat-of-formation value for 291.16°K. that corresponds to −22,800 cal. per mole for the heat of formation of wollastonite from calcium oxide and quartz. Their result is a weighted mean of values covering a range of some 10,000 cal. The two best of these values appear to be those attributed to Roth and Chall and Wagner which lead, respectively, to −19,660 and −21,460 cal. per mole heat of formation from the oxides. A more recent value of Troitzsch[19] is −21,750 cal. per mole at 293.16°K. The present value, $\Delta H_{298.16} = -21{,}250$, intermediates these results and is considered the most reliable.

Using entropy data listed by Kelley[20,21] the reported heat values lead to the following free energies of formation from the component oxides: $\Delta F^0_{298.16} = -8{,}540 \pm 160$ for magnesium metasilicate, $\Delta F^0_{298.16} = -14{,}970 \pm 230$ for magnesium orthosilicate, and $\Delta F^0 = -21{,}250 \pm 160$ for calcium metasilicate.

Summary

A hydrofluoric acid solution calorimeter, employing 20% acid and operating near 75°, is described.

High-Temperature Heat Contents of $3CaO \cdot B_2O_3$, $2CaO \cdot B_2O_3$, $CaO \cdot B_2O_3$, and $CaO \cdot 2B_2O_3$[1]

BY E. G. KING,[2] D. R. TORGESON[2] AND O. A. COOK[3]

In two recent papers,[4,5] heats of formation and low-temperature heat-capacity and entropy data were presented for the four calcium borates, $3Ca \cdot B_2O_3$, $2CaO \cdot B_2O_3$, $CaO \cdot B_2O_3$, and $CaO \cdot 2B_2O_3$. These are all the compounds in the CaO–B_2O_3 system, according to the work of Carlson.[6] The present paper reports high temperature heat content values, thus completing basic data needed for thermodynamic calculations of reactions of these compounds in both the crystalline and liquid states. The results have additional interest in that this is the first complete series of interoxidic compounds for which high temperature heat content measurements have been carried beyond the melting points so that adequate heat of fusion values are available. No previous high temperature heat content data exist for any of these substances.

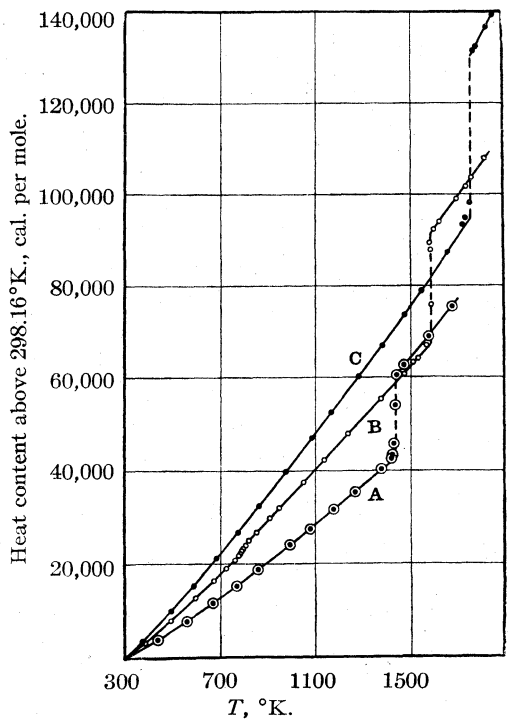

Fig. 1.—Heat contents of calcium borates: A, $CaO \cdot B_2O_3$; B, $2CaO \cdot B_2O_3$; C, $3CaO \cdot B_2O_3$.

Method and Materials

Measurements were made by the "dropping" method, using previously described apparatus.[7,8] During measurement, the samples were enclosed in platinum–rhodium alloy capsules, pure platinum being used in welding shut the capsule necks after evacuating and filling the pore space with helium. The heat contents of the empty capsules were determined by separate experiments. At the highest temperatures, small pinholes developed in the capsules, and it was necessary to weigh capsules and contents after each measurement. The total loss in weight during a complete series of measurements never exceeded 0.5% of the original sample weight. Correction was made on the assumption that boric oxide was lost by volatilization and that the equivalent amount of the borate next higher in calcium oxide had formed. As the net correction always was less than 0.2%, no appreciable error in reported results is involved.

The preparation, analysis, and X-ray diffraction examination of the borates was described by Torgeson and Shomate,[4] whose samples also were used in the present work. It should be noted that the sharpness of the observed melting points and the agreement with results of the National Bureau of Standards[6,9] substantiates the purity of the materials.

Results and Discussion

The experimental heat content values are given in Table I and Figs. 1 and 2, being expressed in defined calories (1 cal. = 4.1833 int. joules)[10] per mole (in vacuum) of borate. Molal weights accord with the 1947 International Atomic Weights. Values marked (t) and (p) show, respectively, effects of pretransition and of premelting or in-

complete melting. Table II gives smooth values of heat contents and entropy increments above 298.16° K. at 100° intervals and at transition and melting points.

The compound $2CaO \cdot B_2O_3$ has a transition at 804° K., with a heat absorption of 1,100 cal. per mole and an entropy change of 1.37 e. u.

With the exception of $CaO \cdot 2B_2O_3$, the compounds melted and recrystallized reversibly under the prevailing experimental conditions. The molten diborate solidified completely in the glassy state (single phase) when dropped from the furnace into the calorimeter. It could be reconverted to the crystalline state by heating for a short time in the region just below the melting point of the crystals. This behavior agrees with the ob-

[a] Base = crystals at 298.16° K. [b] Base = glass at 298.16° K.

servations of Carlson.[6] As a consequence, direct measurements were made of the heat content of the crystals with respect to crystals at 298.16° K. as the base, and of the heat content of glass and liquid with respect to glass at 298.16° K. as the base.

Results marked (m) in Table I were obtained under conditions that resulted in partial reconversion of glass to crystals. These values are given no weight and are not plotted in Fig. 2. Results for the glass are, of necessity, sparse in the region just below the melting point and of lower accuracy than the other values.

It was necessary to obtain the heat of fusion of crystalline $CaO \cdot 2B_2O_3$ by an indirect method. This was accomplished by use of the calorimeter described by Southard[11] and Young[12] and also used by Torgeson and Shomate[4] in their heat of formation determinations of the calcium borates. Using 1.000 *N* hydrochloric acid as solvent, 3.4836 g. of $CaO \cdot 2B_2O_3$-glass was dissolved in 1845.5 g. of acid (identical with procedure of Torgeson and Shomate) and the heat of solution was measured. Three determinations were made, yielding, respectively, −22,720, −22,730, and −22,700 cal. per mole, the mean being −22,720 ± 20 for $CaO \cdot 2B_2O_3$-glass. Torgeson and Shomate obtained −10,080 ± 10 cal. per mole as the heat of solution of $CaO \cdot 2B_2O_3$-crystals. The difference, 12,640 ± 30 cal. per mole, is the heat of transformation of crystals to glass at 298.16° K. Combination of this result and heat content values of crystals and glass from Table II yields 27,060 cal. per mole as the heat of fusion of the crystals at the melting point, 1260° K.

Melting points and heats and entropies of fusion are summarized in Table III. The melting point temperatures are in substantial agreement with determinations of the National Bureau of Standards except in the case of $2CaO \cdot B_2O_3$. The entropies of fusion are remarkably constant when considered on a mean gram-atom basis, 1.69 to 1.83 e. u.

TABLE III

$3CaO \cdot BaOO_3$(l): $C_p = 94.00$

$2CaO \cdot B_2O_3(\alpha)$: $C_p = 43.75 + 11.50 \times 10^{-3}T - 10.69 \times 10^5T^{-2}$

$2CaO \cdot B_2O_3(\beta)$: $C_p = 52.29 + 2.40 \times 10^{-3}T$

$2CaO \cdot B_2O_3$(l): $C_p = 68.20$

$CaO \cdot B_2O_3$(c): $C_p = 31.02 + 9.76 \times 10^{-3}T - 8.07 \times 10^5T^{-2}$

$CaO \cdot B_2O_3$(l): $C_p = 61.70$

$CaO \cdot 2B_2O_3$(c): $C_p = 51.34 + 19.16 \times 10^{-3}T - 17.16 \times 10^5T^{-2}$

$CaO \cdot 2B_2O_3$(l): $C_p = 106.30$

Summary

High temperature heat contents of the calcium borates, $3CaO \cdot B_2O_3$, $2CaO \cdot B_2O_3$, $CaO \cdot B_2O_3$ and $CaO \cdot 2B_2O_3$, were measured from 298.16° K. to temperatures well above their melting points. Melting point temperatures and heats of fusion were determined and also the transition temperature and heat of transition in the case of $2CaO \cdot B_2O_3$.

Heat content and heat capacity equations, adequately representing the measured data, were derived for each borate in the crystalline and liquid states.

Entropy increments above 298.16° K. at 100° intervals and at phase-change points are tabulated, together with smooth values of the heat contents.

Electrophilic Attack on Halogen in a Homogeneous Medium: Reaction of Mercuric Nitrate with some Primary and Secondary Alkyl Bromides

BY O. THEODOR BENFEY*

Introduction

In the work of Dostrovsky and Hughes[1] on the series of bromides, methyl, ethyl, *n*-propyl, isobutyl, neopentyl, reactions expected to proceed by the nucleophilic substitution mechanism S_N2 gave the rate sequence

Me > Et > *n*-Pr > *iso*-Bu ≫ Neopentyl

The sharp fall from isobutyl to neopentyl is attributed to a pronounced steric effect, the remaining rate sequence being explainable on the postulation of an inductive effect of methyl groups even on the β-carbon, opposing the approach of the nucleophilic reagent. Steric hindrance is a contributory factor except for methyl.

In order to bring out the alternative ionization mechanism S_N1, the behavior of the halides was studied by these workers both in the highly ionizing solvent formic acid, and in the presence of the electrophilic reagent silver nitrate, which acts by virtue of its affinity for halogen. In these reactions the rate sequence was changed to

Me < Et > *n*-Pr > *iso*-Bu > Neopentyl

Steric hindrance was shown to be absent, and the last member reacted by a pure S_N1 mechanism. The fact that the Me–Et rate sequence is inverted speaks strongly for the idea that the ethyl halide reacts largely by the same mechanism, the inductive effect being operative in assisting the breaking of the carbon-halogen bond. This strongly suggests that the intermediate members also react by this mechanism in spite of the rate sequence Et > *n*-Pr > iso-Bu being opposite to that expected from the influence of the inductive effect. The authors' suggestion that the wrong sequence beyond ethyl is due to an appreciable incursion of mechanism S_N2 is therefore unlikely. An alternative explanation in the case of the silver ion catalyzed reaction is that the catalytic effect of solid silver halide produced during the reaction decreases along this series.

In the reaction of alkyl halides with mercuric

* Present address: Department of Chemistry, Haverford College, Haverford, Pa.

(1) Dostrovsky and Hughes, *J. Chem. Soc.*, 157 ff. (1946).

ion, the mercuric halide produced, though largely un-ionized, is appreciably soluble, and the catalytic effect of solid metal halide is thus eliminated. The reaction of mercuric nitrate with ethyl, *n*-propyl and isobutyl bromides was therefore studied. Roberts and Hammett[2] have presented strong evidence in the case of benzyl chloride that the reaction proceeds by way of a rate determining formation of a carbonium ion intermediate

$$Hg^{++} + RX \longrightarrow HgX^{+} + R^{+}$$

followed by fast reactions to form the alcohol or alkyl nitrate. The reaction rate of alkyl halides in ionizing solvents is normally accelerated by a factor of several hundred on addition of small concentrations of mercuric nitrate. The acceleration is no doubt due to the driving force derived from the energy of formation of a mercury–halogen bond. Mercuric ion and mercuric salts have a strong affinity for halogen, as shown by the small ionization of the mercuric halides,[3] and by their ability to form complex ions such as $HgCl_4^{--}$.[4] Mercuric nitrate converts neopentyl iodide, notoriously unreactive toward nucleophilic reagents,[1] into the rearranged *t*-amyl alcohol.[5]

Cyclohexyl chloride and bromide react in some reactions like typical secondary halides, while in others their rates are considerably slower.[6] Mercuric ion has a larger accelerating effect than silver ion on the reactions of alkyl halides and is consequently expected to favor even more the mechanism involving an ionic intermediate. A comparison was therefore made between the rates of reaction of cyclohexyl and isopropyl bromides with mercuric nitrate.

Experimental

Apparatus.—The thermostat at 12.50° was the one described previously.[7] That at 25.00° was of the conventional type. The temperatures were determined with thermometers calibrated by the U. S. Bureau of Standards. The thermostat temperatures were constant to ±0.02°.

Materials.—Technical **1,4-dioxane** was purified in 2- to 3-liter quantities by a modification of the method of Beste and Hammett.[8] After treatment on the steam-bath with sodium hydroxide, the filtered product was boiled with 200 cc. of water and 25 cc. of concentrated hydrochloric acid for twelve hours, in a stream of air or nitrogen to carry away the aldehyde formed. The acid was neutralized and the aqueous portion removed with sodium hydroxide pellets. The dioxane was then refluxed over sodium wire for twelve hours and distilled through a 15-plate glass-helices packed column; b. p. 100.9–101.1° (760 mm).

***n*-Pentane** and ***n*-hexane** used for extraction of alkyl halides in the fast kinetic runs were found to be free of halide and were used directly.

Eastman Kodak Co. **ethyl bromide** was distilled through a 15-plate column, b. p. 38.5–38.6°. Analysis for bromide gave 100.0%.

Eastman Kodak Co. ***n*-propyl bromide** and A. D. Mackay **isopropyl bromide** were washed with concentrated hydrochloric acid and dilute sodium hydroxide and dried over sodium sulfate. On fractional distillation *n*-propyl bromide boiled at 71.6–71.7° (761 mm.), isopropyl bromide at 59.1–59.5°.

Eastman Kodak Co. **isobutyl bromide** was shaken with water for one hour to hydrolyze any *t*-butyl bromide. It was washed with concentrated hydrochloric acid and a 10% sodium carbonate solution, dried over sodium sulfate and fractionated, b. p. 91.6–92.0° (762 mm.).

Eastman Kodak Co. **bromocyclohexane** (b. p. 61–62° (15 mm.)) was twice distilled at reduced pressure through a Vigreux column. It was colorless and free from acid.

Colorless C. P. J. T. Baker analyzed **nitric acid** was used in making up the reaction mixtures.

Primary standards for titration were Mallinckrodt ACS grade potassium acid phthalate, and ACS grade potassium chloride which was recrystallized, and dried at 130° *in vacuo* over phosphorus pentoxide.

Merck reagent grade mercuric nitrate and C. P. mercuric bromide were used directly.

Method.—The titration method for following the production of bromide is described in detail by Roberts.[9,2]

The same solvent, "70% dioxane by volume," was used throughout. It was made up by mixing seven parts of dioxane with three parts of water containing the amount of nitric acid required for an acidity of the solvent within the limits 0.281–0.286 *N*. Mercuric nitrate (0.025 *N* appr.) was added and its concentration as well as that of the nitric acid determined by titration. A known volume, usually 100 cc., was transferred into the reaction flask, and placed in the thermostat. For all runs except that of isopropyl bromide at 25°, the alkyl bromide (0.022 *N* appr.) was weighed out in a 1-cc. weighing bottle closed with a well-fitting ground glass stopper. The bottle was inserted in the reaction flask which was shaken rapidly till the bottle opened. The initial time was then taken. It was found that this method was accurate even for appreciably volatile compounds, while the alternative of taking infinity readings was invalidated, except for the very fast runs, by slow complicating reactions, probably between mercury salts and the solvent. In the case of isopropyl bromide the approximate quantity was transferred with a weight pipet, and reproducible infinity readings were obtained.

At measured intervals 10-cc. samples were pipetted out and the reaction stopped by delivering into 5 cc. of 0.1 *N* potassium chloride. The excess chloride ion was then determined. In the case of isobutyl bromide this simple sampling method could not be used because of the formation of a precipitate. The reaction was started as before, but when the reaction had proceeded for a few minutes, 10-cc. samples were transferred into a series of 25-cc. erlenmeyer flasks and were tightly closed with rubber stoppers. To stop the reaction 5 cc. of standard potassium chloride solution was added to the flask which was then allowed to stand so that the precipitate could react completely. On first addition the precipitate turns white and then slowly dissolves. The contents of the flask were washed into a larger erlenmeyer flask and titrated as before.

For the fast reactions of isopropyl and cyclohexyl bromides a pipet with an outflow time of eleven seconds was used. The pipet delivered accurately reproducible volumes. However, the reaction was not completely stopped by addition to potassium chloride solution, and the end-points were not sharp. Samples were therefore delivered into a mixture of 5 cc. of 0.1 *N* potassium chloride, 5 cc. of *n*-pentane (or *n*-hexane) and 5 cc. of water. The organic layer took up the bulk of unreacted alkyl halide, it was separated and washed several times with small amounts of water, the washings being added to the

aqueous layer. The aqueous portion was titrated as before, and gave very sharp end-points.

Roberts and Hammett[2] mention that an impurity in the dioxane slowly reacts with mercuric nitrate forming mercurous salt, but that the error introduced was found to be negligible under the conditions of their kinetics.

In the work here described a fine white precipitate was observed to form slowly in mercuric nitrate solutions in 70% dioxane, when the concentration of nitric acid was 0.015 *N*. Good kinetics were observed for the fast reactions, but considerable interference took place in the slower runs. On increasing the concentration of nitric acid to 0.3 *N* no precipitate appeared except after long ageing of the dioxane before use. This concentration was therefore used throughout.

Rate Calculations

A possible reaction scheme would be

$$RBr + Hg^{++} \xrightarrow{k_1} R^+ + HgBr^+ \qquad (A)$$

$$RBr + HgBr^+ \xrightarrow{k_2} R^+ + HgBr_2 \qquad (B)$$

with an equilibrium controlling the concentrations of the two mercuric ions.

$$Hg^{++} + HgBr_2 \rightleftharpoons 2HgBr^+ \qquad (C)$$

$$K = \frac{[HgBr^+]^2}{[Hg^{++}][HgBr_2]} \qquad (1)$$

The following abbreviations are used

$x_0 = 2[Hg^{++}]_0$ = initial concentration of mercuric ion in equivalents

$x = 2[Hg^{++}] + [HgBr^+]$ = concentration of total mercuric ion in equivalents

$y_0 = [RBr]_0$ = initial concentration of alkyl halide.

$y = [RBr]$

Two methods are used for the approximate evaluation of initial rate constants[10]

Method I.—Assuming that $K = 0$, *i. e.*, that an $HgBr^+$ ion when formed immediately disproportionates into $^1/_2Hg^{++} + {}^1/_2HgBr_2$, the second order rate equation becomes

$$k_a = \frac{2}{(x_0 - y_0)\,t} \ln \frac{y_0 x}{x_0 y} \qquad (2)$$

where t is the time in minutes. The factor 2 is required because one mole of mercuric ion reacts with two moles of alkyl halide. The values of k_a will rise or fall during the reaction depending on the actual values of k_2 and K, but will extrapolate at zero reaction to the correct value k_1.

Method II.—Assuming that k_2 is negligible and that an $HgBr^+$ ion when formed does not disproportionate, a value of k may be calculated, taking one mole Hg^{++} and one mole RBr as equivalent quantities. The rate equation then becomes

$$-dx/dt = k_b [Hg^{++}][RBr] \qquad (3)$$

$$k_b = \frac{1}{(^1/_2x_0 - y_0)} \ln \frac{y_0\,(^1/_2x_0 - (y_0 - y))}{^1/_2x_0\,y} \qquad (4)$$

If $HgBr^+$ disproportionates or reacts further, the titration of total mercuric ion will indicate greater reaction than expected, and the values of k_b will rise. In the case where $^1/_2x_0 < y_0$, the values of k_b will approach infinity as $(y_0 - y)$ approaches $^1/_2x_0$. At zero reaction $k_b = k_1$.

For a full analysis of the observed data into k_1, k_2 and K, we have

$$x_0 = 2[Hg^{++}]_0 = 2[Hg^{++}] + 2[HgBr^+] + 2[HgBr_2] \qquad (5)$$

$$x_0 - x = [HgBr^+] + 2[HgBr_2] \qquad (6)$$

Substituting for $[Hg^{++}]$ and $[HgBr_2]$ in the equilibrium equation

$$K = \frac{[HgBr^+]^2}{[Hg^{++}][HgBr_2]} = \frac{4[HgBr^+]^2}{(x - [HgBr^+])(x_0 - x - [HgBr^+])} \qquad (7)$$

Solving for $[HgBr^+]$ we obtain

$$[HgBr^+]/x = \frac{-x_0/x + \sqrt{(x_0/x)^2 + 4(x_0/x - 1)\,(4/K - 1)}}{2(4/K - 1)} \qquad (8)$$

$$\therefore [Hg^{++}]/x = {}^1/_2 - \frac{-x_0/x + \sqrt{(x_0/x)^2 + 4(x_0/x - 1)(4/K - 1)}}{4(4/K - 1)} \qquad (9)$$

$$\text{Now } -dx/dt = k_1[RBr][Hg^{++}] + k_2[RBr][HgBr^+] \qquad (10)$$

$$\therefore -dx/[RBr]x dt = k_1[Hg^{++}]/x + k_2[HgBr^+]/x = N \qquad (11)$$

In the special case when $K = 4$

$$[HgBr^+]/x = 1 - x/x_0,\ [Hg^{++}]/x = {}^1/_2x/x_0 \qquad (12)$$

For any value of K, tables and graphs may be set up giving values of $[Hg^{++}]/x$ and $[HgBr^+]/x$ as a function of x/x_0.

Experimental Results and their Analysis

Initially all rate constants were calculated according to Method I, assuming $K = 0$. The resulting values of k_a invariably showed an appreciable decrease during the reaction, the final value of k_a being approximately 50% lower than the initial one for ethyl, *n*-propyl and cyclohexyl bromides, while that for isopropyl was even lower. The isobutyl case will be dealt with in the next section.

Values of k_b were calculated by method II, and were found to increase rapidly, approaching infinity as $(y_0 - y)$ approaches $^1/_2x_0$. On extrapolation of k_a and k_b to the point of zero reaction, a good estimate of the actual initial rate constant k_1 is obtained. The value, however, is very sensitive to small variations in the initial values of k_a and k_b and it is subject to the inherent uncertainties of non-linear extrapolation. It may therefore be in error by up to 5%. A plot of k_a and k_b against per cent. alkyl halide reacted is shown for *n*-propyl bromide in Fig. 1.

Isobutyl Bromide. Formation of an Olefin–Mercuric Complex.—In runs in the presence of this halide, an orange yellow precipitate appeared very soon after the beginning of the reaction.

The precipitate (I) was isolated on a large scale using 7 g. of isobutyl bromide in 200 cc. of 3*N* nitric acid. Approximately two equivalents of mercuric nitrate were required to react with the alkyl bromide. The precipitate was filtered,

(10) A similar method is described by Skrabal, "Homogenkinetik," Steinkopf, Dresden, 1941, p. 165.

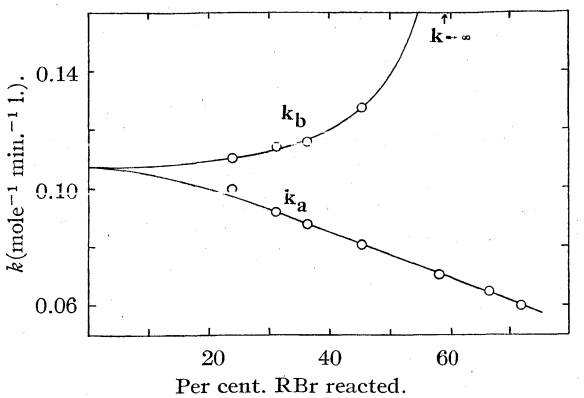

Fig. 1.—Approximate determination of k_1: [n-PrBr] = 0.02185 N, [$Hg(NO_3)_2$] = 0.02575 N, [HNO_3] = 0.281 N, 70% dioxane, 25°.

washed with hot water and dried on a porous plate and in a desiccator. It is insoluble in hot and cold water, alcohol, ether and chloroform. Analysis showed the presence of mercuric ion and the complete absence of mercurous. The compound could not be prepared from isobutanol which is one of the reaction products, nor if mercuric nitrate is replaced by mercuric bromide. Now it is to be expected that an electrophilic attack on isobutyl bromide will produce isobutene as one of its major products. Many reactions of olefins with mercuric salts are reported in the literature,[11] the simplest being an addition compound of one mole olefin to one mole mercuric salt.

A compound of similar properties has been reported by Denigès[12] as being the product of the mercuric nitrate reaction with t-butanol or isobutene. The above procedure was repeated using tertiary butanol instead of isobutyl bromide, and an orange yellow solid (II) was quickly precipitated. Both compounds had the same properties toward solvents, both evolved a gas on treatment with concentrated hydrochloric acid. On heating slowly, their color changed to orange and red, on placing suddenly in an environment at 200° both decomposed, the t-butanol compound with detonation. Contrary to Denigès no mercurous mercury was detected in the t-butanol compound, nor did it decompose in sunlight.

Since Denigès has reported the formation of the precipitate from isobutene, this gas was tested for in the original precipitate I by treating it with concentrated hydrochloric acid and passing the gas evolved into a nitric acid solution of mercuric nitrate. A yellow precipitate III was formed of similar properties to those of I and II. That their physical properties are not identical is probably due to the presence of Hg–Br linkages in I, and to differences in the amount of washing and drying.

The common intermediate from the three starting materials can only be isobutene. Rough titrations on the precipitates suggest the presence of one mercury atom to one isobutene molecule. This suggests the composition of the product from isobutyl bromide to be $C_4H_8 \cdot HgY_2$, and $C_4H_8 \cdot HgBrY$ where Y is NO_3 or OH.

The formation of a compound $C_4H_8 \cdot Hg(NO_3)_2$ under similar conditions to ours is reported by Lucas, Winstein and co-workers.[13,11b] A similar compound with cyclohexene and one of isobutene with silver ion[14] have also been shown to exist.

N-Propyl and Ethyl Bromides. The Cause of the Decrease in Values of k_a—The fall in k_a during the n-propyl bromide reaction may be due to the removal of mercuric ion by olefin to form a soluble complex.

Instantaneous rate constants k'_a were calculated from the formula

$$k'_a = \frac{2}{(x_0 - y_0)(t_2 - t_1)} \ln \frac{y_1 x_2}{x_1 y_2}$$

where (x_1,y_1,t_1), (x_2,y_2,t_2), correspond to alternate reaction samples. Their values for the reaction of n-propyl bromide in the usual conditions are given in Table I, together with the corresponding mean concentration of alkyl halide. Detailed

TABLE I

CALCULATION OF INSTANTANEOUS RATE CONSTANTS k'_a IN THE n-PROPYL BROMIDE–MERCURIC NITRATE REACTION IN 70% DIOXANE AT 25°

[$Hg(NO_3)_2$] = 0.02575 N, [n-PrBr] = 0.02185 N, [HNO_3] = 0.281 N

analysis of the rate constants gives an initial rate k_1 = 0.105 mole^{-1}min.$^{-1}$l. (next section). A second run was carried out, using half the usual concentrations of n-propyl bromide and mercuric nitrate, and adding 0.0125 N mercuric bromide. This duplicates the conditions of the run tabulated in Table I, at the point of half reaction. If the fall in rate constants is due to olefin formation in the first case, then its absence here should yield a rate constant of a value approximately 0.10. If the fall in rate is due to the equilibrium between mercuric ion and mercuric bromide, rate constants in this run should duplicate the previous ones for the same mean alkyl bromide ion concentration.

The values of k'_a for both runs are plotted against mean alkyl halide concentration in Fig. 2. The results leave no doubt that olefin complex for-

mation is not the cause of the fall in rate. It is likely therefore that the decrease in rate constant is due to an equilibrium between mercuric ion, mercuric monobromide ion, and mercuric dibromide.

In a run using mercuric bromide instead of mercuric nitrate, it was shown that catalysis of the reaction by mercuric bromide is negligible under the conditions of the kinetics. Mechanisms A and B alone should therefore account for the rate data.

The value of N was calculated for *n*-propyl bromide according to the left-hand side of equation 11, where $dx/dt = (x_2-x_1)/(t_2-t_1)$, with (x_1,t_1), (x_2,t_2), referring to consecutive points. The values of N were plotted against the mean x/x_0, and a smooth curve drawn through the points to give the corrected values of N. This procedure is necessary because of the small increments (x_2-x_1). The calculated and corrected values of N for *n*-propyl bromide are shown in Table II.

Using the approximate value of the initial rate constant k_1, determined by extrapolation to zero reaction of k_a and k_b, the quantity $k_1[Hg^{++}]/x$ is calculated for differing values of K. The difference $N - k_1[Hg^{++}]/x$ gives a measure of the rate of reaction *B*, *i. e.*, $k_2[HgBr^+]/x$. Hence k_2 may be obtained which must be constant during the reaction. The only constants that fitted the results were $K = 4$, $k_2 = 0$. For $K < 4$, k_2 is negative, for $K > 4$, k_2 increases during the reaction, the increase being more pronounced the greater the value of K.

If this analysis is correct, the ethyl bromide results should yield good rate constants if the same value of K is used. This was found to be the case k_2 again being zero. We may therefore calculate the rate constant k_1 for reaction *A* from the ratio

$$\frac{N}{[Hg^{++}]/x} = \frac{1}{[RBr][Hg^{++}]}\frac{dx}{dt} = k_1$$

Details of the calculation are given for *n*-propyl bromide in Table II. Results for ethyl bromide are shown in Table III.

Isobutyl Bromide.—Due to the formation of an olefin–mercuric salt complex, the rate coefficients k_a fell far more rapidly than in the case of other alkyl halides. An empirical equation of the form

$$k = \frac{2}{(x_0 - 3y_0)t}\ln\frac{y_0}{x_0}\frac{(x_0 - 3(y_0 - y))}{y}$$

gave constant values of k during a major part of the measured reaction. It derives from the expression $-dx/dt = ky(x_0 - 3(y_0 - y))$ and there-

fore coincides with k_1 when (y_0-y) is small. The rate constant obtained in this way had the value $k_1 = 0.0289$ mole^{-1}min.$^{-1}$l. (average deviation of mean ± 0.0002).

Now for ethyl and *n*-propyl bromide the equilibrium constant is given by $K = 4$, and the rate constant k_2 is negligible. The first condition must apply also for isobutyl bromide, since we have only changed the alkyl halide, while the second is highly probable.

Knowing K and an approximate k_1, as well as the experimentally determined dx/dt, we may calculate the value of x that is responsible for this rate of change of concentration. The difference between calculated and observed values of x gives the amount of total mercuric ion complexed for a given amount of alkyl bromide reacted. From this result the proportion of olefin in the product can be determined if we assume that the complex is a mixture of $C_4H_8 \cdot HgY_2$ and $C_4H_8 \cdot HgBrY$ (Y is NO_3 or OH) in the proportion in which Hg^{++} and $HgBr^+$ appear in solution, and that olefin when formed is immediately complexed. A very rough value of 63% olefin formation is obtained for the isobutyl reaction.

Knowing the proportion of olefin formed, we may calculate the amount of total mercuric ion in solution from the experimental titer by subtracting the amount removed by complex formation. This value is used in the rate equation. If the analysis is correct, calculation of the ratio $-dx/[RBr][Hg^{++}]\,dt$ should yield constant values of k_1. The results are given in Table IV. Since the rate fell rapidly values of Δx are small, and liable to appreciable error. The values of N did not warrant the determination of corrected values $N_{cor.}$ Rate constants were therefore calculated directly from N.

TABLE IV

ISOBUTYL BROMIDE–MERCURIC NITRATE REACTION IN 70% DIOXANE AT 25°

$[Hg(NO_3)_2] = 0.02567$ *N*, [iso-BuBr] = 0.02218 *N*, $[HNO_3] = 0.286$ *N*; x_1', x_2' = experimentally determined total concentration of mercuric ion; x = mean concentration of total mercuric ion not complexed with isobutene, assuming 63% olefin formation, and immediate complexing. x'_1, x'_2, x, expressed in cc. 0.02534 *N* $Hg(NO_3)_2$ per 10.00 cc. of sample. $x_0 - x = (1 + 2 \times 0.63)(x_0 - x') = 2.26(x_0 - x')$; $x_0 = 10.13$. $\Delta x/\Delta t$ determined for alternate reaction samples.

t_1, min.	t_2, min.	x_1'	x_2'	x	N	k_1, mole^{-1} min.$^{-1}$ l.
163.3	352.0	9.47	9.07	8.19	0.01295	0.0283

352.0	591	9.07	8.65	7.26	.01275	.0291
471	777	8.84	8.40	6.72	.01165	.0274

A slight fast reaction was observed at the start of the reaction, probably due to a small amount of *t*-butyl bromide impurity. This was corrected for in the rough determination, of k_1, it does not affect the accurate determination, as instantaneous rate constants were calculated in this case.

Isopropyl Bromide.—Steady rate constants ($k_1 = 30.5$ mole^{-1}min.$^{-1}$ l. ($K = 4$)) were obtained in the reaction of this halide at 25°, up to 55% of alkyl halide reacted, followed by a decrease. It suggests slow formation of a soluble olefin–mercury complex due to a few per cent. olefin in the product. Small proportions of olefin (3–7%) are reported as products in the hydrolysis of the halide in formic acid[15] and in dry ethyl alcohol.[16]

An analogous run at 12.5° gave results that fitted the theoretical equations if the equilibrium is given by $K = 8$ and $k_1 = 8.81$ mole^{-1}min.$^{-1}$l. There was no decrease in the constants during the reaction, suggesting that the amount of olefin in the product is sharply reduced as the temperature falls. Hughes and Ingold[16] give evidence that in the S_N1 reactions of tertiary halides an analogous situation is observed. From the rate constants obtained at the two temperatures, an activation energy for the reaction of 16.8 kilocalories per mole is obtained.

Cyclohexyl Bromide.—Numerous reactions of this halide are cited in the literature in which the predominant product is cyclohexene.[17] Lucas, Hepner and Winstein[11b] have shown that unstable complexes are formed between cyclohexene and mercuric ion, followed by the precipitation of a solid which probably has the structure of a true addition compound. In an experiment using 8 g. of mercuric nitrate, 4 g. of cyclohexene, 25 cc. of 6 *N* nitric acid and 25 cc. of dioxane, a pale yellow precipitate was formed after one day. Since the reaction of the halide in our conditions is complete in a few hours, there may be little interference by reaction between cyclohexene and mercuric ion. This was actually found to be the case. Rate constants during the reaction in the usual conditions at 25° were $k_1 = 8.16, 8.13, 8.16, 8.31, 8.72$ mole^{-1}min.$^{-1}$l. The slight rise in rate as the reaction proceeds may be due to a slight incursion of attack by $HgBr^+$. The mean of the first three points gives $k_1 = 8.15$ mole^{-1}min.$^{-1}$l.

Discussion

General.—Sillén and Infeldt[3] have recently measured the equilibrium constant at 25° for the equilibrium $Hg^{++} + HgX_2 \rightleftarrows 2HgX^+$ (X = Br or Cl), in aqueous solution with excess perchlorate ion. The values obtained were $K = 5.8 \pm 0.5$ for X = Br, $K = 1.8 \pm 0.1$ for X = Cl, where K is defined by equation 1, and its analog for the mercuric chloride case. In the measurements here recorded a value of $K = 8$ at 12.5°, and of $K = 4$ at 25°, were obtained.

The rate data given in this paper can be analyzed into good second order rate constants derived according to the system

$$RBr + Hg^{++} \longrightarrow R^+ + HgBr^+$$

if the relative concentrations of the two mercuric ions are controlled by the above equilibrium.

Roberts and Hammett[2] calculated rate con-

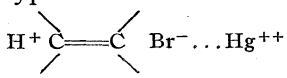
stants k_a for the benzyl chloride reaction assuming $K = 0$ (Method I), and found these values to be constant or drifting upward in 60% dioxane while drifting downward in 75% and 95% dioxane. The fact that these drifts are far smaller than with alkyl bromides is explained by the far lower value of K when X = Cl. The upward drifts can only be explained if attack by $HgCl^+$ and probably by $HgCl_2$ contribute to the total reaction rate. This is possible since even the reaction of benzyl chloride in absence of mercuric nitrate is easily measurable at 50°.[8]

The accelerations caused by nitrate and perchlorate ion in all three media can be explained by their salt effect on the equilibrium. The thermodynamic equilibrium constant K_0 is related to the experimentally determined constant K by the equation $K_0 = Kf_1^2/f_2$, where f_1, f_2 are the activity coefficients of $HgCl^+$ and Hg^{++}, respectively. According to the Debye–Hückel theory for dilute solutions the activity coefficient of an ion is independent of the nature of other ions present, being related only to the ionic strength of the solution according to the equation $-\log f = Az^2\sqrt{\mu}$ where z is the charge of the ion, μ the ionic strength and A a constant for all ions in the same conditions. It follows that $K = K_0 10^{-2A\sqrt{\mu}}$. An increase in ionic strength decreases K and therefore increases the concentration of doubly charged mercuric ion whose reaction is far faster than that of $HgCl^+$. In solvents of low dielectric constant, the Debye–Hückel theory breaks down even at quite low ionic strengths, and the specificity of ions soon becomes apparent. The differing accelerations caused by nitrate and perchlorate ions are probably due to this cause.

By the postulation of the equilibrium C, the effects of added nitrate ion and perchlorate ion become understandable without the assumption that complexes of the type $HgClO_4^+$, $HgNO_3^+$ react at differing rates. It may be that these complexes do exist, but the rate calculations suggest that the only factor influencing the rate of reaction of mercuric mercury is the number of halogens with which it is combined.

The Rate Sequence Ethyl, *n*-Propyl, Isobutyl.—The rate constants for the reaction of these halides were as follows: EtBr 0.210, *n*-PrBr 0.105, iso-BuBr 0.0289 $mole^{-1}min.^{-1}l.$ These rate changes Et > *n*-Pr > iso-Bu are in the same order and of similar magnitude to those found in the reaction with silver nitrate. Heterogeneous catalysis by solid metal halide is therefore eliminated as a cause of the fall in rate along this series. Now the rate series Me < Et > *n*-Pr > iso-Bu can be explained if the determining factor in the stabilization of the transition state is the contribution of hyperconjugation due to the β-hydrogen atoms. Contribution in the transition state of resonance forms of the type



would greatly facilitate ionization on the attack of an electrophilic reagent on halogen. The effect would be far greater in the transition state than in the ground state, and it would be much more marked in a mechanism involving ionization than in one where electron transfer from a nucleophilic reagent compensates the electron demand created by the breaking of the carbon–halogen bond (S_N2).[18] Hyperconjugation effects increase with an increase in the number of available β-hydrogen atoms and therefore explain the rate sequence.

Hughes[19] objects to this explanation on the ground that in the tertiary halides, the rate of ionization increases along the series *t*-butyl, *t*-amyl, α,α-diethyl neopentyl, in spite of the progressive decrease in the number of β-hydrogen atoms. Crowding of methyl groups and hydrogen atoms however increases along this series and the decrease in these compression energies on attaining to the planar carbonium ion configuration may greatly influence the rate sequence.[20] Further progress in attributing rate changes unambiguously to specific electronic or steric influences can only be made when accurate energies and entropies of activation become available.

Cyclohexyl and Isopropyl Bromides.—The results (k_1(Cyclohexyl bromide) = 8.15, k_1(Iso-PrBr) = 30.5 $mole^{-1}min.^{-1}l.$) show that these halides have rates of the same order of magnitude in their reaction with mercuric nitrate. Evidence indicates that the rates of cyclohexyl chloride and bromide are far lower than those of the corresponding isopropyl halide toward iodide ion,[6b] pyridine and piperidine[6a] while the rates are normal toward sodium methoxide.[6a] An inspection of Fisher–Hirschfelder atomic models shows that there is considerable steric hindrance toward the approach of a nucleophilic reagent at the α-carbon atom if the bromine atom is in the radial position. A reagent whose reactivity toward carbon is much greater than that toward hydrogen (*e. g.*, iodide ion) should therefore react at a very slow rate. Methoxide ion however has a strong affinity for hydrogen and can attack the β-hydrogen atom by the bimolecular elimination mechanism E2.[16] In agreement with this, the preponderant product is cyclohexene.[17] There should be no steric hindrance in the reaction of cyclohexyl bromide with mercuric ion, and its rate as well as that of attack by methoxide ion is found to be of similar magnitude to that of isopropyl bromide.

Acknowledgments.—The author wishes to thank the University of London for the award of a postgraduate travelling studentship, and the authorities of Columbia University for extending their hospitality to him. He wishes to record his heartfelt thanks to Professor L. P.

Hammett for suggesting this work and for his continual interest, help and encouragement.

Summary

The reaction of mercuric nitrate with the primary alkyl bromides, ethyl, *n*-propyl, isobutyl and the secondary bromides isopropyl and cyclohexyl has been studied in aqueous dioxane. The reaction is shown to occur by the rate determining attack of doubly charged mercuric ion on halogen, with an equilibrium determining the relative concentrations of mercuric ion, mercuric monobromide ion and mercuric dibromide. Of the three mercuric species involved in the equilibrium only the first is shown to contribute perceptibly to the rate.

A precipitate of the probable composition $C_4H_8 \cdot HgY_2$ and $C_4H_8 \cdot HgBrY$ (Y = NO_3 or OH) forms during the reaction of isobutyl bromide. On making allowance for this secondary reaction the halide fits into the general reaction scheme.

The experimentally determined rate sequence ethyl > *n*-propyl > isobutyl is explained by a hyperconjugation effect. The approximate equality of rates between isopropyl and cyclohexyl bromides is expected because of the absence of steric hindrance in this reaction.

The work of Roberts and Hammett[2] on the analogous benzyl chloride reaction falls in line with the reaction scheme here outlined.

Methyl Silicate from Silicon and Methanol

BY EUGENE G. ROCHOW[1a]

Knowing that hydrocarbon halides will react with elementary silicon in the presence of certain catalysts to yield the corresponding alkyl or aryl halosilanes,[1,2,3,4] it is of interest to inquire whether alcohols will react in similar fashion to form organosilanols or organosiloxanes

$$2ROH + Si \xrightarrow{\text{catalyst}} R_2Si(OH)_2 \xrightarrow{-H_2O} [R_2SiO]_x$$

It was found that of the several lower alcohols tried, only methanol reacted readily to form recognizable products. While the methanol responded to the action of the same copper catalyst used for the reaction of methyl chloride and silicon,[1] it followed an entirely different course of reaction and produced methyl silicate.

$$4CH_3OH + Si \xrightarrow[250^\circ]{Cu} Si(OCH_3)_4 + 4H$$

Some of the hydrogen resulting from the reaction appears in the effluent as molecular hydrogen, while the rest combines with the reactants to form silane linkages and reduction products of methanol:

$$H + Si \longrightarrow -\overset{|}{\underset{|}{Si}}-H$$

$$CH_3OH + 2H \longrightarrow CH_4 + H_2O$$

The reaction further is complicated by the action of the water on some of the methyl silicate to form condensed methoxysilanes, $2Si(OCH_3)_4 + H_2O \rightarrow (CH_3O)_3SiOSi(OCH_3)_3 + 2CH_3OH$, etc. A small fraction of the methyl groups later were shown to be bonded directly to silicon $\left(CH_3-\overset{|}{\underset{|}{Si}}-\right)$ in the manner of the first equation given; no individual methylmethoxysilanes were isolated, however, and the effect was noticed only upon extensive analysis of the intermediate distillation fractions and the solid polymers produced.

Anhydrous *ethanol* was found to react sluggishly with silicon at 280 to 325° in the presence of copper as a catalyst to convert about 10% of the alcohol to condensed ethyl silicates. A search for a more effective catalyst was fruitless. A small amount of material containing C_2H_5–Si bonds was found after one run, but it does not seem likely at this time that ethyl silicate or ethylethoxysilanes can conveniently be prepared from ethanol and silicon in this way.

Experimental

A glass tube 2 cm. in diameter and 50 cm. long was packed with pellets of 90% silicon[5] and 10% copper prepared by pressing the mixed powders in a die and heating the pellets in hydrogen at 1050° for two hours. The tube was sealed to a water condenser leading to a receiver, and the uncondensed products were led through traps held at −80 and −196°. A dropping funnel was connected to the other end of the tube. The tube was heated to 280°[6] and 57.2 g. of anhydrous methanol was allowed to drip in slowly from the funnel. An exothermic reaction set in at once, and the furnace current had to be reduced. A combustible gas (hydrogen) issued from the −196° trap. Thirty-eight grams of liquid was recovered from the receiver, 8.4 g. from the −80° trap, and 2.0 g. from the −196° trap. The liquid in the receiver was found upon distillation to consist of methyl silicate (b. p. 120–122°, m. p. 2°), a little unchanged methanol, some water, and small amounts of materials boiling above and below methyl silicate. The −80° condensate melted at

[a] In the samples so designated, methoxy groups were hydrolyzed off so that CH_3–Si and H–Si groups could be determined more accurately.

about 0° and appeared to consist of the same substances, carried over by uncondensed gas. The −196° condensate had melting and boiling points corresponding to those of methane; when a portion was vaporized through a jet it burned with a hydrocarbon flame, and when the rest was passed through a bunsen burner it burned with a blue flame and formed no white smoke. Examination of the powder left in the tube showed some particles of silicon dioxide, some copper (I) oxide, and some gummy material that appeared to be a condensed silicon ester resin.

Two similar experiments were carried out at 250 and 300° to determine the yield of methyl silicate. Eighty grams of methanol was allowed to drip into a tube of fresh copper–silicon pellets over a period of five hours, and the liquid in the receiver (59 g.) was distilled through a column of about five theoretical plates. Neglecting the amount that may have been in the intermediate fractions, 32.2 g. of methyl silicate (2° boiling range) was obtained. This represents 40.2% of the weight of methanol used, 43.6% of the total products recovered, 51.0% of the distillate, and 48.0% of the theoretical yield if all the methanol were converted to methyl silicate. With the silicon at 250°, a similar charge of methanol gave methyl silicate equivalent to 44.4% of the weight of methanol, 47.8% of the total products recovered, 53.4% of the distillate, and 53% of the theoretical conversion. A slight advantage is shown in operating at 250°.

The reaction was carried out on a larger scale in a steel tube 2.5 cm. in diameter and 240 cm. long, heated to 220° by circulating tricresyl phosphate.[7] The tube was charged with 1315 g. of powder consisting of 90% silicon and 10% copper, previously fired in hydrogen at 1000° for one hour. Several gallons of methanol were pumped into the tube over a period of ten days by injecting approximately 40 g. per hour with a proportioning pump. The 477 g. of condensate from the first 745 g. of methanol yielded 357 g. of methyl silicate, which represents about 75% of the weight of condensate and about 49% of the weight of methanol. The yield of methyl silicate decreased over the period of operation of the tube and fell to zero after about 5700 g. of methanol was injected. The total methyl silicate obtained from the run (1358 g.) represented about 250 g. of silicon. Besides silicon dioxide, copper (I) oxide, and unused silicon and copper, the used powder contained solid materials which were shown by analysis to have Si–H and Si–C bonds. No carbon was deposited.

Analysis.—Many unknown products were obtained during the distillation of the reaction mixtures, most of which could be investigated only by combustion analysis. An arrangement of a weighable silica combustion tube and absorbers was set up, similar to that previously employed for the analysis of silicone resins,[1] except that ground-in glass stoppers were fitted to the combustion tube during weighing. Liquid samples were weighed in a glass bubbler equipped with ground plugs, and were vaporized by the stream of oxygen passing into the combustion tube. Solid samples were weighed in small porcelain boats which were inserted directly into the combustion tube and in which the sample was oxidized at a minimum temperature determined by experiment. The apparatus otherwise was operated as previously described.[1]

The apparatus was tested by analyzing pure ethyl silicate: calcd.: C, 46.1; H, 9.66; Si, 13.5. Found: C, 45.1; H, 9.55; Si, 13.9. The results obtained on a few of the fractions are summarized in Table I. It is seen that some of the samples contained Si-H and Si-CH_3 groups, but that they are mixtures of liquids and complex polymeric solids rather than pure compounds. The presence of Si-H bonds could readily be demonstrated in most of the fractions boiling above and below methyl silicate by the vigorous evolution of hydrogen obtained by treating the sample with 10% aqueous sodium hydroxide. Some of these samples also developed a pressure of hydrogen upon long standing in tightly-capped soft glass bottles.

Warning.—Methyl silicate is believed to be an exceedingly dangerous substance, since small quantities of the liquid or its vapor coming in contact with the eye will cause perforating ulceration of the cornea and possible blindness.[8] The investigation reported herein was conducted before this information was available, but fortunately no ill effects were experienced. Either there must be great variation in personal susceptibility, or there is some deleterious ingredient in the methyl silicate prepared by previous methods. A study of this point would be very welcome. In the meantime, it would be well for investigators to exercise extreme care in handling methyl silicate.

Summary

Methanol vapor is shown to react with elementary silicon at elevated temperatures and in the presence of copper as a catalyst to produce methyl silicate and hydrogen. The various by-products which are observed are believed to be produced by the action of the hydrogen upon the reactants.

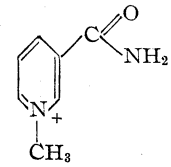
The Location of the Reactive Carbon in N^1-Methylnicotinamide

BY W. EUGENE KNOX AND WILLIAM I. GROSSMAN

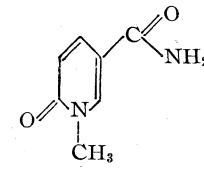
One uncertainty remaining in the structures of Coenzyme I and II as worked out by Warburg,[1] Karrer[2] and Schlenk,[3] involves the site of the reversible oxidation–reduction of the nicotinamide moiety. This uncertainty was recognized by Karrer in his first experiments using N^1-methylnicotinamide iodide as a model compound. Reduction occurs α to the ring nitrogen, but until now means have not been available to locate the reactive carbon in one of the two α-positions. From consideration of the properties of the quinine-oxidizing enzyme detailed below, the oxidation of N^1-methylnicotinamide by this enzyme to the corresponding 6-pyridone[4] enables us to locate the center of reactivity and therefore the site of oxidation–reduction in the 6-position of this quaternary nicotinamide ring. However, there is no direct evidence yet available about the arrangement obtaining in the pyridinonucleotide coenzymes themselves.

Oxidation by the quinine-oxidizing enzyme of rabbit liver is restricted to the unsaturated α-position of many pyridine, quinoline and pyrazine compounds.[5] This is referrable to the fact that only the pseudo-base forms are oxidized, as is evident from the parallelism between the rate of oxidation of various compounds and the ease of their pseudo-base formation.[6] In addition, the enzyme has been found to oxidize 1,2,2,5,5-pentamethyl - 6 - hydroxy - tetrahydropyrazine, which is itself a stable pseudo-base prepared by Dr. John G. Aston.[7] Consequently, if a compound is oxidized by the enzyme, it will be oxidized in the reactive α-position which is the site of unsaturation and of pseudo-base formation. Identification of an enzymic oxidation product will therefore locate the reactive carbon. In compounds such as pyridine, where both positions are similar, neither is "reactive" and no oxidation occurs.

The enzymic oxidation product of quinoline has previously been identified as carbostyril. We have also obtained 34 mg. of isocarbostyril, identified by mixed melting point, from enzymic oxidation of 40 mg. of isoquinoline. The reactivity in these compounds of carbon atoms 2 and 1, respectively, as shown by the enzyme reaction, thus agrees with the sites identified by other means.[8,9] Similarly, the product of the enzymic oxidation of N^1-methylnicotinamide chloride (I) has been identified as 1-methyl-3-carboxylamide-6-pyridone (II). Assay of the product in the enzyme mixture by its ultraviolet absorption at 259 and 290 mμ has shown it to be the sole product of the enzymic oxidation of N^1-methylnicotinamide chloride.[10]



I



II

This oxidation thus identifies the 6-carbon of N^1-methylnicotinamide as the reactive carbon. Because of the limits of enzyme specificity, the rate of oxidation of pure Coenzyme I by the enzyme is so slow as to preclude isolation of palpable amounts of the product for identification of the reactive carbon in this compound. However, N^1-methylnicotinamide also forms a reversibly oxidizable *o*-dihydro compound analogous in every way to the reduced coenzymes. The recent crystallization of this derivative is evidence that only one of the possible *o*-dihydro compounds is formed,[11] and it follows that this is the 1,6-dihydro derivative.

Summary

Oxidation of N^1-methylnicotinamide chloride to the corresponding 6-pyridone by the quinine-oxidizing enzyme shows that the 6-carbon is the reactive position of the quaternary nicotinamide ring.

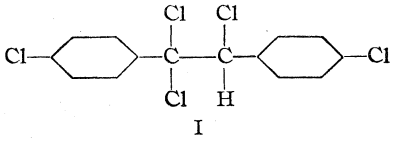
The Preparation of α,α,α'-4,4'-Pentachlorobibenzyl, an Isomer of DDT

BY ELMER E. FLECK

Various attempts have been made to correlate the insecticidal action of DDT and related compounds with the presence of the *p*-chlorophenyl groups[1] or the trichloromethyl group[2] and with the ease with which hydrogen chloride is eliminated from the molecule.[3] Martin[4] has stated that, while high toxicity was not found in all the DDT analogs that are readily dehydrohalogenated, all the analogs that showed high toxicity dehydrohalogenated readily in dilute alcoholic alkali.

It was thought to be of interest to prepare an isomer of DDT which retained the *p*-chlorophenyl groups and was readily dehydrochlorinated, but in which both carbon atoms of the ethyl group were substituted with a *p*-chlorophenyl group. Such a compound has been prepared by the chlorination of *cis*-α,4,4'-trichlorostilbene to form *dl*-α,α,α',4,4'-pentachlorobibenzyl (I). This compound melted at 97–98°. When refluxed for fifteen minutes with 0.1 *N* alcoholic alkali, it readily lost hydrogen chloride to form *cis*-α,α',4,4'-tetrachlorostilbene (II). Anhydrous ferric chloride also dehydrochlorinated I, in the molten condition, to form II, just as DDT is dehydrochlorinated.[5]



I

The identity of II was established by chlorinating it to form the known compound $\alpha,\alpha,\alpha',\alpha'$,4,4'-hexachlorobibenzyl.

Insecticidal tests[6] show that I is ineffective, against house flies, pea aphids, celery leaf tiers, red spider mites, and European corn borers. These results provide evidence that insecticidal action is due to the molecule as a whole rather than to the presence of toxic groups or specific reactions.

Experimental

Preparation of *dl*-α,α,α',4,4'-Pentachlorobibenzyl.—Chlorine was passed through a solution of 7 g. of *cis*-α,4,4'-trichlorostilbene[7] in 75 ml. of carbon tetrachloride for two hours at room temperature. The solution was then concentrated on a steam-bath to a volume of about 15 ml. The prisms that separated, when this solution was cooled in ice, were collected and dried at room temperature in a vacuum; yield, 6.1 g. After recrystallization from alcohol the product melted at 97–98°. No yellow color was given with tetranitromethane.

Anal. Calcd. for $C_{14}H_9Cl_5$: C, 47.43; H, 2.56; Cl, 50.01. Found: C, 47.63; H, 2.92[8]; Cl, 50.32.

***cis*-α,α',4,4'-Tetrachlorostilbene.**—A solution of 0.5 g. of *dl*-α,α,α',4,4'-pentachlorobibenzyl in 50 ml. of 0.1 *N* alcoholic sodium hydroxide was refluxed for two hours. Water was then added to the hot solution until crystallization occurred. The cooled solution yielded 0.45 g. of material that melted at 83–85°. Repeated recrystallization from acetone yielded needles which melted at 166–167°.[9] With tetranitromethane a yellow color was obtained.

When this experiment was repeated quantitatively with a 100-mg. sample and a fifteen-minute reflux period, [illegible] formed indicated that 0.92 α,α,α',

The same [illegible] removal of hydrogen [illegible] α,α,α',4,4'-pentachlorobibenzyl [illegible] ferric chloride was heated in a current of air in a U-tube at 90–95° for half an hour.[5] Gas evolution was complete at the end of five minutes. Recrystallization of the product yielded needles that melted at 166–167°. Mixed melting points showed this product to be identical with that obtained by alkaline hydrolysis.

A quantitative determination showed that 0.98 mole of hydrogen chloride was eliminated by the catalyst.

$\alpha,\alpha,\alpha',\alpha',$4,4'-Hexachlorobibenzyl.—Chlorine was passed through a solution of 0.1 g. of *cis*-α,α',4,4'-tetrachlorostilbene (obtained by hydrolysis) in 5 ml. of carbon tetrachloride for two hours at room temperature. The solution was evaporated to dryness on a steam-bath, and the residue was recrystallized from chloroform. The product melted at 191–192°, and no depression of the melting point was found when this material was mixed with authentic $\alpha,\alpha,\alpha',\alpha',$4,4'-hexachlorobibenzyl.[9]

Summary

A DDT isomer, *dl*-α,α,α',4,4'-pentachlorobibenzyl, has been prepared which has two *p*-chlorophenyl groups, a hydrolyzable chlorine atom, and sensitivity to the catalytic action of anhydrous ferric chloride similar to DDT, but which has little insecticidal action.

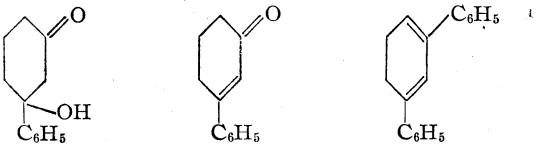
The Reaction of β-Cyclohexanedione (Dihydroresorcinol) and its Ethyl Enol Ether with Phenylmagnesium Bromide

BY G. FORREST WOODS AND IRWIN W. TUCKER

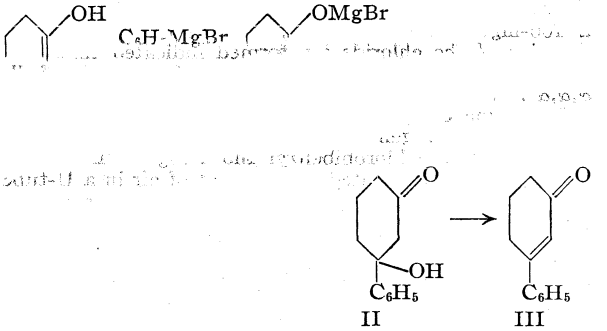
The reaction of dimedone with phenylmagnesium bromide has been previously investigated.[1] We have now studied the corresponding reaction of dihydroresorcinol (I) whose structure is very similar to that of dimedone.

Three products (II, III, and IV) and a tar were isolated after decomposing the Grignard complex.



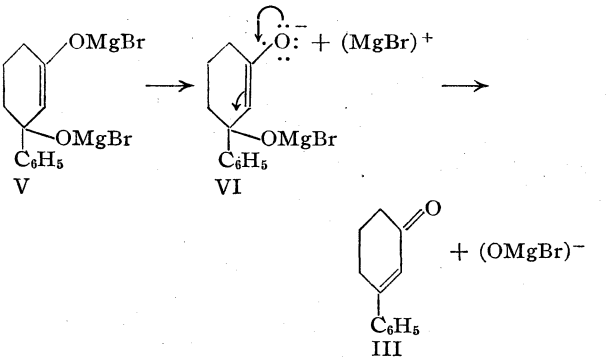
II III IV

The first two substances, II and III, are readily accounted for by the mechanism proposed by Kohler and Erickson[2] for the reaction of strongly enolic β-diketones with Grignard reagents as shown below applied to dihydroresorcinol



II III

The formation of 1,3-diphenylcyclohexadiene-1,3 (IV), however, is difficult to explain. Although this substance would obviously be the product of a double addition of phenylmagnesium bromide to dihydroresorcinol in the β-diketonic form, this concept is hardly acceptable since dihydroresorcinol is known to be strongly enolic.[3] A more reasonable mechanism is shown



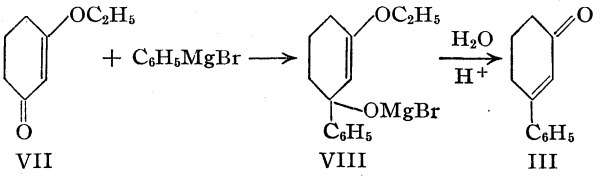
V VI III

If it is assumed that some degree of ionization exists in the magnesium enolate bond of structure (V) leading to structure (VI), then (VI) stabilizes itself by the ejection of the $(O\text{-}Mg\text{-}Br)^-$ ion, which had been activated by both the phenyl group and the ethylenic link, along with a concurrent electron shift. Thus, 3-phenyl-Δ^2-cyclohexenone (III) is generated and then reacts with phenylmagnesium bromide, the addition product subsequently losing water to give IV. In this connection it is interesting to note that the hydrocarbon (IV) was obtained in higher yield almost to the exclusion of the other products by continued refluxing of the Grignard solution after displacement of the ether with benzene. The tar formed in the reaction of dihydroresorcinol with phenylmagnesium bromide is assumed to be a polymer of 1,3-diphenylcyclohexadiene-1,3, a substance which contains both butadiene and styrene-like structures.

[illegible][1] to prove the structure of 3-phenyl-[illegible]enone and 1,3-diphenylcyclohexadi-[illegible]-1,3 by an independent mode of synthesis, and to obtain a good preparative method for these substances. The preparation of the ethyl enol ether of dihydroresorcinol and the subsequent reaction of this substance with phenylmagnesium bromide accomplished the above two points.

The white crystalline silver salt of dihydroresorcinol was obtained by mixing dihydroresorcinol and silver nitrate in water and adjusting the *p*H of the solution. The silver salt thus prepared readily reacts with ethyl iodide in refluxing benzene to yield the ethyl enol ether of dihydroresorcinol.[4] We found this method of preparation superior to the reaction of dihydroresorcinol with sodium ethylate and ethyl iodide, with diethyl sulfate and aqueous sodium hydroxide, or with absolute ethyl alcohol and sulfuric acid. This last method was the mode of preparation of the ethyl enol ether of dimedone.[5]

Dihydroresorcinol ethyl enol ether (VII) reacts with phenylmagnesium bromide to yield 3-phenyl-Δ^2-cyclohexenone (III) as shown



VII VIII III

The intermediate product (the keto alcohol from VIII) was not isolated and it was found, as had been anticipated from previous work, that the

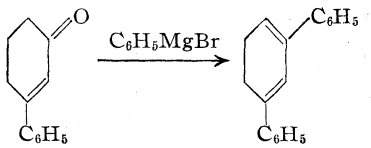
enol ether linkage of VIII was readily cleaved and the molecule dehydrated on treatment with dilute sulfuric acid under the conditions of steam distillation. The product, obtained in 80–85% yield, was identical with the 3-phenyl-Δ^2-cyclohexenone obtained by the reaction of dihydroresorcinol with phenylmagnesium bromide.

3-Phenyl-Δ^2-cyclohexenone (III) had previously been synthesized by Abdullaho[6] by the condensation of phenyl vinyl ketone with acetoacetic ester and the subsequent hydrolysis and decarboxylation of the condensation product. The constants of our product and its derivatives are in good agreement with his. Further, 3-phenyl-Δ^2-cyclohexenone is readily converted to *m*-phenylphenol by dehydrogenation over palladium–charcoal[7] or hydrogenated with palladium-charcoal to 3-phenylcyclohexanone.

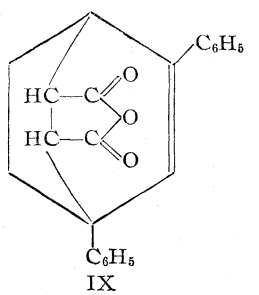
The fact that substance II, 3-phenylcyclohexane-3-ol-1-one, was readily dehydrated by refluxing in benzene in the presence of a trace of iodine to yield 3-phenyl-Δ^2-cyclohexenone establishes the structure of the former.

The structure of substance IV, 1,3-diphenylcyclohexadiene, was established by its synthesis from 3-phenyl-Δ^2-cyclohexenone (III) and phenylmagnesium bromide in good yield and superior quality



III IV

This substance was identical with the corresponding product obtained from the reaction of dihydroresorcinol with phenylmagnesium bromide. That this structure was correct was also shown by the conversion of 1,3-diphenylcyclohexadiene by dehydrogenation over palladium–charcoal to the known *m*-diphenylbenzene[8] and by the isolation of an adduct, for which the structure IX is written, from the Diels–Alder reaction of 1,3-diphenylcyclohexadiene-1,3 with maleic anhydride.



IX

Experimental

Reaction of Phenylmagnesium Bromide with Dihydroresorcinol.—An ethereal solution (1400 ml.) of phenylmagnesium bromide from 1.0 mole of bromobenzene and magnesium turnings was prepared in the pot of a Soxhlet extractor. Finely ground dihydroresorcinol[9] (28 g., 0.25 mole) was introduced into the extraction thimble and the extraction process continued until only a small residue (3 g.) remained unextracted. The Grignard complex solution, which set to a solid on cooling in an ice-bath, was hydrolyzed with dilute aqueous ammonium chloride. The ether solution, dried over anhydrous magnesium sulfate, concentrated to 300–500 ml. and chilled, gave 8 g. of solid which was recrystallized from acetone–petroleum ether (80–100°). This product was 3-phenylcyclohexan-3-ol-one (II) and melted at 155–155.5°. *Anal.* Calcd. for $C_{12}H_{14}O_2$: C, 75.77; H, 7.42. Found: C, 75.94, 75.89; H, 7.70, 7.58.

The ethereal filtrate, after the removal of the above product, was then distilled under reduced pressure. Two substances (III and IV) were obtained after the removal of bromobenzene and biphenyl. Impure 3-phenyl-Δ^2-cyclohexenone (III) was collected which distilled over the range of 106–185° (10 mm.). The main portion of this material distilled from 165–185° (10 mm.). The yield was 15–20 g. This material, which solidified on cooling, yielded coarse white crystals upon recrystallization from petroleum ether (30–60°) which melted at 64.5–66.0°. *Anal.* Calcd. for $C_{12}H_{12}O$: C, 83.68; H, 7.03. Found: C, 83.55, 83.64; H, 7.22, 7.17.

The second product, 1,3-diphenyl-cyclohexadiene-1,3 (IV), distilled over the range of 130–190° (0.2 mm.). The main fraction (5 g.) distilled at 176° (0.2 mm.). This substance was decolorized with norite and crystallized from petroleum ether (30–60°). Upon further recrystallization white crystalline platelets were obtained which melted at 98–99°.[10] *Anal.* Calcd. for $C_{18}H_{16}$: C, 93.10; H, 6.94. Found: C, 93.14, 92.97; H, 6.62, 6.65.

In subsequent reactions 3-phenylcyclohexan-3-ol-1-one (II) was not isolated since it was readily converted in the following operations to 3-phenyl-Δ^2-cyclohexenone (III), a desired product. The original ethereal solution from the Grignard complex was made acid with dilute sulfuric acid and subjected to steam distillation. In this manner the troublesome impurities of bromobenzene and biphenyl were readily eliminated, since 3-phenyl-Δ^2-cyclohexenone and 1,3-diphenylcyclohexadiene-1,3 are only slightly volatile with steam.

Conversion of 3-Phenylcyclohexan-3-ol-1-one to 3-Phenyl-Δ^2-cyclohexanone.—3-Phenylcyclohexan-3-ol-1-one (II) (0.6 g.) was refluxed in toluene (25 ml.) after the addition of a small crystal of iodine. The toluene was removed by distillation under reduced pressure and the residue dissolved in ether and decolorized with norite. The product was recrystallized from petroleum ether which was added after removal of most of the ether. This material melted at 64.5–66.0° and gave no depression in a mixed melting point determination with a sample of 3-phenyl-Δ^2-cyclohexenone obtained previously as above.

Preparation of Dihydroresorcinol Ethyl Ether[11] (VII).—Dihydroresorcinol[9] (50 g.) and silver nitrate (76 g.) were dissolved in 400 ml. of water. To this solution was added dropwise with stirring 1.0 *M* sodium hydroxide until the *p*H of the solution was 5.5–6.0. During this process silver oxide precipitated locally but gradually redissolved while silver dihydroresorcinate precipitated in a white crystalline form. Excessive amounts of sodium hydroxide caused a noticeable darkening of the precipitate and a subsequent lowering in yield of the ultimate product.

(8) France, Heilbron and Hey, *J. Chem. Soc.*, 1288 (1939).

(9) "Organic Syntheses," Vol. 27, John Wiley and Sons, New York, N. Y., p. 21.

(10) This product becomes contaminated readily with either the substances of polymerization or with some *m*-terphenyl (from the oxidation of the diphenylcyclohexadiene). Thus this melting point is obtained only with difficulty.

(11) The development of this method of preparation of the ethyl enol ether of dihydroresorcinol was done by Mr. Bernard Armbrecht. The details given by Merling (*Ann.*, **278**, 28 (1894)) are so brief as to amount only to an indication of procedure.

The silver salt of dihydroresorcinol was isolated by suction filtration and pressed reasonably free of water. The moist precipitate (80–85 g.) was placed in a three-neck flask to which was fitted a mechanical stirrer, a separatory funnel, and a moisture receiving tube itself connected to a reflux condenser. Benzene (300 ml.) was introduced into the three-neck flask and the mixture refluxed with stirring until all the water was removed. To the benzene solution was then added 0.5 mole of ethyl iodide and the refluxing and stirring continued for fifteen minutes. The solution, after removal of the silver iodide by suction filtration, was subjected to distillation under reduced pressure. Ethyl enol ether of dihydroresorcinol (36 g. 51%) distilled at 95–105° (1 mm.). In this preparation it was found that the yield of the ethyl enol ether was not favored by any excess of ethyl iodide while the yield was adversely affected by longer refluxing periods of ethyl iodide with the silver salt of dihydroresorcinol in benzene.

Preparation of 3-Phenyl-Δ^2-cyclohexenone (III) from Dihydroresorcinol Ethyl Ether.—Dihydroresorcinol ethyl ether (70.0 g.) dissolved in 300 ml. of ether was added slowly with stirring to a solution (600 ml.) of phenylmagnesium bromide prepared from bromobenzene and magnesium (0.75 mole). The Grignard complex was decomposed with dilute sulfuric acid. This mixture was subjected to steam distillation until all the bromobenzene and most of the biphenyl had been removed. The residue in the steam pot was extracted with ether. The ether solution was washed with dilute sodium bicarbonate and water, decolorized with norite, and dried over magnesium sulfate. After removal of most of the ether by heating on a steam-bath, the residue was dissolved in petroleum ether (30–60°). This solution deposited white to pale yellow-colored crystals (71 g., 87%) which upon recrystallization melted at 64.5–66° and which gave no depression in a mixed melting point determination with the previously obtained samples of this compound.

The remainder of this product was prepared in the usual manner and recrystallized from alcohol–water. The melting point of the product so obtained was 102–111° and only upon repeated recrystallizations from both alcohol–water and ether–petroleum ether was a product melting at 113.5–118° obtained. Abdullaho[6] reported a melting point of 117–118° for this substance. *Anal.* Calcd. for $C_{12}H_{13}ON$: C, 76.98; H, 7.00. Found: C, 76.95, 77.25; H, 6.59, 6.58.

The red 2,4-dinitrophenylhydrazone of 3-phenyl-Δ^2-cyclohexenone prepared in the usual manner melted at 228–230°. *Anal.* Calcd. for $C_{18}H_{16}O_4N_4$: C, 61.36; H, 4.58. Found: C, 61.21, 61.60; H, 4.17, 4.22.

The semicarbazone of 3-phenyl-Δ^2-cyclohexenone which was prepared in the usual manner and recrystallized from alcohol melted at 227–229° with decomposition. *Anal.* Calcd. for $C_{13}H_{15}ON_3$: C, 68.10; H, 6.59. Found: C, 67.89; H, 6.23.

The *p*-nitrophenylhydrazone of 3-phenyl-Δ^2-cyclohexenone prepared in the usual manner melted at 182.5–185°. *Anal.* Calcd. for $C_{18}H_{17}N_3O_2$: C, 70.35; H, 5.71. Found: C, 70.16, H, 5.67. Abdullaho[6] reported a melting point of 184–185° for this substance.

Reduction of 3-phenyl-Δ^2-cyclohexenone (3.0 g.) was accomplished in ethyl alcohol at atmospheric pressure and room temperature with palladium–charcoal. The hydrogenation was arrested after a 5% excess of hydrogen calculated for saturation of one ethylenic link had been adsorbed. After removal of the catalyst one half of the solution was used for the preparation in the usual manner of the semicarbazone of 3-phenylcyclohexanone which melted at 163.5–164.5° after recrystallization from alcohol–water.[12] *Anal.* Calcd. for $C_{13}H_{17}ON_3$: C, 67.51; H, 7.41. Found: C, 67.35; H, 7.03. The remaining half of the above solution was used to prepare the 2,4-dinitrophenylhydrazone of 3-phenylcyclohexanone, which was yellow and which melted at 183–186°. *Anal.* Calcd. for $C_{18}H_{18}O_4H_4$: C, 61.01; H, 5.12. Found: C, 61.14, 61.20; H, 5.18, 5.51.

(12) A melting point of 167° has been reported for this substance (Boyd, Clifford and Probert, *J. Chem. Soc.*, **117**, 1383 (1920)).

Preparation of 3-Phenylphenol from 3-Phenol-Δ^2-cyclohexenone.—The procedure for dehydrogenation and isolation of the phenol is essentially that of Horning.[7] 3-Phenyl-Δ^2-cyclohexenone (2.0 g.), palladium–charcoal catalyst[13] (0.7 g. 5% Pd), and 15 ml. of cymene were heated under reflux for approximately ninety minutes. This solution upon cooling was filtered and the filtrate extracted three times with Claisen solution (30 ml.). The Claisen solution was extracted once with benzene and then with petroleum ether (30–60°). The alkaline solution was then diluted with an equal volume of water and acidified with concentrated hydrochloric acid. The solid phenol was extracted with ether and the extract dried over magnesium sulfate. Upon evaporation of most of the ether and addition of petroleum–ether (30–60°), 1.25 g. of 3-phenylphenol crystallized on standing. This product after recrystallization from water was a white solid melting at 73.5–74.5°.[14] *Anal.* Calcd. for $C_{12}H_{10}O$: C, 84.68; H, 5.92. Found: C, 84.95, 84.71; H, 6.00, 6.00.

The phenylurethan of 3-phenylphenol was prepared in the usual manner and recrystallized from petroleum ether (90–100°) to which benzene was added to effect solution. The white crystalline product melted at 135–135.5°. *Anal.* Calcd. for $C_{19}H_{15}O_2N$: C, 78.87; H, 5.23. Found: C, 79.19; H, 5.54.

Preparation of 1,3-Diphenylcyclohexadiene-1,3 (IV).—To a solution of phenylmagnesium bromide prepared from 18.3 g. of bromobenzene and 2.8 g. of magnesium in 100 ml. of ether was added 10 g. of 3-phenyl-Δ^2-cyclohexenone dissolved in 100 ml. of ether. After addition of the ketone the reaction mixture was refluxed for thirty minutes, cooled in an ice-bath, and decomposed with cold 6% sulfuric acid. The ether extract was washed with aqueous sodium carbonate and with water and finally dried over anhydrous magnesium sulfate. On evaporation of the ether, 14 g. of solid residue was obtained which corresponds to a theoretical yield of 1,3-diphenylcyclohexadiene-1,3. This material, recrystallized from 95% ethanol, gave 9 g. of product (67%) melting at 96–98°. Recrystallization of this material from ethanol and decolorization with charcoal yielded colorless plates melting at 98–99°. *Anal.* Calcd. for $C_{18}H_{16}$: C, 93.10; H, 6.94. Found: C, 93.14, 92.97; H, 6.65, 6.62.

Maleic Anhydride Adduct of 1,3-Diphenylcyclohexadiene-1,3 (IX).—Maleic anhydride (1.1 g.) and 1,3-diphenylcyclohexadiene-1,3 (2.5 g.) were heated for four hours at 130–150°. The product on cooling was pulverized and warmed with 300 ml. of 10% sodium hydroxide solution. The small residue which remained undissolved was removed by filtration. The alkaline filtrate was acidified to congo red with hydrochloric acid. The precipitate was removed after cooling by filtration and redissolved in acetone and decolorized with Norite. The product (2.0 g.) crystallized upon cooling after the addition of water to the acetone solution, m. p. 149–151.5°. *Anal.* Calcd. for $C_{22}H_{18}O_3$: C, 79.98; H, 5.49. Found: C, 80.17, 80.22; H, 5.70, 5.60.

Preparation of *m*-Diphenylbenzene from 1,3-Diphenylhexadiene-1,3.—1,3-Diphenylcyclohexadiene-1,3 (2.0 g.) in 15 ml. of cymene was heated under reflux in the presence of 0.7 g. of 5% palladized charcoal for three hours, following which time most of the cymene was removed by distillation. The final portion of cymene was removed by using low pressure distillation. The residue was dissolved in hot ethyl alcohol and the catalyst removed by filtration. On cooling, the filtrate deposited *m*-terphenyl (1.3 g.) which was isolated by filtration, m. p. 86.5–86.8°. This product gave no depression with an authentic sample kindly furnished us by Dr. C. F. H. Allen. *Anal.* Calcd. for $C_{18}H_{14}$: C, 93.88; H, 6.12. Found: C, 94.02; H, 6.25.

Summary

1. The reaction of dihydroresorcinol with

(13) "Organic Syntheses," Vol. 26, 1946, p. 77.

(14) Jacobsen and Loch (*Ber.*, **36**, 4085 (1903)) reported 78°, and Errera and La Spada (*Gazz. chim. ital.*, **35**, II, 552) reported 75° for the melting point of this substance.

phenylmagnesium bromide has been shown to yield 3-phenylcyclohexan-3-ol-1-one, 3-phenyl-Δ^2-cyclohexenone and 1,3-diphenylcyclohexadiene-1,3. A mechanism by which the latter substance could be formed is discussed.

2. The syntheses of 3-phenyl-Δ^2-cyclohexenone from the ethyl enol ether of dihydroresorcinol and of 1,3-diphenylcyclohexadiene-1,3 from 3-phenyl-Δ^2-cyclohexenone, are reported.

3. 3-Phenylphenol and *m*-terphenyl are conveniently prepared by the catalytic dehydrogenation, using palladized charcoal, of 3-phenyl-Δ^2-cyclohexenone and 1,3-diphenylcyclohexadiene-1,3, respectively.

The Partition of Acrylonitrile between Styrene and Water

BY WENDELL V. SMITH

A satisfactory discussion of the emulsion copolymerization of styrene and acrylonitrile requires a knowledge of the partition of the acrylonitrile between the water phase and the oil phase, since acrylonitrile is appreciably water soluble. Fordyce and Chapin[1] have compared the composition of the copolymer of styrene and acrylonitrile obtained in emulsion polymerization with that obtained in bulk polymerization and have found the emulsion copolymer to be consistently richer in styrene by a small amount than the bulk polymer produced from the same initial monomer composition. They have suggested that this difference may be due solely to the decrease in acrylonitrile content of the oil phase resulting from the water solubility of the acrylonitrile. The present investigation, which provides the data necessary to test this suggestion, has been carried out primarily to aid in discussing the emulsion copolymerization of these two monomers.

Under the conditions employed in emulsion polymerization, the ternary system, styrene–acrylonitrile–water, can be described sufficiently by specifying the compositions of two liquid phases, one of which may be called the aqueous phase, and the other the oil phase. A good approximation may be made by neglecting the solubility of styrene in the aqueous phase, also a fair approximation is obtained by neglecting the solubility of water in the oil phase (this is a good approximation when the oil phase is rich in styrene but becomes progressively less satisfactory as the acrylonitrile content of the oil phase increases).

Suppose that the system consists of

a volumes acrylonitrile
s volumes styrene
w volumes water

At equilibrium the oil phase will contain practically all the styrene and a_s volumes of acrylonitrile while the water phase will contain practically all the water and a_w volumes of acrylonitrile, where

$$a = a_s + a_w \qquad (1)$$

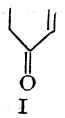
(1) Reid G. Fordyce and Earl C. Chapin, THIS JOURNAL, **69**, 581 (1947).

It is convenient to define a partition coefficient, α, by the relation

$$\alpha = \frac{a_s}{a_s + s} \cdot \frac{a_w + w}{a_w} \qquad (2)$$

Experimentally this partition coefficient may be determined by equilibrating a styrene–acrylonitrile solution of known composition with water and determining the resulting change in acrylonitrile content of the oil phase. If this change in acrylonitrile content is represented by

$$\Delta A = \frac{a}{a + s} - \frac{}{a_s}$$



I

and if the equilibrium acryloni oil phase is represented by

$$A_s = a_s/a_s + s$$

then equations 1 and 2 give

$$\alpha = A_s \left[1 + \left(\frac{w}{a + s}\right) \frac{(1 - A_s)}{\Delta A}\right] \qquad (3)$$

After having determined α it is then possible to reverse the calculation and obtain the equilibrium composition of any mixture of water and oil phase. This may be done by rearranging equation 3 to obtain the quadratic

$$A_s^2 - [R(\alpha - s/a + s) + 1]A_s + R\alpha a/a + s = 0 \qquad (4)$$

where $R = (a + s)/(a + s + w)$. The most convenient method of solving equation 4 for A_s is by successive approximation. Since the first term is small, a first approximation for A_s may be obtained by neglecting A_s^2 and estimating α from Fig. 1 and an estimated value of A_s. From this first approximation a new value of α may be obtained from Fig. 1 and the small correction due to the first term may be calculated. Then a second approximation for A_s may be calculated from equation 4. This may be continued to give any degree of approximation warranted by the experimental work.

One other problem which is treated in the experimental section is that of calculating the acrylonitrile content of a water solution by equilibrating the water solution with styrene and determining A_s, the equilibrium acrylonitrile content of the

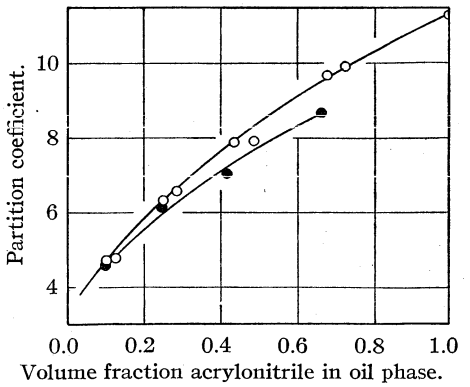


Fig. 1.—Partition coefficient of acrylonitrile between styrene–acrylonitrile solutions and water: 26°, ○; 60°, ●.

styrene solution. In this problem s, $a + w$ and A_s are measured, α is known from the relation between α and A_s, and it is desired to calculate $a/(a + w)$. This is done from equations 1 and 2 giving as a result

$$\frac{a}{a+w} = \left(\frac{s}{a+w}\right)\left(\frac{A_s}{1-A_s}\right)\left(1 - \frac{A_s}{\alpha}\right) + \frac{A_s}{\alpha} \quad (5)$$

Experimental

The compositions of all the styrene–acrylonitrile solutions used in the partition experiments were obtained from refractive index measurements. The relationship between refractive index and composition was established by making styrene–acrylonitrile solutions of known compositions, saturating them with water by adding a very slight excess of water and measuring the refractive indices with an Abbe refractometer. The results used to establish the relationship are given in Table I.

TABLE I

REFRACTIVE INDICES OF STYRENE–ACRYLONITRILE SOLUTIONS SATURATED WITH WATER

A_s	0.00	0.20	0.40	0.60	0.80	1.00
$n^{20}D$	1.5460	1.5167	1.4852	1.4536	1.4220	1.3912

The solutions were made from measured volumes of each ingredient and the above volume fractions of acrylonitrile, A_s, are based on the assumption that the volumes are additive.

The results indicate substantially a linear relationship between refractive index and volume fraction. All compositions were obtained by linear interpolation of the data in Table I.

The partition coefficients were determined by shaking styrene–acrylonitrile solutions with water and determining the refractive indices of the solutions at equilibrium. The initial compositions of the solutions and the initial volume of water and solutions were known. It was found that equilibrium was established rapidly (*i. e.*, in less than one-half hour at room temperature) as judged by constancy of the refractive index. The results are given in Table II.

The second column gives the ratio of the initial volume of aqueous to oil phase. The third and fourth columns give the volume fractions of acrylonitrile in the initial and equilibrated oil phases, respectively; they were obtained from the measured refractive indices and the data of Table I. The partition coefficients, α, in the last column were calculated from the other values using equation 3. The data obtained at 60° are considerably more uncertain than those at 26°. While the solutions and water were only allowed to remain at 60° for twenty minutes, there was evidence that polymer was present at the end. Also the boundaries in the refractometer were quite fuzzy on the samples which had been equilibrated with water at 60°; this was probably due to the formation of a cloudy suspension of water when the styrene solution was cooled down to 20° for making the refractive index measurement. Table II shows that the partition coefficient, α, is a function of the equilibrium acrylonitrile content.

TABLE II

PARTITION COEFFICIENTS OF ACRYLONITRILE BETWEEN STYRENE AND WATER

Temp., °C.	$\frac{w}{a+s}$	$\frac{a}{a+s}$	A_s	α
26	3	0.197	0.125	4.73
26	3	.379	.281	6.55
26	3	.586	.485	7.90
26	3	.788	.723	9.95
26	5	.200	.101	4.67
26	5	.400	.247	6.32
26	5	.600	.434	7.84
26	5	.800	.679	9.68
60	5	.200	.100	4.6
60	5	.400	.243	6.1
60	5	.600	.416	7.0
60	5	.800	.660	8.7

To extend the investigation to even higher acrylonitrile contents, the limiting value of the partition coefficient as the styrene approaches zero was determined from the water solubility of acrylonitrile. This was done first by making use of the above determined partition coefficients. Water was saturated with acrylonitrile by shaking with an excess and allowing it to stand in contact with the acrylonitrile overnight in a separatory funnel. The saturated water was then withdrawn and shaken with styrene, then the refractive index of the styrene layer determined. The results are given in Table III.

TABLE III

WATER SOLUBILITY OF ACRYLONITRILE FROM EQUILIBRIUM WITH STYRENE AT 25°

$\frac{w}{a+s}$	A_s	α	$\frac{a}{a+w}$
10	0.310	6.9	0.0878
5	.213	5.9	.0882

The water solubilities (volume fraction of acrylonitrile, $a/a + w$) given in the above table were calculated from equation 5, using values of α given by Fig. 1.

In order to verify this calculated water solubility and at the same time to get an independent check on our values for the partition coefficients, α, a direct determination of the solubility was made. It was found that 9.2 cc. of acrylonitrile in a total of 100 cc. of water solution gave a single homogeneous phase at 27°, while 9.4 cc. gave a very small amount of a second phase which would not dissolve. Thus, the direct determination gives the solubility as between 9.2 and 9.4%. This is in satisfactory agreement with the value calculated from the equilibration with styrene and thus serves as an independent check on the partition coefficients. Taking the water solubility to be 0.088 (volume fraction) the limiting "partition coefficient" for 0% styrene is 11.3; this neglects the effect of the solubility of water in the acrylonitrile which may give a 10% error in α.

As is to be expected, α varies with the composition of the equilibrium phases. In Fig. 1 α is plotted against the volume fraction of acrylonitrile in the hydrocarbon phase at equilibrium.

Discussion

The partition data given here make it possible to calculate the compositions of the oil phases used

by Fordyce and Chapin[1] in their study of the emulsion copolymerization of styrene and acrylonitrile. In their work the value of R was 0.367 and the temperatures were 60 and 75°. The results of this calculation are given in Table IV.

TABLE IV

ACRYLONITRILE CONTENTS OF THE OIL PHASES PRESENT DURING THE EMULSION COPOLYMERIZATION STUDIES OF FORDYCE AND CHAPIN[1]

Initial mole %	8.24	9.36	14.86	17.90	18.83	24.93
Equilibrium mole %	5.76	6.63	10.9	13.4	14.1	19.4
Initial mole %	32.92	36.32	45.68	66.25	94.64	
Equilibrium mole %	26.5	29.7	38.9	60.5	93.6	

The values given for the initial mole %'s in the table are the acrylonitrile contents of the oil phases before adding to the emulsion while the values for the equilibrium mole %'s are the acrylonitrile contents of the oil phases present in the emulsions during the polymerization. These latter values were calculated from the initial values using equation 4 and values of the partition coefficient, α, given by Fig. 1.

Having calculated the compositions of the oil phases actually present during the emulsion copolymerizations, it is now possible to compare the compositions of copolymers produced in emulsion with those produced in bulk from oil phases of identical composition. The data of Fordyce and Chapin[1] so treated are shown in Fig. 2. It is seen that this correction of the compositions of the emulsion oil phases makes the emulsion and bulk copolymerization composition curves identical within the accuracy of the data. Thus, the suggestion of Fordyce and Chapin that the consistent difference which they found was due to the water solubility of the acrylonitrile is substantiated by this investigation.

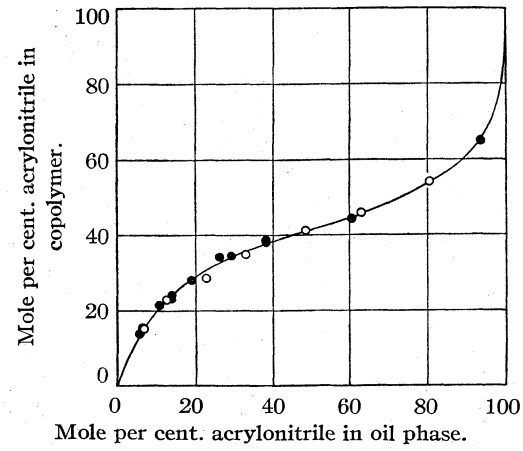

Fig. 2.—Monomer–polymer composition curve for styrene–acrylonitrile with correction for water solubility of the acrylonitrile: bulk polymerization, O; emulsion polymerization, ●.

Summary

The compositions of styrene–acrylonitrile solutions in equilibrium with water–acrylonitrile solutions have been determined. These equilibrium compositions have been used to calculate the acrylonitrile contents of the oil phases present in the emulsion copolymerization experiments of Fordyce and Chapin. It is shown that when this is done the above authors' emulsion data are identical with their bulk polymerization data in regard to composition of polymer produced from a given oil phase.

Some Equilibrium Relations in the System Magnesium Oxide–Sulfur Dioxide–Water (Acid Region) at Pressures below Atmospheric[1]

BY FRANK H. CONRAD AND DONAT B. BRICE

I. Introduction

This is a report of the study of the equilibrium $MgSO_3 \cdot 6H_2O$ + solution + vapor, in the system magnesium oxide–sulfur dioxide–water. It presents the pressure–composition relations at constant temperature (15 and 25°). The liquid phase of this system consists of a solution of the bisulfite of magnesium containing a small amount of the monosulfite. The vapor phase consists of SO_2 and water vapor.

These relations were desired because of the contemplated use of magnesia base cooking liquors in the "Sulfite Pulping Process" in place of calcium base liquor. Hatch[2] has pointed out that magnesia base liquor has the advantages: (a) the spent liquor may be used to recover both the magnesia and the sulfur dioxide; (b) heat is supplied to the process from the burning of the organic solids in the evaporated spent liquor; and perhaps most important; (c) the problem of disposing of the spent liquor is eliminated.

(1) This paper is based on a Dissertation presented by Donat B. Brice in May, 1947, to the Faculty of the Graduate School of the School of Mines and Metallurgy, University of Missouri, Rolla, Missouri, in candidacy for the degree of Master of Science in Chemical Engineering.

II. The Experimental Part

The materials used were "C. P. Analyzed" magnesium oxide containing negligible quantities of sulfate and calcium. The sulfur dioxide and water were treated as described by Conrad and Beuschlein.[3]

The apparatus used in determining the equilibrium pressures was almost identical to that described in "reference 3." The materials for making the equilibrium mixture were prepared in the same manner with the exception of the magnesium oxide.

After equilibrium was obtained, as shown by constant pressure readings, the solid was allowed to settle and a portion of the saturated solution was withdrawn to a weighing pipet. The solution (9 to 12 g.) was drained and washed into a volumetric flask nearly full of water. The tip of the pipet was kept below the surface of the water to prevent the loss of sulfur dioxide. The flask was then filled to volume and the aliquots were withdrawn in a manner similar to the removal of water from a wash bottle. This method was used to avoid the loss of any sulfur dioxide.

Aliquots were analyzed for the total and combined sulfur dioxide by the Hohn method the essentials of which are given by Birchard.[4] The free sulfur dioxide is obtained by subtracting the combined sulfur dioxide from the total sulfur dioxide. The free sulfur dioxide is the actual free sulfur dioxide plus half of the sulfur dioxide in the bisulfite of magnesium, and is more properly called the "available sulfur dioxide" as it indicates the sulfur dioxide in excess of that required to form the monosulfite. The combined sulfur dioxide represents that required to form the monosulfite. These definitions are as set forth by the Technical Association of Pulp and Paper Institute.[5] The standard solutions used in these analyses were sodium thiosulfate and iodine of approximately 0.1 *N* and sodium hydroxide approximately 0.2 *N*. Standardizations of the iodine and thiosulfate were made by the appropriate use of sodium oxalate and potassium permanganate. Since these solutions were standardized frequently the potassium permanganate was used. The sodium hydroxide was standardized against potassium acid phthalate.

The equations for the chemical reactions during analysis and for calculation of the combined sulfur dioxide are similar to those of "reference 3," only replacing the calcium atom by magnesium.

Before making any tests on the ternary system and in order to test the reliability of the results with the particular apparatus used in these experiments, the vapor pressure of water was determined at two temperatures. The vapor pressures obtained agreed with values read from the "International Critical Tables"[6] within 0.5 mm. pressure in all cases. As a further check on both the accuracy of the pressure readings and the analytical reagents used in analysis, the solubility of sulfur dioxide in water at 25° was determined at various pressures. The equilibrium flask was charged with water and sulfur dioxide, agitated at constant temperature in a thermostat, connected to the manometer and pressure readings obtained. It was noted that after two or three minutes the pressure remained constant although tests were allowed to stand for one and one-half hours to ensure that equilibrium had been attained. These data were in good agreement with those given in the "International Critical Tables,"[7] as well as the data of reference 3. The maximum deviation of any one point was 0.1 g. of sulfur dioxide per 100 g. of water. It was concluded from these preliminary tests that the apparatus and method would give results which were sufficiently accurate for the ternary system.

730.3	53.3	26.55	26.75

It was possible to remove only one sample of clear saturated liquid without disturbing the equilibrium in the flask. Duplicate analytical determinations made on some samples checked to within 0.6 g. of sulfur dioxide per 100 g. of water.

Saturation of the liquid phase, with respect to both gas and solid, was approached from both the supersaturated and the unsaturated conditions. In all experiments at 25° except those at atmospheric pressure the temperature at which the gas was admitted was three to five degrees below the final equilibrium temperature. Also, in order to remove any insoluble gaseous impurities admitted with the sulfur dioxide, solutions were boiled at reduced pressures. As sulfur dioxide is more soluble at low temperatures and high pressures, these experiments were approached from supersaturation with respect to the gas.

Equilibrium at 15° was approached from the unsaturated state with respect to both gas and

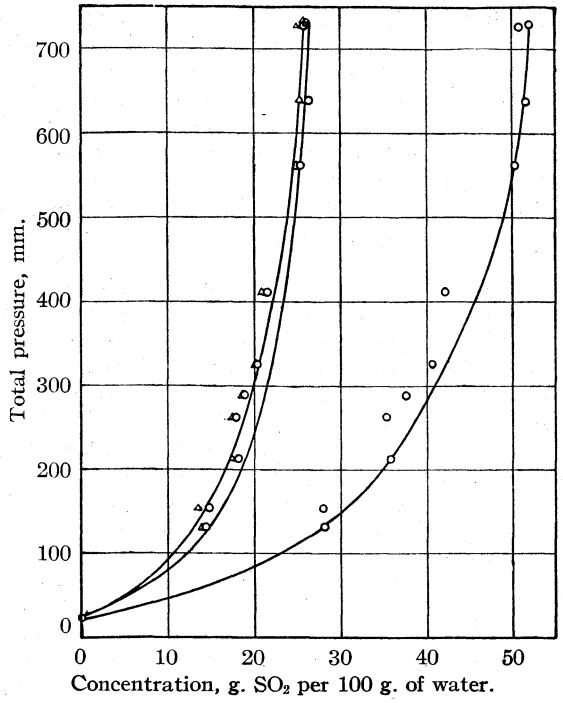

Fig. 1.—Pressure–concentration curves for liquid phase of system $MgO–SO_2–H_2O$; temperature, 25°.

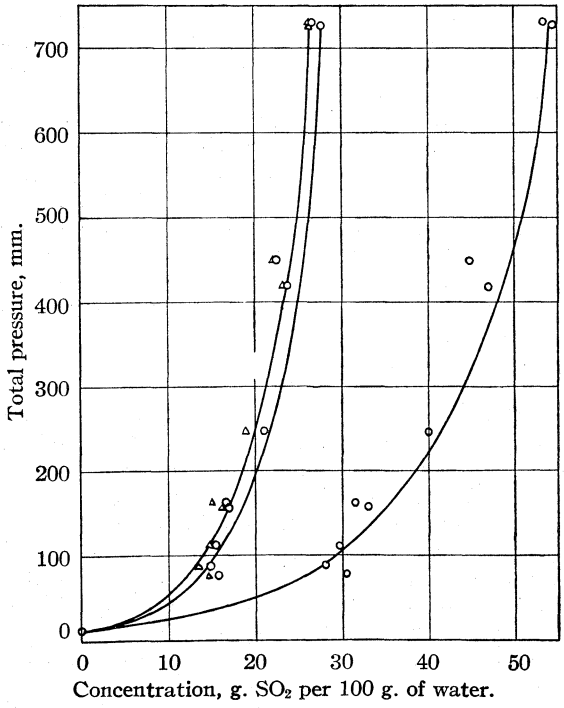

Fig. 2.—Pressure–concentration curves for liquid phase of system $MgO–SO_2–H_2O$; temperature 15°.

solid. The temperature at which the gas was admitted was five to eight degrees higher than the equilibrium temperature. The pressure was greater when the flask was placed in the thermostat than at final equilibrium. Thus these experiments were approached from the unsaturated side with respect to the gas.

In experiments 4 and 6 of Table I sulfur dioxide was added until all the solid phase was dissolved. After the solid was dissolved the solution was subjected to vacuum until solid phase reappeared. When the solid was again present the flask was placed in the thermostat and treated in the same manner as other experiments. Experiments 4 and 6 of Table I thus were approached from the supersaturated condition with respect to both gas and solid.

The curves of Figs. 1 and 2 have been constructed from data obtained. The correlation of these data by smooth curves is good.

In order to show the effect of temperature upon the concentration of sulfur dioxide, experiment "A" (Table I) was made at 35° and atmospheric pressure (in this case 728 mm.). The results of this experiment and the corresponding values at the same pressure (the 15° run was at 727 mm.), read from the curves in Figs. 1 and 2 are plotted in Fig. 3. The temperature concentration relations for the system calcium oxide–sulfur dioxide–water from "reference 3" are also plotted for comparison. It should be noted that the amount of sulfur dioxide in a solution is much greater for the magnesia system than for the calcium system at the same pressure. In the magnesia system the amount of combined sulfur dioxide was always greater than the free, in contrast to that for the calcium oxide system where it was much less. The amounts of combined and free were very nearly equal, the combined being always greater,

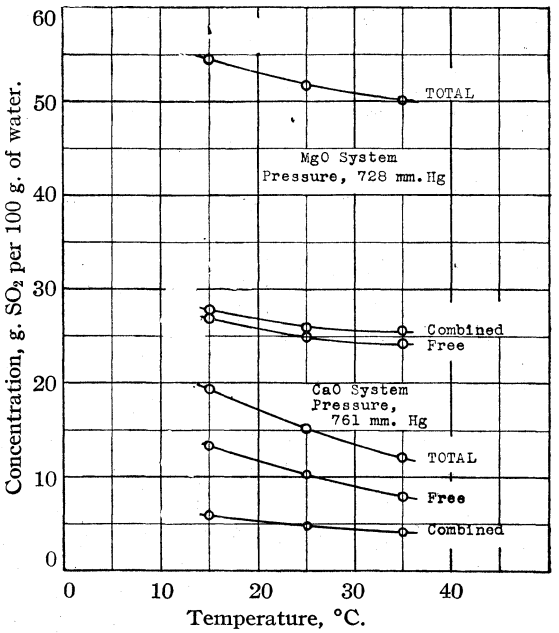

Fig. 3.—Temperature–concentration curves for liquid phase of the systems $MgO–SO_2–H_2O$ and $CaO–SO_2–H_2O$ at atmospheric pressure.

representing slightly more than 0.5 of the total. The combined was never more than 0.52 of the total.

IV. Analysis of the Solid Phase

Samples of the solid, assumed to be $MgSO_3 \cdot 6H_2O$, were removed from the equilibrium flask and analyzed. Samples for experiments 1, 2 and 3, Table III, were drained with suction and then dried to constant weight over 67% sulfuric acid in an atmosphere of carbon dioxide. Hartog[8] reports that crystals of $MgSO_3 \cdot 6H_2O$ are deposited when a solution of $Mg(HSO_3)_2$ is concentrated *in vacuo* at temperatures below 100° and then cooled. The magnesium oxide was determined by the pyrophosphate method and the sulfur dioxide by the Hohn method as previously referred to in the analysis of the liquid.

The mole ratio magnesium oxide to sulfur dioxide indicated a compound containing one mole of magnesium oxide to one of sulfur dioxide, but the amount of magnesium oxide was somewhat high in samples 1 and 2. It was thought that possibly oxidation was taking place in spite of all precautions. It was therefore decided, as other solid samples were removed from the equilibrium flask, to wash them with distilled water until free of solution and analyze a portion immediately for sulfur dioxide and magnesium oxide. Another portion of these same samples was dried as described and analyzed for the magnesium oxide content. It is thus possible to calculate from the weight of the dried sample and the magnesium oxide–sulfur dioxide ratio of the same sample, the amount of magnesium sulfite it would contain and to obtain the hydrate water by difference. Results of these analyses and calculations are shown for samples 5 to 8 (Table III).

TABLE III

COMPOSITION OF THE SOLID PHASE FOR THE SYSTEM MAGNESIUM OXIDE–SULFUR DIOXIDE–WATER

7	.0522	.0615	1.35	6.35
8[a]	.0280	.0416	1.07	5.68
9[a]	.0362	.054	1.06	..
$MgSO_3 \cdot 6H_2O$	40.32	64.06	1.000	6.00

[a] Equilibrium approached from supersaturation.

Samples of solids were obtained from solutions in which the equilibrium had been approached from both the unsaturated and the supersaturated conditions as in the liquid phase investigation. The time allowed for equilibrium to be reached in the preparation of the solid samples was identical with that used in the liquid phase work. Also constancy of pressure readings was likewise used as a criterion of equilibrium, and hence the tests should be comparable with those for the liquid phase. Examination of the results in Table III shows that solids obtained from experiments approached from the supersaturated side have close to the theoretical ratio of one to one for magnesium oxide to sulfur dioxide. The fact that this ratio is slightly greater than one may indicate a small amount of oxidation even though the samples were analyzed for sulfur dioxide without drying. Those approached from the unsaturated side deviated considerably more and the ratio varied from one run to another. It is the opinion of the authors that although equilibrium in the liquid phase was established, such that pressure–concentration curves could be constructed, there was actually some magnesium oxide occluded by the magnesium monosulfite in the solids prepared from the unsaturated side.

Sulfur dioxide was permitted to react with a suspension of magnesium oxide in water, which amounted to having a particle of magnesium oxide as the core with magnesium hydroxide covering the oxide. The sulfur dioxide reacted with the hydroxide and formed a coating of magnesium monosulfite hexahydrate around the magnesium oxide. These particles then after long standing were in equilibrium with the solution of bisulfite of magnesium. Thus, even if occluded magnesium oxide were present it would have little effect upon the liquid phase investigation.

It is realized that the removal of the solid phase from equilibrium with the liquid and gaseous phases may in some cases change the composition of the solid. Attempts were made to obtain data satisfactory for the construction of a modified Schreinemakers diagram as used by Conrad and Beuschlein[3] but the intersections were at such acute angles and so erratic as to make the method of little value.

Summary

1. The total pressure–composition relationships have been determined for the system magnesium oxide–sulfur dioxide–water in the acid region up to atmospheric pressure at 15 and 25°.

2. The total, free and combined sulfur dioxide has been determined for saturated solutions in equilibrium with solid magnesium monosulfite hexahydrate at total pressures of sulfur dioxide and water vapor from the vapor pressure of water to atmospheric pressure for the temperatures 15 and 25°.

3. The temperature–composition relationship has been determined for the total pressure of 728 mm. at temperatures of 15, 25 and 35°.

4. The analysis of the solid removed from the equilibrium is in agreement with the assumed formula of $MgSO_3 \cdot 6H_2O$.

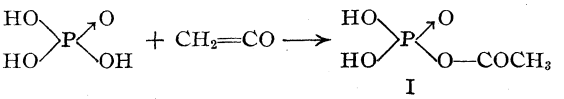
A New Synthesis of Acetyl Dihydrogen Phosphate[1]

BY RONALD BENTLEY[2]

Acetyl dihydrogen phosphate (I) was first synthesized by Lynen[3] who used the catalytic debenzylation of acetyl dibenzyl phosphate. Later, Lipmann and Tuttle[4] described its preparation from silver dihydrogen phosphate and acetyl chloride; in each case the acetyl dihydrogen phosphate was characterized as its sparingly water soluble disilver salt. It has now been found that it may be conveniently and rapidly prepared by acetylating phosphoric acid with ketene, thus confirming the previous observation of Hurd and Dull[5] that "ketene was quantitatively absorbed by phosphoric acid, presumably with the formation of acetylphosphoric acid."

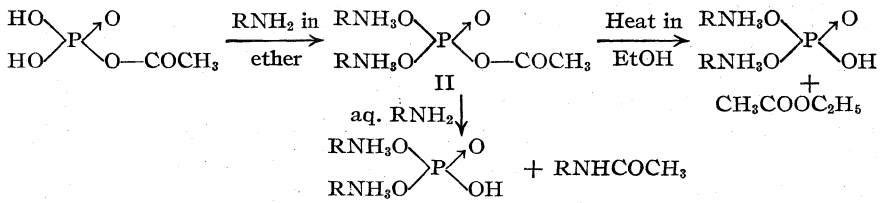


I

Solutions of the free acetyl dihydrogen phosphate were obtained by reaction of the disilver salt with hydrogen sulfide in aqueous suspension or by reaction with ethereal hydrogen chloride. The aqueous solution of the free acid was stable for some hours at 0°; on neutralization with barium hydroxide and addition of silver nitrate, the disilver salt was recovered.

Acetyl dihydrogen phosphate has been widely considered as a possible acetylating agent and also as a phosphorylating agent in physiological systems.[6] It was therefore of interest to study its reactions with various compounds. Aqueous solutions of the sodium salt were found to acetylate ammonia and aniline, but only with low yields. In neutral aqueous solutions no acetylation of γ-phenylaminobutyric acid, choline chloride, guanidine or hydroquinone was observed.

When ethereal acetyl dihydrogen phosphate was treated with aniline, bis-phenylammonium acetyl phosphate (II, R = C_6H_5) precipitated and evaporation of the ethereal mother liquor gave a small amount of acetanilide. Subsequent reaction of the bis-phenylammonium salt with aqueous aniline gave bis-phenylammonium phosphate and acetanilide. Analogous reactions were observed with ammonia.



II

Dibenzyl hydrogen phosphate reacted smoothly with ketene to yield the mixed anhydride, acetyl dibenzyl phosphate, which was converted to acetyl dihydrogen phosphate using Lynen's method. Acetyl dibenzyl phosphate could also be used as an acetylating agent. With aniline in the absence of solvent there was a vigorous reaction; acetanilide and dibenzyl hydrogen phosphate were obtained. Choline chloride dissolved in glacial acetic acid was also acetylated, in the cold, on addition of acetyl dibenzyl phosphate.

Experimental[7]

Preparation of Disilver Acetyl Phosphate.—In a typical run, sirupy phosphoric acid (85%, 10 ml.) dissolved in dry ether (150 ml.) was treated with a ketene stream for thirty minutes with ice cooling. (A ketene lamp similar to that described by Williams and Hurd[8] was used, which produced about 10 g. of ketene in that time. Ten ml. of 85% phosphoric acid required about 12.5 g. of ketene for reaction with the water and phosphoric acid present.) The ketene was led in through a sintered glass bubbler, with vigorous stirring to avoid high local concentrations. The ether solution was extracted with ice water (3 × 50 ml.; all apparatus used was previously chilled in ice) and the aqueous extract rapidly neutralized (*p*H 7.0) by dropwise addition of saturated barium hydroxide solution, with ice cooling and vigorous stirring. The precipitated barium phosphate was centrifuged off and the solution of barium acetyl phosphate was treated with excess of ice cold 10% silver nitrate solution. The pale creamy precipitate was washed with ice-water, alcohol and ether (16.7 g.). Dilution of the mother liquor with one-third volume of ethanol gave a second crop of crystals (5.0 g.).

For recrystallization the disilver salt (7.2 g.) was ground to a smooth paste with ice water, shaken with ice cold 0.25 *M* sodium chloride (150 ml.—a slight deficiency) and allowed to stand for fifteen minutes. The solution was filtered, and treated with 25% silver nitrate (3 ml.). This first precipitate was rejected, and excess 25% silver nitrate was then added. Disilver acetyl phosphate (5.5 g.) formed white prisms, not having a definite m. p.

Anal. Calcd. for $C_2H_3O_5PAg_2$: Ag, 60.9; P, 8.75. Found: Ag, 60.25; P, 8.7.

Acetyl determinations were performed by repeated steam distillation of 15 mg. samples with water (10 ml.) and concentrated sulfuric acid (2 ml.) in a Kjeldahl type apparatus: 35-ml. portions of distillate were collected until a constant blank titration was obtained. *Anal.*

Calcd. for $C_2H_3O_5PAg_2$: CH_3CO, 12.2. Found: CH_3CO, 12.7. The acidity produced on warming 40–50 mg. samples with water at 70–75° for two hours was determined by titration of the filtered solution with 0.01 *N* potassium hydroxide.

$$3C_2H_3O_5PAg_2 + 5OH^- = 2Ag_3PO_4 + HPO_4^= + 3CH_3COO^- + 2H_2O$$

Calculated per cent. purity, 101.3.

Preparation of Acetyl Dihydrogen Phosphate.—(1) Aqueous solution: Disilver acetyl phosphate (1.5 g.) suspended in ice water, was treated with excess hydrogen sulfide, silver sulfide filtered off, and the filtrate freed from hydrogen sulfide by aeration at 0°. The filtrate was made up to 70 ml.: 40 ml. was immediately neutralized with barium hydroxide solution at 0°, and reprecipitated with silver nitrate (recovery, 0.7 g.). The remaining solution was kept for ninety minutes at 0°, and treated in the same way (recovery, 0.4 g.). The precipitates were recrystallized and the per cent. purity determined by hydrolysis with water as previously described: first precipitate, 104.0%; second precipitate, 100.3%.

(2) Ethereal solution: Finely powdered disilver acetyl phosphate (2.0 g.) was suspended in absolute ether (25 ml.), cooled in ice and ethereal hydrogen chloride (1.33 *N*, 8.0 ml.) added dropwise with vigorous stirring. Stirring was continued for a further ten minutes, the mixture filtered, and the silver chloride washed with a little absolute ether to yield an ethereal solution of acetyl dihydrogen phosphate.

Reaction with Aniline in Aqueous Solution.—Disilver acetyl phosphate (2.0 g.) was converted to sodium salt using 0.25 *M* sodium chloride (45 ml.). The filtered solution was treated with aniline (1.2 ml., a large excess) and acetone (5 ml.) to homogenize the solution. The solution, initially at 0°, was brought to room temperature after two hours, and allowed to stand overnight. Hydrochloric acid (1.068 *N*, 18.0 ml.) was added (*p*H 3.0), and the solution extracted with ether: the dried extract was evaporated to yield white, lath-like crystals, m. p. 114–115° (109 mg., 14% yield); no m. p. depression in admixture with authentic acetanilide.

Reaction with Aniline in Ethereal Solution.—An ethereal solution of acetyl dihydrogen phosphate (from silver salt 2.0 g.) was cooled to 0°, and treated with aniline (2.0 g.) in dry ether (15 ml.). A white precipitate of bis-phenylammonium acetyl phosphate (II, R = C_6H_5) (1.7 g.), m. p. 104–105°, soluble in sodium bicarbonate solution with effervescence. (The ethereal mother liquor was extracted with 2 *N* hydrochloric acid to remove excess aniline and yielded a little acetanilide on evaporation.)

Anal. Calcd. for $C_{14}H_{19}O_5N_2P$: CH_3CO, 13.2. Found: CH_3CO, 13.1.

On attempted recrystallization from absolute ethanol, shining plates m. p. 174–175° were obtained (unchanged on recrystallization). With bis-phenylammonium phosphate there was no depression in m. p.

Bis-phenylammonium acetyl phosphate (320 mg.) was dissolved in ice-water and aniline (1.0 ml.) and acetone (3.0 ml.) added. The mixture was placed in an ice-bath, allowed to warm up to room temperature, and kept overnight. A white crystalline precipitate formed (170 mg.), m. p. 174–175°, recrystallizing from ethanol in plates; no depression in admixture with bis-phenylammonium phosphate. The mother liquor was made acid to congo red, extracted with ether, and the dried extract evaporated; the white solid was recrystallized from chloroform-petroleum ether to form white needles (66 mg., including a second crop), m. p. 111–112°. No m. p. depression in admixture with acetanilide.

Bis-phenylammonium acetyl phosphate (200 mg.) was treated with 2 *N* ammonia (5 ml.), when an oil separated; the mixture was allowed to stand overnight, extracted with ether, and the aqueous solution evaporated to dryness *in vacuo*. The solid residue was extracted with warm chloroform, filtered, and the filtrate diluted with petroleum ether (b. p. 30–60°). White crystals separated, m. p. 81°, no depression in admixture with acetamide.

Reaction with Ammonia in Ethereal Solution.—Disilver acetyl phosphate (1 g.) was converted to the free acid in ether. The solution at 0° was treated with an excess of dry ethereal ammonia when diammonium acetyl phosphate crystallized in white plates m. p. 128–130°. It did not analyze too well.

Anal. Calcd. for $C_2H_{11}O_5N_2P$: N, 16.1; CH_3CO, 24.5. Found: N, 17.1; CH_3CO, 23.0.

The solid was allowed to stand overnight in a little aqueous ammonia, and evaporated to dryness *in vacuo:* the crystalline solid was extracted with warm ethanol, the extract being evaporated. The residue was twice recrystallized from chloroform–petroleum ether (b. p. 30–60°), to form white crystals, m. p. 82°, showing no depression with an authentic sample of acetamide.

Preparation of Acetyl Dibenzyl Phosphate.—Dibenzyl hydrogen phosphate was prepared substantially as described by Lossen and Köhler[9]; it was found preferable, however, to saponify the tribenzyl phosphate by refluxing for some hours with 10% alcoholic potassium hydroxide. Evaporation of solvent, solution of the residue in water, acidification and recrystallization from chloroform-petroleum ether gave dibenzyl hydrogen phosphate, m. p. 79.5°.

Dibenzyl hydrogen phosphate (1.0 g.) was dissolved in absolute ether containing a little chloroform, and treated with a ketene stream (about 0.5 g., an excess) at ice temperature. Solvent was removed *in vacuo* (bath temperature, 25°) to yield acetyl dibenzyl phosphate as a viscous, neutral oil, in almost the theoretical yield.

Anal. Calcd. for $C_{16}H_{17}O_5P$: CH_3CO, 13.4. Found: CH_3CO, 13.3.

The oil was dissolved in dry ether (50 ml.), palladium charcoal (500 mg.) was added and the solution hydrogenated with dry hydrogen, about 200 ml. being taken up at S. T. P. After filtration, the ether was extracted with water (2 × 15 ml.) and the solution neutralized with barium hydroxide solution at 0°. Precipitated barium phosphate was filtered off, and silver nitrate solution added. Disilver acetyl phosphate was precipitated (300 mg.); per cent. purity as determined by titration of acid produced on hydrolysis, 95.9.

Reaction of Acetyl Dibenzyl Phosphate and Aniline.—A portion of acetyl dibenzyl phosphate was treated with a slight excess of aniline, the mixture warming up considerably. After reaction, chloroform was added, and excess aniline extracted with 2 *N* hydrochloric acid. The chloroform was next extracted with saturated sodium bicarbonate solution; acidification of this extract gave a white solid, which recrystallized from chloroform–petroleum ether to form plates, m. p. 80°; no m. p. depression admixed with dibenzyl hydrogen phosphate. The chloroform solution was washed with water, dried and evaporated *in vacuo:* the residue quickly crystallized, and was recrystallized from chloroform–petroleum ether, forming white needles, m. p. 115°; mixed m. p. with acetanilide, 115°.

Reaction of Acetyl Dibenzyl Phosphate and Choline.—Dibenzyl hydrogen phosphate (1.0 g.) was converted to its acetyl derivative, the oil being held in vacuum for some time to remove any traces of ketene. Choline chloride (500 mg.) was added, and glacial acetic acid (1 ml.) to form a clear solution. After forty-eight hours, the acetic acid was evaporated *in vacuo*, the residue treated with 2 *N* hydrochloric acid (5 ml.) and an insoluble oil, extracted with ether. The filtered aqueous solution was treated with a slight excess of auric chloride solution; the yellow precipitate (0.762 g.) had m. p. 163–164°, unchanged on recrystallization from hot water. (Literature m. p. of acetylcholine aurichloride is 166°; no depression in admixture with an authentic sample.)

Summary

1. Acetyl dihydrogen phosphate may be con-

(9) W. Lossen and A. Köhler, *Ann.*, **262**, 211 (1891).

veniently prepared by the acetylation of phosphoric acid with ketene in ethereal solution, and is recovered as disilver acetyl phosphate. Similar acetylation of dibenzyl hydrogen phosphate yields acetyl dibenzyl phosphate.

2. Acetyl dihydrogen phosphate will acetylate ammonia and aniline under various conditions. No evidence of phosphorylating reactions could be obtained.

The Structure of Neoprene. I. The Molecular Weight Distribution of Neoprene Type GN

BY W. E. MOCHEL, J. B. NICHOLS AND C. J. MIGHTON

It has been recognized that synthetic high polymers in general are non-homogenous, particularly in respect to molecular weight. Therefore, the molecular weight of a particular polymer cannot be characterized accurately by a single value and there is required a knowledge of the distribution of molecular weights. Any single molecular weight value for a heterogeneous polymer must perforce be an average value and will differ appreciably with the method of averaging. Although it has been shown recently that the tensile strength of some polymers, *e. g.*, cellulose acetate, depends explicitly on the number average molecular weight regardless of the distribution of molecular weights,[1] other properties of high polymers such as plasticity,[2] are influenced markedly by the heterogeneity of molecular weights. The present investigation of the molecular weight distribution of neoprene (polychloroprene) is a part of an extensive study of the structures of these polymers.

There have appeared recently several new methods for determination of molecular weight distribution[3] but the standard method continues to be that of careful fractionation and examination of each fraction. This method also furnishes polymer samples of sufficient homogeneity that they can be used to calibrate the intrinsic viscosity–molecular weight relationship with an absolute method such as osmotic pressure. The two most common methods for fractionation of high polymers are: (1) precipitation by successive additions of a non-solvent to a solution of the polymer and (2) successive extractions of the polymer with solvent/non-solvent mixtures of increasing solvent concentration. It has been shown that neither method can give a really sharp separation of species[4] but the first method appears to be satisfactory for practical purposes if certain precautions are taken. Thus, it is advisable to use a reasonably dilute solution, precipitate at constant temperature and wash the precipitated fractions to remove low molecular weight material.

Experimental

Materials.—A sample of standard, commercial Neoprene Type GN of plasticity classification[5] P3 and age two months was selected for fractionation. Neoprene Type GN is a polychloroprene polymerized in aqueous emulsion in the presence of sulfur and is stabilized with tetraethyl thiuram disulfide.[6] (Neoprene Type GN is identical with GR-M currently manufactured at Louisville by the Office of Rubber Reserve, Reconstruction Finance Corporation.) To obtain the pure polychloroprene, essentially free from soap residues, stabilizers and adjuvants used in the polymerization, 55 g. of the finely-cut neoprene was dissolved in 500 ml. of thiophene-free, dry benzene, and 500 ml. of C. P. methanol was added slowly with stirring, to precipitate the polymer. Further addition of methanol to the clear, supernatant liquid produced no cloudiness. The polymer was washed twice with 100-ml. portions of methanol and dried at room temperature under vacuum. The dry polymer weighed 50.5 g. In these operations and all subsequent handling, the polymer, its solutions and the fractions were kept under an atmosphere of nitrogen.

The benzene–methanol mixture left after precipitation of the polymer was combined with the methanol wash liquors and evaporated to dryness under vacuum. The residue, consisting of 4.6 g. of dark brown, very viscous oil, was not investigated further.

Fractionation.—The purified polychloroprene prepared as described above (50.5 g.) was dissolved in 5 l. of thiophene-free, dry benzene and to the solution was added 0.5 g. of phenyl-α-naphthylamine to inhibit degradation of the polymer. After a sample (150 ml.) of the solution of whole polymer had been removed for test, fraction A was precipitated by the slow addition of methanol, with mechanical stirring, until the solution became hazy at 25°. It was then warmed gently until it became clear, at about 26–28°. Precipitation of the first fraction required 1200 ml. of methanol. The clear, warm solution was cooled slowly to 25° and maintained overnight at constant temperature, during which time the precipitated polymer settled out as a very viscous liquid containing the high molecular weight polymer in solution. The clear, supernatant solution was siphoned off and the fraction was washed twice with a benzene–methanol mixture of the same concentration as the mixture from which the fraction had precipitated. These washings were added to the main solution and the fraction

(5) P3 corresponds to a Williams plasticity range of 116–121; see A. M. Neal and P. Ottenhoff, *Ind. Eng. Chem.*, **36**, 653 (1944), this corresponds approximately to Mooney 2.

(6) A. M. Collins, U. S. Patent 2,264,173.

was dissolved immediately in 200 ml. of thiophene-free, dry benzene. A benzene/methanol azeotrope was distilled from this solution at 30° under vacuum until about 100 ml. had been removed; then another 100 ml. of benzene was added and the distillation was continued until the refractive index of the distillate checked that of pure benzene. The remaining solution of the fraction in pure benzene was used for subsequent measurements.

The above-described procedure was followed for the preparation of the first three fractions since it had been found that evaporation of these fractions to dryness resulted in the formation of small amounts of gel.[7] Remaining fractions were coagulated with methanol after being washed and were then evaporated to dryness under vacuum at room temperature. After approximately half of the polymer had been fractionated a single washing of each fraction was considered sufficient. Eventually, when 28 g. of the neoprene had been precipitated it was necessary to concentrate the solution to about 1% solids again before proceeding with the final fractionations. This was done at 25–30° under vacuum with a slow stream of nitrogen through a fine capillary tube. Finally, when no more material could be precipitated, the remaining solution was evaporated to dryness.

An attempt to improve the homogeneity of neoprene fractions further by solution and reprecipitation gave meaningless results, presumably because of degradative changes occurring during the longer time required for the additional operations. Consequently the neoprene fractions described here were not reprecipitated. Repeated measurements on the whole polymer gave good checks on intrinsic viscosity and osmotic pressure. To diminish the effects of degradative changes, the fractions were dissolved and their molecular weights measured within a few days after preparation.

A total of 17 fractions was obtained from the purified polychloroprene. The dried fractions were dissolved in thiophene-free, dry benzene to make solutions containing 1 g. of polymer and 0.0050 g. of phenyl-α-naphthylamine per 100 ml. of solution. Solids content of each solution was accurately determined by evaporation to dryness at 70° of a 25.00-ml. aliquot (measured at 25.0°) and the remaining solution was used for the determination of number average molecular weight and intrinsic viscosity. To obtain a check on the results a rough fractionation was carried out analogously to get 6 different fractions which would approach the above in homogeneity.

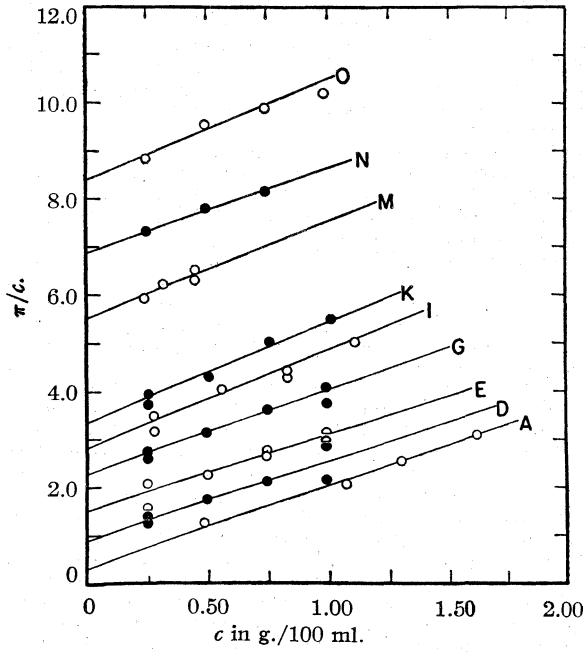

Fig. 1.—π/c *vs.* c curves for representative Neoprene Type GN fractions.

Osmotic Pressures.—The number average molecular weights in benzene solution were measured by means of static type osmometers using gel cellophane membranes (regenerated cellulose that has not been dried). The osmometers used were similar to those described by Schulz and by Wagner[8] and the membrane preparation was the same as that of Wagner.

For each sample, duplicate determinations were made at each of four different concentrations. To minimize the error due to thermometer effect, especially with the benzene solutions employed, the temperature was regulated within ±0.01°. The capillary correction for benzene was measured and since the correction for most solutions in organic solvents does not differ much from that of the pure solvent, separate measurements were not made for each individual solution. The measurements for each sample were plotted as π/c *vs.* c and extrapolated to zero concentration assuming a straight line relationship

$$\frac{\pi}{c} = \frac{RT}{M_n} + Bc$$

which appeared to fit within experimental error in the range of concentrations employed, *i. e.*, 0.25–1.50 g. per 100 ml. Representative curves are given in Fig. 1.

Intrinsic Viscosity.—Viscosities were measured in benzene solution using an Ubbelohde suspended level viscometer[9] modified by substitution of a 50-ml. reservoir for the usual 5–10 ml. bulb. Since the operation of the suspended level viscometer, unlike that of the Ostwald types, is not affected by the volume of liquid in the viscometer, it was possible to make carefully weighed additions of a 1–2% solution of polymer to solvent in the viscometer. Thus the viscosity at various concentrations could be measured without having to clean and refill the viscometer before each determination. The viscometer dimensions were such that the kinetic energy error was only 0.4% in the kinematic viscosity of benzene, having an efflux time of 116.4 seconds, and no correction was applied.

The dry, thiophene-free benzene used as solvent was measured at 25.0° in calibrated pipets and the efflux times were determined at the same temperature with a maximum fluctuation of ±0.02°. The efflux times were checked within ±0.2 second. Normally four additions of the polymer solution were made, keeping the relative viscosity between 1.15 and 1.4.

The concentration of the polymer by weight in the master solution was calculated using 1.23 as the specific gravity of polychloroprene[10] and 0.8735 as the specific gravity of benzene at 25°. The concentration of each solution measured was calculated in g. per 100 ml. and used to determine reduced viscosity, η_{sp}/c. Using a differencing technique[11] the four sets of η_{sp}/c *vs.* c values were fitted to the best straight line for the equation developed by Huggins and others[12]

$$\frac{\eta_{sp}}{c} = [\eta] + k'[\eta]^2 c \qquad (1)$$

(7) A similar observation was made in the case of natural rubber by G. F. Bloomfield and E. H. Farmer, *Trans. Inst. Rubber Ind.*, **16**, 69 (1940); G. Gee and L. R. G. Treloar, *ibid.*, **16**, 184 (1940).

(8) G. V. Schulz, *Z. physik. Chem.*, **A176**, 317 (1936); R. H. Wagner, *Ind. Eng. Chem., Anal. Ed.*, **16**, 520 (1944).

(9) L. Ubbelohde, *ibid.*, **9**, 85 (1937); G. B. Taylor, THIS JOURNAL, **69**, 635 (1947).

(10) L. A. Wood, N. Bekkedahl and F. L. Roth, *Ind. Eng. Chem.*, **34**, 1291 (1942).

(11) J. H. Awbery, *Phys. Soc. Proc.*, **41**, 384 (1929).

(12) M. L. Huggins, THIS JOURNAL, **64**, 2716 (1942); G. V. Schulz and F. Blaschke, *J. prakt. Chem.*, **158**, 130 (1941).

The intrinsic viscosity was thus obtained as the limiting reduced viscosity and simultaneously the constant k' was evaluated. The experimental results are shown graphically in Fig. 2.

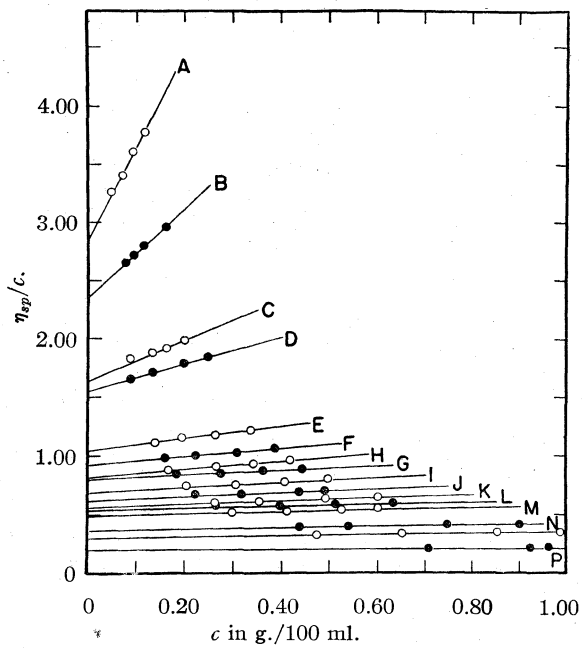

Fig. 2.—η_{sp}/c *vs.* c curves for Neoprene Type GN fractions.

Results and Discussion

The purified polychloroprene was divided into 17 fractions, the last one of which gave such erratic osmotic measurements that its molecular weight could not be calculated. The total weight of fractions isolated from the 49.0 g. of polymer fractionated (50.5 g. minus 1.5 g. for a sample of whole polymer) was 46.48 g. There was thus a loss of 2.52 g. of polymer during the fractionation. On the assumption that this loss had been uniformly distributed over all fractions, the total weight of the isolated fractions was used in calculating what per cent. of the whole each fraction constituted. The results obtained are given in Table I.

TABLE I

FRACTIONATION OF NEOPRENE TYPE GN

Fraction	Weight, g.	%[a]	$\overline{M}_n$	B[c]	[η]	k'
Whole	(49.0)	(100)	114,000	2.14	1.07	0.43

[a] Per cent. of the total isolated in the fractions. [b] Calculated weight; see procedure. [c] Slope term of the osmotic pressure relationship.

Note in Table I that although the number average molecular weight of the *whole* polymer was 114,000 there was present a broad range of molecular species, from 959,000 to less than 20,500 molecular weight. This range, of course would be widened by any degradation which occurred in the period of almost four weeks which elapsed between the precipitation of fraction A and isolation of the final fraction. However, the calculated number average of the molecular weights of the individual fractions was 105,000 compared with 114,000 for the original polymer indicating that degradation had not been extensive.

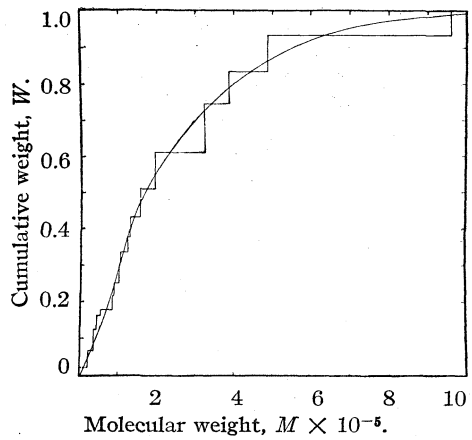

Fig. 3.—Integral molecular weight distribution for Neoprene Type GN.

In Fig. 3 is plotted the molecular weight of each fraction as a part of the whole polymer and from the smoothed curve there is calculated the differential molecular weight distribution given in Fig. 4. This illustrates very well the broad range of molecular weights and shows that the polymer species most abundant are those having molecular weights of about 100,000. The extension of the

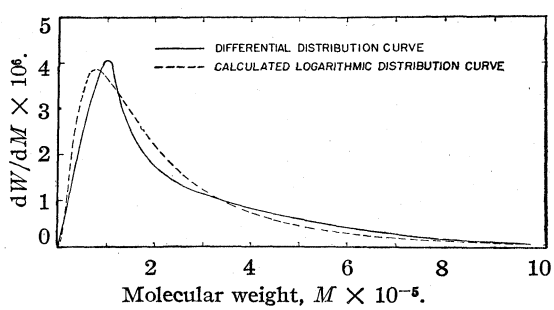

Fig. 4.—Differential molecular weight distribution for Neoprene Type GN.

neoprene distribution curve at the high molecular weight end suggests that there is present some soluble branched and/or cross-linked material, since it has been shown[13] that 10–100 p.p.m. of a cross-linking agent (diisopropenyldiphenyl) in polystyrene gave completely soluble polymers but altered the shape of the distribution curve and markedly increased the length of the high molecular weight end as the concentration of cross-linking agent was increased from 10 to 100 p.p.m.

Decreasing complexity of the fractions as the molecular weight decreases is indicated by the highly significant (probability of occurrence by chance alone is less than 1 in 100) decrease in k' of the viscosity equation (1) from 0.93 for fraction A to 0.406 as an average for fractions D to P. This constant is said to be a characteristic of any given solute–solvent system and is independent of molecular weight.[14] From studies in this laboratory it appears that k' is larger for complex molecules in a given homologous series than for simple, *i. e.*, linear ones. The greater-than-average values of k' for fractions A, B, and C indicate that approximately 25.2% of the neoprene is branched and/or cross-linked appreciably more than the major portion of the polymer. This corresponds to 5.4% of the molecules by number. The major portion of the polymer appears to be uniform in structure, at least within experimental error.

This increase of k' with polymer chain complexity is indicated also by the work of others. For example, Speiser and Whittenberger[15] showed that k' was higher (1.47) for the branched structure, amylopectin, than for the unbranched molecule, amylose ($k' = 0.58$). Also Morrison, Holmes and McIntosh[16] found that k' of solutions of polyvinyl acetate in bis-(2-chloroethyl) ether containing small amounts of ferric chloride increased as the viscosity increased and the solution gelled, indicating branching and cross-linking reactions, but in the presence of air the viscosity decreased, indicating chain scission, while k' remained constant. Furthermore, Spurlin, Martin and Tennent[17] demonstrated that k' is greatest for solutions where the solvents are poorest. Similarly, a given liquid would be a poorer solvent for cross-linked molecules than for linear molecules of the same species. The present investigation has shown that k' for polychloroprene solutions is not increased by heterogeneity of molecular species,[18] as was reported for polystyrene in toluene.[19] The whole polymer had a lower k' than several of the fractions and k' was not raised by mixing two fractions together, *e. g.*, two fractions having respective $[\eta]$ and k' values of 1.56–0.60 and 0.60–0.40, when mixed in approximately equal parts gave $[\eta] = 0.99$ and $k' = 0.43$. Unfortunately the error in k', particularly at low intrinsic viscosity, is frequently quite large, depending in calculation as it does upon the square of the intrinsic viscosity.

The same change in complexity of the fractions is suggested by the change in the slope term B of the osmotic pressure relationship[20]

$$\frac{\pi}{c} = \frac{RT}{M_2} + Bc, \text{ where } B = \frac{RTd_1}{M_1 d_2^2}(0.5 - \mu)$$

c is the solute concentration, M_1 and M_2 are the molecular weights and d_1 and d_2 the densities of the solvent and solute, respectively. The constant μ, which depends upon the entropy and heat of mixing for each solvent–solute combination, approaches the value 0.5 for poor solvents, causing B to approach zero. Thus the somewhat lower values of B for early fractions indicate poorer solutions as would be expected if there were present branched and/or cross-linked polymers, but it is recognized that the variations in B may be influenced also by the different molecular weights of the fractions.

The intrinsic viscosities of Neoprene Type GN fractions ranged from 2.88 to 0.20 as noted in Table I. The calculated weight average of the individual values was 1.18 which is not as close to the observed value, 1.07, for the whole polymer as would be desired. There is apparently an error in the value for fraction G or H since the viscosity would be expected to decrease in going from G to H. The discrepancies, however, are not large enough to nullify the general conclusions drawn in this paper.

The intrinsic viscosity is a measure of the viscosity average molecular weight, which approaches the weight average value fairly closely for most polymers, whereas the osmotic pressure determination measures the number average molecular weight. These relationships can be indicated as follows[21]

$$\text{number average: } \overline{M}_n = \frac{\Sigma NM}{\Sigma N}$$

$$\text{viscosity average: } \overline{M}_v = \left(\frac{\Sigma NM^{a+1}}{\Sigma NM}\right)^{1/a}$$

$$\text{weight average: } \overline{M}_w = \frac{\Sigma NM^2}{\Sigma NM}$$

Of course, if a polymer is homogeneous, *i. e.*, all molecules are of the same size, these averages all reduce to the same value. Consequently by assuming that the neoprene fractions were reasonably homogeneous it was possible to calibrate the

viscosity-molecular weight relationship against the osmotic pressure determinations. The only check on homogeneity of the neoprene fractions was obtained on a fraction from a later, similar, careful fractionation, where the osmotic molecular weights ($\overline{M}_n$) of 186,000 and 190,000 in duplicate determinations, were, within experimental error, the same as those ($\overline{M}_w$), 192,000 and 193,000, obtained by light scattering. The excellence of this agreement was probably fortuitous but the results demonstrate that the fraction was essentially homogeneous.

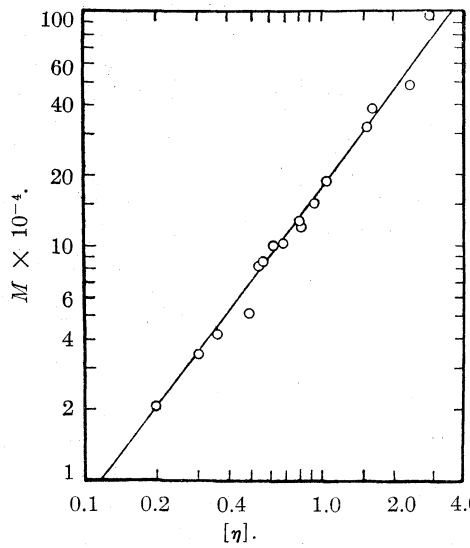

Fig. 5.—Log $\overline{M}_n$ *vs.* log $[\eta]$ for Neoprene Type GN fractions.

The values of $\overline{M}_n$ and $[\eta]$ for fractions A to P are plotted on a log–log scale in Fig. 5. The calculated best straight line is seen to account fairly well for the majority of the experimental points. The equation of this line is $\log M = 5.2466 + 1.367 \log [\eta]$ or $M = 1.76 \times 10^5 [\eta]^{1.37}$ which can be rearranged into the usual form: $[\eta] = KM^a$ where $K = 1.46 \times 10^{-4}$ and $a = 0.73$. A duplicate fractionation of only six fractions gave the equation $[\eta] = 1.26 \times 10^{-4} M^{0.75}$. This expression confirms the one above within experimental error but is less accurate because of the fewer fractions and consequent lower homogeneity of the fractions. It is of interest to note that the exponent "a" has a higher value than the 0.66 reported for GR-S[22] and the 0.67 reported for natural rubber,[23] indicating that polychloroprene chains are somewhat stiffer than those of GR-S or rubber.

Using the data of Table I the weight average and viscosity average molecular weights can be calculated by the above formulas

$$\overline{M}_w = 257{,}000$$
$$\overline{M}_v = 233{,}000$$

The ratio $\overline{M}_v/\overline{M}_w = 0.91$ indicates that the viscosity average approaches the weight average reasonably closely. From $\overline{M}_w/\overline{M}_n = 2.25$ the Lansing and Kraemer[24] non-uniformity coefficient was obtained: $\beta = 1.27$. This value shows that Neoprene Type GN is less homogeneous than sol natural rubber ($\beta = 0.7$)[25] but is more homogeneous than GR-S as indicated by $\beta = 1.60$, calculated from the data of French and Ewart.[22]

A comparison of distribution curves calculated from the non-uniformity coefficients by means of the logarithmic function of Lansing and Kraemer[24] is given in Fig. 6.[26] The neoprene molecular

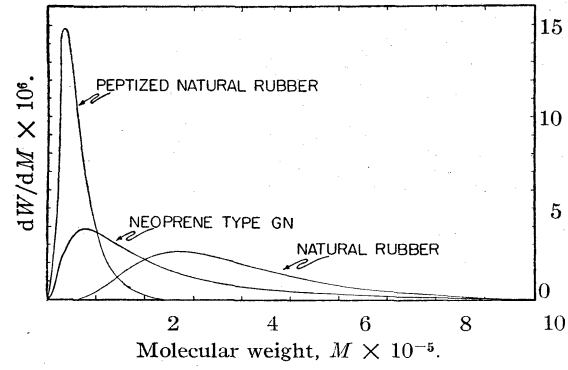

Fig. 6.—Comparison of molecular weight distribution curves for Neoprene Type GN, natural rubber sol and a peptized natural rubber.

weight distribution curve is unlike that of sol natural rubber both in shape and in the molecular weights of the most abundant species, which undoubtedly accounts for some of the differences in physical properties of these rubbers. Natural rubber sol appears to have a somewhat narrower distribution of molecular weights and a more nearly symmetrical curve with a broad maximum at M = 2–300,000. Note, however, that natural rubber peptized with phenylhydrazine[26] exhibits a distribution curve which in shape is more like that of Neoprene Type GN although it does not extend to as high molecular weight as the latter. From the data available it would appear that the distribution curve for GR-S is similar to that of Neoprene Type GN in shape but that the peak occurs at somewhat lower molecular weight.

It is to be noted that the experimental distribution curve for neoprene exhibits a positive skewness and is fairly well represented by the normal logarithmic distribution of Lansing and Kraemer

(25) E. O. Kraemer and J. B. Nichols in T. Svedberg and K. O. Pedersen, "The Ultracentrifuge," Oxford Press, 1940, p. 353. A value of $\beta = 1.0$ is reported here for an early experimental sample of polychloroprene.

(26) Similarly calculated distribution curves based on ultracentrifuge measurements made in this laboratory for GR-S sol rubber, low viscosity (peptized) rubber and an early, experimental sample of neoprene before and after peptization have been published; E. O. Kraemer and J. B. Nichols, *ibid.*, p. 423; L. B. Sebrell, *Ind. Eng. Chem.*, **35**, 736 (1943).

(see Fig. 4). Attempts to apply a two parameter distribution function[27] of the Schulz type to these data have not given particularly consistent results. The Lansing–Kraemer logarithmic distribution is considered a better representation of the data for Neoprene Type GN within the experimental errors of fractionations and molecular weight determinations.

Acknowledgment.—The authors gratefully acknowledge the helpfulness of preliminary experiments on the fractionation of neoprene carried out in this laboratory by Dr. S. L. Scott, now of the Service Department of the du Pont Company. Acknowledgments likewise are made to Dr. F. T. Wall and Dr. H. Mark for many helpful discussions during the course of this research and to Miss B. L. Price for her assistance in the osmotic pressure measurements.

Summary

Polychloroprene rubber, Neoprene Type GN, has been fractionated by partial precipitation from dilute solution in benzene and the fractions examined both osmotically and viscometrically in benzene solutions.

The molecular weight distribution curve for Neoprene Type GN based on osmotic pressure measurements shows a pronounced maximum at 100,000 but has a long extension to molecular weights of over one million, indicating the presence of branched or cross-linked material which is still soluble. The uniformity is somewhat less than that of sol natural rubber, while in shape the neoprene distribution curve resembles more closely that of a peptized natural rubber than fresh sol rubber.

Observed variations in the slopes of the π/c *vs.* c and the η_{sp}/c *vs.* c curves also indicate the presence in solution of complex, branched and/or cross-linked molecules.

Calibration of the intrinsic viscosity-molecular weight relationship by osmotic pressure measurements gave good agreement with the equation $[\eta] = KM^a$, where $K = 1.46 \times 10^{-4}$ and $a = 0.73$.

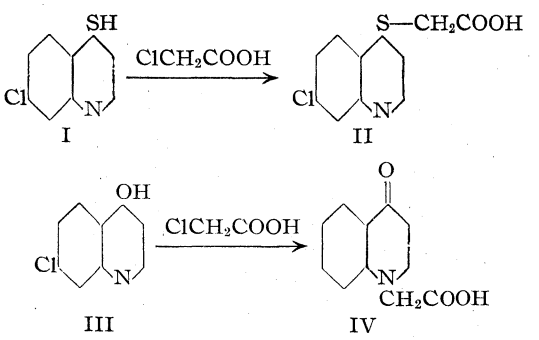
Basic Esters and Amides of 4-Quinolylmercaptoacetic Acid Derivatives

BY ALEXANDER R. SURREY

The present investigation was undertaken to synthesize 4-quinolyloxy-, 4-quinolylamino- and 4-quinolylmercaptoacetic acid derivatives to make them available for pharmacological study.

It was observed that, in alcohol solution, 4,7-dichloroquinoline[1] reacts with thiourea to yield a thiouronium salt which on treatment with sodium carbonate gives 7-chloro-4-quinolinethiol (I) and a small amount of 7,7′-dichloro-4,4′-diquinolylsulfide. The thiol (I) reacts with chloroacetic acid



to give (7-chloro-4-quinolyl)-mercaptoacetic acid (II). The fact that compound II was also obtained by the reaction of 4,7-dichloroquinoline with mercaptoacetic acid indicates that the structure of II must be correct.

The behavior of the thiol, I, with chloroacetic acid is strikingly different from that of the corresponding 4-hydroxyquinoline, III. The reaction of III with chloroacetic acid yields only the 4-keto-1(4)-quinolineacetic acid IV. Similarly, when ethyl chloroacetate was allowed to react with 4-amino-7-chloroquinoline, ethyl 7-chloro-4-imino-1(4)-quinolineacetate (V) was obtained. The formation of IV and V is not unexpected when one considers the known behavior of similar compounds on treatment with alkyl iodide.[2] Hydrolysis of V with 5% sodium hydroxide solution gives the quinolone IV. Both V and the ethyl ester prepared from IV are high melting solids, insoluble in the usual organic solvents. A comparison of the ultraviolet absorption spectra of IV with the mercaptoacetic acid, II, is shown in Fig. 1.[3]

Inasmuch as the 4-amino- and 4-hydroxyquinolines did not give the desired intermediates, the present work was confined mainly to the 4-quinolylmercaptoacetic acid derivatives. The acids (Table I) were prepared from the corresponding 4-chloroquinoline by treatment with mercaptoacetic acid. The basic esters were prepared by ester interchange. Accordingly, the appropriate methyl ester (Table I) was refluxed in Skellysolve

E with an aminoalcohol or a primary tertiary amine, removing the methanol continuously as it formed to yield the basic ester (Table II) or basic amide (Table III). In one instance, the basic ester, diethylaminoethyl-(5-chloro-4-quinolyl)-mercaptoacetate, was prepared by heating the corresponding acid with 1-chloro-2-diethylaminoethane.[4]

Experimental[5]

7-Chloro-4-keto-1(4)-quinolineacetic Acid.—A mixture of 11 g. of 7-chloro-4-hydroxyquinoline, 5.8 g. of chloroacetic acid and 5.4 g. of sodium hydroxide in 32 cc. of water, was heated to dryness in a beaker over a free flame. The solid residue was dissolved in water, filtered hot with charcoal and the filtrate acidified with acetic acid. The separated solid was purified by dissolving in bicarbonate solution, filtering from any insoluble material, and acidifying the filtrate with acetic acid. The yield was 7 g. of a product that melted at 268–269°.

Anal. Calcd. for $C_{11}H_8ClNO_3$: neut. equiv., 237.6. Found: neut. equiv., 237.7.

The ethyl ester was prepared by refluxing 2 g. of the acid in 50 cc. of absolute ethanol containing 2.5 cc. of concentrated sulfuric acid for three hours. It was recrystallized from a large volume of ethanol, m. p. 194–195°.

Anal. Calcd. for $C_{13}H_{12}ClNO_3$: N, 5.27. Found: N, 5.46.

Ethyl 7-Chloro-4-imino-1(4)-quinolineacetate.[6]—A mixture of 5.4 g. of 4-amino-7-chloroquinoline and 4 g. of ethyl chloroacetate in 11 cc. of pyridine was heated on the steam-bath for five minutes, cooled and diluted with water. The product which separated was recrystallized from 100 cc. of ethanol; yield, 3 g., m. p. 265–266° (immersed at 240°).

Anal. Calcd. for $C_{13}H_{13}ClN_2O_2$: N, 10.58. Found: N, 10.37.

Hydrolysis with 5% sodium hydroxide solution gave 7-chloro-4-keto-1 (4)-quinolineacetic acid.

give the yellow thiol which was recrystallized from acetic acid; yield, 12.5 g., m. p. 196–197°.

Anal. Calcd. for C_9H_5ClNS: N, 7.16. Found: N, 6.96.

7-Chloro-4-quinolylmercaptoacetic Acid. Procedure A.—A mixture of 7-chloro-4-quinolinethiol, chloroacetic acid and sodium hydroxide was treated in the same manner as for the 4-hydroxy compound above. The yield was almost quantitative. The acid was purified by solution in 10% sodium carbonate solution followed by precipitation with acetic acid.

Procedure B.—A pyridine solution of 19.8 g. of 4,7-dichloroquinoline and 11 g. of thioglycolic acid was refluxed for three hours, sodium hydroxide added and the pyridine removed by steam distillation. The alkaline solution was treated with acetic acid, the separated solid was heated on the steam-bath with ethanol, and further purified as above; yield 8.5 g. A mixed melting point determination with the acid prepared above showed no depression. Similarly, the methyl esters prepared from both acids were identical.

Procedure C.—The following method was used for the acids described in Table I. Three hundred grams of 4,7-dichloroquinoline, 147 g. of thioglycolic acid and 256 cc. of 35% sodium hydroxide solution in 1.7 liters of absolute ethanol was refluxed with stirring for one hour. The sodium salt of the acid which separated was filtered off, dissolved in water and purified as above. Where the sodium salt failed to separate, refluxing was continued for eight to sixteen hours, the alcohol removed by distillation and the residue dissolved in water and purified as above.

Methyl 7-Chloro-4-quinolylmercaptoacetate.—The methyl esters described in Table I were prepared by refluxing the acids in methanol containing concd. sulfuric acid. The above ester was also prepared from the acid chloride. Five grams of 7-chloro-4-quinolylmercaptoacetic acid and 3.4 g. of phosphorus pentachloride in 100 cc. of dry benzene was refluxed with stirring for one hour. After distilling off the solvent, the residue was refluxed for one hour with methanol. The residue, after removing most of the methanol, was dissolved in water and the solution treated with sodium carbonate solution. The methyl

ester which separated was filtered off and recrystallized from Skellysolve C; yield 2.5 g., m. p. 98–100°.

The **ethyl ester**, after recrystallization from Skellysolve B, melted at 60–61°.

Anal. Calcd. for $C_{13}H_{12}ClNO_2S$: N, 4.97. Found: N, 4.82.

β-Diethylaminoethyl α-(7-Chloro-4-quinolyl)-mercaptopropionate Dihydrochloride.—The procedure described below is the general method used for the preparation of the basic esters described in Table II.

A mixture of one mole of methyl α-(7-chloro-4-quinolyl)-mercaptopropionate and four moles of diethylaminoethanol in Skellysolve E was refluxed with a water separator for about six to twelve hours or until no more methanol separated. The rate of reflux was maintained at such a rate that practically no Skellysolve E was collected along with the methanol. In most cases the theoretical amount of methanol was collected.

The Skellysolve was distilled under reduced pressure and the crude residue was dissolved in ether and washed thoroughly with water. After removing the ether by distillation the residue (60–95% yields) was dissolved in ten volumes of acetone, filtered with charcoal, and to the filtrate was added a slight excess of alcoholic hydrogen chloride. If necessary ether was added to precipitate the hydrochloride. The product was recrystallized from ethanol, yield 45%, m. p. 199–201°.

Anal. Calcd. for $C_{18}H_{23}ClN_2O_2S \cdot 2HCl$: N, 6.37; Cl^-, 16.16. Found: N, 6.05; Cl^-, 15.92.

β-Diethylaminoethyl β-(7-chloro-4-quinolyl)-mercaptopropionate recrystallized from a mixture of isopropanol and acetone, m. p. 175–176.5°.

Anal. Calcd. for $C_{18}H_{23}ClN_2O_2S \cdot 2HCl$: N, 6.37; Cl^-, 16.16. Found: N, 6.20; Cl^-, 15.94.

γ-Diethylaminopropyl 7-chloro-4-quinolylmercaptoacetate recrystallized from isopropanol, yield 60%, m. p. 157.5–158.5°.

Anal. Calcd. for $C_{18}H_{23}ClN_2O_2S \cdot HCl$: N, 6.95; Cl^-, 8.81. Found: N, 6.87; Cl^-, 8.78.

β-Diethylaminoethyl (5-Chloro-4-quinolyl)-mercaptoacetate Hydrochloride.—To a hot suspension of 12.7 g. of 5-chloro-4-quinolylmercaptoacetic acid in 60 ml. of dry isopropanol was added 6.8 g. of 2-chloro-1-diethylaminoethane. After stirring for fifteen minutes a clear solution was obtained. After twenty minutes the contents of the flask solidified, crude yield, 16.5 g., m. p. 177–188°. The product was purified by several recrystallizations from ethanol.

N-2-Diethylaminoethyl 4-Quinolylacetamides (Table III).—The general procedure for the preparation of the basic amides is essentially the same as for the basic esters described above. The appropriate methyl ester (0.1 mole) was refluxed with 0.2 mole of N,N-diethylethylenediamine in 200 cc. of Skellysolve E for about eight hours or until no more methanol was collected. In most instances, a solid product was obtained after removal of the solvent under reduced pressure. These amides could be recrystallized from one of the Skellysolve fractions. The hydrochlorides were prepared in the usual manner.

Acknowledgment.—The author wishes to acknowledge the technical assistance of Miss Marcia Rukwid. The analyses reported were performed by the analytical staff of this Institute.

Summary

The reaction of 7-chloro-4-hydroxyquinoline or 4-amino-7-chloroquinoline with chloroacetic acid or ethyl chloroacetate results in the formation of 1-quinolineacetic acid derivatives. Under similar conditions, 7-chloro-4-quinolinethiol yields the corresponding 4-quinolylmercaptoacetic acid.

The preparation of several 4-quinolylmercaptoacetic and propionic acid derivatives is reported.

Allyl Ethers of Carbohydrates. VI. Polymerization of Allyl Ethers

BY A. N. WRIGLEY AND E. YANOVSKY

The second paper of this series[2] presented data on the gelation time for a number of allyl ethers of polyhydroxy compounds. A rather guarded opinion was expressed regarding the relation between the number of allyl groups in the molecule and the gelation time of the ether, but more direct evidence on this subject was desirable. Experiments with mannitol of different degrees of allylation show clearly the difference in the rate of polymerization of these compounds. Another point of interest is the relation between the configuration and the polymerization rate of isomeric compounds. In the article cited, the gelation time of two such compounds—hexaallylmannitol (220 minutes) and hexaallylsorbitol (240 minutes)—seemed to be identical within experimental error. Similar results were obtained for another pair of isomeric compounds, allyl tetraallyl-α-D-glucoside (274 minutes) and allyl tetraallyl-α-D-galactoside (283 minutes).[3] It seemed desirable, however, to verify this point with a larger number of compounds. Accordingly, besides some of those previously reported, a number of new compounds were made, such as allylated derivatives of erythritol, xylitol, arabitol, dulcitol, talitol and iditol,[4] and their gelation time and the rate of oxygen absorption were measured. And finally some theoretical considerations regarding the polymerization of allyl ethers are presented.

To study the gelation of allyl-D-mannitol of different degrees of allylation, hexaallyl-D-mannitol was prepared as described previously.[2] Approximately tetraallyl-D-mannitol was prepared essentially by the same method but with less concentrated alkali, and 3,4-diallyl-D-mannitol was made by allylating 1,2:5,6-diisopropylidene-D-mannitol, and removing the isopropylidene groups by hydrolysis with dilute hydrochloric acid. Diallylmannitol is a crystalline compound.[5] The gelation time for the three compounds was determined at 120° (above the melting point of diallylmannitol), with oxygen bubbling through at the rate of 7.5 liters per hour. The gelation time was 95 minutes for hexaallylmannitol, 165 minutes for the tetraallyl compound, and 425 minutes for the disubstituted mannitol. This clearly shows that increase in the degree of allylation (for the same compound) reduces the time of gelation.

The rate of oxygen absorption and the gelation time of various completely allylated sugar alcohols at 80° are given in Table I. All the figures in the table represent an average of two or more well agreeing results. It will be observed that with the increase of the chain from 3 to 6 carbons the gelation time decreased from 974 minutes for allyl glycerol to 900 for erythritol, to 602 for pentitols, and to 502 for the hexitols.

TABLE I

GELATION TIME AND OXYGEN ABSORPTION OF ALLYL ETHERS AT 80°

Compound	Gelation time	Oxygen absorption (micrograms per gram per minute)
Triallylglycerol	974	158
Tetraallylerythritol	900	83
Pentaallylxylitol	504	92
Pentaallyl-D-arabitol	700	91
Hexaallyl-D-mannitol	466	77
Hexaallyl-D-sorbitol	474	74
Hexaallyldulcitol	565	77
Hexaallyl-D-talitol	...	85
Hexaallyl-L-iditol	...	81

On the other hand, the rate of oxygen absorption decreased gradually (with the exception of erythritol) from 158 micrograms per gram per minute for glycerol to 92 for pentitols and 79 for hexitols. It is not clear at present why allylxylitol gels faster than allylarabitol or why allyldulcitol gels more slowly than either allylsorbitol or allylmannitol.

In a previous paper[2] Nichols and Yanovsky proposed a scheme based on the hydroperoxide theory of Criegee, Pilz and Flygare and of Farmer and Sundralingam to explain the oxidative polymerization of allyl ethers. It explained satisfactorily the presence of peroxide, epoxide[6] and acrolein during oxidation of allyl ethers. In addition to these products, water appears during the process of gelation. Thus in one experiment 200 g. of hexallylmannitol was heated at 80°, while oxygen was passed through the liquid. The outgoing oxygen was led through two traps immersed in solid carbon dioxide–chloroform–carbon tetrachloride mixture. About 4.4 g. of liquid was collected

(5) Incidental to the preparation of diallylmannitol, some monoallyl-D-mannitol was obtained, which from the method of preparation was judged to be 3-allyl-D-mannitol. Malaprade's reaction (*Bull. soc. chim.*, [4] **43**, 683 (1928); [5] **4**, 906 (1937)), was used to confirm the position of the substituent. A water solution of 0.5556 g. of the monoallylmannitol was treated with 20 ml. of 0.4070 *M* aqueous sodium metaperiodate and diluted to 50 ml. After three hours, 5 ml. and 20 ml. aliquots were titrated for periodate and formic acid, respectively. For each mole of monoallylmannitol, 3.24 moles of periodate were consumed and 1.12 moles of formic acid formed. Somewhat higher results than expected theoretically are due to a reaction between the periodate and the allyl group.

in the traps. The analysis showed that the liquid had about 60% acrolein and about 30% water. Clover[7] found that hydroperoxides of ethers can break down, with the formation of an ester and water. In the case of ethyl benzyl ether hydroperoxide, the principal decomposition product was ethyl benzoate. It is evident that if a similar reaction takes place in allyl ethers, it will proceed according to the equation

$$R{-}O{-}\underset{\displaystyle OOH}{\underset{|}{CH}}{-}CH{=}CH_2 \longrightarrow H_2O + CH_2{=}CH{-}COOR$$

In other words, formation of acrylic ester might be expected.

This hypothesis was put to a test. Allylmannitol (113 g.) was heated at 80° while oxygen was passed through the liquid. The process was stopped at about three-quarters of the way to gelation. Determination of ester equivalent gave the figure 764, corresponding to 9.3% acrylate, or about 0.5 acrylate group per mole of the original allylmannitol. An attempt to identify the acrylic acid as its *p*-bromophenacyl ester was unsuccessful, perhaps because most or all of the acrylate was in a polymerized state. Acrylic ester, if present, probably takes part in the polymerization of allyl ethers.

Experimental

Preparation of 3,4-Diallyl-D-mannitol.—1,2:5,6-Diisopropylidene-D-mannitol was prepared according to directions of Baer.[8] The crude product (m. p., 116–117° as compared with 122° for the recrystallized material) was used for the preparation of 3,4-diallyl-1,2:5,6-diisopropylidene-D-mannitol.

To a well-stirred mixture of 122 g. of diisopropylidene mannitol in 150 ml. of dioxane and 452 g. of allyl bromide heated at 80–85°, 298 g. of 50% sodium hydroxide solution gradually was added during thirty minutes. The heating and stirring was continued for six hours. The organic layer was dried with anhydrous sodium sulfate, and its volatile constituents were removed by distillation at atmospheric pressure. The residue was distilled *in vacuo*, and the fraction distilled at 110–118° at about 1 mm. was collected. The yield was 132 g. of crude diallyl-diisopropylidene-mannitol.

Anal. Calcd. for $C_{18}H_{30}O_6$: allyl, 24.0; isopropylidene, 24.6. Found: allyl, 27.6; isopropylidene,[9] 26.1.

Without further purification this substance was used for the preparation of diallylmannitol. One part of diallyl-diisopropylidene-mannitol was hydrolyzed in eight parts of 50% alcohol containing 0.2% hydrochloric acid at 70°.[10] After eight hours the hydrochloric acid was removed with silver oxide. The precipitate was filtered off and the filtrate evaporated to dryness, yielding 104 g. of crude diallylmannitol from 129 g. of crude diallyl-diisopropylidene-mannitol. The product was purified by dissolving one part in five parts of hot methyl alcohol. Eighteen parts of hot benzene and some decolorizing carbon were added. After removing most of the methyl alcohol by azeotropic distillation, the solution was filtered and allowed to crystallize. After two recrystallizations a constant melting point, 111–112° (cor.), was reached. Diallylmannitol is soluble in water, methyl and ethyl alcohol, pyridine and glacial acetic acid but insoluble in benzene, toluene, ether and hexane. $[\alpha]^{25}D$ for a 4% solution was +42.3° in absolute alcohol and +44.7° in water.

Anal. Calcd. for $C_{12}H_{22}O_6$: hydroxyl, 25.9; allyl, 31.3; C, 54.9; H, 8.45. Found: hydroxyl, 26.4; allyl, 30.1; C, 54.8; H, 8.55.

Preparation of Monoallyl-D-mannitol.—Sixty grams of crude diallylmannitol was dissolved in 100 ml. of hot methyl alcohol, and the solution was clarified with decolorizing carbon. To the boiling solution 800 ml. of hot benzene was gradually added. Boiling was continued for a while after the entire amount of benzene was added. When the total volume was about 800 ml., the solution was allowed to crystallize. The next day 13.5 g. of crystals was filtered off. On further evaporation the solution yielded crystals of diallylmannitol. The 13.5 g. of crystals was dissolved in 80 ml. of boiling methyl alcohol to which 900 ml. of boiling benzene was added. On cooling, 6.5 g. of crystals was obtained, which on one recrystallization gave a constant melting point, 119–120° (cor.); $[\alpha]^{25}D$ for a 4% solution in water was +15.8°. On further evaporation of the filtrate, 4.5 g. of diallylmannitol was obtained.

Anal. Calcd. for $C_9H_{18}O_6$: hydroxyl, 38.3; allyl, 18.5; C, 48.6; H, 8.16. Found: hydroxyl, 37.1; allyl, 18.1; C, 48.4; H, 7.94.

Preparation of Tetraallyl-D-mannitol.—Allylmannitol with approximately four allyl groups was prepared by adding gradually (half an hour) 448 g. of allyl bromide to a stirred and heated (75°) mixture of 56 g. of mannitol and 740 g. of 20% sodium hydroxide solution. The mixture was then stirred and heated for three hours more, after which it was worked up in the usual manner. It yielded 38% of the theoretical value of a product boiling at 159–162° (1 mm.). Analytical results, 46.4% allyl and 11.2% hydroxyl, indicate the presence of 3.8 allyl groups.

Allylation of Polyhydric Alcohols.—Completely allylated sugar alcohols not described previously were prepared by the two-step method described in an earlier paper.[2] In some cases (talitol, for example, where only a small quantity of substance was available) a larger excess of allyl bromide was used to increase the volume of liquid for better stirring and handling. The physical properties and analytical results for these compounds are given in Table II.

Determination of Water.—The water in the acrolein–water mixture was determined with acetylpyridinium chloride reagent.[11]

Determination of Acrolein.—The acrolein was determined by the sulfite method.[12]

Determination of Ester Equivalent.—The ester equivalent was determined—by C. O. Willits and M. S. Gaspar of this Laboratory—by refluxing partially polymerized allyl ether with 0.2 *N* alcoholic sodium hydroxide, for one hour, continuing the refluxing for another hour after an equal amount of water had been added, and titrating the excess alkali electrometrically with 0.1 *N* acid.

Determination of Allyl Groups.—For completely substituted compounds the mercuric acetate modification of the Wijs method[13] gave the most accurate results.

Summary

Completely substituted allyl ethers of erythritol, xylitol, arabitol, dulcitol, talitol and iditol were prepared. With the increase of the chain from three to six carbons, the gelation time decreased, from 974 minutes for allylglycerol to 900 for erythritol, to 602 for pentitols, and 502 for hexitols. On the other hand, the rate of oxygen absorption decreased with the increase of the length of carbon chain. The relation between the configuration and the time of gelation of isomeric allyl ethers is not quite clear. The possibility of the formation of acrylic ester during the oxidative polymerization of allyl ethers is suggested.

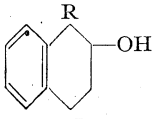
1-Alkyl-1,2,3,4-tetrahydro-2-naphthols

BY B. C. McKUSICK[1a]

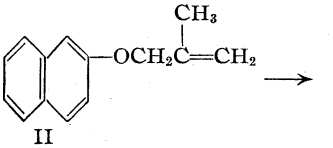
Following the finding that 1,2,3,4-tetrahydro-2-naphthol is an outstanding mosquito-repellent, several of its esters and four of its 1-alkyl homologs (I) were prepared as part of a project sponsored by the Office of Scientific Research and Development (1b) for the synthesis of new insect-repellents. The tetrahydronaphthols were prepared by hydrogenation of the corresponding 1-alkyl-2-naphthols over copper chromite.[2,3,4] The reductions were not perfectly cleancut; decahydro-2-naphthols and probably 5,6,7,8-tetrahydro-2-naphthols were by-products.



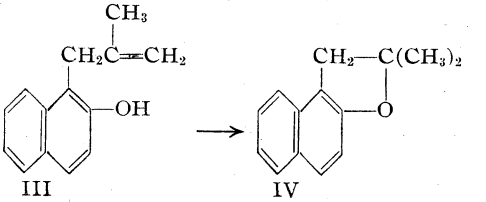
I

The 2-naphthols were synthesized by standard methods, such as reduction of 1-allyl-2-naphthol or 1-acyl-2-naphthols obtained, respectively, by the Claisen or Fries rearrangement. When an attempt was made to hydrogenate 1-*n*-butyro-2-naphthol to 1-*n*-butyl-2-naphthol over copper chromite at 130°, a major reaction was carbon–carbon hydrogenolysis to 2-naphthol and *n*-butanol. In contrast, 1-aceto-2-naphthol is reduced to 1-ethyl-2-naphthol under the same conditions.[2] Clemmensen reduction gave 1-*n*-butyl-2-naphthol in satisfactory yield.

Although allyl-2-naphthyl ether underwent a Claisen rearrangement in the normal manner, the product obtained on heating β-methylallyl-2-naphthyl ether (II) was not the expected 1-(β-methylallyl)-2-naphthol (III), but a neutral substance believed to be the isomeric dihydronaphthofuran (IV). It has been observed previously[5] that 2-(β-methylallyl)-phenols cyclize to dihydrobenzofurans much more readily than do 2-allylphenols.



II



III IV

Esters were prepared from 1,2,3,4-tetrahydro-2-naphthol and its 1-methyl homolog by treating them with acid anhydrides.

[a] Bamberger and Lodter, *Ber.*, **23**, 197 (1890). [b] Pickard and Kenyon, *J. Chem. Soc.*, **101**, 1427 (1912), prepared the *l*-ester. [c] Did not crystallize; Musser and Adkins[2] report m. p. 88–89°.

Experimental

1-Alkyl-2-naphthols.—1-Methyl-2-naphthol was obtained in 65% yield by heating 1,1-methylene-bis-(2-naphthol) with sodium methoxide[6]; it was isolated by distillation rather than extraction with hot water. 1-Ethyl-2-naphthol[7] was prepared from 1-aceto-2-naphthol by high-pressure hydrogenation over copper chromite at 130°.[2] 1-*n*-Propyl-2-naphthol,[8] m. p. 55–57° (recrystallized from hexane), was obtained in 91% yield by low-pressure hydrogenation of 1-allyl-2-naphthol[9] in 95% ethanol at 25° in the presence of Adams platinum oxide catalyst. 1-*n*-Butyl-2-naphthol, m. p. 82–83°, was prepared by the Clemmensen reduction of 1-*n*-butyro-2-naphthol.[8]

1-Alkyl-1,2,3,4-tetrahydro-2-naphthols.—These were obtained by hydrogenation of the corresponding 2-naphthols in the presence of copper chromite catalyst at 200° under hydrogen pressures of 3000–5000 lb./sq. in.[2,3,4] The hydrogenations were generally complete in two to five hours. They were equally successful with or without a solvent; usually none was used, but an equal volume of absolute ethanol was sometimes added. The weight of catalyst was 5–15% of the weight of naphthol. For the best results it was desirable to distil the naphthols over 2% by weight of Raney nickel before hydrogenation. Alternatively, poisons could be removed from a naphthol by shaking it at 200° with copper chromite and hydrogen under high pressure; one had then but to add a fresh batch of catalyst to the mixture and hydrogenate in the usual way.

To work up a reaction mixture,[4] it was diluted with an equal volume of benzene, the catalyst was removed by filtration, and the filtrate was extracted several times with 10% sodium hydroxide solution (no final washing with water), dried with magnesium sulfate, and distilled through a short Vigreux column.

In the case of 1-methyl-2-naphthol as with 2-naphthol,[4] there was no tendency for the reduction to go beyond the tetrahydro stage. The higher homologs slowly took up hydrogen after the calculated quantity had been absorbed and it was apparent from the fact that the fore-runs had lower indices of refraction than the main cuts that some decahydronaphthol had been formed. Contrary to experience in the preparation of 1,2,3,4-tetrahydro-2-naphthol,[4] the after-runs and residues from the distillations usually contained some unchanged starting material.

Some of the final products may well have contained several per cent. of impurities. In the first place, in contrast to the situation in the preparation of 1,2,3,4-tetrahydro-2-naphthol,[4] it was difficult to extract unchanged starting material or isomeric 5,6,7,8-tetrahydro-2-naphthol with alkali, the difficulty increasing with molecular weight. Secondly, purification by distillation was hindered by the closeness in boiling points of a product and its possible impurities, *i.e.*, the decahydronaphthol (boiling point lower), the naphthol (boiling point higher), and most troublesome of all, the isomeric 5,6,7,8-tetrahydro-2-naphthol (boiling point about the same). The presence of 5,6,7,8-tetrahydro-2-naphthols was not actually demonstrated in the present reductions but their presence is probable from the fact that 6–10% of one is formed during the hydrogenation of 2-naphthol under the same conditions.[4]

The tetrahydronaphthols together with their properties are listed in Table I.

1,2,3,4-Tetrahydro-2-naphthyl Esters.—The acetate, propionate and butyrate of 1,2,3,4-tetrahydro-2-naphthol[4] and the acetate of 1-methyl-1,2,3,4-tetrahydro-2-naphthol were prepared by heating the alcohols with a 20% excess of the proper anhydride for several hours on a steam-bath and distilling the reaction mixtures under reduced pressure. The properties of the esters are listed in Table I.

1,2-Dihydro-2,2-dimethylnaphtho[2,1-b]furan (IV).—β-Methylallyl chloride (139 g.) was added to a well-stirred mixture of 200 g. of 2-naphthol, 79 g. of 95% sodium methoxide, 3 g. of potassium iodide and 1 liter of methanol in an ice-bath. The mixture stood at room temperature for several days, was diluted with water, and the oil which precipitated was taken up in ether. The extract was washed successively with 10% sodium hydroxide solution and water, dried and distilled. The crude β-methylallyl 2-naphthyl ether (II), 142 g. of material distilling at 90–137° (0.3 mm.), was heated at 200° under nitrogen for six hours and distilled. The product was collected at 96–99° (0.3 mm.), $n^{25}D$ 1.6024, weight 100 g. (36% yield based on 2-naphthol). It was insoluble in Claisen[10] alkali, did not reduce dilute potassium permanganate in acetone, and only very slowly decolorized bromine in carbon tetrachloride. No hydrogen was absorbed when an alcohol solution was shaken with hydrogen at 25° and a pressure of 3 atm. in the presence of Adams platinum oxide catalyst. *Anal.* Calcd. for $C_{14}H_{14}O$: C, 84.8; H, 7.1; Found: C, 84.4; H, 7.6.

Hydrogenolysis of 1-*n*-Butyro-2-naphthol.—A mixture of 35.8 g. of 1-*n*-butyro-2-naphthol[8] and 4 g. of copper chromite catalyst was heated at 130° under an initial hydrogen pressure of 4000 lb./sq. in. Approximately

two molar equivalents of hydrogen was absorbed in twenty minutes, after which no more was absorbed. The reaction mixture was taken up in acetone, filtered and distilled. Redistillation of the fore-run gave 3.4 g. of *n*-butanol (27% yield), identified by odor, boiling point (116.5–117.5°) and refractive index ($n^{25}D$ 1.3970). The amount obtained was less than the actual yield due to accidental loss of part of the fore-run. The main distillate, a solid weighing 24 g., was collected at 117–146° (1.0 mm.). It proved to be a mixture of 2-naphthol and 1-*n*-butyl-2-naphthol, with over half of it by weight the former. Fairly pure samples of each, melting at 120–121° and 77–80°, respectively, were isolated by fractional crystallization from hexane, but complete separation by this means was not practical.

Summary

Four 1-alkyl-1,2,3,4-tetrahydro-2-naphthols have been prepared by hydrogenation of the corresponding 1-alkyl-2-naphthols over copper chromite.

Instead of undergoing the Claisen rearrangement, β-methylallyl 2-naphthyl ether rearranges to what is believed to be a dihydronaphthofuran. Hydrogenation of 1-*n*-butyro-2-naphthol gives *n*-butanol and 2-naphthol besides the expected 1-*n*-butyl-2-naphthol.

Arylcycloalkylamines. I. 2-Phenylcyclopropylamine

BY ALFRED BURGER AND WILLIAM L. YOST[1]

Both 1-phenyl-2-aminopropane and 1-amino-2-phenylpropane exhibit such striking effects on the central nervous system that structural variations of these drugs have received wide attention. It appeared of interest to investigate what changes in the pharmacological action of these drugs would result from the incorporation in a ring of the two-carbon chain separating the aryl from the amino group. The cyclopropyl ring was chosen as the first example because of the known analgesic and anesthetic properties of cyclopropane, cyclopropyl methyl ether (Cyprome), cyclopropyl ethyl ether (Cypreth), cyclopropylcarbinol, and related compounds.[2] It has been suggested[3] that "alicyclic residues might confer desirable pharmacological properties if introduced into compounds containing auxapharm groups. . . ." The auxapharm group in the compounds under consideration in this article is the phenethyl group.

The synthesis of the geometrically isomeric 2-phenylcyclopropylamines is reported here. The starting material was ethyl 2-phenylcyclopropanecarboxylate which had first been obtained by Buchner and Geronimus[4] from the condensation of styrene with ethyl diazoacetate. These authors heated the reagents in a sealed tube and had to cope with the high pressures of nitrogen from the reaction. These conditions were improved in the present work by slowly dropping a stoichiometric mixture of the diazo ester and styrene into an excess of styrene at 125°. Fractionation of the reaction mixture yielded from 75 to 85% of ethyl 2-phenylcyclopropanecarboxylate as a colorless oil of b. p. 103–105° (0.5–0.7 mm.).

Buchner and Geronimus hydrolyzed their ester to an acid of m. p. 105° to which they assigned the structure of *trans*-2-phenylcyclopropanecarboxylic acid. They arrived at this conclusion by nitrating their acid, reducing the nuclear nitro group, and oxidizing the resulting aminophenylcyclopropanecarboxylic acid with permanganate to *trans*-cyclopropanedicarboxylic acid. When we saponified our ester, a mixture of two isomeric carboxylic acids was always obtained which could be separated by fractional crystallization from water. The less soluble material, which we designate as 2-phenylcyclopropanecarboxylic acid A, crystallized as slender needles, m. p. 93°, and represented 74% of the total mixture.

Benzene extraction of the mother liquors of this acid yielded about 13% of a material melting at 106–107° for which we propose the name of 2-phenylcyclopropanecarboxylic acid B. Its identity with that described by the earlier investigators was corroborated by conversion of its chloride to the amide of m. p. 187–188° [190–191°(cor.)]. The amide reported in the literature[4] melts at 187–188°.

The relation of the two acids was established when it was found that the acid chloride of either product may be hydrolyzed to the A-acid, or ammonolyzed to the same amide of m. p. 190–191°. This indicates that the B-acid is probably inverted by thionyl chloride to the same acid chloride as that obtained from the A-acid, but the less likely possibility must be considered that a B-acid chloride first formed is inverted to derivatives of the A-series by hydrolysis or ammonolysis. These observations coupled with the predominant formation of the A-acid in their preparation from styrene, permit the conclusion that the acid of m. p. 93° is the more stable of a pair of geometrical isomers. It should be noted that the amide described by Buchner and Geronimus is a derivative of the lower-melting isomer they never isolated.

We considered the possibility that the addition of ethyl diazoacetate to styrene might have led to esters containing the ethylenic bond. This is, however, unlikely because the presence of the cy-

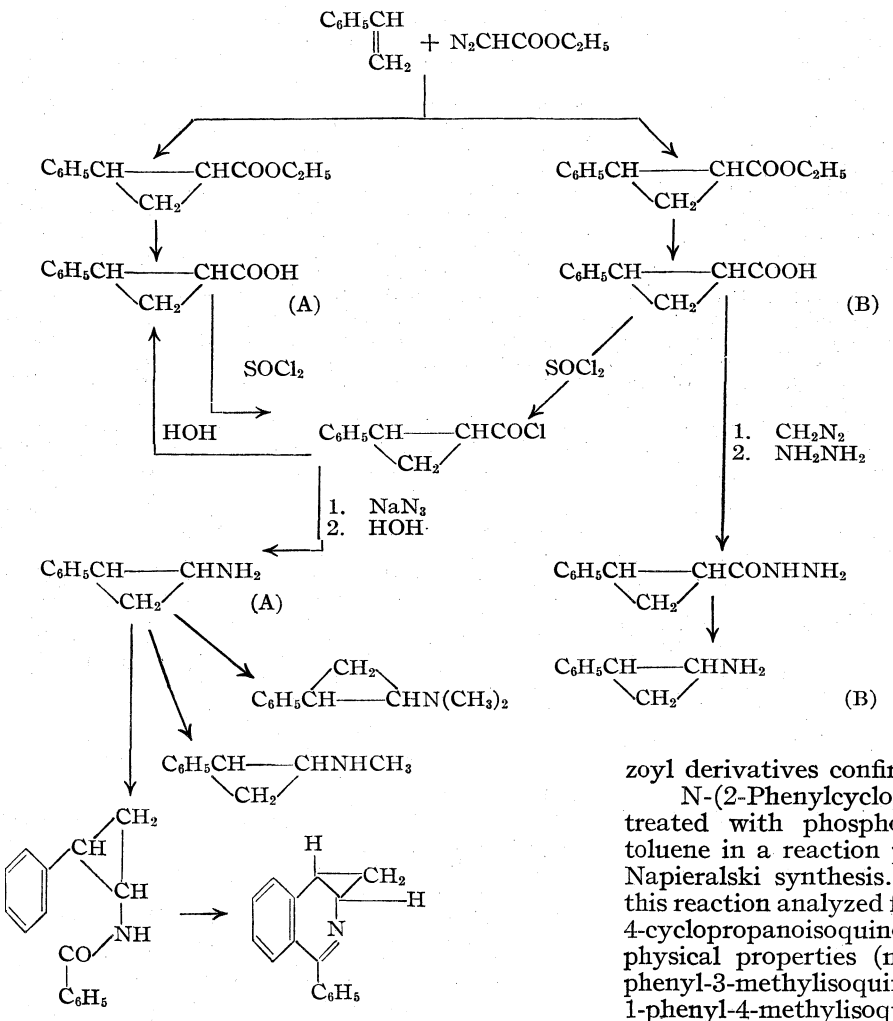
(4) Buchner and Geronimus, *Ber.*, **36**, 3782 (1903).



clopropane ring system had already been established[4] for the acid melting at 106–107°, and the acid A can be obtained from it by means of reagents which are known not to open the cyclopropane ring.

The absolute configuration of the isomeric 2-phenylcyclopropanecarboxylic acids has not been established with certainty. The greater stability of the A-isomer casts some doubt on the previous assignment of the *trans* configuration to the B-isomer. The isomerization of the higher- to the lower-melting isomer by thionyl chloride is in accord with the general ease of conversion of *cis* to *trans* isomers by acids, acid halides, etc.

2-Phenylcyclopropane carboxamide A withstood Hofmann degradation under a number of experimental variations, and no amine could be obtained in this manner. Likewise, the A-acid (m. p. 93°) did not respond to the Schmidt reaction. However, it was found possible to subject its chloride to the Curtius degradation with sodium azide in boiling toluene; the isocyanate formed by this procedure was hydrolyzed readily to an oily 2-phenylcyclopropylamine which was characterized as the hydrochloride and benzoyl derivative. The yield of amine was 83%.

Since acid B furnishes the same chloride as its stereoisomer, it could obviously not be degraded to the amine of its own configuration by the same procedure. It was possible, however, to convert the methyl ester of acid B to a crystalline hydrazide which differed from the hydrazide of acid A prepared for comparison. Diazotization of the B-hydrazide, thermal rearrangement of the azide, and hydrolysis of the isocyanate led to a new 2-phenylcyclopropylamine, different from that obtained by Curtius degradation of acid A. The properties of the hydrochloride and benzoyl derivatives confirmed this difference.

N-(2-Phenylcyclopropyl)-benzamide A was treated with phosphorus pentoxide in boiling toluene in a reaction patterned on the Bischler–Napieralski synthesis. The base obtained from this reaction analyzed for 1-phenyl-3,4-dihydro-3,-4-cyclopropanoisoquinoline. It differed in its physical properties (m. p. 109.5–110°) from 1-phenyl-3-methylisoquinoline (m. p. 89–90°)[5] and 1-phenyl-4-methylisoquinoline [liquid, b. p. 210° (20 mm.)][6] which might have conceivably been formed by rearrangement.

Methyl-(2-phenylcyclopropyl)-amine was prepared from 2-phenylcyclopropylamine A by the Decker method,[7] and dimethyl-(2-phenylcyclopropyl)-amine by methylation of the primary amine with formaldehyde and formic acid.

The pharmacological action of the amines described in this article will be reported by Dr. E. J. Fellows of Temple University Medical School.

Acknowledgment.—We are grateful to Smith, Kline and French Laboratories for a generous grant which made this investigation possible.

Experimental[8]

Ethyl 2-Phenylcyclopropanecarboxylate.—This ester was prepared by a modification of the directions of Buchner and Geronimus.[4] A solution containing 167 g. (1.61 moles) of stabilized styrene and 183 g. (1.61 moles) of

(8) All melting points are corrected. The microanalyses were performed by Clark Microanalytical Laboratories, Urbana, Illinois.

ethyl diazoacetate was cooled to 0° and dropped into 83.5 g. (0.803 mole) of styrene with stirring, in a dry nitrogen atmosphere, at 125–135°. The rate of addition was so adjusted that the exothermic reaction held the temperature without heating. After eight hours, the gas evolution stopped, and the pale reddish mixture was distilled. A low-boiling fraction consisting largely of unchanged styrene (41% of the total amount used) was separated, and the ester was collected. It boiled at 103–105° (0.5–0.7 mm.), 105–110° (1–2 mm.), or 131° (10 mm.). The yield was 208 g. (68% based on ethyl diazoacetate, 77% based on unrecovered styrene).

2-Phenylcyclopropanecarboxylic Acid A.—A solution of 207.8 g. of the ester and 64.5 g. of sodium hydroxide in 80 cc. of water and 600 cc. of ethanol was refluxed for nine hours, the alcohol was removed by distillation, and the residue was dissolved in water. The carboxylic acid was liberated with 200 cc. of concentrated hydrochloric acid. It precipitated as an oil which solidified soon, or directly as crystals which were filtered and washed with water. The amber solid was recrystallized from boiling water in which it is soluble to about 1%.

The cooled solution deposited 131.6 g. (74.5%) of colorless felted needles which melted, after further recrystallization, at 93°.

Anal. Calcd. for $C_{10}H_{10}O_2$: C, 74.05; H, 6.22; mol. weight, 162.2. Found: C, 74.24; H, 6.35; mol. weight, 161.8.

2-Phenylcyclopropanecarboxylic Acid B.—When the aqueous mother liquors from the recrystallization of the A-acid were concentrated and extracted with benzene, addition of low-boiling petroleum ether to the extract caused precipitation of compact crystals. The material weighed 12–13% of the calculated amount and melted, after recrystallization from boiling water, or benzene-petroleum ether, at 106–107°.

Anal. Calcd. for $C_{10}H_{10}O_2$: C, 74.05; H, 6.22; mol. wt., 162.2. Found: C, 74.27; H, 6.09; mol. wt., 161.7.

2-Phenylcyclopropanecarbonyl Chloride.—A solution of 4.62 g. (0.0285 mole) of 2-phenylcyclopropanecarboxylic acid A or B in 15 cc. of dry benzene was refluxed with 4 cc. (*ca.* 0.057 mole) of thionyl chloride for five hours, the volatile liquids were removed, and the residue once more distilled with benzene. Fractionation of the residue yielded 4.82 g. (93.6%) of a colorless oil boiling at 108–110° (2–2.1 mm.).

Hydrolysis of the acid chloride with cold water always furnished a quantitative yield of the pure A-acid, m. p. 93°.

2-Phenylcyclopropanecarbonamide A.—When the acid chloride just described was mixed with ice-cold 20% ammonium hydroxide, the amide formed in a yield of 81%. Recrystallized from boiling water, the pale brown platelets melted at 190–191°.

The mixture melting point of the amides obtained independently from the A- or B-acid *via* their common chloride showed no depression.

2-Phenylcyclopropanecarboxylic Acid Hydrazide A.—A solution of 0.9 g. of methyl 2-phenylcyclopropanecarboxylate A ($n^{27.5}D$ 1.5263, prepared from the acid with diazomethane in almost quantitative yield) and 15 cc. of 100% hydrazine hydrate in 2 cc. of absolute ethanol was refluxed gently for five hours, and most of the liquid removed under reduced pressure. The residue was dried in a vacuum desiccator over phosphorus pentoxide, and recrystallized from absolute ethanol with the aid of some dry ether. The yield of colorless crystals was 0.75 g. (84%), m. p. 127.5–129.5°.

Anal. Calcd. for $C_{10}H_{12}N_2O$: N, 15.90. Found: N, 15.97, 16.15.

2-Phenylcyclopropylamine A.—A three-necked flask was equipped with a mercury-sealed stirrer, a dropping funnel, and a reflux condenser, and the condenser was connected, through a drying tube, with an azotometer arranged to collect nitrogen over water. A mixture of 15 g. of *technical* sodium azide[9] and 50 cc. of dry toluene was stirred and warmed and a solution of 10 g. of 2-phenylcyclopropanecarbonyl chloride in 50 cc. of dry toluene was added slowly. Evolution of nitrogen began almost immediately and was essentially complete when the solvent began to boil. After forty minutes 96 to 98% of nitrogen had collected in the azotometer.

Inorganic salts were filtered and washed well with dry benzene, and the solvents were removed under reduced pressure. The residual isocyanate was a clear red oil of characteristic odor. It was cooled to 10°, and treated cautiously with 100 cc. of 35% hydrochloric acid in small portions with shaking. After most of the evolution of carbon dioxide had subsided the mixture was refluxed for thirteen hours, the cooled solution was diluted with 75 cc. of water and extracted with three 50-cc. portions of ether. The acid solution was evaporated under reduced pressure with occasional additions of toluene to reduce foaming.

The almost dry residue was cooled to 0°, and made strongly alkaline with a 50% potassium hydroxide solution. The amine was extracted into several portions of ether, dried over potassium hydroxide, the solvent was removed, and the base fractionated. The colorless mobile oil boiled at 69–71° (0.5 mm.), 74–81° (1.7 mm.), and weighed 6.15 g. (83%).

Conversion to the hydrochloride proceeded best in ethyl acetate–ether solution. Over-neutralization had to be avoided because of the formation of yellow decomposition products. The crude salt, obtained in a yield of 95%, was recrystallized by dissolving it in the least amount of cold methanol, and precipitating with absolute ethyl acetate and ether. The colorless needles thus obtained sintered at 151.5°, m. p. 153.5–156.5° (dec.).

Anal. Calcd. for $C_9H_{12}ClN$: C, 63.71; H, 7.13; N, 8.26; Cl, 20.90. Found: C, 63.55; H, 7.53; N, 8.13; Cl, 21.05.

The **benzoyl derivative** was prepared by a Schotten-Baumann reaction. The colorless crystals were recrystallized from absolute methanol, m. p. 122–123.5°.

Anal. Calcd. for $C_{16}H_{15}NO$: N, 5.90. Found: N, 6.03.

2-Phenylcyclopropanecarboxylic Acid Hydrazide B.—Methyl 2-phenylcyclopropanecarboxylate B was prepared from the acid with diazomethane in a yield of 92%. The oily ester showed $n^{29}D$ 1.5215. The hydrazide was obtained from the ester in the same manner as the A-isomer. The yield was 83.8%. The colorless crystals, collected from alcohol–ether, melted at 111–112°. The **hydrochloride** melted at 188–191°.

Anal. Calcd. for $C_{10}H_{13}ClN_2O$: N, 13.16. Found: N, 13.17.

The **isopropylidene derivative**, prepared from the hydrazide and acetone, melted at 166–166.5°.

Anal. Calcd. for $C_{13}H_{16}N_2O$: N, 12.95. Found: N, 13.18.

2-Phenylcyclopropylamine B.—To a stirred solution of 7.5 g. of the B-hydrazide in 70 cc. of water and 20 cc. of 35% hydrochloric acid, a solution of 3.6 g. of sodium nitrite in 10 cc. of ice water was added at −3° to +5°. A yellow oil precipitated from the mixture. After another ninety minutes at 0 to 5°, the mixture was extracted with four 30-cc. portions of ether, the combined extracts were dried over sodium sulfate, and the ether was removed at 20°. The light red residue was dissolved in toluene and decomposed by heating until the evolution of nitrogen ceased. The solvent was stripped under reduced pressure, the dark isocyanate hydrolyzed by refluxing with 25 cc. of 35% hydrochloric acid for five and one-half hours, and the acid was distilled *in vacuo*. The residue was made strongly alkaline with 40% potassium hydroxide solution at 0°, the liberated amine extracted into ether, and dried over potassium hydroxide. After removal of the ether, the colorless oil boiled at 79–80° (1.5–1.6 mm.). The yield was 2.5 g. (44%).

(9) From Fairmount Chemical Co., Newark, N. J.

The **hydrochloride** crystallized from ethyl acetate and ether. The colorless crystals melted at 164–166° (dec.).

Anal. Calcd. for $C_9H_{12}ClN$: C, 63.71; H, 7.13. Found: C, 63.62, 63.89; H, 7.13, 7.36.

A mixture melting point with the stereoisomeric hydrochloride (m. p. 153.5–156.5°) was 94–104° (dec.).

The **benzoyl derivative** crystallized from dilute ethanol, m. p. 119–120°.

Anal. Calcd. for $C_{16}H_{15}NO$: N, 5.90. Found: N, 6.07.

A mixture melting point with the A-benzoyl derivative (m. p. 122–123.5°) showed a 20–30° depression.

(2-Phenylcyclopropyl)-dimethylamine.—Following general directions[10] for the methylation of primary amines, 10.2 g. of a 40% aqueous formaldehyde solution was added to a cooled solution of 5 g. of 2-phenylcyclopropylamine A in 13.2 g. of 90% formic acid, and the mixture was refluxed overnight. The cooled reaction mixture was treated with 5.5 cc. of concentrated hydrochloric acid, the solution was evaporated under reduced pressure, the residue was made alkaline with a 50% potassium hydroxide solution, and the amine extracted into ether. After drying over potassium hydroxide and distillation of the ether, the colorless amine boiled at 70–70.5° (1.3–1.5 mm.).

The **hydrochloride** was prepared in dry ether solution and weighed 2.0 g. (27%). After recrystallization from ethyl acetate–ether, the colorless crystals showed m. p. 187–189° (dec.).

Anal. Calcd. for $C_{11}H_{16}ClN$: C, 66.82; H, 8.16. Found: C, 66.85, 66.93; H, 8.20, 8.22.

(2-Phenylcyclopropyl)-methylamine.—A solution of 5 g. of 2-phenylcyclopropylamine A and 4.3 g. of benzaldehyde in 10 cc. of absolute ethanol was refluxed for three hours, the solvent was stripped under reduced pressure, and the benzal derivative distilled once. The colorless oil boiled at 170–172° (2 mm.). It was not purified further. The yield was 6 g. (70%).

A mixture of 6 g. of (2-phenylcyclopropyl)-benzalamine and 7.7 g. of methyl iodide was heated in a sealed tube at 95° for seven hours. The dark red viscous reaction product was boiled with 75 cc. of 95% ethanol for four hours, the solvent was removed under reduced pressure, the base was liberated with 40% potassium hydroxide solution and extracted with ether. The extract was dried over potassium hydroxide, the ether evaporated, and the amine distilled. The colorless mobile distillate, obtained in a yield of 25%, boiled at 88–90° (1.5 mm.).

The colorless **hydrochloride** crystallized from ethanol–ether, m. p. 99–124.5°. Repeated recrystallizations did not narrow this melting point range.

Anal. Calcd. for $C_{10}H_{14}ClN$: N, 7.63. Found: N, 7.53.

1-Phenyl-3,4-dihydro-3,4-cyclopropanoisoquinoline.—A solution of 5 g. of N-(2-phenylcyclopropyl)-benzamide A in 100 cc. of dry toluene was refluxed with 5 g. of phosphorus pentoxide for twenty minutes. Another 5 g. of phosphorus pentoxide was added, and boiling was continued for forty minutes. The mixture was cooled, the toluene decanted, and the residue was decomposed with ice and slow warming until the ice was melted. The resulting solution was cleared, washed with ether, and made strongly alkaline with a 40% potassium hydroxide solution. The reaction product was extracted with four 75-cc. portions of benzene, and the solvent was evaporated. The oily residue solidified to pale brown prisms which were recrystallized from absolute ethanol. The yield was 21%, m. p. 109.5–110.5°.

Anal. Calcd. for $C_{16}H_{13}N$: C, 87.64; H, 5.97. Found: C, 88.17; H, 5.75.

The hydrochloride was hygroscopic. The **dilituarate** consisted of yellow prisms which were recrystallized from water and melted at 137–140° with darkening, and decomposed at 156–161°.

Anal. Calcd. for $C_{20}H_{16}N_4O_5$: N, 14.28. Found: N, 14.04.

Summary

Condensation of styrene with ethyl diazoacetate yields two stereoisomeric 2-phenylcyclopropanecarboxylic acids. The higher-melting member of this pair rearranges to the lower-melting one by way of their common chloride. Both acids have been degraded to the corresponding stereoisomeric 2-phenylcyclopropylamines by different modifications of the Curtius reaction. Secondary and tertiary amines in this series have been prepared, and the benzoyl derivative of the more readily accessible 2-phenylcyclopropylamine has been cyclized to a compound which probably is 1-phenyl-3,4-dihydro-3,4-cyclopropanoisoquinoline.

Methyl 2,6-Anhydro-α-D-altroside and Other New Derivatives of Methyl α-D-Altroside[1]

BY DAVID A. ROSENFELD, NELSON K. RICHTMYER AND C. S. HUDSON

In continuation of earlier researches in this Laboratory on methyl α-D-altroside,[2] we now wish to describe a number of new crystalline derivatives of this glycoside. Our primary objective was the study of 6-desoxy-D-altrose (D-altromethylose), the corresponding L-form having been obtained previously as a sirup by Freudenberg and Raschig.[3] From methyl α-D-altroside, following the general procedure described by Haskins, Hann and Hudson,[4] we were successful in preparing, in crystalline form, methyl 2,3,4-tribenzoyl-6-tosyl-α-D-altroside (I), methyl 2,3,4-tribenzoyl-6-iodo-6-desoxy-α-D-altroside (II), methyl 6-iodo-6-desoxy-α-D-altroside, and methyl 2,3,4-tribenzoyl-6-desoxy-α-D-altroside (III). However, our attempts to transform this last-named compound to the desired methyl 6-desoxy-α-D-altroside and to 6-desoxy-D-altrose have so far yielded only sirups. Gut and Prins[5] have also described these two com-

(1) Presented in part before the Division of Sugar Chemistry and Technology at the Atlantic City meeting of the American Chemical Society, April 14, 1947.

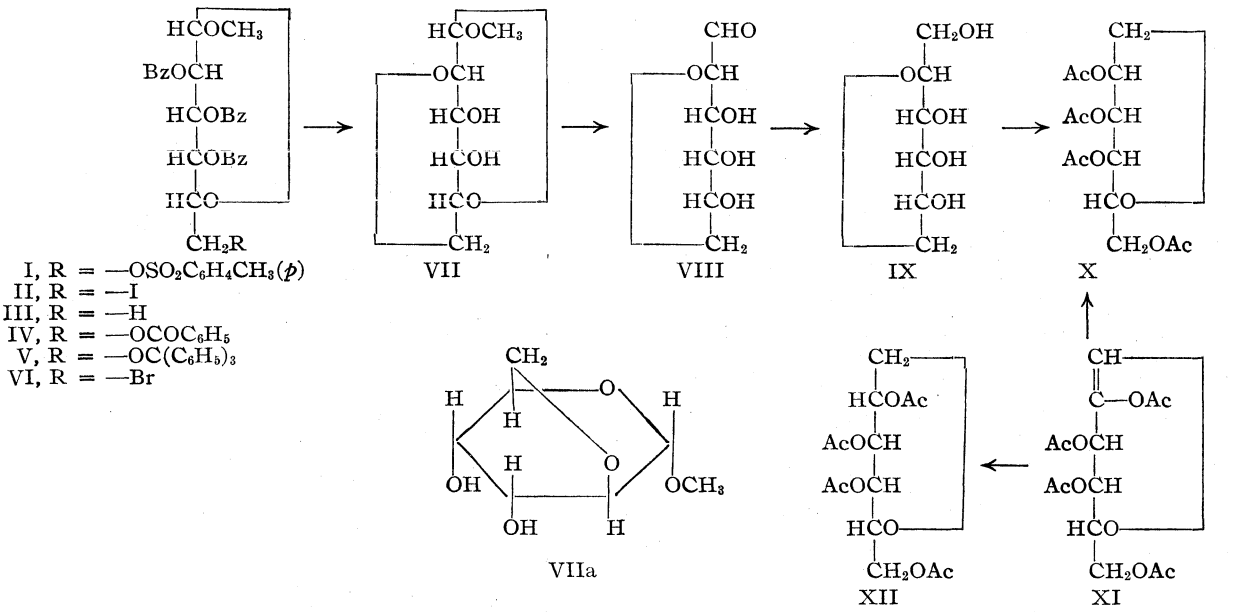
(5) M. Gut and D. A. Prins, *Helv. Chim. Acta*, **29**, 1555 (1946).



pounds recently as sirups, as well as the triacetyl derivatives analogous to our crystalline tribenzoates. A sirupy D-altromethylose has been reported also by Iwadare.[6]

The reaction of methyl α-D-altroside with benzoyl chloride in pyridine readily yields the expected tetrabenzoyl derivative (IV). The reaction with one equivalent of triphenylchloromethane in pyridine, followed by benzoylation, produces methyl 2,3,4-tribenzoyl-6-trityl-α-D-altroside (V); the corresponding triacetyl derivative has also been crystallized. By removal of the triphenylmethyl residue from V, and subsequent tosylation of the free hydroxyl group, we have converted this trityl compound to the tosyl derivative (I). A second correlation has been achieved by the action of phosphorus pentabromide upon V, whereby the trityl ether group was replaced by a bromine atom, and the resulting methyl 2,3,4-tribenzoyl-6-bromo-6-desoxy-α-D-altroside (VI) was then reduced with hydrogen and Raney nickel to methyl 2,3,4-tribenzoyl-6-desoxy-α-D-altroside (III).

Haskins, Hann and Hudson[4] have shown that methyl 2,3,4-tribenzoyl-6-tosyl-α-D-mannoside is converted readily by an excess of warm sodium hydroxide to methyl 3,6-anhydro-α-D-mannoside. Under identical conditions, methyl 2,3,4-tribenzoyl-6-tosyl-α-D-altroside (I) likewise undergoes debenzoylation and loss of the tosyl group to form an anhydride, which melts at 98° and has $[\alpha]^{20}D$ + 44.6° in water. In the sugars which are known to form a 3,6-anhydroglycopyranoside from a 6-substituted glycopyranoside, namely, D-glucose, D-mannose and D-galactose,[7] the hydroxyl group on carbon 3 is on the same side of the sugar ring as the side chain carbon 6, that is, on the left in the usual Fischer projection formula; in the D-altroside only the hydroxyl on carbon 2 can be written on the left. A 2,6-anhydro ring might thus be anticipated rather than a 3,6-anhydro ring, and the new compound was indeed proved to be methyl 2,6-anhydro-α-D-altropyranoside (VII and VIIa). The simplest method of distinguishing between a 2,6-ring and a 3,6-ring, assuming the original 1,5-ring to be intact, was to apply the method of periodate oxidation. A 3,6-anhydride would not be expected to react with sodium metaperiodate; our 2,6-anhydro compound, having two adjacent hydroxyl groups, consumed rapidly one equivalent of oxidant, and liberated neither formic acid nor formaldehyde.

Further proof of the structure of methyl 2,6-anhydro-α-D-altropyranoside (VII) was secured by a series of reactions which ruptured the 1,5-ring and left the 2,6-ring intact. The glycosidic methyl group was first removed by mild acid hydrolysis, and the resulting 2,6-anhydro-D-altrose (VIII) was reduced with hydrogen and Raney nickel to an anhydrohexitol (IX) which might be named 2,6-anhydro-D-altritol, but is preferably called 1,5-anhydro-D-talitol. While neither VIII nor IX has yet been obtained in crystalline form, the latter yielded a tetraacetyl derivative (X) which separated as prisms melting at 107°, and with $[\alpha]^{20}D$ −16.2° in chloroform. These data are in good agreement with those of the prismatic crystals of melting point 108° and $[\alpha]^{22}D$ −15.3° described by Freudenberg and Rogers.[8] Their compound, prepared by the catalytic hydrogenation of 2,3,4,-6-tetraacetyl-2-hydroxy-D-galactal (XI), could be either 2,3,4,6-tetraacetyl-1,5-anhydro-D-talitol

(X) or 2,3,4,6-tetraacetyl-1,5-anhydro-D-galactitol (XII), because the addition of hydrogen to the ethylenic linkage could give rise to either or both of these isomers. Our work identifies their compound as the D-talitol derivative (X) because only that one is possible if we start with a D-altrose derivative. The recent synthesis in this Laboratory of 2,3,4,6-tetraacetyl-1,5-anhydro-D-galactitol (XII),[9] which is quite different from the compound first described by Freudenberg and Rogers, and now by us, completes the series of compounds and correlates all three researches.

We have prepared the methyl 2,6-anhydro-α-D-altroside (VII) by the action of alkali not only upon the 6-tosyl derivative (I) but also upon the 6-bromo derivative (VI) and the 6-iodo derivative (II). Although the formation of methyl 3,6-anhydroglycosides from 6-bromo compounds has been reported previously,[10] we believe that this is the first time that a cyclic anhydride of a glycoside has been obtained from a 6-iodo compound. However, the reaction was accompanied by the formation of a highly colored solution with attendant low yield of the anhydro compound, and the reaction cannot be recommended for preparative purposes.

It will be interesting to learn whether the compound reported by Steiger and Reichstein[11] to be an isopropylidene derivative of a methyl anhydro-D-altroside, of melting point 132° and $[\alpha]^{18}D$ −43.0°, is the 3,4-isopropylidene derivative of methyl 2,6-anhydro-β(or α)-D-altroside.

Although methyl 2,6-anhydro-α-D-altropyranoside does not show the extreme sensitivity to acids that is shown by the 3,6-anhydro derivatives of methyl α-D-galactopyranoside[12] and methyl α-D-glucopyranoside,[13] and appears to be completely stable under ordinary conditions in the laboratory, it is hydrolyzed readily by *N* hydrochloric acid at 20°. We were unable to compare the rate of hydrolysis of methyl 2,6-anhydro-α-D-altropyranoside with that of methyl α-D-altropyranoside because D-altrose, the hydrolysis product of the latter, readily forms 1,6-anhydro-D-altrose (= D-altrosan<1,5>β<1,6>) in acid solution. However, sucrose is hydrolyzed about twenty-two times faster, and methyl α-D-glucopyranoside only about one-ninetieth as fast as methyl 2,6-anhydro-α-D-altroside under comparable conditions.

Experimental Part

Methyl α-D-altroside was prepared from methyl α-D-glucoside essentially as described in a preceding publication,[2] except that ethylene dichloride was used as a solvent whenever possible instead of the more expensive chloroform. The **methyl 2,3-ditosyl-4,6-benzylidene-α-D-glucoside**[14] which was used in our earlier study crystallized as needles melting at 147–148°. A new modification has since been obtained in large, chunky prisms which melt at 154–155°. The two forms have identical rotations, $[\alpha]^{20}D$ +11.8° in chloroform (*c*, 6). In contrast to the behavior of the two modifications of the corresponding derivative of methyl β-D-glucoside reported by Littmann and Hess,[14] either form of our compound can be obtained as desired by inoculating an ethylene dichloride solution of either form with the appropriate seed crystal.

Anal. Calcd. for $C_{28}H_{30}O_{10}S_2$: C, 56.93; H, 5.12. Found (155° form): C, 57.04; H, 5.28.

In the transformation of each 100 g. of ditosyl compound to the methyl 2,3-anhydro-4,6-benzylidene-α-D-alloside it was necessary to use 1500 ml. of ethylene dichloride and 450 ml. of methyl alcohol (including 0.85 mole of sodium methoxide) to maintain a homogeneous solution.

In our most recent preparations of methyl α-D-altroside we have found it unnecessary to isolate the methyl 2,3-ditosyl-4,6-benzylidene-α-D-glucoside, and considerable time may be saved by using a modified procedure. Thus, 100 g. of well-dried, crude methyl 4,6-benzylidene-α-D-glucoside was dissolved in 600 ml. of a "practical" grade of pyridine (dried over sticks of potassium hydroxide, and filtered) and 250 g. of *p*-toluenesulfonyl chloride was added. The reaction mixture, after three days at room temperature, was decomposed with ice and water, and the product extracted with ethylene dichloride. Pyridine was removed from this extract by washing with cold dilute sulfuric acid, and after further washing with water, aqueous sodium bicarbonate, and water, and drying with granular calcium chloride, the volume was adjusted to 1500 ml. The solution was cooled in the refrigerator and to it was added a cold solution of 450 ml. of methyl alcohol containing 1.4 moles of sodium methoxide (twice the theoretical amount required to effect detosylation and anhydride formation on the assumption that the starting material was all in the form of the ditosyl compound). The mixture was kept in the refrigerator for three days, with occasional shaking at first to prevent the separation of the liquid into two layers, and then allowed to stand at room temperature for two additional days. The solution was diluted with water, and the ethylene dichloride layer and extracts washed with water, dried over granular calcium chloride, and concentrated *in vacuo*. The crystalline anhydroalloside, filtered and washed with the aid of ether, weighed 70 g., representing 75% of the theoretical amount based on the 100 g. of methyl 4,6-benzylidene-α-D-glucoside.

The alkaline hydrolysis of the anhydroalloside to methyl 4,6-benzylidene-α-D-altroside and the subsequent mild acid hydrolysis to methyl α-D-altroside were then carried out as previously described.[2]

Methyl 2,3,4,6-Tetrabenzoyl-α-D-altroside (IV).—A solution of 5 g. of methyl α-D-altroside in 75 ml. of pyridine was cooled in an ice-bath, and to it was added 15 ml. of benzoyl chloride. After standing for twenty-four hours at room temperature, the mixture was poured into one liter of ice and water, and the precipitated gum was washed thoroughly by stirring with fresh portions of water several times during the course of the next few days. Crystals were first observed after the gum had stood under water in the refrigerator for about two months. The crystalline product weighed 7 g. and was recrystallized five times from ethyl alcohol as large, brilliant prisms; the m. p. was 94–96°, and $[\alpha]^{20}D$ +32.6° in chloroform (*c*, 4).

Anal. Calcd. for $C_{35}H_{30}O_{10}$: C, 68.84; H, 4.95. Found: C, 68.97; H, 4.94.

Methyl 2,3,4-Triacetyl-6-trityl-α-D-altroside.[15]—A mixture of 6.75 g. of methyl α-D-altroside and 13 g. of triphenylchloromethane in 50 ml. of pyridine was heated for three hours on the steam-bath, cooled, 25 ml. of acetic anhydride added, and the mixture allowed to stand for three days at room temperature. At the end of that time the flask contained a considerable number of large, colorless crystals which were removed by filtration, washed with pyridine, and recrystallized from a mixture of chloroform and pentane as prisms melting at 175°. The action of hot aqueous sodium hydroxide upon the compound liberated pyridine, which was recognized by its odor, and triphenylcarbinol, which was identified by its melting point and by a mixed melting point with an authentic specimen. These properties, together with analyses of the substance, indicate that it is the double compound of pyridine hydrochloride with triphenylcarbinol (probably present as an impurity in the triphenylchloromethane), melting at 174°, which was described by Helferich and Sieber.[16]

Anal. Calcd. for $C_{24}H_{22}ClNO$: C, 76.68; H, 5.90; Cl, 9.43; N, 3.73. Found: C, 76.69; H, 6.05; Cl, 9.57; N, 4.01.

The filtrate from the double compound was diluted with ice water and the precipitated solid extracted with chloroform. The chloroform solution was washed with 20% aqueous copper sulfate or cold, dilute sulfuric acid to remove the pyridine, then with water, aqueous bicarbonate, and water, dried with granular calcium chloride, and concentrated to a sirup which crystallized readily. The product weighed 9 g. It was recrystallized three times from chloroform by the addition of ether and isopentane, and then twice from alcohol. The elongated prisms melted at 165–166° after sintering a few degrees lower, and showed $[\alpha]^{20}D$ +44.8° in chloroform (*c*, 2).

Anal. Calcd. for $C_{32}H_{34}O_9$: C, 68.31; H, 6.09. Found: C, 68.55; H, 6.17.

Methyl 2,3,4-Tribenzoyl-6-trityl-α-D-altroside (V).—Ten grams of methyl α-D-altroside in 100 ml. of pyridine was heated for three hours with 15.8 g. of triphenylchloromethane, then cooled, and 27.4 ml. of benzoyl chloride added. After two days the mixture was decomposed by pouring into ice water. The next day the precipitated gum was extracted with chloroform, and the solution washed successively with water, cold dilute sulfuric acid, water, aqueous sodium bicarbonate, and water. This solution was dried with Drierite, filtered, and concentrated *in vacuo* to a sirup. The first crystalline material was obtained by fractional extraction of this sirup with ethyl alcohol; the radiating clusters of small needles melted about 96–98°, and were not very soluble in alcohol. When these crystals were found to be readily recrystallizable from ether, the several alcohol solutions and residue were combined and concentrated again to a sirup which was dissolved in ether and crystallized with the aid of isopentane. The product separated in large prisms, and weighed 29 g. The melting point of 83–85° with evolution of gas indicated solvent of crystallization; the material lost weight slowly at room temperature, and finally reached a constant weight, when heated at 70°, with a loss corresponding to one molecule of ether of crystallization.

Anal. Calcd. for $C_{47}H_{40}O_9 \cdot (C_2H_5)_2O$: ether, 9.01. Found: ether, 8.86.

Finally, the compound was purified by recrystallizing it from chloroform by the addition of absolute alcohol, from which it separated in small plates. After five recrystallizations the melting point was 139–140°, and the rotation, $[\alpha]^{20}D$, was +15.2° in chloroform (*c*, 4).

Anal. Calcd. for $C_{47}H_{40}O_9$: C, 75.38; H, 5.38. Found: C, 75.43; H, 5.49.

Methyl 2,3,4-Tribenzoyl-6-tosyl-α-D-altroside (I). (a) From Methyl α-D-Altroside.—A solution of 10 g. of methyl α-D-altroside in 150 ml. of pyridine was cooled in an ice-bath and stirred vigorously while a cold solution of 11 g. of *p*-toluenesulfonyl chloride (1.1 molecular equivalents) in 20 ml. of pyridine was added dropwise. The mixture was left for six hours at 20°, then 20 ml. (3.3 molecular equivalents) of benzoyl chloride was added and the mixture kept at 20° for an additional eighteen hours. Decomposition was effected by pouring the mixture into 2 liters of ice and water. The aqueous layer was decanted, and the gummy residue was triturated with water, twice with 200 ml. of 2% aqueous sodium bicarbonate solution, then three times with water, and drained as well as possible. The heavy gum was extracted twice with boiling ethyl alcohol, two 200-ml. portions usually being sufficient to dissolve the material. The solutions deposited about 7 g. (21%) of product melting at 144–146°; small additional amounts were obtained by reworking the mother liquors. A number of variations on this procedure failed to improve the yield, and no methyl 2,3,4,6-tetrabenzoyl-α-D-altroside could be isolated from the non-crystalline residues. The methyl 2,3,4-tribenzoyl-6-tosyl-α-D-altroside was purified by several recrystallizations from alcohol; it formed acicular prisms which melted at 149–150° and showed $[\alpha]^{20}D$ +30.3° in chloroform (*c*, 3).

Anal. Calcd. for $C_{35}H_{32}O_{11}S$: C, 63.63; H, 4.88. Found: C, 63.77; H, 4.74.

(b) From Methyl 2,3,4-Tribenzoyl-6-trityl-α-D-altroside (V).—In order to correlate the 6-trityl derivatives with the 6-tosyl derivatives, the following experiment was performed. Five grams of the methyl 2,3,4-tribenzoyl-6-trityl-α-D-altroside was dissolved in 100 ml. of warm glacial acetic acid, the solution was cooled to room temperature, and 3 ml. of glacial acetic acid saturated with gaseous hydrobromic acid was added. After thirty minutes the mixture was poured into one liter of ice water, and extracted with chloroform; the chloroform solution was washed with aqueous bicarbonate and water, dried with Drierite, and concentrated *in vacuo* to a sirup. Upon the addition of methyl alcohol the sirup yielded 0.64 g. of triphenylcarbinol. The mother liquor was concentrated to a dry sirup, taken up in pyridine, and 5 g. of *p*-toluenesulfonyl chloride added. After three days at room temperature the reaction mixture was decomposed with ice and water, and the product extracted with chloroform, which was then washed, dried, and concentrated to a sirup in the usual manner. The product was crystallized with the aid of ether and pentane to yield 1.6 g. of the desired methyl 2,3,4-tribenzoyl-6-tosyl-α-D-altroside; after two recrystallizations from ethyl alcohol the acicular prisms melted at 149–150° and showed $[\alpha]^{20}D$ +29.9° in chloroform (*c*, 2) in good agreement with the values reported in the preceding paragraph. A mixture of the two samples showed no depression in melting point.

Methyl 2,3,4-Tribenzoyl-6-iodo-6-desoxy-α-D-altroside (II).—A solution containing 5 g. of methyl 2,3,4-tribenzoyl-6-tosyl-α-D-altroside and 5 g. of sodium iodide in 40 ml. of acetonylacetone was heated at 70° for eighteen hours. The precipitated sodium *p*-toluenesulfonate, filtered from the solution after cooling, weighed 1.4 g. (theory, 1.5 g.). The filtrate, upon dilution with water, deposited 4.8 g. of product which was recrystallized several times from acetone by the slow addition of water. The acicular prisms of the purified substance melted at 143–145°, and showed $[\alpha]^{20}D$ +2.5° in chloroform (*c*, 4).

Anal. Calcd. for $C_{28}H_{25}IO_8$: C, 54.56; H, 4.09. Found: C, 54.98; H, 4.27.

Methyl 6-Iodo-6-desoxy-α-D-altroside.—Debenzoylation of the preceding compound catalytically with barium methoxide, followed by removal of the barium ions by

(15) First prepared by Mr. Frank G. Young in this Laboratory during the summer of 1940.

(16) B. Helferich and H. Sieber, *Ber.*, **59**, 600 (1926). A double compound presumed to consist of pyridine and triphenylchloromethane, melting at 173–174°, has been described by C. A. Kraus and R. Rosen [THIS JOURNAL, **47**, 2744 (1925)]; the analyses, reported only for chlorine, are not sufficient to enable one to decide whether their compound was also identical with that of Helferich and Sieber.

precipitation with the equivalent amount of sulfuric acid, yielded almost the theoretical amount of methyl 6-iodo-6-desoxy-α-D-altroside. The product, recrystallized four times from chloroform by the addition of ether or isopentane, formed clusters of rectangular prisms melting at 105–106°. The $[\alpha]^{20}D$ value was +91.4° in chloroform (*c*, 1) and +79.3° in water (*c*, 1).

Anal. Calcd. for $C_7H_{13}IO_5$: C, 27.65; H, 4.31. Found: C, 27.76; H, 4.58.

Methyl 2,3,4-Tribenzoyl-6-bromo-6-desoxy-α-D-altroside (VI).—To a solution of 22.9 g. of methyl 2,3,4-tribenzoyl-6-trityl-α-D-altroside in 200 ml. of dry, alcohol-free chloroform was added a mixture of 12.2 g. of phosphorus tribromide and 7.2 g. of bromine in 200 ml. of chloroform, corresponding to a 50% excess of the amount of phosphorus pentabromide required for the reaction. After three hours the reaction mixture was decomposed with ice water, and the chloroform layer separated and washed successively with water, aqueous bicarbonate, water, aqueous thiosulfate, and water, dried with Drierite, and concentrated *in vacuo* to a sirup. The product crystallized readily upon the addition of methyl alcohol in a yield of 13.2 g. (76%); from the mother liquor, concentrated to a sirup and taken up in ether, was obtained 6.8 g. (85%) of triphenylcarbinol which had been formed by hydrolysis of the other cleavage product, triphenylbromomethane.

The methyl 2,3,4-tribenzoyl-6-bromo-6-desoxy-α-D-altroside was freed from a small amount of levorotatory material by six recrystallizations from hot methyl alcohol; the rotation $[\alpha]^{20}D$ ±0.0° in chloroform (*c*, 8; *l*, 4) was unchanged by eight additional recrystallizations from a mixture of chloroform and pentane. The product separated as prisms melting at 146–147°.

Anal. Calcd. for $C_{28}H_{25}BrO_8$: C, 59.06; H, 4.43. Found: C, 59.11; H, 4.46.

Methyl 2,3,4-Tribenzoyl-6-desoxy-α-D-altroside (III).—Five grams of powdered methyl 2,3,4-tribenzoyl-6-iodo-6-desoxy-α-D-altroside and 1 ml. of Raney nickel catalyst were suspended in 200 ml. of methyl alcohol containing 1.7 ml. of diethylamine, and the mixture was shaken with hydrogen at atmospheric pressure. The absorption of one equivalent of gas was complete in about fifty minutes. The catalyst was removed by filtration, and the filtrate was concentrated *in vacuo*. The crystalline residue was stirred with several portions of water to remove the diethylamine hydroiodide, and the residue was recrystallized from methyl alcohol in a yield of 2.7 g. After three additional recrystallizations the small, chunky prisms melted at 134–135° and showed $[\alpha]^{20}D$ −15.5° in chloroform (*c*, 3).

Anal. Calcd. for $C_{28}H_{26}O_8$: C, 68.56; H, 5.34; OCH_3, 6.33. Found: C, 68.69; H, 5.18; OCH_3, 6.32.

In the same manner, 5.0 g. of slightly impure methyl 2,3,4-tribenzoyl-6-bromo-6-desoxy-α-D-altroside yielded 3.0 g. of reduction product. After two recrystallizations from methyl alcohol the small, chunky prisms melted at 133–134°, and a mixture with the compound prepared from the iodo derivative melted at 133–135°; the specific rotation, however, was −19.6° in chloroform, and after twenty-five recrystallizations the substance still contained a small amount of more levorotatory impurity as shown by the value $[\alpha]^{20}D$ −17.3°.

Methyl 2,6-Anhydro-α-D-altropyranoside (VII). (a) From Methyl 2,3,4-Tribenzoyl-6-tosyl-α-D-altroside (I).—A mixture of 10 g. of methyl 2,3,4-tribenzoyl-6-tosyl-α-D-altroside, 150 ml. of methyl cellosolve, and 67 ml. of 1 *N* sodium hydroxide (4.4 molecular equivalents) was heated on the steam-bath for one hour. The solution was cooled, neutralized with carbon dioxide, and concentrated *in vacuo* to dryness; a 50-ml. portion of ethyl acetate was added, and the mixture concentrated again to dryness. The product was removed from the mixture of solid sodium salts by extracting three times with 100-ml. portions of boiling anhydrous ethyl acetate. The extract, upon concentration *in vacuo*, left a sirup which crystallized after standing a few days. The average yield from a number of such experiments was 1.7 g. The methyl 2,6-anhydro-α-D-altroside was recrystallized first from acetone by the cautious addition of ether, and then from ethyl acetate, as large elongated prisms, melting, when pure, at 97–98°, and with $[\alpha]^{20}D$ +44.6° in water (*c*, 2).

Anal. Calcd. for $C_7H_{12}O_5$: C, 47.72; H, 6.87; OCH_3, 17.61. Found: C, 47.74; H, 6.97; OCH_3, 17.55.

(b) From Methyl 2,3,4-Tribenzoyl-6-bromo-6-desoxy-α-D-altroside (VI).—The catalytic debenzoylation of methyl 2,3,4-tribenzoyl-6-bromo-6-desoxy-α-D-altroside with sodium methoxide, unlike that of the analogous iodo compound, failed to yield a crystalline product. Accordingly, 50 ml. of an aqueous solution of such a preparation, containing about 2.6 g. of methyl 6-bromo-6-desoxy-α-D-altroside ($[\alpha]^{20}D$ about +80° in water), was heated for two hours on the steam-bath with 2.5 g. of sodium hydroxide. The light-brown solution was neutralized with carbon dioxide, decolorized with activated carbon, and concentrated *in vacuo* to dryness. The product was extracted with hot ethyl acetate, and 1.6 g. of methyl 2,6-anhydro-α-D-altroside was obtained; it was identified, after several recrystallizations, by its melting point, mixed melting point, and rotation.

(c) From Methyl 6-Iodo-6-desoxy-α-D-altroside.—A solution containing 2.2 g. of methyl 6-iodo-6-desoxy-α-D-altroside and 2.2 g. of sodium hydroxide in 35 ml. of water was heated on the steam-bath for two hours. The dark, reddish-brown solution was neutralized with carbon dioxide, treated with carbon, concentrated to dryness, and extracted with ethyl acetate as above. Evaporation of the ethyl acetate left 0.85 g. of a yellowish-red sirup which did not crystallize when inoculated with the expected 2,6-anhydro compound. The sirup was therefore acetylated with acetic anhydride and pyridine at room temperature. The product was isolated in the usual manner, yielding 1.5 g. of a sirup which crystallized when inoculated with the known diacetate of the 2,6-anhydro compound (see below). One recrystallization from chloroform by the addition of pentane produced 1.0 g. of yellowish prisms; the colored impurity was removed by a fractional recrystallization, and the diacetate was obtained as the characteristic colorless elongated prisms, identical in melting point and rotation with those described in the following paragraph.

Methyl 2,6-Anhydro-3,4-diacetyl-α-D-altroside.—Acetylation of the purest 2,6-anhydroaltroside (prepared from methyl 2,3,4-tribenzoyl-6-tosyl-α-D-altroside) with acetic anhydride and pyridine in the usual manner furnished the diacetate in practically quantitative yield. The product was recrystallized twice from chloroform by the addition of pentane, separating as elongated prisms of m. p. 100–101° and $[\alpha]^{20}D$ +32.5° in chloroform (*c*, 2). These values were unchanged by two additional recrystallizations.

Anal. Calcd. for $C_{11}H_{16}O_7$: C, 50.76; H, 6.20; OCH_3, 11.92. Found: C, 50.96; H, 6.53; OCH_3, 11.80.

Oxidation of Methyl 2,6-Anhydro-α-D-altroside with Sodium Metaperiodate.—To a solution of 0.5292 g. of the anhydro compound in 75 ml. of water was added 15 ml. of 0.4445 *M* sodium periodate solution, and the mixture diluted exactly to 100 ml. with water. The first rotation was observed twenty minutes after adding the reagent and was unchanged after four days; the value $[\alpha]^{20}D$ +113.5° was calculated for the expected oxidation product, the dialdehyde $C_7H_{10}O_5$. The first determination of the amount of reagent consumed showed that the reaction was complete at the end of forty-five minutes, and the value of 1.03 molecular equivalents of periodate had changed only to 1.07 molecular equivalents after four days. Neither formic acid nor formaldehyde could be detected in the reaction mixture.

Hydrolysis of Methyl 2,6-Anhydro-α-D-altroside with Hydrochloric Acid.—In 0.1 *N* hydrochloric acid at 20° there was no appreciable hydrolysis of the anhydroaltroside in nineteen hours; when the solution was heated in a

boiling water-bath, hydrolysis appeared to be complete within one hour. For a 2% solution of the anhydroaltroside in 0.01 *N* hydrochloric acid at 98°, the unimolecular velocity coefficient, calculated in minutes and decimal logarithms, was 0.0062; the time required for 50% hydrolysis was forty-nine minutes. Methyl α-D-glucoside in 0.1 *N* hydrochloric acid, other conditions being the same, yielded a unimolecular velocity coefficient of 0.00068; on the assumption that the rate is proportional to the acidity, this indicates that methyl 2,6-anhydro-α-D-altroside is hydrolyzed about ninety times as rapidly as methyl α-D-glucoside.

The hydrolysis of methyl 2,6-anhydro-α-D-altroside by 1 *N* hydrochloric acid at 20° was readily observed with the saccharimeter. A 4% solution required 2712 minutes for 50% hydrolysis, and the velocity coefficient was calculated to be 0.000111. An equimolecular solution of sucrose (7.8%) under the same conditions had a velocity coefficient of 0.00244 and the time required for 50% hydrolysis was 121 minutes. Hence, sucrose is hydrolyzed about 22 times as rapidly as an equimolecular solution of the anhydroaltroside.

The solutions obtained by the hydrolysis of the anhydroaltroside had a rotation, calculated as a 2,6-anhydro-D-altrose, of $[\alpha]^{20}D$ −21°. A few drops of solution restored the color to Schiff reagent within a few seconds; crystalline D-altrose restored the color slowly, and D-glucose not at all. In a separate experiment, using *N* sulfuric acid followed by neutralization with solid barium carbonate, we have been unable to obtain a crystalline 2,6-anhydroaltrose.

Hydrogenation of 2,6-Anhydro-D-altrose and the Isolation of Tetraacetyl-1,5-anhydro-D-talitol (X).—The solution obtained by the hydrolysis of several portions of methyl 2,6-anhydro-α-D-altroside (total weight 4.0 g.) with dilute hydrochloric acid were combined, neutralized to litmus with dilute sodium hydroxide, and concentrated *in vacuo* to 50 ml. The solution was transferred to the glass liner of a steel bomb, and hydrogenated, in the presence of 3 g. of Raney nickel, for six hours at 100° under a pressure of 1500 lb. per square inch. The solution no longer reduced Fehling solution. It was concentrated *in vacuo* to a dry sirup, and acetylated with 50 ml. of acetic anhydride and 50 ml. of pyridine. The acetylated product was isolated in the usual manner, and crystallized spontaneously from its concentrated ether solution. The yield was 5.5 g., or 73%. The tetraacetyl-1,5-anhydro-D-talitol thus obtained was recrystallized twice from ether, then twice from chloroform by the addition of pentane. The elongated prisms melted at 106–107°, and showed $[\alpha]^{20}D$ −16.2° in chloroform (*c*, 5); Freudenberg and Rogers[8] reported prisms of m. p. 108° and $[\alpha]^{22}D$ −15.31° in chloroform (*c*, 2).

Anal. Calcd. for $C_{14}H_{20}O_9$: C, 50.60; H, 6.07. Found: C, 50.62; H, 6.13.

The Specific Rotation of 1,5-Anhydro-D-talitol (IX).—The deacetylation of 2.4566 g. of tetraacetyl-1,5-anhydro-D-talitol by 0.5 ml. of 3% sodium methoxide in 50 ml. of methyl alcohol, followed by careful concentration of the solution in a desiccator over granular calcium chloride, yielded a sirup which in separate experiments we have been unable to crystallize. This sirup was dissolved and transferred quantitatively to a 25-ml. volumetric flask, and its rotation determined in a 4-dm. tube. Our value $[\alpha]^{20}D$ −11.4° in water (*c*, 4.85) is somewhat higher than the $[\alpha]^{23}D$ −7.34° reported by Freudenberg and Rogers for their sirup which was prepared in a different manner.

Acknowledgment.—The authors wish to thank Dr. Arthur T. Ness, Mr. Charles A. Kinser, Mrs. Betty G. Mount and Mrs. Margaret M. Ledyard of this Institute for carrying out the microchemical analyses.

Summary

Ten new crystalline derivatives of methyl α-D-altroside have been described. One of these, prepared by the action of alkali on the 6-tosyl, 6-bromo, or 6-iodo derivative, is methyl 2,6-anhydro-α-D-altropyranoside; this is a new type of anhydroglycoside, in contrast to the 3,6-anhydroglycosides of D-glucose, D-mannose, and D-galactose.

The acid hydrolysis of methyl 2,6-anhydro-α-D-altroside, followed by catalytic hydrogenation of the 2,6-anhydro-D-altrose, yields 1,5-anhydro-D-talitol; the crystalline tetraacetate of this substance has been identified with the product obtained previously by W. Freudenberg and K. F. Rogers by the catalytic hydrogenation of 2,3,4,6-tetraacetyl-2-hydroxy-D-galactal.

The Constituents of Sierra Juniper Wood (*Juniperus occidentalis*, Hooker)

BY E. F. KURTH AND HOMER B. LACKEY*

Sierra Juniper is native to altitudes ranging from 3,000 to 11,000 feet in California, Oregon, Washington, and Western Idaho. It is a low, broadheaded tree, 20 to 65 feet high, with thick trunk and stout horizontal branches. The larger trees may reach a circumference of nine feet and an age of 2,000 years. The heartwood is pale reddish-brown and the sapwood is nearly white.

It appears that no previous investigation has been made of the extractive from this species. Because large numbers of the trees are found in proposed reclamation areas, it became advisable to ascertain the constituents of the extractives from the wood.

* A part of the research reported in this paper was submitted in partial fulfillment of the requirements for degree of Master of Science in Chemistry, Oregon State College, June, 1948.

Experimental

The material for the investigation was collected from trees felled for the purpose in the vicinity of Bend, Oregon, and included cross sections from the top and bottom of logs, stumpwood and rootwood. After the bark was removed, representative specimens of sapwood, heartwood, whole wood, stumpwood and rootwood were shredded separately in a Greundler Peerless Grinder. At the time of shredding, the moisture content of the wood was roughly 40 to 50%. For quantitative yield of extractive, samples of the shredded wood were room-dried to under 10% moisture content and then further ground in a Wiley mill to pass a 40-mesh standard U. S. sieve.

The results of extractions with ethyl ether in Pyrex glass Soxhlet extractors, and calculated on the oven-dry weight of wood, are shown in Table I. Further extraction of the ether extracted wood with acetone gave roughly an additional 1% of reddish-brown phlobaphene.

TABLE I

YIELD OF EXTRACT WITH ETHYL ETHER

Material	Per cent.
Top log	4.21
Butt log	3.36
Stumpwood	2.96
Rootwood	4.01
Sapwood	3.52
Heartwood	6.50

For the purpose of obtaining sufficient quantities of extractive to determine its chemical composition, the freshly shredded moist wood was extracted with acetone in a large metal Soxhlet-type extractor. This extractor held about 10 pounds of wood and the solvent was contained in a 45-liter, round bottom Pyrex-glass flask, which was externally steam-heated.

The acetone extracts from the wood samples were concentrated by distillation at reduced pressure in a water-bath. After the acetone had been removed, the dark colored sirupy extracts were steam distilled to remove volatile oil.

Composition of the Volatile Oil.—The aqueous condensates from the distillation with steam of the extracts from cross sections from the bole of the tree contained a crust of colorless crystals. After drying on a porous plate the crystals melted at 78° and when recrystallized from hot methanol, melted at 87°. They formed a urethan, m. p. 106–107° with phenyl isocyanate. These are the properties of cedrol, $C_{15}H_{26}O$, a tertiary alcohol occurring in few other conifers. The yield was 0.9 to 1.25% of the weight of the wood.

The volatile oils from the stumpwood and rootwood were nearly colorless liquids from which crystals did not separate. They were removed from the aqueous layer by shaking out with petroleum ether in a separatory funnel.

Thirty-five grams of the oil from the rootwood extract was distilled at a pressure of 9 mm. from a 60-ml. round-bottomed flask heated in an oil-bath. Twenty-eight grams of a clear colorless oil distilled between 130 to 170°. A dark brown residue, presumably decomposition and polymerization products, remained. The oil was fractionally distilled at 41 mm. into two distinct fractions. The first fraction, a clear colorless oil amounting to 49.3% of the original rootwood oil, was identified as cedrene, $C_{15}H_{24}$. It had the following properties: b. p., 131–133° (18 mm.), 264° (759.8 mm.); sp. gr. 0.9322 $^{20}/_{20}$; sp. rotation, $[\alpha]^{20}D$ in chloroform −58° 5′; refractive index, 1.5008^{20}°. A dilute solution in 95% ethanol gave an immediate reddish color which changed to red-violet upon the addition of a solution of one-tenth g. of vanillin dissolved in 100 ml. of concentrated hydrochloric acid.

The second fraction was the white crystalline solid cedrol, $C_{15}H_{26}O$. It distilled between 155 to 165° at 41 mm., melted at 86°, and had a specific rotation, $[\alpha]^{20}D$ +8° 29′. The urethan from phenyl isocyanate melted at 106–107°. The cedrol crystals when dissolved in absolute ethanol and dehydrated with concentrated phosphoric acid gave cedrene, which gave the typical color with the vanillin–hydrochloric acid reagent.

Separation of Phlobaphene.—The thick, dark-colored residues from the separation of the volatile oil were placed in a separatory funnel and shaken with successive portions of ethyl ether. The insoluble material was then refluxed for an hour with more ether, whereupon a reddish-brown residue was obtained that dried to an amorphous powder.

This material gave a green-black coloration with dilute solutions of iron salts, precipitated gelatin from solution, and upon methylation with dimethyl sulfate in alkaline solution followed by oxidation with potassium permanganate gave veratric acid, m. p. 177°, methyl ester m. p. 55–57°. The dried product was only slightly soluble in water. This indicated that a catechol phlobaphene is present in Sierra juniper wood. The yield was roughly 1% of the weight of the whole wood.

Separation of Petroleum Ether Solubles.—The ether solutions from the separation of the phlobaphene were washed with water, dried over anhydrous sodium sulfate, and the solvent was removed under reduced pressure. The dark colored resinous material was then extracted with petroleum ether. This solvent extracted a reddish yellow product and gave a dark colored resinous precipitate.

The petroleum ether solutions were next shaken in a separatory funnel with successive portions of 5% potassium carbonate solution to separate acidic substances from neutral materials. Complete separation of the sapwood extract, as judged by the color of the aqueous layer, was comparatively sharp after shaking with four portions of potassium carbonate solution. The coloring matter was more difficult to remove with the other wood extracts, which required up to 9 extractions with fresh portions of potassium carbonate solution. The petroleum ether solutions were then washed with water and dried over anhydrous sodium sulfate overnight. The ether was removed under reduced pressure and the residues weighed. The amounts of neutrals and acids found, as well as those of other components, are given in Table II. The method of separation is summarized in Fig. 1.

TABLE II

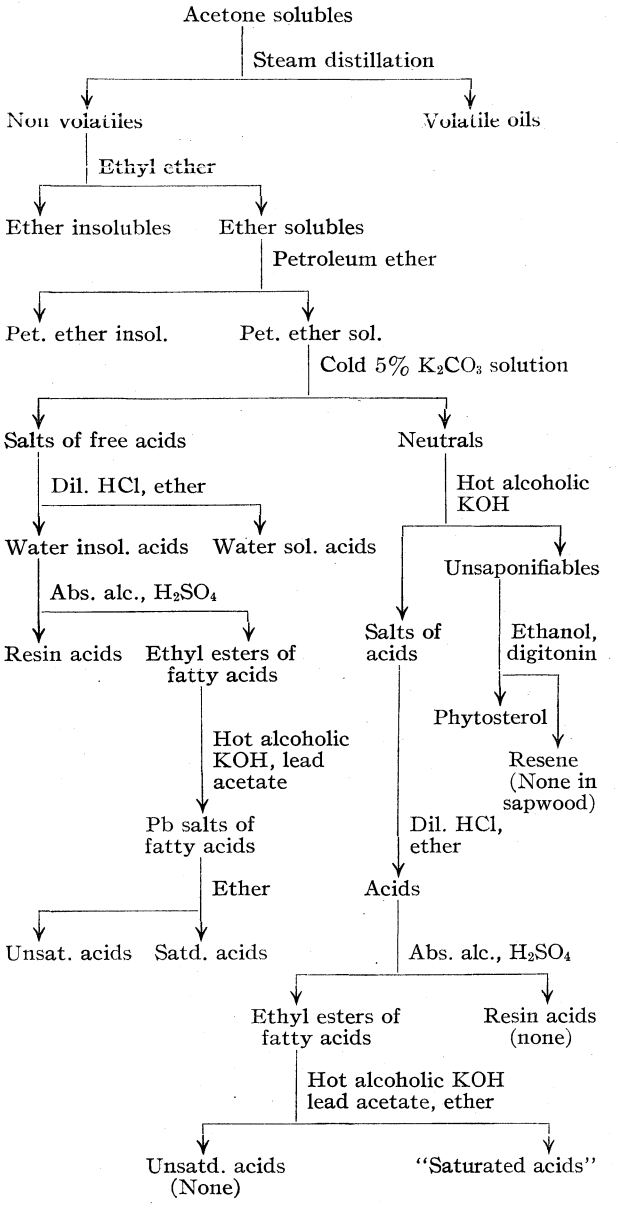
COMPOSITION OF PETROLEUM ETHER EXTRACT FROM SIERRA JUNIPER (YIELD FROM SAPWOOD 2.53%; FROM WHOLE WOOD 3.01%)

	Per cent. of total pet. ether extract	
	Sapwood	Whole wood
Free acids	27.9	43.6
Fatty acids	21.6	26.4
Resin acids	6.3	17.3
Combined acids	27.1	6.9
Fatty acids	27.1	6.9
Resin acids	0.0	0.0
Total acids	55.0	50.5
Saturated fatty acids	30.9	14.6
Unsaturated fatty acids	17.7	16.0
Resin acids	6.3	17.3
Unsaponifiables	45.0	49.5
Volatile oils		1.0
Phytosterol	45.0	5.0
Resene		43.5
Water solubles	None	Trace

Esterification of the dry acidic fractions with ethanol and sulfuric acid gave a separation into fatty acids and resin acids. The resin acid fraction from all of the wood extracts was dark colored and non-crystallizable from a variety of solvents. The neutral equivalent varied from 297 to 337, whereas that for abietic acid is 302.4.

The fatty acid fractions were further separated into presumably saturated and unsaturated acids by the difference in solubilities of their lead salts in ether. The unsaturated fatty acids thus obtained were red colored liquids, which gave iodine numbers by the Hanus method ranging from 56.7 to 68.1 and neutralization equivalents ranging from 338 to 346. This indicated that acids with more than 18 carbon atoms were present. Oxidation with cold alkaline potassium permanganate resulted in the isolation of dihydroxystearic acid, m. p. 129.5°, which indicated that oleic acid was present in the mixture.

Fig. 1.—Separation of the juniper wood extract



The saturated fatty fraction was soluble in warm methanol and crystallized from this solvent on standing. After several recrystallizations, white waxy solids were obtained, which melted at 72.5–73°. Decomposition took place at temperatures above 100°, which demonstrated a relative low stability to heat. The crystals were soluble in warm dilute sodium hydroxide, but were insoluble in 5% sodium bicarbonate solution. Neutralization values of 677 to 684 were obtained. Other investigators have obtained similar acids from Jack pine and Swedish Tall oil[1,2,3] and considered them lactonic acids.

After refluxing the crystals for one-half hour with an excess of alcoholic potassium hydroxide, acidifying the solution, extracting with ether, drying and recrystallizing, the neutral equivalent was lowered to between 396 to 422. This indicates that the material could be the dibasic lactonic acid of the same melting point described by Sandquist.[3]

The neutral fractions were saponified with 7% alcoholic potassium hydroxide by the modified Kerr–Sarber method of Jamieson[4] and separated into unsaponifiable matter and acids. No resin acids or ether soluble lead salts were found present in the acid fraction. The only acid isolated had the same properties as that described in the preceding paragraphs.

Unsaponifiables.—A one per cent. solution of the unsaponifiables in absolute ethanol was heated and to it was added an equal volume of a 1% solution of digitonin in 95% ethanol. After standing in a refrigerator for forty-eight hours, white crystals of phytosterol digitonide separated. The yield of digitonide was quantitative from the sapwood unsaponifiable matter inasmuch as no residue was found in the filtrate. The unsaponifiable from the whole wood contained only approximately 10% of sterols. The bulk of the unsaponifiable matter from this extract was not precipitated by digitonin.

The phytosterol was recovered from the unsaponifiable matter by crystallization from hot dilute alcohol. The light colored crystals, which separated, were decolorized with charcoal, and recrystallized successively from hot dilute ethanol and acetone. The properties are shown in Table III. From the experimental data in this table, the product appears to be a mixture of *alpha* and *beta* sitosterol.

TABLE III

PROPERTIES OF THE PHYTOSTEROL

	Sierra juniper wood	α-Sitosterol[4]	β-Sitosterol[4]
Melting point, °C.	134–136.5	135–136	139–140
Melting point of acetate, °C.	125.5–128		127–128
Specific rotation $[\alpha]^{20}D$ in $CHCl_3$	−21.25	−13.45	−36.11

The filtrate from the precipitation of the phytosterol digitonide from the whole wood unsaponifiables was concentrated and diluted with water, whereupon a resene was precipitated. This was recrystallized successively from hot dilute ethanol, methanol and acetone and had a melting point of 76–78.5°. It was slightly soluble in hot water and very soluble in petroleum or ethyl ether, benzene and chloroform. The compound was optically inactive. Molecular weight, as found by the Rast camphor method, together with carbon and hydrogen analyses indicated the empirical formula to be $C_{18}H_{31}O$.

Calcd. for $C_{18}H_{31}O$: C, 82.10; H, 11.86; molecular weight, 263.4. Found: C, 81.72; H, 12.10; molecular weight 262.0.

An acetate was formed by refluxing the resene for one-half hour with acetic anhydride and anhydrous sodium acetate. It had a melting point of 102–104°. Formation of the acetate established the resene as an alcohol.

Petroleum Ether Insoluble Fraction.—Investigation of this fraction gave many variable results. It appeared to be in various stages of oxidation and polymerization. In addition to being soluble in ethyl ether it was soluble in ethyl acetate, partly soluble in hot methanol and hot benzene. The product from the top log cross section, amounting to 46.2% of the ethyl ether extract, upon saponification with sodium hydroxide gave an insoluble sodium salt. The material soluble in sodium hydroxide was a mixture of resin and fatty acids. Decomposition of the insoluble sodium salt with dilute acid precipitated a light brown granular solid with a neutral equivalent of 791.

The product from a cross section of a butt log with some dry rot at the core gave on redissolving in ethyl ether and upon slow evaporation of the solvent, light fluffy crystals.

(4) Jamieson, George S., "Vegetable Fats and Oils," A. C. S. Monograph No. 58, 2nd ed., Reinhold Publishing Corp., New York, N. Y., 1943.

These were recrystallized from hot benzene and then had the following properties: insoluble in water, petroleum ether and carbon tetrachloride; slightly soluble in ethyl ether, benzene, and ethyl acetate; and soluble in alcohol, acetone, and sodium bicarbonate solution; m. p. 229°, neutral equivalent 153, molecular weight 294, C 60.8%, and H 7.42%. This indicated an empirical formula of $C_{15}H_{22}O_6$. Methoxl groups were absent.

The compound formed a mono methyl ester with methanol in the presence of concentrated sulfuric acid that had the following properties: m. p. 136–137°, neutral equivalent 290, saponification equivalent 164. The ester was soluble in sodium bicarbonate solution and after saponification the original compound was recovered. These properties indicated a dibasic acid.

The compound was obtained in only small yield from one specimen of Sierra juniper wood containing dry rot.

Inasmuch as it was not isolated from sound wood it is questionable whether it is a normal constituent of wood with no decay.

Summary

1. The ethyl ether soluble content of Sierra juniper wood was found to range between 2.96 to 6.5%. Approximately an additional one per cent. of material is soluble in acetone which is chiefly a catechol phlobaphene. A part of the ethyl ether extractive is soluble in petroleum ether. This amounted to 2.53% on the weight of sapwood and 3.01% on the weight of the whole wood from a cross section of the trunk. A detailed analysis of the petroleum ether solubles is tabulated.

2. The constituents of the petroleum ether extract were resin acids, oleic acid and high molecular weight lactonic acids, a mixture of alpha and beta sitosterol and a hydroxy resene, $C_{18}H_{31}O$. The resin acids occurred only in the free state.

3. The volatile oil from the trunk of the tree ranged from 0.9 to 1.25% and was apparently entirely cedrol. That from the rootwood was a mixture of cedrene and cedrol.

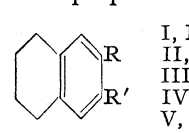
The Jacobsen Reaction. IX.[1] 6,7-Dialkyltetralins

BY LEE IRVIN SMITH AND CHIEN-PEN LO[2]

The only tetraalkylbenzenes so far studied with reference to their behavior under the conditions of the Jacobsen rearrangement are those in which the alkyl groups are methyl and ethyl. Tetraalkylbenzenes of known structure, having alkyl groups above ethyl, and with straight or branched chains, are practically unknown, and the variety and number of such compounds necessary for an extended study of the Jacobsen reaction make the preparation of the starting materials and reference compounds a very formidable task. In the previous paper[1] it was shown that a cyclic chain attached at two ortho-positions to a benzene ring could take the place of two alkyl groups in a tetraalkylbenzene, and it was shown that 6,7-diethyltetralin (a 1,2,4,5-tetraalkylbenzene) underwent the Jacobsen reaction in the normal fashion to produce 5,6-diethyltetralin (a 1,2,3,4-tetraalkylbenzene). Indeed, Schroeter and Gotzky[3] had already shown that two cyclic chains, involving the 1,2,4,5-positions of a benzene ring could replace four alkyl groups, for these authors observed that octahydroanthracene, subjected to the conditions of the Jacobsen reaction, underwent rearrangement to octahydrophrenanthrene, a 1,2,3,4-tetrasubstituted benzene. 6,7-Dialkyltetralins are quite readily prepared in some variety; moreover, these substances, as well as their rearrangement products, are readily dehydrogenated to the corresponding naphthalenes, so that the problems of identification can be solved without much difficulty.

Arnold and Barnes[1] have recently proposed a theory for the mechanism of the Jacobsen reaction. According to this theory, the migrating alkyl group is detached from the sulfonic acid molecule as a cation; this cation then replaces the more hindered sulfonic acid group of the (di)-sulfonic acid, leading to the rearranged sulfonic acid. As a necessary consequence of this theory, migration of a *n*-propyl group in a polyalkylbenzene would involve simultaneous isomerization of the group to iso-propyl, since the latter is the more stable of the two propyl cations under the conditions of the rearrangement.

With the objectives of testing this corollary of the suggested mechanism, and of extending the data on the Jacobsen reaction to groups other than methyl and ethyl, five (four of them new compounds) 6,7-dialkyltetralins have been prepared and subjected to the conditions of the Jacobsen rearrangement. Each tetralin was dehydrogenated to the corresponding naphthalene and the latter identified—hence, incidental to this work, a number of new 2,3- and 1,2-dialkylnaphthalenes have been prepared and characterized.



I, R = R′ = CH_3
II, R = CH_3, R′ = *n*-C_3H_7
III, R = CH_3, R′ = iso-C_3H_7
IV, R = C_2H_5, R′ = iso-C_3H_7
V, R = R′ = *n*-C_3H_7

When 6,7-dimethyltetralin (I) was subjected to the conditions of the Jacobsen reaction, it was converted into 5,6-dimethyltetralin, in analogy

(2) Abstracted from a thesis by Chien-Pen Lo, presented to the Graduate Faculty of the University of Minnesota, in partial fulfillment of the requirements for the Ph.D. degree, September, 1947.

(3) Schroeter and Gotzky, *Ber.*, **60**, 2035 (1927).

with the previously studied conversion of 6,7-diethyltetralin into the 5,6-isomer.[1] However, when the two alkyl groups are identical, the rearrangement of 6,7-dialkyltetralins to the 5,6-compounds gives no clue as to whether an alkyl group, or the cyclic chain has migrated, for in either case the product would be the same 5,6-dialkyltetralin. Hence it became necessary to study some 6,7-dialkyltetralins in which the substituents were different; for this purpose tetralins II, III, and IV were prepared and characterized; compound V, with two *n*-propyl groups, was also included for comparison.

6-*n*-Propyl-7-methyltetralin II, under the conditions of the Jacobsen rearrangement, was converted into a liquid hydrocarbon which yielded benzene-1,2,3,4-tetracarboxylic acid upon oxidation and 1-*n*-propyl-2-methylnaphthalene upon dehydrogenation. The liquid product was therefore 5-*n*-propyl-6-methyltetralin. There are, *a priori*, four routes for a rearrangement: (a) the propyl group may migrate from the 6- to the 8- (=5) position; (b) the methyl group may migrate to the 5- (=8) position; (c) the tetramethylene ring may open and then close in the *o*-position to the methyl group; and (d) the ring may open and then close in the *o*-position to the propyl group. The product resulting from (a) would, in accordance with the theory of Arnold and Barnes, be 5-isopropyl-6-methyltetralin, and not the *n*-propyl isomer; from (b) and (c) there would result 5-methyl-6-*n*-propyltetralin; route (d) is the only one which would lead to the product actually obtained, namely, 5-*n*-propyl-6-methyltetralin. Hence, the rearrangement proceeded *via* route (d) unless the very improbable assumption is made that a *n*-propyl cation does not rearrange to isopropyl but is stable in the presence of a great excess of sulfuric acid.

6-Isopropyl-7-methyltetralin III, under the conditions of the Jacobsen rearrangement, was converted into 6-methyltetralin, identified by dehydrogenation to 2-methylnaphthalene. In this rearrangement, the *iso*-propyl group became detached and did not re-enter the molecule, a behavior of isopropyl groups for which there is much precedent.[4]

6-Isopropyl-7-ethyltetralin IV, and 6,7-di-*n*-propyltetralin V, when subjected to the conditions of the Jacobsen rearrangement, gave only small amounts of oily products which could not be identified. The bulk of the material was destroyed or else converted into sulfonic acids which were hydrolyzed to hydrocarbons with difficulty—a fact which excluded sulfonic acids of 1,2,3,4-tetraalkylbenzenes.

The results of these experiments, together with those of Arnold and Barnes, show that 6,7-dialkyltetralins undergo the Jacobsen rearrangement to 5,6-dialkyltetralins when one or both of the alkyl groups are methyl or ethyl, or when one group is methyl and the other is *n*-propyl. In the last case, however, it is the tetramethylene ring which migrates rather than either alkyl group. When one of the alkyl groups is methyl and the other is isopropyl, the isopropyl group is lost and the product is a 6-monoalkyltetralin. Moreover, there are certain 6,7-dialkyltetralins which give as products only small amounts of complex mixtures —a behavior paralleling that of 5,6,7,8-tetrahydrobenz(f)-indan and of *s*-hydrindacene, studied by Arnold and Barnes.[1]

(4) For example, see Newton, THIS JOURNAL, **65**, 2439 (1943).

Experimental Part[5]

The Jacobsen Reactions.—The general procedure was as follows: a mixture of the 6,7-dialkyltetralin (18 g.) and sulfuric acid was stirred and slowly heated. The color became red, then dark. Complete solution usually occurred at a temperature of about 80°. The mixture was kept at 95° for fifteen minutes, and then allowed to cool to room temperature and stand overnight. The mixture was diluted somewhat with water, and was then distilled with superheated steam (temperature of the reaction mixture, 150°). The distillate was extracted with ether, the extract was washed with aqueous sodium hydroxide, the solvent was evaporated and the residual material was distilled.

6,7-Dimethyltetralin (18 g.) yielded a light yellow oil (5 g.) which, on redistillation, gave colorless 5,6-dimethyltetralin (4.3 g.) boiling at 110–115° (7 mm.) and having $n^{20}D$ 1.5530. This material (8 drops) was heated with aqueous nitric acid (3 cc. 1:2) to 199–200° for three and one-half hours. The solution was evaporated to dryness, the residue was dissolved in ether, and to this solution was added an ethereal solution of diazomethane (from 2 g. of nitrosomethylurea). The ether was evaporated and the residue, crystallized twice from methanol, melted at 130–131° alone or when mixed with an authentic specimen of tetramethyl benzene-1,2,3,4-tetracarboxylate. Dehydrogenation of the 5,6-dimethyltetralin (1 cc.) led to 1,2-dimethylnaphthalene, identified as the picrate, m. p. and mixed m. p., 129–130°.

6-*n*-Propyl-7-methyltetralin (18 g.) yielded 5-*n*-propyl-6-methyltetralin (4.8 g., 25%), b. p. 140–145° (13.5 mm.). The product was converted to tetramethyl benzene-1,2,3,4-tetracarboxylate, m. p. and mixed m. p. 130–131°, as described above, and was dehydrogenated to 1-*n*-propyl-2-methylnaphthalene, identified as the picrate, m. p. and mixed m. p. 118–119°.

6-Isopropyl-7-methyltetralin (18 g.) yielded a yellow oil (7 g.), separated into three fractions by distillation: I, b. p., 95–105° (4.5 mm.) (2.1 g.), II, b. p. 122–130° (4.5 mm.) (3.0 g.), III, residue (0.8 g.). Fraction II gave no benzene tetracarboxylic acid upon oxidation, and was identified as 6-methyltetralin by dehydrogenation to 2-methylnaphthalene, m. p. and mixed m. p. of the picrate 115–117°.

6-Isopropyl-7-ethyltetralin (8 g.) (oleum, 10% sulfur trioxide, 40 cc. used instead of sulfuric acid) yielded an oil (1.2 g.) which gave no benzene tetracarboxylic acid on oxidation and which gave no picrate after dehydrogenation.

6,7-Di-*n*-propyltetralin (18 g.) gave less than 1 cc. of yellow oil from which no identifiable material could be isolated.

1-Tetralone was prepared from tetralin in 36% yield by the procedure of Thompson.[6] The product boiled at 125–126° (8 mm.), and gave a semicarbazone which, after crystallization from aqueous ethanol, melted at 215–217°.[7]

1-Methyl-1-tetralol.—To an ethereal solution of methylmagnesium iodide (prepared from magnesium 1.7 g.,

(5) Microanalyses by Sherman Sundet, Roger Amidon, Jay S. Buckley.

(6) Thompson, *Org. Syntheses*, **20**, 94 (1940).

(7) Kipping and Hill, *J. Chem. Soc.*, **75**, 148 (1899), reported the m. p. as 217°.

methyl iodide 5.5 cc. and ether 30 cc.) was added a solution of 1-tetralone (6.7 g.) in ether (10 cc.). The mixture was refluxed, and then decomposed by addition of iced ammonium chloride solution. The mixture was extracted with ether, the extract was washed with ammonium chloride solution, and the solvent was removed. The residue (7 g., 94%) solidified and then melted at 77–79°. After recrystallization from petroleum ether, the substance melted at 86–87°.[8]

1-Methylnaphthalene.—A mixture of 1-methyl-1-tetralol (3 g.) and a palladium–charcoal catalyst (0.3 g., 10%) was heated at 230–270° for three hours. The product was dissolved in ether, the catalyst was removed, and the solution was washed with aqueous sodium hydroxide (5%). Removal of the ether left 2.5 g. (95%) of residual oil which boiled at 94–96° (5 mm.), and had $n^{20}D$ 1.6037.[9]

Picrate.—The above oil (0.5 cc.) was added to methanolic picric acid and the solution was cooled. The yellow needles were removed and recrystallized from methanol. The product then melted at 141–142°.[10] *Anal.* Calcd. for $C_{17}H_{13}O_7N_3$: C, 54.99; H, 3.53. Found: C, 54.54; H, 3.56.

6-Propionyltetralin.[11]—Propionic anhydride (43.4 g.) was slowly (one hour) added to a cooled (0°) and stirred mixture of tetralin (6.6 g.), nitrobenzene (200 cc.) and aluminum chloride (150 g.). The mixture was gradually (two and one-half hours) allowed to attain room temperature and then was poured over ice and hydrochloric acid (100 cc.) and extracted with benzene. The extract was washed with water, aqueous sodium carbonate (10%) and water and dried over calcium chloride. Benzene, tetralin and nitrobenzene were removed by distillation under reduced pressure, and the residue was distilled. The product weighed 43 g. (68%), boiled at 160–163° (11 mm.) and had $n^{29}D$ 1.5508.

The semicarbazone, after crystallization from ethanol, melted at 209°.[12] *Anal.* Calcd. for $C_{14}H_{19}ON_3$: C, 69.11; H, 7.87. Found: C, 69.33; H, 8.06.

6-*n*-Propyltetralin.—A mixture of amalgamated zinc (360 g., 20 mesh), water (360 cc.), acetic acid (480 cc.), hydrochloric acid (720 cc.) and 6-propionyltetralin (61 g.) was refluxed for seventy-six hours, more hydrochloric acid (total 900 cc.) being added from time to time. The cooled mixture was extracted with ether, the extract was washed with water, aqueous sodium hydroxide (10%), and water, the solvent was removed, and the residue was distilled. The product, a colorless liquid, weighed 53 g. (92%), boiled at 123–125° (10 mm.) and had $n^{29}D$ 1.5253. *Anal.* Calcd. for $C_{13}H_{18}$: C, 89.60; H, 10.41. Found: C, 89.29; H, 10.47.

Trinitro-6-*n*-propyltetralin.—The tetralin (1 g.) was slowly dropped into a cold (0°) mixture of sulfuric acid (5 cc.) and fuming nitric acid (5 cc.). The mixture was allowed to stand for ten minutes and was then poured over ice and extracted with ether. The extract was washed with water, dilute sodium hydroxide, water, and was dried. The solvent was removed and the residue was crystallized twice from methanol. The colorless prisms (0.5 g.) melted at 97–98° and became first yellow, then red, when allowed to stand in the light. No attempt was made to determine the position of the nitro groups. *Anal.* Calcd. for $C_{13}H_{15}O_6N_3$: C, 50.5; H, 4.85. Found: C, 50.7; H, 5.12.

6-*n*-Propyltetralin Sulfonamide.—Chlorosulfonic acid (5 cc.) was added dropwise to a cold solution of the tetralin (1 g.) in chloroform (5 cc.). The mixture was allowed to attain room temperature and was poured over ice. The organic layer was removed, washed with water, and evaporated. The residual sulfonyl chloride was an oil which was converted directly to the sulfonamide by boiling it with ammonium hydroxide (5 cc.) for five minutes. The solid was dissolved in aqueous sodium hydroxide (5%), the solution was filtered, and the filtrate was acidified. The solid, after crystallization from ethanol, melted at 117–119°. No attempt was made to determine the position of the sulfonamide group. *Anal.* Calcd. for $C_{13}H_{19}O_2NS$: C, 61.5; H, 7.5. Found: C, 61.8; H, 8.1.

β-(4-*n*-Propyl)-benzoylpropionic Acid.—Aluminum chloride (75 g.) was added, in small portions, to a cooled (0°) mixture of succinic anhydride (25 g.), nitrobenzene (250 cc.) and *n*-propylbenzene (33 g.).[13] The mixture was stirred for two hours and then poured over iced hydrochloric acid and steam-distilled. The oily residue, which solidified on cooling, was dissolved in aqueous sodium carbonate (10%), the solution was warmed with charcoal, filtered, and the filtrate was acidified. The solid was removed and crystallized from methanol. It weighed 35 g. (63%) and melted at 108–115°. After two recrystallizations from benzene, the substance melted at 120–121°. *Anal.* Calcd. for $C_{13}H_{16}O_3$: C, 70.89; H, 7.32. Found: C, 70.97; H, 7.60.

The *p*-phenylphenacyl ester, recrystallized twice from ethanol, melted at 85–86°. *Anal.* Calcd. for $C_{27}H_{26}O_4$: C, 78.3; H, 6.28. Found: C, 78.7; H, 6.51.

The semicarbazone, after crystallization from dilute ethanol, melted at 171–172°. *Anal.* Calcd. for $C_{14}H_{19}O_3N_3$: C, 60.6; H, 6.91. Found: C, 60.1; H, 7.15.

3-(4-*n*-Propyl)-phenylpyridazinone-6, prepared from the acid by the procedure of Gabriel and Colman,[14] and crystallized from dilute ethanol, melted at 103.5–104.5°. *Anal.* Calcd. for $C_{13}H_{16}ON_2$: C, 72.2; H, 7.46. Found: C, 72.6; H, 7.62.

γ-(4-*n*-Propyl)-phenylbutyric Acid.—The above keto acid (55 g.) was refluxed with amalgamated zinc (100 g.), hydrochloric acid (175 cc.) and water (75 cc.) for twenty-four hours, during which time three 50-cc. portions of hydrochloric acid were added. The top layer solidified when the mixture was cooled; the solid was removed and crystallized from petroleum ether (b. p. 30–60°), when it weighed 36.5 g. (71%) and melted at 65–66°. *Anal.* Calcd. for $C_{13}H_{18}O_2$: C, 75.69; H, 8.79. Found: C, 75.93; H, 9.01.

The *p*-phenylphenacyl ester, crystallized from ethanol, melted at 105–106°. *Anal.* Calcd. for $C_{27}H_{28}O_3$: C, 80.97; H, 7.05. Found: C, 81.23; H, 7.19.

7-*n*-Propyl-1-tetralone.—Sulfuric acid (150 cc., 80%) and γ-(4-*n*-propyl)-phenylbutyric acid (30 g.) were heated on the steam bath for one hour. The cooled solution was poured over ice and extracted with ether. The ether extract was washed with aqueous sodium hydroxide (5%), dried, and the solvent was removed. The residue, on distillation, gave 19.5 g. (71%) of a colorless liquid which boiled at 150–155° (8 mm.) and had $n^{29}D$ 1.5455. *Anal.* Calcd. for $C_{13}H_{16}O$: C, 82.93; H, 8.57. Found: C, 82.51; H, 8.70.

The semicarbazone, crystallized twice from ethanol, melted at 197–198°. *Anal.* Calcd. for $C_{14}H_{19}ON_3$: C, 68.54; H, 7.81. Found: C, 68.70; H, 7.86.

6-*n*-Propyltetralin.—The above 7-*n*-propyltetralone (14.5 g.) reduced by the method of Clemmensen as previously described, gave the hydrocarbon (6.6 g., 49%) boiling at 105–109° (5 mm.). Converted to the sulfonamide, as described above, the product melted at 117.5–118.5° alone or when mixed with the sulfonamide prepared from the tetralin resulting from reduction of 6-propionyltetralin.

2-*n*-Propylnaphthalene Picrate.—6-*n*-Propyltetralin (1 cc.) and a palladium–charcoal catalyst (10%, 0.1 g.)[15] were heated at 200–240° under a current of carbon dioxide for three hours. The product was taken up in ethanol,

(8) von Auwers, *Ann.*, **415**, 169 (1918), reported the m. p. as 88–89°.

(9) Anderson and Short, *J. Chem. Soc.*, 485 (1933), reported the b. p. as 100–105° (5 mm.).

(10) Lesser, *Ann.*, **402**, 10 (1913), and Meyer and Fricke, *Ber.*, **47**, 2770 (1914), reported the m. p. as 141–142°.

(11) Barnes, Ph.D. Thesis, University of Minnesota, 1943.

(12) Barbot, *Bull. soc. chim.*, [4] **47**, 1314 (1930), reported 224–225°, but gave no analysis.

(13) Gilman and Catlin, "Org. Syntheses," Coll. Vol. I, 471 (1941).

(14) Gabriel and Colman, *Ber.*, **32**, 399 (1899).

(15) Linstead and Thomas, *J. Chem. Soc.*, 1127 (1940).

the catalyst was removed and ethanolic picric acid (15 cc.) was added to the filtrate. The cooled solution deposited yellow needles which, after crystallization from ethanol, melted at 91°.[16]

6-Acetyltetralin.—This was prepared by the procedure of Barnes[11] essentially as described for the propionyl derivative, but substituting acetic anhydride for propionic anhydride. The product, obtained in 60% yield, was a yellow oil which boiled at 151–156° (10 mm.) and had $n^{29}D$ 1.5593.

The semicarbazone, recrystallized from ethanol, melted at 233–234°.[17]

6-Tetralyldimethylcarbinol.—A solution of 6-acetyltetralin (43.5 g.) in ether (20 cc.) was slowly (forty-five minutes) added to a Grignard reagent prepared from magnesium (6 g.), methyl iodide (36 g.) and ether (120 cc.). After addition was complete, the mixture was refluxed for thirty minutes, then cooled and poured carefully over iced ammonium chloride. The ether layer was removed and the aqueous layer was extracted with ether. The combined organic solutions were washed with ammonium chloride solution and dried over sodium sulfate. The solvent was removed and the residue was distilled. The product (39.3 g., 83%) boiled at 138–141° (5 mm.), and had $n^{20}D$ 1.5497. *Anal.* Calcd. for $C_{13}H_{18}O$: C, 82.1; H, 9.53. Found: C, 82.5; H, 9.23. Although water (1.8 cc., calcd. 2.7 cc.) was eliminated from the carbinol (29 g.) when it was heated to 150–160° with fused potassium acid sulfate (25 g.), the product (12.5 g.) was a mixture (b. p. 133–160° (10 mm.)) from which no pure material could be isolated. When heated with hydriodic acid and red phosphorus, the carbinol was converted into a thick oil which did not distill at 200° (5 mm.).

6-Isopropyltetralin.—The above carbinol (24 g.) was dissolved in ethanol (24 cc.) and the solution was refluxed with Raney nickel catalyst (1 g.) for an hour. The catalyst was removed, the filtrate was diluted with ethanol to 60 cc. and reduced over copper chromite catalyst (6 g.)[18] in a bomb at a temperature of 225° and initial hydrogen pressure of 1670 lb. The reduction was complete in one hour. The reaction product, processed in the usual way, yielded 19 g. (86%) of a colorless liquid which boiled at 120–123° (12 mm.), and had $n^{29}D$ 1.5246. *Anal.* Calcd. for $C_{13}H_{18}$: C, 89.6; H, 10.41. Found: C, 89.9; H, 10.58.

Trinitro-6-isopropyltetralin.—The trinitro compound, prepared as described above for the *n*-propyl isomer, melted at 141–142°. It also became yellow, then red, in the light. *Anal.* Calcd. for $C_{13}H_{15}O_6N_3$: C, 50.5; H, 4.85. Found: C, 50.9; H, 5.27.

6-Isopropylsulfonamide.—The hydrocarbon was converted into the sulfonamide by the procedure described above for the *n*-propyl isomer. The product, after crystallization twice from dilute methanol, melted at 157–158°. The position of the sulfonamide group was not determined. *Anal.* Calcd. for $C_{13}H_{19}O_2NS$: C, 61.5; H, 7.51. Found: C, 61.6; H, 7.95.

6-Isopropyltetralin was also prepared by direct alkylation of tetralin (396 g.) with isopropyl bromide (123 g.) at 60° in the presence of aluminum chloride (20 g.). The product was processed in the usual way. The fraction boiling at 123–125° (15 mm.) weighed 43 g. (24%), had $n^{29}D$ 1.5429, and gave the same sulfonamide, m. p. 158°, described above. When tetralin (500 cc.) and isopropyl acetate (52 g.) reacted in the presence of aluminum chloride (80 g.), a product resulted from which, on distillation, a fraction (30 g., 34%) was isolated having $n^{29}D$ 1.5250 and boiling at 113–115° (8–9 mm.). This likewise gave the sulfonamide, m. p. 157°. The middle fraction (25 g.), b. p. 149–152° (8–9 mm.), solidified on cooling and, after two crystallizations from ethanol, melted at 73–74°. It was identified as octahydroanthracene by the m. p. and analysis.[19] *Anal.* Calcd. for $C_{14}H_{18}$: C, 90.33; H, 9.68. Found: C, 90.45; H, 9.68. The mother liquor from this solid was a colorless oil boiling at 150–155° (10 mm.). and having $n^{29}D$ 1.5579. It was identified as 6-acetyltetralin by the m. p. and mixed m. p. (232–235°) of the semicarbazone. The high boiling fraction was a yellow oil, b. p. 215–220° (9 mm.) having the composition $C_{20}H_{24}$. Analysis and b. p. indicated that this was α-phenyl-δ-2-tetralylbutane.[20] *Anal.* Calcd. for $C_{20}H_{24}$: C, 90.85; H, 9.15. Found: C, 90.99; H, 9.11.

β-(4-Isopropyl)-benzoylpropionic acid (64.8 g., 59%) was prepared from succinic anhydride (50 g.) and isopropylbenzene (66 g.) by action of aluminum chloride (150 g.) in nitrobenzene (500 cc.) essentially according to Barnett and Sanders.[21] The product, crystallized twice from benzene, melted at 141°. The *p*-phenylphenacyl ester, crystallized from ethanol, melted at 101.5–102.5°. *Anal.* Calcd. for $C_{27}H_{26}O_4$: C, 78.26; H, 6.28. Found: C, 78.42; H, 6.42. The semicarbazone, crystallized from ethanol, melted at 182–182.5° (dec.). *Anal.* Calcd. for $C_{14}H_{19}O_3N_3$: C, 60.63; H, 6.91. Found: C, 60.48; H, 7.08. 3-(4-Isopropyl)-phenylpyridazinone, prepared by action of hydrazine and alkali upon the keto acid, and crystallized from ethanol, melted at 166–167°. *Anal.* Calcd. for $C_{13}H_{16}O_2N_2$: C, 72.19; H, 7.46. Found: C, 72.18; H, 7.16.

γ-4-(Isopropyl)-phenylbutyric acid (37 g., 72%) was prepared from the above keto acid (55 g.) by Clemmensen reduction, according to the procedure of Barnett and Sanders.[22] The product boiled at 180–185° (11 mm.) and solidified on standing. Recrystallized from petroleum ether (b. p. 30–60°) it formed colorless prisms melting at 48–50°. The *p*-phenylphenacyl ester, after crystallization from ethanol, melted at 91–92.5°. *Anal.* Calcd. for $C_{27}H_{28}O_3$: C, 80.97; H, 7.05. Found: C, 81.22; H, 7.25.

7-Isopropyl-1-tetralone (16.5 g., 72%) was obtained by action of sulfuric acid (80%, 125 cc.) upon the above phenylbutyric acid.[23] The product boiled at 153–155° (12 mm.) and melted at 36°. The semicarbazone, after crystallization from ethanol, melted at 199–200°. *Anal.* Calcd. for $C_{14}H_{19}ON_3$: C, 68.54; H, 7.81. Found: C, 68.65; H, 7.97.

This tetralone (14.5 g.) was refluxed with amalgamated zinc (100 g.), water (75 cc.) and hydrochloric acid (175 cc.) for ten hours, during which two 50-cc. portions of hydrochloric acid were added. There resulted 9.7 g. (72%) of 6-isopropyltetralin, which boiled at 123–125° (9 mm.) and had $n^{29}D$ 1.5245. The sulfonamide melted at 158–159° and was identical with the one described above.

2-Isopropylnaphthalene.—The tetralin (17.4 g.) and sulfur (6.4 g.) were heated at 200° (temperature of the metal-bath) for one hour, and then at 265–270° for thirty minutes. The reaction mixture was distilled; the distillate weighed 12 g. (70%), boiled at 126–129° (10 mm.) and had $n^{20}D$ 1.5730. The picrate, obtained by dissolving the hydrocarbon in methanolic picric acid and cooling the solution, melted at 93–94°.[24]

6-Methyltetralin was prepared by catalytic reduction of 2-methylnaphthalene, according to the procedure of Fieser and Jones,[25] although it was found that the starting material had to be pre-treated with Raney nickel catalyst before a smooth reduction occurred. The product, obtained in 94% yield, boiled at 220–222° (736 mm.), 100–103° (12 mm.), and had $n^{20}D$ 1.5358.

(16) Haworth, Letsky and Mavin, *J. Chem. Soc.*, 1784 (1932), gave the m. p. as 89–90°.

(17) Hesse, *Ber.*, **53**, 1645 (1920), reported 234–235°; Barbot (ref. 12) reported 257–258°.

6-Acyl-7-alkyltetralins.—These were prepared from the alkyltetralins, by action of the corresponding acid anhydride in the presence of aluminum chloride, with nitrobenzene as the solvent. A representative procedure is given.

6-Acetyl-7-methyltetralin.—Acetic anhydride (50 cc.) was added slowly (forty minutes) to a cooled (0°) and stirred mixture of 6-methyltetralin (62 g.), nitrobenzene (350 cc.), and aluminum chloride (143 g.). The mixture was stirred at room temperature for two hours and then was decomposed by pouring it into iced hydrochloric acid. The mixture was extracted with benzene and the extract was washed successively with hydrochloric acid, aqueous sodium hydroxide (10%), and water. The solvents were removed by distillation under reduced pressure and the residue was distilled. There resulted 62 g. (77%) of a yellow oil which boiled at 155–159° (10 mm.) and had $n^{20}D$ 1.5511. *Anal.* Calcd. for $C_{13}H_{16}O$: C, 82.93; H, 8.57. Found: C, 83.04; H, 8.78. The 2,4-dinitrophenylhydrazone, crystallized once from acetone and twice from a mixture of ethyl acetate and methanol, melted at 172–173°. *Anal.* Calcd. for $C_{19}H_{20}O_4N_4$: C, 61.92; H, 5.47. Found: C, 62.09; H, 5.67.

6-Propionyl-7-methyltetralin: yield 76%, b. p. 162–166° (11 mm.), $n^{20}D$ 1.5479. *Anal.* Calcd. for $C_{14}H_{18}O$: C, 83.12; H, 8.97. Found: C, 82.72; H, 8.84. The 2,4-dinitrophenylhydrazone, crystallized twice from ethyl acetate, melted at 153–154°. *Anal.* Calcd. for $C_{20}H_{22}O_4N_4$: C, 62.81; H, 5.80. Found: C, 63.07; H, 5.78.

6-Acetyl-7-*n*-propyltetralin: yield 72%, b. p. 150–155° (5 mm.); $n^{20}D$ 1.5445. *Anal.* Calcd. for $C_{15}H_{20}O$: C, 83.28; H, 9.32. Found: C, 82.94; H, 9.20. The 2,4-dinitrophenylhydrazone, crystallized twice from ethyl acetate–methanol, melted at 133–134°. *Anal.* Calcd. for $C_{21}H_{24}O_4N_4$: C, 63.69; H, 6.25. Found: C, 63.81; H, 6.31.

6-Propionyl-7-*n*-propyltetralin: yield 78%, b. p. 182–186° (16 mm.), $n^{20}D$ 1.5350. *Anal.* Calcd. for $C_{16}H_{22}O$: C, 84.42; H, 9.63. Found: C, 83.84; H, 9.95. The 2,4-dinitrophenylhydrazone crystallized twice from ethyl acetate–methanol, melted at 123–124°. *Anal.* Calcd. for $C_{22}H_{26}O_4N_4$: C, 64.37; H, 6.38. Found: C, 64.63; H, 6.51.

6-Acetyl-7-isopropyltetralin: yield 66%; b. p., 147–150° (4 mm.), $n^{20}D$ 1.5460. *Anal.* Calcd. for $C_{15}H_{20}O$: C, 83.28; H, 9.32. Found: C, 82.73; H, 9.45. The 2,4-dinitrophenylhydrazone, crystallized twice from ethyl acetate–methanol, melted at 166–167°. *Anal.* Calcd. for $C_{21}H_{24}O_4N_4$: C, 63.69; H, 6.25. Found: C, 63.84; H, 6.31. It was planned to convert 6-acetyl-7-isopropyltetralin into 6,7-diisopropyltetralin, *via* the dimethyl carbinol which would result by addition of methylmagnesium iodide to the acetyl compound. However, the only product isolated as a result of this reaction was unchanged 6-acetyl-7-isopropyltetralin (20 g. from 30 g. used), b. p., 138–141° (2 mm.), $n^{20}D$ 1.5408, m. p. and mixed m. p. of the semicarbazone, 166–167°. No further study of this reaction was made; it is likely that the reaction involved almost entirely enolization of the ketone, but this was not investigated.

6-Propionyl-7-isopropyltetralin: yield 57%, b. p. 170–175° (14.5 mm.), $n^{20}D$ 1.5382. *Anal.* Calcd. for $C_{16}H_{22}O$: C, 83.42; H, 9.63. Found: C, 83.53; H, 9.69. The 2,4-dinitrophenylhydrazone, crystallized twice from ethyl acetate–methanol, melted at 141–142°. *Anal.* Calcd. for $C_{22}H_{26}O_4N_4$: C, 64.37; H, 6.38. Found: C, 64.85; H, 6.57.

6,7-Dialkyltetralins.—These were, except where noted otherwise, prepared from the corresponding 6-acyl-7-alkyltetralins, by the Clemmensen method. The procedure, in general, followed those already given above for similar reductions.

6,7-Dimethyltetralin (57 g., 89%) was prepared by reduction of 2,3-dimethylnaphthalene (62 g.) in ethanol in the presence of Raney nickel catalyst.[26] The product boiled at 112–115° (9.5 mm.)[27] and had $n^{20}D$ 1.5360.

6,7-Dimethyltetralin-5-sulfonamide.—Chlorosulfonic acid (2.8 cc.) was dropped into a cold (0°) solution of the tetralin (1 cc.) in chloroform (5 cc.). The mixture was allowed to stand at room temperature for twenty minutes, then was poured over ice and extracted with chloroform. The extract was washed with water, dried, the solvent was removed, and the residual oil was boiled with ammonium hydroxide. The mixture was diluted with water, and the solid was removed and crystallized several times from some dilute ethanol. It then melted at 135–136°.[28] *Anal.* Calcd. for $C_{12}H_{17}O_2NS$: C, 60.22; H, 7.16. Found: C, 60.48; H, 7.27. 6-Ethyl-7-methyltetralin, from 6-acetyl-7-methyltetralin: yield 81%, b. p. 121–124° (10 mm.), $n^{20}D$ 1.5272. *Anal.* Calcd. for $C_{13}H_{18}$: C, 89.59; H, 10.41. Found: C, 89.34; H, 10.71.

6-(7-Methyltetralyl)-dimethylcarbinol.—A solution of 6-acetyl-7-methyltetralin (37.6 g.) in ether (20 cc.) was slowly added to a Grignard reagent prepared from magnesium (4.8 g.), methyl iodide (13 cc.) and ether (40 cc.). The mixture was refluxed for thirty minutes, then cooled, poured into iced ammonium chloride solution and extracted with ether. The extract was washed with aqueous ammonium chloride and water, the solvent was removed and the residue was distilled. The carbinol (32 g., 78%) formed a light yellow oil which boiled at 135–136° (3 mm.) and had $n^{20}D$ 1.5435. *Anal.* Calcd. for $C_{14}H_{20}O$: C, 82.3; H, 9.87. Found: C, 83.0; H, 9.50.

6-Isopropyl-7-methyltetralin.—The above carbinol (32 g.) in ethanol (32 cc.) was refluxed with Raney nickel catalyst for one hour. The catalyst was removed and the filtrate was diluted to 70 cc. by addition of ethanol. This solution, together with copper chromite catalyst (9 g.) was heated to 220–225° for two hours in a bomb under an initial hydrogen pressure of 1820 lb. The catalyst was removed by centrifugation, the solvent was removed by distillation under reduced pressure, and the residue was distilled. The product, a colorless liquid, boiled at 113–116° (6 mm.) and had $n^{20}D$ 1.5250. *Anal.* Calcd. for $C_{14}H_{20}$: C, 89.29; H, 10.71. Found: C, 89.46; H, 10.84. The hydrocarbon (8 drops) and nitric acid (3 cc., 1:2) were heated at 190–200° for sixteen hours. The solution was evaporated to dryness and the residue was taken up in ether. Ethereal diazomethane (from 2 g. of nitrosomethylurea) was added, the solution was evaporated, and the residue was crystallized twice from methanol. The product melted at 141–142° alone or when mixed with an authentic specimen of tetramethyl pyromellitate.

6-*n*-Propyl-7-methyltetralin, from 6-propionyl-7-methyltetralin: yield 84%, b. p., 130–135° (11 mm.), $n^{20}D$ 1.5250. *Anal.* Calcd. for $C_{14}H_{20}$: C, 89.30; H, 10.71. Found: C, 88.87; H, 10.62. Oxidation of the hydrocarbon, as described above, gave tetramethyl pyromellitate, m. p. and mixed m. p. 141–142°.

6-*n*-Propyl-7-ethyltetralin, from 6-acetyl-7-*n*-propyltetralin: yield 78%, b. p. 114–117° (2.5 mm.), $n^{20}D$ 1.5228. *Anal.* Calcd. for $C_{15}H_{22}$: C, 89.04; H, 10.96. Found: C, 88.66; H, 10.95.

6,7-Di-*n*-propyltetralin, from 6-propionyl-7-*n*-propyltetralin: yield 80%, b. p. 157–162° (12 mm.), $n^{20}D$ 1.5234. Oxidation of the hydrocarbon, as described above, gave tetramethyl pyromellitate, m. p., and mixed m. p., 141–142°. *Anal.* Calcd. for $C_{16}H_{24}$: C, 88.82; H, 11.18. Found: C, 88.95, 88.61; H, 11.51, 11.15.

6-Isopropyl-7-ethyltetralin, from 6-acetyl-7-isopropyltetralin: yield 61%, b. p. 127–130° (5 mm.), $n^{20}D$ 1.5200. *Anal.* Calcd. for $C_{15}H_{22}$: C, 89.04; H, 10.96. Found: C, 89.50; H, 11.02.

6-Isopropyl-7-*n*-propyltetralin, from 6-propionyl-7-isopropyltetralin: yield 53%, b. p. 157–160° (15 mm.), $n^{20}D$ 1.5238. *Anal.* Calcd. for $C_{16}H_{24}$: C, 88.82; H, 11.18. Found: C, 88.59; H, 11.04.

2,3-Dialkylnaphthalenes.—These were prepared by dehydrogenation of the corresponding 6,7-dialkyltetralins by heating them to 220–250° in a current of carbon dioxide and in the presence of a palladium-charcoal (10%)

(26) Craig, Ph.D. Thesis, University of Minnesota, 1947.

(27) Coulson, *J. Chem. Soc.*, 1305 (1938), reported the b. p. as 244–246°.

(28) Coulson, ref. 27, reported the m. p. as 135°.

catalyst for approximately three hours. The catalyst was used in an amount roughly 10% of that of the dialkyltetralin taken. The reaction product was taken up in ether, the catalyst was removed, and the naphthalene was distilled. The picrates were prepared by dissolving the hydrocarbon in methanolic picric acid and cooling the solution. They were recrystallized from ethanol or methanol.

2-Ethyl-3-methylnaphthalene, from 6-ethyl-7-methyltetralin: yield 85%, b. p. 109–112° (3 mm.), $n^{20}D$ 1.5658. *Anal.* Calcd. for $C_{13}H_{14}$: C, 91.71; H, 8.29. Found: C, 91.17; H, 8.67. Picrate, yellow needles, m. p., 129–130°. *Anal.* Calcd. for $C_{19}H_{17}O_7N_3$: C, 57.14; H, 4.29. Found: C, 57.45; H, 4.57.

2-Isopropyl-3-methylnaphthalene, from 6-isopropyl-7-methyltetralin: yield 99%, b. p. 130–132° (7 mm.), $n^{20}D$ 1.5599. *Anal.* Calcd. for $C_{14}H_{16}$: C, 91.25; H, 8.75. Found: C, 91.54; H, 8.83. Picrate, yellow needles, m. p., 133–136°. *Anal.* Calcd. for $C_{20}H_{19}O_7N_3$: C, 58.11; H, 4.63. Found: C, 58.17; H, 4.66.

2-*n*-Propyl-3-methylnaphthalene, from 6-*n*-propyl-7-methyltetralin: yield 70%, b. p. 121–123° (3 mm.), $n^{20}D$ 1.5647. *Anal.* Calcd. for $C_{14}H_{16}$: C, 91.25; H, 8.75. Found: C, 91.20; H, 8.95. Picrate, yellow needles, m. p., 110–112°. *Anal.* Calcd. for $C_{20}H_{19}O_7N_3$: C, 58.11; H, 4.63. Found: C, 57.85; H, 4.87.

2-*n*-Propyl-3-ethylnaphthalene from 6-*n*-propyl-7-ethyltetralin: yield 81%, b. p. 131–134° (4 mm.), $n^{20}D$ 1.5752. *Anal.* Calcd. for $C_{15}H_{18}$: C, 90.85; H, 9.15. Found: C, 90.47; H, 9.02. Picrate, yellow needles, m. p., 92–93°. *Anal.* Calcd. for $C_{21}H_{21}O_7N_3$: C, 59.01; H, 4.95. Found: C, 59.15; H, 5.09.

2,3-Di-*n*-propylnaphthalene from 6,7-di-*n*-propyltetralin: The tetralin (17.2 g.) and sulfur (4.8 g.) were heated at 200–205° for one hour and then at 270–275° for one hour. The product was distilled, then allowed to stand over sodium for several hours, and redistilled. It weighed 13 g. (77%), boiled at 155–158° (8.5 mm.), and had $n^{20}D$ 1.5601. *Anal.* Calcd. for $C_{16}H_{20}$: C, 90.50; H, 9.50. Found: C, 90.33; H, 9.56. Picrate, yellow needles, m. p., 83–84°. *Anal.* Calcd. for $C_{22}H_{23}O_7N_3$: C, 59.86; H, 5.25. Found: C, 59.70; H, 5.38.

2-Isopropyl-3-ethylnaphthalene, from 6-isopropyl-7-ethyltetralin: yield 95%, b. p., 132–135° (5 mm.), $n^{20}D$ 1.5742. *Anal.* Calcd. for $C_{15}H_{18}$: C, 90.85; H, 9.15. Found: C, 90.58; H, 9.11. Picrate, yellow needles, m. p., 117–119°. *Anal.* Calcd. for $C_{21}H_{21}O_7N_3$: C, 59.01; H, 4.95. Found: C, 58.66; H, 5.06.

2-Isopropyl-3-*n*-propylnaphthalene, from 6-isopropyl-7-*n*-propyltetralin: yield 95%, b. p., 135–138° (5 mm.), $n^{20}D$ 1.5604. *Anal.* Calcd. for $C_{16}H_{20}$: C, 90.50; H, 9.49. Found: C, 90.27; H, 9.90. This naphthalene failed to form a picrate when treated with methanolic picric acid.

2-Methoxalyl-1-tetralone, m. p., 64–65°, was prepared from 1-tetralone in 59% yield by the procedure of Bachmann and Thomas,[29] who reported it to melt at 65.5–66.5°.

2-Carbomethoxy-1-tetralone was prepared from the methoxalyl compound in 91% yield, according to Bachmann and Thomas.[29]

2-Methyl-2-carbomethoxy-1-tetralone, m. p., 58–59.5°, was prepared in 80% yield by alkylation of the carbomethoxytetralone with methyl iodide, following Bachmann and Thomas[29] who reported the m. p. as 56.5–57.5°.

2-Methyl-1-tetralone, b. p. 138–140° (15 mm.),[30] was obtained in 91% yield by alkaline hydrolysis of 2-methyl-2-carbomethoxy-1-tetralone according to the general procedure of Kloetzel.[31] The semicarbazone, crystallized from ethanol, melted at 201–202°.[32]

2-Methyl-1-*n*-propyltetralol.—A solution of *n*-propylmagnesium bromide (prepared from magnesium 1.1 g., *n*-propyl bromide 4.5 cc., and ether 30 cc.) was cooled and stirred while a solution of 2-methyl-1-tetralone (5 g.) in ether (20 cc.) was slowly added. The mixture was refluxed for one and one-half hours, then poured into ammonium chloride solution and extracted with ether. The extract was washed successively with aqueous ammonium chloride and water, the solvent was removed, and the residue was distilled. The product, 4.8 g. (75%) was a colorless liquid boiling at 146–150° (14–15 mm.), which solidified on cooling. Twice crystallized from petroleum ether (b. p. 30–60°), the substance melted at 82–83°. *Anal.* Calcd. for $C_{14}H_{20}O$: C, 82.4; H, 9.8. Found: C, 83.1; H, 9.7.

2-Methyl-1-*n*-propylnaphthalene.—The above tetralol (3 g.) was heated to 230–270° for three hours with palladium–charcoal catalyst (0.3 g., 10%). The mixture was taken up in ether, the catalyst was removed, and the solvent was evaporated. There resulted 2.4 g. of oil which boiled at 102–105° (5 mm.), and had $n^{20}D$ 1.5961. *Anal.* Calcd. for $C_{14}H_{16}$: C, 91.25; H, 8.75. Found: C, 91.08; H, 8.97.

Picrate.—The naphthalene (0.5 cc.) was dissolved in methanolic picric acid (6 cc.), the solution was cooled and the yellow crystals were removed and crystallized from methanol. The picrate then melted at 118–119°. *Anal.* Calcd. for $C_{20}H_{19}O_7N_3$: C, 58.11; H, 4.63. Found: C, 57.98; H, 4.49.

2-Methyl-1-isopropyl-1-tetralol.—A solution of isopropylmagnesium bromide (prepared from magnesium 1.5 g., isopropyl bromide 6 cc., and ether 30 cc.) was cooled and to it was added a solution of 2-methyl-1-tetralone (6.4 g.) in ether (20 cc.). The reaction mixture was then processed as described for the *n*-propyl isomer. The product (5.4 g.) boiled at 126–129° (14 mm.), and had $n^{20}D$ 1.5562. *Anal.* Calcd. for $C_{14}H_{20}O$: C, 82.4; H, 9.8. Found: C, 84.0; H, 8.4. This tetralol (4 g.) was not dehydrated when it was refluxed with acetic acid (40 cc.) for one hour; there was recovered 3 g. of unchanged material, b. p. 127–131° (14 mm.), having $n^{20}D$ 1.5568.

2-Methyl-1-isopropylnaphthalene.—The above tetralol (3 g.) was dehydrated and dehydrogenated in one operation by heating it to 230–270° for three hours with palladium–charcoal catalyst (0.3 g., 10%). Isolated as described above for the *n*-propyl isomer, the product (1.8 g.) boiled at 92–95° (4 mm.), and had $n^{20}D$ 1.5992. *Anal.* Calcd. for $C_{14}H_{16}$: C, 91.25; H, 8.75. Found: C, 91.02; H, 8.62.

Picrate, prepared as described above and crystallized from methanol, formed needles melting at 142–143°. *Anal.* Calcd. for $C_{20}H_{19}O_7N_3$: C, 58.11; H, 4.63. Found: C, 58.15; H, 4.85.

The methods used for synthesis of the 2-methyl-1-propylnaphthalenes failed when applied to the synthesis of the 1-methyl-2-propyl isomers. Thus, 2-carbomethoxy-1-tetralone could not be alkylated with *n*-propyl bromide, by the procedure of Bachmann and Thomas[29]; the only product that could be isolated was recovered 2-carbomethoxy-1-tetralone (75%). Nor was the direct alkylation of 1-tetralone successful. Action of methyl iodide upon the sodium derivative of the tetralone in liquid ammonia failed to produce any methyltetralone; action of isopropyl bromide upon the sodium derivative of the tetralone, formed in benzene by action of freshly prepared sodamide likewise failed; nor was the action of potassium *t*-butoxide in butanol effective in bringing about any reaction between 1-tetralone and isopropyl bromide.

Summary

1. Five 6,7-dialkyltetralins have been subjected to the conditions of the Jacobsen rearrangement. 6,7-Dimethyltetralin rearranged to 5,6-dimethyltetralin; 6-methyl-7-*n*-propyltetralin rearranged to 6-methyl-5-*n*-propyltetralin, the struc-

(29) Bachmann and Thomas, THIS JOURNAL, **63**, 598 (1941).

(30) Tishler, Fieser and Wendler, *ibid.*, **62**, 2866 (1940), reported the b. p. as 136–137° (16 mm.).

(31) Kloetzel, *ibid.*, **62**, 1708 (1940).

(32) Krollpfeiffer and Schaefer, *Ber.*, **56**, 631 (1923), give 199–201°; Mayer and Stamm, *Ber.*, **56**, 1424 (1923), give 200–201°; Kloetzel, Ref. 31, gives 203–205°; and Tishler, Fieser and Wendler, Ref. 30, give 205–206°.

ture of the *n*-propyl group remaining unaltered. 6-Isopropyl-7-methyltetralin gave 6-methyltetralin, the isopropyl group being eliminated. 6-Isopropyl-7-ethyltetralin and 6,7-di-*n*-propyltetralin were largely decomposed to products obtained in small yields only, and which could not be identified.

2. The theoretical aspects of these results have been discussed with reference to the theory of Arnold and Barnes on the mechanism of the Jacobsen rearrangement.

3. Satisfactory laboratory methods for preparation of the two 6-propyltetralins, *n*- and *iso*-, have been developed, and it has been shown that the structure of the *n*-propyl group remains unaltered when *n*-propylbenzene undergoes a Friedel–Crafts reaction with succinic anhydride.

4. Seven new 6,7-dialkyltetralins have been synthesized, in which one or both of the alkyl groups is methyl, ethyl, *n*-propyl or isopropyl.

5. The corresponding 2,3-dialkylnaphthalenes (and their picrates) have been prepared by dehydrogenation of the 6,7-dialkyltetralins. Syntheses of 1-isopropyl-2-methylnaphthalene and of 1-methylnaphthalene have been developed.

6. Several new intermediate ketones (acyl tetralins) and carbinols have been synthesized and characterized.

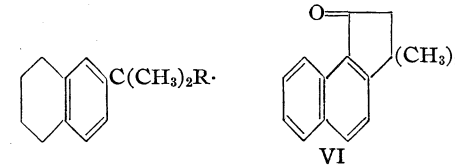
The Reaction between Tetralin and β,β-Dimethylacrylic Acid

BY LEE IRVIN SMITH AND CHIEN-PEN LO[1]

The reaction between benzene or an alkylbenzene and β,β-dimethylacrylic acid in the presence of aluminum chloride leads to a β-aryl-isovaleric acid.[2] However, when a polyalkylbenzene is used in this reaction, one or more of the following abnormal transformations may occur: (a) the condensation may occur at a position other than the one involved when the acid chloride (ordinary Friedel–Crafts reaction) is used, as is the case with 1,2,3-trimethylbenzene[3]; (b) one of the alkyl groups may rearrange to another position on the benzene nucleus, as is the case with 1,2,4-trimethylbenzene[3]; (c) one of the alkyl groups may be eliminated during the reaction, as is the case with 1,3,5-trimethylbenzene.[4]

In order to explore the limits of this reaction, tetralin has been condensed with β,β-dimethylacrylic acid in the presence of aluminum chloride. Only one acid (70% yield) was isolated; this was identified as β-(6-tetralyl)-isovaleric acid, I, by comparison with a specimen synthesized by an independent method. Thus tetralin, unlike other polyalkylbenzenes, behaves normally in this condensation.

6-(Tetralyl)-dimethylcarbinol, II,[5] was converted by action of hydrochloric acid into the chloride III, which (without isolation) was used to alkylate diethyl malonate. The substituted malonic ester IV (also without isolation) was hydrolyzed to the malonic acid V, and V, on decarboxylation, gave the isovaleric acid I, identical with the product obtained from β,β-dimethylacrylic acid and tetralin.



VI

I, R = —CH_2COOH
II, R = OH
III, R = Cl
IV, R = —$CH(COOC_2H_5)_2$
V, R = —$CH(COOH)_2$

Cyclization of the acid I, by action of sulfuric acid, in view of the work of Cauquil and Barrera[6] on the closely related β-(6-tetralyl)-butyric acid, should lead to a mixture of two tetrahydrobenzhydrindones, linear and angular. However, cyclization of β-(2-naphthyl)-propionic acids generally leads to only one benzindanone, the angular.[7] The acid I was therefore converted into the methyl ester and the latter was smoothly dehydrogenated to methyl β-(2-naphthyl)-isovalerate by action of palladium–charcoal catalyst—a result substantiating the findings of Newman and Zahm[8] that a carbomethoxy group is not affected by the hydrogen evolved during dehydrogenation. The methyl ester was hydrolyzed to β-(2-naphthyl)-isovaleric acid, and the acid, subjected to the action of sulfuric acid was dehydrated to a single benzhydrindone assigned structure VI.

Experimental[9]

β-(6-Tetralyl)-isovaleric Acid (I).—To a stirred and cooled (−10°) solution of β,β-dimethylacrylic acid (7.5 g.) in tetralin (37.5 g.), powdered aluminum chloride (13.3 g.) was added (fifteen minutes) in small portions. The mixture was thereafter stirred at −10° for one hour, at room temperature for two hours, and poured into iced hydrochloric acid. The acid fraction of the product, a

yellow oil, was dissolved in dilute acetic acid and the solution was set aside in a refrigerator. The yellow solid, twice recrystallized from petroleum ether (b. p., 30–60°), weighed 9 g. (68%) and melted at 88°.

Anal. Calcd. for $C_{15}H_{20}O_2$: C, 77.81; H, 9.02. Found: C, 77.55; H, 8.68.

β-(6-Tetralyl)-β-methyl-α-carboxypropionic Acid (V).—A solution of 6-tetralyldimethylcarbinol[6] (II) (19 g.) in petroleum ether (20 cc., b. p., 40–75°) was saturated with dry hydrogen chloride at 0°, allowed to stand at room temperature for thirty minutes, then washed several times with water and dried over sodium sulfate. This solution of the crude chloro compound was added to an ethereal suspension of sodiomalonic ester (from ethyl malonate 16.5 g., sodium 2.3 g., ether 100 cc.) and the mixture was refluxed for several hours. Water was added carefully, and the organic layer was removed and washed successively with water, dilute hydrochloric acid, and water, and dried. The solvents were removed and the residual red oil was hydrolyzed by refluxing it for six hours with a solution of potassium hydroxide (22.5 g.) in methanol (70 cc.). The mixture was diluted with water and thoroughly extracted with ether. The aqueous layer was warmed to remove dissolved ether, and was acidified with dilute sulfuric acid. Some solid separated; the whole was extracted with ether and the ether solution was extracted with aqueous sodium carbonate (10%). Ether was removed from the aqueous extract, which was then acidified and set aside in a refrigerator. The product deposited as an oil which later solidified; after crystallization from ethanol, it weighed 4 g. and melted at 154–155° with effervescence.

Anal. Calcd. for $C_{16}H_{20}O_4$: C, 69.54; H, 7.30. Found: C, 69.66; H, 7.62.

β-(6-Tetralyl)-isovaleric Acid (I).—The above malonic acid (2 g.) was heated at 180° until effervescence ceased (about thirty minutes). The residue was recrystallized from petroleum ether (b. p. 30–60°), when it melted at 88–89°, alone or when mixed with I prepared from dimethylacrylic acid.

Methyl β-(6-Tetralyl)-isovalerate.—The acid I (7 g.) was refluxed in methanol (30 cc.) with sulfuric acid (1 cc.) for two hours. The methyl ester (5.2 g., 70%), isolated in the usual way, boiled at 161–164° (11 mm.) and had $n^{20}D$ 1.5250. *Anal.* Calcd. for $C_{16}H_{20}O_2$: C, 78.01; H, 9.00. Found: C, 78.02; H, 8.75.

Methyl β-(2-Naphthyl)-isovalerate.—The above ester (4 g.) was heated in a stream of carbon dioxide with palladium–charcoal catalyst (0.1 g.) at 220–260° for three hours and then at 300° for thirty minutes. The product was dissolved in ethanol, the solution was filtered from the catalyst, and solvent was removed, and the residue was distilled. The distillate (2.8 g., 71%) boiled at 174–177° (10 mm.), and had $n^{20}D$ 1.5700. *Anal.* Calcd. for $C_{16}H_{18}O_2$: C, 79.31; H, 7.49. Found: C, 79.03; H, 7.20.

β-(2-Naphthyl)-isovaleric Acid.—The above methyl ester (2.6 g.) was hydrolyzed by refluxing it with aqueous sodium hydroxide (20 cc., 20%) for one hour. The acid was obtained as a colorless solid (2.4 g., 98%) which, after crystallization from petroleum ether (b. p. 30–60°) melted at 86–87°. The mixed m. p. with I (m. p. 88°) was 79–81°. *Anal.* Calcd. for $C_{15}H_{16}O_2$: C, 78.92; H, 7.06. Found: C, 78.93; H, 7.36.

3,3-Dimethylbenz(e)indanone-1 (VI).—A solution of the above acid (1 g.) in sulfuric acid (8 cc.) was allowed to stand at room temperature for five hours. It was then poured over ice, the semi-solid precipitate was removed by ether extraction and crystallized twice from aqueous ethanol, when it melted at 65.5–67°.

Anal. Calcd. for $C_{15}H_{14}O$: C, 85.68; H, 6.71. Found: C, 85.04; H, 6.81.

Summary

1. The reaction between tetralin and β,β-dimethylacrylic acid in the presence of aluminum chloride has been shown to yield predominantly (70%) a single acid, identified as β-(6-tetralyl)-isovaleric acid by an independent synthesis. No other product was isolated.

2. This acid has been converted (3 steps) into β-(2-naphthyl)-isovaleric acid, and the latter has been cyclized to a benzhydrindone.

3. Tetralin, unlike other polyalkylbenzenes, behaves normally in this condensation.

MINNEAPOLIS 14, MINNESOTA
RECEIVED FEBRUARY 21, 1948

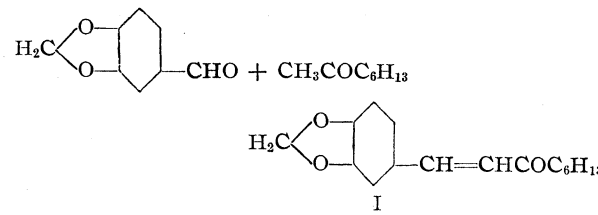
[A JOINT CONTRIBUTION FROM THE INSECTICIDE FELLOWSHIP, MELLON INSTITUTE, AND THE RESEARCH LABORATORY, DODGE & OLCOTT, INC.]

Methylenedioxyphenyl Cyclohexenones

BY OSCAR F. HEDENBURG AND HERMAN WACHS

In the search for new synthetic insecticidal materials which were to take the place of pyrethrins, 3-alkyl-5-(3,4-methylenedioxyphenyl)-2-cyclohexene-1-ones were prepared. These compounds are of very definite value where they are used as such, but they are of particular interest because of their ability to synergize the action of pyrethrins to an extraordinary degree.[1,2] They also share with pyrethrins the property of being practically nontoxic to warm-blooded animals.

The alkyl 3,4-methylenedioxystyryl ketones, precursors of the cyclohexenones, were prepared by the condensation of piperonal with methyl ketones in the presence of alkali. For example, methyl hexyl ketone gives hexyl 3,4-methylenedioxystyryl ketone I. This crystalline product is effective as an insecticide against flies, but is of little practical use because of its limited solubility in the usual vehicles, kerosene and Freon. Reduction of the ethylenic bond of I gave a liquid, soluble in kerosene and Freon but with little insecticidal activity.



I

The condensation of hexyl 3,4-methylenedioxy-

(1) Hedenburg, pending patent applications.

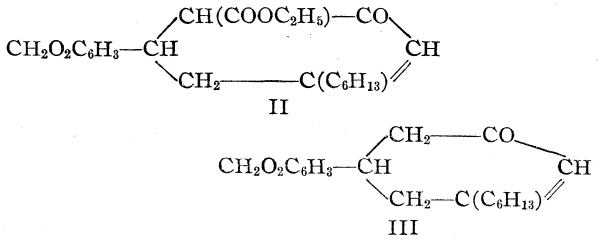
styryl ketone with ethyl acetoacetate[3,4] gave a 50% yield of crystalline 3-hexyl-5-(3,4-methylenedioxyphenyl)-2-cyclohexen-1-one (III). Saponification of the mother liquor gave more of the cyclohexenone, presumably formed from the initial cyclized addition product II. Saponification equivalents of the crude reaction product indicated approximately 30% of II. The crude reaction mixture is being used for insecticidal purposes, under the name of "Piperonyl Cyclonene."



II

III

The condensation of ethyl acetoacetate with the isobutyl styryl ketone gave approximately the same proportion of ketone and ester but only 15% of the ketone could be obtained in crystalline form. The amyl compound failed to give any solid product.

Catalytic hydrogenation of III gave the cyclohexanone, which was ineffective as an insecticide. It is therefore apparent, at least in this series of substances, that the conjugated system, =CH—CO—, is essential for insecticidal activity.

Experimental

Hexyl 3,4-Methylenedioxystyryl Ketone, I.—To a stirred mixture of 38.4 g. (0.3 mole) of methyl hexyl ketone, 48 g. of methanol and 7.5 g. of 20% sodium hydroxide was added 45 g. (0.3 mole) of piperonal over a period of thirty minutes, keeping the temperature between 20 and 25°. Stirring was continued until crystallization began and the mixture was then allowed to stand overnight. The usual manipulations gave 68 g. of solid product which can be either recrystallized from methanol or distilled *in vacuo*. The ketone boils from 175–185° at 1 mm. and gives light yellow crystals melting at 61°.

Anal. Calcd. for $C_{16}H_{20}O_3$: C, 73.82; H, 7.74; CO, 10.73. Found: C, 73.61; H, 7.63; CO, 10.84.

Amyl 3,4-Methylenedioxystyryl Ketone.—The amyl ketone, prepared by the above method, boils from 171–181° at 1.3 mm. and melts at 73°.

Anal. Calcd. for $C_{15}H_{18}O_3$: C, 73.15; H, 7.37; CO, 11.37. Found: C, 73.41; H, 7.48; CO, 11.34.

Isobutyl 3,4-Methylenedioxystyryl Ketone.—The isobutyl ketone boils from 166–173° at 2 mm. and melts at 66.5°.

Anal. Calcd. for $C_{14}H_{16}O_3$: C, 72.39; H, 6.94; CO, 12.05. Found: C, 72.51; H, 7.14; CO, 11.88.

Piperonylmethyl Hexyl Ketone.—An alcohol solution of I was hydrogenated at room temperature and under 20 lb. pressure, using palladium–charcoal catalyst, until one mole of hydrogen was absorbed. The liquid product boils at 204° at 4.5 mm., has a specific gravity of 1.0539 at 25° and a refractive index of 1.5109 at 20°.

Anal. Calcd. for $C_{16}H_{22}O_3$: C, 73.25; H, 8.46; CO, 10.69. Found: C, 73.39; H, 8.23; CO, 10.31.

3-Hexyl-5-(3,4-Methylenedioxyphenyl)-2-cyclohexen-1-one, III.—To a stirred solution of 24.1 g. of sodium in 600 cc. of absolute alcohol was added 260 g. of I and then, over a period of fifteen minutes, 143 g. of ethyl acetoacetate. During the addition the bath temperature was 21.5° while the temperature of the solution rose to 24°. Stirring was continued for one hour while the bath temperature was raised to 33°. One hundred cc. of benzene was then added to dissolve the remaining solid, after which the solution was allowed to stand in the bath overnight.

The solution was poured into 100 g. of concentrated hydrochloric acid in 1200 cc. of water, 350 cc. of benzene was added, the mixture was thoroughly agitated, the bottom layer separated and extracted with 50 cc. of benzene. The combined benzene solution was washed with salt water, neutralized with sodium bicarbonate, shaken with Celite, filtered, and the benzene was finally removed *in vacuo*. The product, weighing 320 g., was a thick, reddish oil of specific gravity 1.136 at 25° and with a saponification value of 60. After standing for five weeks, the solid which had crystallized from the oil was isolated by centrifugation. About 160 g. of white crystals was obtained melting at 59° after recrystallization from alcohol.

Anal. Calcd. for $C_{19}H_{24}O_3$: C, 75.8; H, 8.0. Found: C, 75.9; H, 8.1.

Saponification of the above mother liquor with 0.5 *N* potassium hydroxide gave more of the cyclohexenone, identified by mixed melting point.

3-Hexyl-5-(3,4-methylenedioxyphenyl)-cyclohexanone.—An alcohol solution of the cyclohexenone readily absorbed one mole of hydrogen at room temperature and atmospheric pressure, using palladium–charcoal catalyst. The cyclohexanone is a liquid which could not be crystallized at −20°. It has a specific gravity of 1.0754 at 25° and a refractive index of 1.528 at 20°.

Anal. Calcd. for $C_{19}H_{26}O_3$: C, 75.46; H, 8.66; CO, 9.26. Found: C, 75.21; H, 8.69; CO, 9.15.

3-Isobutyl-5-(3,4-methylenedioxyphenyl)-2-cyclohexen-1-one.—Prepared by the procedure used for the hexyl compound, there was obtained a pale orange product, which melted at 70.5° after recrystallization from alcohol.

Anal. Calcd. for $C_{17}H_{20}O_3$: C, 74.9; H, 7.4; CO, 10.28. Found: C, 74.9; H, 7.2; CO, 10.35.

The oxime of the isobutyl cyclohexenone melts at 106.5°.

Anal. Calcd. for $C_{17}H_{21}O_3N$: C, 71.08; H, 7.37; N, 4.87. Found: C, 69.84; H, 7.29; N, 4.80.

Summary

Alkyl 3,4-methylenedioxystyryl ketones, as well as their condensation products with ethyl acetoacetate, were prepared and found to be useful as non-toxic insecticides and as synergists for pyrethrins.

Hydrogenation of the methylenedioxystyryl ketones and of the cyclohexenones destroys the insecticidal activity.

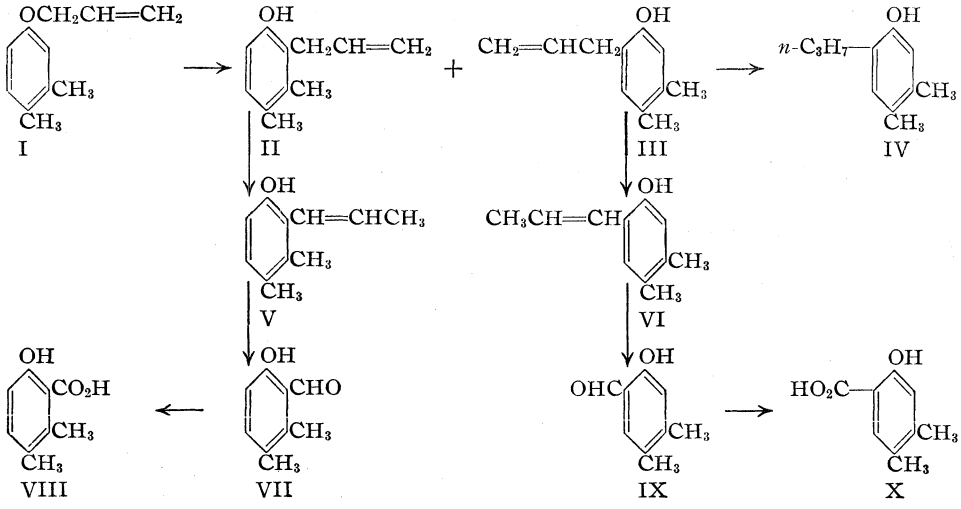
The Claisen Rearrangement of Allyl 3,4-Dimethylphenyl Ether[1]

BY C. S. MARVEL AND N. A. HIGGINS[2]

In connection with an investigation of inhibitors we had need for a sample of 3,4-dimethyl-6-propylphenol (IV) and prepared it by the Claisen rearrangement of allyl 3,4-dimethylphenyl ether (I) followed by hydrogenation



We found that the rearrangement of the allyl ether (I) gave rise to a mixture of phenols (II and III) as might be expected from the report of Claisen and Eisleb[3] on the behavior of allyl 3-methylphenyl ether. Reduction of this mixture gave a mixture of the two propyl phenols from which a single isomer separated as a crystalline solid, m. p. 59°, in 52% yield.

Since it appears that no one has carefully examined the isomers that may be formed in an allyl rearrangement of this type,[4] we have established the structure of the two isomers and determined their ratio in our rearrangement mixture.

The mixed phenols (II and III) were isomerized with alkali to give the mixed propenyl phenols (V and VI), which were then ozonized to give the mixed aldehydes (VII and IX). These aldehydes are known compounds[5] and have different crystalline forms so the mixture obtained by ozonization could be separated mechanically into the two pure aldehydes. The identities of these aldehydes were confirmed by oxidation to the known acids (VIII and X).[5]

By the quantities of the two aldehydes obtained, it was established that in the original rearrangement 70 ± 5% of the 6 isomer (III) and 30 ± 5% of the 2 isomer (II) was produced. Hence the pure *n*-propylphenol which was obtained by hydrogenation must have been the desired 3,4-dimethyl-6-*n*-propylphenol (IV).

Experimental

Allyl 3,4-Dimethylphenyl Ether.—To 175 ml. of absolute alcohol in a 500-ml., three-necked flask, fitted with stirrer, dropping funnel, and condenser were added 11.5 g. (0.5 mole) of sodium chips. When solution was effected, 61.0 g. (0.5 mole) of 4-hydroxy-1,2-dimethylbenzene was added and the flask heated in an oil-bath to 85–90°. The mixture was stirred, and 41.8 g. (0.55 mole) of distilled allyl chloride was added slowly. The reaction mixture was heated for fifteen hours, stirring being discontinued after seven hours. The cooled reaction mixture was poured into 1 liter of water in a separatory funnel and the layers separated. The aqueous layer was extracted with two 100-ml. portions of petroleum ether (b. p. 35–45°) and the extract was combined with the previous organic layer. This solution was washed with 10% sodium hydroxide solution to remove unreacted starting material, dried over anhydrous magnesium sulfate, and distilled in a modified Claisen flask. The allyl 3,4-dimethylphenyl ether, 66.1 g., b. p. 75–79° (3 mm.), $n^{20}D$ 1.5200, d^{20}_4 0.9543, was obtained in 82% yield.

Anal. Calcd. for $C_{11}H_{14}O$: C, 81.45; H, 8.70; MR, 49.87. Found: C, 81.40; H, 8.70; MR, 51.28.

Mixed 2- and 6-Allyl-3,4-dimethylphenols.—Allyl 3,4-dimethylphenyl ether, 66.1 g. (0.41 mole), was rearranged by heating with one-half its weight of freshly distilled diethylaniline in a 245° bath for one-half hour. The boiling point of the mixture rose gradually during this time from 218 to 231°. The cooled mixture was dissolved in petroleum ether (b. p. 35–45°) and the diethylaniline removed by several washes with dilute sulfuric acid. The product was then removed as the potassium salt by extraction with aqueous-alcoholic potassium hydroxide (35 g. of potassium hydroxide, 25 g. of water, 90 g. of methanol) in four equal portions. The alkaline solution was washed with petroleum ether, acidified, and extracted exhaustively with petroleum ether. The petroleum ether solution was dried over anhydrous magnesium sulfate and distilled in a modified Claisen flask. The mixed 2- and 6-allyl-3,4-dimethylphenols distilled at 82–85°

(1 mm.), $n^{20}D$ 1.5434, d^{20}_4 0.9671. The yield was 46.8 g. or 71% of the theoretical amount.

Mixed 3,4-Dimethyl-2-propylphenol and 3,4-Dimethyl-6-propylphenol.—Hydrogenation of 46.8 g. of the mixed 2- and 6-allyl-3,4-dimethylphenols in ethanol solution at 25° with a Raney nickel catalyst proceeded smoothly and the theoretical amount of hydrogen was absorbed in twenty minutes. The catalyst was removed by filtration and the mixture distilled in a modified Claisen flask to yield 30.6 g. (65%) of mixed 3,4-dimethyl-2-propylphenol and 3,4-dimethyl-6-propylphenol, b. p. 77–77.5° (<1 mm.).

3,4-Dimethyl-6-propylphenol.—The mixture of 3,4-dimethyl-2-propylphenol and 3,4-dimethyl-6-propylphenol was a very viscous oil. When this material had stood for two weeks, crystals began to form; crystal growth proceeded, but the whole of the material did not crystallize. The crystals were removed by filtration through a sintered glass filter; thus 16.0 g. (52%) of the material was obtained as a white crystalline solid. This was recrystallized four times from petroleum ether (b. p. 35–45°) to a constant melting point of 59°.

Anal. Calcd. for $C_{11}H_{16}O$: C, 80.45; H, 9.75. Found: C, 80.49; H, 9.83.

Mixed 3,4-Dimethyl-2-propenylphenol and 3,4-Dimethyl-6-propenylphenol.—To a 500-ml. round-bottomed flask containing 152 g. of *n*-amyl alcohol was added 105 g. of potassium hydroxide flakes. The mixture was refluxed for a short time, the clear supernatant liquid decanted, and to it was added 40 g. (0.247 mole) of the rearrangement product from allyl 3,4-dimethylphenyl ether (2- and 6-allyl-3,4-dimethylphenols). The solution was heated at the boiling point for twenty-four hours, the amyl alcohol removed by steam distillation, and the remaining solution acidified with phosphoric acid. The acidified solution was extracted with four 100-ml. portions of ether and the ether solution dried over anhydrous magnesium sulfate and distilled without fractionation. A yield of 24.6 g. (61.6%) of mixed 3,4-dimethyl-2-propenylphenol and 3,4-dimethyl-6-propenylphenol was obtained.

Anal. Calcd. for $C_{11}H_{14}O$: C, 81.45; H, 8.70. Found: C, 81.90; H, 8.59.

4,5- and 5,6-Dimethylsalicylaldehydes.—A solution of 8.4 g. (0.052 mole) of mixed 3,4-dimethyl-2-propenylphenol and 3,4-dimethyl-6-propenylphenol in 400 ml. of chloroform was ozonized for six hours at 0° with approximately 4% ozone. The chloroform solution of the ozonide was treated with 120 ml. of water, and the chloroform was distilled from the mixture under reduced pressure. After the chloroform had been completely removed, the flask was heated vigorously and the contents distilled. A yield of 4.95 g. (63.8%) of aldehyde was obtained from the steam-distillate by ether extraction, while 1.4 g. of material remained in the pot.

The aldehyde thus obtained was converted to the bisulfite addition product by shaking vigorously with nearly saturated sodium bisulfite solution at about 40°. The white crystalline addition product was removed by suction filtration, washed repeatedly with ether, and finally decomposed with 150 ml. of warm 3% hydrochloric acid. The purified aldehyde was recovered by ether extraction, drying of the extract, and removal of the solvent by distillation. The solid, light-yellow aldehyde thus obtained was recrystallized from petroleum ether (b. p. 35–45°), the solution being allowed to cool very slowly so that large crystals formed. Two types of crystals were formed, long spike-like needles of 5,6-dimethylsalicylaldehyde and lustrous plates of the 4,5-isomer; a quantity of the material was separated into its component crystals mechanically. Thus it was determined that 70 ± 5% of the material crystallized as plates and 30 ± 5% as needles. The two crops of crystals were separately recrystallized first from dilute alcohol and then from petroleum ether (b. p. 35–45°). The plates of 4,5-dimethylsalicylaldehyde melted at 69° and the needles of 5,6-dimethylsalicylaldehyde at 70°.

Anal. Calcd. for $C_9H_{14}O_2$: C, 72.00; H, 6.72. Found: Plates—C, 72.04; H, 6.65; Needles—C, 72.10; H, 6.60.

Clayton[5] who prepared a similar mixture of aldehydes from a Reimer–Tiemann reaction on 3,4-dimethylphenol found that 4,5-dimethylsalicylaldehyde crystallized in plates, m. p. 71°, and the 5,6-isomer in needles, m. p. 72°.

4,5-Dimethylsalicylic Acid.—About 0.1 g. of 4,5-dimethylsalicylaldehyde was sprinkled into 0.6 g. of fused sodium–potassium hydroxide (50–50 containing a little water) at 210° in a nickel crucible. As soon as gas evolution had ceased the mixture was cooled, dissolved in water, filtered, and acidified. The 4,5-dimethylsalicylic acid which precipitated was collected on a filter, dried, and recrystallized from aqueous methanol. The purified product melted at 197.6°. The literature[5] reports a melting point of 198–199°.

5,6-Dimethylsalicylic Acid.—This material was prepared from 5,6-dimethylsalicylaldehyde exactly as described above for 4,5-dimethylsalicylic acid. The 5,6-dimethylsalicylic acid melted at 140°. Clayton[5] describes this acid as melting at 142–143°.

Summary

The rearrangement of allyl 3,4-dimethylphenyl ether gives 70 ± 5% of 6-allyl-3,4-dimethylphenol and 30 ± 5% of 2-allyl-3,4-dimethylphenol.

Reduction of this mixture of allyl phenols gives a 50% yield of crystalline 3,4-dimethyl-6-*n*-propylphenol.

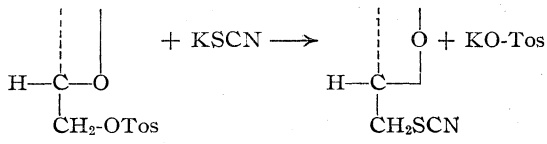
The Thiocyanation of Polysaccharide Tosyl Esters

BY J. F. CARSON AND W. DAYTON MACLAY

The replacement of tosyloxy groups in the primary position of carbohydrates by iodine[2] as a method of distinguishing primary from secondary hydroxyl groups has had a wide application. In polysaccharide chemistry, the reaction has been applied quantitatively to cellulose,[3] partially substituted ethyl cellulose[4] and cellulose acetate,[4,5] and to arabogalactan[6] from larch wood. It has now been found that polysaccharide tosyl esters undergo an analogous reaction with alkali thiocyanates to yield thiocyano derivatives. The replacement of tosyloxy in a number of polysaccharide tosyl esters by thiocyanate has been investigated, and the reaction has been found to have approximately the same degree of specificity for primary tosyloxy groups as the familiar iodination reaction.

Müller and Wilhelms[7] found that tetra-acetyl-6-tosyl β-glucose and triacetyl-6-tosyl α-methylglucoside when heated with potassium thiocyanate in acetone at 130° formed the corresponding 6-thiocyanates according to the equation



The 6-thiocyanates were observed to be very stable in contrast to the previously known 1-thiocyanates and showed no tendency to rearrange to the isothiocyanates even at elevated temperatures. A tosyl or mesyl group in the 3 position was found to be unreactive to thiocyanate. The apparent specificity of thiocyanate substitution for primary tosyloxy groups in glucose derivatives cannot be extended to non-carbohydrate materials, since tosyl esters of secondary alcohols have been observed to react with thiocyanates under mild conditions. Cholesterol *p*-toluenesulfonate[8] and ethyl α-tosylpropionate[9] both react with potassium thiocyanate in acetone or alcohol solution to yield the corresponding thiocyano derivatives.

In the present work, potato starch, cellulose, guar mannogalactan, and corn-cob and lima-bean pod hemicelluloses have been tosylated and the esters reacted with sodium thiocyanate in acetonyl acetone at 110–112°. The tosyl esters were also iodinated by heating at 110–112° with sodium iodide in acetonyl acetone, and the primary hydroxyl content as determined by iodine substitution was compared with values obtained by thiocyanation. The results are compiled in Table I.

Discussion of Results

A potato starch tosyl ester, when treated with sodium thiocyanate for varying periods of time, yielded tosyl thiocyano derivatives containing approximately 0.94 equivalent of thiocyanate per anhydroglucose repeating unit. Iodination of the same tosylate likewise yielded iodo compounds containing 0.93 to 0.95 equivalent of iodine per repeating unit.[10]

Thiocyanation and iodination of the cellulose tosyl esters gave more variable results than starch, but approximately one thiocyano group was introduced per anhydroglucose unit. Thiocyanation of a tosyl ester of wood pulp cellulose yielded derivatives containing 0.95 to 1.03 equivalents per repeating unit. Iodination of the same ester for seven hours produced a derivative with 0.98 equivalent of iodine per unit. Thiocyanation of a tosyl ester of regenerated cellulose (Cellophane) yielded derivatives with thiocyanate contents varying from 0.90 to 1.09.

Two different tosyl esters of guar mannogalactan, the water-soluble polysaccharide of guar endosperm (*Cyamopsis tetragonoloba* Taub) when thiocyanated for different periods of time yielded derivatives with thiocyanate contents varying from 0.44 to 0.52 equivalent per anhydrohexose unit. Iodination gave slightly higher replacement values from 0.50 to 0.56 equivalent per anhydrohexose unit. If the two reactions are assumed to be specific for primary hydroxyl in this polysaccharide, approximately half of the primary alcohol groups must be blocked by linkages of the 1,6 type.[11] This observation is at variance with the report of Moe, Miller and Iwen[12] who postulated 1,4 link-

(9) Gerrard, Kenyon and Phillips, *J. Chem. Soc.*, 153 (1937).

(10) The theoretical thiocyanate or iodine content should be slightly less than unity because of the presence of a small number of 1,6 linkages in the amylopectin component of potato starch.

(11) Swanson (abstract of paper delivered at Division of Sugar Chemistry, American Chemical Society, New York, Sept., 1947) has obtained by hydrolysis of methylated guar polysaccharide 2,3,4,6-tetramethylgalactose and unidentified trimethyl and dimethyl sugars. From the quantities isolated, the author suggests that the polysaccharide consists of a main chain of anhydromannose units with a side unit of galactose attached to every other mannose unit.

[a] Sulfur was determined gravimetrically by the Parr bomb method. [b] Nitrogen was determined by the Kjeldahl method. [c] The number of equivalents of thiocyanate (m) per repeating unit was calculated from nitrogen analyses by the formula

$$m = \frac{u + 154.18n}{113.11 + (1401/N)}$$

where n = number of tosyl groups per repeating unit in original ester; N = % nitrogen; and u = average repeating unit, *i. e.*, 162.1 for a hexosan. For the corncob and lima bean pod hemicelluloses, the calculated values of u were, respectively, 137 and 141, on the assumption that the material unaccounted for as xylan, uronic anhydride, and methoxyl is hexosan. The theoretical percentage of sulfur was calculated by the formula:

$$\% \text{ S} = \frac{3206n}{u + 154.18n - 113.11n}$$

Calculation of thiocyanate content from sulfur analyses would have yielded slightly lower values in each case. [d] Iodine was estimated by the method of Clark, "Semimicro Quantitative Analysis," Academic Press, New York, N. Y., 1943, p. 62. [e] The number of equivalents of iodine per repeating unit was calculated from iodine analyses assuming no loss of tosyl ester except by replacement.

ages from the observation that guar mannogalactan consumes one mole of periodate.[13]

Thiocyanation and iodination of a corn-cob hemicellulose tosylate gave unexpectedly high values for thiocyanate and iodine substitution. Analysis of the hemicellulose indicated that approximately 96% could be determined as xylan[14] and methoxy uronide. Lignin content was not greater than 1%. Since the anhydroxylose units

(13) Investigations in this Laboratory of the periodate oxidation of mannogalactan are also in disagreement with the report of Moe, *et al.*[12] It has been observed that in the oxidation of guar polysaccharide, formic acid is always produced (0.3 to 0.4 mole per equivalent of polysaccharide) and that consumption of paraperiodic acid (buffered at *p*H 5) or of sodium metaperiodate at temperatures from 5° to 25° was greater than one mole, the rate curve having such a shape that it was difficult to determine the exact consumption of oxidant.

(14) Bennett (*J. Agr. Res.*, **75**, [1] 43 (1947)), in investigations of an unfractionated sample of corn cob hemicellulose, reported the presence of a trace of L-arabinose in the acid hydrolysate. Our hemicellulose fraction was found to be free of arabinose to the extent that no test could be obtained with diphenylhydrazine or benzylphenylhydrazine.

of the xylans are considered to be in the pyranose form,[15] the actual replacement by iodine or thiocyanate should not be greater than 0.04 equivalent per average repeating unit. A tosyl ester containing 1.81 tosyl groups per average repeating unit yielded thiocyanates containing 0.18 to 0.22 equivalent of thiocyanate per repeating unit and iodination gave a replacement of 0.18 equivalent.

The lima bean pod hemicellulose fraction had analyses indicating that 82% of the polysaccharide could be accounted for as xylan, uronic anhydride and methoxyl. Arabinose could not be detected. On the assumption that the material unaccounted for by these analyses is hexosan, the maximum degree of replacement should be approximately 0.18 equivalent per average repeating unit (weighted average of xylan, methoxy uronide and hexosan). Thiocyanation and iodination of a tosylate with a low ester content (0.53 equivalent of tosyl per unit) seemed to confirm this supposition. Both reactions proceeded to the extent of 0.15 equivalent per unit. However, iodination of a tosyl ester having a higher tosyl content (1.53 equivalents per unit) gave higher values which would indicate a primary hydroxyl content of 0.29 to 0.33. Thiocyanate substitution was also significantly higher than before, 0.20 to 0.24 equivalent per repeating unit.

When these reactions are applied to polysaccharides, two conditions are presupposed: (1) that substantially all of the primary alcohol groups are tosylated and (2) that the replacement occurs only at the primary position. Complete tosylation of the polysaccharide would automatically satisfy the first condition, but this often leads to dark-colored degraded products containing some nitrogen and chlorine. Purves and co-workers[16] have measured the relative rates of tosylation in the unsubstituted positions of cellulose acetate and ethyl cellulose and found them to be in the ratios, respectively, of 2.2:0.11:23 and 2.3:0.07:15 for the 2,3 and 6 hydroxyls. Other polysaccharides may not have such a favorable ratio for attaining complete esterification of the primary alcohol groups. On the other hand, lima bean pod hemicellulose tosylate appeared to undergo iodination and the corncob hemicellulose tosylate apparently underwent both iodination and thiocyanation in secondary positions. Malm, *et al.*,[5] have reported that in the tosylation and subsequent iodination of cellulose acetate or regenerated cellulose, the amount of iodine introduced increased when the time of reaction in either the tosylation or the iodination step was extended. These discrepancies would be particularly significant in assigning structures to polysaccharides with a low primary hydroxyl content and would restrict the utility of the reactions to very crude approximations of primary hydroxyl content.

Acknowledgment.—The authors wish to thank L. M. White and A. Bevenue for the determinations of nitrogen and sulfur.

Experimental

Polysaccharides

Potato Starch.—A commercial sample was used without purification.

Cellulose samples used were Dupont Cellophane and Brown Co. "Solka Floc," a purified wood pulp in a finely divided form. The latter had a xylan content of 2.5%.

Lima Bean Pod Hemicellulose.—The pods from lima beans of normal canning maturity were extracted successively with benzene–ethanol (2:1), boiling water and boiling 0.5% ammonium oxalate. The material was delignified by the sodium chlorite procedure of Wise, *et al.*,[17] and the holocellulose extracted successively with boiling water, 2% sodium carbonate, and 5% potassium hydroxide at room temperature for one hour under nitrogen. The hemicellulose isolated from the potassium hydroxide extraction was re-dissolved in alkali and precipitated with copper sulfate according to the directions of Angell and Norris.[18]

Anal. Uronic anhydride, 9.0%; xylan, 72%; methoxyl, 1.4%; and $[\alpha]^{20}D$ −45.3 (*c*, 1.28 in 2% potassium hydroxide).[19]

Corn-cob Hemicellulose.—This material was prepared in the same manner as the lima bean pod hemicellulose. *Anal.* Uronic anhydride, 6.2%; xylan, 89.3%; methoxyl, 0.7%; and $[\alpha]^{20}D$ −98.2 (*c*, 0.917 in 2% potassium hydroxide).[19]

Guar Mannogalactan.—The water-soluble fraction was isolated from guar flour (*Cyamopsis tetragonoloba* Taub) obtained from General Mills, Inc. An aqueous dispersion of the flour was first digested with trypsin to remove proteins, then centrifuged, and the extract was clarified by filtration. The polysaccharide was isolated as a white fibrous precipitate when the filtrate (after concentration *in vacuo* to a 0.4% solution) was poured into two and one-half volumes of ethanol. It was purified by washing with 70% ethanol–1% hydrochloric acid, neutral 70% ethanol, 95% ethanol and acetone. *Anal.* Nitrogen, 0.07%; anhydromannose, 59%[20]; anhydrogalactose, 32%; uronic anhydride, 3.5%; pentosan <1%; and $[\alpha]^{20}D$ +61° (*c*, 0.57 in water).[19]

Tosylation

Potato starch, guar mannogalactan, and the hemicelluloses were pretreated by pasting with boiling water, coagulating with pyridine, and removing the water by washing with pyridine to obtain the polysaccharide in a reactive form. The wood-pulp and the Cellophane were steeped in 25 to 30 parts of 5% sodium hydroxide for one hour at 20°, and were then washed with water until free of alkali and the water was replaced by pyridine.

Esterification was performed in a mixture of pyridine and *p*-toluenesulfonyl chloride, the latter in an excess of four to five times the calculated quantity. Tosylation was allowed to proceed at 20–23° (after initial cooling of the reaction mixture) for periods of time varying from two days to three weeks. The esters were isolated and purified in the usual manner. Under these conditions, starch and guar polysaccharide could be tosylated to a degree of 1.7 to 2.0 tosyl groups per repeating unit in forty-eight

hours on a shaking machine. Cellulose samples required from four to five days at 20° with shaking for the same degree of esterification; the hemicelluloses reacted very slowly, a high degree of tosylation requiring from two to three weeks. The esters had nitrogen contents of 0.05% or less.

Thiocyanation and Iodination

Replacement of tosyloxy by thiocyanate was effected by heating a mixture of 2 g. of tosyl ester, 200 ml. of freshly distilled acetonyl acetone, and 6 g. of sodium thiocyanate (dried *in vacuo* at 100°) under anhydrous conditions at 110–112° for periods of time as indicated in Table I. Low values for nitrogen were usually obtained unless the reaction mixture was heated for at least five hours.

The starch and mannogalactan tosylates were almost completely soluble in the hot reaction medium, the cellulose tosylates were partly soluble and the hemicellulose esters swelled without appreciable solution. The thiocyanotosylates were recovered in quantitative yields by pouring into four volumes of ice water. The esters were washed repeatedly with distilled water, 95% ethanol, and finally with ether. For analyses, they were dried *in vacuo* at 70° over phosphorus pentoxide. The thiocyano derivatives when dried were powdery materials, white to a light grey in color. Their solubility behavior was very similar to that of the corresponding iodo compounds.

Iodination was performed under conditions comparable to the thiocyanation procedure. Five grams of sodium iodide was used for each gram of tosyl ester and 100 ml. of acetonyl acetone. No apparent difference was noted in iodination at 100 and 110°, although thiocyanation at the lower temperature was, in some cases, slightly slower than at 110°.

Summary

The replacement of tosyloxy in the primary position by thiocyanate has been found to be applicable to several polysaccharide tosyl esters. When applied to potato starch, cellulose, and guar mannogalactan, the reaction had approximately the same degree of specificity for replacement of the tosyloxy group in the primary position as the iodination reaction.

Both thiocyanation and iodination of the tosylate of the water-soluble polysaccharide of guar indicate that approximately half of the primary hydroxyl groups are involved in linkages.

Thiocyanation and iodination of a corn-cob hemicellulose tosyl ester and iodination of a lima bean pod hemicellulose tosylate yielded substitution to a greater extent than was expected, from the structure of these materials, indicating that possibly some secondary tosyloxy groups were replaced.

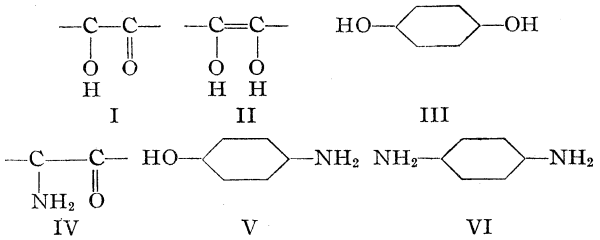
Oxidation Processes. XXI.[1] The Autoxidation of the *p*-Phenylenediamines

BY JAMES E. LUVALLE, DUDLEY B. GLASS AND ARNOLD WEISSBERGER

Introduction

Previous papers of this series discussed the autoxidation of α-ketols, I,[2] enediols, II,[3] hydroquinones, III,[4] and α-aminoketones, IV.[5] The present paper deals with the autoxidation of *p*-phenylenediamines, VI, and, briefly, of *p*-aminophenols, V.



I II III

IV V VI

Like the dihydroxy compounds, these substances react with molecular oxygen, and the reaction proceeds in two univalent steps.[6] From the results of earlier papers of this series,[3,4,5] the rate of the over-all reactions can be expected to depend upon the rate of formation of the semiquinone, upon its concentration in the various equilibria involved, and upon its reactivity with oxygen.

$$R + O_2 \longrightarrow T + H_2O_2 \qquad (1)$$

The intensely colored intermediate products of *p*-phenylenediamines, *Wurster's salts*, exist as free radicals, semiquinones, in dilute solution,[6] and as dimers or higher polymers in higher concentration.[6c] These semiquinones are much more stable than the corresponding fully oxidized quinonediimines,[6b,7] and quinoneimines[7] which are readily hydrolyzed to the corresponding quinones. Moreover, the higher N-methylated diamines undergo a demethylation reaction when oxidized. Thus, N,N′-tetramethyl-*p*-phenylenediimine loses a methyl group with formation of N,N′-trimethyl-*p*-phenylenediamine and formaldehyde,[6,7] and N,N′-tetramethyl-, N,N′-trimethyl-, and N-dimethyl-*p*-phenylenediamine couple in oxidizing solutions with a *p*-substituted phenol to give an identical indoaniline dye.[8] The latter reaction shows that the trimethyl-*p*-phenylenedi-

amine also undergoes demethylation upon oxidation in a rapid reaction.

The concentration of *Wurster's salts*, the semiquinones, in the equilibrium

$$R + T \rightleftharpoons 2S \qquad (2)$$

increases with increasing methylation of the amino group.[6b] The *rate of reaction* of the semiquinones with molecular oxygen may also be expected to vary within wide limits, depending on kind and number of substituents.

In a first approximation we consider resonance as the main stabilizing factor for the semiquinones.[6] The principal structures of the semiquinones of *p-phenylenediamine* are given in Fig. 1a. The cationic semiquinone, SH_2^+, has three pairs of equivalent structures, the neutral molecule, SH, has no equivalent structures, and the anionic semiquinone, S^-, has again three equivalent structures. For this reason, SH_2^+ and S^- should be stable and exist in appreciable concentrations in their respective *p*H ranges, at variance with SH, which is expected to be unstable. When two R groups are on one hydrogen, the negative semiquinone ion will not be stabilized by structures shown in Fig. 1a.

The ionic species for the N-alkylated-*p*-phenylenediamines are given in Fig. 2a. The semiquinones of *monalkyl-p-phenylenediamine* and *s-dialkyl-p-phenylenediamine* resemble *p*-phenylenediamine. The anionic semiquinone of *as-N-dialkyl-p-phenylenediamine* lacks structures a′, b, b′, c and c′ and is therefore probably about as unstable as the neutral semiquinone. *Trialkyl-p-phenylenediamines* do not form an anionic semiquinone, and *tetramethyl-p-phenylenediamine* even lacks a neutral semiquinone.

The principal resonance forms of the semiquinones of the *p*-aminophenols are given in Fig. 1b. None of the semiquinones has equivalent resonance states. The neutral semiquinone, SH, is probably represented by group (b) because the hydroxyl group will lose a proton more readily than the amino group. The structures of group (a) under SH are tautomers of the structures of group (b).

The ionic species for the semiquinones of the three types of *p*-aminophenols are given in Fig. 2b. The dimethyl semiquinone exists only as SH_2^+ and SH. The remainder may exist as cation, neutral molecule, or anion depending on the *p*H.

Michaelis and Schubert[9] have investigated the dependence of the *concentration of certain semiquinones* upon *p*H. If the oxidized form, T, is stable, the semiquinone concentration has a maximum when half of the initial quantity of diamine is oxidized, *i. e.*, when R = T. At this point

$$(S/a)_{max.} = \sqrt{K_s}/(2 + \sqrt{K_s}) \qquad (3)$$

where a is the concentration of R + T + S[9] and

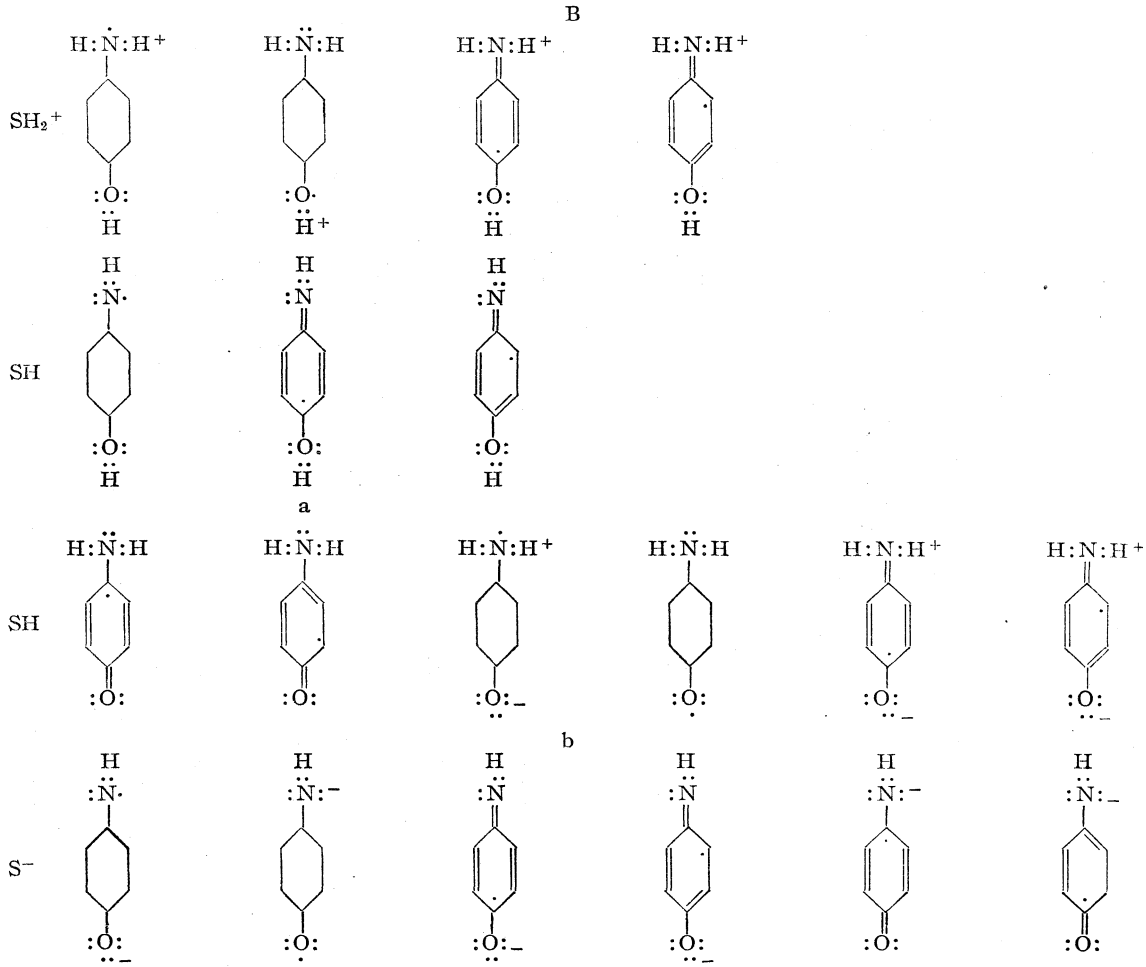

Fig. 1.—(A) Principal structures of the *p*-phenylenediamine semiquinones. (Note that the anionic semiquinone would only occur for the N-dialkyl-substituted diamine.) (B) Principal structures of the *p*-aminophenol semiquinones. (Note that for the neutral semiquinone, structures b are much more likely than structures a. Structures a are tautomeric with structures b.)

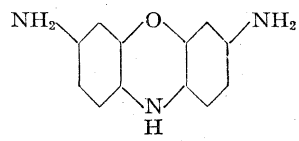
K_s is the semiquinone formation constant of equation (2).

Semiquinone formation constants for oxonine over the *p*H range −6 to +12 are plotted in Fig. 3 from the data of Table II of Michaelis and Granick.[10] The ionic states of R, S and T are those assigned by these authors. The figure shows that



the concentrations of the several *ionic species of S* go through two minima and one maximum between *p*H 2 and 12.

If the rate of a reaction is determined by the over-all semiquinone concentration, then the rate at 50% completion will vary with *p*H as $(S/a)_{max.}$ However, according to Figs. 1 and 2, SH_2^+, SH and S^- cannot be expected to have the same reactivity. Differences in the reactivity of the ionic species will therefore be superimposed upon the changes in semiquinone concentration with *p*H. It follows that quite complicated rate–*p*H curves can be expected for substances such as the *p*-phenylenediamines.

(10) Michaelis and Granick, THIS JOURNAL, **63**, 1636 (1941).

Experimental

Technique, Materials, Calculations

The techniques and apparatus were the same as in previous investigations of this series.[2,3,4,5] Measurements of *p*H were made with a Beckman Model G *p*H meter. The temperature of the thermostat was 19.97 ± 0.02°. Buffers were C. P. or reagent grade chemicals and used at a concentration of 0.200 *M*. Doubly distilled water was used in all experiments, and absolute alcohol in making the aqueous alcoholic solutions.

All experiments reported in this paper were run in solutions 0.005 *M* in potassium thiocyanate and potassium cyanide, respectively. Under these conditions, metallic-ion catalysis was negligible, and the data were reproducible. In the absence of these substances, the experiments were very erratic. In some experiments, in absence of potassium cyanide and potassium thiocyanate, cupric ion was added. This eliminated the induction period and increased the total uptake by approximately 50%.

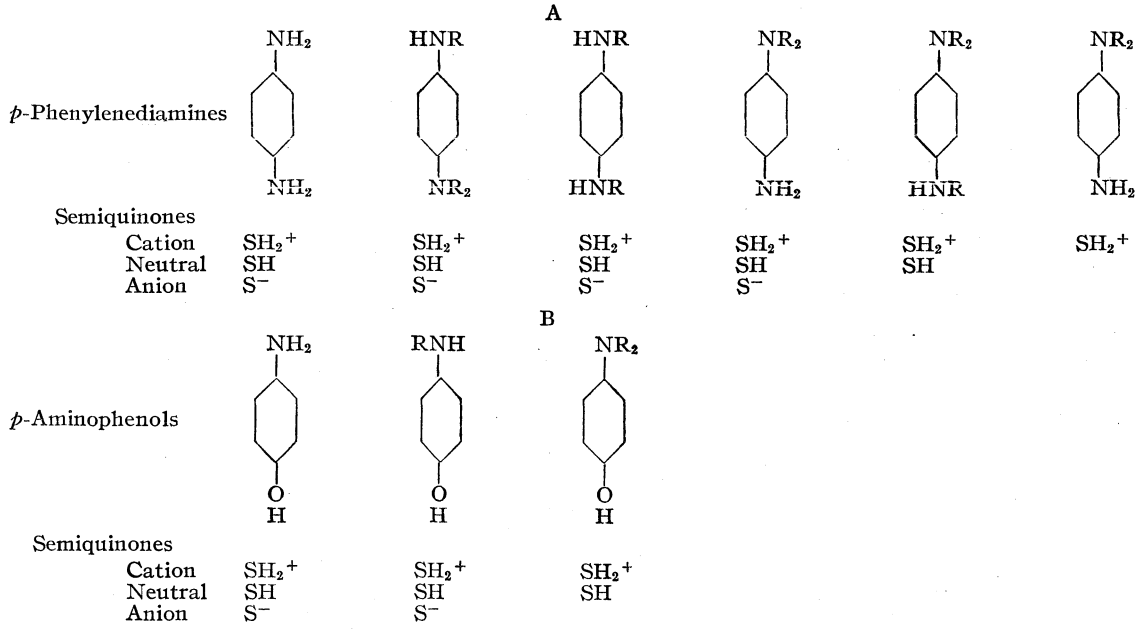


Fig. 2.—(A) Ionic species of the *p*-phenylenediamines; R represents any alkyl group, usually CH_3 or C_2H_5. (B) Ionic species of the *p*-aminophenols.

The final products of the reaction of diaminodurene were identified as duroquinone by mixed melting point, ammonia by smell, and hydrogen peroxide.[2a] The overall consumption of oxygen indicates a similar course of the oxidation of the other compounds reported in this paper. However, the hydrogen peroxide presumably reacts with the quinonoid products.

Organic Preparations

Eastman Kodak Co. Grade chemicals were used as starting materials for the preparation of all compounds. When working with the free bases, they were kept under an atmosphere of hydrogen or nitrogen to reduce oxidation by the air. All of the products were dried in a vacuum desiccator over sulfuric acid. High-grade filter paper (*e. g.*, Whatman no. 12) was used for all filtrations.

***p*-Phenylenediamine Dihydrochloride.**—Fifty-four grams of *p*-phenylenediamine was dissolved in a solution of 200 ml. of water and 90 ml. of concentrated hydrochloric acid. The resulting solution was treated with Filtrol and filtered while still hot. The dihydrochloride was precipitated by the addition of 100 ml. of concentrated hydrochloric acid. The product was removed by filtration, dissolved in 200 ml. of hot water, and precipitated with 100 ml. of concentrated hydrochloric acid. The precipitate was removed by filtration, washed with alcohol, and dried.

N-Methyl-*p*-phenylenediamine Dihydrochloride.—The salt was recrystallized twice from three volumes of methanol which contained a few drops of concentrated hydrochloric acid.

N,N′-Dimethyl-*p*-phenylenediamine Dioxalate.—The salt was recrystallized twice from 60% aqueous alcohol. In the first recrystallization the hot solution was treated with Darco and filtered; in the second recrystallization, the hot solution was filtered without the Darco treatment.

N,N-Dimethyl-*p*-phenylenediamine Hydrochloride.—N,N-Dimethyl-*p*-phenylenediamine was distilled under reduced pressure. The fraction that boiled at 134–135° at 12 mm. (68 g.) was collected and converted to the hydrochloride by dissolving in 200 ml. of methanol and 43 ml. of concentrated hydrochloric acid. The solution was allowed to stand at 0° until crystallization was complete. The precipitate was removed by filtration and recrystallized from methanol.

N,N,N′-Trimethyl-*p*-phenylenediamine Dihydrochloride.—This material was prepared satisfactorily in fairly large batches from N,N-dimethyl-*p*-phenylenediamine by a modification of the method used by Michaelis, Schubert and Granick.[6b]

A mixture of 170 g. of N,N-dimethyl-*p*-phenylenediamine hydrochloride, 190 g. of *p*-toluenesulfonyl chloride, and 400 ml. of pyridine was heated on the steam-bath for two hours. At the end of this time, the reaction mixture was poured into 2 liters of water and stirred until crystallization occurred. The precipitate was removed by filtration, washed with water, and recrystallized from 95% alcohol. There resulted 190 g. of 4′-dimethylamino-*p*-tolylsulfonanilide which melted at 125–126°.

A solution of 11.5 g. of sodium in 500 ml. of absolute alcohol was added to 145 g. of 4′-dimethylamino-*p*-tolylsulfonanilide in 1 liter of absolute alcohol. After 75 g. of methyl iodide had been added, the mixture was boiled under reflux for twenty hours. At the end of this time, 800 ml. of 5% alkali was added and the alcohol was removed by distillation under reduced pressure. The residue was diluted with 1.5 liters of warm water and the mixture was stirred for thirty minutes. The precipitate was removed by filtration, washed with water, and recrystallized twice from 95% alcohol. The resulting 4′-dimethylamino-N-methyl-*p*-tolylsulfonanilide (80 g.) melted at 101–101.5°. *Anal.* Calcd. for $C_{16}H_{20}N_2O_2S$: N, 9.20. Found: N, 9.20.

The 4′-dimethylamino-N-methyl-*p*-tolylsulfonanilide (41 g.) was hydrolyzed by heating on the steam-bath for four hours with 40 ml. of acetic acid and 80 ml. of concentrated sulfuric acid. The reaction mixture was dissolved in 800 ml. of water and made alkaline with 275 ml. of 40% sodium hydroxide. The diamine[11] was extracted with ether, the ethereal solution was dried over sodium hydroxide pellets, and the ether was evaporated. The residue was dissolved in 375 ml. of acetone and the salt was precipitated by the addition of 20 ml. of concentrated hydrochloric acid. The precipitate was removed by filtration, washed with acetone, and dissolved in 100 ml. of warm methanol containing 1 ml. of concentrated

(11) Care should be taken to prevent the diamine from coming in contact with the skin. It has a strong irritating and numbing action.

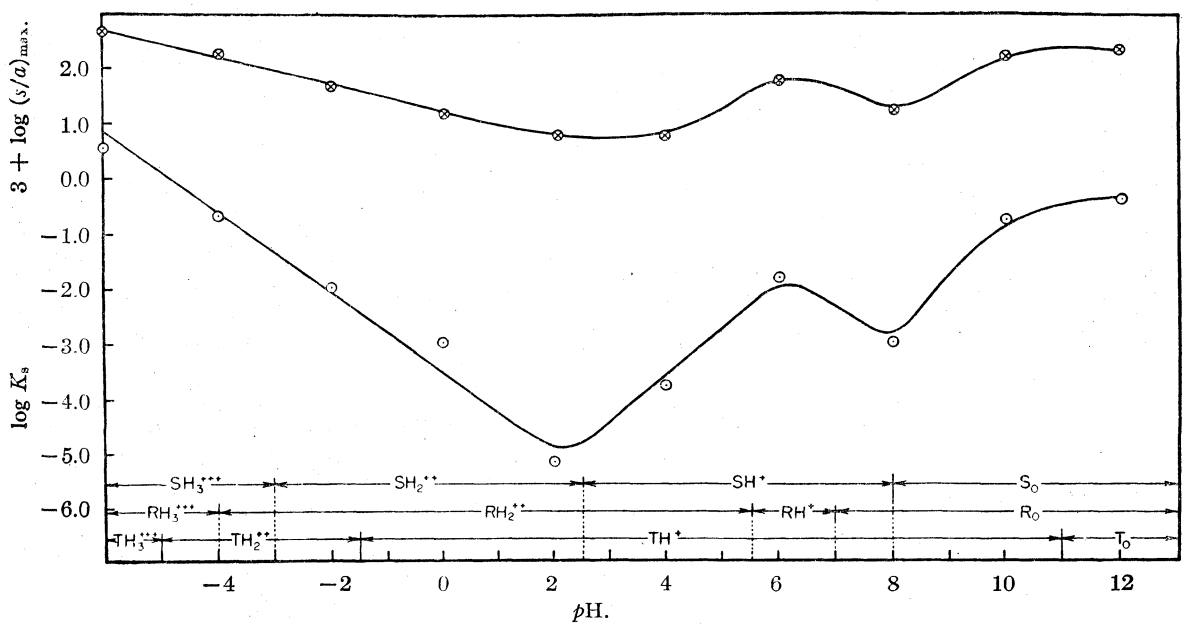

Fig. 3.—Oxonine: -⊙-⊙-, log K_s–*p*H; -⊗-⊗-, 3 + log $(S/a)_{max.}$–*p*H, S_0 and SH_3^{+++} are quite stable; SH^+ and SH_2^{++} exist only at low concentrations. Data are from Table II of Michaelis and Granick (THIS JOURNAL, **63**, 1636 (1941)).

hydrochloric acid. This solution was diluted slowly with 250 ml. of acetone. The product was removed by filtration, washed with acetone, and dried; yield, 19 g.

N,N,N′,N′-Tetramethyl-*p*-phenylenediamine Dihydrochloride.—The salt was recrystallized twice from 85% aqueous alcohol which contained a small amount of concentrated hydrochloric acid.

Octamethyl-*p*-phenylenediamine was prepared from diaminodurene and methyl iodide.[6d] The hydrochloride was recrystallized from 1,2-ethanol acetone.

N,N-Diethyl-*p*-phenylenediamine Hydrochloride.—The free base was distilled under reduced pressure. The fraction that boiled at 115–116° at 5 mm. (131 g.) was dissolved in 200 ml. of absolute alcohol, and 68 ml. of concentrated hydrochloric acid was added. The salt which crystallized was removed by filtration, washed with alcohol containing a little hydrochloric acid, and dried.

N,N-Di-*n*-propyl-*p*-phenylenediamine Sulfate.—A solution of 177 g. of N,N-di-*n*-propylaniline in a mixture of 1 liter of water and 250 ml. of concentrated hydrochloric acid was cooled to 0° and 70 g. of sodium nitrite in 200 ml. of water was added during a period of five minutes. The solution was stirred at 0–1° for thirty minutes and then made alkaline with 200 ml. of concentrated ammonium hydroxide. The crystals were removed by filtration, washed with water, and recrystallized twice from 95% alcohol. There resulted 85 g. of N,N-di-*n*-propyl-4-nitrosoaniline which melted at 43–44°. *Anal.* Calcd. for $C_{12}H_{18}N_2O$: N, 13.58. Found: N, 13.70.

N,N-Di-*n*-propyl-4-nitrosoaniline (20.6 g.) was placed in the Parr reduction apparatus with 100 ml. of absolute alcohol and 5 g. of Raney nickel, and reduced at a temperature of 60° and a hydrogen pressure of 3 atmospheres. The reaction mixture was filtered and a solution of 5.6 ml. of concentrated sulfuric acid in 25 ml. of absolute alcohol was added. The precipitate was removed by filtration, washed with alcohol, and recrystallized from 125 ml. of absolute alcohol. The product weighed 20 g. *Anal.* Calcd. for $C_{12}H_{20}N_2 \cdot H_2SO_4$: N, 9.65. Found: N, 9.35.

4-Amino-N,N-dimethyl-*o*-toluidine Dihydrochloride.—N,N-Dimethyl-4-(*p*-nitrophenylazo)-*o*-toluidine was prepared by the method of Fieser and Thompson[12] and recrystallized from acetic acid. The melting point of this material was 121–122°. The azo compound (28.4 g.) was placed in the Parr reduction apparatus with 100 ml. of absolute alcohol and 5 g. of Raney nickel, and reduced at a temperature of 50° and a hydrogen pressure of 3 atmospheres. The catalyst was removed by filtration and the alcohol was distilled under reduced pressure. Acetic anhydride (50 ml.) was added and the mixture was heated on the steam-bath for one hour. The reaction mixture was diluted with 300 ml. of water, neutralized with sodium carbonate, and acidified with 50 ml. of concentrated hydrochloric acid. The mixture was stirred for ten minutes and the precipitate was removed by filtration. The filtrate was made alkaline with 40% sodium hydroxide solution and the product extracted with ether. The ethereal solution was dried over anhydrous magnesium sulfate and the ether was evaporated. The residue (15.6 g.) was dissolved in 100 ml. of 15% hydrochloric acid and the solution was boiled under reflux for one hour. This solution was concentrated to a thick syrup under reduced pressure and the residue was crystallized from 60 ml. of absolute alcohol. The product was removed by filtration, washed with absolute alcohol, and recrystallized from absolute alcohol containing a little concentrated hydrochloric acid. There resulted 12 g. of product. *Anal.* Calcd. for $C_9H_{14}N_2 \cdot 2HCl$: N, 12.55. Found: N, 12.66.

4-Amino-N,N-diethyl-*m*-toluidine Hydrochloride.—The salt was recrystallized twice from 95% alcohol which contained 2% concentrated hydrochloric acid.

Diaminodurene Dihydrochloride.—Dinitrodurene (21 g.) was placed in the Parr reduction apparatus with 100 ml. of absolute alcohol and 3 g. of Raney nickel, and reduced at a temperature of 60° and a hydrogen pressure of 3 atmospheres. The catalyst was removed by filtration and 50 ml. of concentrated hydrochloric acid was added, all at once, with vigorous stirring. The precipitate was removed by filtration and dissolved in boiling water. This solution was treated with Darco, filtered, and diluted with 25 ml. of concentrated hydrochloric acid. The precipitate was removed by filtration and recrystallized as before but without the Darco treatment. There resulted 15 g. of diaminodurene dihydrochloride. *Anal.* Calcd. for $C_{10}H_{16}N_2 \cdot 2HCl$: N, 11.81. Found: N, 11.98.

1-(*p*-Aminophenyl)-pyrrolidine Hemisulfate Dihydrate.—A mixture of 13.4 g. of *p*-nitrochlorobenzene and 12.1 g. of pyrrolidine was heated at 95–100° in a sealed tube

(12) Fieser and Thompson, THIS JOURNAL, **61**, 376 (1939).

for six hours. The reaction mixture was stirred with 100 ml. of water and the product was removed by filtration, washed with water, and recrystallized twice from acetic acid. There resulted 10 g. of 1-(*p*-nitrophenyl)-pyrrolidine that melted at 167–168°. *Anal.* Calcd. for $C_{10}H_{12}N_2O_2$: N, 14.58. Found: N, 14.62.

The 1-(*p*-nitrophenyl)-pyrrolidine (10 g.) was placed in 100 ml. of absolute alcohol and reduced to the diamine by the method used to reduce dinitrodurene. The catalyst was removed by filtration and a solution of 2.8 ml. of concentrated sulfuric acid in 10 ml. of water was added to the filtrate. After dilution with 50 ml. of alcohol, the precipitate was removed by filtration, washed with alcohol, and recrystallized from 100 ml. of 75% aqueous alcohol. There resulted 9 g. of product. *Anal.* Calcd. for $C_{10}H_{14}N_2 \cdot 0.5H_2SO_4 \cdot 2H_2O$: N, 11.33. Found: N, 11.65.

1-(4-Amino-*m*-tolyl)-pyrrolidine Hemisulfate.—A mixture of 22.4 g. of 2-nitro-5-iodotoluene and 12 g. of pyrrolidine was heated at 95–100° in a sealed tube for one hour and the reaction mixture was stirred with 100 ml. of water. The precipitate was removed by filtration and recrystallized twice from acetic acid. There resulted 8 g. of 1-(4-nitro-*m*-tolyl)-pyrrolidine that melted at 86–88°. This nitro compound was reduced by the method used for dinitrodurene. The catalyst was removed and a solution of 1.2 ml. of concentrated sulfuric acid in 15 ml. of absolute alcohol was added. The precipitate was removed by filtration, washed with alcohol, and recrystallized twice from 80% aqueous alcohol. There resulted 5 g. of product. *Anal.* Calcd. for $C_{11}H_{16}N_2 \cdot 0.5H_2SO_4$: N, 12.43. Found: N, 12.29.

1-(*p*-Aminophenyl)-piperidine Hemisulfate.—A mixture of 79 g. of *p*-nitrochlorobenzene and 100 ml. of piperidine was heated at 95° for four hours in a flask attached to an air condenser. At the end of this time, the reaction mixture was diluted with 200 ml. of water and stirred thoroughly. The precipitate was removed by filtration, washed with water, and recrystallized twice from 200 ml. of 95% alcohol. There resulted 70 g. of 1-(*p*-nitrophenyl)-piperidine that melted at 103–103.5°. *Anal.* Calcd. for $C_{11}H_{14}N_2O_2$: N, 13.58. Found: N, 13.69.

The 1-(*p*-nitrophenyl)-piperidine (20.6 g.) was reduced by the method used for dinitrodurene. The catalyst was removed and a solution of 2.8 ml. of concentrated sulfuric acid in 150 ml. of alcohol was added to the filtrate. The precipitate was removed and recrystallized twice from 300 ml. of 75% aqueous alcohol. There resulted 10 g. of 1-(*p*-aminophenyl)-piperidine hemisulfate. *Anal.* Calcd. for $C_{11}H_{16}N_2 \cdot 0.5H_2SO_4$: N, 12.43. Found: N, 12.34.

1-(4-Amino-*m*-tolyl)-piperidine Sulfate.—A mixture of 26.3 g. of 2-nitro-5-iodotoluene and 20 ml. of piperidine was heated in an oil-bath at 110° for four hours. The oily reaction mixture was washed with water and crystallized from 50 ml. of methanol. The crystals were stirred with 80 ml. of 15% hydrochloric acid, the insoluble material was filtered off (unreacted 2-nitro-5-iodotoluene), and the filtrate was poured into water containing an excess ammonium hydroxide. The precipitate was removed by filtration, washed with water, and recrystallized from 50 ml. of methanol. There resulted 12.5 g. of 1-(4-nitro-*m*-tolyl)-piperidine that melted at 53–54°. This nitro compound was reduced by the method used for dinitrodurene. The catalyst was removed and a solution of 3.2 ml. of concentrated sulfuric acid in 5 ml. of water was added. The precipitate was removed by filtration, washed with alcohol, and recrystallized twice from 75 ml. of 75% aqueous alcohol. There resulted 14 g. of 1-(4-amino-*m*-tolyl)-piperidine sulfate. *Anal.* Calcd. for $C_{12}H_{18}N_2 \cdot H_2SO_4$: N, 9.72. Found: N, 9.69.

1-(*p*-Aminophenyl)-morpholine Hemisulfate Hydrate.—A mixture of 80 g. of *p*-nitrochlorobenzene and 100 g. of morpholine was heated at 115–120° for three and one-half hours. The reaction mixture was ground in a mortar with 300 ml. of warm water. The solid was removed by filtration, washed with water, and the product recrystallized twice from 150 ml. of acetic acid. There resulted 85 g. of 1-(*p*-nitrophenyl)-morpholine that melted at 150–151°. A portion of this nitro compound (20.8 g.) was mixed with 200 ml. of absolute alcohol and reduced by the method used for dinitrodurene. The catalyst was removed and a solution of 2.8 ml. of concentrated sulfuric acid in 40 ml. of water was added. The mixture was heated to a boil, filtered, and allowed to cool. The product was removed and recrystallized from 75% aqueous alcohol. There resulted 15 g. of 1-(*p*-aminophenyl)-morpholine hemisulfate hydrate. *Anal.* Calcd. for $C_{10}H_{14}N_2O \cdot 0.5H_2SO_4 \cdot H_2O$: N, 11.42. Found: N, 11.43.

1-(4-Amino-*m*-tolyl)-morpholine Sulfate.—A mixture of 80 g. of 2-nitro-5-iodotoluene and 61 g. of morpholine was heated at 95–100° for four hours. The reaction mixture was ground in a mortar with 500 ml. of water and the solid was separated. The solid was added to 800 ml. of 15% hydrochloric acid. The mixture was stirred and heated at 70–80° for twenty minutes. After cooling, the mixture was filtered and the filtrate made alkaline with concentrated ammonium hydroxide. The precipitate was removed by filtration and recrystallized twice from acetic acid. There resulted 33 g. of 1-(4-nitro-*m*-tolyl)-morpholine that melted at 142–143°. The nitro compound (22.2 g.) was mixed with 200 ml. of absolute alcohol and reduced by the method used for dinitrodurene. The catalyst was removed and a solution of 5.6 ml. of concentrated sulfuric acid in 100 ml. of water was added. The mixture was warmed until solution took place and then was allowed to cool. The product was separated and recrystallized from 75% aqueous alcohol. There resulted 20 g. of 1-(4-amino-*m*-tolyl)-morpholine sulfate. *Anal.* Calcd. for $C_{11}H_{16}N_2O \cdot H_2SO_4$: N, 9.65. Found: N, 9.67.

***p*-Aminophenol Hydrochloride.**—A boiling solution of 100 g. of the salt in 150 ml. of water containing 1 ml. of concentrated hydrochloric acid was treated with Darco, filtered, and allowed to cool. The precipitate was removed by filtration and recrystallized from water.

***p*-Methylaminophenol Hemisulfate.**—The salt was recrystallized twice from water which contained 0.1% sulfuric acid.

***p*-Dimethylaminophenol Hemisulfate.**—The salt was dissolved in boiling 75% aqueous alcohol, treated with Darco, filtered, and cooled. The solid was separated and recrystallized from 75% aqueous alcohol.

Calculations and Results

All calculations of $\log(V'_i - V_i)$–time curves were made by Guggenheim's method,[13] as outlined in a previous paper.[4c] The oxygen uptake–time curves represent several types: (1) first-order reactions, denoted by (1st), (2) autocatalytic reactions, denoted by (α), and (3) reactions which are initially autocatalytic, reach saturation and then follow the first-order law, denoted by (β).

The mean values for the reaction-rate constants, k, of (1) and (3) are taken in the first-order part of the reactions. This part always includes the point at which the reaction is 50% complete. For comparison, the k values of the autocatalytic reactions (2) were therefore taken at 50% completion of the reactions. Figure 4 shows Guggenheim curves of 1st, α-, and β-type reactions of various *p*-phenylenediamines. The β-curves may remain first-order up to the end or drop off near the end of the reaction.

In addition, there are several curves which can be dissected and allotted to consecutive reactions. In the autoxidation of *N,N'-dimethyl-*

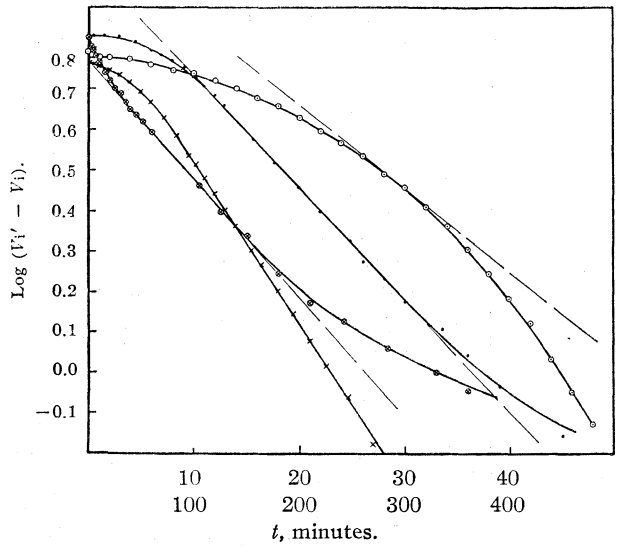

Fig. 4.—Types of Guggenheim curves: -⊙-⊙-, diaminodurene, α-curve, upper time scale; -⊗-⊗- N-dimethyl-*p*-phenylenediamine in presence of 6.00×10^{-4} *M* benzoquinone at *p*H 7.57. Composite curve with rapid initial reaction, lower time scale; -×-×- N-dimethyl-*p*-phenylenediamine at *p*H 7.88, β-curve, lower time scale; -●-●- N-dimethyl-*p*-phenylenediamine at *p*H 7.56, β-curve, lower time scale.

p-phenylenediamine at *p*H 11.33, a rapid autocatalytic reaction is followed by a slower first-order reaction. The uptake–time curves are given in Fig. 5. The upper curve shows the total uptake–time curve, and the lower curve gives the uptake of the first six milliliters of oxygen on an expanded time scale. The theoretical uptake for the oxidation of the diamine to the diimine according to equation (1) is 6.0 ml. Hence, the autoxidation of the diamine takes place in the autocatalytic reaction, and the following first-order reaction represents the autoxidation of some secondary product of the diimine, presumably the quinone.

The uptake–time curves for the autoxidation of *N,N'-tetramethyl-p-phenylenediamine* at *p*H 6.65 and *p*H 13.20 are given in Fig. 6. There is a definite break in each curve after approximately three milliliters of oxygen have been absorbed, and the Guggenheim curve for the total reaction (Fig. 7) shows two distinct sections with a transition period. The theoretical uptake for the autoxidation of the diamine to the semiquinone is 3.0 ml., and the inspection of the reaction mixture shows that Wurster's Blue accumulates to a high concentration. The rate constant for the first three milliliters of oxygen uptake belongs, therefore, to the autoxidation of the diamine to the semiquinone, while the latter portion of the uptake represents the autoxidation of the semiquinone to the diimine. Inasmuch as the latter portion of the uptake exceeds three milliliters, the diimine again undergoes secondary reactions.

The tabulated rate data for *p*-phenylenediamine and some of its alkyl derivatives, and for the *p*-aminophenols, may be obtained in the form of an American Documentation Institute Document.[14]

The rates are all in such a region that, from the point of view of accuracy of measurement, the data are of equal significance. However, the measurement on tetramethyl-*p*-phenylenediamine at *p*H 13.2, though it is also in an easily observed region of rate, may be less reliable because of the possibility of demethylation and the possibility of higher solubility of oxygen at very high *p*H.

Discussion

Type of Curve and Mechanism.—An α-curve, exemplified by dihydroxydurene,[4a,15] is again found on the autoxidation of diaminodurene. The recoverable product from the autoxidation of diaminodurene is duroquinone. In some experiments, however, the autoxidation was completed about a half hour before the precipitation of the duroquinone, which probably is formed by hydrolysis of the duroquinonediimine. Thus, diaminodurene autoxidizes by the mechanism of Classes I-A-3[15] or I-C.[15] With the exception of diaminodurene, all of the *p*-phenylenediamines autoxidize by a mechanism giving a β-type curve. Only occasionally, at low *p*H or high *p*H, will a compound give an α-type curve. The β-curves

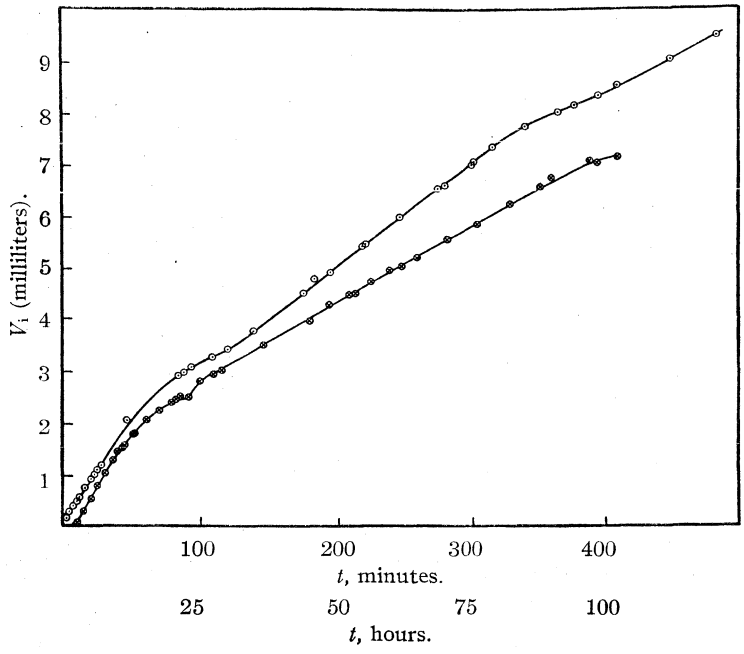

Fig. 6.—Uptake–time curves for N,N′-tetramethyl-*p*-phenylenediamine: -⊙-⊙-, *p*H 6.65, upper time scale; -⊗-⊗-, *p*H 13.20, lower time scale.

correspond to the mechanism of Class II-A-3 which was assigned to the *p*-phenylenediamines in an earlier paper of this series.[15] Kinetically, it is difficult to distinguish Class II-A-3 from Class I-E.[15] The rate of autoxidation for the latter mechanism is determined by the rate of *formation* of the semiquinone, but, for the former mechanism, the rate of *autoxidation* of the semiquinone enters into the rate equation. Class II-A-3 is differentiated from Class I-E by the appearance of intensely colored fairly stable semiquinones during the course of the reaction. These latter were observed with all of the *p*-phenylenediamines investigated in the present study.

If the rate of autoxidation of the semiquinone is high compared with the rate of formation of the semiquinone, the latter is rate-determining, and the concentration of semiquinone is low. Insofar as the rate of autoxidation of the semiquinone drops, it becomes more and more rate-determining, and the concentration of the semiquinone increases until eventually the mechanism becomes that found with tetramethyl-*p*-phenylenediamine.

Addition of quinone to a diamine in the proper concentration before autoxidation eliminates the induction period and causes a (β) reaction to become first-order throughout its course. The necessary concentration of quinone varies with the diamine between one-twentieth of the concentration of the diamine and less. The rate constant is identical with that derived from the autoxidation of the diamine alone. If less than the critical concentration of quinone is added, the induction period is not completely eliminated. If more than this critical concentration of quinone is added, a very rapid initial uptake of 10–20% of the total oxygen consumption during thirty to sixty seconds is followed by the normal first-order reaction. The elimination of the induction period appears to be caused by the poised equilibrium

$$R + Q \rightleftarrows S_{diamine} + S_{quinone}$$

Effect of Solvents.—Experiments with diaminodurene and *p*-diethyl-*o*-toluidine show that the rate in 20% ethanol solutions is lower than in water. Since the semiquinones are more stable in alcoholic solution than in water,[6b] the lower rate may be due to the increased stability of the semiquinone.

Rate Dependency upon the Concentrations of Substrate and Oxygen.—Experiments with N-dimethyl-*p*-phenylenediamine, N,N′-trimethyl-*p*-phenylenediamine, and diaminodurene show that the rate is first-order with respect to the *initial concentration* of the *diamine*. The rate

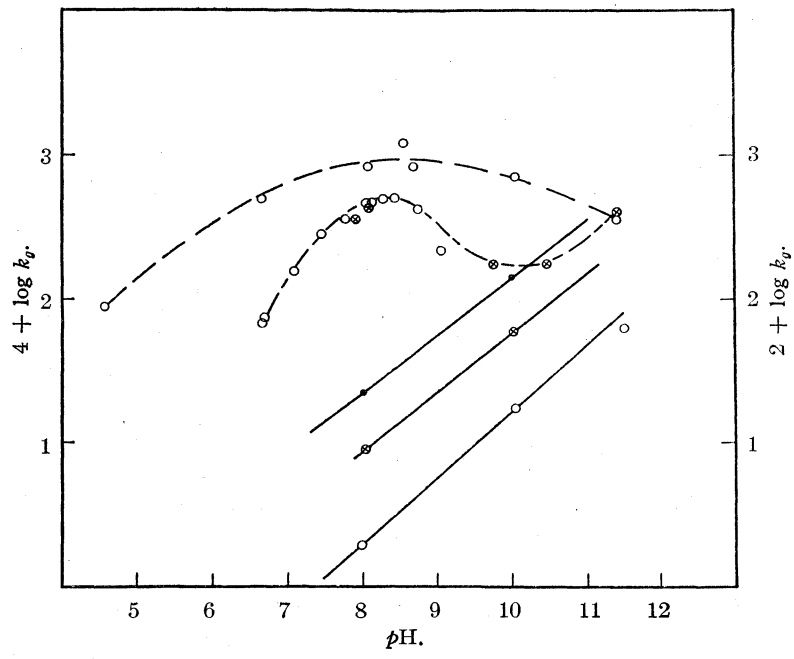

Fig. 8.—Straight lines refer to right-hand ordinate, 2 + log k_g: -O-O-, *p*-aminophenol; -●-●-, *p*-methylaminophenol; -⊗-⊗-, *p*-dimethylaminophenol. Curves refer to left-hand ordinate, 4 + log k_g: ———, *p*-diethylamino-*o*-toluidine; O, in presence of 2.00 × 10^{-4} *M* benzoquinone; ⊗, in absence of benzoquinone; -⊖- -⊖-, diaminodurene.

laws observed give no reason to assume a more complicated dependency for any of the other compounds in the range of concentration investigated.

A few experiments with N,N′-trimethyl-*p*-phenylenediamine indicate that the *rate dependency with respect to oxygen varies* with the *p*H. At *p*H 7.8 and 11.3, the rate is about of order 0.8 with respect to oxygen, while at *p*H 9.8 the rate appears to be first-order with respect to oxygen. These data indicate that the mechanism of Class I-E[15] may also occur with the *p*-phenylenediamines. The effect of added quantities of the diimines was not investigated because of the instability of these compounds in aqueous solution.[7]

Dependency of Rate on *p*H.—The data for *p*-aminophenol and the N-methylated *p*-aminophenols (Fig. 8) are not sufficient to warrant a detailed discussion. However, from the points measured it appears that the change of the rate of autoxidation of *p*-aminophenol itself with *p*H is not far from linear in the range investigated. It is known that the salts of *p*-aminophenol are stable, while the free base reacts with oxygen, and the anion of the base might be expected to have an even higher autoxidation rate in line with the results on desylamine and on dihydroxy compounds. The low slope (about 0.4) of the curves may suggest that the reactivity of the anions is not very much higher than that of the neutral molecules.

The rate–*p*H relation of *p*-phenylenediamine and of the N-alkylated *p*-phenylenediamines shown in Fig. 9 is rather complicated. For N-tetramethyl-*p*-phenylenediamine, the figure gives

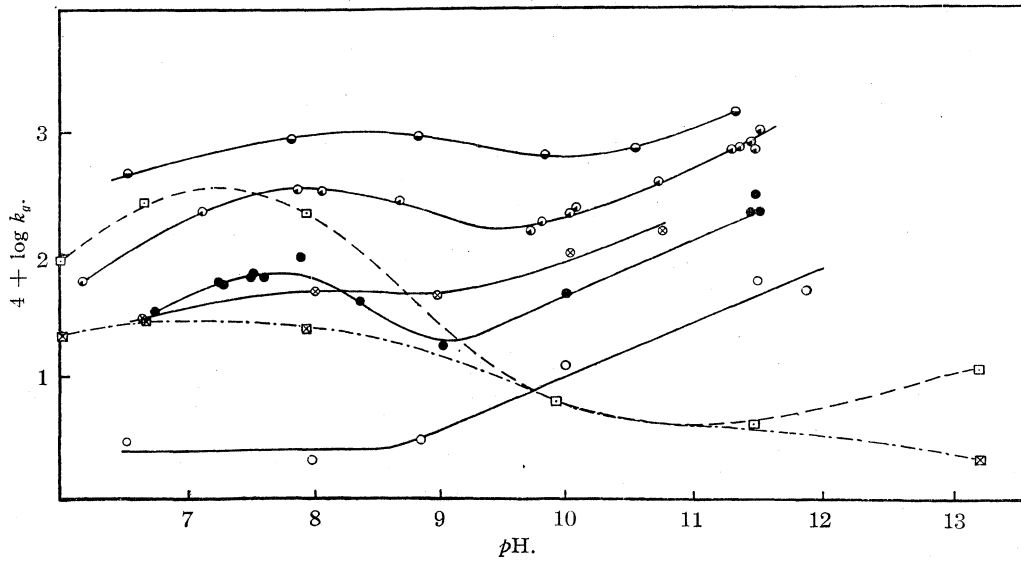

Fig. 9.—*p*-Phenylenediamines, 4 + log k_g − *p*H: -O-O-, *p*-phenylenediamine; -⊗-⊗-, N-methy -*p*-phenylenediamine; -●-●-, N-dimethyl-*p*-phenylenediamine; -◒-◒-, N,N′-dimethyl-*p*-phenylenediamine; N-methyl, N′-dimethyl-*p*-phenylenediamine; -⊡-⊡-, N,N′-tetramethyl-*p*-phenylenediamine, semiquinone formation; -·⊠-·⊠-·, N,N′-tetramethyl-*p*-phenylenediamine, semiquinone autoxidation.

the data for the oxidation to the semiquinone and for the oxidation of the semiquinone. The salts of these compounds with strong acids are known to be stable, while the free bases are oxidized by air. Accordingly, all curves may be extrapolated to reaction rates close to zero at very low *p*H. Our measurements begin between *p*H 6 and 7, in most cases in a distinctly ascending part of the rate-*p*H curve. However, between *p*H 7 and 9, maxima are reached, and the rates begin to drop. The drop of the curves is not steady but leads to minima at *p*H about 10 and from there on the rates increase again sharply. For *p*-phenylenediamine itself and N-methyl-*p*-phenylenediamine, the maximum and minimum are very flat, almost fused into a region of inflection.

The increase in k in the lower *p*H region can be ascribed to a predominance of the liberation of the free base, *i. e.*, to a formation of R from RH^+. The drop from the maximum to the minimum may be ascribed either to a decrease in the total concentration of the semiquinone or to a shift in the ionic equilibrium of the semiquinone in favor of less reactive ionic species, or to both. A definitive discussion is not possible with the present information, but some suggestions are offered in the following:

Table I gives the number of equivalent structures of the semiquinones of *p*-phenylenediamine and of its N-alkyl derivatives. The lack of any entry indicates that the compound in question does not exist. We learn from the table that of all semiquinones listed, SH_2^+ can be expected to be the predominant ionic species of the semiquinones at low and medium *p*H. It is noteworthy in this connection that the more or less steep drop in rate constant, k, with increasing *p*H is common to all *p*-phenylenediamine compounds investigated. Michaelis has stated that SH_2^+ in equilibrium with other ionic species of the semiquinones of *p*-phenylenediamines has a maximum concentration at about *p*H 4, and from this its concentration drops with increasing *p*H. We are therefore inclined to believe that the drop in the rate of autoxidation of the *p*-phenylenediamine compounds between *p*H 7 and 10 is due to a decrease in concentration of the semiquinone species, SH_2^+.

TABLE I

NUMBER OF EQUIVALENT STRUCTURES FOR THE SEMIQUINONE SPECIES OF *p*-PHENYLENEDIAMINE AND ITS N-ALKYL DERIVATIVES

No. of N-Alkyl groups	SH_2^+	SH	S^-
0	3	0	3
1	3	0	3
2 sym.	3	0	3
2 asym.	2	0	0
3	3	0	
4	3		

The steep rise in k above a *p*H of about 10 remains to be explained. Two alternative suggestions are offered. The increase may be due to an increased concentration of SH, provided that SH is more reactive than SH_2^+; the latter can be safely assumed because of the instability of SH to be expected from Table I and Fig. 2. The other reason for the increase of k with *p*H above 10 would be an increase in the concentration of S^-; this explanation cannot be completely excluded. However, the uniformly steep gradient of k *versus* *p*H at a *p*H higher than 10 for *p*-phenylenediamine, methyl-*p*-phenylenediamine, the dimethyl-*p*-phenylenediamines and trimethyl-*p*-phenylenediamine, as contrasted with the retarded and questionable (see Fig. 9) flat increase in k of tetramethyl-*p*-phenylenediamine, favors the former explanation; Fig. 2 and Table I show that SH can be formed by all the compounds listed except by tetramethyl-*p*-phenylenediamine, while S^- would also not be formed by the trimethyl compound. Inasmuch as the first acid ionization constant for the *p*-phenylenediamines occurs at extremely high pK values, the increase in rate above $p\mathrm{H}_{min.}$ cannot be attributed to the formation of R^-. As the slopes above $p\mathrm{H}_{min.}$ are the same for all the N-alkyl-*p*-phenylenediamines except the N-tetramethyl compound, Table II, it appears that the increase in rate may be attributed to the increase in the concentration of SH.

TABLE II

COMPARISON OF SLOPES OF k_g–*p*H CURVES

Compound	Slope of k_g–*p*H curve above $p\mathrm{H}_{min.}$	$p\mathrm{H}_{min.}$
p-Phenylenediamine	0.44	8.5 (inflection)
N-Methyl-*p*-phenylenediamine	.41	8.5 (inflection)
N,N′-Dimethyl-*p*-phenylenediamine	.32	10
N-Dimethyl-*p*-phenylenediamine	.43	9.1
N,N′-Trimethyl-*p*-phenylenediamine	.44	9.5
N,N′-Tetramethyl-*p*-phenylenediamine	.27(?)	11–12(?)
p-Diethylamino-*o*-toluidine hydrochloride	.38	10.1
p-Aminophenol	.46 straight line	
N-Methyl-*p*-aminophenol	.40 probable straight line	
N-Dimethyl-*p*-aminophenol	.39 probable straight line	

Figure 8 shows that the *addition of benzoquinone* to a concentration of 2×10^{-4} M merely changes the reaction from β to first-order but does not affect the *p*H dependency.

Effect of Substituent on Rate.—N-Methylation increases the rate of autoxidation of *p-aminophenol;* the rate of the dimethyl compound was between that of the monomethyl derivative and the parent substance. Figure 9 affords a comparison of the effect of N-methylation upon the rate of autoxidation of *p*-phenylene-

diamine. The dimethyl derivative autoxidizes most readily at all *p*H values investigated; next ranks the trimethyl derivative, and the rates of the asymmetrical dimethyl and the monomethyl compounds lie between the higher methylated products and the parent substance. N-Tetramethyl-*p*-phenylenediamine autoxidizes relatively fast at low *p*H but more slowly than the parent substance at high *p*H values.

A comparison of rates for different substances which have not been studied over a considerable *p*H range requires caution because it is not known whether at an arbitrarily chosen *p*H value one substance may not be close to its maximum autoxidation rate while any other substance is measured in a relatively slow part of the rate–*p*H curve. However, a comparison at *p*H 8 of closely related compounds should furnish some information because at this *p*H the *k*–*p*H curve for most substances is either close to a maximum or flat. The comparison at *p*H 8 and 11.5 is given in Table III. It is obvious that asymmetrical dialkylation has an effect of about the same order of magnitude, irrespective of whether methyl, ethyl, or propyl groups are introduced. However, it may be significant that the diethyl compound has the highest rate of autoxidation.

TABLE III

EFFECT OF SUBSTITUENTS UPON THE RATE OF AUTOXIDATION (RELATIVE RATES)

Compound	$\frac{k_g\ (p\text{H } 11.5)}{k_g\ (p\text{H } 8)}$
p-Phenylenediamine	29
N-Methyl-*p*-phenylenediamine	3
N-Dimethyl-*p*-phenylenediamine	3.2
N,N′-Dimethyl-*p*-phenylenediamine	1.6
N,N′-Trimethyl-*p*-phenylenediamine	2.3
N,N′-Tetramethyl-*p*-phenylenediamine	0.018
N-Diethyl-*p*-phenylenediamine	5.4
N-Di-*n*-propyl-*p*-phenylenediamine	....
Diaminodurene	0.44
N-Diethylamino-*o*-toluidine	0.93
4-Amino-N,N′-dimethyl-*m*-toluidine	10
N-(4-Aminophenyl)-piperidine	11
N-(4-Aminophenyl)-morpholine	....
N-(4-Aminophenyl)-pyrrolidine	22
N-(4′-Amino-3′-methylphenyl)-piperidine	0.61
N-(4′-Amino-3′-methylphenyl)-morpholine	4
N-(4′-Amino-3′-methylphenyl)-pyrrolidine	11
Octomethyl-*p*-phenylenediamine	No measurable rate

The effect of ring alkylation is illustrated by a comparison of N-diethyl-*p*-phenylenediamine with N-diethylamino-*o*-toluidine and of N,N′-dimethyl-*p*-phenylenediamine with 4-amino-N,N′-dimethyl-*m*-toluidine. The introduction of a methyl group into the ring in the *meta*-position to the diethylamino group causes a considerable increase in the reaction rate. This can be expected in view of the electron-releasing effect of the methyl group upon the neighboring amino group. However, if the methyl group is present in the *ortho*-position to the dimethylamino group of N-dimethyl-*p*-phenylenediamine, the reaction rate is cut down considerably. Presumably, a steric interference of the ring methyl group with the N-methyl groups makes less probable a configuration necessary for the formation of the semiquinone.

Diaminodurene exhibits a reaction rate close to that of N,N′-dimethyl-*p*-phenylenediamine. Figure 8 gives the rate–*p*H dependency for diaminodurene. In the *p*H range investigated it shows a broad flat maximum, but no minimum, *i. e.*, no rise in oxidation rate at *p*H higher than 10.

If the two alkyl groups in N-dialkyl-*p*-phenylenediamine are fused to form a ring, compounds result, some of which are listed in Table III.

The *piperidine* derivatives autoxidize considerably more slowly than N-diethyl-*p*-phenylenediamine and N-diethylamino-*o*-toluidine, respectively. Substitution of a *morpholone* ring for the piperidine ring further diminishes the autoxidation rate. However, a remarkable effect is obtained when the six-membered ring of piperidine is shrunk to the five-membered ring of *pyrrolidine*. Table III shows that the resulting pyrrolidine derivatives autoxidize at surprisingly high rates, particularly at *p*H 11. It is difficult to explain this effect. However, we are inclined to believe that the strain upon the C–N–C angle in the five-membered ring favors the π nature of the remaining nitrogen bonds and thus the formation of the semiquinone.

Summary

The autoxidation of *p*-phenylenediamine and of several of its derivatives has been investigated over a wide *p*H range.

Oxidation Processes. XXII. Some Biological Implications in Autoxidation Mechanisms

BY JAMES E. LUVALLE

Autoxidation, *i. e.*, oxidation by molecular oxygen, supplies much of the energy needed for synthetic processes by biological systems. Frequently the idea is expressed that enzymes react by chain mechanisms, and in the case of reactions with oxygen, *via* organic peroxide formation. Both suggestions are usually based upon the data for the autoxidation of organic systems involving unsaturated hydrocarbons. The postulates of chain reactions and organic peroxide formation are not necessary, however, to explain enzymatic action, and an alternate mechanism involving semiquinone formation is set forth here which gives a better explanation of the observed facts.

Two mechanisms have been shown to occur in the oxidation of organic systems by molecular oxygen. Hydrocarbon (saturated and unsaturated) systems have been shown to autoxidize by a chain mechanism involving free radicals and the formation of organic peroxides (hydroperoxides) as the bivalently oxidized product.[1] The intermediate free radical, R·, is assumed to be stabilized to some extent by resonance. All the hydrocarbons which have been shown to undergo this chain autoxidation are characterized by the extreme instability of the bivalently oxidized molecule, R″ (the primes denote that two electrons have been removed); the addition of an electron donor stabilizes it; hence, the radical O_2^- combines with R″ to form RO_2^-.

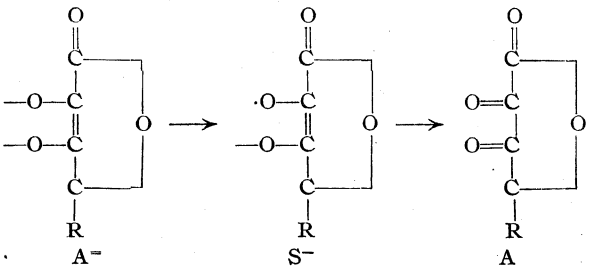
$$R\cdot + :O\overset{\cdot\cdot}{\underset{\cdot\cdot}{=}}O: \longrightarrow R-\ddot{O}-\ddot{O}:$$

which then reacts

$$R-\ddot{O}-\ddot{O}: + RH \longrightarrow R-\ddot{O}-\ddot{O}-H + R\cdot$$

to form the hydroperoxide and another radical, R·. Aldehydes also autoxidize by a chain mechanism involving peroxide formation.

A second mechanism, named the semiquinone mechanism, has been established for the autoxidation of enediols, eneamines and their vinylogs like hydroquinone and *p*-phenylenediamine.[2] The semiquinones (free radicals) are much more stable than the free radicals formed in the chain mechanism. The bivalently oxidized product is stabilized by a rearrangement of bonds to form a quinonoidal structure. The compound undergoing autoxidation is frequently characterized by the stability of the neutral molecule and the extreme reactivity of one or more of its ions.[3] Thus, in *l*-ascorbic acid, the divalent ion is much more reactive than the monovalent ion or the neutral molecule.



This molecule shows the typical bond rearrangement which takes place in the semiquinone mechanism.

In metallic ion catalysis of either mechanism and in inhibition of the semiquinone mechanism, the catalyst or inhibitor apparently forms a complex with the substrate and this complex reacts with oxygen.[1a,1e,2a,3c]

In the peroxide mechanism, the free radical is stabilized to some extent by resonance, and the bivalently oxidized product is stabilized only by addition of an electron donor to form the peroxide radical. In the semiquinone mechanism, the free radical is stabilized quite strongly by resonance, the bivalently oxidized product is stabilized by a rearrangement of bonds, and the ion (or ions) is (are) frequently more reactive than the parent substance.

Many enzymatic mechanisms involve oxidation by oxygen. Waters[4] has recently discussed autoxidation in biological systems. He suggests chain mechanisms to explain the data and he also points out the objections to chain mechanisms. Hinshelwood[5] has proposed a group of enzymes spatially arranged, with free radical groupings at given spots (active centers) on their surfaces. These radicals are assumed to have a temporal existence. Michaelis[6] has suggested that both electron donor and acceptor are bound in adjacent sites on the enzyme surface and that they remain there until reaction takes place.

Virtually every coenzyme discussed by Waters[4]

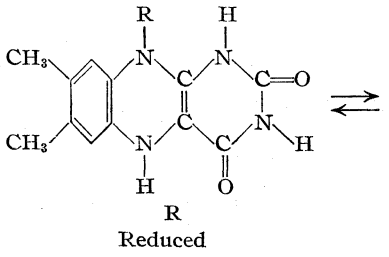
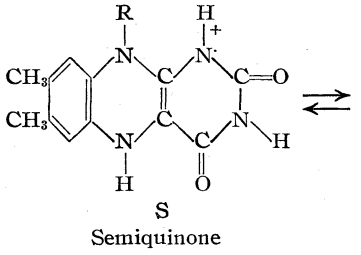
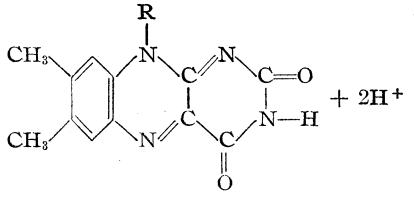
that reacts with oxygen can stabilize itself in the oxidized state by a bond rearrangement, *i. e.*, there is no necessity of proposing the formation of organic peroxides. For example, riboflavin nucleotides are the prosthetic groups of the flavo (yellow) enzymes. Let R represent the ribose group, the phosphate linkage, and the adenine group.



R
Reduced



S
Semiquinone



T
Oxidized

On oxidation, the bonds rearrange similarly to the rearrangement for the semiquinone mechanism. It is probable that even the oxidases that reduce oxygen to water do not form organic peroxides. Formation of enzyme peroxide probably leads to inactivation of the enzyme. Ionization preceding or following the oxidation adequately explains the hydrogen balance without introducing the idea of atomic hydrogen exchange (Wieland's dehydrogenation theory). Certainly in aqueous solution at the *p*H of normal cell activity there is an adequate supply of hydrogen ions to give instantaneous exchange.

LuValle and Goddard[7] have suggested that electron donor and electron acceptor are bound in a complex and that reaction takes place by the semiquinone mechanism. Either the donor or acceptor may combine with the enzyme, followed by a univalent oxidation–reduction, and this enzyme–semiquinone complex will then react with the other reactant to form the final products. By this mechanism the semiquinones are never free in the solution; they only exist bound to the enzyme. It is shown that the semiquinone mechanism can explain the observed kinetics for many respiratory enzymes. This mechanism does not involve bound peroxide formation or exchange of hydrogen atoms. Chain mechanisms are not necessary to explain the observed data.

Summary

The chain peroxide mechanism of autoxidation is briefly compared with the semiquinone mechanism. It is pointed out that the coenzymes involved in biological oxidation–reductions are much more likely to undergo reaction with oxygen *via* the semiquinone mechanism than by the chain, bound peroxide mechanism.

Preparation of 1-C^{14}-Propene-1 and the Mechanism of Permanganate Oxidation of Propene[1]

BY B. A. FRIES[2] AND M. CALVIN

The preparation of 1-C^{14}-propene-1 was undertaken in order to have available propene labelled in a terminal position and, incidentally, to study the stability of the double bond to migration when preparing propene under a variety of conditions. During the course of this investigation, a reliable procedure for the degradative analysis of the propene had to be developed. This analytical problem led to a study of the oxidative degradation of propene with permanganate.

A number of methods were available for the preparation of propene. Several of these methods were tried with C^{14} labelled materials, while others were discarded when preliminary tests with nonradioactive materials indicated either very poor yields or impure products. The first three of the following methods were actually employed for radioactive propene synthesis: (1) dehydration of *n*-propanol with metaphosphoric acid, (2) dehydration of *n*-propanol over heated alumina, (3) pyrolysis of *n*-propyltrimethylammonium hy-

(1) This paper is based on work performed under Contract Number W-7405-eng-48 with the Atomic Energy Commission in connection with the Radiation Laboratory of the University of California, Berkeley, California.

droxide, (4) pyrolysis of methyl *n*-propyl xanthate, and (5) dehydrobromination of *n*-propyl bromide with alcoholic potassium hydroxide. Extensive rearrangement of the double bond was found to occur when preparing propene by dehydration with metaphosphoric acid and with heated aluminum oxide. However, the pyrolysis of the quaternary ammonium base gave little, if any, rearrangement and the product consisted principally of 1-C^{14}-propene-1 ($CH_3—CH=\overset{*}{C}H_2$), whereas in the other cases, mixtures of 1-C^{14}-propene-1 and 3-C^{14}-propene-1 ($\overset{*}{C}H_3—CH=CH_2$) were obtained.

Degradation Procedure. Permanganate Oxidation of Propene.—A number of procedures were available for the analysis of the labelled propene, including oxidative degradation with permanganate or dichromate, ozonolysis and glycol formation with hydrogen peroxide, acetyl peroxide or Prévost reagent, and subsequent oxidation and splitting of the glycol with periodate. Ozonolysis of propene gives rise to a mixture of formaldehyde and acetaldehyde, which are not too easily separated. Preliminary glycol formation and periodate oxidation also yields these same two aldehydes and in addition involves more manipulation. Acid permanganate oxidation should produce acetic and carbonic acids if propylene glycol is an intermediate. This appeared to be a satisfactory procedure, particularly since Evans[3] reported that propylene glycol was converted quantitatively to acetic acid and carbon dioxide with neutral permanganate at 50°, although in the presence of alkali, oxalic acid was formed. Hence, examination of the acetic and carbonic acids for C^{14} should indicate the extent of labelling of the two terminal carbon atoms of the propene. However, rearrangement of the double bond might also occur during the analysis, but this could not be determined until some radioactive propene had been prepared. Although permanganate oxidation was chosen for the degradative analysis, in one instance ozonolysis was employed to confirm the results of the permanganate method.

The following procedure was first tested with non-radioactive propene. Approximately three millimoles of propene was introduced into an evacuated 3-necked flask of about 385 ml. volume. Fifty ml. of water or buffer solution was added through a dropping funnel. An induction stirrer[4] was used to agitate the aqueous phase. An amount of 0.4 *N* potassium permanganate calculated to be just sufficient to oxidize propene to propylene glycol was added over a period of forty-five minutes. This was followed by the addition of 110% of the amount of 2 *N* potassium permanganate required for the oxidation of propylene glycol to acetic and carbonic acids. This addition required forty-five minutes, after which the solution was stirred fifteen minutes more. A sulfuric acid-acidified solution of ferrous sulfate was added to reduce all manganese to the manganous state and simultaneously liberate carbon dioxide. The flask was connected to a sodium hydroxide absorber and swept with nitrogen gas to collect this carbon dioxide fraction. The solution remaining was steam distilled to recover acetic acid. This latter was titrated with sodium hydroxide and evaporated to dryness as sodium acetate. The weight of the salt obtained and its subsequent combustion to carbon dioxide when compared with the titration value indicated that the salt was the acetate. This procedure was studied at several values of *p*H and at two temperatures. The results are shown in Table I.

TABLE I

OXIDATION OF PROPENE WITH POTASSIUM PERMANGANATE AT SEVERAL VALUES OF *p*H

Starting solution	0.04 *N* NaOH	0.02 *N* NaOH	0.1 *M* $PO_4^{=}$ *p*H 7.4	Distilled water	0.1 *M* $PO_4^{=}$ *p*H 6.0	0.1 *M* $PO_4^{=}$ *p*H 4.0
Temp., °C.	35	35	35	35	25	25
Moles CO_2/ moles C_3H_6	1.54	1.31	1.28	1.11	0.94	0.94
Moles acetic acid/ moles C_3H_6	0.18	0.38	0.46	0.57	0.73	0.70
Acetic acid/CO_2	0.11	0.29	0.36	0.51	0.78	0.75

It can be seen that in weak acid solution about 70% of the theoretical amount of acetic acid and 90% of the theoretical amount of carbonic acid may be recovered. This calculation was based on the splitting of propene at the double bond to yield equimolar amounts of acetic and carbonic acids. There was no significant change in yield of these two fractions on decreasing the *p*H from 6 to 4 and stronger acid was avoided to reduce the possibility of a shift of the double bond in propene during the analysis. In the subsequent use of this procedure with the various samples of radioactive propene, the reaction was carried out at *p*H 4 and at room temperature. Inasmuch as the total carbon recovery in the carbon dioxide and acetic acid fractions was quite low (70–80%) an attempt was made to locate the missing carbon. The solution remaining after steam distillation of the acetic acid was made 6 *N* in sulfuric acid and 0.5 *M* in chromic oxide, heated to boiling and swept with oxygen for one hour. Considerable carbon and C^{14} activity was found in this fraction. The inclusion of this additional carbon boosted the total carbon recovery to 85–95%.

There were several indications that this oxidizable residue was oxalic acid. First, oxalic acid may be found during alkaline permanganate oxidation of propylene glycol.[3] Second, oxalic acid is oxidized very slowly at 25° and *p*H 4 by potassium permanganate or manganese dioxide and therefore, the oxalic acid would be stable, if present. Third, the nature of the analytical procedure eliminated the possibility of a one carbon compound, since these compounds (methyl alco-

hol, formaldehyde, formic acid), if not completely oxidized by the permanganate, would be volatilized during the steam distillation. In addition, subsequent specific activity determinations of this fraction (see Discussion) eliminated the possibility of a three carbon compound and corresponded well with a two-carbon substance. Hence, this residue was either oxalic, glycolic or glyoxylic acid. The last two of these may be intermediates in the formation of oxalic acid. Ethylene glycol also satisfies the chemical properties set for the residue, but it is difficult to see why this glycol should remain unoxidized while propylene glycol, a probable intermediate in the above oxidation, is apparently completely reacted.

In one experiment with radioactive propene, the isolation of oxalic acid was attempted. After the addition of the last permanganate, all manganese was removed as manganese dioxide by centrifugation. Inactive sodium oxalate was added as a carrier and the oxalate was ultimately precipitated as calcium oxalate after separation from phosphate by employing the scheme of Swift.[5] The completeness of recovery of oxalate could not be accurately determined, but appeared to be nearly quantitative. However, since the calcium salts of glycolic and glyoxylic acid are relatively insoluble, they might have been carried down with the calcium oxalate if present. The calcium oxalate was titrated with permanganate in the usual manner, and the carbon dioxide was collected and analyzed for C^{14} activity. The titration agreed within 3% with the formula calcium oxalate for the calcium precipitate; however, since the amount of carrier was about four times the amount of oxalate expected, the presence of other insoluble calcium salts might have been masked. The amount of C^{14} found as oxalate was about 70% of the amount found by direct chromic oxide oxidation of the residue in another experiment using radioactive propene from the same preparation.

Ozonolysis Method.—A highly refined procedure was not developed but the following scheme gave a satisfactory check with the result of the acid permanganate oxidation. About three millimoles of propene was transferred to the ozonolysis vessel, 15 ml. of ethyl chloride was added and the vessel immersed in a Dry Ice–acetone-bath. A current of oxygen containing 2–3% ozone was bubbled through the solution until the solution turned blue (indicating excess ozone). The vessel and contents were warmed to 0°, 10 ml. of water added and shaken with the ethyl chloride. The ethyl chloride was removed by evaporation under house vacuum. The aqueous solution, which now contained formaldehyde and acetaldehyde, was made alkaline with sodium hydroxide. Excess potassium permanganate was added and the solution heated to 50°. The formaldehyde was oxidized to carbon dioxide while the acetaldehyde was oxidized to acetic acid. From this point on, the analysis was carried out in the same manner as the permanganate procedure. In this ozonization some propene probably was swept out of the solution by the current of oxygen, while some of the aldehydes were lost during the evaporation of ethyl chloride. In addition some ethyl chloride remained in the aqueous phase and was oxidized to acetic acid. Although the total carbon recovery was high and C^{14} recovery was low, the distribution of C^{14} should not be affected.

Preparation of 1-C^{14}-*n*-Propanol ($CH_3—CH_2—\overset{*}{C}H_2OH$).—The principal intermediate in the synthesis of propene was *n*-propanol. The starting point of this synthesis was barium carbonate containing C^{14}. Ethylmagnesium bromide was carbonated with the $C^{14}O_2$ obtained from 21 millimoles of barium carbonate containing approximately 800 microcuries of C^{14}. A vacuum line technique (4) was employed. Solid sodium propionate was recovered in 95% yield. A very high specific activity product was not required in this experiment and a large dilution of C^{14} activity could be tolerated. Consequently, the reduction of the acid to alcohol was carried out on the *n*-propyl ester. The use of this ester eliminated the subsequent separation of two alcohols following the hydrogenation. The esterification was carried out on a 40 millimole scale by adding inactive sodium propionate to 1.62 g. (16.8 millimoles) of the radioactive salt. The esterification was driven to completion by azeotropic distillation. The solid salt was refluxed for several hours with a mixture of 9.0 ml. of *n*-propyl alcohol, 10.0 ml. of benzene and 1.1 ml. of concentrated sulfuric acid. Water was removed as the ternary azeotrope (68.5°) with *n*-propyl alcohol and benzene. A 16-inch, 6-mm. i. d., vacuum-jacketed, unpacked column was used for the distillation. When the temperature of the distillate reached 74°, the flask was cooled and 1.0 g. of calcium carbonate was added to destroy excess sulfuric acid. The distillation was continued, the remaining benzene being removed as the binary azeotrope (77.1°) with *n*-propyl alcohol. The distillation was stopped when the temperature reached 92°. The ester–alcohol solution remaining was removed from the calcium sulfate–calcium carbonate residue by vacuum transfer. This solution, about 8 ml. was pipetted into a high pressure hydrogenation bomb (Aminco, 43 ml. size) containing 2.0 g. of copper chromite catalyst (Adkins). The bomb was charged with 2500 p. s. i. of hydrogen, heated to 250° and maintained there for nine hours. The contents of the bomb were transferred on the vacuum line into a flask containing calcium oxide where the alcohol was dried. The alcohol was again transferred on the vacuum line into a small distilling flask and fractionally distilled using the column described above. The fraction boiling from 96–97° was recovered. The fraction boiling below 96° (about 2 ml.) was returned to the distilling flask with 2.5 ml. of *n*-propyl alcohol and the mixture redistilled. This was repeated again with 2.0 ml. of *n*-propyl alcohol. The 96–97° fractions were combined with the first fraction collected. In this manner 10.3 ml. of 1-C^{14}-*n*-propyl alcohol was obtained. The individual steps in the above procedure were tested first with inactive materials. These tests gave yields of 90–95% for the carbonation of ethylmagnesium bromide and 95% for the esterification and hydrogenation when measured by saponification. In the radioactive synthesis, the carbonation yield was 95%. The chemical yields of the other steps were not checked because the amount of alcohol which remained with the ester after azeotropic distillation was not known. About 80% of the starting C^{14} was recovered in the final product, which contained 4.58×10^6 c./min./ml. or about 50 μc/ml.

Preparation of 1-C^{14}-*n*-Propyl Bromide.—Propyl bromide was prepared from *n*-propanol by the phosphorus and bromide method,[6] but additional phosphorus and bromine were added. The yield of propyl bromide was 76% based on propanol. A low C^{14} activity sample of propanol was prepared by dilution of the high activity material for use in this preparation.

Dehydration of *n*-Propanol with Metaphosphoric Acid.—A 2-ml. sample of propanol containing 6350 c./m. C^{14} per millimole of alcohol (prepared by dilution of the high activity product) was dehydrated to propene by dropwise addition of the alcohol to 3 ml. of metaphosphoric acid at 250° according to the method of Newth.[7] Water and

alcohol were condensed in a trap at −20° while the propene was passed through Drierite, then condensed in a Dry Ice trap. Considerable alcohol distilled out of the flask without reacting and the yield of propene was 40% based on the starting propanol. The gas sample was analyzed by mass spectrometer.[7a] The analysis of the gas showed 80% propene, 9% butenes, 9% butanes and pentanes and 1% pentenes and hexenes. The propanol was analyzed by mass spectrometer and found to be 99.5% pure; the impurity may have been butyl alcohol.

Dehydration of *n*-Propanol over Heated Aluminum Oxide.—A 2-ml. portion of the above dilute propanol was dehydrated by dropwise addition over a period of thirty minutes into a vertically mounted quartz furnace tube containing aluminum oxide at 390°. The aluminum oxide was 12–24 mesh Alorco Alumina (Aluminum Company of America, Grade F-1) packed in a bed 23 cm. long and 0.7 cm. in diameter. Traps were arranged as in the previous experiment. Continuous nitrogen sweeping was maintained to reduce the residence time in the catalyst. The contact time was approximately 5 seconds. A second sample of alcohol was dehydrated over laboratory prepared aluminum oxide obtained by precipitation of aluminum hydroxide from reagent grade aluminum nitrate. The catalyst temperature was 415° while the contact time was only 2 seconds. The analysis of the first of these gas samples was 97% propene and 3% butenes, while the second gas sample contained 95% propene, 3.5% butenes, 0.5% propane and 0.5% *n*-butane. The yield of propene was about 95% in both cases.

Pyrolysis of *n*-Propyltrimethylammonium Hydroxide.—The quaternary ammonium bromide was prepared by the addition of 5 ml. of *n*-propyl bromide (containing 8300 c./m. C^{14}/millimole) to excess $(CH_3)_3N$ in alcohol and refluxing for several hours. The solvent was evaporated, the bromide dissolved in water and excess freshly prepared silver oxide was added to convert the bromide to hydroxide. After filtering silver bromide and excess silver oxide the aqueous solution was boiled to dryness in a system containing a cold water condenser, a 1 *N* hydrochloric acid wash bottle to remove $(CH_3)_3N$, a tube of Drierite and a liquid nitrogen trap to condense propene. The system was swept with nitrogen during the heating. The yield of propene was approximately 90%. Analysis of the gas showed 99% propene, 0.5% butenes and 0.5% ethylene.

Pyrolysis of Methyl *n*-Propyl Xanthate.—The procedure of Schurmann and Boord[8] was employed for preparing the xanthate ester, however, the final ester was not purified by vacuum distillation as carried out by these authors. The decomposition of the ester took place very slowly and after boiling for twenty-four hours, only half the ester was decomposed. The slow decomposition of primary xanthates was observed by Whitmore and Simpson.[9] The system was swept with a slow current of nitrogen and the gases were passed through a 1 *N* sodium hydroxide wash bottle to remove COS and CH_3SH, then through a drying tube and finally into a liquid nitrogen trap. The yield of propene was about 25% and the gas composition was 56% propene, 38% butenes, 1.4% ethene, 14% COS while the remainder of the gas consisted of several sulfides and mercaptans. This method of propene preparation, besides giving a gas difficult to free of sulfur compounds also contained an extraordinarily large amount of butene. The use of this method was not attempted with radioactive propanol.

Dehydrobromination of *n*-Propyl Bromide with Alcoholic Potassium Hydroxide.—Propene was prepared by refluxing the bromide with excess potassium hydroxide dissolved in absolute ethanol in a system similar to those described above. The yield of propene was about 10%, the bulk of the product being ethyl propyl ether. Nef[10] reported a yield of 20% propene. Analysis of the gas sample showed 75% propene, 16% butenes, 3% isobutane, 3% ethyl propyl ether and traces of ethane, propane and propyl bromide. The use of this method was not attempted with radioactive propyl bromide.

Radioactivity Determination.—The procedures developed by Dauben, Reid and Yankwich[4] were employed for sample preparation and counting.

Results and Discussion

In Table II a summary of the results of the permanganate degradations of the various samples of propene is presented. Since the mechanism of permanganate oxidation of propene, the reliability of this oxidation as an analytical procedure, and the nature of the labelling of the propene could not be determined independently, it was necessary to examine the data from these three points of view. The fact that different specific activities were found in the various fractions from propene prepared by different methods proved that rearrangement of the double bond to the equilibrium mixture did not occur during the analysis. Inspection of experiments 1, 2, and 3 showed that extensive migration of the double bond occurred during the preparation by these methods and, in fact, the propene produced in experiments 1 and 3 consisted of equilibrium mixtures of 1-C^{14}-propene-1 and 3-C^{14}-propene-1. However, the propene derived from the quaternary ammonium base (experiment 4) showed little, if any, rearrangement of the double bond and the product consisted, almost entirely, of 1-C^{14}-propene-1.

The mechanism which has been assumed for the oxidative splitting of olefins with permanganate consists of rupture of the molecule at the site of the double bond with the production of acetic and carbonic acids in the case of propene. If the acetic acid was to be used as a measure of labelling of the methyl group of propene, it was necessary to demonstrate that all the C^{14} activity was present in the methyl group of the acetic acid. Therefore in the pyrolysis of a sample of barium acetate to acetone and barium carbonate, the latter should contain no C^{14}. A sample of acetate from experiment 2, when pyrolyzed, showed that 5% of the C^{14} present was present in the carboxyl group. The pyrolysis of a sample of synthetic methyl-labelled acetate[11] yielded 1.5–2% of the total activity in the barium carbonate which would correspond to 3–4% of the activity apparently present in the carboxyl group. Hence, the above result may be taken to mean that little, if any, carboxyl activity was present and that the carboxyl group of the acetate was derived solely from the central carbon atom of the propene. Therefore, in every case shown in Table II, the specific activity of the methyl carbon of acetic acid may be obtained by doubling the specific activity shown for acetic acid. If acetic acid is obtained only from splitting of propene at the double bond, then

[a] In this calculation only the olefin content of the gas sample used in the potassium permanganate analyses was taken into account. The presence of labelled butene and other olefins derived from the original labelled propanol introduces some error in the calculation of yields as well as in the specific activity of the various fractions. This error cannot be corrected, since neither the number of C^{14} labelled atoms per molecule nor the isomers were known.

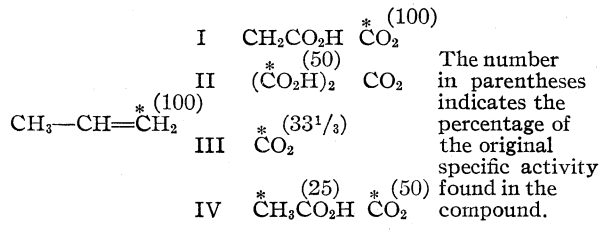
a case in which there was no activity in the acetate fraction would prove that all the C^{14} was in the methylene carbon of the propene. This was the case in experiment 4 where only 3% of the C^{14} activity was present in the acetate. This particular propene sample was checked by the ozonization analysis previously described and no activity could be found in the acetate. Therefore, the propene produced in experiment 4 consisted of the isomer 1-C^{14}-propene-1 to the extent of 97–100%. This result also demonstrated that acetic acid can arise only from the CH_3—CH= portion of the molecule. Accordingly, acetate was the most reliable indicator of the activity of the CH_3— position in propene and this was true even though acetic acid was not recovered in 100% yield.

The specific activity of the carbon dioxide fraction always was found to be lower than that calculated on the basis of the specific activity of the acetate. Thus, in experiment 1, the specific activity of the starting propanol was 6350 c./m. per millimole. Since all the C^{14} was located in the 1-position in the propanol, the specific activity of this particular carbon atom was also 6350 c./m. per millimole of carbon. The specific activity of the methylene carbon of the propene produced in experiment 1 was, therefore, $6350 - (2 \times 1610) = 3130$ c./m. per millimole C, but the specific activity found in the carbon dioxide fraction was only 2790 c./m. In experiment 2 the results were similarly 4150 c./m. *versus* 3980 c./m.; in experiment 4, 8040 c./m. *versus* 7600 c./m. These data indicated that the carbon dioxide–carbon was not derived exclusively from the methylene carbon, but probably from the methyl and central carbon atoms as well to a small extent.

Examination of the oxalic acid fraction revealed that the oxalate contained the methylene carbon atom of propene. The possibility of one carbon compounds being present in this residue has been considered already and has been eliminated on the basis of oxidation and volatility. The possibility that relatively large amounts of some three carbon compounds might be present may be eliminated on the basis of the specific activity of the fractions. If this oxidizable residue were entirely a three carbon compound, the specific activity in the active position would be three times the value shown in Table II. In experiment 4, the specific activity reported, when multiplied by three would give a result much higher than the original specific activity present in the starting material. On the other hand, if the substance were a two carbon compound, the specific activity in the labelled position corresponded closely to that known to be present in the methylene carbon. These results demonstrated that some propene was split at the CH_3—CH bond, perhaps to the extent of 15–20%. The —CH=CH_2 group was oxidized to oxalic acid, while the CH_3-group was split off as a one carbon compound, presumably oxidized to carbon dioxide, although some may not have been oxidized beyond methanol or formaldehyde. These last two compounds would not be recovered in the analytical procedure and this may account for the incomplete recovery of C^{14} and total carbon. The specific activity of C^{14} in the carbon dioxide fraction (representing the =CH_2 group) was therefore low due to the carbon dioxide which arose from the methyl group and probably from the central carbon atom as well.

In the alkaline oxidation of propylene glycol,[3] the yield of carbon dioxide was over one mole per mole of glycol, while acetate was lower and oxalate higher than that obtained from the acid oxidation. This led to the performance of an alkaline oxidation on propene from experiment 4. The oxidation was carried out in the same manner as those previously described except that the medium was 0.04 *N* in sodium hydroxide. The number of moles of carbon dioxide, acetic acid, and oxalic acid obtained per mole of propene were 1.64, 0.33, and 0.16, respectively. The specific activities of these three fractions were, respectively, 3410, 560, and 4370 c./m. per millimole of carbon. The yield of carbon dioxide was very high and its spe-

cific activity was very low, indicating that a considerable portion of it had come from carbon atoms other than the methylene group of the propene. Quantitative estimates, based upon relative yields and specific activities, indicated that nearly half of the propene had been completely oxidized to carbon dioxide, the remainder going partly ($^1/_3$) to acetic acid and carbon dioxide and partly ($^1/_6$) to oxalic acid and carbon dioxide. Still another route of oxidation was required to account for the small amount of activity found in the acetate fraction. This could be accounted for by some symmetrical intermediate (retaining the methyl group) such as isopropyl alcohol or acetone. There are three, and probably four, paths through which propene may be oxidized by permanganate. In the acid oxidation, path I predominates ($^5/_6$) with paths II and III contributing minor and approximately equal parts. Somewhat similar conclu-



sions were deduced for the alkaline permanganate oxidation of propionic acid by Nahinsky and Ruben.[12]

On the basis of the acetic acid specific activity, the propene prepared with metaphosphoric acid was a 50–50 equilibrium mixture of the two forms of labelled propene, the propene prepared from commercial aluminum oxide was 65% 1-C^{14}-propene-1 and 35% 3-C^{14}-propene-1, the propene prepared from the laboratory alumina was approximately a 50–50 equilibrium mixture; while the propene derived from the quaternary ammonium hydroxide was 97% 1-C^{14}-propene-1 and 3% 3-C^{14}-propene-1.

Isomerization during olefin preparation by dehydration reactions has been reported frequently,[13–16] while many cases have been reported where little or no isomerization occurred.[17–20] Asinger[13] found general isomerization of the double bond all along the carbon chain when dodecanol was dehydrated over alumina at 370–380° or with metaphosphoric acid. Isomerization was observed with alumina at temperatures as low as 250° where the dehydration reaction was incomplete. Pines[17] obtained only butene-1 when dehydrating *n*-butanol over alumina although Matignon, Moureau, and Dode[14] reported 15% butene-2 when using pure alumina and 90% with impure alumina. Pines believed the isomerization reported by Matignon occurred during analysis. Appleby, Dobratz and Kapranos[18] and Komarewsky, Uhlick and Murray[19] employing spectroscopic examination found no isomerization during the dehydration of primary hexanol, heptanol and octanol over alumina. Ewell and Hardy[21] studied the isomerization of pentenes over alumina and showed that the reaction required several hours to come to equilibrium. In the present study dehydration of *n*-propanol with alumina or phosphoric acid resulted in complete equilibration of the two isomeric forms. The ease of isomerization may be due to the symmetrical structure of propene.

Pyrolysis of *n*-propyltrimethylammonium hydroxide gave essentially pure 1-C^{14}-propene-1 in 90% yield. A side reaction of this pyrolysis results in the formation of methanol and a mixed tertiary amine. von Braun[22] found 5–10% methanol while Hanhart and Ingold[23] and Ingold and Vass[24] obtained 16–19% methanol on pyrolysis of the above quaternary base. The yield of propene in the present experiment falls between these two sets of results. This procedure appears to be a good, general, preparative method since the yields of olefins although falling off with higher olefins, does not drop below 70% even in the case of octene.[24]

Acknowledgment.—Our thanks are due to Mrs. Martha Kirk for her technical assistance in this work and particularly for the performance of many isotopic analyses.

Summary

1-C^{14}-propene-1 has been prepared. The migration of the double bond under a variety of experimental conditions in the preparation of propene has been investigated. The mechanism of the permanganate oxidation of the labelled propene has been examined. It has been found to proceed by several paths the relative importance of which depends upon the experimental conditions, especially the *p*H.

Polarography in Liquid Ammonia. I. The Alkali Metals

BY H. A. LAITINEN AND C. J. NYMAN

Up to the present time, no research has been carried out on polarographic measurements in liquid ammonia, although the dropping mercury electrode has been used in this solvent. Murtazaev[1] has measured electrocapillary curves of salts in liquid ammonia and has shown that chloride, bromide and iodide ions are adsorbed at the mercury–solution interface, causing shifts in the electrocapillary maximum similar to those observed in aqueous solution. Pleskov and Monosson[2] have measured the potential of the electrocapillary maximum in 0.1 normal ammonium nitrate solution at −35° and found it to be 0.386 v. more positive than the potential of a lead electrode in 0.1 normal lead nitrate solution. Dropping amalgam electrodes were used by Pleskov[3] and by Pleskov and Monosson,[4] in their determination of the standard electrode potentials of the alkali metals in liquid ammonia. Since it was known that the dropping mercury electrode would function in liquid ammonia, a polarographic study of the reduction of the alkali metal ions was undertaken.

Experimental

The electrolysis cell shown in Fig. 1a was used for all the experiments in this investigation unless otherwise specified. A platinum wire was sealed through the bottom of the cell so that the mercury pool could be used as the non-polarizable electrode. A conventional H-type cell, as shown in Fig. 1b, was used when it was desired to have the anode and cathode compartments separated; a sintered glass disc prevented mixing of the solutions in the two sides of the cell. When using this cell, two connections to the drying system (Fig. 2) were necessary.

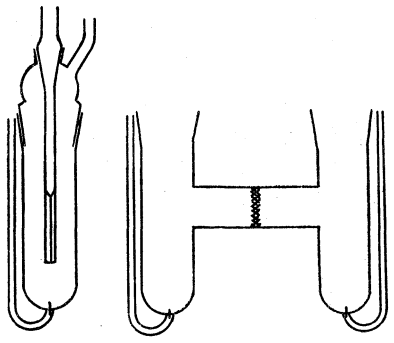

Fig. 1.—Electrolysis cells.

Using the apparatus shown in Fig. 2, the following procedure was carried out in the preparation of air-free anhydrous liquid ammonia solutions. The cell was connected to the drying system as shown at A after a weighed sample had been introduced into it. Ampules B and B′ each contained a small piece of sodium metal, approximately 1 g., in order to dry the ammonia. The system was evacuated through tube C, and after ampule B was cooled with a Dry Ice and acetone-bath, gaseous ammonia was allowed to enter the system through tube D. When 35 to 40 cc. had condensed, the ammonia was distilled from ampule B to B′, and then into the electrolysis cell until the desired volume was obtained. Stopcock E was then closed, and the bath surrounding the cell was brought to −36° by the addition of warm acetone. The solution was allowed to stand for one hour to be certain that the indifferent electrolyte had reached solubility equilibrium. Occasional stirring was achieved by opening stopcock E and evaporating ammonia into ampule B′, which was cooled with a Dry Ice and acetone-bath. In this evaporation, small bubbles formed which stirred the solution, but which did not cause any splattering on the walls of the cell.

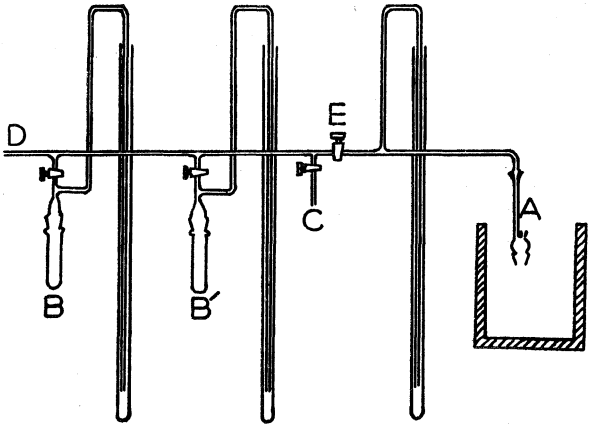

Fig. 2.—Drying system for the preparation of anhydrous liquid ammonia solutions.

The thermostat consisted of a one-gallon Dewar flask filled with acetone, a copper cooling coil, a cone drive stirrer and a toluene expansion udder for controlling the temperature. The toluene expanded against a mercury filled U-tube outside the bath forcing the mercury into a capillary. Electrical contact was made through the bottom of the U-tube and through the capillary. A leveling device for controlling the amount of mercury was sealed into the bottom of the U-tube. As the temperature rose and contact was made through the mercury in the U-tube, a mercury relay switch was actuated starting the pump which circulated cold acetone through the cooling coil. This thermostat held the temperature at a constant value of $-36.0 \pm 0.2°$.

Dropping mercury electrode 1 had the following characteristics in a saturated solution of tetrabutylammonium iodide in liquid ammonia at −36°. At a pressure of 20 cm., the drop time was 6.4 seconds (open circuit), and the value of m was 0.844 mg./sec. Under similar conditions, electrode 2 had an m of 1.184 mg./sec., and a drop time of 5.1 seconds (open circuit). As a comparison, electrode 1 had the following characteristics in air-saturated water at 25°. At a pressure of 20 cm., the drop time was 7.1 seconds (open circuit), and the value of m was 1.14 mg./sec.

The polarograph used was a Sargent Model XX. The calibration of this instrument was checked by inserting

a known resistance in place of the electrolysis cell and measuring accurately the applied potential. With these data, the current flowing through the circuit could be calculated and compared with that indicated by the recorder. All applied potential values were checked by means of a student type potentiometer.

The ammonia used in these investigations was obtained from the Matheson Company and was dried as previously described before use. The alkali metal salts were C. P. materials of commerce and were dried at 110° before use. The tetrabutylammonium iodide was prepared by a slight modification of the method used by Cox, Kraus and Fuoss,[5] as previously described by Laitinen and Wawzonek.[6] That this material was free of alkali metal ions was indicated by the fact that the residual current curve showed no wave at potentials corresponding to their reduction.

Data and Discussion

The expression

$$E_{d.e.} = E_{1/2} - \frac{RT}{nF} \ln i/(i_d - i)$$

is the equation of the current–voltage curve obtained for the reduction of a metal ion at the dropping mercury electrode when the metal is soluble in mercury.[7] $E_{d.e.}$ is the potential of the dropping mercury electrode; $E_{1/2}$ is the half-wave potential; i_d is the diffusion current; and i is the current which flows at a potential $E_{d.e.}$. A plot of $E_{d.e.}$ *versus* $\log i/(i_d - i)$ should be a straight line with a slope of $-2.303RT/nF$, if the reduction process is reversible. The half-wave potentials of the alkali metal ions were obtained from a plot of this type by determining the potential at which $\log i/(i_d - i)$ was zero. Typical polarograms are shown in Fig. 3 and Fig. 4.

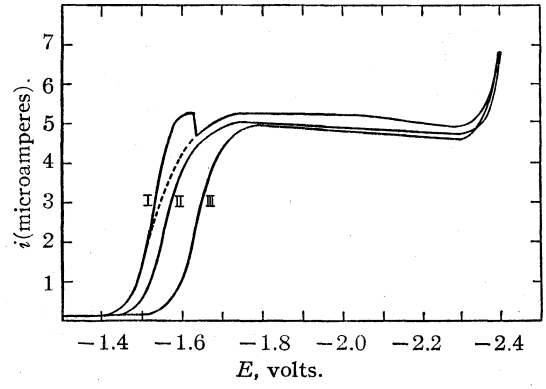

Fig. 3.—Polarograms of sodium, potassium and rubidium iodides in saturated tetrabutylammonium iodide: curve I, 9.8×10^{-4} *M* RbI; curve II, 1.00×10^{-3} *M* KI; curve III, 1.04×10^{-3} *M* NaI.

It is possible to evaluate the half-wave potentials theoretically either by an equation derived by Lingane[8] or by one derived by von Stackelberg.[9]

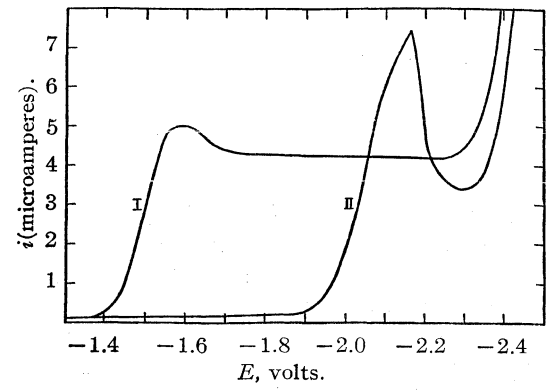

Fig. 4.—Polarograms of cesium and lithium chlorides in saturated tetrabutylammonium iodide: curve I, 8.1×10^{-4} *M* CsCl; curve II, 1.01×10^{-3} *M* LiCl.

The latter is more convenient in the case of the alkali metals, as the standard electrode potentials of the metals are not necessary. The half-wave potential as measured polarographically is equal to the potential of an amalgam electrode in the cell

$$M(Hg)_x\ (C_a) \mid M^+\ (C_s) \mid \text{Ref. elect.}$$

when the concentration of metal ion in the solution is equal to the concentration of metal in the amalgam. For the dropping mercury electrode to have the same potential as the amalgam electrode in the above cell, the diffusion coefficients of the ion in solution and the metal in the amalgam must be equal. The potential E of the amalgam electrode in the above cell is given by the equation

$$E = E_{1/2} - \frac{RT}{nF} \ln \frac{C_a}{C_s}$$

where C_a is the concentration of metal in the amalgam and C_s is the concentration of metal ion in the solution. The data necessary for calculation of the half-wave potentials are available, since Pleskov and Monosson[3,4] have made such measurements in the evaluation of the standard electrode potentials of the alkali metals in liquid ammonia. A lead electrode in 0.1 normal solution of lead nitrate was used by these authors as a reference electrode. In the experimental determination of the half-wave potentials, a mercury pool in a saturated solution of tetrabutylammonium iodide was used as the reference electrode. In order to relate the two reference electrodes, the following cell was prepared. The dropping mercury electrode and a quiet mercury pool were placed in one compartment of the cell shown in Fig. 1b. The solution in this compartment was 0.001 molar with sodium iodide and saturated with tetrabutylammonium iodide. The other compartment contained a lead electrode in 0.1 normal lead nitrate solution. Since the half-wave potential of sodium ion must be a constant, it was determined against each electrode, and the difference between the two values must be equal to the difference of potential between the two reference electrodes. The mercury

pool was found to be 0.318 v. more positive than the lead electrode.

Table I contains the values of the half-wave potentials calculated from the data of Pleskov and Monosson, as well as the values observed with the dropping mercury electrode in 0.001 molar metal iodide solution with a saturated solution of tetrabutylammonium iodide as indifferent electrolyte. The observed values have been corrected for the iR drop through the solution. The slopes of the plots of $E_{d.e.}$ *versus* $\log i/(i_d - i)$ are also recorded.

Li^+	−1.658	0.351	0.1	−1.632	−1.67	−0.058
Na^+	−1.337	.564	.1	−1.302	−1.31	− .057
K^+	−1.287	.770	.1	−1.245	−1.24	− .056
Rb^+	−1.229	.367	.1	−1.202	−1.21	− .061
Cs^+	−1.078	.192	.01	−1.018	−1.15	− .065

In the case of lithium, a large maximum (see Fig. 4) approximately equal to the diffusion current was observed, and smaller maxima were observed with rubidium and cesium ions. All of these maxima decreased when the concentration of the reducible ion was lowered to 2×10^{-4} molar, and they practically disappeared in the case of rubidium and cesium ions. Attempts to eliminate the lithium maximum by the use of gelatin did not succeed, and the problem was not investigated further.

It is seen that there is a reasonable agreement between the observed and calculated values of the half-wave potentials, and that the slope of $E_{d.e.}$ *vs.* $\log i/(i_d - i)$ plot approaches the reversible value −0.047, but in no case was a reversible slope obtained.

The half-wave potentials of the alkali metal ions become more positive as the atomic number increases. There are two reasons why this inverse order of reduction might be expected. The solvation energy of the smaller ions is greater than for the larger ions, and, therefore, more energy must be supplied to the smaller ions to reduce them. The free energy of amalgamation of the metals, as indicated by the difference of potential between the metal and its amalgam, shows a tendency to increase as the atomic number increases. These two factors are working in the same direction, and, therefore, an inverse order of the ease of reduction is a logical one.

The diffusion currents of the alkali metal ions, as measured in liquid ammonia at −36°, are recorded in Table II. A saturated solution of tetrabutylammonium iodide served as the supporting electrolyte. As a comparison, theoretical values were calculated by means of the Ilkovic equation[10,11]

$$i_d = 605nCD^{1/2}m^{2/3}t^{1/6}$$

which relates the diffusion current i_d (microamperes) of an ion to n, the number of faradays of electricity required per mole of electrode reaction, to its concentration C (millimoles per liter), to its ionic diffusion coefficient D ($cm.^2$/sec.), and to the capillary characteristics m (mg./sec.) and t (sec.). The ionic diffusion coefficient D can be evaluated by means of the expression[12,13]

$$D = RT\lambda^0/zF^2$$

where R is 8.317 volt-coulombs per degree, T is the absolute temperature, λ^0 is the equivalent conductance of the ion at infinite dilution (ohm^{-1}-$cm.^2$-equiv.$^{-1}$), z is the charge of the ion, and F is 96,500 coulombs. The remaining terms in the Ilkovic equation are experimental quantities which are easily obtained.

TABLE II

DIFFUSION CURRENTS OF THE ALKALI METAL IONS IN LIQUID AMMONIA AT −36°

Ion	λ_0, ohm^{-1}-$cm.^2$ equiv.$^{-1}$	$D \times 10^5$, $cm.^2$/sec.$^{-1}$	$m^{2/3}t^{1/6}$, mg.$^{2/3}$-sec.$^{-1/2}$	C, mm./l.	i_d (calcd.), microamperes	i_d (obs.), microamperes	% Diff.
Li^+	122	2.59	0.893	1.01	2.78	3.11	12
Na^+	135	2.86	1.256	1.04	4.23	4.84	14
K^+	174	3.69	1.262	1.00	4.64	4.71	2
Rb^+	179	3.80	1.262	0.98	4.62	5.06	10
Cs^+	180	3.82	1.273	0.81	3.83	4.21	10

Table II contains the data necessary for and the results of such calculations. The values for the equivalent ionic conductance at infinite dilution were obtained by interpolation between the data of Pleskov and Monosson[14] at −40° and data which they recalculated for −33.5° from the work of Franklin and Kraus.[15] Since no values were available for rubidium and cesium at −33.5°, the same correction which was applied to potassium was used to correct the values for these ions from −40 to −36°.

The diffusion currents calculated from the Ilkovic equation are lower than the observed values. The discrepancy can largely be attributed to the failure to obtain complete suppression of the migration current. The concentration of indifferent electrolyte was 0.0057 molar ±5% and, therefore, the ratio of indifferent electrolyte to reducible ion was about 6 to 1. Assuming as a first approximation the mobilities of all ions to be equal, the migration current would represent 7% of the total current.

Another cause for the observation of abnormally high diffusion currents lies in the failure of Ilkovic equation at excessively rapid drop rates. At the potentials at which the diffusion currents of the alkali metal ions were measured, the drop time was 1.0 to 2.2 seconds. Lingane and Lover-

idge[16] and Buckley and Taylor[17] have observed abnormally high values of the quantity $i_d/Cm^{2/3}t^{1/6}$ at drop times less than three seconds unless a suppressor, such as gelatin, was present.

The use of some other supporting electrolyte with a higher solubility was not attempted because of the difficulty involved in finding one which was not reduced at very negative potentials and which could also be freed easily from traces of the alkali metal ions. In all probability, better agreement between the observed and calculated values of the diffusion current would be obtained if higher ratios of non-reducible to reducible ion were to be used.

(17) F. Buckley and J. K. Taylor, *J. Research Nat. Bur. Standards*, **34**, 97 (1945).

Summary

The half-wave potentials of the alkali metal ions in liquid ammonia were found to agree with those calculated theoretically, and the reduction process appeared to be reversible.

The diffusion currents of the alkali metal ions were measured and compared with those calculated from the Ilkovic equation.

Mechanical Properties of Substances of High Molecular Weight. IV. Rigidities of Gelatin Gels; Dependence on Concentration, Temperature and Molecular Weight[1]

BY JOHN D. FERRY

Earlier measurements[2] have shown that the rigidity of a gelatin gel is approximately proportional to the square of the concentration, and it is well-known that the rigidity decreases with increasing temperature[3] or with degradation.[4] Previous work has, however, been confined to samples of unknown molecular weight. The series of degraded gelatins described by Scatchard, Oncley, Williams and Brown[5] has now afforded the opportunity of studying samples of known average molecular weight and molecular size distribution. The method of propagation of transverse vibrations[6] permits absolute measurements of rigidity to be made conveniently at concentrations lower than those usually employed by previous investigators. This paper reports rigidity measurements by the transverse vibration method on certain of the gelatin samples studied by Scatchard, Oncley, Williams and Brown, together with several other gelatins from different sources.

Materials and Method

The following gelatin samples were employed: four of the series of degraded ossein gelatins,[5] originally furnished through the kindness of Dr. D. Tourtellotte of the Knox Gelatin Company; one sample each of ossein (A-O), porkskin (A-P), and calfskin (A-C) gelatin, furnished by the Atlantic Gelatin Company; and one calfskin gelatin (EK-120), purchased from the Eastman Kodak Company. Table I lists the values of number-average molecular weight, M_n, derived from osmotic pressure and viscosity measurements.[7] Values of α, the fraction of bonds broken in the parent molecule, and M_w, the weight-average molecular weight, as calculated from the statistics of degradation,[5] are also included for the degraded series. They are omitted for the other samples because it is not certain that the details of the statistical treatment are applicable to those.

EK–120		37	

The degraded samples were furnished as sterile stock solutions, at a concentration of about 60 g./l., in 0.15 *M* sodium chloride at *p*H 7; the others, furnished in solid form, were dissolved in 37° and adjusted to the same *p*H and salt concentration, unless otherwise specified. Stock solutions were kept at 0°, except for occasional brief warming to 37° to withdraw samples, with sterile precautions. From studies of the rate of degradation,[5,7] no perceptible change in molecular weight would be expected for several years under these conditions. The measurements described here were completed in less than two years. Recent unpublished measurements on similar samples indicate that there is no change after five years.

The stock solutions, after warming at 37° for one hour, were diluted with 0.15 *M* sodium chloride (unless otherwise specified) to the desired concentrations and transferred to rectangular glass cells provided with clamps[8] to hold the

(8) Designed by Dr. S. H. Armstrong, Jr.

vibrator plates in place until rigidity had developed. The solutions were usually covered with paraffin oil to prevent evaporation. The velocity of propagation of transverse waves, V, was measured as previously described.[6] The modulus of rigidity is given by $G = V^2\rho$, where ρ is the density. The latter value was calculated from the density of the salt solution and an assumed value of 0.70 for the partial specific volume of gelatin. Damping was not measured. For each gel at each temperature, measurements of V were made at four or five different frequencies, covering a range of about twofold; these values usually agreed within 1–2% of the mean for the strongest gels and within 5% for the weakest. The rigidity was calculated from the mean value in each case. Measurements on three separate series of gels prepared from the same stock solution showed agreement to about the same extent (represented in Fig. 2). Since one year had elapsed between the first and the third series, this agreement confirms absence of degradation in storage.

There was no evidence of dispersion of the rigidity; the frequency ranges employed varied from about 1250–2500 cycles for the strongest gels to about 320–630 cycles for the weakest. Absence of dispersion indicates that the rigidity thus measured dynamically can be taken as identical with that which would be measured by the static methods used by previous investigators[2]; it is certainly of the same order of magnitude. A direct comparison of dynamic and static rigidities will be reported subsequently.[9]

Results

Changes of Rigidity with Time at Constant Temperature.—When a solution was quickly cooled from 37 to 15° and held at the latter temperature, gelation occurred within half an hour, with development of a measurable rigidity. The rigidity increased rapidly at first and continued to rise slowly for many hours without attaining a constant value. However, when a solution was first chilled at 0° for a day or more, and then quickly warmed to and held at 15°, the rigidity fell rapidly from its value characteristic of the lower temperature and reached an essentially constant value, usually within five hours. These changes are illustrated in Fig. 1 for sample EK-120 at a concentration of 25.7 g./l. and *p*H 5.4 (no salt). Similar measurements on several other samples at various concentrations showed the same behavior; when a chosen temperature was approached from above, the rigidity failed to attain a constant value in as long a period as fifty hours, but when it was approached from below, the rigidity became constant within five hours. These observations agree with earlier studies of the optical rotation,[10] specific volume,[11] and light scattering[12] of gelatin gels, in which equilibrium was always more rapidly attained after precooling.

Accordingly, the following procedure was adopted for all subsequent experiments: each solution, after introduction into the cell, was quickly cooled and kept at 0° for about twenty-four hours; the rigidity of the gel at 0° was measured; the temperature was raised a few degrees and kept constant (±0.1°) for five to twelve hours, and the rigidity was again measured; and this process was repeated until the gel melted. Since the initial measurement does not involve approach from a lower temperature, it cannot be compared with the others; and even at 10° the rigidity values are slightly higher when the chilling at 0° is prolonged for several weeks instead of limited to twenty-four hours. However, above 10° the results appear to be independent of the time of chilling. All the values are quite closely reproducible when the above procedure is followed.

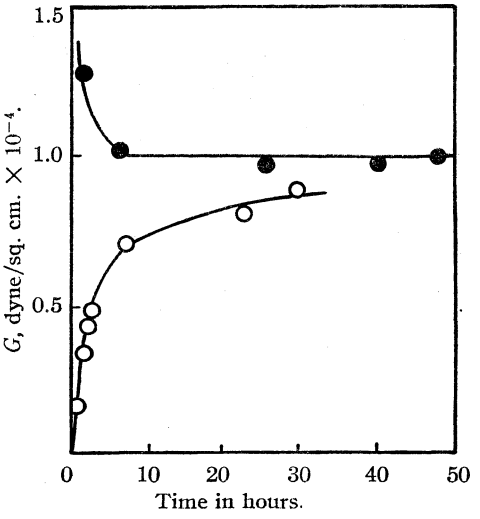

Fig. 1.—Change of rigidity with time at 15°, sample EK-120, concentration 27.4 g./l., *p*H 5.4: ●, after warming from 0°; ○, after cooling from 37°.

Dependence of Rigidity on Concentration.—The rigidities of gels of sample L1-00 are plotted against the square of the concentration in Fig. 2 for several temperatures. Close proportionality is observed up to a concentration of about 60 g./l.; the values of G/c^2 in (dyne/sq. cm.)(g./l.)$^{-2}$ are 44 at 0°, 23 at 15°, and 12 at 21.8°. For a sample of similar molecular weight, A-O, over a much higher concentration range (up to 160 g./l.), there is slight downward curvature (Fig. 3); while for a sample of lower molecular weight, Ll-80, in the more dilute range there is slight upward curvature (Fig. 4).

Dependence of Rigidity on Temperature.—Values of G/c^2 for sample L1-00 are plotted against temperature in Fig. 5. The rigidity falls rapidly with increasing temperature, and vanishes at about 30°. It follows from Fig. 2, of course, that the curves for several different concentrations coincide. Nevertheless, these curves presumably diverge just below the melting point (where the rigidity disappears), because the latter is a function of concentration. For a gelatin with this molecular weight, the melting point, determined[13] after chilling for twenty-four hours at 0°, varies from 28.2° at a concentration of 20 g./l. to 30.6°

are undoubtedly too low, it is possible that the inflection point in Fig. 5 is an artifact and the curve representing fully developed rigidity should more nearly follow the dashed line.

Rigidities for different gelatin samples, all at a concentration of 40 g./l., are plotted against the temperature in Fig. 6. The marked decrease in rigidity with increasing temperature is seen in each case; the curves form a coherent family except for that of sample A-C. Below 10° the curves are broken because, as pointed out above, they probably do not represent equilibrium values.

EK-120	37	5.6	3.0

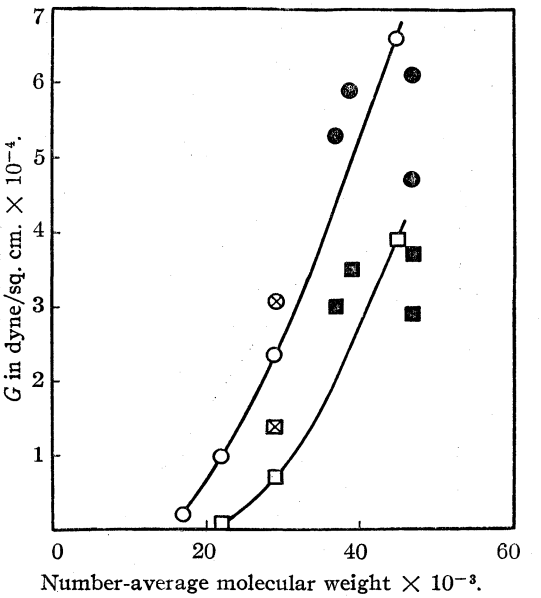

Fig. 7.—Rigidity plotted against number-average molecular weight, at 5° (circles) and 15° (squares): open points, degraded series; crossed points, mixture; solid points, additional samples.

points for the degraded series fall on a smooth curve. The scatter of the other points indicates that gelatins from various sources have roughly similar rigidities when compared on the basis of number-average molecular weight, but that the exact value of the rigidity is influenced by the details of preparative procedure. These data suggest further that the rigidity may depend more on the details of preparation than on the nature of the tissue source (ossein, porkskin or calfskin).[14]

Rigidities of a Mixture of Samples.—Two samples of widely different average molecular weight, L1-00 and L1-180, were combined in equal proportions by weight, yielding a mixture with $M_n = 29{,}500$ and $M_w = 57{,}500$, The rigidities of the mixture are compared with those of the original samples, all at a concentration of 57.5 g./l., in Fig. 8. (The points for L1-180 represent measurements at 40 g./l., corrected by the factor $(57.5/40)^2$.) The rigidity of the mixture does not correspond to the arithmetic mean of values for the individual samples, $(G_1 + G_2)/2$; instead, it

(14) A few measurements were made on several fractionated calfskin gelatin samples, sent by Dr. S. E. Sheppard of the Eastman Kodak Company to Professor Scatchard, in which the distribution of molecular weights was presumably far sharper than in the degraded series described here. The temperature dependence of rigidity for the fractionated samples was very similar to that shown Figs. 5 and 6, but the dependence on number-average molecular weight was quite different from that shown in Fig. 7. For M_n ranging approximately from 80,000 to 120,000, as estimated by Mr. R. H. Wagner in Dr. Sheppard's laboratory, the rigidity was almost independent of molecular weight and slightly less than that of our sample L1-00 at comparable concentration and temperature. This behavior was in agreement with unpublished measurements of the rigidity of these samples obtained by Dr. R. C. Houck in Dr. Sheppard's laboratory. The relation of these results to the measurements reported in this paper is not clear.

agrees closely with values calculated as $[(\sqrt{G_1} + \sqrt{G_2})/2]^2$, given by the dashed curve. Thus the square roots of the rigidities, rather than the rigidities themselves, are additive.

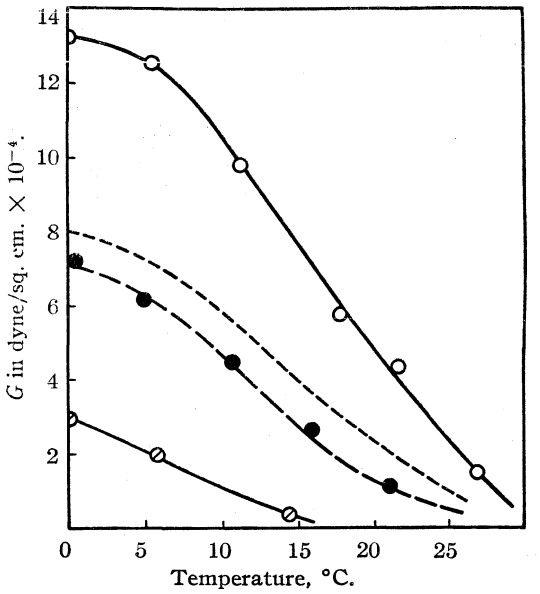

Fig. 8.—Comparison of rigidities of a mixed sample and of its components, at a concentration of 57.5 g./l.: ○, L1-00 (G_1); ⊘, L1-180 (G_2); ●, mixture of equal parts by weight. ---, $(G_1 + G_2)/2$ (calculated); ———, $[(\sqrt{G_1} + \sqrt{G_2})/2]^2$ (calculated).

Rigidities of the mixture at 5 and 15°, corrected to a concentration of 40 g./l., are included in the plot against M_n in Fig. 7; they do not fall on the curve for the individual degraded samples. However, when M_w is taken as the independent variable, points for the mixtures fall on the curves for the individual samples. Moreover, the square root of the rigidity is found to be a linear function of the weight average molecular weight (Fig. 9). It can easily be shown from the definition[5] of M_w that additivity of $\sqrt{G}$ for different samples on a weight concentration basis, as shown in Fig. 8, is a necessary consequence of the linear relation exhibited in Fig. 9.

Points interpolated at other temperatures and plotted as in Fig. 9 also give straight lines of equal slope, and their intercepts follow an exponential function of the reciprocal absolute temperature. These relations can be combined in the empirical equation

$$\sqrt{G} = 0.00484(M_w - 1.20 \times 10^{10} e^{-7330/RT}) \quad (1)$$

which expresses the rigidities of every gel of the degraded series at a concentration of 40 g./l. from 5° to the melting point; the fit is within experimental error except near the melting point for the most degraded samples.

Discussion

The highly elongated shape of the largest gelatin molecules in these mixtures[4,15] makes plausible the concept of gelation as network formation by cross-linking through secondary forces of attraction.[16] Some of the bonds may be represented by regions of local crystallinity, as postulated by Herrmann and Gerngross[17] (although their X-ray evidence was based on gels far more concentrated than those described here); others may be formed by lateral association of chain segments in pairs. The stability and low internal viscosity of gelatin gels suggest that there are specific loci of attraction widely spaced along the molecules,[18] corresponding either to sequences of easily crystallizable amino acids in the polypeptide chain (a series of glycine residues, for example), or to combinations of certain side chains resulting in strong attraction. Between these loci the attractive forces must be relatively slight; otherwise highly unstable gels such as those encountered in denatured proteins or inorganic colloids would be expected.

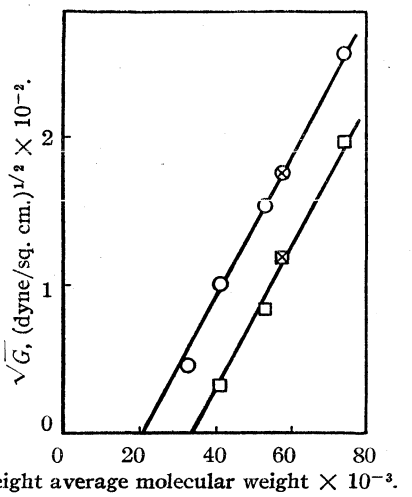

Fig. 9.—$\sqrt{G}$ plotted against weight-average molecular weight, at 5° (circles) and 15° (squares). Open points are degraded series; crossed points, mixture.

In such a network, the number of useful junctions which contribute to the rigidity is smaller than the total number of bonds or cross-links because of (a) bonds in the "sol fraction" which is not attached to the network, (b) possible cyclic structures, and (c) a number of bonds equal to the number of molecules initially present (half the number of loose ends) which will not contribute to the network.[19] Decrease in rigidity due to decreasing concentration, increasing temperature, or decreasing molecular weight may involve a decrease in the total number of bonds per cc. (n_t), an increase in the number of useless bonds per cc. (n_a), or both.

The fact that the rigidity is proportional to the

square of the concentration except near the melting point or when M_w is small indicates that, with the latter exceptions, the ratio of useless to total bonds is independent of concentration. Either $G \propto (n_t - n_a)$, as would be expected for rubberlike elasticity, and $n_t \propto c^2$, following a binary association; or $G \propto (n_t - n_a)^2$, which might correspond to a stiff strutted structure, and $n_t \propto c$, a peculiar type of association recently postulated by Doty for polyvinyl chloride solutions.[20] At present it is not possible to distinguish between these two alternatives.

Decrease in rigidity with increasing temperature must be due primarily to decrease in n_t. At the same time, the change is probably enhanced, at least near the melting point, by an increase in n_a, since the contributions to n_a from loose ends remain constant and those in the sol fraction should increase.

The decrease in rigidity with decreasing average molecular weight is clearly not due solely to the increase in loose ends, since in this case the total number of bonds should be constant and either G or $\sqrt{G}$ should be a linear function[19] of $1/M_n$. The total number of bonds evidently varies with average molecular weight, and with molecular weight distribution. Further work will be needed to explain the form of the empirical relationship given in equation (1).

(20) P. Doty, H. Wagner and S. Singer, *J. Phys. Colloid Chem.*, **51**, 32 (1947).

Summary

1. The rigidity of a gelatin gel at a given temperature reaches a constant value more rapidly if the temperature is approached from below than from above.

2. For a sample of slight degradation (M_n = 45,000), the rigidity was closely proportional to the square of the concentration up to 60 g./l. At higher concentrations, it increased somewhat less rapidly; for a sample of higher degradation, somewhat more rapidly, than with the square of the concentration.

3. For all samples and at all concentrations, the rigidity decreased gradually with increasing temperature from 0° to the melting point.

4. The rigidity decreased markedly with increasing degradation, or decreasing average molecular weight.

5. An empirical equation for the dependence of rigidity on temperature and weight average molecular weight is given.

Chemical Composition and Properties of Guar Polysaccharides[1,2]

BY EILEEN HEYNE AND ROY L. WHISTLER

Endosperm of the guar seed consists principally of a galactomannan polysaccharide. It is thus analogous to the endosperm of locust beans which are widely used in commerce, and to galactomannans from other sources. Guar, a drouth-resistant legume of the genus *Cyamopsis*, is native to India where it is used for food and feed. The endosperm can be employed industrially in many ways, such as a size for paper and textiles, a dispersing agent, and a thickener. These uses have resulted in the recent growing of the guar plant in commercial quantities in the United States. As yet, however, little information is available with regard to the fundamental composition and structure of the endosperm polysaccharides. This report covers a preliminary investigation of the general composition and properties of the guar endosperm and particularly of the water soluble component which constitutes the major portion of the endosperm.

Experimental

Material.—Guar flour, produced by grinding the endosperm of the decorticated guar seed, was obtained through the kindness of General Mills, Inc. The grayish-white flour contained 0.60% nitrogen, 0.06% phosphorus, 1.06% ash and 1.5% ethanol solubles from twenty-four hours of Soxhlet extraction.

Analytical Methods.—Galactose anhydride content was determined by the following procedure: One gram of polysaccharide material ground to pass a 60-mesh sieve was dissolved in 150 ml. of 5% nitric acid by heating the mixture to 100°. After hydrolysis for three and one-half hours at this temperature, the solution was concentrated on a steam-bath to a volume of 25 ml. and 5.6 ml. of concentrated nitric acid was added to make a solution concentration of 25%. The solution was then oxidized according to the methods proposed by Tollens,[3] Van der Haar,[4] and Wise and Peterson.[5] The weight of the solution was reduced to 20 g. by heating on a steam-bath. Because of the high galactose content of the preparations, it was not found necessary to add the 500 mg. of pure mucic acid recommended by earlier works. The crystallization of mucic acid was allowed to proceed for forty-eight hours at a temperature of 0° ± 0.1° obtained with a large constant temperature bath. The solubility of mucic acid at 0° is 0.0175 g. per 100 ml. The amount of galactose anhydride equivalent to mucic acid was found by multiplying the weight of mucic acid obtained in this procedure by the factor 1.33. This factor was computed from data obtained on the analysis of a mixture of galactose and mannose combined in such proportions as to give the same yield of mucic acid as the guar samples.

Mannose anhydride content was determined through isolation of mannose phenylhydrazone by Nowotnowna's[6] modification of Schorger's[7] and Tollens'[8] procedure.

Both mannose and galactose are of the D-series as evidenced by the optical rotations of their derivatives. Mannose phenylhydrazone from guar showed the same optical mutarotation as the derivative of D-mannose[9] changing from $[\alpha]^{25}D$ +21 (1 hour) → −3 (33 hours) → +35 (216 hours) (*c*, 1 in pyridine). Melting point and mixed melting point with D-mannose phenylhydrazone were 182.5°. The benzimidazole of galactose prepared from guar hydrolyzate after D-mannose had been removed as the phenylhydrazone agreed with the known rotation of D-galactose benzimidazole[10] $[\alpha]^{25}D$ +43.3 (*c*, 0.5 in 5% citric acid).

Pentosans were determined by isolation of the furfural-phloroglucinol complex.[11]

Viscosities were determined at approximately 0.2% concentrations in 1 *N* sodium hydroxide solution at 25°. Solution of the sample was obtained by shaking it overnight in an atmosphere of nitrogen. Viscosity measurements were made twenty hours after the addition of alkali.

Water Fractionation.—An 0.8% aqueous suspension of guar flour was prepared by sprinkling 4-g. portions of the flour into 500-ml. portions of distilled water stirred in a Waring Blendor and by repeating this procedure until 8 liters were obtained. The viscous dispersion was autoclaved at 15 pounds pressure for three hours (*p*H 5.8) and immediately centrifuged in a supercentrifuge (40,000 r. p. m.) to remove the insoluble component. Longer periods of autoclaving did not appreciably change the ratio of soluble to insoluble fractions. The insoluble component was gradually added to ethanol stirred in a Waring Blendor, filtered, and stirred three further times with fresh portions of ethanol in the Blendor. After the final washing and filtration, the brown flocculent precipitate was dried over calcium chloride in a vacuum desiccator. The residue represented approximately 7.8% of guar flour.

The soluble component was recovered by adding an equal volume of ethanol with rapid stirring to the centrifugate; preferably the ethanol was added to small portions of solution stirred in a Waring Blendor. Precipitated material was filtered and washed four successive times with fresh portions of ethanol in the Blendor. The white fibrous precipitate was dried as described above and represented approximately 86.5% of the guar flour. A small amount of carbohydrate was not recovered by this method of treatment. The isolated material contained 0.15% nitrogen, 0.3% or less pentosan, 35.6% D-galactose anhydride and 63.1% D-mannose anhydride. The absence of glucose was indicated by the fact that after nitric acid oxidation of the hydrolyzate and separation of mucic acid, it was not possible to crystallize potassium acid saccharate from the mother liquor. Neither was it possible to isolate glucose as the benzimidazole from the sugar hydrolyzate. Intrinsic viscosity in 1 *N* sodium hydroxide was 5.57; $[\alpha]^{25}D$ +54.5 (*c*, 1 in 1 *N* sodium hydroxide). No uronic acid was detected by the quantitative method of Whistler, Martin and Harris.[12]

Ethanol Fractionation.—Subfractionation of the water soluble component was accomplished by gradual addition of ethanol to the aqueous centrifugate recovered from the separation of insoluble component. Ethanol was added drop by drop from a separatory funnel to 11 l. of the strongly stirred centrifugate. At the first appearance of precipitate the addition of ethanol was stopped and the mixture was supercentrifuged. The solution was allowed to stand for twenty-four hours to allow any additional precipitate to form. If a precipitate formed, the solution was allowed to stand an additional twenty-four hours. If no precipitate occurred, the solution was stirred and further addition of ethanol was made. In this manner a number of fractions were obtained as shown in Fig. 1.

The first precipitate occurred at an alcohol concentration of 20% by volume and the last at 40%. When the alcohol concentration reached 31%, an additional increase of 2% concentration brought about a slow but continuous precipitation which continued for three days. This precipitate which accumulated from 31 to 33% alcohol concentration represented 58% of the total soluble component. Approximately 93% of the soluble component was precipitated by ethanol. Precipitated fractions were washed through four fresh portions of ethanol and dried as described above.

After separation of the above individual fractions, the solution was concentrated under reduced pressure to 1.5 l. and 0.4 l. of ethanol was added. This procedure precipitated fraction number 15. The centrifugate from the precipitation was concentrated under reduced pressure to 280 ml. and 3 l. of ethanol was added to produce fraction number 16. On concentration of the final centrifugate to dryness on the steam bath, fraction 17 was obtained.

Preparation of Guaran.—Material of uniform chemical composition was separated from the water soluble component by discarding the first 10% of material which precipitated up to an ethanol concentration of 25% and then collecting all material which precipitated up to an ethanol concentration of 40% by volume. While only the first 3–5% of ethanol precipitated material appeared to be different from the central fraction, the first 10% which precipitated was discarded simply as a precaution against possible contamination of the central fraction. This material separating between ethanol concentrations of 25–40% and called guaran contained 34.5% D-galactose anhydride, 63.4% D-mannose anhydride and 0.1% nitrogen. The rotation was $[\alpha]^{25}D$ +53 (*c*, 1 in 1 *N* sodium hydroxide). Guaran is not oxidized by Fehling solution. Addition of small amounts of Fehling solution to aqueous solutions of guaran causes the precipitation of a polysaccharide–copper complex.

Acid Hydrolysis of Guaran.—A 1% water solution of guaran was prepared by dispersing 5.50 g. of guaran of known moisture content in 500 ml. of distilled water and by heating this dispersion in an oil-bath at 100° until solution was accomplished. Twenty-five per cent. by weight sulfuric acid was added to make a 1% acid solution. Hydrolysis was carried out at 100°. Rotation measurements were made on 15-ml. aliquots which were removed from the reaction flask and cooled to 25°. The specific rotation changed from an initial value of about +59 to a final value of +37.

Enzymatic Hydrolysis of Guaran.—A 1% water solution prepared as above was treated with a commercial diastase in the proportion of 0.1 g. of diastase for each 100 ml. of solution. Viscosity measurements taken in an Ostwald–Cannon–Fenske tube indicated a decrease to about one-third the initial value in a period of eighteen hours.

Esterification of Guaran.—Freshly precipitated guaran was freed of ethanol by stirring with glacial acetic acid for fifteen minutes and by filtering off the excess reagents. To the pretreated guaran was added 33 parts pyridine and 33 parts acetic anhydride. The mixture was heated in an oil-bath with stirring for four to five hours at 105°. The acetate was then precipitated by pouring the solution into excess ethanol stirred in a Waring Blendor. The precipitate was filtered and washed in the Blendor four successive times with fresh portions of ethanol. The final product was air dried. It was a white, very fibrous material closely resembling amylose triacetate in appearance.

Acetyl content, 44.8%; theory, 44.78%; $[\alpha]^{25}D$ 34° (*c*, 1 in chloroform), m. p. 224–226°.

The acetate could be cast into a film by standard methods.[13] The films were lustrous, clear, strong, and flexible. When placed in water at 95–100°, films containing 20% dibutyl phthalate plasticizer could be elongated 550%. The stretched films were birefringent in polarized light but showed no detectable crystallinity on examination with X-rays. When broken under stress, the elongated films developed many longitudinal cracks.

A 2% solution of guaran triacetate dissolved in chloroform was fractionally precipitated by dropwise addition of ethanol with rapid stirring. Seven fractions were obtained each of which possessed a constant rotation of $[\alpha]^{25}D$ 34° (*c*, 1 in chloroform).

Results and Discussion

Guar flour consists principally of carbohydrate material. There is present only 1.5% fatty material or other substances extractable by ethanol. The low nitrogen value indicates the presence of but 3.5–4.0% protein. Only very small amounts of phosphorus-containing compounds are present. From this principally carbohydrate material it is, therefore, not surprising that a water soluble polysaccharide can be easily separated in 86–7% yield. The polysaccharide contains 35.6% D-galactose anhydride and 63.1% D-mannose anhydride. No ketoses[14,15] or uronic acids have been detected in the polysaccharide material. The absence of uronic acids differentiates the polysaccharide from the great majority of plant gums and mucilages.

Information with regard to the homogeneity of the soluble component is obtained by ethanol fractionation of its aqueous solution and comparison of the various fractions. The per cent. of the material received in each fraction is shown in Fig. 1, and the amount precipitated at different concentrations of ethanol is shown in Fig. 2. Comparison of the various fractions as to mannose anhydride content, specific optical rotation, and intrinsic viscosity are shown in Figs. 3, 4 and 5, respectively. These graphs indicate that the first 2.5% of the soluble component to be precipitated is of slightly different composition and lower viscosity than the main portion of the soluble component whose fractions are similar. The lower mannose anhydride content (40.2%) of the first material precipitated may relate it to the water insoluble component which has a mannose anhydride content of 39.1%. It is possible that some of the insoluble component is solubilized by the autoclave treatment. The graphs also indicate that there is present in the soluble component about 3% of very low molecular weight material which judged by its low mannose anhydride content and negative rotation is quite different from the main polysaccharide fractions.

Collectively, the graphs suggest that the water soluble component of guar endosperm consists principally (90–95%) of a polysaccharide which precipitates in a narrow range of ethanol concentration. Further evidence for the homogeneity of the polysaccharide material is the observation that when its acetate in chloroform solution is fractionated into seven parts by gradual ethanol addition, all fractions are found to possess identical optical rotations. Since the polysaccharide contains 34.5% D-galactose anhydride and 63.4% D-mannose anhydride, it may properly be termed a galactomannan. For convenience in designation, this particular polysaccharide fraction in this and future papers is given the name "guaran."

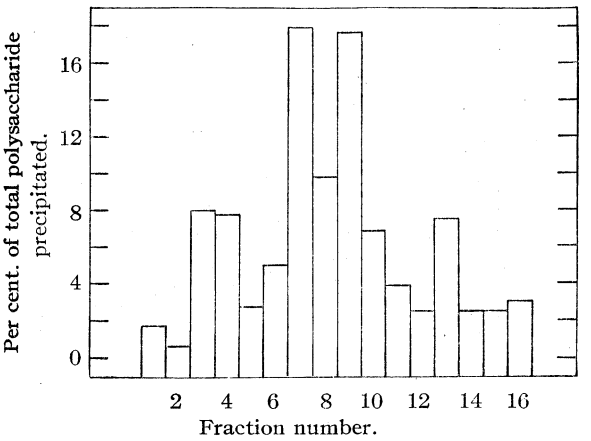

Fig. 1.—Per cent. of guar in each fraction.

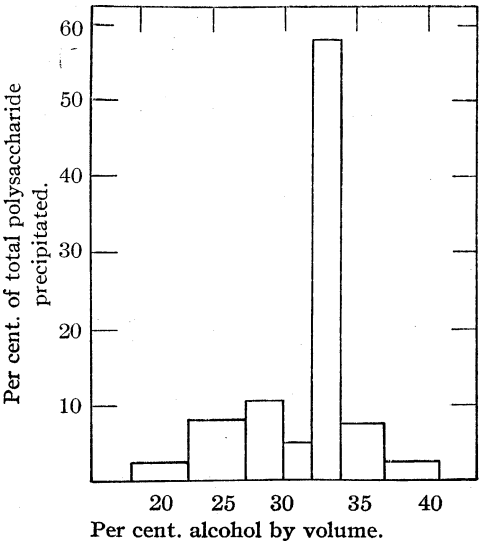

Fig. 2.—Per cent. polysaccharide precipitated at various alcohol concentrations.

On heating guaran in acid solution it undergoes hydrolysis and the specific optical rotation changes from a value of about +59 to +37. This change from a positive to a less positive value is indicative of the predominance of α-D-glycosidic links and is in agreement with the view of Lew and Gortner[16] who suggest the presence of alpha linkages in the galactomannan of carob bean endosperm. A further indication of the predominance of alpha link-

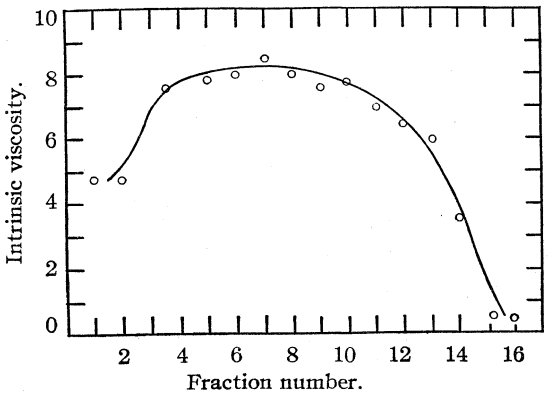

Fig. 5.—Intrinsic viscosity of guar fractions.

ages in guaran is the fact that its solutions are hydrolyzed by diastase, the viscosity decreasing to a value about one-third or less of the original.

Films produced by casting guaran acetates are clear, lustrous, strong, and pliable. Films plasticized with 20% dibutyl phthalate may be easily stretched in water at 100° to elongations of about 550%. During the stretching the film properties change from isotropic to anisotropic. The elongated films when broken under stress tend to shatter in lines parallel to the direction of elongation. Furthermore, a pronounced birefringence is developed during the process of elongation. These occurrences are all indications of the presence of anisodimensional and perhaps linear molecules which are orientated when the film is subjected to plastic flow. However, while the presence of linear molecules is indicated, X-ray analysis of the elongated films failed to give evidence of crystallinity. Films of uniform linear molecules would be expected to produce a fiber pattern or evidence some degree of crystallinity. Failure to obtain this effect may be accounted for by assuming that the guaran chains consist of D-galactose and D-mannose units arranged in random order or that the principal chain may possess branches of very short length. Therefore, although the chains become ordered when the films undergo plastic flow, an orderly three dimensional arrangement of sugar units is not brought about.

Acknowledgment.—The authors wish to express their appreciation to Dr. H. J. Yearian for the X-ray work and to Mrs. Ann Kimmell and Mrs. Helen Gleason for their assistance in part of the analytical determinations.

Summary

Guar flour can be readily separated into a water soluble (86–87%) and a water insoluble component. The water soluble component contains only small amounts of nitrogen and phosphorus impurities.

By gradual addition of ethanol to an aqueous solution of the water soluble component, it is separated into 17 fractions. Analyses of the fractions indicate that the third to the twelfth fractions are identical as to composition and represent a galactomannan polysaccharide which contains 34.5% D-galactose anhydride and 63.4% D-mannose anhydride. This polysaccharide is given the name "guaran."

Presence of α-D-glycosidic linkages in guaran is indicated by its rapid acid hydrolysis with accompanying decrease in specific rotation and by its hydrolysis under the action of diastase.

Guaran may be esterified easily to the triacetate which may be cast into a strong, flexible film. On stretching to 550% the film becomes strongly birefringent but yields only an amorphous X-ray pattern. It is assumed that the guaran molecules are linear or highly anisodimensional but have either a random distribution of D-galactose and D-mannose units in the molecular chains or that the chains have very short branches.

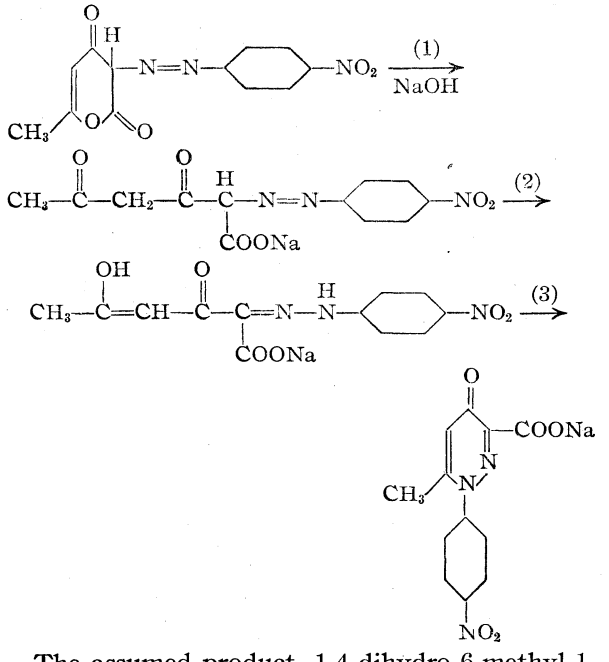
A New Synthesis of 4-Pyridazones

BY JACK F. MORGAN

During an investigation of azo dyes derived from substituted 1,2-pyran-2,4(3)-diones, it was observed that many of these dyes gradually fade in color when heated in dilute alkaline solutions. For example, when an aqueous alcohol solution of 6-methyl-3-*p*-nitrophenylazo-1,2-pyran-2,4(3)-dione was refluxed for one to two hours with an equi-molar amount of sodium hydroxide, a good yield of a very pale yellow carboxylic acid resulted. This acid had the same empirical formula as the original dye as shown by analysis and neutralization equivalent. Obviously, some sort of rearrangement of the original molecule had taken place. The apparent course of the reaction is shown below.



The assumed product, 1,4-dihydro-6-methyl-1-(*p*-nitrophenyl)-4-oxo-3-pyridazinecarboxylic acid, is in agreement with the experimental product in regard to empirical formula, neutralization equivalent, expected color and expected melting point. In addition, the steps outlined above represent a logical sequence of events when considered in the light of known facts regarding the chemical behavior of similar compounds.

Step 1.—The 1,2-pyran-2,4(3)-dione ring is quite stable toward acid hydrolysis but is cleaved at the oxygen bridge in hot alkaline solutions.

Step 2.—Azo compounds derived from aliphatic active methylene compounds like acetoacetic ester are in tautomeric equilibrium with the corresponding hydrazones.[1]

(1) Frank C. Whitmore, "Organic Chemistry," D. Van Nostrand Co., New York, N. Y., p. 755.

Step 3.—Aryl hydrazones of this general type are known to undergo ring closure to form pyridazones.[2]

The conversion of the azo compound to the pyridazone may be carried out about equally well in either aqueous–alcohol or water alone. The alkali used may be sodium hydroxide, sodium carbonate or sodium bicarbonate. The reaction proceeds satisfactorily when excessive amounts of sodium bicarbonate are used though too much sodium hydroxide may have a harmful effect on yields.

The main advantage of the method of synthesis under discussion is that it leads to products not available by other reactions. Thus all the pyridazones prepared by this method were new and no other method was available for their preparation. This pyridazone synthesis seems to be fairly general in application though an exhaustive study was not made to determine its limitations. The reaction did fail when applied to 3-(2,5-dichlorophenylazo)-4-hydroxycoumarin.

The azo compounds required as starting materials were easily prepared from 1,2-pyran-2,4(3)-diones and the appropriate diazo compounds in either alkaline or slightly acid solution. The corresponding pyridazones are most conveniently prepared without isolation or purification of the azo intermediates.

General methods for the preparation of the 1,2-pyran-2,4(3)-diones used in this work are adequately described in the literature.[3,4,5,6] One of these compounds, 6-ethyl-1,2-pyran-2,4(3)-dione (m. p. 107–108°) had not previously been described in the literature. This product was prepared in 70% yield from 6-ethyl-3-propionyl-1,2-pyran-2,4(3)-dione[4,5] by the method of Collie.[3]

Experimental

The general procedure for preparing 4-pyridazones is illustrated by the following example which includes the preparation of the azo intermediate.

1,4-Dihydro-6-methyl-1-(*o*-nitrophenyl)-4-oxo-3-pyridazinecarboxylic Acid.—*o*-Nitroaniline (11 g., 0.08 mole) was dissolved in a hot solution of concentrated hydrochloric acid (40 ml.) and water (50 ml.), poured onto ice and diazotized in the usual manner by rapid addition of a slight excess of sodium nitrite solution. This solution (250 ml.) was then added to a stirred solution of 6-methyl-1,2-pyran-2,4(3)-dione (10.8 g., 0.085 mole) and sodium carbonate (35 g.) in water (550 ml.). The coupling reaction was complete within fifteen minutes. The resultant slurry was stirred and heated at the reflux temperature for two and one-half hours. The hot clear solution was neutralized (*p*H 6–7) with acetic acid, treated with charcoal and filtered. The filtrate was then acidified (*p*H 2) with hydrochloric acid and cooled in ice. The

pale yellow crystals were removed by filtration, washed with water and dried to obtain 15.8 g. (72%) of 1,4-dihydro-6-methyl-1-(*o*-nitrophenyl)-4-oxo-3-pyridazinecarboxylic acid melting at 224° (uncor.).

Summary

A new synthesis of 4-pyridazones has been described. Alkaline hydrolysis of 6-alkyl-3-arylazo-1,2-pyran-2,4(3)-diones results in cleavage of the pyran-2,4(3)-dione nucleus followed by rearrangement to 1,4-dihydro-6-alkyl-1-aryl-4-oxo-3-pyridazinecarboxylic acids.

Succinic Acid Derivatives of 4-Nitro-4′-aminodiphenylsulfone and of 4,4′-Diaminodiphenylsulfone

BY HUGO BAUER

Recent studies in experimental tuberculosis carried on in this institute[1] have demonstrated that potentiation is obtained in combined therapy with streptomycin and certain derivatives of 4,4′-diaminodiphenylsulfone. The presence of one free amino group appears to be essential for good action. It seemed desirable to test the chemotherapeutic properties of *n*-acylamide and ester derivatives. Compounds of this type were obtained by the preparation of succinic acid derivatives of diaminodiphenylsulfone. Furthermore, derivatives of succinic acid have been found to be active in tuberculosis.[2]

The action of succinic acid or succinic anhydride upon 4,4′-diaminodiphenylsulfone has been reported to lead to the formation of a disubstituted product.[3] An attempt was made to obtain the monosubstituted product by heating equivalent amounts of diaminodiphenylsulfone with succinic acid. From the reaction mixture 4-amino-4′-succinimidodiphenylsulfone (II) could be isolated in poor yield (12–13% of the calcd.).

Better results were obtained by starting with 4-nitro-4′-aminodiphenylsulfone. At a temperature of about 220°, it combines easily with succinic anhydride, yielding 4-nitro-4′-succinimidodiphenylsulfone (I). The products obtained from I by hydrolysis, esterification, ammonolysis and reduction are shown in Table I. The nitro group was reduced with hydrogen at atmospheric pressure in presence of Raney nickel catalyst, with excellent yields.

Compound II was tested[1c] alone and in combination with streptomycin in experimental tuberculosis in guinea pigs. The chemotherapeutic effectiveness was in the same range as that found for promin, but inferior to that of 4-amino-4′-*n*-propylaminodiphenylsulfone.[1b,c] Compound VII showed approximately the same activity in experimental tuberculosis as compound II.[4]

Compounds II, IV, VII and IX, also were active when tested in experimental pneumococcus infection in mice.[5]

Experimental

4-Nitro-4′-succinimidodiphenylsulfone (I).—A mixture of 27 g. of 4-nitro-4′-aminodiphenylsulfone and of 12 g. of succinic anhydride was heated in an oil-bath at 220° for thirty minutes. A clear orange melt resulted which crystallized upon cooling. The crude product melted at 230–232°. From hot glacial acetic acid cream-colored needles (29.5 g.) of m. p. 240–241° were obtained (calcd. 35 g.). The substance is soluble in hot acetone, hot glacial acetic acid, sparingly in hot dioxane.

4-Amino-4′-succinimidodiphenylsulfone (II).—Either 4,4′-diaminodiphenylsulfone or compound (I) was used

as starting material. The first procedure was rather unsatisfactory and was abandoned in favor of the second.

1. A mixture of finely powdered 4,4′-diaminodiphenylsulfone (50 g.) and succinic acid (24 g.) was heated in an oil-bath at 200–210° for two to three hours, until the evaporation of water ceased and a homogeneous liquid was formed. After cooling, the cake was powdered. The reaction product consisted of a mixture of mono- and disubstituted derivatives, besides unreacted diaminodiphenylsulfone. Eight batches were combined and extracted with three liters of warm acetone. II was isolated by fractional crystallization from acetone and acetone-alcohol mixture. The fractions of m. p. 200–230° were combined (about 85 g.) and recrystallized from acetone, thus giving about 65 g. of material of m. p. 220–223°. The melting point was raised to 226–227° by repeated recrystallization.

Using succinic anhydride instead of succinic acid offered no advantage in preparing the compound.

2. Compound I (5 g.) was suspended in 100 cc. of 95% alcohol and shaken with Raney nickel catalyst in a hydrogen atmosphere at atmospheric pressure and room temperature. The calculated amount of hydrogen was taken up in seven to eight hours. (The time should be considerably shortened with application of higher pressures.) The reaction product was brought in solution by heating with the addition of acetone. From the filtered and concentrated solution, 3.8 g. of beautiful needles of m. p. 226–227° were obtained (83% of the calcd.). After recrystallization from acetone, the m. p. was 227–228°.

4-Nitro-4′-β-carboxypropionylaminodiphenylsulfone (III): Hydrolysis of I.—Compound I (7.2 g., $^1/_{50}$ mole) was heated to boiling with 100 cc. of 95% alcohol. With vigorous shaking, 5 cc. of 5 *N* sodium hydroxide solution (calcd. 4.0 cc.) was added until an almost complete solution was formed. The orange solution including a small amount of insoluble material, was cooled with running water, whereupon the sodium salt crystallized as a white crystalline powder. The sodium salt was isolated, dissolved in water, the solution was filtered and acidified with 2 *N* hydrochloric acid. A colorless, voluminous precipitate of the free acid separated which, after filtering and drying, weighed 7.3 g. and melted at 200–202°.

From alcohol clusters of fine, pale yellow needles of m. p. 205° were obtained.[6] The compound is soluble in sodium hydrogen carbonate solution. When heated with an excess of sodium hydroxide, it is split with formation of 4-nitro-4′-aminodiphenylsulfone.

4-Amino-4′-β-carboxypropionylaminodiphenylsulfone (IV).—Compound III was reduced with Raney nickel catalyst and hydrogen in alcoholic suspension. From alcohol colorless crystals, containing alcohol of crystallization, of m. p. 185–186° were obtained. The alcohol can be removed by heating at 110°. From hot water the compound crystallizes with 0.5 mole of water, showing m. p. 140–143°. It is soluble in ammonia; from this solution it is precipitated by dilute hydrochloric acid and dissolved by an excess of acid, when freshly precipitated. After short standing the base crystallizes again. The hydrochloride was obtained by addition of an excess of concentrated hydrochloric acid. It contained two moles of water and melted at 202–204°. For analysis the water was removed by heating *in vacuo* at 100° for two hours.

A yellow water-insoluble diazo compound was formed by diazotization of the suspension of IV in 2 *N* hydrochloric acid, which coupled with β-naphthol with a deep red color.

Compound IV was also obtained by hydrolysis of II with about 40% yield, when heated with 4 *N* hydrochloric acid for five minutes. Succinic acid was partially split off.

4-Nitro-4′-β-carboethoxypropionylaminodiphenylsulfone (V): 1. Alcoholysis of I.—Compound I (5 g.) was heated in a sealed tube with absolute alcohol and ten drops of concentrated hydrochloric acid at 200° for six hours. Small yellow crystals formed. The product was boiled with alcohol, the insoluble residue weighed 2.8 g. It was recrystallized from hot pyridine with addition of alcohol. Pale yellow crystals (2.3 g.) were obtained, m. p. 222–223°.

2. Esterification of III.—Compound III (10 g.) was suspended in 150 cc. of absolute ethyl alcohol and, without cooling, dry hydrochloric acid gas was passed through until the mixture was saturated. After cooling, the reaction mixture was poured in ice water and filtered. The crystalline product was suspended in water containing a little ammonia, filtered and dried; yield 10.7 g., m. p. 223°. When recrystallized as before it melted at 223–224°.

4-Nitro-4′-β-carbomethoxypropionylaminodiphenylsulfone (VI) was prepared according to the procedure V 2.

4-Amino-4′-β-carboethoxypropionylaminodiphenylsulfone (VII).—The procedure II 2 was used.

4-Nitro-4′-β-carbamylpropionylaminodiphenylsulfone (VIII): Ammonolysis of I.—Ammonolysis of I with al-

(6) Previously prepared by Q. Mingoia and F. Berti, *Arquiv. biol. (Sao Paolo)*, **27**, 55 (1943); *C. A.*, **39**, 2057 (1945); a m. p. of 194° is reported.

coholic ammonia gave the succinamide derivative, with admixture of the ethyl ester V.

Compound I (14.4 g.), finely powdered, was allowed to stand in saturated alcoholic ammonia for six days, with occasional shaking. The appearance changed while the heavy crystalline powder became more voluminous. When all heavy material had disappeared, the product was filtered off and washed with alcohol. It melted at 228–232°. After recrystallization from a mixture of pyridine and acetone it melted at 240°. The admixture of the ester was detected only after reduction (see below).

A pure preparation was obtained by ammonolysis with concentrated aqueous ammonium hydroxide. Compound I was warmed with 28% ammonium hydroxide in a stoppered bottle at 60° for two days. The product was washed with water and crystallized from pyridine. To remove pyridine of crystallization, the crystals were suspended in warm alcohol; the volume of the material increased considerably. After washing with alcohol and drying, the m. p. was 242°.

The compound was not soluble in alcohol or acetone, sparingly soluble in dioxane or glacial acetic acid, soluble in hot pyridine.

4-Amino-4′-β-carbamylpropionylaminodiphenylsulfone (IX).—Compound VIII, obtained by alcoholic ammonolysis, was reduced with Raney nickel catalyst and hydrogen in alcoholic suspension. The crude reduction product melted at 135°. Most of it was soluble in hot water. When recrystallized from hot water, containing a little ammonia, colorless fine needles were obtained of m. p. 140°. The solubility in water at 26° was 0.4%. The water-insoluble material was identified with VII by melting point and analysis.

4-Nitro-4′-β-phenylcarbamylpropionylaminodiphenylsulfone (X).—Compound I (13.5 g.) was refluxed with aniline for fourteen hours. After dilution with alcohol, 10.5 g. of material m. p. 205–210° was isolated. From hot acetone (charcoal) cream crystals of m. p. 225–226° were obtained. It is sparingly soluble in hot alcohol.

4-Amino-4′-β-phenylcarbamylpropionylaminodiphenylsulfone (XI) was prepared from X using the procedure II 2.

4-Nitro-4′-β-cyclohexylcarbamylpropionylaminodiphenylsulfone (XII).—Compound I (7.2 g.) was refluxed with cyclohexylamine for five hours. The yield was 8.7 g., the m. p. 276°. Recrystallized from glacial acetic acid, the cream needles melted at 275–276°. The compound was not soluble in alcohol or acetone, soluble in hot pyridine and hot glacial acetic acid.

4-Amino-4′-β-cyclohexylcarbamylpropionylaminodiphenylsulfone (XIII) was prepared from XII using the procedure II 2.

Summary

The preparation of succinic acid derivatives of 4-nitro-4′-aminodiphenylsulfone and of 4,4′-diaminodiphenylsulfone has been described. 4-Amino-4′-succinimidodiphenylsulfone (II) and 4′-amino-4′-β-carboethoxypropionylaminodiphenylsulfone (VII) were tested in experimental pneumonia and tuberculosis and found to be active. 4-Amino-4′-β-carboxypropionylaminodiphenylsulfone (IV) and 4-amino-4′-β-carbamylpropionylaminodiphenylsulfone (IX) were also active in experimental pneumococcus infections in mice.

Kinetic Analysis of Irreversible Consecutive Reactions

BY JEN-YUAN CHIEN

The kinetics of consecutive reactions have been of considerable interest since even simple chemical change may go through a number of intermediate steps. When the rate constants of each step are comparable in magnitude, the integration of the kinetic equations presents considerable difficulties. Especially when reactions of high order in the intermediate steps are involved, the resulting system of non-linear differential equations can only be solved by successive approximations. Hill[1] has recently outlined a general scheme of such methods, but the amount of labor required would be tremendous because of the fact that the rate constants themselves are the unknown parameters sought. In this paper, certain types of two step irreversible consecutive reactions are considered, where the solution in closed form has been found. These solutions serve as an extension to the summary of formulas compiled by Moelwyn-Hughes.[2]

(2) E. A. Moelwyn-Hughes, "Physical Chemistry," Cambridge University Press, Appendix 9, 1940, pp. 633–641.

Integration of the Kinetic Equations

I. Uni-unimolecular Reaction.—The general solution for a unimolecular reaction chain of any number of steps has been found.[3] For the particular case of a two-step reaction

$$\mathrm{A} \xrightarrow{k_1} \mathrm{B} \xrightarrow{k_2} \mathrm{C} \qquad (\mathrm{I})$$

starting with a_0 mole of A, the solution may be expressed in terms of a dimensionless variable τ and a dimensionless parameter κ in the following form, where A, B and C are concentrations of A, B and C, respectively, at t.

$$\left.\begin{aligned} A &= a_0\tau \\ B &= a_0\left(\frac{\tau^\kappa - \tau}{1-\kappa}\right) \\ C &= a_0 - A - B \end{aligned}\right\} \quad (1)$$

where

$$\tau = e^{-k_1 t} \text{ and } \kappa = k_2/k_1$$

II. Uni-bimolecular reaction.—Two separate cases are to be considered, one with a single

(3) H. Bateman, *Proc. Camb. Phil. Soc.*, **15**, 423 (1910).

starting material and the other with two starting materials.

$$\begin{array}{lcccc} \text{(a)} & \mathrm{A} & \xrightarrow{k_1} & \mathrm{B} & \\ & & & 2\mathrm{B} & \xrightarrow{k_2} \mathrm{C} \\ t = 0: & a_0 & & 0 & 0 \\ t \quad : & x_1 & & x_2 & x_3 \end{array} \qquad \text{(IIa)}$$

These kinetic equations describe the processes:

$$\begin{cases} \mathrm{d}x_1/\mathrm{d}t = -k_1x_1 & \text{(2i)} \\ \mathrm{d}x_2/\mathrm{d}t = k_1x_1 - k_2x_2^2 & \text{(2ii)} \\ \mathrm{d}x_3/\mathrm{d}t = {}^1/_2k_2x_2^2 & \text{(2iii)} \end{cases}$$

Integration of (2i) gives

$$x_1 = a_0e^{-k_1t} \qquad (3)$$

and then the Riccati equation (2ii) becomes

$$\mathrm{d}x_2/\mathrm{d}t = a_0k_1e^{-k_1t} - k_2x_2^2 \qquad (4)$$

On using the transformation

$$x_2(t) = \frac{1}{k_2u(t)}\frac{\mathrm{d}u(t)}{\mathrm{d}t} \qquad (5)$$

which transforms the non-linear first order equation (4) in x_2 into a linear second order equation in $u(t)$

$$\mathrm{d}^2u/\mathrm{d}t^2 - a_0k_1k_2e^{-k_1t}\,u = 0$$

A further change of the independent variable t to $\tau = e^{-k_1t}$ yields an equation of the Bessel type[4]

$$\frac{\mathrm{d}}{\mathrm{d}\tau}\left(\tau\frac{\mathrm{d}u}{\mathrm{d}\tau}\right) - \kappa u = 0,\ \kappa = a_0k_2/k_1 \qquad (6)$$

The solution of (6) is

$$u = \alpha J_0(2i\sqrt{\kappa\tau}) + \beta' iH_0^{(1)}(2i\sqrt{\kappa\tau})$$

where α,β' are arbitrary constants, $i = \sqrt{-1}$, and J_0, $H_0^{(1)}$ are Bessel functions of the first and third kind of order zero respectively. Then, by the recurrence relations of Bessel functions[5]

$$\frac{\mathrm{d}J_0(2i\sqrt{\kappa\tau})}{\mathrm{d}\tau} = -\sqrt{\frac{\kappa}{\tau}}\,iJ_1(2i\sqrt{\kappa\tau})$$

$$i\frac{\mathrm{d}H_0^{(1)}(2i\sqrt{\kappa\tau})}{\mathrm{d}\tau} = \sqrt{\frac{\kappa}{\tau}}\,H_1^{(1)}(2i\sqrt{\kappa\tau})$$

and hence the solution[6] for x_2 is, by (5)

$$x_2 = a_0\sqrt{\frac{\tau}{\kappa}}\,\frac{iJ_1(2i\sqrt{\kappa\tau}) - \beta H_1^{(1)}(2i\sqrt{\kappa\tau})}{J_0(2i\sqrt{\kappa\tau}) + \beta iH_0^{(1)}(2i\sqrt{\kappa\tau})} \qquad \text{(7i)}$$

where the arbitrary constant β is determined by the initial condition $x_2(0) = 0$, which gives

$$\beta = \frac{iJ_1(2i\sqrt{\kappa})}{H_1^{(1)}(2i\sqrt{\kappa})} \qquad \text{(7ii)}$$

For $x_3(t)$, use is made of (2ii) and (2iii), *i. e.*

$$x_3 = \frac{k_1}{2}\int_0^t x_1\mathrm{d}t - \frac{x_2}{2} = \frac{a_0}{2}(1-\tau) - \frac{x_2}{2}$$

The complete solution of the problem is summarized as

$$\left.\begin{aligned} A &= a_0\tau \\ B &= a_0\sqrt{\frac{\tau}{\kappa}}\,\frac{iJ_1(2i\sqrt{\kappa\tau}) - \beta H_1^{(1)}(2i\sqrt{\kappa\tau})}{J_0(2i\sqrt{\kappa\tau}) + \beta iH_0^{(1)}(2i\sqrt{\kappa\tau})} \\ C &= {}^1/_2(a_1 - A - B) \end{aligned}\right\} \qquad (8)$$

where

$$\tau = e^{-k_1t},\ \kappa = a_0k_2/k_1,\ \beta = iJ_1(2i\sqrt{\kappa})/H_1^{(1)}(2i\sqrt{\kappa})$$

$$\begin{array}{lcccc} \text{(b)} & \mathrm{A} & \xrightarrow{k_1} & \mathrm{B} & \\ & & & \mathrm{B}+\mathrm{D} & \xrightarrow{k_2} \mathrm{C} \\ t = 0: & a_0 & & 0 \quad d_0 & 0 \\ t \quad : & a_0 - x & & x - y \quad d_0 - y & y \end{array} \qquad \text{(IIb)}$$

The kinetic equations are

$$\begin{cases} \mathrm{d}(a_0 - x)/\mathrm{d}t = -k_1(a_0 - x) & \text{(9i)} \\ \mathrm{d}y/\mathrm{d}t = k_2(x - y)(d_0 - y) & \text{(9ii)} \end{cases}$$

Integration of (9i) gives

$$x = a_0(1 - e^{-k_1t})$$

then (9ii) becomes

$$\mathrm{d}y/\mathrm{d}t = k_2(a_0 - a_0e^{-k_1t} - y)(d_0 - y)$$

This is also a Riccati equation which in general cannot be solved. However, it is known that if one particular solution y_1 is found, the equation can be reduced to linear form by the transformation $y = y_1 \pm 1/v$. Following Bruins[7] $y_1 = d_0$ is obviously a solution, and

$$y = d_0 - 1/v(t)$$

leads to an equation for $v(t)$

$$\frac{\mathrm{d}v}{\mathrm{d}t} - a_0k_2(\lambda_0 - e^{-k_1t})\,v = k_2$$

where $\lambda_0 = (a_0 - d_0)/a_0$ The solution of this linear differential equation in v is

$$v = \tau^{-\lambda_0\kappa}\,e^{\kappa\tau}\left[-\frac{\kappa^{(1-\lambda_0\kappa)}}{a_0}\,\Gamma(\lambda_0\kappa,\kappa\tau) + \gamma\right] \qquad \text{(10i)}$$

where

$$\tau = e^{-k_1t},\quad \kappa = a_0k_2/k_1$$

and

$$\Gamma(n,x) = \int_0^x \xi^{n-1}\,e^{-\xi}\,\mathrm{d}\xi \qquad \text{(10ii)}$$

is the incomplete Γ-function.[8] Evaluation of the arbitrary constant γ by the initial condition gives

$$y = d_0\left[1 - \frac{\tau^{\lambda_0\kappa}\,e^{-\kappa\tau}}{e^{-\kappa} - (1-\lambda_0)\kappa^{(1-\lambda_0\kappa)}\{\Gamma(\lambda_0\kappa,\kappa\tau) - \Gamma(\lambda_0\kappa,\kappa)\}}\right] \qquad (11)$$

Hence

$$\left.\begin{aligned} A &= a_0\tau \\ D &= d_0\frac{\tau^{\lambda_0\kappa}\,e^{-\kappa\tau}}{e^{-\kappa} - (1-\lambda_0)\kappa^{(1-\lambda_0\kappa)}\{\Gamma(\lambda_0\kappa,\kappa\tau) - \Gamma(\lambda_0\kappa,\kappa)\}} \\ C &= d_0 - D \\ B &= a_0 - A - C \end{aligned}\right\} \qquad (12)$$

where

$$\tau = e^{-k_1t},\ \kappa = a_0k_2/k_1,\ \lambda_0 = (a_0 - d_0)/d_0$$

(6) Tables of $J_0(ix)$, $-iJ_1(ix)$, $iH_0^{(1)}(ix)$ and $-H_1^{(1)}(ix)$ are given in E. Jahnke and F. Emde, "Tables of Functions," Dover Publications, New York, N. Y., 1943, pp. 224–229, 236–243.

(7) E. M. Bruins, *Rec. trav. chim.*, **59**, 739 (1940).

(8) Values of $I(x,n) = \Gamma(n,x)/\Gamma(n)$ have been tabulated by K. Pearson, "Tables of the Incomplete Γ-function," His Majesty's Stationery Office, London, 1922.

For the particular case when $a_0 = d_0$, it is necessary to return to (10i) and in this case

$$v = e^{\kappa\tau}\left[\frac{\kappa}{a_0}\{-Ei(-\kappa\tau) + Ei(-\alpha)\} + \gamma'\right]$$

where

$$-Ei(-x) = \int_x^\infty \frac{e^{-\xi}}{\xi}\,d\xi$$

is the exponential integral,[9] and α is some positive number.[10] Evaluation of γ' by the initial condition gives

$$D = a_0\frac{e^{-\kappa\tau}}{e^{-\kappa} + \kappa\{-Ei(-\kappa\tau) + Ei(-\kappa)\}} \qquad (12')$$

III. Bi-unimolecular Reaction.—One of the two possible cases of consecutive bi-unimolecular reactions is

$$\begin{array}{lccc} & 2A \xrightarrow{k_1} & B \xrightarrow{k_2} & C \\ t = 0: & a_0 & 0 & 0 \\ t\ \ : & a_0 - 2x & x - y & y \end{array} \qquad (III)$$

The kinetic equations are

$$\begin{cases} \dfrac{d(a_0 - 2x)}{dt} = -k_1(a_0 - 2x)^2 & (13i) \\ dy/dt = k_2(x - y) & (13ii) \end{cases}$$

Integration of (13i) gives

$$a_0 - 2x = a_0/(1 + a_0k_1t) \qquad (14)$$

Then (13ii) becomes

$$\frac{dy}{dt} + k_2y = \frac{a_0^2}{2}\frac{k_1k_2}{1 + a_0k_1t}\,t \qquad (15)$$

This linear equation has the solution

$$y = e^{-k_2t}\left[\frac{a_0^2}{2}k_1k_2\int^t \frac{te^{k_2t}}{1 + a_0k_1t}\,dt + \gamma\right]$$

The indefinite integral in the above expression for y can be evaluated by a change of variable. Let

$$\tau = 1 + a_0k_1t, \text{ and } \kappa = k_2/a_0k_1$$

then

$$\frac{a_0^2}{2}k_1k_2\int^t \frac{te^{k_2t}}{1 + a_0k_1t}\,dt = \frac{a_0}{2}\kappa e^{-\kappa}\left[\int^\tau e^{\kappa\tau}\,d\tau - \int^\tau \frac{e^{\kappa\tau}}{\tau}\,d\tau\right]$$
$$= \frac{a_0}{2}\left[e^{\kappa(\tau-1)} - \kappa e^{-\kappa}\,Ei(\kappa\tau) + \text{const.}\right]$$

where the exponential integral[11]

$$Ei(x) = \int_{-\infty}^x \frac{e^\xi}{\xi}\,d\xi$$

And therefore

$$y = \frac{a_0}{2}\left[1 - \kappa e^{-\kappa\tau}\,Ei(\kappa\tau) + \gamma'e\kappa(1 - \tau)\right]$$

Evaluation of the constant γ' by the initial condition $y(0) = 0$ gives

$$y = \frac{a_0}{2}\left[1 - e^{-\kappa(\tau-1)} - \kappa e^{-\kappa\tau}\{Ei(\kappa\tau) - Ei(\kappa)\}\right] \qquad (16)$$

Thus the complete solution[12] is

$$\left.\begin{aligned} A &= a_0/\tau \\ B &= \frac{a_0}{2}\left[e^{-\kappa(\tau-1)} + J\right] - \frac{A}{2} \\ C &= \frac{a_0}{2}\left[1 - e^{-\kappa(\tau-1)} - J\right] \end{aligned}\right\} \qquad (17)$$

where

$$\tau = 1 + a_0k_1t,\ \kappa = k_2/a_0k_1$$

and

$$J = \kappa e^{-\kappa\tau}\{Ei(\kappa\tau) - Ei(\kappa)\}$$

IV. Bi-bimolecular Reaction.—Two particular cases of reactions of this type where solutions to the kinetic equations have been found are

$$\begin{array}{lccc} \text{(a)} & 2A \xrightarrow{k_1} & B & \\ & & 2B \xrightarrow{k_2} & C \\ t = 0: & a_0 & 0 & 0 \\ t\ \ : & x_1 & x_2 & x_3 \end{array} \qquad (IVa)$$

The kinetic equations are

$$\begin{cases} dx_1/dt = -k_1x_1^2 & (18i) \\ \dfrac{dx_2}{dt} = \dfrac{k_1}{2}x_1^2 - k_2x_2^2 & (18ii) \\ \dfrac{dx_3}{dt} = \dfrac{k_2}{2}x_2^2 & (18iii) \end{cases}$$

Integration of (18i) gives

$$x_1 = \frac{a_0}{1 + a_0k_1t} \qquad (19)$$

Then

$$\frac{dx_2}{dt} = \frac{k_1}{2}\frac{a_0^2}{(1 + a_0k_1t)^2} - k_2x_2^2 \qquad (20)$$

This is also a Riccati equation[13] and inspection shows that

$$X_2 = \frac{\alpha a_0}{1 + a_0k_1t}$$

is a particular solution, where α is a constant so chosen as to satisfy the equation. Thus

$$\alpha = \frac{1}{2\kappa}(1 + \sqrt{1 + 2\kappa}),\quad \kappa = k_2/k_1$$

Let the general solution be

$$x_2 = X_2 + 1/v(t)$$

then the equation for v will be

$$dv/dt - 2k_2X_2v = k_2 \qquad (21)$$

The solution to this equation is

$$v = \tau^{\mu+1}\left[-\frac{\kappa}{a_0\mu}\tau^{-\mu} + \gamma\right]$$

where $\tau = 1 + a_0k_1t$ and $\mu = 2\alpha\kappa - 1 = \sqrt{1 + 2\kappa}$.

(9) "Tables of Sine Cosine and Exponential Integrals," Federal Works Agency, New York, 1940; or E. Jahnke and F. Emde, "Tables of Functions," *loc. cit.*, pp. 6–9.

(10) Here the indefinite integral is changed to a definite integral with a lower limit α by changing the additive constant γ' to avoid the difficulty of infinite Ei(0).

(11) In Jahnke and Emde, *loc. cit.*, this function is tabulated under the notation $\overline{\text{Ei}}(x)$.

(12) The solution of this type of reaction has been previously reported by A. A. Balandin and L. S. Leebenson, *Comp. rend. URSS.*, **39**, 22 (1943), but apparently they gave a wrong sign on J for both B and C.

(13) The equation (20) can also be solved by the following transformation

$$x_2 = \frac{1}{k_2u}\frac{du}{dt},\quad 1 + a_0k_1t = e^s$$

which leads to a second order linear equation in u with constant coefficients:

$$\frac{d^2u}{ds^2} - \frac{du}{ds} - \kappa u = 0,\quad \kappa = k_2/k_1$$

Determination of the arbitrary constant γ from the initial condition $x_2(0) = 0$ leads to

$$v = -\frac{\kappa\tau}{a_0\mu}\left[1 + \frac{\mu - 1}{\mu + 1}\tau^{\mu}\right] \tag{22}$$

Therefore

$$x_2 = \frac{a_0}{2}\frac{1}{\kappa\tau}\left[\mu + 1 - \frac{2\mu}{1 + \frac{\mu - 1}{\mu + 1}\tau^{\mu}}\right] \tag{23}$$

Integration of (18iii) by using (18ii) gives

$$x_3 = \frac{a_0}{4}\left(1 - \frac{1}{\tau}\right) - \frac{x_2}{2}$$

Thus the complete solution[14] is

$$\left.\begin{aligned} A &= a_0/\tau \\ B &= \frac{a_0}{2}\frac{1}{\kappa\tau}\left[\mu + 1 - \frac{2\mu}{1 + \frac{\mu - 1}{\mu + 1}\tau^{\mu}}\right] \\ C &= \frac{1}{2}\left[\frac{a_0}{2} - \frac{A}{2} - B\right] \end{aligned}\right\} \tag{24}$$

where

$$\tau = 1 + a_0k_1t, \quad \kappa = k_2/k_1, \quad \mu = \sqrt{1 + 2\kappa}$$

(b) $2\mathbf{A} \xrightarrow{k_1} \mathbf{B} + \mathbf{D} \xrightarrow{k_2} \mathbf{C}$ (IVb)

	A		B	D	C
$t = 0$:	a_0		0	d_0	0
t :	$a_0 - 2x$		$x - y$	$d_0 - y$	y

The kinetic equations are

$$\begin{cases} \mathrm{d}(a_0 - 2x)/\mathrm{d}t = -k_1(a_0 - 2x) & \text{(25i)} \\ \mathrm{d}y/\mathrm{d}t = k_2(x - y)(d_0 - y) & \text{(25ii)} \end{cases}$$

Integrating (25i) gives

$$a_0 - 2x = \frac{a_0}{1 + a_0k_1t}$$

Then (25ii) becomes

$$\frac{\mathrm{d}y}{\mathrm{d}t} = k_2\left(\frac{1}{2}\frac{a_0^2k_1t}{1 + a_0k_1t} - y\right)(d_0 - y) \tag{26}$$

As in the case IIb, $y_1 = d_0$ is obviously a solution of this Riccati equation, so

$$y = d_0 - 1/v(t)$$

leads to a linear equation in v

$$\frac{\mathrm{d}v}{\mathrm{d}t} - k_2\left(\frac{1}{2}\frac{a_0^2k_1t}{1 + a_0k_1t} - d_0\right)v = k_2$$

The solution for v is

$$v = e^{\lambda_0\kappa\tau}\tau^{-\kappa}\left[\frac{2\kappa}{a_0}\int^{\tau} e^{-\lambda_0\kappa\tau}\tau^{\kappa}\,\mathrm{d}\tau + \gamma\right]$$

or

$$v = e^{\lambda_0\kappa\tau}\tau^{-\kappa}\left[\frac{2}{a_0\lambda_0}(\lambda_0\kappa)^{-\kappa}\,\Gamma(\kappa + 1, \lambda_0\kappa\tau) + \gamma'\right] \tag{27}$$

where

$$\tau = 1 + a_0k_1t, \quad \kappa = k_2/2k_1, \quad \lambda_0 = (a_0 - 2d_0)/a_0$$

and $\Gamma(n,x)$ is the incomplete Γ-function defined previously by (10ii). By the initial condition $y(0) = 0$, the constant γ' is evaluated and then

$$y = d_0\left[1 - \frac{\tau^{\kappa}e^{-\tau}}{1 - \left(\frac{1 - \lambda_0}{\lambda_0}\right)(\lambda_0\kappa)^{\kappa}e^{\lambda_0\kappa}\{\Gamma(\kappa + 1, \lambda_0\kappa\tau) - \Gamma(\kappa + 1, \lambda_0\kappa)\}}\right] \tag{28}$$

Therefore the complete solution is

$$\left.\begin{aligned} A &= a_0/\tau \\ D &= d_0\frac{\tau^{\kappa}e^{-\tau}}{1 - \left(\frac{1 - \lambda_0}{\lambda}\right)(\lambda_0\kappa)^{\kappa}e^{\lambda_0\kappa}\{\Gamma(\kappa + 1, \lambda_0\kappa\tau) - \Gamma(\kappa + 1, \lambda_0\kappa)\}} \\ C &= d_0 - D \\ B &= {}^1/_2(a_0 - A) - C \end{aligned}\right\} \tag{29}$$

where

$$\tau = 1 + a_0k_1t, \quad \kappa = k_2/2k_1, \quad \lambda_0 = (a_0 - 2d_0)/a_0$$

For the special case when $\lambda_0 = 0$, *i. e.*, $a_0 = 2d_0$, equation (28) becomes indeterminate, but the solution is easily obtained from (27) where the integral gives an algebraic function of τ, and the particularly simple result

$$D = \frac{a_0}{2}\frac{(\kappa + 1)\tau^{\kappa}}{1 + \kappa\tau^{\kappa+1}} \tag{29'}$$

is obtained.

Discussion

All the solutions obtained for the two step irreversible consecutive reactions considered above have been expressed in terms of a dimensionless variable τ and some dimensionless parameters defined for each type of reaction in question. The general behavior of these solutions is shown in Figs. 1 and 2 for hypothetical reactions with $\kappa = 0.5$. For the reaction type IIb and IVb, equal initial concentrations for A and D are assumed. In these plots, $1/1 + a_0k_1t$ is chosen as abscissa. This particular choice appears to be most suitable to show the different characters of the reaction mechanism. It is obvious that if the first step is bimolecular, the decay curve for A will be linear. A unimolecular step will result in a change of the direction of curvature in the formation curve of both B and C, while no inflection point will be found on the curve if the steps involved are bimolecular. Therefore, such a plot will give directly an insight into the reaction mechanism. A linear time scale is also attached on the top of each curve.

Experimentally the aim is always the evaluation of the rate constants of each step and thus an assignment of possible reaction mechanism. In view of the difficulties involved in a simultaneous evaluation of the two rate constants, it appears desirable to follow the decay of the initial compound **A**. This will give the rate constant k_1 immediately. The evaluation of κ can then be made, by comparing the experimental formation curve of either the product C or the intermediate B, or the decay curve of the other starting compound D, to

(14) The solution of this problem has been considered by J. Hirniak, *Acta Physico-chimica URSS*, **14**, 613 (1941). He arrived at essentially the same result as (24) but through an entirely different and lengthy derivation. However, his b differs from μ of this paper, which should be identical, because he overlooked the fact that four molecules not two of **A** are consumed to give one molecule of **C**.

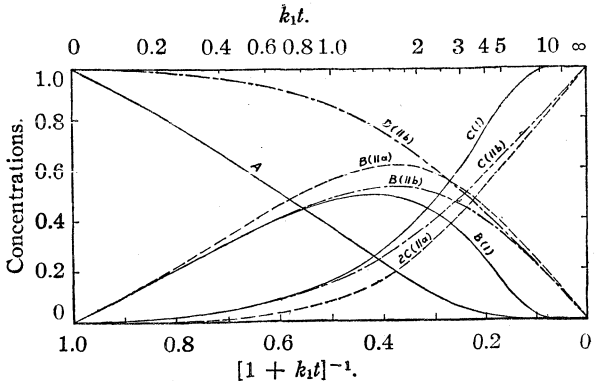

Fig. 1.—Uni-uni- and uni-bi-molecular reactions, $a_0 = 1$, $k = 0.5$.

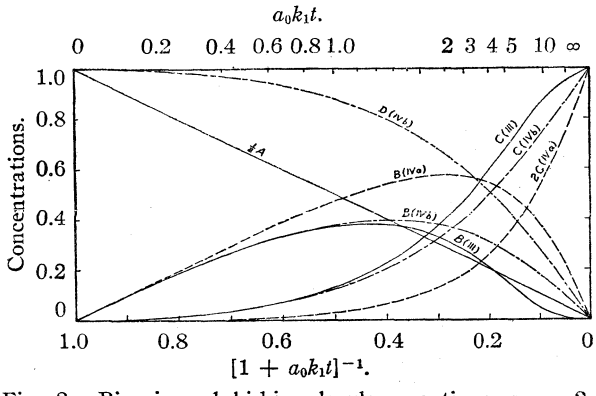

Fig. 2.—Bi-uni- and bi-bi-molecular reactions, $a_0 = 2$, $k = 0.5$.

a set of computed curves. It might be mentioned here that for the special case of reaction type I, Swain[15] has devised a graphical method of evaluating k_1 and k_2 from a single experimental curve of $(a_0 - A + C)$.

Experimental studies on the kinetics of consecutive reactions have been handicapped by their complexity. The present analysis shows definitely that a separate determination of the kinetic behavior of the initial step leads to an essential simplication of the problem. With the value of a_0 chosen as 1 or 2, depending on the reaction mechanism of the first step of the reaction, the graphs shown in Figs. 1 and 2, with different values of κ can be constructed and can then be used to analyze all experimental data in any given case. This procedure amounts to plotting all experimental values of concentrations relative to the concentration of the initial compound A and on a time scale of $(1 + a_0k_1t)^{-1}$. A similar procedure has been used for the study of concurrent consecutive reactions.[16]

It is interesting to note here that for the reaction type III, the formation curve of C as computed from equation (17) could well be represented by an empirical unimolecular equation with an apparent induction period. For example, for $a_0 = 2$ and $\kappa = 0.5$, the theoretical curve and an empirical equation like

$$C' = 1 - e^{-0.253(\tau - 1.50)} \qquad (30)$$

agree very well from 15 to 90% completion of the reaction as shown in Table I. This case corresponds to an apparent unimolecular rate constant of approximately half the true value of k_2. As κ decreases the agreement will be better, and finally when $a_0k_1 \longrightarrow \infty$

$$\lim_{a_0k_1 \to \infty} J = k_2e^{-k_2t} \lim_{a_0k_1 \to \infty} \frac{\int_{k_2/a_0k_1}^{k_2t} \frac{e^\xi}{\xi} d\xi}{a_0k_1} =$$

$$k_2e^{-k_2t} \lim_{a_0k_1 \to \infty} \frac{e^{k_2/a_0k_1}}{a_0k_1} = 0$$

Therefore

$$C \xrightarrow[a_0k_1 \to \infty]{} \frac{a_0}{2}(1 - e^{-k_2t})$$

which is the unimolecular formation of C from B as would be expected.

TABLE I

COMPARISON OF EQUATIONS (17) AND (30) FOR $a_0 = 2$ AND $\kappa = 0.5$

τ	C	C'	Δ%
1.0	0		
1.4	0.029		
1.8	.092	0.073	−21
2.2	.166	.162	−3.0
2.6	.242	.243	+0.4
3.0	.314	.316	+0.6
3.5	.398	.398	±0.0
4.0	.473	.468	−1.1
5.0	.593	.588	−0.8
6.0	.682	.680	−0.3
8.0	.794	.807	+1.6
10.0	.855	.884	+3.4
20.0	.943	.991	+5.1

In conclusion, it is hoped that the solutions of irreversible consecutive reactions here presented will be useful for the study of many organic reactions. Some of the results appear to be particularly simple to apply. The only limitation will lie in the reversibility of the reactions. For such cases the kinetic equations have not been integrated at the present moment.

Acknowledgment.—The author is indebted to Professor R. E. Langer of the Mathematics Department, University of Wisconsin, for valuable suggestions and to Professor G. Glockler for a discussion of the topic involved.

Summary

1. Solutions in closed form for some two step irreversible consecutive reactions are presented, with the results expressed in terms of a dimension-

(15) C. G. Swain, THIS JOURNAL, **66**, 1696 (1944).

(16) C. Potter and R. R. McLaughlin, *Can. J. Research*, **B25**, 405 (1947).

less variable and dimensionless parameters. Uni-bi-, bi-uni- and bi-bi-molecular reactions are the cases considered.

2. Experimental evaluation of the rate constants is discussed. A separate determination of the rate of decay of the initial substance is desirable for the interpretation of the mechanism and the evaluation of rate constants.

3. Practical applications of the results are limited only by the possible reversibility of the reaction steps involved.

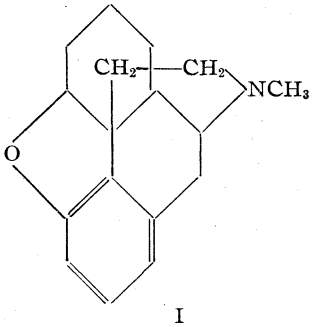
The Synthesis of Ring Systems Related to Morphine. I. 9,10-Dioxo-13-cyanomethyl-5,8,9,10,13,14-hexahydrophenanthrene

BY MARSHALL GATES AND WILLIAM F. NEWHALL

A synthesis of the ring system (I) present in morphine and its close relatives has not yet been achieved although a number of interesting at-

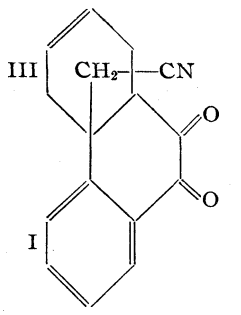


I

tempts have been reported.[1] We have been engaged for some time in an attempt to synthesize derivatives of such a ring system which might be compared with certain degradation products of the morphine alkaloids. Such a synthesis would offer a rigorous solution to the question of the point of attachment of the ethanamine side chain of morphine. The appearance in recent months of several publications[1a,c,d] bearing on this general problem has prompted us to offer our results for publication.

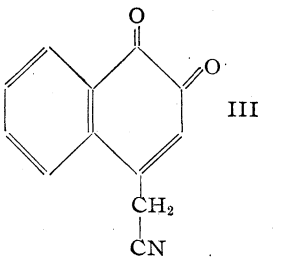
We have developed a convenient synthesis for 9,10 - dioxo - 13 - cyanomethyl - 5,8,9,10,13,14-hexahydrophenanthrene (II) which appears to be flexible enough to allow the introduction of substituents into rings I and III by suitable choice of starting materials.

The starting point for the preparation of this substance is the 4-(carbethoxycyanomethyl)-1,2-naphthoquinone of Sachs and Craveri,[2] which is available from ammonium 1,2-naphthoquinone-4-sulfonate by an improved procedure in 91% yield. This material is reduced, hydrolyzed and decarboxylated in one step giving 4-cyanomethyl-1,2-



II

naphthohydroquinone in 91% yield. Dichromate oxidation of this hydroquinone in glacial acetic acid affords 4-cyanomethyl-1,2-naphthoquinone (III)[3] in 83% yield.



The quinone III condenses readily with butadiene in acetic acid to give the diketone II. Excellent quality adduct is readily obtained in 56% yield.[4] Its formulation as II appears to be required by the fact that its azine IV, easily prepared by condensation with *o*-phenylenediamine, yields 1,2,3,4-dibenzophenazine (9,10-phenanthrenequinone azine) (V) on distillation with zinc dust.

Experiments are in progress on the reduction of II by a variety of methods. We hope to effect a

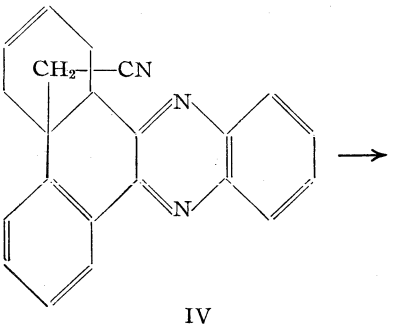
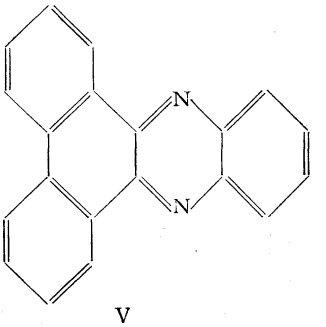
(3) The position of the cyanomethyl group in this substance has been conclusively demonstrated by Miss Elizabeth R. Carmichael, working in this laboratory on another problem, by hydrolyzing and decarboxylating the azine of this substance to 4-methyl-1,2-naphthophenazine [Fieser and Bradsher, THIS JOURNAL, **61**, 417 (1939)] which was compared with an authentic sample kindly furnished us by Professor Louis F. Fieser of Harvard University.

(4) Compare the work of Fieser and Bradsher, THIS JOURNAL, **61**, 417 (1939), in which 2,3-dimethylbutadiene was shown to add slowly to 4-benzyl- and 4-dicarbethoxymethyl-1,2-naphthoquinones.



IV



V

ring closure to the 9 position through the nitrogen atom.

We are also investigating the condensation of III with other dienes, such as chloroprene, 2-ethoxybutadiene, piperylene, isoprene and others, and are in process of preparing derivatives of II and III carrying hydroxyl and alkoxyl groups in the 3 and 4 positions of II (5 and 6 positions of III).

We wish gratefully to acknowledge the help of a Frederick Gardner Cottrell Special Grant-in-aid from the Research Corporation with which a part of the expenses of this work have been defrayed.

Experimental Part[5]

4-Carbethoxycyanomethyl-1,2-naphthoquinone was prepared from ammonium 1,2-naphthoquinone-4-sulfonate[6] by a modification of the method of Sachs and Craveri.[2] A solution of 20 g. of ethyl cyanoacetate in 300 cc. of methanol was added with vigorous stirring to a solution of 30 g. of ammonium 1,2-naphthoquinone-4-sulfonate in 500 cc. of water. Thirty cc. of 25% sodium hydroxide was then added, and the resulting deep purple solution, on acidification to congo red with 12 *N* hydrochloric acid, yielded 28.8 g. (91%) of bright yellow material, m. p. 129.9–130.4°.

4-Cyanomethyl-1,2-naphthohydroquinone.—A solution of 20 g. of 4-carbethoxycyanomethyl-1,2-naphthoquinone in the minimum quantity of methanol was reduced by excess sodium hydrosulfite solution. After the color had been completely discharged, 30 cc. of 25% sodium hydroxide solution was added, and the mixture was refluxed until a test portion turned clear red with no purple on exposure to air. This required about seventy minutes. While still warm the mixture was acidified to congo red, and on cooling 13.4 g. (91%) of 4-cyanomethyl-1,2-naphthohydroquinone crystallized as colorless or pink needles, m. p. 220–227° with much decomposition. For analysis, a small sample was crystallized several times from dilute alcohol containing stannous chloride and a little hydrochloric acid and dried at 110° and 10^{-4} mm. Its melting point is not a reliable criterion of purity.

(5) All melting points are corrected.

Anal. Calcd. for $C_{12}H_9O_2N$: C, 72.35; H, 4.55; N, 7.03. Found: C, 72.36; H, 4.64; N, 6.63.

The hydroquinone is easily soluble in methanol, moderately soluble in cold acetic acid, and sparingly soluble in cold benzene. It dissolves in concentrated sulfuric acid with the production of a deep blue color changing to blue-green, then to amber-green, finally to a clear amber-yellow.

4-Cyanomethyl-1,2-naphthoquinone (III) was prepared by oxidation of the above hydroquinone as follows: A warm suspension of 13.4 g. of 4-cyanomethyl-1,2-naphthohydroquinone in 200 cc. of glacial acetic acid was treated with a solution of 6 g. of sodium dichromate in aqueous acetic acid. On cooling, the quinone separated as yellow needles (10.9 g., 83%), m. p. 190–194°, with decomposition. A small sample was recrystallized several times from alcohol and dried at 110° and 10^{-4} mm. for analysis, m. p. 191–194° with decomposition.

Anal. Calcd. for $C_{12}H_7O_2N$: C, 73.08; H, 3.58. Found: C, 73.22; H, 3.69.

The quinone is moderately soluble in methanol, sparingly soluble even in hot benzene, and moderately soluble in glacial acetic acid. Its solution in concentrated sulfuric acid is orange-yellow.

9,10-Dioxo-13-cyanomethyl-5,8,9,10,13,14-hexahydrophenanthrene (II).—A suspension of 3.0 g. of 4-cyanomethyl-1,2-naphthoquinone in 40 cc. of glacial acetic acid and 20 cc. of butadiene was heated for twenty-two hours in a pressure bottle suspended in an oil-bath maintained at 80–85°. After cooling and opening, the excess butadiene was removed and the acetic acid decanted from the well-formed light tan prisms of adduct, m. p. 176–180°, which had separated. Crystallization from methanol with the aid of norite afforded 2.1 g. (56%) of colorless prisms, m. p. 181–182°. A small amount of additional material could be obtained from the filtrate. For analysis, a small sample was crystallized several times from methanol and dried at 110° and 10^{-4} mm., m. p. 185.6–186.6°.

Anal. Calcd. for $C_{16}H_{13}O_2N$: C, 76.47; H, 5.21. Found: C, 76.40; H, 5.22.

The diketone II dissolves in concentrated sulfuric acid to give a pale yellow solution, and is soluble in aqueous alkali with the production of a yellow color. It is sparingly soluble in cold methanol and in cold acetic acid.

The azine of 9,10-dioxo-13-cyanomethyl-5,8,9,10,13,14-hexahydrophenanthrene was prepared by refluxing 100 mg. of the adduct described above with an equivalent amount of *o*-phenylenediamine in benzene containing a few drops of acetic acid. The solvent was removed and the residue in ether was extracted several times with dilute acid, twice with carbonate, dried and concentrated. The colorless solid residue (129 mg., m. p. 169–171.5°) was crystallized several times from methanol and dried at 110° and 10^{-4} mm. for analysis, 60 mg., m. p. 173.3–173.8°.

Anal. Calcd. for $C_{22}H_{17}N_3$: C, 81.70; H, 5.30; N, 12.99. Found: C, 81.78; H, 5.63; N, 13.09.

The azine is sparingly soluble in cold benzene, moderately soluble in methanol.

Zinc Dust Distillation of the Azine of 9,10-Dioxo-13-cyanomethyl-5,8,9,10,13,14-hexahydrophenanthrene.—The azine of III (60 mg.), intimately mixed with zinc dust was heated at 350° (salt-bath) at atmospheric pressure for one hour in a microsublimation apparatus. During this time a sublimate of bright yellow crystals (21 mg., m. p. 193–206°) appeared on the cold finger. Several recrystallizations from alcohol yielded 4 mg. of pale yellow needles, m. p. 223.4–223.9°, whose mixed m. p. with 9,10-phenanthrenequinone azine of m. p. 223.9–224.4° was 223.4–224.9°.

Summary

A convenient preparation of 9,10-dioxo-13-

cyanomethyl - 5,8,9,10,13,14 - hexahydrophenanthrene as an intermediate and model compound for the synthesis of substances containing the morphine ring system has been developed.

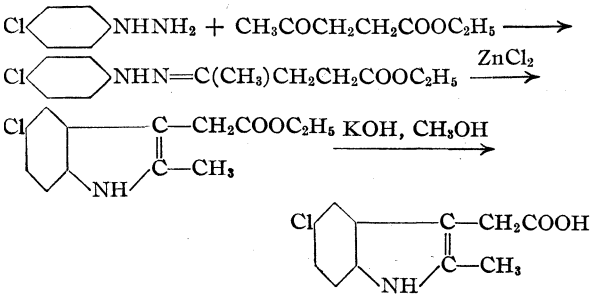
Amino Acid Conversion Products. IV. Some Substituted 3-Indoleacetic Acids and Some Substituted Phenylhydrazones of β-Formylpropionic Acid[1]

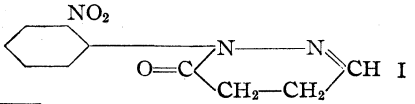
BY FRANK J. STEVENS[2] AND SIDNEY W. FOX

The natural plant growth hormone, 3-indoleacetic acid[3] (*heteroauxin*), and the substituted phenoxyacetic acids[4] have received much attention as stimulants of plant growth. A search of the literature does not reveal many syntheses of indoleacetic acid derivatives for phytological studies. The indoleacetic acid derivatives containing the types of substitution which have been useful in the phenoxyacetic acid series, are of especial interest. The present paper deals with the preparation of a number of such substances.

For the compounds reported here, the reactions involved are typified by the sequence below. In this example, the chlorophenylhydrazone of levulinic ester was converted *via* Fischer's ring closure[5] to the substituted indoleacetic acid



In attempts to cyclize β-formylpropionic acid phenylhydrazones, there was obtained in some cases an anhydride of the type reported as a by-product by Fischer in his experiments on cyclization of the phenylhydrazone of levulinic acid.[6] In the present study, ring closure of this type was obtained with the phenylhydrazone and *o*-nitrophenylhydrazone of β-formylpropionic acid. The product in the case of the nitrophenylhydrazone was 4,5-dihydro-2-(*o*-nitrophenyl)-3(2)-pyridazone, represented by I.



Of the compounds prepared in the present series, the 2-methyl-5-chloro derivative was more active in preliminary Pea Tests[7] than the 2-methyl-5-chloro and 2-methyl-7-chloro or 2-methyl-5,7-dichloro derivatives of 3-indoleacetic acid.

The indoleacetic acids reported all are substituted in the 2-position. For the corresponding unsubstituted indoleacetic acids obtained from β-formylpropionic acid, only the phenylhydrazones are recorded here. Ring closure has not been effected as readily with these latter compounds as with the derivatives of levulinic acid. The synthesis of indoleacetic acid itself, however, has been accomplished, and work is continuing on this series.

Experimental

All m.p.'s were corrected.

All nitrogen analyses were made by the micro Dumas method.

Levulinic Acid *o*-Nitrophenylhydrazone.—A hot solution of 7.65 g. (0.05 mole) of *o*-nitrophenylhydrazine[8] in 150 cc. of 20% acetic acid was added to 5.8 g. (0.05 mole) of levulinic acid (stores) in 200 cc. of hot water. The red-orange oil which precipitated crystallized upon cooling; yield 10.2 g. (81%). The solid was recrystallized from ethanol with the addition of water; m. p. 149–150°. Two more such recrystallizations raised the m. p. to 150–150.5°.

Anal. Calcd. for $C_{11}H_{13}O_4N_3$: N, 16.7. Found: N, 16.9, 16.3.

Ethyl Levulinate *o*-Nitrophenylhydrazone.—Dry hydrogen chloride was bubbled rapidly into a solution of 1.00 g. (0.0040 mole) of levulinic acid *o*-nitrophenylhydrazone in 60 cc. of absolute ethanol, and the solution was refluxed for two hours. The preparation was diluted with 200 cc. of water and extracted with four 50-cc. portions of ether. The combined ether extracts were washed with sodium bicarbonate solution and water. After drying with Drierite the ether was distilled off and the residue was recrystallized from ethanol; yield 0.88 g. (80%), m. p. 57.5–58.5°. Recrystallization from ethanol with the addition of water gave orange crystals of m. p. 58.5–59°. A mixed m. p. with the ester prepared from ethyl levulinate[9] and *o*-nitrophenylhydrazine showed no depression.

Anal. Calcd. for $C_{13}H_{27}O_4N_3$: N, 15.1. Found: N, 14.9.

2-Methyl-7-nitro-3-indoleacetic Acid.—To 20.0 cc. of a saturated solution of zinc chloride in concentrated hydrochloric acid solution, 2.0 g. (0.0071 mole) of the ester hydrazone was added and the mixture was refluxed

for one hour. The resultant solution was extracted with four 50-cc. portions of ether, and the combined extract was dried. The ether was distilled off and the residue refluxed with 25 cc. of 2% ethanolic sodium hydroxide for one hour. Twenty-five cc. of water was added and the alcohol was removed by distillation. The alkaline solution was then extracted with 100 cc. of ether, and the extract was discarded. The solution was made acid with dilute hydrochloric acid solution, and extracted with three 50-cc. portions of ether. The combined ether extracts were dried and the ether removed by distillation; yield 0.47 g. (28%), the material decomposed about 245°. Recrystallization from acetic acid with the addition of water gave a material that melted 265° (dec.). The substance was soluble in ethanol, acetic acid, and sodium bicarbonate solution, but insoluble in water.

Anal. Calcd. for $C_{11}H_{10}O_4N_2$: N, 12.0. Found: N, 11.9, 11.8.

Other treatments which were unsuccessfully tested for ring closure were: heating with zinc chloride alone, and in boiling xylene, and heating with aluminum chloride in hexane.

Ethyl Levulinate *o*-Chlorophenylhydrazone.—A hot solution of 17.9 g. (0.10 mole) of *o*-chlorophenylhydrazine hydrochloride,[10] 8.5 g. (0.104 mole) of sodium acetate, and 25 g. of acetic acid in 200 cc. of water was slowly added to 14.4 g. (0.10 mole) of ethyl levulinate in 300 cc. of hot water. The light yellow oil, which immediately precipitated, solidified after cooling. The precipitate was filtered and washed with water; yield 25.5 g. (95%). Recrystallization from ethanol with the addition of water gave a white crystalline precipitate of m. p. 58.5–59.5°. The material was unstable, however, and soon turned to a dark oil. Kögl and Kostermans[11] reported that levulinic acid *p*-tolylhydrazone behaved similarly. The chlorophenylhydrazone was not analyzed.

2-Methyl-7-chloro-3-indoleacetic Acid.—A mixture of 3.0 g. (0.012 mole) of freshly prepared *o*-chlorophenylhydrazone and 15 g. of zinc chloride was heated at 100° for one hour, and the melt was dissolved in 50 cc. of 1 *N* hydrochloric acid solution. The brown oil which separated was extracted with two 100-cc. portions of ether. The ether extract was dried with Drierite and evaporated. The residual brown oil was refluxed for forty minutes with 25 cc. of 10% methanolic potassium hydroxide.

After addition of 50-cc. of water, the methanol was removed under reduced pressure by distillation. The aqueous solution was extracted once with ether, and acidified with hydrochloric acid solution, whereupon a brown oil precipitated. This was taken up in ether and shaken with half-saturated sodium bicarbonate solution. The bicarbonate layer was separated and acidified. The brown oil which resulted was extracted from its aqueous suspension with four 50-cc. portions of ether. The combined ether extracts were dried with Drierite and the ether was distilled off under reduced pressure. The residue was dissolved in acetic acid, decolorized with Norit and concentrated in a vacuum desiccator over sodium hydroxide. The solid obtained was 0.8 g. (30%) with a m. p. of 157–159°. The material was recrystallized thrice from benzene, and once from benzene with addition of hexane after decolorization. There resulted white slender needles of m. p. 164–164.5°.

Anal. Calcd. for $C_{11}H_{10}O_2NCl$: C, 59.06; H, 4.51; N, 6.26; neut. equiv., 223.5. Found: C, 59.45; H, 4.47; N, 6.12, 6.36; neut. equiv. (phenolphthalein), 226, 225. A 7.5-g. portion of ester hydrazone, treated as above, yielded 2.7 g. (43%) of crude product.

The products gave a test with Ehrlich reagent which was negative in the cold but positive upon warming.

Ethyl Levulinate *p*-Chlorophenylhydrazone.—This compound was prepared in 63% yield in the same way as the *o*-chlorophenylhydrazone by use of the *p*-chlorophenylhydrazine.[8] The unstable product, when freshly prepared, had a m. p. of 104–106°. An earlier preparation of this compound[12] recorded a m. p. of 112–113°.

2-Methyl-5-chloro-3-indoleacetic Acid.—Six grams (0.022 mole) of crude ester was mixed thoroughly with 36 g. of zinc chloride and heated in an oil-bath at 125–135° for one hour. The solidified melt was distributed between 80 cc. of 1 *N* hydrochloric acid and 100 cc. of ether. The acid layer was further extracted with ether until a negative test with Ehrlich reagent was obtained (three 100-cc. portions of ether). The combined ether extracts were evaporated, after drying, and the residue was refluxed for twenty minutes with a solution of 3.0 g. of potassium hydroxide in 25 cc. of methanol.

The solvent was diluted with 50 cc. of water, and the alcohol removed under vacuum. The solution was extracted with 100 cc. of ether and the extract was discarded. The solution was then acidified with hydrochloric acid and the oily liquid was extracted with ether until the indole test was negative. The substance was shaken from the ether into 100 cc. of half-saturated sodium bicarbonate solution, which was separated and carefully acidified. The oily precipitate was extracted with four 100-cc. portions of ether. The extract was dried and the ether was distilled off from a residue of 2.2 g. (45%) of m. p. 183–186° (dec.). Recrystallization from benzene with addition of hexane gave 1.8 g. of m. p. 190° (dec.). Another recrystallization did not raise the m. p.

Anal. Calcd. for $C_{11}H_{10}O_2NCl$: C, 59.06; H, 4.51; N, 6.26; neut. equiv., 223.5. Found: C, 58.94; H, 4.34; N, 6.36, 6.37; neut. equiv., 221, 224.

The acid was soluble in alcohol, ether and benzene, insoluble in water and hexane.

Ethyl Levulinate 2,4-Dichlorophenylhydrazone.—A hot solution of 9.3 g. (0.044 mole) of 2,4-dichlorophenylhydrazine hydrochloride,[13] 30 g. of acetic acid and 4.5 g. of sodium acetate in 100 cc. of water was added to a solution of 7.5 g. (0.052 mole) of ethyl levulinate in 200 cc. of water. The light brown oil which separated crystallized on cooling. The crystals were collected, washed with ethanol, and dried in a vacuum desiccator. The yield was 12.2 g. (91%), m. p. 74–76° (dec.). This hydrazone, also, decomposed in the air.

2-Methyl-5,7-dichloro-3-indoleacetic Acid.—Ten grams (0.033 mole) of ester hydrazone was heated with 50 g. of anhydrous zinc chloride at 165–170° for one hour. The solidified melt was distributed between 100 cc. of ether and 100 cc. of 1 *N* hydrochloric acid. The acid solution was extracted with three 100-cc. portions of ether. The combined ether extracts were dried and the ether was evaporated. The residue was refluxed with 5 g. of potassium hydroxide dissolved in 50 cc. of methanol for twenty minutes. None of the extracts gave a positive indole test.

After addition of 50 cc. of water, the methanol was removed under reduced pressure. The basic solution was extracted with ether, and the extract discarded. The solution was then acidified with dilute hydrochloric acid and the oil which separated was extracted with three 100-cc. portions of ether. The combined extracts were shaken with 100 cc. of half-saturated sodium bicarbonate solution, the latter separated, carefully acidified, and extracted with three 100-cc. portions of ether. After drying, the extract was concentrated to 3.2 g. (38%) of solid of m. p. 215° (dec.). Recrystallization from benzene by addition of hexane raised the m. p. to 220–221° (dec.).

Anal. Calcd. for $C_{11}H_9O_2NCl_2$: C, 51.16; H, 3.52; N, 5.43; neut. equiv., 258. Found: C, 50.81; H, 3.33; N, 5.42, 5.36; neut. equiv., 262, 260.

Substituted Phenylhydrazones of β-Formylpropionic Acid.—The phenylhydrazones of β-formylpropionic acid were prepared from the acid[14] with the phenylhydrazines

described above, in about 60% yield. The m. p.'s and N contents of those not found in the literature are presented in Table I.

TABLE I

PHENYLHYDRAZONES OF β-FORMYLPROPIONIC ACID

Substituents of phenylhydrazine	M. p., °C. cor., dec.	Nitrogen, % Calcd.	Found
2-Nitro	155–156	17.7	17.4 17.4
2-Chloro	180–185.5	12.4	12.3 12.2
2,4-Dichloro	181–182	10.7	10.4 10.6

4,5-Dihydro-2-(*o*-nitrophenyl)-3(2)-pyridazone.—One gram (0.0042 mole) of the *o*-nitrophenylhydrazone of β-formylpropionic acid was dissolved in concentrated sulfuric acid. After twenty-four hours at room temperature, the solution was poured into a large amount of water. The aqueous solution was extracted with ether, and the ether extract dried with Drierite. The ether was allowed to evaporate and the residue crystallized from hot benzene. There was obtained 0.5 g. (54%) of crystals of m. p. 99–102°. Several recrystallizations from ethanol with addition of water raised the m. p. to 101.5–102°. The compound was not soluble in 5% hydrochloric acid solution, nor immediately soluble in cold 5% sodium hydroxide solution. It dissolved slowly in cold, rapidly in hot, sodium hydroxide solution to give a deep red-brown solution. The color of the solution changed to yellow upon acidification. Analysis indicated this compound to be the pyridazone.

Anal. Calcd. for $C_{10}H_9O_3N_3$: N, 19.2. Found: N, 19.4, 19.2.

Acknowledgments.—Dr. S. W. Loo, now of the Botany Department of the University of Peking, was very helpful in the testing of the compounds. We are indebted to General Mills for a generous supply of technical grade glutamic acid.

Summary

The preparation of a series of substituted 2-methyl-3-indoleacetic acids and of a series of substituted phenylhydrazones of β-formylpropionic acid has been described.

Relative Rates of Propylation of Monoalkylbenzenes

BY FRANCIS E. CONDON

Repeated observations by many workers that monoalkylation of benzene is accompanied by considerable polyalkylation have indicated that aromatic alkylation, like halogenation[1] and nitration,[2] is faster for an alkylbenzene than for benzene.[3] As indicated by Francis and Reid,[4] the rate of alkylation of a monoalkylbenzene relative to that of benzene can be evaluated from the composition of the reaction mixture. Although they favored the view that the rates are equal, some of their calculations showed that, under some conditions, benzene appeared to be twice as readily ethylated as ethylbenzene.[5] They pointed out, however, that this may not represent the true relative reactivities of benzene and ethylbenzene because the reaction mixture was not homogeneous and because of the possibility of simultaneous dealkylation of polyethylbenzenes.

In the work reported herein, the rates of propylation of toluene, ethylbenzene, cumene and *t*-butylbenzene relative to the rate of propylation of benzene were determined, in competition-type experiments, in homogeneous reaction mixtures and under conditions which were shown to be ineffective for dealkylation of the polyisopropylbenzenes produced. In one series of runs, boron fluoride etherate, which is completely miscible with these hydrocarbons, was used as a catalyst. In other runs, aluminum chloride was the catalyst and nitromethane was the solvent.[6]

(4) Francis and Reid, *Ind. Eng. Chem.*, **38**, 1194 (1946).

(5) Coincidentally, relative rates calculated from the data of Slanina, Sowa and Nieuwland, THIS JOURNAL, **57**, 1547 (1935), indicate that benzene is apparently about twice as readily propylated as cumene.

I. Experimental Part

Materials.—Commercial C. P. benzene and toluene were distilled, discarding the first and last ten per cents., approximately.

Ethylbenzene, *p*-cymene (both Eastman Kodak Co. White Label) and *t*-butylbenzene (from hydrogen fluoride alkylation of benzene with isobutylene) were distilled in a Podbielniak Hypercal column with Heligrid packing[7]; only middle fractions of constant boiling point were used.

Nitromethane from the Commercial Solvents Corporation was distilled from an ordinary Claisen flask and the first and last ten per cents., approximately, were discarded.

Boron fluoride etherate was obtained from Eastman Kodak Company. The formula $BF_3 \cdot (C_2H_5)_2O$ was assumed.

Reagent quality anhydrous aluminum chloride was used.

The propylene was a high-purity product of Phillips Petroleum Company.

Alkylation Procedure.—Alkylation was carried out in a 500-cc. flask provided with a mercury-sealed Hershberg stirrer,[8] an inlet tube for propylene, a thermometer, and a reflux condenser, the top of which communicated through a Drierite-filled drying tube with a water-bubbler that indicated any escape of propylene. The flask was charged with a mixture of 100–150 g. of aromatic hydrocarbons and boron fluoride etherate or nitromethane and aluminum chloride. The stirrer was started and the

(6) Schmerling, paper presented before the Petroleum Division, ACS Meeting, New York, September, 1947.

(8) Hershberg, *ibid.*, **8**, 313 (1936).

temperature of the mixture was adjusted to 40° by a water-bath. Propylene, dried with Drierite, was introduced above the surface of the mixture only as rapidly as it was absorbed. After two and one-half to five hours in the boron fluoride runs, or one-half to three hours in the aluminum chloride runs, the addition of propylene was stopped, and the catalyst was washed out with water and with sodium hydroxide solution. Enough of the latter was used to remove all nitromethane. After a final wash with water, the mixture was dried with calcium chloride. Tests showed that this rather extensive treatment did not alter the composition of mixtures of aromatic hydrocarbons; and recoveries after fractional distillation quite generally reached 96–97 mole per cent. of the aromatics charged.

Analytical Procedure.—The products were analyzed by fractional distillation in a Podbielniak Hypercal column. Cut points were selected on the basis of analyses of mixtures of known composition. A high-boiling residue, generally less than 10% of the material distilled, was not completely analyzed, but its molecular weight was determined cryoscopically in benzene or, in many cases, was estimated from its probable composition as a mixture of polyalkylbenzenes, so that the composition of the total mixture could be computed in mole fractions.

Calculations.—The relative rate of propylation (benzene = 1) was calculated for toluene, ethylbenzene and *t*-butylbenzene by the well-known formula[2]

$$k'/k = \log (c'/c_0')/\log (c/c_0)$$

derived from the rate equations for irreversible propylation

$$dc/dt = -k(C_3H_6)c \text{ and } dc'/dt = -k'(C_3H_6)c'$$

in which c_0 and c, and c_0' and c', are initial and final mole fractions of benzene, and of alkylbenzene, respectively, in the hydrocarbon part of the reaction mixture. The relative rate of propylation of cumene was evaluated from the formula

$$\log (c + c' - (k'/k)c') = (k'/k) \log c$$

which was derived (for a reaction mixture initially containing no cumene) from the rate equations

$$dc/dt = -k(C_3H_6)c \text{ and } dc'/dt = k(C_3H_6)c - k'(C_3H_6)c'$$

and which is equivalent to the formula derived by Francis and Reid.[4]

Tests for Dealkylation.—Three experiments were made to determine if dealkylation of polyisopropylbenzenes occurred during propylation of benzene, inasmuch as such dealkylation would lead to too low a relative rate of propylation of cumene.

Experiment 1.—A homogeneous mixture of benzene (508 g., 76.0 mole per cent.), polyisopropylbenzenes (mol. wt. = 200; mainly triisopropylbenzenes obtained by vacuum distillation of accumulated residues boiling above 215° from benzene–propylene alkylations) (125.5 g., 7.3 mole per cent.), nitromethane (83.0 g., 15.7 mole per cent.), and aluminum chloride (10.8 g., 1.0 mole per cent.) was stirred at 40° for several hours and samples were withdrawn at intervals for analysis. The results were

Time, minutes	0	33	95	181	323	555
Composition, wt. %						
Benzene	79.6	79.6	79.8	80.2	79.7	79.2
Diisopropylbenzenes	1.5	2.1	2.0	1.6	1.9	2.2
Residue	18.9	18.3	18.2	18.2	18.4	18.6

No cumene was found in any of the samples, nor did the composition of the mixture apparently change.

Experiment 2.—A homogeneous mixture of benzene (304.6 g., 59.9 mole per cent.), polyisopropylbenzenes (76.2 g., 5.8 mole per cent.), nitromethane (111.0 g., 27.9 mole per cent.), and aluminum chloride (55.7 g., 6.4 mole per cent.) was treated as in Expt. 1. The results of analysis of samples were

Time, minutes		0	33	136
Composition, wt. %	Benzene	80.0	77.9	76.3
	Cumene	..	2.4	5.1
	Diisopropylbenzenes	..	0.9	3.2
	Residue	20.0	18.8	15.4

Depropylation took place under these conditions. The conditions of this experiment were, however, more conducive to depropylation than the conditions used in the propylation experiments. The concentrations of both the polyisopropylbenzenes and the catalyst were higher than in the propylation runs.

Experiment 3.—A homogeneous mixture of benzene (61.3 mole per cent.), *p*-cymene (21.7 mole per cent.), nitromethane (15.8 mole per cent.), and aluminum chloride (1.2 mole per cent.) was stirred at 65° and propylene was passed into it for two hours. The catalyst was washed out with water and the nitromethane with sodium hydroxide solution, and the alkylate was dried and analyzed by fractional distillation. No toluene was found, indicating that depropylation of the cymene did not take place; furthermore, the recovered cymene was pure *p*-cymene, with no *o*- and no *m*-cymene, indicating that no depropylation of the isopropylcymenes produced in the reaction took place.

In addition, it is noteworthy that no xylenes were found among the products of propylation of toluene-containing mixtures, indicating that no demethylation took place during propylation; and no diethylbenzenes were found among the products of propylation of ethylbenzene-containing mixtures, indicating that no deëthylation took place.

II. Results

The results from 51 competition experiments are summarized in Table I. In the first row are averages of two runs each in which the reaction mix-

TABLE I

RELATIVE RATES OF PROPYLATION AT 40° (BENZENE = 1)

Catalyst	Toluene	Ethylbenzene	Cumene	*t*-Butylbenzene
Boron fluoride	2.09 ± 0.10	1.73 ± 0.06	....	1.23 ± 0.06
Aluminum chloride	2.10 ± 0.15	1.81 ± 0.14	1.69 ± 0.05	1.40 ± 0.16

tures contained 27 mole per cent. boron fluoride and 27 mole per cent. diethyl ether. In the second row are averages of from 7 runs in the case of *t*-butylbenzene to 19 runs in the case of cumene, for aluminum chloride concentrations of 1.0 to 7.7 mole per cent. and nitromethane concentrations of 12.7 to 42 mole per cent. No dependence of the rate ratios on either of these concentrations could be found in runs in which one was varied while the other was held constant, although the results for any one compound were quite scattered, as is indicated by the rather large average deviation from the mean. This scattering is attributable to limitations in the analytical method (fractional distillation). The fact that the relative rates were independent of the aluminum chloride concentration, within experimental error, whereas the rate of depropylation was demonstrated to be dependent on the aluminum chloride concentration (see Experimental Part), indicates that not enough depropylation was taking place in those runs in which the conditions were most favorable for it (high aluminum chloride concentration and long contact time) to influence detectably the apparent relative rates. (Noteworthy here are results of some preliminary attempts to measure relative rates of alkylation with isobutylene. It appeared that *t*-butylbenzene was three to six times as readily butylated as benzene when the aluminum chloride concentration was about 4 mole per cent. but 12–14 times as readily when the catalyst concentration was only 1.3 mole per cent. The lower apparent relative rate is attributable to a greater amount of dealkylation, which would be easier for a *t*-butyl than for an isopropyl group, in the presence of the greater catalyst concentration.)

III. Discussion

The relative rates of propylation of the alkylbenzenes listed in Table I are in the same order as their relative rates of chlorination and bromination.[1] In order to account for this order of reactivity, both steric hindrance in the ortho position, increasing with the size of the alkyl group, and a no-bond resonance involving the α-hydrogen atoms of the alkyl group have been suggested.[9]

(9) See Berliner and Bondhus, THIS JOURNAL, **68**, 2355 (1946), for a review and additional references.

The most important factor in propylation appears to be steric hindrance in the ortho positions. The propylation of toluene gives 31% *o*-, 25% *m*-, and 44% *p*-cymene,[10] and the propylation of cumene gives 7% *o*-, 43% *m*-, and 50% *p*-diisopropylbenzene[11]; and, relative to one position in benzene, the rate of propylation of toluene is $6 \times 2.10 = 12.6$, and that of cumene is $6 \times 1.69 = 10.1$; so that the relative rate of propylation of toluene in an ortho position is $12.6 \times 0.31/2 = 1.95$, and the relative rate of propylation of cumene in an ortho position is $10.1 \times 0.07/2 = 0.35$; similarly, the relative rates of propylation of toluene and cumene in a meta position are $12.6 \times 0.25/2 = 1.6$ and $10.1 \times 0.43/2 = 2.2$, respectively, and in the para position, $12.6 \times 0.44 = 5.5$ and $10.1 \times 0.50 = 5.1$, respectively.[12] That is, the rates of propylation in the meta and para positions are approximately the same for toluene and cumene, whereas the rate of propylation in an ortho position of cumene is only about one-sixth the rate of propylation in an ortho position of toluene, and the difference, which is attributable to steric hindrance, is sufficient to account for all the difference in reactivities of toluene and cumene.

Acknowledgment.—Phillips Petroleum Company made possible the publication of this work.

Summary

The relative rates of propylation of benzene, toluene, ethylbenzene, cumene and *t*-butylbenzene are 1, 2.1, 1.8, 1.7 and 1.4, respectively. Steric hindrance in the ortho positions, increasing with the size of the alkyl group, appears to be the principal cause of the differences in rates of propylation of the alkylbenzenes.

Interchange Reactions of Orthothioformates and Mercaptoles

BY W. E. MOCHEL, C. L. AGRE[1] AND W. E. HANFORD[2]

Interchange reactions of carboxylic esters and alcohols have been known for some years,[3] and the related interchanges in the cases of ortho esters[4] and of ketals[5] have been reported. Work in this Laboratory has now shown that oxygen-for-sulfur interchanges in orthiothioformates and mercaptoles[6] can be readily carried out, furnishing a convenient means of preparation of orthoformates and ketals.[7] Thus, in the presence of a catalyst such as zinc chloride the following reactions take place.

$$HC(SC_2H_5)_3 + 3ROH \longrightarrow HC(OR)_3 + 3C_2H_5SH \quad (1)$$

$$(CH_3)_2C(SC_2H_5)_2 + 2ROH \longrightarrow (CH_3)_2C(OR)_2 + 2C_2H_5SH \quad (2)$$

Since the orthothioformates and mercaptoles are easily prepared in nearly quantitative yields, the corresponding orthoformates and ketals frequently can be prepared more easily by the above reactions than by more conventional means. These interchanges were found to be equilibrium reactions and can be shifted to give high yields of the desired ortho esters or ketals by removal of the low-boiling thiol. Evidence for the reverse of reaction (1) above exists in the reported preparation of an orthothioformate from ethanedithiol and ethyl orthoformate,[8] with the liberation of ethanol, but the equilibrium nature of the reaction was not demonstrated. These reactions are normally very slow, but they may be greatly accelerated by Friedel–Crafts type catalysts. While strong acids, such as sulfuric or *p*-toluenesulfonic, at elevated temperatures were found to decompose the oxygen ortho esters in some cases,[9] forming normal esters and the corresponding ethers, such catalysts were satisfactory for the preparation of ketals. However, the ketals should not be worked up in the presence of acid since they may be converted to unsaturated ethers.[10]

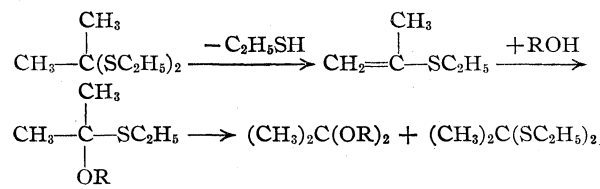
The mechanism of these reactions has not been established. However, from the type of catalyst involved it would appear that the mechanism is ionic in nature and may be identical with that for the acid-catalyzed formation of ketals from ketones and orthoformates. Post has proposed a mechanism for the latter reaction[11] and, by analogy, the following stepwise addition mechanism may be postulated for the reaction of an alcohol with ethyl orthothioformate.

$$HC(SC_2H_5)_3 + H^+ \rightleftharpoons HC(SC_2H_5)_2S(H^+)C_2H_5 \rightleftharpoons$$

$$C_2H_5SH + HC^+(SC_2H_5)_2 \xrightleftharpoons{ROH} HC(SC_2H_5)_2OR + H^+$$

$$HC(SC_2H_5)_2OR \rightleftharpoons HC(SC_2H_5)(OR)_2 \rightleftharpoons HC(OR)_3$$

In support of the proposed stepwise addition mechanism in the mercaptole interchange is the the isolation of a high-boiling, sulfur-containing compound believed to be the monothioketal. In the mercaptole reaction, however, there is the possibility of formation of an unsaturated sulfide by the elimination of one mole of thiol,[12] followed by the addition of alcohol to give a monothioketal[13] which could disproportionate to yield the ketal and mercaptole.[14] However, no sulfur compounds boiling in the range of the expected unsaturated sulfides were found in the reaction mixtures.



Experimental

Ethyl Orthoformate.—A mixture of 98 g. (0.5 mole) of ethyl orthothioformate[15] and 92 g. (2.0 moles) of absolute ethanol was refluxed with 2 g. of fused zinc chloride for ten hours while 90% of the theoretical amount of ethanethiol was slowly removed by distillation at 35–37° through a 20-inch Fenske ring-packed column with adjustable take-off head. The remaining material was distilled and, after removal of the excess ethanol, 49 g. (66% yield) of ethyl orthoformate was collected at 144–146°, $n^{24}D$ 1.3917.

Butyl Orthoformate.—A mixture of 39.2 g. (0.2 mole) of ethyl orthothioformate and 59 g. (0.8 mole) of *n*-butanol was refluxed with 1 g. of fused zinc chloride for six hours during which time 91% of the theoretical thiol was liberated and removed by distillation. The reaction mixture was cooled and washed with water to remove the catalyst. The product was dried with anhydrous sodium sulfate and distilled to yield 12 g. (46%) of butyl orthoformate distilling at 240–244°, $n^{23}D$ 1.4198.

From a mixture of 58.8 g. (0.3 mole) of ethyl orthothioformate and 89 g. (1.2 moles) of *n*-butanol refluxed

(15) Prepared in nearly quantitative yield from ethyl formate and ethanethiol by the method of Holmberg, *Ber.*, **40**, 1740 (1907).

with 1 ml. of concentrated sulfuric acid for thirty minutes and then distilled there was obtained nearly the theoretical yield of ethanethiol at 35–40°. Fractionation of the residue directly gave 30 g. (98% yield) of *n*-butyl formate, b. p. 107–110°, $n^{25}D$ 1.4896, and 36 g. (93%) of *n*-butyl ether, b. p. 140–141°, $n^{25}D$ 1.4005.

2,2-Dimethoxybutane.—A mixture of 178 g. (1 mole) of 2,2-di-(ethylmercapto)-butane,[16] 128 g. (4 moles) of methanol and 3 g. of hydrogen chloride was heated under a 20-inch Fenske ring-packed column with adjustable take-off head, and ethanethiol was removed as formed. After fourteen hours, 119 g. of distillate had been removed at 35–40°. By iodine titration this was shown to contain 85% of ethanethiol, indicating that 82% of the theoretical ethanethiol had been removed. The residue was made very slightly alkaline with sodium methoxide and distilled. At 40–65° there was collected 98 g. of methanol and methanol/ketal binary. The column was then put under 100 mm. pressure and a fraction taken off at 50–51° (100 mm.). This consisted of 58 g. (49% yield) of 2,2-dimethoxybutane,[17] $n^{31}D$ 1.3878. An additional 5 g. was obtained by pouring the methanol fraction into a large volume of water, separating and distilling the organic layer. Assuming a stepwise exchange with a complete first step, the yield of ketal isolated was 83% of theoretical as indicated by thiol obtained. A high boiling fraction, 93–102° (100 m.), was obtained by further distillation. This contained sulfur and liberated more thiol on treatment with methanol and acid; it presumably was the 2-methoxy-2-(ethylmercapto)-butane but it was not purified and analyzed.

(16) Mann and Purdie, *J. Chem. Soc.*, 1549 (1935).

(17) Killian, Hennion and Nieuwland, THIS JOURNAL, **56**, 1384 (1934).

In another experiment using *p*-toluenesulfonic acid as catalyst and a 500% excess of methanol, a 91% yield of a 2,2-dimethoxybutane/methanol constant boiling mixture containing 25% of the ketal was obtained at 65°. The pure ketal was isolated by drowning the mixture in water, separating and distilling the organic layer.

Following the standard procedure for the preparation of mercaptoles, 2,2-di-(cyclohexylmercapto)-butane was prepared in 57% yield; b. p. 175–176° (3 mm.), $n^{23}D$ 1.5305.

Anal. Calcd. for $C_{16}H_{30}S_2$: S, 22.37. Found: S, 21.92.

In a 1-liter flask was placed 160 g. (0.55 mole) of 2,2-di-(cyclohexylmercapto)-butane, 110 ml. of methanol (500% excess) and 8.1 g. of dry *p*-toluenesulfonic acid. This mixture was heated under a small column and distillate slowly collected at 64°. After two and one-half hours an additional 700 ml. of methanol was added. At the end of five and one-half hours the temperature had reached 70° and the distillate amounted to 210 g. Redistillation of this distillate yielded 204 g. of a 2,2-dimethoxybutane/methanol mixture boiling at 65°, $n^{23}D$ 1.3330. This binary contained 10% of the ketal, or 31% of the theoretical yield.

Summary

It has been found that alcohols react with orthothioformates or mercaptoles in the presence of acidic catalysts to yield the corresponding orthoformates or ketals, or their decomposition products.

The Exchange Reaction between Methane and Deuteromethanes on Silica–Alumina Cracking Catalysts

BY G. PARRAVANO, E. F. HAMMEL[1] AND HUGH S. TAYLOR

The following research originated in a discussion at the Gibson Island Conference on Catalysis, June 1941, in which one of us (H. S. T.) suggested that the cracking of petroleum hydrocarbons on silica–alumina catalysts should be initiated by the breaking of, at least, one C–H bond in the hydrocarbon molecule. Otherwise, it was not possible for the carbon core of a hydrocarbon chain to come within the radius of chemical interaction with the catalyst surface. The plausibility of such a view is at once evident by inspection of a molecular model of a hydrocarbon molecule, as constructed with the Fisher–Hirschfelder atom models. At the same time, the suggestion was viewed by some with skepticisim, since it was believed that the idea could not be put to experimental test.

A study of the exchange reaction between hydrocarbons and deuterohydrocarbons in contact with silica–alumina catalysts permits, however, a direct and convincing test of the idea, and under quite stringent conditions.

It is generally agreed, from the known stability of the methane molecule, that if exchange can be demonstrated between methane and deuteromethanes at temperatures below those at which catalytic cracking of higher hydrocarbons is carried out, there can be no reasonable doubt that, in the cracking reaction, the C–H bonds must be readily and freely broken as postulated. The preliminary exploration of this reaction was carried out by Mr. E. F. Hammel in 1941. The quantitative examination of the process is recorded in the following paragraphs.

(1) Present address: P. O. Box 1663, Santa Fe, New Mexico.

Experimental Details

Materials.—Methane from a commercial tank was used, without purification. A mass spectrographic analysis showed a purity of ~96%. Deuteromethanes were prepared by means of the reaction between heavy water and aluminum carbide. The deuterium oxide employed came from our supply of heavy water. The deuterium oxide distilled over C. P. aluminum carbide, and the temperature was raised to 70°. At this temperature the reaction proceeds very smoothly. It was found that, at room temperature, no reaction takes place, in agreement with Urey and Price.[2] The gas collected showed with the mass spectrometer the following composition: CD_4 40%, CD_3H 5.7%, CH_2D 1%, CH_3D 0.3%, CH_4 53%.[3]

(2) H. C. Urey and D. Price, *J. Chem. Phys.*, **2**, 300 (1934).

(3) This gas composition is abnormal. It can only have been produced by successive interactions of H_2O and of D_2O with the carbide. Since the heavy water used was of high purity we can only conclude that the carbide sample used held tenaciously by adsorption the light water and that this reacted first before the heavy water came in contact with the catalyst.

Ethylene and hydrogen were supplied from commercial tanks, without any further purification.

The silica–alumina cracking catalyst, C-825-C, was a high-quality commercial silica–alumina catalyst kindly furnished by the M. W. Kellogg Company.

Analytical Procedure.—The progress of the reaction was followed by measurements of the intensity peaks for each mass. The mass spectrometer used was of the 60° Nier type.

Experimental Procedure.—Known amounts of the deuteromethane mixture were diluted with an equal amount of methane. The following composition resulted for the reacting mixture: CD_4 20.2%, CD_3H 2.8%, CD_2H_2 0.5%, CH_3D 0.15%, CH_4 76.2%. The mixture of reacting gases was introduced into a horizontal cylindrical Pyrex vessel of 100 cc. volume which contained a layer of catalyst. Equal amounts of gas were withdrawn from time to time and transferred to the analytical vessel.

All the runs were carried out at a pressure of 150 mm.

Experimental Results.—The data obtained at 345° are summarized in Table I, in which the change in concentration for masses 19 and 20 is expressed in relative values of the mass spectrometer intensity peaks. These data serve to show that the exchange takes place at that temperature. At 384° the exchange takes place much faster. By plotting the logarithms of the concentrations of masses 20 and 19 as a function of the time at the two temperatures 345 and 384° straight lines result from which the value for the activation energy, E, has been calculated to be 13 kcal.

Since the exchange reaction is indicative of dehydrogenation activity with the silica–alumina catalyst a special test was made of its hydrogenating activity. On the same catalyst it was found that the hydrogenation of the ethylenic double bond occurs very rapidly at 345°, using an equimolecular mixture of ethylene and hydrogen.

TABLE I

RATES OF EXCHANGE FOR CD_4 AND CHD_3

Hours								
0	6	24	48	72	96	120	168	192
Ratio Mass 20/Mass 19								
6.25	3.75	1.39	0.65	0.51	0.48	0.47	0.48	0.51

General Discussion

From the study of the interaction of methane and deuteromethanes on silica–alumina catalyst it is concluded that exchange of C–H bonds occurs freely in a methane molecule in contact with cracking catalysts. K. Morikawa, W. S. Benedict and H. S. Taylor[4] demonstrated that the same exchange also occurs between CH_4 and CD_4 on a nickel catalyst at temperatures as low as 138° with an activation energy of 19 kcal. The fact that the exchange of C–H bonds of a hydrocarbon molecule occurs at temperatures far below the cracking temperatures appears to be convincing evidence that the first step of a cracking process is a dehydrogenation of the hydrocarbon molecule. The dehydrogenated molecule can be better held and strongly attached to the catalyst surface by catalyst-carbon linkages. The second step, which occurs at higher temperature, is the C–C bond scission, and the consequent formation of lighter hydrocarbon fragments, which then evaporate from the catalyst as saturated or unsaturated molecules dependent on the hydrogen concentration on the surface. A direct test of these two steps in the cracking of hydrocarbons was also obtained by K. Morikawa, W. S. Benedict and H. S. Taylor[5] in the case of nickel catalyst, from kinetic measurements. They showed that in the case of ethane and propane the two reactions of exchange and C–C bond scission occur at different rates in separable temperature ranges, with different dependence on the pressure of hydrogen.

In the case of cracking catalysts it can therefore also be concluded that the activated adsorption of hydrocarbons is a dissociative adsorption. On the same catalyst the ethylenic double bond is easily hydrogenated.

Acknowledgment.—One of us (G. P.) wishes to express his appreciation for fellowship aid in the prosecution of this work from a postwar Italo-American Committee for Italian Scholars and for the opportunities thereby provided in the U. S. A.

Summary

1. The exchange reaction between methane and deuteromethanes on silica–alumina cracking catalysts occurs measurably at temperatures of 345° and higher.

2. The activation energy between 345 and 384° is 13 kcal.

3. A mechanism for the cracking process of hydrocarbons is postulated. This mechanism involves two steps: scission of C–H bonds, and then scission of C–C bonds.

4. Ethylene hydrogenation takes place on the same catalyst in the same temperature range.

Structure and Activity of the Chromium–Aluminum Oxide Catalyst System

BY ROBERT P. EISCHENS[1] AND P. W. SELWOOD

This paper describes the continuation of structure studies on the chromium–aluminum oxide catalyst system.[2] The change of surface area, as a function of chromium concentration, has been determined. Activity tests have been run, using the cyclization of *n*-heptane as the test reaction, and the results have been correlated with magnetic data previously reported.[3]

Experimental

Surface areas were obtained on the undiluted catalysts by low temperature nitrogen adsorption and the BET equation.

The activity tests were run on a series of catalysts which had been prepared by impregnating γ-alumina with chromic acid solution, followed by reducing with hydrogen.[3] The catalysts varied in concentration from 1.9% to 34.5% chromium after reduction. All catalysts with a chromium concentration of more than 2% were diluted down to 2% with γ-alumina before pelleting. The pellets were 4 mm. long and 5 mm. in diameter. The pelleted catalysts were heated at 500° for twenty hours as a pretreatment, and to burn off the stearic acid used as an aid in pelleting.

The catalytic apparatus was built according to specifications furnished by Dr. H. Pines of this Laboratory. The reactor block was made of aluminum-bronze and was heated electrically. Temperature control was obtained by means of the differential expansion of the block and a porcelain rod. A small bellows type pump was used.

The reactor was made of 20-mm. Pyrex tubing. It was 80 cm. long and had ground glass connections at both ends. The reactor top has two inlets, one for feed and one for the regeneration gas. A thermowell extended from the reactor top down into the catalyst bed. The lower 20 cm. of the reactor was filled with porcelain rings. The space above the catalyst bed was packed with Berl saddles.

The *n*-heptane, obtained from the Westvaco Chlorine Products Company, had a boiling point of 98.44°, a freezing point of −90.66°, a density of 0.68382 g. per ml. and a refractive index of 1.38779, 20°/D.

All tests were run at 490°. The temperature control was accurate to within two degrees. The space velocity was 50 cc. of liquid *n*-heptane per gram of chromium per hour. Since 25 g. of catalyst was used and the chromium concentration was 2%, this space velocity corresponds to a feed rate of 25 cc. per hour. The test duration was one hour.

The catalyst was regenerated and carbon determined by burning with air for ten hours at 490°. After the regeneration, hydrogen was passed through the reactor for one hour before each test was started.

The products were condensed in a water condenser and collected in a bulb cooled with ice-water. The noncondensable gases were collected over water in a calibrated bottle. The density of the gas was determined by comparing its weight with that of an equal volume of air under the same conditions.

The liquid product was analyzed for toluene by means of the refractive indices. It was assumed that everything in the product, except the toluene, had the same refractive index as *n*-heptane. A calibration curve for the analysis was obtained from a series of mixtures of toluene and pure *n*-heptane.

The results reported are the average of several runs. In each test the runs were repeated until three values were obtained in which the maximum difference was 2% toluene. This required at least four and usually five different runs because the activity of the first run in each series tended to be very low.

Results

The susceptibility isotherm for an impregnation type series is given in Fig. 1. This isotherm has been presented in a previous paper.

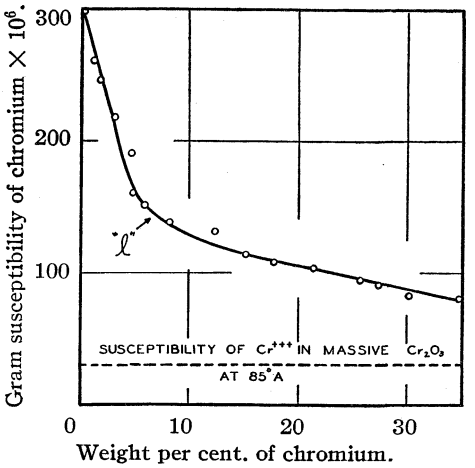

Fig. 1.—Susceptibility isotherm at 85° A. for chromia impregnated on alumina. The susceptibility of chromium in pure chromia at 85° A. is also shown.

The surface areas of catalysts of two impregnation series were measured. In one the carrier was γ-alumina; in the other it was *boehmite*. Figure 2 shows the results of these measurements.

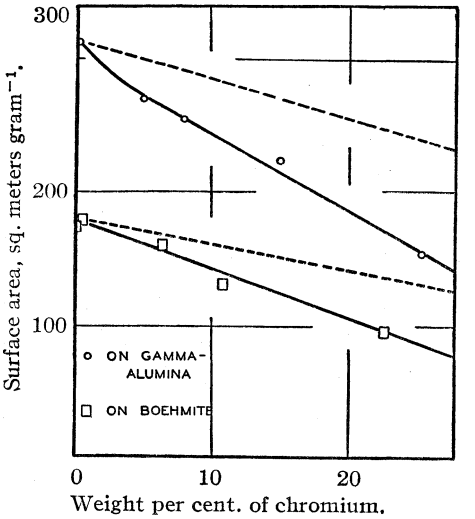

Fig. 2.—Effect of chromium concentration on surface area.

It is seen that the surface area falls off in practically a straight line for both series.

It has been shown that a point "1" of the isotherm only about one-ninth of the alumina surface could be covered by chromia and that the average chromium atom is in a crystallite about three atom layers thick.[3]

There are two possible pictures of the surface of the catalyst which could explain the fact that only a small part of the total surface is covered at the "1" point. In the first, the alumina surface is only covered in spots. Each of the spots is a crystal nucleus of chromium oxide. There are large areas of exposed alumina between the spots. A second possible representation of the surface would have a large part of the "nitrogen" area in regions inaccessible to the chromium. In this case the crystal nuclei might be touching.

The basic difference of these two extreme views lies in the manner in which they explain why only a small fraction of the alumina is covered. The first view assumes that there is enough attraction or lattice stability in the chromia nuclei so that the chromia will go together into piles rather than spread out evenly over the alumina surface. In the second case, the fraction of area covered represents all of the surface which the chromia is able to reach. The rest of the area is concealed in "caves" and "pores" and there is no exposed alumina.

If the chromia is gathered in piles on the alumina and the latter has large areas exposed, one would expect only a gradual decrease in the total area of the catalyst, as the chromium concentration is increased. At the "1" point only a small fraction of the alumina area would be covered and this decrease would be partially compensated by the area contributed by the chromia. If the entire available area were covered, it is probable that the chromia layer would cover and plug up some of the pores, making them inaccessible to the gas. In this case the area, as measured by the nitrogen, would decrease more rapidly before the "1" point than it would at higher concentrations. One would then expect a curve of area *versus* chromium concentration to have the same general shape as the susceptibility isotherm.

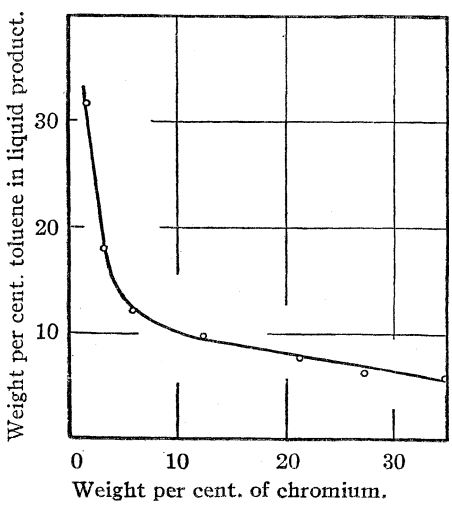

Fig. 3.—Catalytic activity as a function of chromium concentration.

The data presented in Fig. 2 shows that there is no sharp decrease in area in the low concentration region. It is, therefore, indicated that the view of the surface, as being covered with small piles of chromia, is the more nearly correct.

Since the surface area data are reported as square meters per gram of catalyst, one would expect a gradual dropping off of the area as the concentration of chromium is increased because the chromia contributes to the weight of the sample and probably has a much lower area than an equal weight of alumina.

If the assumption is made that the total area of the catalyst is due only to the alumina, one can calculate the apparent area per gram of alumina by dividing the observed area by the weight fraction of alumina. The results of these calculations are plotted by the dotted lines in Fig. 2. It is seen that, even with the above assumption, the apparent area per gram of alumina decreases as the chromium concentration is increased. This would indicate that more and more of the alumina area is covered as the concentration increases. Thus, there must be a spreading of the chromia clusters. The fact that these calculations are based on the probably invalid assumption that all of the area is due to the alumina does not invalidate the conclusion. The assumption is, in reality, the most severe test of the conclusion. If the chromia also contributes to the area, the alumina area drops off at a faster rate than indicated by the dotted line.

The results of the activity tests, reported as per cent. toluene in the liquid product, are given in Fig. 3. Pure alumina has no activity in this reaction. Since the magnetic data have been reported as susceptibility per gram of chromium, it was desirable to present the activity results so that a direct comparison could be made. To facilitate this, the same amount of chromium was used in each test. This also made it possible to have a constant space velocity without changing the pumping rate for the various samples.

On the average about 90% of the feed is recovered as liquid product. The carbon laydown accounts for a little less than 2%. Although the volume of gas formed appears to be roughly proportional to the amount of toluene in the liquid product, the weight per cent. of gas is not consistent. This is probably accounted for by the fact that small variations in the amount of cracking would not affect the volume of the gas nearly as much as they would affect the density. The cracking product gases have a much greater density than the hydrogen given off in the dehydrocyclization.

The supplementary data are given in Table I.

TABLE I

CATALYTIC ACTIVITY OF Cr_2O_3/Al_2O_3

Wt. % chromium[a]	Liters of gas[b]	Wt. % gas	Wt. % carbon[d]	Wt. % liq. prod.[d]	Wt. % toluene[c,d]
1.9/1.9	6.0	5.3	1.9	91	31.3
2.0/3.2	4.2	4.7	1.8	91	18.1
2.0/5.7	3.0	3.7	1.6	88	11.7
2.0/12.2	2.3	4.2	1.8	91	9.6
2.0/21.1	2.1	3.5	1.6	91	7.6
2.0/27.2	2.1	3.9	1.7	90	6.3
2.0/34.5	2.2	3.2	1.5	89	5.8

[a] The designation 2.0/5.7 means that the catalyst contained 2.0% Cr but that this was made by mechanically diluting a 5.7% Cr impregnate with an appropriate amount of γ-alumina. [b] 25°, 750 mm. pressure. [c] In liquid product. [d] The difference between 100 and the sum of columns 3, 4 and 5 is experimental error.

A comparison of Figs. 1 and 3 shows that there is apparently a close relationship between the activity of the chromia–alumina catalyst and the magnetic susceptibility of the chromium in the catalyst. It is important to remember that thus far this relationship has been shown to hold for a series of catalysts, the method of preparation of which is identical and which differ only in the concentrations of chromium. The only other catalysts tested were those for which the impregnation was carried out at different temperatures, as previously reported. In this case there also appeared to be a relationship between susceptibility and activity. However, these results were not extensive enough to warrant definite conclusions.

In order to discuss the relationship between the susceptibility and activity it is desirable to briefly review the work that has been done in this study of the chromium–aluminum oxide catalyst system.

First, it has been shown that the susceptibility per gram of the chromium in the catalyst varies with the concentration according to the susceptibility-composition isotherm. There is a sharp break in this isotherm at the "1" point. At concentrations below this point the slope of the curve is much greater than at higher concentrations. At this point there are important changes in the factors which determine the Weiss constant, Δ, in the Curie–Weiss law, $\chi = C/(T + \Delta)$. The Weiss constant is a measure of the interaction between electrons in adjacent atoms. The factors which determine the Curie constant (C) are also important in that the apparent valence of the chromium depends on the values of C. The shape of the isotherm has been interpreted on the basis of changes in the coördination number of chromium atoms with respect to other chromium atoms in the corundum structure. This interpretation leads to the belief that the chromia layer is three atom layers deep at the "1" point and that only a small fraction of the total alumina area is covered with chromia.

The weight of the evidence which has been gathered from many sources, such as the isotherm, Weiss constant measurements, and the effects of temperature of impregnation, heat treatment, and co-precipitation, points to the one basic fact, that the susceptibility in this system is a direct measure of the dispersion of the chromium. X-Ray studies verify these conclusions. It is commonly accepted that dispersion is an important factor, but of course not the only one, in the activity of catalysts, because it determines how much of the active element is exposed and available to the reactants. Thus, the conclusion may be drawn that the close relationship found between activity and susceptibility is due to the fact that they are both closely related to the underlying phenomenon of dispersion.

Acknowledgment.—It is a pleasure to acknowledge the support of the Sinclair Refining Company in connection with this work.

Summary

Surface area measurements have been made which, when taken together with magnetic data, support the view that at the "1" point of the susceptibility isotherm, the chromia is scattered over the surface of the alumina in small piles approximately three atom layers deep. Activity tests of a series of chromium–aluminum oxide catalysts, used in the cyclization reaction, show that there is a close relationship between the magnetic susceptibility and the activity of the chromium in the catalyst.

Donor-Acceptor Bonding. IV. Ammonia-Boron Trifluoride[1]

BY A. W. LAUBENGAYER AND G. F. CONDIKE[2]

Monoammonia-boron trifluoride, $H_3N:BF_3$, is the classical example of a molecular addition compound involving donor–acceptor bonding. Its formation was first observed by Gay-Lussac[3] and the system was further investigated by Davy,[4] who reported obtaining not only the mon-ammonate, but also di- and tri-ammonates, the last two described as colorless liquids. The properties of monoammonia-boron trifluoride were studied by Mixter[5] and by Kraus and Brown,[6] and Balz and Zinser[7] reported vapor pressure data for the complex. The information in the literature is often contradictory and very incomplete.

Accordingly, the present investigation has been undertaken as a comprehensive study of the ammonia–boron trifluoride system. The properties of monoammonia-boron trifluoride, the only addition compound found to exist between ammonia and boron trifluoride, have been studied in detail and the consequences of donor–acceptor bonding in this sytem are discussed.

Experimental

Determination of Mole Combining Ratio.—Known amounts of ammonia and boron trifluoride were brought together in an evacuated glass apparatus in mole ratios varying from 0.4:1 to 3:1 and allowed to come to equilibrium at 25°. The combining ratio of the two gases was calculated from the residual pressure of the system by assuming that the uncombined gas, present in excess, obeys the ideal gas laws. Table I lists the results, which clearly show that only the compound monoammonia–boron trifluoride, $H_3N:BF_3$, was formed. It accumulated as a white solid when the gases were mixed and at no time was any transparent liquid produced.

TABLE I

Moles NH_3 added per mole BF_3	Residual pressure, mm.	Moles NH_3 combining per mole BF_3
0.399	71.6	0.994
1.000	1.4	0.996
1.440	49.6	1.020
1.990	112.2	1.004
2.530	174.6	1.030
2.950	225.6	1.015
		Average 1.009

Preparation and Analysis.—Ammonia-boron trifluoride was prepared in quantity by mixing anhydrous ammonia and boron trifluoride in a one-liter three-necked flask. An outlet tube was provided for excess gases, and the flask was cooled with ice water. The vessel was first swept out with ammonia and then a slow flow of this gas was maintained. Boron trifluoride was admitted at such a rate that approximately equimolar quantities of the reactants were provided. Since any uncombined boron trifluoride fumed immediately in contact with moist air, it served as its own indicator at the outlet tube. The addition compound accumulated in the reaction flask as a white powder.

To establish the composition of the product, ammonia was liberated by boiling the compound with an excess of a concentrated solution of sodium hydroxide, and was then absorbed and titrated in the usual manner. Boron was determined as boric acid by dissolving a weighed sample of the product in a slight excess of dilute sodium hydroxide and titrating the solution by the mannitol method, in which paranitrophenol was used as the first and phenolphthalein as the second indicator.

Anal. Calcd. for $H_3N:BF_3$: NH_3, 20.05; B, 12.75. Found: NH_3, 20.05, 19.90, 19.85; B, 12.80, 12.72, 12.65.

Melting Point and Density.—The melting point of ammonia-boron trifluoride was found to be 163 ± 1°, the determination being made rapidly on a Dennis–Shelton melting point bar[8] in order to avoid serious thermal decomposition. The density was determined pycnometrically to be 1.864^{25}_4 using benzene as the immersion reference liquid.

Solubility, Polarity and Molecular Weight in Solution.—The solubilities of the compound in several solvents other than water were tested microscopically by observing the progress of evaporation of the solvent from a well-stirred mixture of a drop of the solvent and a small amount of the solid compound. In solvents of low dipole moment (0.00 to 1.12 debye units), such as benzene, carbon disulfide, carbon tetrachloride and diethyl ether, the compound appeared to be insoluble; slight solubility in cyclohexanol (1:5) and somewhat greater solubility in methanol (1.68) and in ethyl alcohol (1.70) were observed. These results indicate that the compound itself probably has a considerable dipole moment.

In water the solubility, quantitatively determined, proved to be 36.0 g. per 100 g. of solvent at 25°. The aqueous solution is remarkably stable at this temperature. Thus the powder X-ray diffraction pattern was unchanged by recrystallizing a sample of the compound from water. Furthermore, the molecular weights, determined cryoscopically in three aqueous solutions containing, respectively, 15.77, 8.15 and 6.04 g. of the compound per 1000 g. of water were 81.0, 83.9 and 82.4. Since the molecular weight calculated for the compound $H_3N:BF_3$ is 84.8, the latter is evidently not appreciably hydrolyzed, dissociated nor associated in aqueous solution at about 0°.

Crystallographic and X-Ray Examination.—A microscopic examination of ammonia-boron trifluoride recrystallized from water was made. The compound crystallizes in rhomb-shaped plates which exhibit symmetrical extinction. The crystals are in the orthorhombic system, a combination of prism faces (110) and basal pinacoids (001) being common. The prism–prism interfacial angles are 57°30′ ± 15′ and 121°30′ ± 15′. $2V = 90° \pm 3°$; $2E$ 146° ± 2°; OA Plane = 100. The direction of vibration of α is parallel to the b crystallographic axis, β to the a axis, and γ to the c axis. Refractive indices (white light): $\alpha = 1.335$, $\beta = 1.34$–1.35, $\gamma = 1.36$. It was dif-

3.60	Medium
3.00	Medium
2.55	Medium
2.19	Weak

Calorimetric Determination of Heat of Formation.—A Bunsen ice calorimeter was used[9] to measure the total heat effect produced at 0° by dissolving 100 cc. of gaseous boron trifluoride in diethyl ether and then introducing 100 cc. of ammonia gas into the solution. The reactions indicated by the equations took place

$$BF_3(g) + (C_2H_5)_2O(l) = (C_2H_5)_2O{:}BF_3(sol) + \Delta H$$
$$(C_2H_5)_2O{:}BF_3(sol) + NH_3(g) = (C_2H_5)_2O(l) + H_3N{:}BF_3(s) + \Delta H_2$$

The sum of these reactions is

$$BF_3(g) + NH_3(g) = H_3N{:}BF_3(s) + \Delta H_3$$

The value 41.3 kcal. per mole was obtained for ΔH_3, the heat of formation of solid ammonia–boron trifluoride from the gases at 0°.

Thermal Decomposition.—Rapid heating of ammonia-boron trifluoride results in an initial fusion of the solid; then decomposition occurs and the melt resolidifies and partially sublimes. One of the products of the thermal decomposition was shown to be ammonium fluoborate by a study of the optical properties and the powder X-ray diffraction patterns of the crystals obtained by recrystallizing the soluble part of the product from water. The other product, insoluble in water, was identified as boron nitride, BN, by X-ray diffraction and by the fact that it yielded boric acid and ammonia upon hydrolysis by boiling water.

Quantitative measurements demonstrated that the thermal decomposition, which becomes appreciable at 125° and proceeds rapidly at 150°, is represented by the equation

$$4H_3N{:}BF_3 = 3NH_4BF_4 + BN$$

These results suggest that the values reported by Balz and Zinser[7] as equilibrium vapor pressures of the ammonia complex, actually are those of ammonium fluoborate. This interpretation was confirmed by making equilibrium vapor pressure measurements on the two systems. The straight line obtained by plotting the values of log p against $1/T$ for ammonium fluoborate was found to be identical with the curves obtained by us and those obtained by Balz and Zinser by heating ammonia–boron trifluoride. It is to be noted that boron nitride has a vapor pressure of only 9.4 mm. at 1240°,[10] and that its contribution to the total pressure of the system in the temperature range studied is negligible.

Saturation Vapor Pressure and Heat of Sublimation of NH_4BF_4.—From the vapor pressure–temperature data obtained, the characteristic equation for NH_4BF_4 was calculated to be $\log_{10}p$ (mm.) $= -2469/T + 6.82$. The heat of sublimation of NH_4BF_4 is 11.3 kcal.

Discussion

The experimental results obtained in this investigation are in line with the general theory dealing with donor-acceptor bonding previously outlined.[9,11,12] The nitrogen atom in ammonia can donate its unshared pair of electrons to establish a shared electron pair bond to the boron atom in boron trifluoride and a one:one molecular addition complex is formed. It is conceivable that $H_3N:BF_3$, under conditions other than those we have used, might combine with more ammonia.

$$H_3N{:}BF_3 + NH_3 = [(NH_3)_2BF_2]^+F^-$$

However, such an ionic di-ammonate presumably would not be a liquid, as reported by Davy.[4]

The remarkable resistance to hydrolysis observed for $H_3N:BF_3$ would seem to be a result of the fact that, in forming the addition compound, both nitrogen and boron go from a coördination number of 3 to 4. This increase in the numbers of neighboring atoms strongly bonded to the central atoms appears to protect them from hydrolysis.

The configuration of $H_3N:BF_3$ may be expected to involve essentially tetrahedral bonding for both the nitrogen and boron atoms to give an ethane-like molecule. Professor Hoard of this Laboratory is now undertaking the X-ray determination of the crystal structure of the complex. It seems likely that hydrogen bonding will be pronounced in the solid.

The high polarity of $H_3N:BF_3$ and the resultant low solubility in non-polar solvents and high solubility in polar solvents is to be expected from its structure. The formation of a donor-acceptor bond between the nitrogen and boron atoms involves a considerable displacement of charge. In addition, when the complex is formed the fluorine atoms probably move from positions coplanar with boron to tetrahedral positions. The three B–F bond dipoles no longer counterbalance each other but make a considerable contribution to the polarity of the complex.

Summary

1. Only one compound, ammonia–boron trifluoride, $H_3N:BF_3$, has been found to exist between ammonia and boron trifluoride at 25°. It has been prepared in quantity and its properties have been studied.

2. Cryoscopic measurements indicate that in

(9) Laubengayer and Finlay, THIS JOURNAL, **65**, 884 (1943).

water solution $H_3N:BF_3$ exists as a monomeric molecular species, and that it is not appreciably dissociated.

3. Optical studies have been made on crystals of ammonia–boron trifluoride, and its powder X-ray diffraction pattern has been established.

4. The heat of formation of solid ammonia–boron trifluoride from the gases at 0° has been determined calorimetrically as 41.3 kcal.

5. It has been shown that the compound undergoes irreversible thermal decomposition at temperatures above 125° according to the equation: $4H_3N:BF_3 \xrightarrow{125^\circ} 3NH_4BF_4 + BN$.

6. Vapor pressure measurements obtained when ammonia–boron trifluoride is heated give values shown to be those of ammonium fluoborate, the only decomposition product volatile in the temperature range studied. The P.T. equation for NH_4BF_4 is $\log_{10} p(\text{mm.}) = -2469/T + 6.82$. The molar heat of sublimation of NH_4BF_4 is 11.3 kcal.

Thermodynamics of Sodium Chloride in 50 Mole Per Cent. Aqueous Methanol from E. m. f. Measurements on Cells with Transference

BY J. P. BUTLER AND A. R. GORDON

While concentration cells with transference have been used extensively in the study of electrolytes in aqueous solution[1,2] and have yielded some of the most precise thermodynamic data now available for such solutions, lack of transference numbers has so far prevented their use with solvents other than water. One interesting exception is provided by the work of Harned and Dreby[3] who employed cells with and without transference to yield indirectly transference numbers for hydrochloric acid in dioxane–water mixtures. Recent measurements in this laboratory[4] have now made possible the use of this method for sodium chloride in 50 mole per cent. methanol–water solution. Apart from testing the precision of the measurements with a solvent other than water, the primary purpose of this research was to determine whether the thermodynamic mean ionic diameter was significant when comparing ionic transport processes in two different solvents.

The cells, the preparation of the electrodes, and the general experimental technique have been previously described.[2] In all cases, the observed e. m. f. has been corrected for bias potential as described by Hornibrook, Janz and Gordon. One rather surprising result was that the bias potentials for stable pairs of electrodes were of the same order as those found in aqueous solution, *viz.*, 0.03 mv. or less. Even more surprising was the fact that the bias potential for a given pair was not only independent (within a microvolt or so) of the salt concentration in the mixed solvent, but had also the same value within similar limits after the electrodes had stood for half an hour in a solution with pure methanol or pure water as solvent. This suggests that lightly plated, electrolytically anodized Ag/AgCl electrodes are considerably sturdier than is generally assumed, provided a galvanometer of high currect sensitivity is used.

The solutions were prepared as described by Schiff and Gordon.[5] In computing the volume concentration C from the mass concentration, the density measurements of Shemilt, Davies and Gordon[4] were employed; these give for the range of interest here

$$C/m = 0.88123(1 - 0.0134m) \qquad (1)$$

where m is the molality.

The results are summarized in Table I under the heading E_{obs}. Only average values for round concentrations are given in the table; the method by which these were obtained from the results of individual runs, carried out at concentrations differing slightly from those recorded, will be described below.

TABLE I

The e. m. f. of a cell of the type Ag,AgCl/NaCl(m_1)//NaCl(m_2)/AgCl,Ag is of course given by the familiar expression

$$E = kt^0_+ \Delta \log ym + \Delta F(t_+) \qquad (2)$$

Here, k = 118.28 mv., t^0_+ is the limiting transference number for the cation (0.4437), Δ stands for function (m_1) − function (m_2), and $F(t_+)$ is given by

$$F(t_+) = k \int_0^m (t_+ - t^0_+)\, d \log \gamma m \qquad (3)$$

Eq. 2 can be solved by the usual method of suc-

cessive approximations, employing the transference data of Shemilt, Davies and Gordon,[4] to yield a consistent set of $\Delta \log \gamma = \log \gamma_1 - \log \gamma_2$.

On theoretical grounds, the activity coefficient should be given by

$$\log \gamma^* = -\alpha\sqrt{C}/(1 + \beta\sqrt{C}) + 0.4343\{j^3(X_3/2 - 2Y_3) + j^5(X_5/2 - 4Y_5)\} - \log (1 + 0.05m) \quad (4)$$

where,[6] for a solvent of dielectric constant[7] 49.84, $\alpha = 1.0072$, $\beta = 0.4125a$, $j = 11.24/a$, and a is the mean ionic diameter in ångströms. The leading term is the usual Debye–Hückel expression, the second contains the "extended terms" of the theory, which have been tabulated as functions of $\beta\sqrt{C}$ by Gronwall, LaMer and Sandved,[8] and the last takes account (with 50 mole per cent. aqueous methanol as solvent) of the change in concentration scale of the electrolyte from mole fraction to molality. If Equation 4 is valid for the concentration range involved, and if the correct value of a has been selected, $\Delta \log \gamma/\gamma^*$ should be uniformly zero. If, on the other hand, Eq. 4 is valid for the lower concentrations but not for those as great as $m_1 = 0.05$, and if once again the correct value of a has been chosen, $\Delta \log \gamma/\gamma^*$ should be a constant for the lower values of m_2, this constant being identically the difference between $\log \gamma$ and $\log \gamma^*$ at 0.05 molal.

Figure 1 shows the result of such an extrapolation with $a = 4.45$ Å.; this corresponds to $\beta = 1.836$ and $j = 2.526$. The quantity plotted is $\Delta \log \gamma/\gamma^*$ for each of the experiments, the abscissas being m_2, expressed in moles per kg. solvent. The value selected for a was chosen after a series of trials with a values ranging from 4 to 5 Å. It is at once evident from the figure that Eq. 4 with $a = 4.45$ adequately represents the activity coefficients up to about 0.025 molal. The figure also gives an idea of the precision and reproducibility of the measurements, the radius of circles corresponding to 5 microvolts in the e. m. f. The maximum deviation of any of the points from the smooth curve corresponds to 0.025 mv., and in only three cases is the discrepancy greater than 0.01 mv. The precision thus is comparable with the best that has been attained in this type of measurement with aqueous solutions.

The plot also serves as a convenient and precise means of obtaining the "observed" value of the e. m. f. for the round concentrations entered in Table I; from the mean of the observed values of $\Delta \log \gamma/\gamma^*$ for the individual runs and the known value of $\Delta \log \gamma^*$ for the round concentrations, an observed value of $\Delta \log \gamma$ and consequently of the e. m. f. may be obtained at once. From the continuous curve of the figure, the values of $\log \gamma$ entered in Table II were obtained; obviously, the

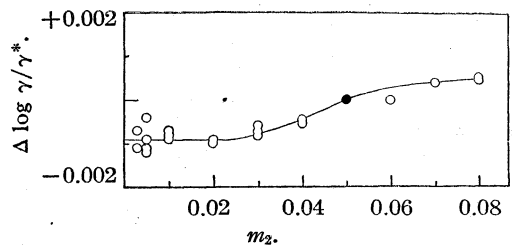

Fig. 1.

first four entries are also identically $\log \gamma^*$. Table II also gives the values of $F(t_+)$ corresponding to the tabulated values of the activity coefficients.[9] The self-consistency of the two tables is shown by the column headed $E_{\text{calcd.}}$ in Table I, which gives the e. m. f. computed from Eq. 2 by interpolation in Table II. While the precision and reproducibility of the measurements leaves little to be desired, it must nevertheless be remembered that the transference data on which the calculation of the activity coefficients is based, are at best accurate to a part in four thousand; this would correspond for the first entry in Table I to an uncertainty of 0.0003 in $\log \gamma$. We believe, however, that the results recorded here show that cells with transference can yield thermodynamic data of high precision with solvents other than water.

TABLE II

$m^{1/2}$	$1 + \log \gamma$	$F(t_+)$, mv.	$m^{1/2}$	$1 + \log \gamma$	$F(t_+)$, mv.
0.04	0.9639	−0.150	0.20	0.8552	−0.492
.08	.9318	.272	.24	.8343	.549

.16	.8782	.434	.32	(.7987)	(− .661)

Two other points deserve mention. The mean ionic diameter found here is the same as that reported by Brown and MacInnes[1] for sodium chloride in aqueous solution.[10] Thus, if a mean ionic diameter determined thermodynamically is significant in transport processes, the ratio of the limiting ion conductances in the mixture to those in water should (on the simple hydrodynamic picture) be close to the reciprocal of the ratio of the viscosities. Actually, as Schiff and Gordon[5] have shown, the limiting conductances in the mixture for sodium and chloride ions are 13% and 28% less than would be predicted from viscosity alone.

(6) The values of k and of the universal constants are those suggested by Manov, Bates, Hamer and Acree, THIS JOURNAL, **65**, 1765 (1943).

(7) Albright and Gasting, **68**, 1061 (1964).

(8) Gronwall, LaMer and Sandved, *Physik. Z.*, **29**, 358 (1928).

(9) For convenience in interpolating, the values of $F(t_+)$ in the table are carried to a greater number of significant figures than is entirely justified by the precision of the transference data.

(10) The smaller value (4.12 Å.) reported by Janz and Gordon[2] results from their use of the empirical Hückel extension to the original Debye–Hückel equation involving the introduction of a term linear in the concentration. It is well known that while this form is applicable over a wider concentration range than is the Debye–Hückel equation itself, its use removes any precise significance from the value of β used in the extrapolation; actually, the activity coefficients reported by Brown and MacInnes and by Janz and Gordon are in excellent agreement in spite of the different analytic forms used to represent the data in the two cases. It is the mean ionic diameter obtained when the linear term is not employed that should be compared with that derived from Eq. 4. In this connection see Brown and MacInnes[1] and Hornibrook, Janz and Gordon.[3]

If ion solvation in the mixture is primarily by water rather than methanol molecules, and if the Debye–LaMer diameter is a true measure of the diameter of the solvated ions, this would account for the surprising agreement between the values of a in the two cases. It would still leave unexplained, however, the decreased ion conductances in the mixture as compared with those predicted by the Walden rule, unless some additional factor, significant only in the transport process, is postulated, *e. g.*, hydrogen bonding between the water molecules in the hydrated sheath about the ions and the "free" methanol molecules of the solvent.

Secondly, it should be observed that the a value found here is considerably less than the critical Bjerrum[11] distance, given for 1:1 electrolytes by $e^2/2DkT = 5.6$ Å. for a solvent of dielectric constant 50 at 25°. Thus on the Bjerrum picture there should be considerable ion-pair formation, yet the form of the ion conductance *vs.* concentration curves[5] for this salt shows that association must be slight.

A consideration of the data presented here and of the ion conductances suggests (to us at any rate) that the use of a mixed solvent complicates the problem considerably, and that measurements in a one-component non-aqueous solvent may yield data which are more easily interpreted.

Summary

1. The e. m. f. of the cell with transference Ag,AgCl/NaCl(m_1)//NaCl(m_2)/AgCl,Ag, with 50 mole per cent. aqueous methanol as solvent, has been measured at 25° for sodium chloride concentrations from 0.003 to 0.08 M.

2. The precision and reproducibility of the results are comparable with those obtained with this type of cell for aqueous solutions. The bias potential between stable pairs of electrodes is 0.03 mv. or less, and is independent within one or two microvolts of the electrolyte concentration, just as is the case when water is solvent.

3. The activity coefficients, computed from the e. m. f. data and the known transference numbers, were extrapolated by means of the Gronwall, LaMer and Sandved extension to the Debye–Hückel equation, which represents the coefficients up to 0.025 M when the value selected for the mean ionic diameter is 4.45 Å. For higher concentrations, the observed values lie below those predicted by the equation.

4. The value found for the ionic diameter is in fortuitously exact agreement with that for this salt in water, and is definitely less than the critical Bjerrum distance for this solvent. The significance of the mean ionic diameter in its relation to the ion conductances for the salt in water and in methanol–water solution is discussed.

Mixed Adsorption of Radon and Argon on Silica Gel

BY BENJAMIN P. BURTT[1] AND J. D. KURBATOV

Mixed adsorption studies using radon in various gases at 1 atm. have been made by Siebert[2] at −80°, by Francis[3] with silica gels of various states of hydration, by Becker and Stehberger[4] and, using charcoal, by Nikitin and Joffe.[5]

The present work lies in the general field of mixed gas adsorption. The adsorbent was silica gel and all the experiments were conducted at 25 ± 3°. Adsorption isotherms of radon in air, in carbon dioxide and in argon at near atmospheric pressure were obtained. Approximately 1×10^{-16} g. atom of radon at partial pressures around 1×10^{-10} mm. was used.

Adsorption isotherms for air, argon and carbon dioxide were determined under the same experimental conditions as for radon. A brief study was also made of the mixed adsorption of carbon dioxide and air using conventional pressure–volume methods with subsequent analysis of the gas. A more thorough study was made of the mixed adsorption of argon and carbon dioxide applying both methods of conventional analysis and radioactive tracer technique. The adsorption of argon from air was investigated using radioactive argon as a tracer.

Description of the Apparatus and Procedure

The apparatus shown in Fig. 1 was constructed for mixed adsorption studies using radioactive gases. It was also suitable for the measurement of the simple adsorption of gases by pressure–volume methods.

The mixture of radioactive gas and the gas accompanying it is stored in buret S. Chosen volumes of the mixture can be transferred to the evacuated system as well as to the ionization chamber for analysis. The ionization chamber was connected to a Wulf bifilar electrometer. The gas is confined during adsorption in the system, A and E (total volume 26 cc.). About 0.8 g. of silica gel is placed in the removable adsorption flask E. With-

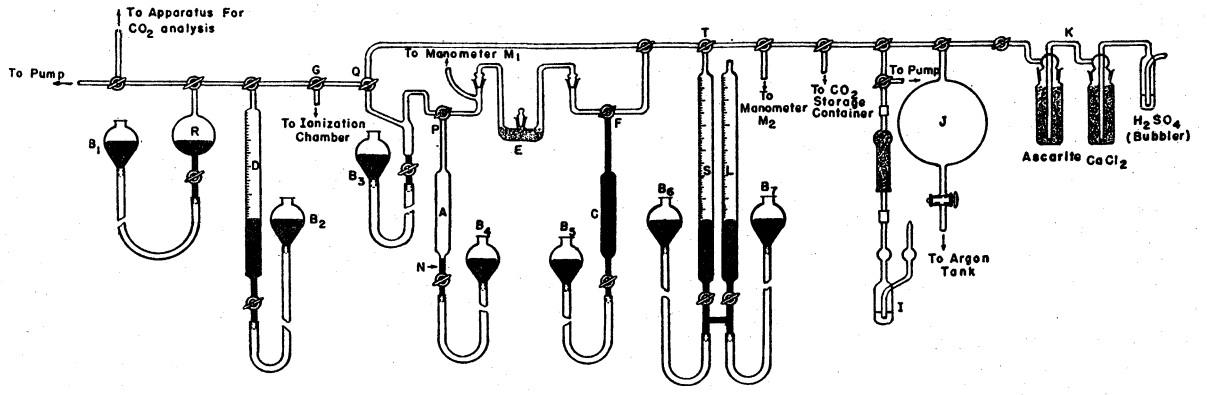

Fig. 1.—Apparatus for adsorption of gases.

out disturbing the equilibrium established, the sample of gas in pipet A is isolated from the system and removed to the ionization chamber for analysis.

To measure simple adsorption, a known quantity of gas was added to the evacuated system; after equilibrium had been established the quantity remaining in the gas phase was determined from the final pressure, volume and temperature.

In the experiments on the mixed adsorption of carbon dioxide with air, and with argon, the amount of carbon dioxide at equilibrium was determined by removing the gas in pipet A into a gas buret for absorption in potassium hydroxide.

Experimental Results

The Adsorption of Air, Argon and Carbon Dioxide on Silica Gel at 25°.—The adsorption isotherms of air, argon and carbon dioxide are plotted in Fig. 2. It was found in agreement with previous work, that carbon dioxide is adsorbed to a greater extent than air or argon. Air is adsorbed only slightly more than argon.

The data for the three isotherms were fitted by the method of least squares to the Freundlich equation

$$y = kx^{1/n} \qquad (1)$$

where y is the number of gram moles adsorbed per gram of gel and x is the number of gram moles per cc. in the gas phase. The data also conform to the Langmuir equation

$$y = y_m b'x/(1 + b'x) \qquad (2)$$

In these equations x and y have the same meanings as in the Freundlich equation, y_m is the number of gram moles of gas adsorbed per gram of silica gel when the surface is covered with a unimolecular layer and b' is the adsorption coefficient.

An estimate of the heat of adsorption of a gas can be made from the value of the adsorption coefficient b'. Laidler, Glasstone and Eyring[6] derived an expression for b' in terms of the heat of adsorption per molecule E. With some approximations the value of E can be calculated from b'.

For carbon dioxide b' and y_m are obtained by plotting equation (2) in the form

$$\frac{1}{y} = \frac{1}{y_m b'x} + \frac{1}{y_m} \qquad (3)$$

The isotherms of argon, air, and radon were experimentally linear and b' could not be obtained in this way. However, an approximate value of b' is calculated for these gases from the adsorption isotherms and estimated surface area of the adsorbent as follows. Brunauer and Emmett[7] found the area of silica gels with 6 to 9% water to be about 600 sq. m. per gram. The silica gels in this work averaged 6.27% water and the surface area is assumed to be of the same order of magnitude. The values of y_m are estimated using the above surface area for silica gel. These values of y_m are then used to calculate the adsorption coefficients b' from the adsorption isotherms. By this method the heat of adsorption of radon in air or argon is evaluated to be of the order of 9000 calories per mole (a 50% error in estimating the surface area would produce an error of about 350 cal./mole). It may be seen that this method gives values of the correct order of magnitude. The calculated value for argon is 5,500 calories per mole

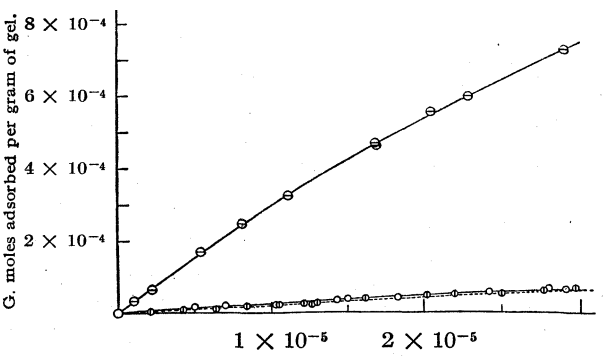

Fig. 2.—Adsorption isotherms of air, argon and carbon dioxide on silica gel, temp. 25°, wt. gel. = 0.8216 g.: -⊖-⊖-⊖- CO_2, -⊙-⊙-⊙-⊙- A, -O-O-O- air.

while data in the literature range from 2,500 to 3,600.[8,9,10,11,12] The value for carbon dioxide calculated from a plot of equation (3) is 7,700 calories per mole. The value calculated using the estimated surface area is 7300 calories per mole, whereas values from 6,900 to 7,900 are reported by other investigators.[8,10,13] The calculated value for air is 5,500 calories per mole and the values in the literature for oxygen and nitrogen are from 3,000 to 5,500 calories per mole.[10,13,14,15]

In addition to the per cent. adsorbed, a distribution coefficient α (the quantity of gas adsorbed per gram of adsorbent divided by the quantity of gas per cc. of space) is calculated. Slight unavoidable variations in the weight of the gel and the volume of the system from one experiment to the next do not affect α, whereas they may affect the per cent. adsorbed.

The results of the calculation are given in Table I for each gas at the same concentration in the gas phase (corresponding to a pressure of 557 mm.).

TABLE I

Gas	G. mole per cc. of space $\times 10^5$	G. mole adsorbed per gram gel $\times 10^5$	α	% of total gas adsorbed
Argon	3	6.52	2.1	6.5
Air	3	6.89	2.3	6.8
Carbon dioxide	3	78.20	26.1	45.4

Mixed Adsorption Studies with Radon—Radon and Air.—The adsorption isotherm for radon in air at near atmospheric pressure is given in Fig. 3. The log–log plot is linear and of approximately unit slope. Decreasing the pressure of the accompanying air to 120 mm. produces no measurable change in the adsorption of radon. The value of the distribution coefficient α of radon obtained from the plot is 28.5. Approximately 50% of the total radon is adsorbed, the variations being due to slight differences in the weight of gel and the volume of the system.

The results of this work are in agreement with the Langmuir theory of mixed adsorption. The equations derived by Markham and Benton[16] predict that a decrease in air pressure produces no appreciable change in the adsorption of radon under these experimental conditions. No change in the adsorption of radon is observed with a decrease in air pressure.

Radon and Carbon Dioxide.—Figure 3 shows the adsorption of radon from carbon dioxide and from air at near atmospheric pressure to be the same at concentrations of radon below 3×10^{-16} g. atom/cc. At higher concentrations of radon its adsorption is less from mixtures with carbon dioxide than from mixtures with air at one atmosphere total pressure.

Studies were made of the adsorption of radon from radon-air-carbon dioxide mixtures when the total pressure of the gases was approximately one atmosphere. The adsorption of radon in mixtures containing as much as 25% carbon dioxide was not measurably different from the adsorption of radon in air alone.

The Langmuir equations predict a straight line of unit slope for the log–log plot as long as the concentration of radon is very small compared to that of carbon dioxide. In this experimentation the slope of the isotherm was slightly less than unity even though the concentration of radon was negligible. This could be partially explained by postulating that the surface of the gel is heterogenous and the adsorption of radon takes place primarily on the points of greatest unsaturation. Upon increasing the concentration of radon in the gas phase above 3×10^{-16} g. atom/cc., the active points on the gel become more nearly saturated and further increases in the partial pressure of radon do not result in a proportional increase in the amount adsorbed per gram of silica gel.

Radon and Argon.—The adsorption isotherm of radon from radon–argon mixtures at near atmospheric pressure is also given in Fig. 3. The log–log plot is experimentally linear, of approximately unit slope and lies considerably above the corresponding isotherm of radon in air.

At the same partial pressure of radon in the gas phase approximately 50% more radon is adsorbed in the presence of argon than in the presence of

(16) E. C. Markham and A. F. Benton, THIS JOURNAL, **53**, 497 (1931).

air. Decreasing the pressure of argon decreases the adsorption of radon. From Table II it can be seen that α, the distribution coefficient for radon in argon, decreases simultaneously with the pressure of the argon.

TABLE II

MIXED ADSORPTION OF RADON AND ARGON

G. atoms Rn to system $\times 10^6$	Pressure argon, mm.	α, Radon
35.1	704	42.8
133	701	42.7
360	690	42.4
74.6	684	39.5
133	345	38.6
52.7	280	37.1
384	114	35.6
42.6	105	34.9

These observations indicate that the adsorption of radon is enhanced by the presence of argon.

The Langmuir theory predicts that the plot of the amount adsorbed per gram of gel against the amount per cc. in the gas phase should be linear. In this respect the data agreed with the theory of mixtures. The Langmuir theory also predicts that for the argon–radon mixtures approximately 1% more radon should be adsorbed than from a mixture with air.

A comparison of the adsorption of radon in air, in argon and in carbon dioxide is made in Table III showing the amount of radon adsorbed per gram of silica gel corresponding to a given partial pressure of radon in the gas phase in each of the three accompanying gases.

TABLE III

COMPARISON OF THE ADSORPTION OF RADON ON SILICA GEL IN THE PRESENCE OF CARBON DIOXIDE, AIR AND ARGON

Temperature 25°; average weight of gel 0.75

Accompanying gas, at mm.	Concentration of radon in gas phase, g. atoms/cc. $\times 10^{16}$	G. atoms of radon adsorbed/gram of gel $\times 10^{16}$
CO_2 at 704	7.00	165.0
Air at 735	7.00	194.0
Argon at 684	7.00	300.0
CO_2 at 704	4.00	100.0

Argon at 684	1.00	43.0
CO_2 at 704	0.70	18.8
Air at 735	0.70	21.0
Argon at 684	0.70	30.2

Mixed Adsorption of Argon—Argon and Carbon Dioxide.—The adsorption of the two gases was measured at various mole fractions of pure argon and carbon dioxide, maintaining a constant total quantity (1×10^{-3} g. mole) of carbon dioxide and of argon. The conventional procedure of analysis for the carbon dioxide content was compared with the use of a radioactive tracer (A^{37}). Isotope A^{37} has a half life of 34.1 days[17] and it was prepared in the Ohio State University cyclotron by bombardment of potassium chloride. The results for the adsorption of carbon dioxide in the presence of argon are shown in Fig. 4. No

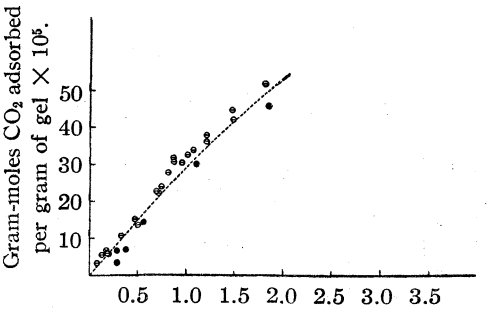

Fig. 4.—Mixed adsorption of argon and carbon dioxide: on silica gel, adsorption of CO_2 from A–CO_2 mixtures compared to adsorption of pure CO_2: total g. moles A + CO_2 = 1×10^{-3}; temp., 25°; av. wt. gel, 0.75 g.; -----, adsorption isotherm of pure CO_2; ⊖, adsorption of CO_2 from A–CO_2 mixtures by pressure change and CO_2 analysis; ●, adsorption of CO_2 from A–CO_2 mixtures by pressure change and use of radioactive argon (A^{37}) as tracer.

significant change in the adsorption of carbon dioxide in the presence of argon was detected. The results of the conventional method were slightly higher, in general, than the simple adsorption isotherm for carbon dioxide, while those obtained using A^{37} were slightly below the isotherm. Figure 5 shows the adsorption of stable argon from mixtures with carbon dioxide as determined by the use of radioactive argon. There was no measurable change in the adsorption of argon due to the pressure of carbon dioxide.

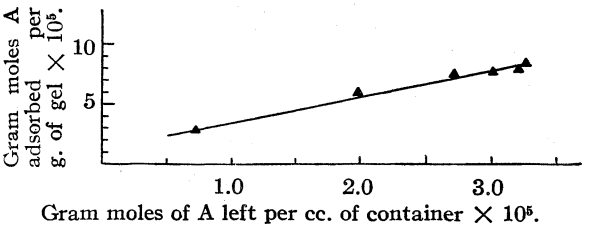

Fig. 5.—Mixed adsorption of argon and carbon dioxide, adsorption of argon on silica gel: adsorption of A from A–CO_2 mixtures, total g. moles A + CO_2 = 1×10^{-3}; temp., 25°, av. wt. gel., 0.75 g.

Argon and Air.—It has been reported that argon and nitrogen, and argon and oxygen mutually increase one another's adsorption at 0°.[18,19] Using radioactive argon similar results were obtained. Radioactive argon is added to

air and the adsorption of the stable argon from air is traced. Approximately 13% of the total argon present in air was found to be adsorbed.

In these studies with radioactive argon it has been found that the use of radioactive tracer for mixed gas adsorption is feasible and gives more consistent results than the conventional method. In cases where the chemical analysis of the gas mixture is difficult by ordinary means, the use of a radioactive tracer, if available, provides a convenient method for studying mixed adsorption. It is recognized that the technique described here using separate samples of silica gel for each experiment does not insure that the adsorbent has exactly the same adsorption properties in each experiment. Experiments in which the only variable was the sample of silica gel used showed this error to be of the order of 3%.

Acknowledgment.—The authors greatly appreciate the support given to this research by Professor Alpheus Smith and by Professor M. L. Pool. We also express our thanks to the Alumni Fund for a grant in aid for purchase of equipment.

Summary

1. An apparatus is described suitable for studying binary mixed gas adsorption in which one component is radioactive or contains radioactive atoms as a tracer. The apparatus is also suitable for certain mixed adsorption studies by conventional means. Simple adsorption isotherms were obtained for air, argon and carbon dioxide on silica gel at 25°.

2. Adsorption isotherms for radon in air, in argon and in carbon dioxide on silica gel at 25° were studied. The isotherm in air follows Henry's law and substantiates the Langmuir theory of mixed adsorption as applied to low concentrations. The adsorption of radon is slightly suppressed in carbon dioxide. The studies with radon in argon show that the adsorption of radon is enhanced in the presence of argon even though a very small fraction of the total surface of silica gel is covered by radon.

3. The heat of adsorption of radon in air and in argon was estimated from the data obtained to be of the order of magnitude of 9,000 calories per mole.

4. Methods are described for the use of radioactive argon to follow the adsorption of argon in mixtures with carbon dioxide and with air.

SYRACUSE, N. Y. RECEIVED JANUARY 2, 1948

NOTES

The Reduction of 6-Methyl-8-(4′-diethylamino-1′-methylbutylidene)-aminoquinoline

BY H. J. BARBER, D. H. O. JOHN AND W. R. WRAGG

The recent publication by Elderfield, *et al.*,[1] reporting a study of the synthesis of Plasmochin by the reductive condensation of 1-diethylaminopentanone-4 (I) with 6-methoxy-8-aminoquinoline (II), from which a satisfactory method did not ensue, is of considerable interest to us since we were concerned during the war with a similar process which gave Plasmochin in excellent yield. We wish therefore to record some additional data.

Early in our work we investigated a process revealed by Bergmann[2] for the reductive condensation of 6-methoxy-8-nitroquinoline with (I), following his conditions as closely as practicable (our palladium/barium sulfate catalyst was prepared by the method of Sabalitschka and Moses[3]), but we could not obtain any Plasmochin. A second Bergmann, patent[4] claims, but does not exemplify, the reductive condensation of (I) and (II).

Preparation of the Schiff base, 6-methoxy-8-(4′-diethylamino - 1′ - methylbutylidene) - aminoquinoline (III), was accomplished by Elderfield, *et al.*,[1] by the interaction of (I) and (II) using ethylbenzene as an entrainer to remove water, but condensation under these conditions was slow and far from complete. The Schiff base may be obtained in almost quantitative yield using the diethyl ketal of (I), instead of (I) itself, (*cf.* van Shelven[5]) by the procedure described[6] for 6-methoxy - 8 - amino - 1,2,3,4 - tetrahydroquinoline (IV). The Schiff base, without distillation, could then be reduced in ethyl acetate solution at 60° and 450 lb. hydrogen pressure in the presence of a platinum/charcoal catalyst, but the results were not consistent. Considerable improvement was effected by using an Adams platinum oxide catalyst[7] at the same pressure but at room temperature. Reproducible results were obtained and an 80% over-all yield (calculated on (II)) of distilled Plasmochin base was obtained on a production scale.

In our experience the reduction is very susceptible to minor changes in materials, catalyst or

reaction conditions and unless hydrogenation proceeds rapidly and smoothly, by-products are formed. In one explanation of the imidazole formation observed in their reductive condensations of (I) and (II), Elderfield and Kreysa[8] suggest that on reduction of the Schiff base (III), saturation of the pyridine ring occurs before substantial reduction of the azomethine linkage. This clearly requires qualification since under conditions now reported the reverse is the case. However, the more drastic hydrogenation conditions and the different catalyst used by Elderfield, *et al.*, might have caused the reaction to follow the alternative course. That these latter conditions led to extensive nuclear reduction is in accord with our experience since we used similar conditions except for the solvent employed, for making tetrahydro-Plasmochin and (IV), the published yield and analysis[6] of which have been overlooked by Elderfield, *et al.*[8]

It is of interest to note that Andersag also reports a failure to achieve more than a few per cent. yield of Plasmochin by the aminoketone route.[9]

A considerable part of this experimental work was carried out by H. G. Thompson and A. C. Benzie.

The Preparation of 1-(*p*-Nitrophenyl)-1,3-butadiene

BY E. C. COYNER AND G. A. ROPP[1]

In the continuation of a study[2] on Diels–Alder reactions with 1-aryl-1,3-dienes, 1-(*p*-nitrophenyl)-1,3-butadiene and its adduct with maleic anhydride have been prepared and characterized.

The diene was synthesized in two steps by a modification of the procedure described in a review[3] of German war-time investigations on extensions of the Meerwein[4] reaction.

$$CH_2{=}CH{-}CH{=}CH_2 + ClN_2C_6H_4NO_2\text{-}p \longrightarrow ClCH_2{-}CH{=}CH{-}CH_2C_6H_4NO_2\text{-}p + N_2$$

$$ClCH_2{-}CH{=}CHCH_2C_6H_4NO_2\text{-}p + KOH \longrightarrow CH_2{=}CH{-}CH{=}CHC_6H_4NO_2\text{-}p + KCl + H_2O$$

The chlorobutene, obtained in the first step, may be distilled successfully in small quantities under high vacuum, but it was found that this operation could be omitted as well as the removal of impurities, chiefly *p*-nitrophenol, from the chlorobutene by steam distillation. Actually, inclusion of these operations, as described in the Germany report, give only very low yields of diene, whereas the abbreviated procedure given in detail below resulted in a yield of 61% of purified product based on *p*-nitroaniline. Furthermore, the product is described in the German report as an oil, but in this work 1-(*p*-nitrophenyl)-1,3-butadiene was found to crystallize in yellow needles, m. p. 78.0–78.8°. It reacts readily with maleic anhydride and has been kept at room temperature in dark bottles for several months with no apparent decomposition.

Studies are now underway on the reactions of 1-(*p*-nitrophenyl)-1,3-butadiene with unsymmetrical dienophiles.

Experimental

1-(*p*-Nitrophenyl)-4-chloro-2-butene.—Technical *p*-nitroaniline was recrystallized once from ethanol and 140 g. (one mole) was dissolved in a hot solution of 240 cc. concentrated hydrochloric acid and 100 cc. of water. The solution was stirred rapidly and cooled in an ice–salt-bath. After 100 g. of ice was added, a solution of 70 g. of sodium nitrite in 120 cc. of water was run in during one hour while the temperature was kept between −4 and +4.5°. Stirring was continued for an additional twenty minutes and the reaction mixture was filtered. The filtrate was kept at 0° while it was added over a period of ninety minutes to a well-stirred mixture of 1 liter of acetone, 80 g. of sodium acetate dissolved in 100 cc. of water, 30 g. of cupric chloride dissolved in 50 cc. of water, and 130 cc. of liquid butadiene. The reaction mixture was maintained at −3 to +5° by means of an ice–salt-bath during the addition and was then allowed to warm to room temperature. Stirring was continued for an additional sixteen hours. One liter of ether was then added to extract the oily product, and the ethereal solution was separated, washed four times with 1-liter portions of water and dried over anhydrous magnesium sulfate. Removal of the solvent on the steam-bath gave 187.5 g. (88.6%) of crude 1-(*p*-nitrophenyl)-4-chloro-2-butene as a dark brown oil.

1-(*p*-Nitrophenyl)-1,3-butadiene.—The crude chlorobutene was dissolved in a solution of 500 cc. of ligroin and 500 cc. of benzene and treated with 5 g. of activated charcoal under reflux for two hours. The charcoal was removed by filtration, the solvents were evaporated on the steam-bath and the residual oil was dissolved in 400 cc. of methanol. This solution was then stirred at 15–33° while a solution of 112 g. of potassium hydroxide in 600 cc. of methanol was added over thirty minutes. Stirring was continued for an additional five minutes and the precipitated light yellow crystalline diene was removed by filtration; it was washed thoroughly with water and dried in a vacuum desiccator to give 76.5 g. of product, m. p. 75.0–76.8. The methanolic filtrate was added to 1200 cc. of water to precipitate 41.5 g. of less pure, dark brown product, which upon recrystallization from 400 cc. of ligroin gave 30 g. of light yellow crystalline diene, m. p. 75.5–76.8°. The total yield of product, m. p. 75.0–76.8° is therefore 106.5 g. (61% based on *p*-nitroaniline). A highly purified sample, m.p. 78.0–78.8°, was prepared by repeated recrystallizations from ligroin and from methanol.

Anal. Calcd. for $C_{10}H_9O_2N$: C, 68.56; H, 5.18. Found: C, 68.44, 68.44; H, 5.07, 4.96.

Adduct with Maleic Anhydride, 3-(*p*-Nitrophenyl)-1,2,3,6-Tetrahydrophthalic Anhydride.—A mixture of one-hundredth mole quantities of 1-(*p*-nitrophenyl)-1,3-butadiene (1.75 g.) and maleic anhydride (0.98 g.) was heated at 70° for fifteen minutes, during which time the melt solidified. The solidified cake was then heated under reflux with 3 cc. of xylene for ten minutes and cooled to room temperature. The solid product was re-

moved by filtration and recrystallized once from glacial acetic acid and three times from ethyl acetate to give pale yellow crystals, m. p. 170.9–172.0°.

Anal. Calcd. for $C_{14}H_{11}O_5N$: C, 61.54; H, 4.06. Found: C, 61.33, 61.60; H, 4.04, 3.99.

Hydroxyethylmorphine

BY WARNER W. CARLSON AND L. H. CRETCHER

The typical result of alkylating the phenolic hydroxyl of morphine has been found to be the production of codeine-like effects, almost regardless of the chemical nature of the alkylating group.[1] However, since no reference could be found to the preparation of a hydroxyalkyl ether derivative of morphine, the alkaloid was hydroxyethylated by the procedure previously developed for use with nitrogenous phenols.[2]

Toxicity of the derivative was determined by the subcutaneous (abdominal) injection of graded doses of the compound in white mice (17 to 19 g. weight range). The results are given in Table I, along with the values listed by Small and Eddy[1] for the parent alkaloid and its methyl and ethyl ethers. Introduction of the hydroxyethyl group was found to produce a marked decrease both in acute toxicity and convulsant action. Hydroxyethylmorphine also failed to elicit the Straub reaction or circus movements in the animals. In its actions the hydroxyethyl derivative resembles γ-isomorphine, which has an LD 50 of 2000 mg./kg. and does not produce the Straub reaction or circus movements in mice.[1]

TABLE I

ACUTE TOXICITY OF HYDROXYETHYLMORPHINE TO WHITE MICE

Substituent at position 3	LD 50 mg./kg., as free base	Convulsant action, mg./kg.	Straub reaction
HO—	531	531	Present
CH_3O—	241	161	Present
C_2H_5O—	136	122	Present
HOC_2H_4O—	2500	2500	Absent

A preliminary estimate of analgesic potency in white mice was made by the method of Woolfe and MacDonald,[3] morphine and codeine being used as reference compounds. The results are given in Table II, from which it is estimated that codeine is approximately 1/10, and hydroxyethylmorphine 1/15, as analgesic as the parent alkaloid.

Experimental

Hydroxyethylmorphine.—A mixture of 5.7 g. of morphine, 8.3 g. of potassium carbonate, and 100 g. of ethylene carbonate[2] (in excess as solvent) was heated with stirring for seventy-five minutes at 98°, cooled, and poured into an excess of cold aqueous alkali. The solution was extracted three times with 50-cc. portions of chloroform, the extracts united and the product extracted by 20 cc. of 0.1 *N* hydrochloric acid. The solution was made alkaline and the product again extracted into chloroform; because of the marked water solubility of the derivative, it was not feasible to wash the extract. The chloroform solution was evaporated to a sirup under reduced pressure, the residue dissolved in boiling absolute alcohol, and the solution cooled, hydroxyethylmorphine crystallizing. Recrystallized from the same solvent (30 cc. of alcohol per g. of compound) the derivative was obtained as colorless crystals; m. p. 190°; yield, 4.6 g.; $[\alpha]_D$ −124.8° (methanol).

TABLE II

ANALGESIC POTENCY OF HYDROXYETHYLMORPHINE

The Ultraviolet Absorption Spectra of 1,1′- and 2,2′-Binaphthyl

BY VERNON L. FRAMPTON, JOSEPH D. EDWARDS, JR., AND HENRY R. HENZE

In a very recent article concerning the ultraviolet absorption spectra of some naphthalene derivatives, Friedel, Orchin and Reggel[1] call attention in a footnote to differences between the spectra as determined by them for 1,1′- and 2,2′-binaphthyl and those noted previously by Adams and Kirkpatrick.[2] The significance of these data is such as to warrant this communication to confirm the location of the absorption maxima reported by Friedel, Orchin and Reggel, since, as they appear to us, the ultraviolet absorption spectra of 1,1′-binaphthyl and, especially, of 2,2′-binaphthyl were of fundamental importance in the selection by Adams, *et al.*, of a binaphthyl as the basic nucleus of gossypol.

1,1′-Binaphthyl has been resynthesized[3] by three different procedures, namely: (a) by the Wurtz–Fittig reaction[4] starting with 1-chloronaphthalene; (b) according to the method of Ull-

mann[5] using 1-bromonaphthalene; (c) utilizing the Grignard reaction[6] with 1-bromonaphthalene. The melting points of the samples of 1,1′-binaphthyl[7] prepared by these procedures were 157.5, 157.2 and 157.5°, respectively; a mixture of the three preparations melted at 157.5°.

In Fig. 1 are presented the ultraviolet absorption spectra for these three samples, which were determined with a Beckman quartz spectrophotometer using 95% ethyl alcohol as solvent, together with the data[8] taken from the Fig. 2 published by Adams and Kirkpatrick.[2] In our Fig. 1 are included also data recorded still earlier by Pestemer and Cecelsky[9] using a hexane solution of 1,1′-binaphthyl. The low wave length absorption band which we report is at 220–224 millimicrons, which is in satisfactory agreement with the band at 226 millimicrons reported by Friedel, *et al.*,[1]

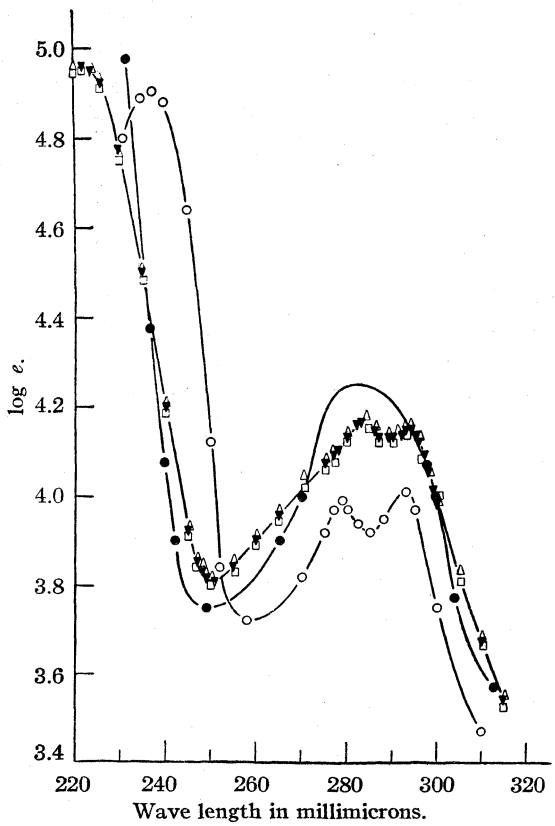

Fig. 1.—Ultraviolet absorption spectra for 1,1′-binaphthyl: ▼, 1,1′-binaphthyl prepared by the Wurtz–Fittig synthesis; △, Ullmann synthesis; □, Grignard synthesis; O, data of Adams and Kirkpatrick; ●, data of Pestemer and Cecelsky.

but is in disagreement with the location of the absorption band at 238 millimicrons according to Adams and Kirkpatrick.

2,2′-Binaphthyl,[10] melting at 187°, was synthesized through the Grignard reaction with 2-iodonaphthalene. The absorption spectrum for 2,2′-binaphthyl is presented in Fig. 2. In agreement with the findings of Friedel, *et al.*, a thorough investigation throughout the region 260–300 millimicrons did not yield evidence for the existence of an absorption maximum at 297 millimicrons, as reported by Adams and Kirkpatrick. Otherwise, the absorption spectra for 2,2′-binaphthyl are in reasonable agreement.

The Purification of Neopentane by Mercury Photosensitization[1]

BY B. DEB. DARWENT AND E. W. R. STEACIE

In a study of the mercury photosensitized reactions of neopentane it was found necessary to

prepare extremely pure samples of that hydrocarbon. The Grignard reaction of tertiary butyl chloride with methylmagnesium chloride was used to produce the neopentane. The product was washed with 85 and 95% sulfuric acid and then photobrominated to ensure the complete removal of unsaturates, since isobutene is the most likely impurity. The residual bromine and any hydrogen bromide formed were removed by distilling the mixture through 40% potassium hydroxide (aqueous) and over solid potassium hydroxide. The resulting neopentane was finally purified by low temperature distillation in a column of conventional design. The distillate was assumed to be pure when the temperature remained constant at 9.6° for thirty to sixty minutes under total reflux. This "pure" neopentane was taken off in four consecutive fractions, the purity of which was checked by determining the vapor pressure–temperature relations of large samples over a wide range of temperature. No indications of impurity could be detected.

Preliminary experiments showed that the rates of the mercury photosensitized reaction of different samples, though surprisingly low, were very variable. Samples of the unreacted and of the "partially decomposed" neopentane were analyzed by the mass spectrometer with the following results:

	Percentages					
Sample	A	B	C	D	E	F
Neopentane	96.4	99.6	99.9	100	100	100
n-Pentane	1.1	..	...	...	...	...
Dimethylcyclopropane	1.6	0.4	trace	...	...	...
C_6 hydrocarbons	1	..	...	...	...	...

in which Sample A was the "pure" unreacted neopentane and B to F were "partially decomposed" samples. It was stated by the analyst that samples D, E and F were "apparently of the same purity as the neopentane used for calibrating as obtained from Dr. F. D. Rossini, National Bureau of Standards, Standard Sample No. 299–5s. It is certified to be 99.96% pure; impurity 0.04 ± 0.02%."

Accordingly a large sample of crude (undistilled) neopentane (about 30 liters of gas) was subjected to prolonged mercury sensitization by circulating a mixture of gaseous neopentane and mercury through a quartz vessel illuminated by a low pressure mercury lamp, the radiation from which consisted largely of the unreversed 2537 Å. line, for seventy to eighty hours, roughly distilled into 5 fractions and analyzed on the mass spectrometer. The results were:

	Percentages				
Fraction no.	1	2	3	4	5
Neopentane	99 (8)[a]	99 (7)[a]	99 (6)[a]	99 (4)[a]	99 (0)[a]
Hexane	0.2	0.3	0.4	0.6	1.0

[a] The figures in parentheses are uncertain.

Hence, in the absence of very efficient fractionation, mercury photosensitization is an efficient method of obtaining neopentane of high purity. This method of purification is possible only because neopentane is remarkably resistant to attack by $Hg(^3P_1)$ atoms whereas the impurities react readily to give, ultimately, heavy polymers and non-condensable gases (hydrogen and methane) which are easily separated from the unreacted neopentane.

The Grignard reaction was carried out by Dr. A. Cambron and Mr. R. A. B. Bannard of these laboratories, and the mass spectrometer analyses by Dr. Fred L. Mohler of the National Bureau of Standards, Washington, D. C., to whom our thanks are due. The laboratory assistance of Mr. J. R. Pilon is gratefully acknowledged.

The Reduction of *p*-Hydroxyformanilide by Lithium Aluminum Hydride to N-Methyl-*p*-aminophenol

BY JACOB EHRLICH

This reduction of an anilide to a secondary amine proceeds smoothly in tetrahydrofuran as solvent. The method is applicable to various amides using diethyl ether or tetrahydrofuran as solvent, to be reported in a later communication.

Experimental

A solution of 1.9 g. (0.05 mole)[1] of lithium aluminum hydride in 36 cc. of anhydrous tetrahydrofuran[2] was prepared in a 3-neck conical flask provided with sealed stirrer, thermometer, reflux condenser, hopper[3] and calcium chloride guard-tube.[4] The solution was brought to 20–25° and 2.75 g. (0.02 mole) of *p*-hydroxyformanilide was added in small portions during thirty minutes, cooling externally with ice-water to maintain this temperature. The hopper was flushed with 4 cc. of tetrahydrofuran and the charge stirred twenty minutes more at 20–25°. Dur-

(1) Assuming only one labile hydrogen (phenolic) in 1 mole of *p*-hydroxyformamilide, then 0.25 mole of $LiAlH_4$ would be destroyed prior to any reduction. The reduction of the formyl radical would consume a further 0.5 mole of $LiAlH_4$, making a 4:3 molar ratio of anilide:$LiAlH_4$. If the amido hydrogen is also labile, the ratio becomes 1:1. If the formyl hydrogen is labile, the ratio becomes 4:5. However, these calculations are only of academic interest, for the 0.02:0.05 molar ratio was arrived at empirically. If less $LiAlH_4$ is employed, the yield drops proportionally.

(2) The tetrahydrofuran was obtained from E. I. du Pont de Nemours and Co. This was rendered water and peroxide free by storing 500 cc. in an amber bottle over 75 g. of flake sodium hydroxide for two weeks, occasionally shaking. The clear, colorless supernatant liquor was decanted (from now discolored solids) for use in the reductions without further purification. On dissolving the $LiAlH_4$ in the tetrahydrofuran the heat of solution will raise the temperature to about 50°.

(3) Similar in construction (but smaller capacity) to that described by Swift and Billman, *Ind. Eng. Chem., Anal. Ed.*, **17**, 600 (1945). However, this may be omitted and the same results obtained by using a removable rubber stopper.

(4) In various reductions no special precautions, except the exclusion of atmospheric moisture, were employed, and no uncontrolled or explosive reaction was observed. However, as an added precaution, it would be desirable to conduct the reaction under an atmosphere of dry nitrogen.

ing this period a thin slush formed. The temperature was then raised to 63–66° and maintained for ten minutes. The pale pink slurry was then chilled to 20–25°, 77 cc.[5] of 3 *N* hydrochloric acid added *cautiously* from a dropping funnel (ice-water cooling as required), resulting in a pale slightly cloudy solution.

The charge then was steam-distilled (about 90 cc. distillate) to remove the solvent, digested while hot with 0.3 g. of Norit and 0.2 g. of Filter-Cel and filtered with suction. The colorless filtrate was cooled to 0–5°, 10 cc. of concentrated hydrochloric acid added, then titrated at this temperature with molar sodium nitrite solution to a strong blue streak (ten minutes end-point) on starch-iodide paper. Almost the theoretical amount was required. During the titration pale yellow nitrosamine needles separated. The crystals were filtered with suction, washed with water and dried at 55°; yield 2.66 g., m. p. 134–135°. The filtrate, on extraction with ether, yielded an additional 0.12 g.; total yield 92%.

On recrystallizing the combined crops from 10% ethanol, in the presence of a little Norit, the m. p. was raised to 135.5°, identical with purified N-nitroso-N-methyl-*p*-aminophenol prepared from photographic Metol as shown by mixed m. p.

(5) The first 20 cc. of 3 *N* hydrochloric acid must be fed very slowly, dropwise. During this period the main heat effect is evident and the bulk of the hydrogen gas evolved (by decomposition of the excess lithium aluminum hydride). Thereafter the balance may be added faster. Prior to the acid addition the calcium chloride tube is removed (*versus* any back pressure) and the flask vented to the hood.

The Constitution of Citrinin

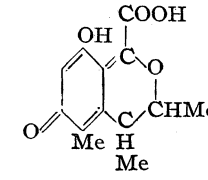
BY T. S. GORE, T. B. PANSE AND K. VENKATARAMAN

The structures originally assigned[1] to citrinin (I) and its degradation products (II) and (III) are untenable in the light of their behavior towards diazonium salts.[2] Cram[3] has now shown by synthesis and direct comparison that (III) is 4-methyl-5-ethylresorcinol, a conclusion at which we had arrived by circumstantial evidence. The 2,4 and 4,6-compounds were ruled out by the ability of (III) to form disazo dyes. Comparison of the absorption spectra and the color reactions of the bis-benzeneazo derivative of (III) with those of 2,4- and 4,6-bis-benzeneazoresorcinol and a series of analogous dyes showed that (III) is 5-methyl-4-ethylresorcinol (IV) or 4-methyl-5-ethylresorcinol (V). The absorption curves for 2,4-bis-benzeneazoresorcinol, 2,6-bis-benzeneazo-5-methyl-4-ethyl resorcinol and the bis-benzeneazo derivative of (III) had a well-defined, high intensity band in the visible region ($\lambda_{max.}$ ∽ 415 mμ; $\epsilon_{max.}$ ∽ 60,000). 4,6-bis-Benzeneazoresorcinol and 4,6-bis-benzeneazo-2-ethylresorcinol exhibited a band of relatively low intensity in the visible region ($\lambda_{max.}$ ∽ 415 mμ; $\epsilon_{max.}$ ∽ 20,000) and absorption maxima in the near ultraviolet ($\lambda_{max.}$ ∽ 340 mμ; $\epsilon_{max.}$ 36,000).

(1) Raistrick, Robinson, *et al.*, *Phil. Trans. Roy. Soc.*, **B220**, 269, 297 (1931).
(2) Gore, *et al.*, *Nature*, **157**, 333 (1946).
(3) Cram, THIS JOURNAL, **70**, 440 (1948).

Shah and Robinson's synthesis[4] of (IV) was repeated, and it was found to melt at 79–82° (Shah and Robinson, m. p. 75–80°), while (III) as a monohydrate melts at 68–69°, and after dehydration at 98–99°; the m. p. of (III) was considerably depressed by admixture with (IV). Cram[3] has quoted us erroneously as reporting a m. p. of 65–70° for (III). The bis-benzeneazo derivatives of (III) and (IV) melted, respectively, at 171° and 188°, and the mixed m. p. was lower. It followed therefore that (III) is 4-methyl-5-ethylresorcinol. However, this is in conflict with the observation of Hetherington and Raistrick[1] that neither of the acids obtained by oxidation of the dimethyl ether of (III) gave the anthrachrysone reaction. We prepared 3,5-dimethoxy-2-methylbenzoic acid (VII) by the methylation of the corresponding α-resorcylic acid,[5] and found that it readily gave a bordeaux-red color on warming with sulfuric acid (the anthrachrysone reaction); Cram has recorded that the acid (VI) synthesized by him corresponds in its properties to one of Hetherington and Raistrick's acids. The m. p. (157–158°) reported for (VI) by Cram is in agreement with ours, while Hetherington and Raistrick's two acids melted at 142–146° and 98–99°.

From the formulation of (III) as 4-methyl-5-ethylresorcinol, the properties of (II), including the formation of (III) from (II) by alkali fusion, are fully explained by the structure 4-methyl-5-(1-methyl-2-hydroxy)-propyl-resorcinol, proposed



by Cram. The experimental results of Hetherington and Raistrick[1] and the behaviour of citrinin towards diazonium salts[2] would then agree with the above constitution for citrinin.

The Employment of Sodium Hydride as a Condensing Agent

BY NATHAN GREEN AND F. B. LAFORGE

Sodium hydride is now being produced on a large scale, and its advantages as a catalyst in various organic reactions have been indicated by Hansley and Carlisle.[1] Its use in this Laboratory in the preparation of ethyl β-oxocaprylate, ethyl β-carbethoxy-α-oxo-enanthate, and 5-carbethoxy-dihydrocinerone has been described in previous articles.[2,3] We have since employed this reagent in

(1) Hansley and Carlisle, *Chem. Eng. News*, **23**, 1332 (1945).
(2) Soloway and LaForge, THIS JOURNAL, **69**, 2677 (1947).
(3) LaForge and Soloway, *ibid.*, **69**, 2932 (1947).

the preparation of carbethoxy derivatives of other ketones, and of their substitution products, for Claisen condensations of alkyl esters with ketones, and for cyclizations of the Dieckman type. It probably could be used with advantage for many reactions where powdered sodium or sodium ethylate is usually employed. We are therefore presenting some observations which we have made in the use of this catalyst in these reactions.

The reaction of ketones with ethyl carbonate starts promptly when the finely ground catalyst is employed, but with the coarser material there is a considerable lag, or occasionally the reaction may not start at all. Since at present sodium hydride is supplied only in the coarser size, which is easier and less hazardous to handle but less reactive, it is generally necessary to reduce the particle size by some means of grinding.

A laboratory apparatus for this purpose has been designed by V. L. Hansley[4] in which reactions are carried out in a revolving closed cylinder containing steel balls. Since this rather expensive equipment will not be generally available, we have employed the same principle in connection with the usual glass apparatus. When several ceramic spheres about 13 mm. in diameter are placed in the reaction flask with the solvent and the ethyl carbonate, and rolled slowly over the catalyst with a glass paddle stirrer for about thirty minutes, the particle size of the sodium hydride is reduced sufficiently so that the reaction starts soon on addition of a small quantity of the ketone. Care should be taken not to add very much of the ketone until the reaction, which is observed by the evolution of hydrogen, has definitely started. When the experiment is performed in this manner, the yield in the case of ethyl β-oxocaprylate is usually 80 to 85% of the theoretical.

In the preparation of sodium derivatives of β-keto esters the reaction starts at once regardless of the physical state of the sodium hydride, and the addition of the ester is regulated according to the rate of evolution of hydrogen. The solvent is generally anhydrous ether. Dioxane, in which most sodium enolates are soluble, is sometimes used.

Alcohol-free sodium alcoholates are conveniently prepared by dropping a slight excess of the alcohol on sodium hydride covered with benzene and, after refluxing, distilling off the solvent until it is alcohol-free, as shown by measurement of the refractive index. Sodium hydride dissolves more readily than sodium lumps or wire.

The following examples illustrate the employment of sodium hydride in reactions referred to above.[5]

Ethyl-3-oxo-6-octenoate[6] was prepared from 58 g. (2.4 moles) of sodium hydride covered with 300 ml. of dry ether and 283 g. (2.4 moles) of ethyl carbonate in a nitrogen atmosphere by dropping 136 g. (1.2 moles) of 5-heptene-2-one into the stirred suspension over a period of five hours. More ether was added as the contents of the flask thickened. Acetic acid was added in quantity equivalent to the sodium hydride diluted with ice and water, and the reaction product was isolated from the ethereal solution by removing first the ether and then the excess ethyl carbonate in vacuum: b. p. 110–120° (10 mm.), $n^{25}D$ 1.4460, yield 188 g. (85%).

Anal. Calcd. for $C_{10}H_{16}O_3$: C, 65.19; H, 8.76. Found: C, 64.67; H, 8.80.

2,4-Nonanedione.—A mixture of 28.8 g. (0.2 mole) of ethyl caproate and 12.7 g. (0.22 mole) of dry acetone was added to 4.8 g. (0.2 mole) of sodium hydride covered with 10 ml. of dry ether. The evolution of hydrogen started after refluxing for several minutes, and more ether was added as solid material separated. Refluxing was continued for one hour. Ice and water containing a suitable quantity of sulfuric acid were added, and the reaction product was isolated from the ethereal solution and distilled from a modified Claisen flask: b. p. 94–98° (11 mm.), $n^{25}D$ 1.4222, yield 16.8 g. (54%).

2,5-Dioxo-1,4-cyclohexandicarboxylic Acid Diethyl Ester.—The Dieckman cyclization between two molecules of ethyl succinate occurs smoothly on addition of the ester to two equivalents of sodium hydride covered with a small quantity of ether and refluxing until the evolution of hydrogen has ceased. Upon addition of dilute acid the reaction product separates in crystalline form on removal of the ether and it can be recrystallized from ethanol (m. p. 130–131°).

Ethyl β-Carbethoxy-γ-oxo-pelargonate.—To 4.8 g. (0.2 mole) of sodium hydride covered with 100 ml. of ether, 37.2 g. (0.2 mole) of ethyl β-oxocaprylate was slowly added with stirring, more ether being added as the contents of the flask thickened. It was refluxed for thirty minutes, after which 37 g. (0.22 mole) ofe thyl bromoacetate was added dropwise at a rate to cause gentle refluxing of the ether. The reaction was completed by further refluxing for thirty minutes, after which the separated sodium bromide was dissolved by addition of water containing 5% of sulfuric acid. The ethereal layer was washed and dried and the solvent removed. The residue was distilled on a modified Claisen flask: b. p. 133–136° (0.4 mm.), $n^{25}D$ 1.4388. The yield was 46 g. (84.5%).

Anal. Calcd. for $C_{14}H_{24}O_5$: C_2H_5O, 32.4. Found: C_2H_5O, 33.0.

The Action of Copper Sulfate on the Phenylosazones of the Sugars. VI.[1] Gentiobiose Phenylosotriazole[2]

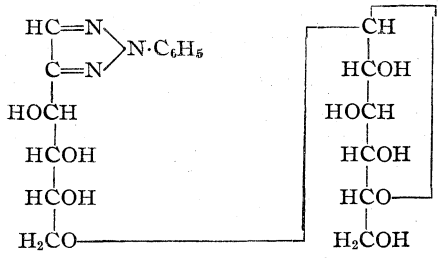
BY W. T. HASKINS, RAYMOND M. HANN AND C. S. HUDSON

In continuation of the investigation of the conversion of the sugar phenylosazones to the corresponding phenylosotriazoles through the action of copper sulfate, we have prepared the phenylosotriazole of gentiobiose. This phenylosotriazole differs from those described in the previous articles in that its crystals contain one molecular equivalent of ethanol which is tenaciously retained at ordinary temperatures even in moderately high

(1) Number V was published in THIS JOURNAL, **69**, 1461 (1947).

(2) Presented in part before the Division of Sugar Chemistry and Technology at the Chicago meeting of the American Chemical Society, April 19–23, 1948.

vacuum but is eliminated *in vacuo* at elevated temperatures. It is also unique in that its heptaacetate and heptabenzoate crystallize readily whereas, among the other disaccharide phenylosotriazoles investigated, only one crystalline acyl derivative has been obtained (cellobiose phenylosotriazole heptaacetate). Acid hydrolysis of gentiobiose phenylosotriazole produces a high yield (93%) of D-glucose phenylosotriazole and D-glucose (65%) as expected from the accompanying formula.



Gentiobiose Phenylosotriazole

We are indebted to Mr. Charles A. Kinser and Mrs. Betty Mount for the microchemical analyses.

Experimental

Gentiobiose Phenylosotriazole.—To a suspension of 10 g. of gentiobiose phenylosazone[3] in 900 ml. of boiling water was added a hot solution of 5.3 g. (1.1 molecular equivalents) of copper sulfate pentahydrate in 100 ml. of water. Solution of the phenylosazone took place rapidly and after refluxing for thirty minutes the solution was cooled, filtered, and the excess copper removed from the filtrate as the sulfide; the copper-free solution was neutralized with 10 g. of barium carbonate and following filtration, concentrated *in vacuo* to a thick reddish sirup. The sirup was dried by successive evaporations with three 25-ml. portions of absolute alcohol, and dissolved in 25 ml. of warm absolute alcohol, filtered to remove a small amount of inorganic contaminant and diluted with 35 ml. of ether; upon scratching, the product separated as somewhat gelatinous flocs which were recovered by filtration and washed with cold absolute alcohol and ether; yield 5.3 g. An additional 1.2 g. of product was obtained by concentration of the mother liquor; total yield 6.5 g. (71%). The material was recrystallized from 5 parts of absolute alcohol forming minute needles which melted at 91–93°[4] with foaming and rotated −34.3° in aqueous solution (*c*, 0.83). Analyses showed that the material contained one molecular equivalent of ethanol of crystallization which was retained tenaciously *in vacuo* at temperatures below the sintering point; at 97° *in vacuo* the alcohol was removed leaving an amorphous glassy material of no definite melting point; its analysis corresponded closely to that of an unsolvated disaccharide phenylosotriazole. The crystalline alcoholate was readily soluble in water, pyridine and hot alcohol and sparingly soluble in ether, acetone, ethyl acetate and cold alcohol. Upon separating from solution in impure form it shows a marked tendency to form gelatinous precipitates rather than discrete crystals.

Anal. Calcd. for $C_{18}H_{25}N_3O_9 \cdot C_2H_5OH$: C, 50.73; H, 6.60; loss on drying, 9.7. Found: C, 50.94; H, 6.39; loss on drying, 9.5.

Anal. (of the alcohol-free amorphous material). Calcd. for $C_{18}H_{25}N_3O_9$: C, 50.58; H, 5.90. Found: C, 50.56; H, 5.99.

On refluxing 1.2 g. of the crystalline alcoholate with 50 ml. of 0.5 *N* hydrochloric acid for six hours and chilling the solution, a 93% yield of D-glucose phenylosotriazole (m. p. 195–196°) was obtained and the concentrated aqueous mother liquor, after neutralization with silver carbonate, yielded 65% of D-glucose ($[\alpha]^{20}D$ +52.5°).

Gentiobiose Phenylosotriazole Heptaacetate.—A solution of 1.0 g. of gentiobiose phenylosotriazole monoalcoholate in a mixture of 8 ml. of acetic anhydride and 0.25 g. of fused sodium acetate was heated on the steam bath for two hours, cooled, and poured into ice water; the crystalline heptaacetate (1.6 g., quantitative) was recrystallized from 10 parts of alcohol and formed clumps of very fine needles melting at 144–146° and rotating −28.1° in chloroform solution (*c*, 0.84). It was readily soluble in chloroform, acetone–ether and warm alcohol and nearly insoluble in water and hexane.

Anal. Calcd. for $C_{32}H_{39}N_3O_{16}$: C, 53.26; H, 5.45; CH_3CO, 41.8. Found: C, 53.53; H, 5.62; CH_3CO, 41.6.

Gentiobiose Phenylosotriazole Heptabenzoate.—To a solution of 0.5 g. of gentiobiose phenylosotriazole monoalcoholate in 5 ml. of pyridine was added 2 ml. of benzoyl chloride; after standing at 25° for twenty-four hours the mixture was poured into ice water and the gummy precipitate washed by decantation with dilute sodium bicarbonate solution and water. The damp precipitate was digested on the steam-bath with 25 ml. of alcohol when spontaneous crystallization occurred; the cooled mixture was filtered and washed with alcohol yielding 1.2 g. (quantitative) of the heptabenzoate. The compound was recrystallized by dissolving it in 10 parts of chloroform and adding 20 parts of hexane or 50 parts of absolute alcohol; it crystallized as fine, short needles melting at 122–123° and rotating +1.5° in chloroform solution (*c*, 0.88). It is soluble in chloroform, ether, acetone and pyridine and sparingly soluble in water, hexane and hot alcohol.

Anal. Calcd. for $C_{67}H_{53}N_3O_{16}$: C, 69.60; H, 4.62; C_6H_5CO, 63.6. Found: C, 69.40; H, 4.57; C_6H_5CO, 63.3.

The Separation of Iodine-131 from Tellurium

BY MILTON LEVY, ALBERT S. KESTON AND SIDNEY UDENFRIEND

The irradiated unit[1] supplied by the U. S. Atomic Energy Commission as a source of I^{131} contains 50 g. of tellurium. The chromic or nitric acid oxidations such as have been used in working up cyclotron targets proved cumbersome in the case of the pile units because of the large amount of tellurium. The following method based on fusion with sodium hydroxide has proven rapid and reliable.

The tellurium powder is transferred to a 100-ml. Pyrex kjeldahl flask (through a powder funnel) containing 5 g. of sodium hydroxide pellets. The

(1) Catalog item No. 37, "Radioisotopes," Catalog No. 2, revised September, 1947, U. S. Atomic Energy Commission, Oak Ridge, Tenn.

mixture is shaken and heated gently to drive out water and then to a dull red (above 452°, the m. p. of tellurium). The mixture is held at this high temperature for about five minutes with occasional shaking during the progress of heating. The flask is allowed to cool somewhat and then plunged into 100 ml. of water in a large mortar. The flask breaks and both it and the solid contents are coarsely powdered with a pestle. The aqueous layer with suspended tellurium is transferred to a liter erlenmeyer flask with suction and the residue in the mortar extracted with several 50-ml. portions of hot water until only minor amounts of radioactive materials are being transferred. The extracts and washings are heated to boiling to coagulate the precipitate. The solution is cooled and filtered to remove tellurium.

The remainder of the isolation requires an all-glass-standard taper distilling apparatus consisting of a 500-ml. flask, an adapter with addition tube, an adapter and condenser and a receiving adapter arranged to dip into a receiving solution. The filtered alkaline extract is run into the distilling flask, which contains a few boiling stones, and evaporated to a volume of about 50 ml. The distillate contains no radioactive material and is discarded. A concentrated solution of potassium permanganate is added in excess to oxidize all iodine in the alkaline solution to iodate. The receiving flask is changed to one containing a dilute solution of sodium sulfite and sodium carbonate (about 1 mg. of each in several ml. of water). The delivery tip is covered by this solution. Fifty ml. of concentrated sulfuric acid is added through the addition tube. Care is necessary because of the heat developed. After the sulfuric acid has been added, 1 g. of oxalic acid dissolved in a minimal amount of hot water is added. The iodate is reduced to iodine. The mixture is now distilled until substantially all of the radioactivity has collected in the receiver where the iodine is converted to iodide. The solution of iodide containing some carbonate, sulfite and sulfate is used directly in most of our work.

The tellurium residue when dissolved in nitric acid containing a small amount of chloride ion, gave, in the presence of excess dissolving silver, a silver chloride precipitate which contained relatively little radioactivity. When unirradiated tellurium to which I^{131} has been added is dissolved in this way, substantially all the radioactivity is coprecipitated with the silver chloride. Portions of the irradiated tellurium gave large amounts of I^{131} in the silver chloride precipitate. Since the tellurium residue from the pile unit contained little I^{131} and all other fractions except the final product contained not more than 10% of the radioactivity of the final product, we believe the yield to be 85–95% of the I^{131} originally present.

The exposures of the operators (two) during the working up of a unit by the method is minimized by the use of lead bricks, long handled tongs and rapid handling of materials. On pocket ionization chambers 0.04–0.06 roentgen was registered on the day of processing a unit. This is well below the allowed maximum of 0.1 roentgen per day. Film badges[2] worn during the week including the day of the preparation showed less than ten per cent. of the permitted maximum exposure for the week.

The irradiated tellurium units used in this investigation were supplied by the Clinton Laboratories and obtained on allocation from the U. S. Atomic Energy Commission.

This work was supported by a grant from the American Cancer Society, recommended by the Committee on Growth of the National Research Council.

Preparation of *t*-Butylamine

BY D. E. PEARSON, J. F. BAXTER AND K. N. CARTER

Tertiary butylamine has been made by the hydrogenation of 2,2-dimethylethylenimine[1] and by the reaction of *t*-butylmagnesium chloride and methoxyamine.[2] Simple hydrolysis of the readily obtainable *t*-butylurea (E. K.) with aqueous alkali is too slow for satisfactory use. Smith and Emerson[3] accomplished the hydrolysis indirectly by reaction with phthalic anhydride and subsequent hydrolysis of the resulting phthalimide. It has now been found that the amine is readily prepared from *t*-butylurea by saponification in aqueous ethylene glycol solution. The procedure shown has been checked according to "Organic Syntheses" recommendations.

$$(CH_3)_3CHNHCONH_2 + 2NaOH \longrightarrow (CH_3)_3CNH_2 + NH_3 + Na_2CO_3$$

Procedure

A 1-liter round-bottomed, S. T. flask was equipped with an upright condenser, and a glass tubing was led from the top of the condenser to a small flask immersed in ice-water. The trap was unnecessary, if sufficiently cold water was used in the condenser. The flask was charged with sodium hydroxide (60 g., 1.5 moles) dissolved in 75 cc. of water, *t*-butylurea (70 g., 0.6 mole) and 225 cc. of ethylene glycol (practical grade), and the mixture refluxed for four hours. The liquid temperature was 115° when refluxing started and fell to 86° at the end. The *t*-butylurea gradually dissolved, and a gelatinous mass of sodium carbonate was formed. Shorter reflux gave lower yields; longer periods gave no increase. Lower concentrations of ethylene glycol gave proportionately lower yields. The flask was then cooled, equipped for distillation and the fraction boiling at 40–60° was collected in an ice-cooled receiver. The crude amine, including any in the trap, weighed 37–39 g. It was dried with 5–7 g. of solid sodium hydroxide. If a lower, aqueous

(3) Smith and Emerson, THIS JOURNAL, **67**, 1862 (1945).

layer formed, it was removed in a small separatory funnel, and the amine was redried with fresh sodium hydroxide for eight to ten hours. The filtered amine was then distilled through a short, Vigreux column into an ice-cooled receiver equipped with a soda-lime tube. The yield was 31–34 g. (71–78%), b. p. 44–46°, m. w. 73 by glass electrode titration. Double quantities also were used with no significant change in yields. It is suggested that the procedure, with obvious modifications in details, is probably applicable to the preparation of *t*-amylamine from *t*-amylurea.

Colored Complexes of Tungsten Hexafluoride with Organic Compounds

BY HOMER F. PRIEST AND WALTER C. SCHUMB

It was observed in the course of a study of the reduction of tungsten hexafluoride by organic compounds that when the hexafluoride was dissolved in certain of these compounds deep colors were produced. Apparatus was devised in which tungsten hexafluoride could be added as liquid to a sample of the organic liquid, an atmosphere of dry air being maintained above the solution. Solutions were also prepared quantitatively by distilling the pure hexafluoride into a known weight of organic solvent contained in weighed cylindrical comparison tubes for a Coleman spectrophotometer (Model 14). The tubes could be sealed off and reweighed so as to obtain the weight of added fluoride. Spectrometric traces were made, all values being obtained by use of the potentiometer drum rather than by direct galvanometer deflection.

The tungsten hexafluoride had been prepared from metallic tungsten and fluorine, followed by redistillation to eliminate any WOF_4 which might be present. Analysis of the hexafluoride showed it to be better than 99% pure. The organic solvents employed were of carefully selected purity; thus, analytical reagent grade, thiophene-free benzene; reagent grade acetone, toluene, *sym*-tetrachloroethane, ethyl alcohol and diethyl ether; Eastman Kodak Co. pure grade cyclohexane, cyclohexanone, and *n*-decane; dioxane free from unsaturated compounds. Most of the liquids were dried over anhydrous calcium sulfate and redistilled.

A summary of the qualitative observations made on the solution of tungsten hexafluoride in the different organic solvents is shown in Table I.

From these results it appears that the presence of certain functional groups in the solvents employed results in similar colors; thus the colors in benzene and toluene are similar, as are those in diethylcarbitol and diethyl ether. Ketones, such as acetone and cyclohexanone, give similar colors which intensify on standing and may be due to polymerization of the ketone rather than to the formation of a complex with the hexafluoride. Chlorinated solvents and hydrocarbons containing no functional groups give no colors. Alcohol also gives no color, but it is to be expected that alcoholysis of the hexafluoride could interfere with complex formation.

Because of the intense color given by benzene, a quantitative study was made of this solvent. At concentrations above 0.04 molar the color appeared to remain stable for several weeks. Solutions were made up at three concentrations of tungsten hexafluoride, 0.048, 0.118 and 0.121 molar, and the optical densities of these solutions were measured at 520, 550, 560 and 570 μ. A plot of optical density *vs.* concentration of tungsten hexafluoride gave straight lines, indicating that the colored material follows Beer's law, and that the concentration of the colored complex is directly proportional to the tungsten hexafluoride concentration. By absorption measurements carried out on four solutions of tungsten hexafluoride and benzene in carbon tetrachloride, results were obtained which led to the conclusion that the concentration of the colored complex also varies directly as the benzene concentration, from which fact it is concluded that the complex contains one molecule of benzene per molecule of the hexafluoride, $WF_6 \cdot C_6H_6$.

It has been noted previously by others,[1] as well

Ethyl alcohol	None	White crystals		
Carbon tetrachloride	None	White crystals		
sym-Tetrachloroethane	None	Solidified		
n-Decane	None	Solidified		
Cyclohexane	None	Solidified		
Diethylcarbitol	Violet–brown	None	Brown	
Diethyl ether	Violet–brown	None	Brown	
Dioxane	Pale red	White solid	Orange	Some crystals deposited

(1) See, for example, Fischer, *Z. anorg. Chem.*, **81**, 170 (1930); Kalischer, "Zur Kenntnis der Halogenide des höherwertigen Wolframs und Molybdäns," Berlin, 1902; Roscoe, *Ann.* **162**, 351 (1872).

as by ourselves, that colored solutions are also formed by tungsten hexachloride in various solvents; but we feel that the two cases are not comparable, for the following reasons. (1) Tungsten hexachloride itself has a blood-red color, so that solutions in various solvents showing a red, brown, or yellow color are reasonably to be expected, whereas tungsten hexafluoride itself is colorless. (2) The red solution of the hexafluoride in benzene freezes to a colorless crystalline solid, which on warming regains its color. (3) If the hexafluoride were reduced by solvent to lower valences of tungsten, the solution could not be expected to follow Beer's law, as was found to be the case. Furthermore, the colored solution of the hexafluoride in benzene remained unaltered for weeks, indicating lack of reaction, whereas the hexachloride solutions change gradually, owing to reduction of the tungsten.

Thiodiglycol Monoacetate by the Photochemical Addition of Mercaptoethanol to Vinyl Acetate

BY WALTER H. C. RUEGGEBERG, JACOB CHERNACK, IRA M. ROSE AND E. EMMET REID

The photochemical addition of mercaptans to olefins has been studied in this Laboratory[1] for several years. Recently, the photoaddition of ethanolmercaptan to vinyl chloride yielding 2-chloroethyl-2-hydroxyethyl sulfide (semi-mustard) was reported by Fuson and Ziegler[2] and from this Laboratory.[3] Inasmuch as the monoacetate of thiodiglycol has not been reported previously in the literature to the best of our knowledge, it appeared worthwhile to synthesize this half-ester through the photochemical addition of ethanolmercaptan to vinyl acetate.

It was soon learned, however, that the reaction rate depended strongly upon the purity of vinyl acetate used. Thus, for example, when freshly distilled vinyl acetate was mixed with mercaptoethanol, the mixture warmed up immediately. Titration of the residual mercaptan with iodine in methanol solution showed that 80% of the mercaptan had reacted after the first hour. On the other hand, if stabilized vinyl acetate (Eastman Kodak Co., practical grade) is employed in the process, no reaction is observed until the mixture is irradiated from an S-4, 100 watt mercury vapor lamp (General Electric Co.) in the presence of 1% of diphenyl disulfide, as catalyst.

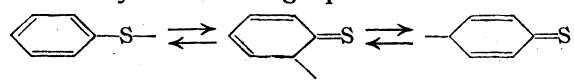
$$HOCH_2CH_2{-}S{-} + CH_2{=}CH{-}O{-}\overset{\overset{O}{\|}}{C}{-}CH_3 \longrightarrow$$

$$HOCH_2CH_2{-}S{-}CH_2{-}\underset{\underset{O}{\|}}{CH}{-}O{-}\overset{\overset{O}{\|}}{C}{-}CH_3 \quad (a)$$

$$HOCH_2CH_2{-}S{-}CH_2{-}\underset{\underset{O}{\|}}{CH}{-}O{-}CCH_3 + HOCH_2CH_2SH \longrightarrow$$

$$HOCH_2CH_2{-}S{-}CH_2CH_2{-}O{-}\overset{\overset{O}{\|}}{C}{-}CH_3 + HOCH_2CH_2S{-} \quad (b)$$

Although disulfides such as diamyl disulfide are known to accelerate the photoaddition of mercaptoethanol to vinyl chloride,[3] it has been shown that diphenyl disulfide is a catalyst superior to aliphatic disulfides in this type of reaction.[1] Two reasons for this behavior may be cited. First, diphenyl disulfide absorbs light more strongly than dialkyl disulfides in the visible and near ultraviolet regions of the spectrum,[1] indicating that free radicals are more easily obtained; secondly, the stabilizing influence of resonance on the thiophenyl radicals should prolong their lives thus increasing reaction probability. The three resonance forms of the thiophenyl radicals may be represented by the following equilibria



In the disulfide-free reaction, the primary dissociation is that of the splitting of the S—H bond

$$HOCH_2CH_2SH + h\nu \longrightarrow HOCH_2CH_2{-}S{-} + H{-}$$

This reaction is then followed by a chain mechanism given by equations (a) and (b), above.

Thiodiglycol monoacetate, so prepared, is a water white liquid resembling thiodiglycol itself in odor and having the physical properties listed in Table I. It is soluble in water, benzene, carbon tetrachloride, chloroform, ethyl ether and acetone but insoluble in hexane or cyclohexane.

(3) Rueggeberg, Cook and Reid, *ibid.*, **13**, 110 (1948).

standing one hour, an iodimetric titration of the reaction mixture in methanol indicated that about 80% of the mercaptan had undergone reaction. The mixture was allowed to stand at room temperature for one week prior to being distilled. Distillation of the product resulted in the recovery of unused mercaptoethanol and vinyl acetate and a residue yield of crude thiodiglycol monoacetate weighing 54.4 g. This material on distillation boiled at 137–138° at 8 mm.; yield of distilled product, 51%. *Anal.* Calcd. for $C_6H_{12}O_3S$: S, 19.5. Found: S, 19.2.

Photosynthesis in Presence of Diphenyl Disulfide.—Vinyl acetate, 90 g., (practical grade, stabilized) obtained from the Eastman Kodak Company was mixed with 78 g. of mercaptoethanol obtained from the Carbide and Carbon Chemicals Corporation. No reaction ensued. These reagents together with 0.8 g. of diphenyl disulfide (1% of the mercaptan used) were placed in a 300-ml. Pyrex test-tube and suspended in a water-bath at 20–25°. An S-4, 100-watt mercury vapor lamp was also suspended under water and placed 11 cm. from the center of the test-tube. On turning on the light the temperature of the reaction mixture rose from 22 to 34° receding slowly after about one hour of irradiation. Irradiation was continued for an additional two hours and subsequently, the reaction product was distilled. After two distillations 72 g. of a product was obtained boiling at 147.7 to 148° at 13–14 mm.

Anal. Calcd. for $C_6H_{12}O_3S$: C, 43.9; H, 7.4; S, 19.5. Found: C, 43.7; H, 7.4; S, 19.9.

Preparation of Vanillonitrile and Vanillic Acid from Vanillin

BY CONRAD SCHUERCH, JR.

The acid catalyzed condensation of hydrazoic acid with aldehydes is included in the more general Schmidt reaction,[1] and in the case of acetaldehyde, benzaldehyde and *m*-nitrobenzaldehyde, results in the corresponding nitriles and N-substituted formyl derivatives.

$$\text{I.}\quad RCHO + HN_3 \xrightarrow{H^+} RC{\equiv}N + H_2O + N_2$$

$$\text{II.}\quad RCHO + HN_3 \xrightarrow{H^+} RNH{-}CHO + N_2$$

Vanillin has now been found to react readily in the presence of sulfuric acid according to equation I, and crystalline vanillonitrile has been easily isolated in a yield of about 70%. The formanilide, which was presumably formed at the same time according to equation II, did not interfere appreciably in the purification of the nitrile. When the original reaction mixture was diluted with water and boiled, hydrolysis of the nitrile occurred and almost pure vanillic acid crystallized in more than 70% yield from the liquors. This observation is of interest because vanillic acid is not readily available by the direct oxidation of vanillin, and because Pearl's catalytic oxidation with silver oxide[2] was found to be somewhat sensitive to obscure differences in the experimental conditions. Substitution of veratraldehyde for the vanillin used in the condensation with hydrazoic acid resulted in more than an 80% yield of crystalline veratric acid, and a small amount of 4-aminoveratrole (equation II) was also isolated from the hydrolysate.

As would be expected from the known reactions of ketones and the mechanism recently proposed for the Schmidt reaction[3,4,5,6] vanillin reacted with hydrazoic acid in the presence of reagents such as a dioxane solution of hydrogen chloride, that are milder than sulfuric acid. Although it is probable that a proper choice of solvent would give a homogeneous system and a smooth condensation with much smaller quantities of acid than those now used, the decrease might well alter the relative amounts of the products formed.[1]

Acknowledgment.—The author wishes to express his gratitude to Professor C. B. Purves for his kind interest and assistance in this and related work.

Vanillonitrile and Vanillic Acid.—One hundred grams (0.658 mole) of pure vanillin was dissolved completely in 375 ml. of concentrated reagent grade sulfuric acid kept at 0–10° in a 2-liter 3-necked flask, with mercury-sealed stirrer, condenser, thermometer and gas exit tube attached. Powdered sodium azide (45 g., 0.69 mole), contained in a small flask attached to the reaction vessel by means of a rubber connector, was added to the red solution at 0–11° over a period of one and one-half hours. The cooling bath was removed and the mixture was stirred for another half hour. The flask was again chilled and about 900 ml. of distilled water was added cautiously from a separatory funnel without allowing the temperature to rise above 18°. This addition caused the nitrile to separate as a yellow solid which completely filled the aqueous layer. When desired, the nitrile could be extracted with ether, and isolated after washing the extract with small amounts of sodium bisulfite and sodium bicarbonate solutions. The yield from smaller quantities of reactants was about 70% and most of the product melted at 87.5–88.3°; m. p. 89–90° is the recorded value for vanillonitrile.[7]

When vanillic acid was required, the original reaction mixture was diluted with 900 ml. of water as already described. The stirrer and thermometer were then removed and washed with 100 ml. of water which was added to the reaction flask, and the mixture boiled gently under reflux. Crystals of vanillic acid appeared after two and one-half hours, and after three hours of boiling the mixture was allowed to cool overnight. The crystals were filtered with suction under an efficient hood, washed five times with a total volume of 1700 ml. of distilled water and dried: yield of vanillic acid 81.5 g. or 73.8%; m. p., 201–203°; and neutralization equivalent (by electrometric titration to *p*H 7), 171. Calcd. for vanillic acid, neut. equiv., 168. Decolorization and recrystallization from water gave beautiful needles but raised the m. p. only slowly. A melting point of 208–210° was obtained,

however, by extracting the crude crystals once with absolute ether in a Soxhlet apparatus. A mixed melting point with authentic vanillic acid[2] with the recorded m. p. 208–210°[8] was undepressed.

Veratric Acid and 4-Aminoveratrole.—The condensation of veratraldehyde 27.6 g., sodium azide 12.5 g. and concentrated sulfuric acid 118 ml. was essentially as described above but the time of hydrolysis was somewhat longer. Slightly discolored veratric acid, 25.4 g. or 84%, separated from the reaction mixture. One recrystallization from water and ethanol gave a pure product with the recorded[9] m. p. 179–181°. Extraction of the acid mother liquor with benzene gave less than 1 g. of oily crystals. The acidic solution was made strongly alkaline and extracted again with benzene. Evaporation of this extract and distillation of the residue under reduced pressure yielded 1.6 g. of colorless crystals that darkened in air. Their melting point of 87–88° agreed with that reported for 4-aminoveratrole.[10]

[CONTRIBUTION FROM THE STEELE CHEMICAL LABORATORY OF DARTMOUTH COLLEGE, AND THE CHEMISTRY DEPARTMENT OF THE UNIVERSITY OF MICHIGAN]

8-Amino-2,4-Dimethylquinoline[1]

BY WYMAN R. VAUGHAN[2]

As a consequence of the tremendous recent interest in the derivatives of 8-aminoquinoline as antimalarial drugs it was found desirable to develop a satisfactory synthesis for 8-amino-2,4-dimethylquinoline. The present procedure was found to be a rapid and efficient method for the preparation of this substance, one of its advantages being that it obviates any extensive purification of the intermediate 8-nitro-2,4-dimethylquinoline.

Experimental

8-Nitro-2,4-dimethylquinoline.—One mole (157 g., 150 ml.) of 2,4-dimethylquinoline[3] was cooled to 0° and treated with 250 ml. of concentrated sulfuric acid which was added as rapidly as possible with good mechanical stirring. The resulting solution was then cooled to 0° and treated with a solution of 115 g. of potassium nitrate in 300 ml. of concentrated sulfuric acid with vigorous mechanical stirring, the temperature being maintained between 0 and 5° by means of an ice–salt-bath. When all of the nitrating solution had been added, the mixture was stirred for an additional fifteen minutes without cooling and then was poured onto 2500 g. of cracked ice. The resulting mixture was treated with 1500 ml. of concentrated ammonia and diluted to 6 l. with cold water, cooled to room temperature and filtered. The filter cake was placed in a 2-l. beaker with 1 l. of cold water and stirred vigorously until a uniformly fine suspension was obtained. It was then filtered with good suction, and the moist filter cake was recrystallized from 1 l. of 95% ethanol using norit and a heated funnel: yield 113–115 g. (51–67%), m. p. 115–125°.[4] This impure product is a mixture of 8-nitro-2,4-dimethylquinoline with one or more isomers. A second isomer, m. p. 109.6–110.1° cor., was isolated from the mother liquors from the recrystallization of the major product, but the structure of this substance has not as yet been determined.

Anal. Calcd. for $C_{11}H_{10}O_2N_2$: N, 13.86. Found: N, 14.0.

In view of the work of Price, Velzen and Guthrie[5] who isolated 6-nitro-2,4-dimethylquinoline, it would appear that this substance is either 5- or 7-nitro-2,4-dimethylquinoline, probably the former in view of the well-known resistance of the 7-position in quinoline toward nitration.[6]

8-Amino-2,4-dimethylquinoline.—A solution of 101 g. (0.5 mole) of 8-nitro-2,4-dimethylquinoline (m. p. 115–125°) in 375 ml. of concentrated hydrochloric acid was added from a dropping funnel to a well-stirred solution of 375 g. of stannous chloride dihydrate in 136 ml. of concentrated hydrochloric acid, the temperature being maintained at 40–50° by means of an ice-bath. Near the end of the reduction a yellow precipitate appeared. After complete addition of the nitro compound to the reducing solution there was added 2000 g. of cracked ice and a cooled solution of 850 g. of potassium hydroxide in 1 l. of water. The resulting mixture was vigorously stirred for 30 minutes and then filtered, and the residue was washed in the funnel with three portions of cold water totaling 1 l. The filter cake was pressed dry and then was dissolved in 1 l. of water containing 50 ml. of concentrated hydrochloric acid. In order to effect solution the mixture was boiled and then was treated at the boiling temperature with a liberal quantity of norit and filtered through a steam-heated funnel. Upon cooling there separated from the filtrate a mass of golden yellow needles, 71–87 g.[7] This product was dissolved in 500 ml. of boiling water, and the resulting solution was treated with 30 ml. of concentrated ammonia. The 8-amino-2,4-dimethylquinoline separated as an oil which solidified upon rapid cooling with continuous agitation. The mixture was allowed to stand for 30 minutes at room temperature, and then it was filtered: yield 51–61 g. (59–71%), m. p. 86–90°. If a very pure product is desired, the initial product may be recrystallized directly from 70–90° ligroin (10 ml. per g.) or converted to the hydrochloride, which is readily recrystallized from water. Highly purified 8-amino-2,4-dimethylquinoline is a colorless crystalline substance, m. p. 93.7–94.2° cor.[8]

shortly after its resumption the appearance of an abstract of a paper by Wibaut and Kooyman[3] made it inadvisable to proceed further along those lines. The applicability of the reaction scheme having been proved, we wish to report the synthesis and properties of 2-methyl-3-*n*-propylpyridine and of 2-methyl-3-*n*-butylpyridine together with those of certain intermediates used in their preparation.

Ethyl α-*n*-butyl β-aminocrotonate, for which no literature reference was found, was prepared from ethyl α-*n*-butylacetoacetate, ammonia and ammonium nitrate. It had a melting point of 41–42° and a boiling point of 116–118° (10 mm.).

Products of the Interaction of Potassium Dihydrogenphosphide and *n*-Heptyl Bromide in Liquid Ammonia

BY GEORGE W. WATT AND R. C. THOMPSON, JR.

Alkali and alkaline earth metal dihydrogenphosphides prepared by the reaction between phosphine and solutions of these metals in liquid ammonia[1,2] continue to find application in the synthesis of derivatives of phosphine.[3]

Several years ago we studied several reactions of potassium dihydrogenphosphide in liquid ammonia and since further work is not anticipated it seems worth while to report the synthesis of *n*-heptylphosphine and its conversion to a product believed to be *n*-heptyl-phosphonous acid.

Phosphine was prepared by the action of sodium hydroxide solution on phosphonium iodide and dried over potassium hydroxide pellets. The dry gas was led into a solution of 2.7 g. of potassium in approximately 100 ml. of anhydrous liquid ammonia (contained in a flask provided with a stirrer and reflux condenser) until the characteristic blue color of the potassium solution was discharged. All reactants were protected from contact with the atmosphere. *n*-Heptyl bromide (11.9 g.) was added to the resulting pale yellow solution of potassium dihydrogen phosphide and the reaction mixture was stirred for two hours at −33.5°. The ammonia was evaporated and the residual liquid was removed in an atmosphere of carbon dioxide, extracted with 2 *N* hydrochloric acid solution, and the acid-insoluble fraction was distilled in an atmosphere of carbon dioxide to provide 6 ml. of a clear liquid, b. p., 73–74° at 30 mm. Boiling point determinations using capillary tubes gave consistently a value of 169.5°. This is a reasonable value for the boiling point of the anticipated *n*-heptylphosphine[4] which was apparently the primary reaction product. Despite precautions taken to avoid atmospheric oxidation while handling samples for analysis, this product was oxidized to a substance having an analytical composition corresponding to *n*-heptylphosphonous acid.

Anal. Calcd. for $C_7H_{17}PO_2$: C, 51.19; H, 10.44; P, 18.89. Found: C, 50.91; H, 10.48; P, 19.10.

This substance gave a negative test for halogen, exploded upon contact with fuming nitric acid, and was soluble in glacial acetic acid. Upon exposure to the atmosphere for several hours, it was further oxidized to a viscous liquid that boiled above 225°.

With potassium dihydrogenphosphide in liquid ammonia at −33.5°, bromo and iodobenzene react slowly, and ammonium chloroacetate reacts more rapidly to form products that have not been identified.

the experimental part. The azoxy compound was formed with zinc and ammonium chloride instead of the hydroxylamine usually obtained with this reagent. Polymeric products were obtained in the reduction of nitro to amino with zinc and hydrochloric acid; of nitro to azo with stannous chloride; of azoxy to azo with iron filings; and of azo to hydrazo with zinc and alcoholic sodium hydroxide. The azoxy compound polymerized on heating with benzoyl peroxide and the benzidine and azo compounds on heating without catalyst. The hydrazo compound decomposed on heating with benzoyl peroxide apparently without polymerization.

Experimental

Yields, physical properties, and analyses for the following products are listed in Table I.

***m*-Nitrostyrene** was prepared by the decarboxylation of *m*-nitrocinnamic acid by a procedure similar to that previously attempted.[2] A mixture of 20 g. of *m*-nitrocinnamic acid (E. K. Co.), 75 ml. of quinoline, and 3 g. of copper powder were heated at 185–190° so as to produce a steady evolution of carbon dioxide. After one and one-half hours of heating the mixture was acidified with 50% excess 3 *N* hydrochloric acid and steam distilled. The distillate was extracted with chloroform and the combined extracts were dried over anhydrous sodium sulfate. After distilling off the chloroform, the residue was fractionated from a modified Claisen flask to give 9.3 g., 60% of the theoretical amount, of *m*-nitrostyrene, b. p. 90–96° (3.5 mm.), $n^{20}D$ 1.5836. Refractionation through a partial take-off column, 0.75 × 8 in. packed with Fenske rings gave a center cut, b. p. 96° (3.5 mm.), $n^{20}D$ 1.5830. With larger quantities longer reaction times were required and lower yields were obtained than in the above experiment.

3,3′-Divinylazoxybenzene was prepared by the reduction of *m*-nitrostyrene with sodium methoxide in methanol[3] or by reduction with zinc and ammonium chloride in aqueous ethanol.[4] Heating the fused solid at 80° with 0.5% benzoyl peroxide gave an insoluble, infusible polymer.

3,3′-Divinylazobenzene.—To 0.68 g. of 3,3′-divinylhydrazobenzene in 75 ml. of ethanol was added 10 g. of ferric chloride hexahydrate in 25 ml. of hot water. After fifteen minutes water was slowly added to precipitate the azo compound which was twice recrystallized from alcohol–water. Oxidation with sodium hypobromite or air in alcoholic sodium hydroxide also converted the hydrazo to the azo compound. Attempts to convert the azoxy to the azo compound by heating with iron filings gave polymeric products. The sample analyzed melted at 84° (cor.); Komppa[1] reported a m. p. of 38°. Heating at 110° for twenty-four hours gave an insoluble polymer which decomposed before melting when heated.

3,3′-Divinylhydrazobenzene was prepared by zinc and alcoholic sodium hydroxide reduction[5] of *m*-nitrostyrene. Attempts to reduce the azo to hydrazo compound with zinc and alcoholic sodium hydroxide gave only a polymer. On heating a mixture of solid the hydrazo compound and 0.5% benzoyl peroxide to 110° decomposition without apparent polymerization occurred.

2,2′-Divinylbenzidine was prepared in 30% yield by treating 3,3′-divinylhydrazobenzene with concd. hydrochloric acid in ether,[6] m. p. 123° (cor.); reported[1] m. p. 124°. Heating to 135° converted the benzidine to an infusible, insoluble polymer.

***m*-Aminostyrene Polymer.**—Reduction of *m*-nitrostyrene with zinc and hydrochloric acid gave a polymer which was precipitated as the hydrochloride on addition of excess hydrochloric acid to its aqueous acid solution.

p-Alkoxybenzyl Grignard Reagents

BY M. G. VAN CAMPEN, DONALD F. MEISNER[1] AND STANLEY M. PARMERTER[2]

The alkoxybenzylmagnesium halides are valuable intermediates in the synthesis of stilbene derivatives particularly in the study of synthetic estrogenic agents. However, the general impression exists that these Grignard reagents cannot be prepared. This impression is probably due to the fact that in attempts to form the Grignard from such halides as *p*-methoxybenzyl chloride by the usual procedure, a nearly quantitative yield of the *p*,*p*′-dialkoxybibenzyl is obtained. By using a modification of the method reported by Gilman[3] for the preparation of allyl Grignard reagents, it is possible to prepare *p*-alkoxybenzylmagnesium chlorides in acceptable yields. This is accomplished primarily by the use of a large excess of magnesium powder and slow addition of a dilute ether solution of the benzyl halide to the magnesium. Using the following general procedure 90% yields of *p*-methoxybenzylmagnesium chloride and *p*-benzyloxybenzylmagnesium chloride are consistently obtained.

Procedure.—A mixture of 2 to 2.5 g. atoms of magnesium turnings and 2 to 2.5 g. atoms of magnesium

powder is vigorously stirred under 1 liter of refluxing anhydrous ether. One mole of the alkoxybenzyl halide dissolved in 1 l. of ether is added over a two to five hour interval. The resulting Grignard reagent is then filtered through glass cotton to remove the finely divided magnesium powder, which if not removed usually reacts with objectionable vigor during the ultimate decomposition with water or dilute acid. The yield is estimated by the usual acidimetric titration.

COMMUNICATIONS TO THE EDITOR

CHEMICAL REACTIONS IN MOVING BOUNDARY SYSTEMS OF WEAK ELECTROLYTES

Sir:

In moving boundary systems containing partially neutralized weak acids or bases there exists the possibility of chemical reactions at the moving boundary which cause the mobility calculated from the boundary velocity and the conductivity of the leading solution to be lower than the ionic mobility.[1] This is illustrated by experiments 2 and 3 in which the indicator electrolyte is a salt of weak acid (cacodylic acid) having a higher pK than the leading weak electrolyte (acetic acid). The following reaction goes to completion

$$\mathrm{Cac^-} + \mathrm{HOAc} \rightleftharpoons \mathrm{HCac} + \mathrm{OAc^-} \quad K_{25^\circ} = 25 \quad (1)$$

to the right at the moving boundary so that none of the acetic acid remains behind that boundary. The concentration of the sodium acetate is 0.05 N (at 0°) in all experiments, and it has been shown that the concentration and pH of the indicator electrolyte (α solution) is unimportant over a wide range.

The moving boundary equation[2] cannot be applied to acetate ion in the presence of acetic acid, but a term may be added for the acetic acid as follows so that the moving boundary equation for acetate constituent becomes

$$T^{\gamma}_{\mathrm{OAc^-}} = V^{\beta\gamma}(C^{\gamma}_{\mathrm{OAc^-}} + C^{\gamma}_{\mathrm{HOAc}}) = \frac{u^{\gamma}_{\mathrm{OAc^-}} C^{\gamma}_{\mathrm{OAc^-}}}{\kappa^{\gamma}\ 1000/F} \quad (2)^3$$

From equation (2) we see that the mobility, u, calculated from the boundary velocity in this case is the "constituent" mobility. The acetate ion mobility, $u^{\gamma}_{\mathrm{OAc^-}}$

$$u = V^{\beta\gamma}\kappa^{\gamma}\frac{1000}{\mathrm{F}} = u^{\gamma}_{\mathrm{OAc^-}}\frac{(C^{\gamma}_{\mathrm{OAc^-}})}{(C^{\gamma}_{\mathrm{OAc^-}} + C^{\gamma}_{\mathrm{HOAc}})} \quad (3)$$

calculated from the constituent mobility obtained in experiments 2 and 3 by using equation (3) are -17.62×10^{-5} and -17.55×10^{-5} in agreement with the average value, -17.53×10^{-5}, obtained in experiments 1 and 4.

However, in systems containing weak electrolytes the constituent mobility is not always obtained as illustrated by experiment 5. Whether or not a chemical reaction takes place depends upon the pK and relative mobility of the indicator ion. In this experiment the mobility calculated is slightly lower than the ionic mobility because the acetate ion does not disappear in the $\beta\gamma$ boundary, owing to the slight dissociation of the acetic acid left behind the moving boundary.

SYNTHESIS OF DL-THREONINE

Sir:

The structure α-amino-β-hydroxy-n-butyric acid contains two dissimilar asymmetric carbon atoms and hence exists as four optical isomers and

(1) Dr. Harry Svensson, Institutes of Physical and Biological Chemistry, Upsala, Sweden, has independently recognized this fact in work initiated in September, 1946 (*Acta Chem. Scand.*, in press), personal communication.

(2) Weber, *Sitzungsber. Akad. Wissensch. Berlin*, 936 (1897); Svensson, *Ark. Kem. Min. Geol.*, **17A**, No. 14 (1943); Longsworth, THIS JOURNAL, **67**, 1109 (1945).

(3) The symbols have the meanings used by Longsworth ($C_{\mathrm{OAc^-}}$ is taken as negative).

two racemic modifications. Attempts to synthesize one of these racemic modifications, the essential amino acid DL-threonine, have invariably given poor results, though some of the syntheses have produced the diastereoisomeric DL-allothreonine in good yields. Efforts to convert DL-allothreonine into DL-threonine have met with little success.

It has now been found that esters of N-acyl-DL-allothreonine are converted into DL-threonine in high yield by transformation into the corresponding oxazolines followed by hydrolysis of the latter with mineral acid.

N-Benzoyl-DL-allothreonine was treated with diazomethane and the methyl ester (m. p. 110–111°. *Anal.* Calcd. for $C_{12}H_{15}O_4N$: C, 60.76; H, 6.36. Found: C, 60.86; H, 5.99.) on reaction with excess thionyl chloride at room temperature gave 2-phenyl-5-methyl-4-carbomethoxyoxazoline hydrochloride, m. p. 118–119°, in quantitative yield. *Anal.* Calcd. for $C_{12}H_{13}O_3N\cdot HCl$: C, 56.36; H, 5.52. Found: C, 56.50; H, 5.71. Hydrolysis with dilute hydrochloric acid followed by isolation and recrystallization gave pure D-threonine in 70% yield. *Anal.* Calcd. for $C_4H_9O_3N$: C, 40.33; H, 7.62; N, 11.76. Found: C, 40.35; H, 7.70; N, 11.46. By the same sequence of steps N-benzoyl-DL-threonine was converted into pure DL-allothreonine in 77% over-all yield.

A practical synthesis of DL-threonine from acetoacetic ester has been developed by the use of this inversion. Ethyl α-acetamidoacetoacetate, obtained in 88% yield from acetoacetic ester via reductive acetylation of ethyl α-phenylazoacetoacetate, was hydrogenated in aqueous solution with Adams catalyst to give on concentration a mixture of diastereoisomeric ethyl α-acetamido-β-hydroxy-*n*-butyrates containing 80–85% N-acetyl-DL-allothreonine ethyl ester. A purified sample of this product melted at 76–77°. *Anal.* Calcd. for $C_8H_{15}O_4N$: C, 50.78; H, 7.99. Found: C, 50.54; H, 8.04. The crude hydrogenation product was treated with thionyl chloride, and the solution was refluxed with water to decompose the intermediate oxazoline. An isolated sample of this 2,5-dimethyl-4-carbethoxyoxazoline hydrochloride melted at 105–106°. *Anal.* Calcd. for $C_8H_{13}O_3N\cdot HCl$: C, 46.27; H, 6.79; N, 6.75; N. E., 207.7. Found: C, 46.11; H, 6.87; N, 6.97; N. E., 202.2. The aqueous solution was concentrated dry and the amino acid hydrochloride taken up in isopropanol and precipitated with aniline. The crude product (89% yield from ethyl α-acetamidoacetoacetate) was a mixture of DL-threonine and DL-allothreonine containing 83% of the former (microbial assay).

Pure DL-threonine was obtained by separation of the sodium salt from anhydrous alcohol, reconversion into the free acid and recrystallization by precipitation from aqueous solution with alcohol. The over-all yield of DL-threonine from acetoacetic ester was 57%. *Anal.* Found: C, 40.42; H, 7.32; N, 11.82. This product was found 100% pure by microbial assay and better than 99% pure by solubility analysis.

Additional work now in progress indicates that the "oxazoline inversion" described may be a general method for the interconversion in high yield of diastereoisomeric α,β-amino alcohols.

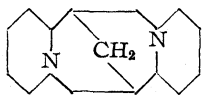
THE TOTAL SYNTHESIS OF SPARTEINE

Sir:

We wish to report a convenient total synthesis of *dl*-sparteine (I). The *Lupin* alkaloid *l*-



I

sparteine was first isolated in 1851 and the correct structure (I) was confirmed by Clemo and Raper[1] in 1933. *l*-Sparteine is used in medicine chiefly as a cardiac stimulant and a diuretic.[2] *d*-Sparteine and the naturally occurring alkaloid pachycarpine[3] have been shown to be identical.[4]

Our synthesis of *dl*-sparteine proceeds in two steps from ethyl 2-pyridylacetate. The first step was the preparation of 1-carbethoxy-4-keto-3-(2′-pyridyl)-pyridocoline by condensation of ethyl orthoformate with ethyl 2-pyridylacetate in the presence of acetic anhydride according to the method of Clemo, Morgan and Raper.[5] The second step was that of reductive cyclization, which was reported first from this Laboratory[6] for the synthesis of pyrrolizidines. 1-Carbethoxy-4-keto-3-(2′-pyridyl)-pyridocoline in dioxane was hydrogenated over copper chromite at 250° and 350 atm. in one and one-half hours. The product was separated into three fractions: b. p. 90–120°, 120–126°, 140–148° (1.25 mm.). The second and largest fraction gave a **monopicrate** (m. p. 136–137°; *Anal.* Calcd. for $C_{21}H_{29}N_5O_7$: C, 54.42; H, 6.31; N, 15.11. Found: C, 54.55; H, 6.49; N, 15.18) and a **dipicrate** (m. p. 208°; *Anal.* Calcd. for $C_{27}H_{32}N_8O_{14}$: C, 46.82; H, 4.66; N, 16.18. Found: C, 46.76; H, 4.88; N, 16.28). The analyses and melting points of the derivatives are consistent with the assignment of the *dl*-sparteine structure to the synthetic free base. Clemo and Leitch[7] reported a **monopicrate**

(m. p. 135°) and a **dipicrate** (m. p. 206–207°) of *dl*-sparteine, which they obtained from naturally occurring *dl*-lupanine. As a further proof of identity, our *dl*-sparteine was converted to *dl*-oxysparteine, m. p. 110–111°, by treatment with alkaline potassium ferricyanide. The melting point of *dl*-oxysparteine has been reported as 110–111°,[5] 112–113°,[4] 113°.[7] Finally, the infrared absorption spectra of our synthetic *dl*-sparteine dipicrate and an authentic sample of *l*-sparteine dipicrate (m. p. 208°) were found to be identical in solution.[8]

We are aware of the desirability of resolving *dl*-sparteine and of isolating the other two racemates of I. We also foresee the applicability of our method to the synthesis of other bases related to sparteine.

(8) The authors are indebted to Mrs. James L. Johnson for determination of the infrared absorption spectra.

A CRYSTALLINE FACTOR FUNCTIONALLY RELATED TO FOLIC ACID

Sir:

In a systematic study of factors functionally related to *p*-aminobenzoic acid and folic acid and occurring in liver extracts used for the treatment of pernicious anemia, a factor was discovered which prevented the toxic action of methylfolic acid[1] upon the growth of *Leuconostoc mesenteroides* 8293. In a medium previously described[2] but supplemented with 300 γ of thymine per 10 cc., the ratio of methylfolic acid to folic acid just necessary for maximum inhibition was 3,000. The addition of this factor in adequate amounts (equivalent to 0.01–0.03 γ of crystalline material per 10 cc.) increases the antibacterial index about tenfold.

A medium suitable for quantitative assay was obtained by the addition of 0.03 γ of folic acid and 200 γ of methylfolic acid per 10 cc. to the above medium. Under these conditions increasing concentrations of the factor resulted in increasing growth levels.

Employing this assay, a principle has been isolated from hog liver in crystalline form. Recrystallized from isopropyl alcohol, this principle appears as fine, colorless prisms, m. p. 189–190°. Under the testing conditions, the factor is several times as active as folic acid in promoting a half-maximum growth response.

Extracts prepared from either liver, hog duodenal mucosa, or grass are highly active, but milk, muscle tissue and yeast extract are relatively poor sources of active material. Liver extracts used in treatment of pernicious anemia are relatively potent, and some experimental extracts of high potency (determined clinically) assayed by the above method appear to contain as much as 1% of this factor.

Preliminary investigation of the structure of the compound indicated that it was thymidine[3] or a structurally related compound.

We acknowledge our indebtedness to Eli Lilly and Company for their coöperation. Particular thanks are due Drs. Ewald Rohrmann and Edward D. Campbell for their coöperation in furnishing experimental extracts and analytical facilities.

(1) Crude mixture from the condensation of α,β-dibromobutyraldehyde, 2,4,5-triamino-6-hydroxypyrimidine and *p*-aminobenzoylglutamic acid obtained from Dr. E. L. R. Stokstad [Franklin, *et al.*, *J. Biol. Chem.*, **169**, 427 (1947)].

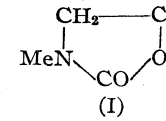
THE KINETICS OF THE POLYMERIZATION OF CARBONIC ANHYDRIDES

Sir:

Carothers (*Chem. Rev.*, **8**, 353 (1931)) has divided polymerizations into two types, "addition" and "condensation." In the former type, initiation, propagation, transfer and termination reactions are involved (*cf.* Bamford and Dewar, *Proc. Roy. Soc.* (*London*), **192**, 309 (1948)), but in condensation polymerizations only chain-growth occurs, and in this reaction every species reacts with every other. There is, however, a third type of polymerization in which there are only two reactions, initiation, and a propagation reaction where the polymers do not react with each other, but only with the monomer. The polymerizations of carbonic anhydrides (*e. g.*, I) appear to belong to this third type, and are also important since they can be used to synthesize polypeptides of some complexity. The reactions involved are

$$M + A \longrightarrow X + CO_2 \quad (k_1) \qquad (1)$$
$$M + X \longrightarrow X + CO_2 \quad (k_2) \qquad (2)$$

where M denotes the carbonic anhydride, X any polymer species, and A the initiator which may be a hydroxylic or amino compound.



(I)

$$MeNHCH_2CO(NMeCH_2CO)_nNMeCH_2CONMe_2$$

(II)

Although a complete formal solution of the kinetic equations is impossible, the following methods are available for the absolute determina-

tion of the velocity constants k_1 and k_2. If (M) = M_0 and (A) = A_0 when $t = 0$, and (A) = A_∞ when (M) = 0, it can be shown that

$$k_2/k_1 = (M_0 - A_0 + A_\infty)/(A_0 \log (A_0/A_\infty) - A_0 + A_\infty) \quad (3)$$

Since end-group estimation gives $A_0 - A_\infty$, this equation enables k_2/k_1 to be evaluated.

The experimental conditions can be adjusted so that the concentration of initiator (A) is approximately constant, when it can be shown that there is a maximum rate given by

$$[\mathrm{d(M)/d}t]^2_{\max.} = \frac{1}{27} k_1 k_2 A_0 (2M_0 + k_1 A_0/k_2)^3 \quad (4)$$

A simpler procedure, however, is to use the preformed polymer to initiate the polymerization, so that the second step (equation (2)) is isolated. The molar concentration of polymer (X_0), is thus constant, and the rate of disappearance of carbonic anhydride is given by

$$-\mathrm{d(M)/d}t = k_2 X_0 (\mathrm{M}) \quad (5)$$

The kinetics of the polymerization of sarcosine carbonic anhydride (I) is being investigated. The polymer (II) used for initiating is obtained as a colorless, hygroscopic solid by the action of dimethylamine on the anhydride (I) in dioxane.

The polymerization in nitrobenzene is followed manometrically by the evolution of carbon dioxide. In accordance with equation (10) the reaction shows first-order dependence on (M); this confirms the assumption that k_2 is independent of the molecular weight of the polymer, for molecular weights between about 500 and 5000. Preliminary measurements indicate that the velocity constant, k_2, can be expressed by the equation

$$k_2 = 1600e^{-5,800/RT} \text{ liters mole}^{-1} \text{ sec.}^{-1}$$

The low value of the frequency factor is noteworthy.

We hope to extend this investigation to other carbonic anhydrides and to co-polymerizations.

NEW BOOKS

Chemical Insect Attractants and Repellents. By VINCENT G. DETHIER, A.M., Ph.D., Professor of Zoology and Entomology, The Ohio State University; formerly Entomologist, Inter-Allied Malaria Control Commission, Gold Coast, B. W. A. The Blakiston Company, Philadelphia, Pennsylvania, 1947. xv + 298 pp. Illustrated. 15.5 × 23.5 cm. $5.00.

The manner in which various chemicals attract or repel insects is of considerable interest to both chemists and entomologists working in economic entomology, to students of insect ecology and to others. The subject has also intrigued biologists not so well acquainted with the peculiarly specialized behavior of the insect world. Although the literature on attractants and repellents is extensive, most of the effort has been expended on research by the trial-and-error method, with not enough consideration of the chemical, physical, physiological and botanical factors involved. In an effort to remedy the situation and to impart a greater impetus to research in this field, Dr. Dethier has undertaken the difficult task of assembling and correlating the widely scattered literature. In this respect he has done a commendable piece of work.

The text is not a compilation of formulas of attractant and repellent substances. Rather it represents a theoretical approach to the study of the subject. The book is divided into ten chapters. An introductory chapter is followed by six that deal specificially with attractants, one with repellents, and two that are devoted to a more general discussion. There are approximately 750 literature citations.

Although the importance of research on insect repellents, especially for those insects that transmit disease, such as malaria-carrying mosquitoes, is pointed out, no mention is made of the extensive studies carried on during the recent war by the Bureau of Entomology and Plant Quarantine, United States Department of Agriculture; neither are the excellent fundamental studies on repellents by DeLong at the Ohio State University, nor is adequate treatment given the work of Granett at Rutgers University. The important subject of mothproofing warrants more than a brief paragraph. The book contains numerous errors in chemical nomenclature and in the structural formulas of compounds. These errors might have been avoided if the manuscript had been submitted to an organic chemist for review. Nevertheless the book is a valuable one and meets a definite need for both the chemist and the entomologist.

H. L. HALLER

Fundamentals of Photographic Theory. By T. H. JAMES, Ph.D., and GEORGE C. HIGGINS, Ph.D., Research Laboratories of Eastman Kodak Company. John Wiley and Sons, Inc., 440 Fourth Avenue, New York 16, N. Y., 1948. vii + 286 pp. 14 × 22 cm. Price, $3.50.

The recognized standing of the authors, not to mention coöperation by members of the Eastman staff, arouses in the reader expectations which are not disappointed. By concentrating upon black and white photography, exclusive of cameras or accessories, a coverage of the central theme admirable from physical, chemical and psychophysical standpoints is achieved. Consistent use of the sensitivity-speck basis for the latent image, together with the Gurney–Mott hypotheses, resolves in plausible fashion a great variety of complicated or at first sight contradictory phenomena. The chemistry of essential dark-room procedures is set forth in detail, but some will regret the omission of intensification, reduction and toning. Conflicting theories are critically examined in the light of data and of physico-chemical generalizations. Objective and subjective evaluations of photographic images are

carefully distinguished, then aptly correlated. Outstanding is the graphic solution of the complete problem of tone reproduction, first suggested by L. A. Jones, which gives due weight to the sensitivity relations of the human eye. A short list of well-chosen references is found at the end of each chapter.

Few photographers are sufficiently equipped, instrumentally or through training, to put the entire book into practice. But it is at least consoling to realize that as an art photography has anticipated not a few theoretical conclusions.

GEORGE S. FORBES

Radioactive Tracers in Biology. An Introduction to Tracer Methodology. By MARTIN D. KAMEN, Associate Professor of Chemistry, Chemist to the Edward Mallinckrodt Institute of Radiology, Washington University, St. Louis, Missouri. Academic Press, Inc., 125 East 23rd Street, New York, N. Y., 1947. xiii + 281 pp. 38 figs. 16 × 23.5 cm. Price, $5.80.

This long-needed book on tracer techniques reviews the pertinent underlying concepts of nuclear physics, surveys contemporary tracer methods, and indicates their potentialities and limitations. As the Academic Press' first volume in a series of monographs on Organic and Biological Chemistry, which has subsequently come under the editorship of Louis F. Fieser and Mary Fieser, Dr. Kamen's book was an immediate sell-out. Doubtless the second printing, which buyers are now awaiting, will include corrections of numerous misprints and small errors which inevitably resulted from Dr. Kamen's speed record of less than three months for the actual writing of the entire book. If this speed left rough spots, nevertheless all the new workers in the many fields of application of radioactive isotopes should read Dr. Kamen's book, and will be grateful to him for providing it.

The first four chapters, of nearly a hundred pages, contain the essential facts necessary to the worker in any field of science or engineering who would use radioactive tracers. The balance of the book specializes these principles to specific applications in the life sciences, especially in studies of intermediary metabolism where radioactive tracers are an indispensable tool. Every new user of radioactive isotopes should certainly become conversant with the contents of this book. Seasoned workers will feel the book is introductory, but a small reader-survey has shown this reviewer that engineers, some chemists, radiologists, and physicians find the book advanced enough to require at least one or two rereadings.

Recently there have been a number of Isotope Conferences on a variety of scientific subjects, at each of which much time was consumed in reviews of elementary principles because this material was not conveniently available. The planners of future Isotope Conferences should presuppose that the audience and the conferees have at least mastered the topics presented in Kamen's book, and should now pitch their programs at the intermediate level instead of at the introductory level.

Among detection techniques, Kamen rightly advocates simple devices such as the Lauritsen electroscope wherever they can be used. The detailed instructions for building a Geiger–Müller counter were cogent in June, 1946, when the manuscript was completed, but since then a large variety of counters and electronic auxiliaries have become available commercially. Most new workers will prefer to buy rather than to build. Similarly, the homemade standards using uranium oxide should now be replaced by radium D-E beta ray standards distributed by the National Bureau of Standards.

The description of general methods and techniques deals primarily with C^{11} and C^{14} which are taken as prototypes of all other isotopes. Thus C^{11} presents the difficulty of a short half-period (twenty minutes), but emits easily detected energetic positron beta-rays (maximum energy 0.98 Mev) as well as the corresponding annihilation radiation (0.51 Mev) which can be measured readily using gamma-ray detecting instruments. Whereas C^{11} requires cyclotron production and, like other positron emitters, cannot be prepared by irradiation in a uranium pile, the long-lived C^{14} is now readily obtainable from the pile. However, the long half-period of C^{14} is associated, as usual, with a very low energy radiation (maximum energy of beta rays 0.15 Mev) which makes its detection correspondingly difficult. Also the very long half-period (5000 years) of C^{14} argues against its use in many investigations, especially in human subjects, because of the persistence of its radiation and the possible accumulation of biologically harmful total radiation doses.

Unfortunately, an extensive table of radioactive isotopes and their properties was not included in the first printing. A 4-page table of organic syntheses with radioactive isotopes is provided and should prove valuable and convenient for reference.

ROBLEY D. EVANS

Organic Analytical Reagents. By FRANK J. WELCHER, Ph.D., Associate Professor of Chemistry, Extension Division, University of Indiana. D. Van Nostrand and Co., Inc., 250 Fourth Avenue, New York, N. Y. Vol. I, xv + 442 pp. + 63 tables, 1947; Vol. II, xi + 530 pp. + 69 tables, 1947; Vol. III, xi + 593 pp. + 111 tables, 1947; Vol. IV, xiii + 624 pp. + 68 tables, 1948. All 15 × 23 cm. $8.00 per volume; price for set $28.00.

The first half of the twentieth century has been characterized by an extraordinary increase in the rate of magnitude of production of scientific data. In the field of organic chemistry, for example, this has resulted in the discovery and/or synthesis of an appalling number of new compounds. Unfortunately, however, the extension of prior means and the development of new tools for recording and organizing this mass of information has not kept a corresponding pace. Consequently, there has now resulted a condition in which new evidence daily accumulates that unless systematic, convenient and economically practicable means for location and evaluation of all the facts relevant to a desired compound or method are soon developed, further progress will be seriously retarded or even significantly impaired. For this reason all means whose objectives are primarily to systematize, classify, coördinate and organize this flood of data comprise a contribution to scientific progress which may (at its best) be just as valuable as the original components of the discoveries themselves. This four-volume work by Dr. Welcher represents an example of an effort to overcome in a particular area the serious inadequacies mentioned.

The principal objective of this work has been to assemble in one place a description of all organic compounds used through 1945 in the analysis of inorganic substances and to discuss their mode of employment. The scope of the book does *not* include application of organic reagents to the detection, determination, or identification of organic compounds.

The four volumes comprise a total of sixty-seven chapters; these cover 827 organic reagents and require 9042 citations of the literature. The organization is such that all information relative to a particular compound is brought together in one place, extensive diversification in its uses being there systematically subclassified. Chemically related reagents are grouped together in chapters within which the sequence is alphabetical. With the text for each reagent is associated the corresponding series of citations to the original literature. Each volume includes an alphabetical name index of the organic reagents and also a subclassified index in which, under headings representing applications, the various reagents of the particular volume are alphabetically listed. However, no cumulative master index covering all four volumes is given.

Since the arrangement of topics is somewhat arbitrary it can, perhaps, best be surveyed by a review of the chapter sequences and headings. Volume I begins with

five short general chapters as follows: electronic theory of valence, coördination compounds, chelate compounds, types of chelate rings, and the effect of structure on solubility. The subsequent twelve chapters are devoted to hydrocarbons, substitution products of hydrocarbons, alcohols, phenols, miscellaneous phenolic compounds, aminophenols, phenolsulfonic acids, 8-hydroxyquinoline and its derivatives, azo derivatives of 8-hydroxyquinoline, ethers, aldehydes and ketones.

Volume II comprises ten chapters treating the following: organic acids, halogenated acids, hydroxy acids, amino acids, miscellaneous acids, acyl halides, acid anhydrides, esters, amines (255 pages) and quaternary ammonium compounds.

Volume III contains nineteen chapters headed as follows: pyridine and its derivatives, quinoline and quinoline derivatives, dipyridyl and related compounds, pyrazolone derivatives, miscellaneous heterocyclic nitrogen compounds, dioximes, acyloin oximes, hydroxyoximes, isonitroso compounds, nitrosophenols, miscellaneous oximes, cupferron and neocupferron, nitrosoamines, rhodanine and its derivatives, carbazides and thiocarbazides and semicarbazides, carbazones, thiocarbazones and miscellaneous imino compounds.

Volume IV concludes the set with seventeen chapters dealing with acidic nitro compounds, arsonic acids, dithiocarbamates, xanthates, miscellaneous sulfur compounds, sulfonic acids, sulfuric acids, seleninic acids, alkaloids, diazonium compounds, carbohydrates, miscellaneous natural substances, miscellaneous compounds, lake-forming dyestuffs, hydroxyanthraquinone dyes, miscellaneous dyes and dyes used in the detection of nitrite.

For the preparation of the various organic reagents the author, guided by the principle that it be the most adaptable in the average chemistry laboratory, has selected only one. This severe restriction is to be deplored as in some cases organic chemists would regard the choice as inadequate. The organic nomenclature is generally definite, but some peculiar sequences are employed. References to Beilstein are associated with many (but not all) compounds, but much inconsistency exists in the method. Although reference is made to the main series of Beilstein's fourth edition, references to the equally important first supplementary series are not always included and the even more important second supplementary series seems to have been ignored.

The set of books will be of most value to chemists concerned with inorganic analysis.

ERNEST H. HUNTRESS

The Chemistry of Acetylenic Compounds. Vol. I. The Acetylenic Alcohols. By A. W. JOHNSON, PH.D. with a foreword by Sir Ian Heilbron, D.S.O., D.Sc., F.R.S. Edward Arnold and Co., London, England. Longmans, Green and Company, New York, N. Y., 1946. xvii + 394 pp. 14.5 × 22 cm. Price $9.50.

This first volume of a projected three volume set dealing with the acetylenic compounds presents an excellent discussion of the chemistry of the acetylenic alcohols up to September, 1945. The author has subdivided the acetylenic alcohols into three groups, (I) compounds containing one acetylenic bond and one hydroxyl group, (II) compounds containing one acetylenic bond and more than one hydroxyl group and (III) hydroxyl compounds containing more than one acetylenic bond. Each group of compounds is discussed in a logical manner under the headings, historical, nomenclature, formation, physical properties, reactions of the hydroxyl group, reactions of the acetylenic bonds, reactions involving the free ethynyl group and reactions involving the whole molecule. The main body of this book was written before 1940 and in order to bring it up to date an appendix has been added which covers the more recent developments in the field. Chapters on the chemistry of the rubenes, on the application of acetylenic carbinol reactions in the sex hormone field, and on physical constants of acetylenic alcohols are also included as appendices to the main body of the book.

This is a very valuable critical résumé of the chemistry of acetylenic alcohols and will be indispensable to research workers in the field. It will also serve as interesting reading for anyone who wants to become informed on these highly useful reactions and the properties of this group of organic compounds.

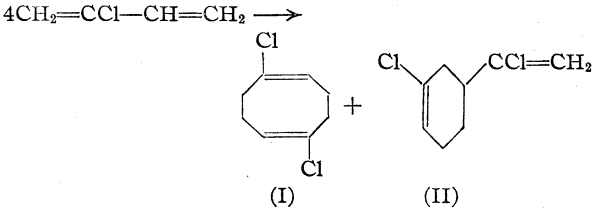
[CONTRIBUTION NO. 244 FROM THE CHEMICAL DEPARTMENT, EXPERIMENTAL STATION, E. I. DU PONT DE NEMOURS & COMPANY]

Cycloöctadienes from Dienes

BY R. E. FOSTER AND R. S. SCHREIBER

It has been reported[1] that an 8-carbon ring dimer was isolated from still residues obtained during the purification of monomeric chloroprene (2-chloro-1,3-butadiene). This dimer was assigned the structure 1,5-dichloro-1,5-cycloöctadiene (I) and presumably was formed by the spontaneous dimerization of chloroprene. The 6-membered ring dimer (II) was also isolated.



(I) (II)

Further, at the Reconstruction Finance Corporation Neoprene Plant, Louisville, Ky., operated by the E. I. du Pont de Nemours and Company, Mallonee and and Wooding isolated a third, lower-boiling product which tentatively has been assigned the structure 3-chloro-1-vinyl-1,3-cyclohexadiene. This material probably was formed by the dehydrochlorination of 1,3-dichloro-1-vinyl-3-cyclohexene, an isomer of (II).

Carothers[2] demonstrated earlier that a mixture of dimers was obtained by heating monomeric chloroprene. The components of this mixture were not identified, but it seems probable on the basis of comparable boiling points that two, or perhaps all three, of these compounds were present in the "β-polychloroprene" described by Carothers.

The purpose of this paper is to report the confirmation of the dimerization of chloroprene to a mixture of 6- and 8-membered ring compounds and to record two additional examples of the dimerization of conjugated dienes, 1,3-butadiene itself and 2,3-dichloro-1,3-butadiene,[3] to the corresponding cycloöctadienes.[4]

By heating chloroprene at 80° for one hundred and twenty hours in the presence of phenothiazine to inhibit polymerization and activated charcoal,[5] greater than 20% conversion to dichloro-1,5-cycloöctadiene was obtained.[5a] In addition, the two 6-membered ring compounds mentioned above were isolated. The structures of the carbon skeletons of these three materials were established by the reduction of the chloro compounds over platinum oxide in the presence of sodium acetate to the known saturated hydrocarbons. The fraction boiling at 147–149° was presumed to be impure cycloöctane on the basis of its boiling point and freezing point (9°); the 8-carbon ring was confirmed by oxidation with nitric acid to suberic acid.

The dimerization of 1,3-butadiene at 100–120° proceeded to give a preponderance of vinylcyclohexene, although the presence of 1–5% of an 8-membered ring dimer was demonstrated. The total dimerization product was hydrogenated and fractionated. The infrared spectra of the final fractions were compared with those of known mixtures of cycloöctane and ethylcyclohexane (see Fig. 1), and the proportion of cycloöctane in the

(1) Brown, Rose and Simonsen, *J. Chem. Soc.*, 101 (1944).

(2) Carothers, Williams, Collins and Kirby, THIS JOURNAL, **53**, 4211 (1931).

(3) Carothers and Berchet, U. S. Patent 1,965,369.

(4) During the preparation of this paper, it was brought to our attention that Dr. Karl Ziegler has reported the conversion of 1,3-butadiene at temperatures above 200° to a mixture of vinylcyclohexene, cycloöctadiene, and octahydrobiphenyl. Details of this work have not been published. Ziegler, "A New Approach to the Cycloöctane Series," meeting of the German Chemical Society, Heidelberg, April 15–18, 1947.

(5) Although the evidence is not unequivocal, there are indications that the yield of dimers is improved by the inclusion of activated charcoal, possibly as a result of the increased surface area.

(5a) Cope and Bailey, THIS JOURNAL, **70**, 2205 (1948), have developed a modified procedure for conducting this dimerization at atmospheric pressure.

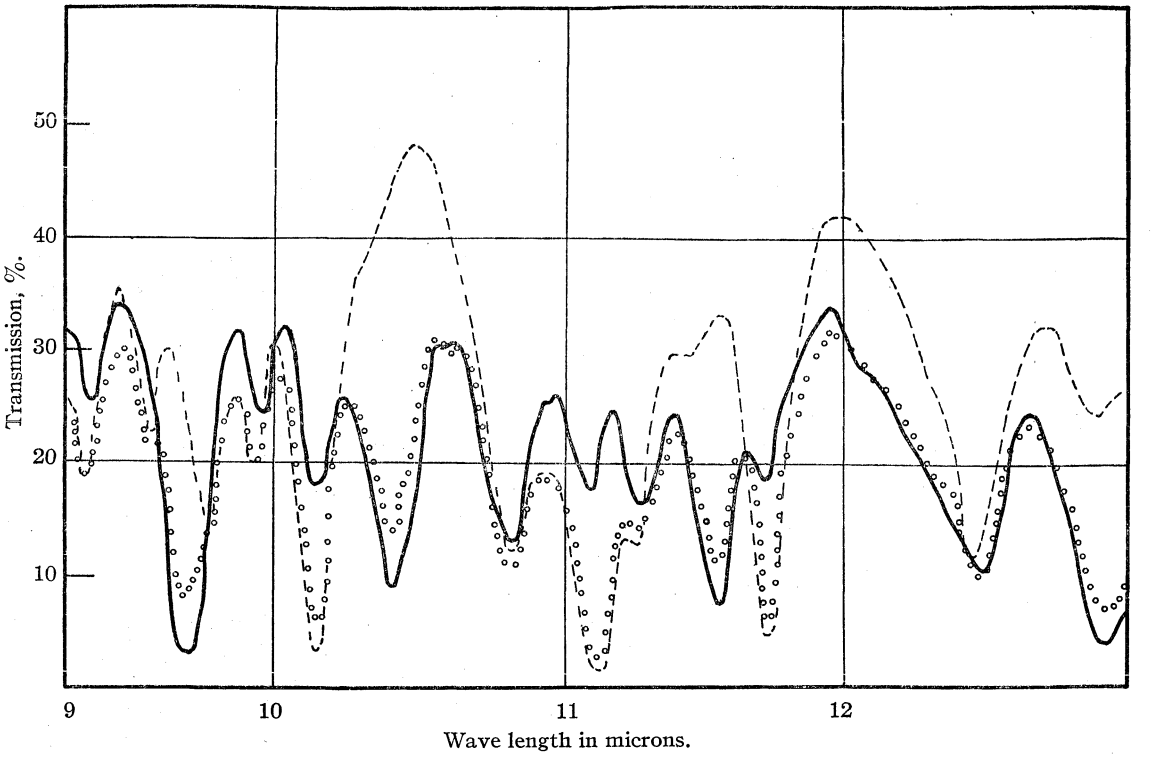


Fig. 1.—Infrared absorption spectra of cycloöctane, —; ethylcyclohexane, ---; and 1:1 cycloöctane–ethylcyclohexane, O-O-O.

total reduced dimer mixture was readily calculated. The identity of the final fractions was established by isolating cycloöctane in the pure state and subsequently oxidizing it to suberic acid.

The dimerization of 2,3-dichloro-1,3-butadiene was carried out at 80° for one hundred and twenty hours. Only one dimeric product, formed in 12.5% yield, was isolated; the remainder was converted to polymer. The dimer was shown to possess an 8-carbon ring by reduction to cycloöctane.

Experimental

Dimerization of Chloroprene.—One hundred and fifty grams of chloroprene, 3 g. of phenothiazine, and 10 g. of Darco (Grade S-51) were sealed in a pressure bottle under nitrogen and agitated at 80° for one hundred and twenty hours. The dark, mobile product was filtered to remove a small amount of polymer and charcoal (15 g.) and the filtrate (119 g.) was distilled. Unchanged monomer (25 g.) was removed at atmospheric pressure and the remainder was distilled under reduced pressure. The following fractions were obtained: (A) 3-chloro-1-vinyl-1,3-cyclohexadiene (15 g., 16%) 67–70° (17 mm.); (B) 3-chloro-1-α-chlorovinyl-3-cyclohexene (19 g., 20%) 96–100° (17 mm.); (C) dichloro-1,5-cycloöctadiene (28.2 g.) 109–118° (17–18 mm.). Infrared data indicated this last fraction to contain 75% 8-membered ring compound which corresponds to 22% yield of dichloro-1,5-cycloöctadiene. The total yield of dimeric products was 66% based on 96 g. of chloroprene, the amount consumed during the reaction.

These samples were refractionated for analysis. Fraction A: B. p. 61–62° (8.5 mm.), $n^{25}D$ 1.5138, d^{25}_4 1.051, *Anal.* Calcd. for C_8H_9Cl: C, 68.33; H, 6.45; Cl, 25.22; mol. wt., 141. Found: C, 67.45, 67.31; H, 6.49, 6.51; Cl, 27.02, 26.75; mol. wt., 154, 155 (ebullioscopic method in benzene).

Fraction B: B. p. 89–89.5° (8 mm.), $n^{25}D$ 1.5138, d^{25}_4 1.169. *Anal.* Calcd. for $C_8H_{10}Cl_2$: C, 54.26; H, 5.69; Cl, 40.05. Found: C, 54.91, 54.96; H, 5.83, 5.94; Cl, 39.62, 39.73.

Fraction C: B. p. 105–106° (8 mm.), $n^{25}D$ 1.5312; d^{25}_4 1.203. *Anal.* Calcd. for $C_8H_{10}Cl_2$: C, 54.26; H, 5.69; Cl, 40.05. Found: C, 54.47, 54.77; H, 5.97, 5.99; Cl, 39.42, 39.45.

Reduction of Fraction C.—A mixture of 9 g. of the dimer boiling at 109–118° (17–18 mm.), 50 ml. of glacial acetic acid, 13 g. of hydrated sodium acetate, and 1 g. of platinum oxide was agitated under 45 lb. hydrogen pressure until the reduction in pressure was 18 lb. (theory, 17.5 lb.). This mixture was filtered into water and subsequently extracted with an ether–benzene solution (1:1, by volume). The organic layer was dried over magnesium sulfate and distilled through a small column. The cycloöctane, boiling at 147–149°, 2.2 g. (34.4%), was employed in the following oxidation.

One gram of the hydrocarbon was added to 10 ml. of concentrated nitric acid (sp. gr. 1.42) and heated at 78–80° for twenty-four hours. The mixture was cooled in an ice-bath and the crystalline solid, 0.35 g., was isolated by filtration. The crude material crystallized from water as white plates, m. p. 140–141°. A mixture with an authentic sample of suberic acid melted at 140–141°.

Reduction of Fractions A and B.—In a manner similar to that described above, Fractions A and B were hydrogenated to give in each case ethylcyclohexane, b. p. 130–131°, $n^{25}D$ 1.4342.

Dimerization of Butadiene.—A mixture of 4800 g. of butadiene, 480 g. of Darco (Grade S-51), and 100 g. of *p-t*-butylcatechol was heated in a 3-gal. autoclave at 120° for sixty hours. At the end of this time, 490 g. of butadiene was recovered by venting the autoclave through a Dry Ice trap. The product was filtered (3861 g.) and hydrogenated at room temperature under 1500 lb. pres-

sure in the presence of 15 g. of ruthenium dioxide. From the reduced hydrocarbon mixture, ethylcyclohexane (2355 g.) was removed at 130–131°, or 68–69° (100 mm.), $n^{25}D$ 1.4312. The residue was rapidly distilled through a short-path still to remove the hydrocarbon from *p*-butylcatechol. This distillate was separated by distillation through a 10-inch helices-packed column into the following fractions: (D) b. p. 135–142°, $n^{25}D$ 1.4480, 18.5 g.; (E) b. p. 143–150°, $n^{25}D$ 1.4531, 30.8 g.; (F) b. p. 151–153°, $n^{25}D$ 1.4551, m. p. 6–7°, 1.1 g. On the basis of refractive indices and infrared data, these fractions contain: (D) 66% cycloöctane; (E) 86% cycloöctane; (F) 94% cycloöctane. The total yield of cycloöctane amounted to approximately 1%. Fractionation and infrared analyses of smaller preparations indicated cycloöctane yields of 3–5%. Fraction F was conclusively identified by nitric acid oxidation to a solid acid, m. p. 140–141°, which showed no depression in melting point when mixed with an authentic sample of suberic acid.

Dimerization of 2,3-Dichloro-1,3-butadiene.—A mixture of 91.3 g. of 2,3-dichloro-1,3-butadiene,[3] 3 g. of phenothiazine, and 5 g. of Darco (Grade S-51) was agitated in a pressure bottle at 80° for one hundred and twenty hours. The resulting solid mass was extracted with several 200-ml. portions of ethanol. The alcohol was removed through a Vigreux column and the tarry solid was distilled at reduced pressure to give 11.3 g. (12.5%) of a solid, b. p. 140–146° (3.6 mm.). This was the only distillable product, and on crystallization from an acetone–alcohol–water mixture (5:5:1, by volume) gave white plates, m. p. 98–99°. The material appeared to be a very stable compound.

Anal. Calcd. for $C_8H_8Cl_4$: Cl, 57.66; mol. wt., 246. Found: Cl, 57.0, 56.8; mol. wt., 241, 241 (ebullioscopic method in benzene).

This material was hydrogenated in acetic acid solution in the same manner as that described for the dimer from 2-chloro-1,3-butadiene. The reduction mixture was added to water, and the hydrocarbon was isolated by extraction with benzene. The organic solution was dried and distilled, and the fraction boiling at 140–150° was shown to be approximately 80% cycloöctane by comparison of its infrared absorption curve with that of an authentic sample of cycloöctane.

The Removal of Chlorine from Dichloro-1,5-cycloöctadiene.—The action of sodium in liquid ammonia was found to effect the removal of the halogens from dichloro-1,5-cycloöctadiene without simultaneous reduction of the carbon–carbon double bonds.

Thirty-six grams of dichloro-1,5-cycloöctadiene was mixed with 200 ml. of liquid ammonia and approximately 100 ml. of absolute ether was added to effect homogeneity. Ten grams of sodium was added in small pieces and the mixture was stirred and allowed to reflux under a Dry Ice condenser until the sodium had dissolved. This required about two hours. The ammonia was then allowed to evaporate and the residue was filtered. There was obtained 43.4 g. of black solid (theory for NaCl is 23.2 g.), suggesting that considerable polymerization of the product had occurred. The filtrate was dried and distilled; the product boiling at 149–160° weighed 3.9 g., which corresponded to a 19% yield of cycloöctadiene. This was redistilled, and the pure material boiling at 150–152° was presumed to be 1,5-cycloöctadiene.

Anal. Calcd. for C_8H_{12}: C, 88.82; H, 11.18. Found: C, 88.78, 88.99; H, 10.94, 11.11.

Cope and Bailey[5] have found conditions for this reaction which give a 56% yield of the product.

Acknowledgment.—The authors are indebted to Dr. J. W. Stillman, under whose supervision the microanalyses were carried out, and to Miss Doris Huck for the infrared curves.

Summary

The dimerization of chloroprene to a mixture of 6- and 8-membered ring compounds has been confirmed. This unusual dimerization to 8-membered ring compounds has been extended to 1,3-butadiene and 2,3-dichloro-1,3-butadiene.

Cyclic Polyolefins. II. Synthesis of Cycloöctatetraene from Chloroprene[1]

BY ARTHUR C. COPE AND WILLIAM J. BAILEY[2]

Cycloöctatetraene has been prepared by the thirteen-step Willstätter synthesis from pseudopelletierine,[3,4] and by a catalytic process from acetylene.[5] We have continued an investigation of synthetic routes to cycloöctatetraene in a search for a reasonably short synthesis which could be adapted to the preparation of functional derivatives of cycloöctatetraene, which are not accessible through any reactions reported for the hydrocarbon.[5] This paper describes a seven-step synthesis of cycloöctatetraene from chloroprene (2-chloro-1,3-butadiene).

A method for the preparation of a cyclic dimer of chloroprene containing an eight-membered ring (previously isolated from chloroprene distillation residues[6]) has been developed by Foster and Schreiber.[7] By a modification of their procedure, chloroprene was heated in the presence of phenothiazine as a polymerization inhibitor and converted into a mixture of dimers. The eight-membered ring dimer (I) was separated from six-membered ring dimers by fractional distillation, treatment with alcoholic alkali to remove a dimer containing reactive chlorine which otherwise was difficult to separate, and refractionation. The eight-membered ring structure of I is established by its hydrogenation to cycloöctane,[6,7] which we have

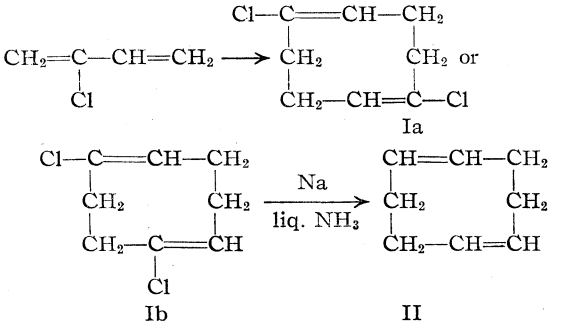
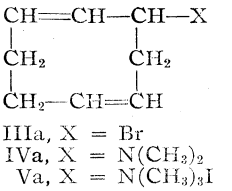
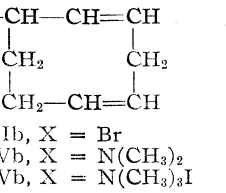
confirmed. The chloroprene units in the dimer may be joined head to tail (Ia) or head to head (Ib), or both structures may be present. These possibilities were not investigated, because the chlorine was replaced by hydrogen and the possibility for isomerism removed in the next step of the synthesis. The dehalogenation was accomplished by reaction of I with sodium in liquid ammonia.[7] Highest yields (56%) of 1,5-cycloöctadiene (II) were obtained with a low reaction temperature (−75 to −50°) and a short reaction time (three minutes), after which sodium compounds were neutralized and excess sodium decomposed by adding solid ammonium nitrate. These conditions minimized the polymerization which occurred as a side reaction. Titration showed that 90% of the chlorine in I was removed as ionic chlorine under these conditions. The structure of II was established by quantitative hydrogenation to cycloöctane, and by ozonization followed by oxidation with hydrogen peroxide, which gave succinic acid.



Reaction of an excess of II with N-bromosuccinimide in the presence of benzoyl peroxide[8] gave a stable monobromo substitution product (III) in 45–57% yield. Although the methylene groups in 1,5-cycloöctadiene are equivalent, rearrangement could occur either during the substitution reaction (through an intermediate free radical) or through an allylic shift of the bromo compound. Consequently the product may have structure IIIa, IIIb or be a mixture of the two. Reaction of III with dimethylamine gave a 61% yield of a dimethylaminocycloöctadiene (IV), which likewise may have structure IVa or IVb; the displacement reaction presents an added possibility for an allylic rearrangement.



IIIa, X = Br
IVa, X = $N(CH_3)_2$
Va, X = $N(CH_3)_3I$



IIIb, X = Br
IVb, X = $N(CH_3)_2$
Vb, X = $N(CH_3)_3I$

IV was proved to be a dimethylaminocycloöctadiene by quantitative hydrogenation to dimethylaminocycloöctane, which was identified as the methiodide. IV reacted with methyl iodide to give a methiodide, V, which was converted to the quaternary base and distilled to give a cycloöctatriene, VI. VI differed in index of refraction, density and ultraviolet absorption spectrum (Fig. 1) from 1,3,5-cycloöctatriene (prepared from pseudopelletierine).[4] Comparison of the ultraviolet absorption curves of VI and 1,3,5-cycloöctatriene (also shown in Fig. 1) indicates that VI probably is a mixture of 1,3,5-cycloöctatriene (VIa) and 1,3,6-cycloöctatriene (VIb), such as might be formed from a mixture of quaternary salts (Va and Vb). The ultraviolet absorption curve for 1,3,5-cycloöctatriene has a maximum at 2650 Å.[4] In VI the maximum is displaced to 2500 Å., while for structure VIb the maximum would be expected to fall nearer 2200 Å.

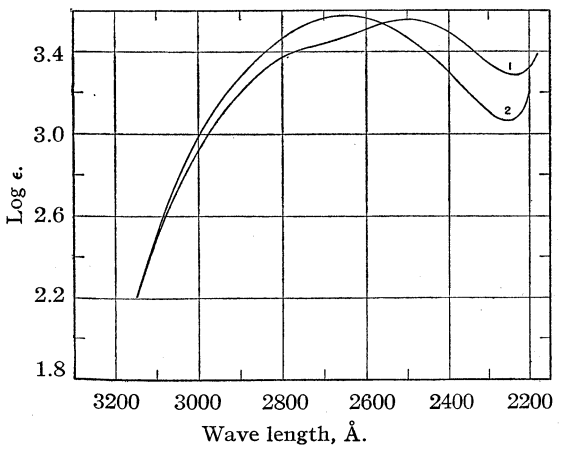


Fig. 1.—Curve 1, absorption spectrum of cycloöctatriene (VI); curve 2, absorption spectrum of 1,3,5-cycloöctatriene (ref. 4).

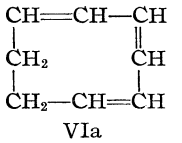
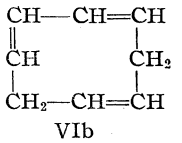


VIa



VIb

The possibility of conducting a similar sequence of reactions beginning with a dibromo derivative of cycloöctadiene was next investigated. 1,5-Cycloöctadiene (II) reacted with two molar equivalents of N-bromosuccinimide in the presence of benzoyl peroxide to give a dibromo compound, which was treated directly with an excess of dimethylamine. In this way a bis-(dimethylamino)-cycloöctadiene (VII) was obtained in an over-all yield of 34% from II. VII might be expected to be a mixture from its method of preparation, but proved to be practically homogeneous and identical with the compound believed to be 1,6-bis-(dimethylamino)-2,4-cycloöctadiene which is an intermediate in the Willstätter synthesis of cycloöctatetraene. Identity of the diamines from the two syntheses was established by correspondence

(8) Ziegler, Späth, Schaaf, Schumann and Winkelmann, *Ann.*, **551**, 80 (1942); Schmid and Karrer, *Helv. Chim. Acta*, **29**, 573 (1946).

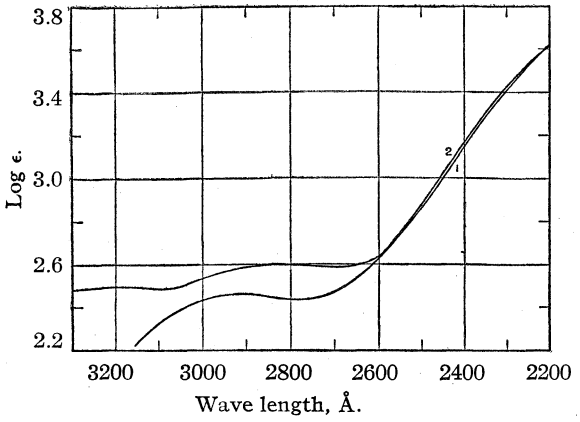


Fig. 2.—Curve 1, absorption spectrum of 1,6-bis-(dimethylamino)-2,4-cycloöctadiene (VII) derived from 1,5-cycloöctadiene; curve 2, absorption spectrum of 1,6-bis-(dimethylamino)-2,4-cycloöctadiene prepared from pseudopelletierine (ref. 4).

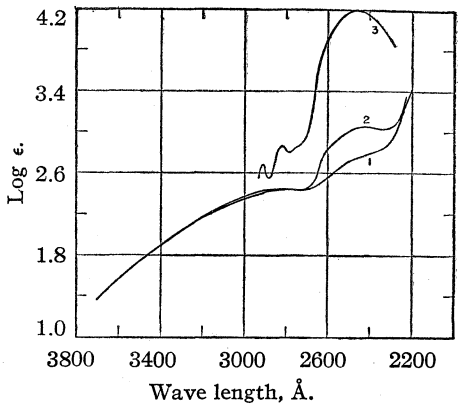

Fig. 3.—Curve 1, absorption spectrum of cycloöctatetraene prepared from acetylene; curve 2, absorption spectrum of cycloöctatetraene (containing approximately 8% of styrene) prepared from chloroprene; curve 3, absorption spectrum of styrene.[12]

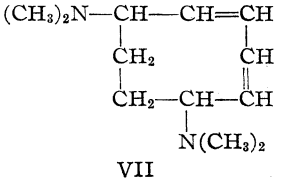
in melting points of the dipicrates and dimethiodides, and comparison of ultraviolet absorption spectra (Fig. 2). Also VII was hydrogenated to 1,4-bis-(dimethylamino)-cycloöctane, which was identified as the dipicrate and dimethiodide. The formation of VII from II can be explained by rearrangement during the bromination of II, yielding 1,6-dibromo-2,4-cycloöctadiene, or by formation of 3,4-dibromo-1,5-cycloöctadiene followed by a double allylic rearrangement either before or during the displacement reaction with dimethylamine. The tendency of the double bonds to become conjugated undoubtedly accounts for the formation of VII, regardless of the step at which the rearrangements occur.



VII

The remaining steps in the synthesis of cycloöctatetraene followed the sequence of reactions used by Willstätter. VII was converted to the dimethiodide, which with silver hydroxide gave the quaternary base. Very slow distillation of the latter at 0.15–1 mm. gave a 15.5% yield of cycloöctatetraene, which was established as identical with a sample prepared from acetylene by correspondence in index of refraction, melting point, mixed melting point, ultraviolet (Fig. 3) and infrared[9] absorption spectra. The spectra indicated the presence of approximately 8% of styrene in this sample of cycloöctatetraene, presumably formed by rearrangement during decomposition of the quaternary base.

(9) We are indebted to Dr. R. C. Lord, Jr., and Mr. R. S. McDonald for the infrared data.

Experimental[10]

Dichloro-1,5-cycloöctadiene (I).—A stabilized 50% solution of chloroprene in xylene[11] was distilled rapidly in a nitrogen atmosphere without appreciable fractionation to obtain chloroprene containing 10–12% xylene. This distillate (2.5 kg.) and 45 g. of phenothiazine were placed in a 3-liter three-necked flask equipped with a thermometer, a mercury-sealed stirrer and a reflux condenser which was connected to a nitrogen cylinder through a line containing a mercury pop-valve. Air in the system was displaced with nitrogen, and the mixture was stirred slowly under nitrogen and heated at a temperature which maintained a slow reflux. The temperature of the liquid rose from 61 to 80° during sixty hours and was kept at 80–84° for an additional seventy hours by regulating the bath temperature. Hydrogen chloride escaped through the pop-valve during the heating period. The mixture was transferred to a 2-liter round-bottomed flask connected to a water-cooled condenser, receiver, Dry Ice trap and a water pump, and distilled as rapidly as possible under reduced pressure without fractionation. After separation of recovered chloroprene, which collected in the Dry Ice trap, the distillation was continued at 20–30 mm. and completed at a pressure of about 1 mm. with an oil pump protected from hydrogen chloride with soda-lime towers. This operation separated polymer and phenothiazine from the distillate containing dimers. The distillate was fractionated fairly rapidly under nitrogen at 3 mm. pressure through a total condensation, variable take-off column with a 30 × 2 cm. section packed with glass helices. This distillation separated an additional portion of recovered chloroprene, xylene, and crude six-membered ring dimers (b. p. up to 76° (3 mm.)) from the highest boiling fraction, b. p. 76–90° (3 mm.), containing the eight-membered ring dimer (and some six-membered ring dimers). The last fraction was heated for twenty-four hours at 60° with a solution equivalent to 90 g. of sodium hydroxide in 1400 ml. of absolute alcohol (prepared by adding sodium and water to absolute alcohol). The alcoholic solution was added to 2 l. of water and the product was extracted with four-400 ml. portions of benzene. The extracts were dried over anhydrous magnesium sulfate and concentrated. The residue was fractionated carefully through the 30 × 2 cm. helix-packed column in an atmosphere of nitrogen. Several such

(10) Melting points are corrected and boiling points are uncorrected. We are indebted to Mr. S. M. Nagy, Mr. Philip H. Towle and Mrs. Louise W. Spencer for analyses.

(11) Obtained from the Organic Chemicals Department, E. I. du Pont de Nemours and Co., Inc., Wilmington, Del.

preparations yielded the following data: xylene present in the chloroprene dimerized, 10–12%; chloroprene recovered, 13–16%. The following percentages are based on the weight of chloroprene actually consumed in the reaction (subtracting the amount recovered): polymer formed, 9–23%; yield of crude six-membered ring dimers, 40–46%; yield of the fraction containing the eight-membered ring dimer from the first fractionation, 23–25%; yield of dichloro-1,5-cycloöctadiene (I) after alkali treatment and refractionation, 10–13%; b. p. 88–89° (3.3 mm.); 92–94° (3.8 mm.); $n^{25}D$ 1.5300–1.5310.

Anal. Calcd. for $C_8H_{10}Cl_2$: C, 54.26; H, 5.69; Cl, 40.05. Found: C, 54.11; H, 5.74; Cl, 39.9.

Preliminary fractionation to remove most of the six-membered ring dimers should precede alkali treatment of the product, as in the procedure described. Otherwise a compound which corresponded closely in analysis to $C_8H_{10}(OC_2H_5)Cl$ was formed in an amount corresponding to about half of the yield of I. This compound, evidently derived from a 6-membered ring dimer containing a reactive chlorine atom, boiled approximately 3° higher than I and its presence complicated the fractionation.[12]

A sample (10.00 g.) of the dichloro-1,5-cycloöctadiene in 60 ml. of glacial acetic acid was hydrogenated in the presence of 14.5 g. of anhydrous sodium acetate and 1.1 g. of pre-reduced Adams platinum oxide catalyst; 101% of four molar equivalents of hydrogen was absorbed. The solution was made basic with sodium carbonate and extracted with ether. Fractionation through a 15 × 1.2 cm. helix-packed column yielded 3.74 g. (59%) of cycloöctane, b. p. 148–149°; $n^{25}D$ 1.4557; m. p. 12.0°.

1,5-Cycloöctadiene (II).—Sodium (39.3 g., 1.7 moles) was dissolved in 2.5 l. of liquid ammonia in a 3-liter three-necked flask equipped with a stirrer, dropping funnel and thermometer. The ammonia solution was cooled to −75° in a Dry Ice–trichloroethylene-bath and a solution of 75 g. (0.42 mole) of dichloro-1,5-cycloöctadiene in 100 ml. of dry ether (also cooled with Dry Ice) was added with stirring during three-quarters of one minute. The mixture was stirred for two minutes, during which time the temperature of the liquid rose to −55 to −45°. Powdered ammonium nitrate (80 g.) was then added rapidly (one-half minute) and the ammonia was allowed to evaporate through a water-cooled reflux condenser while the reaction mixture stood overnight. Water was added to the residue and the product was extracted with ether, dried over magnesium sulfate and distilled. The yield of 1,5-cycloöctadiene was 25.4 g. (56%); b. p. 148–149°; $n^{25}D$ 1.4905; d^{25}_4 0.8818.[13]

Anal. Calcd. for C_8H_{12}: C, 88.82; H, 11.18. Found: C, 89.13; H, 11.22.

A polymeric residue of 13.2 g. remained after distillation of the product. Titration of an aliquot portion of the aqueous solution after separation of the product showed the presence of 90% of the theoretical 0.84 equivalent of chloride ion.

Hydrogenation of a 1.21-g. sample of 1,5-cycloöctadiene in 20 ml. of glacial acetic acid in the presence of 0.1 g. of reduced platinum oxide required 101% of two molar equivalents of hydrogen. The product was identified as cycloöctane by its physical properties after purification by extraction from alkaline solution and distillation through a Craig micro column[14]; $n^{25}D$ 1.4555; m. p. 11.2°.

A 1.00-g. sample of 1,5-cycloöctadiene in 25 ml. of ethyl acetate was ozonized at −30°. The ethyl acetate was removed under reduced pressure and the ozonide was decomposed by heating on the steam-bath for three hours with 12 ml. of 30% hydrogen peroxide in 20 ml. of glacial acetic acid. After concentration under reduced pressure, the residue was dissolved in a sodium bicarbonate solution, which was extracted with ether to remove any neutral material. The alkaline solution was acidified and extracted with ether in a continuous extractor for two days. The ether extract was distilled and the residue recrystallized from water. Succinic acid was isolated in a yield of 1.62 g. (74%), m. p. and mixed m. p. with a known sample 186–187°.

Reaction of 1,5-Cycloöctadiene with N-Bromosuccinimide.—1,5-Cycloöctadiene (16.4 g.) in 50 ml. of dry carbon tetrachloride was stirred under reflux (80°) for one hour with 9.0 g. of N-bromosuccinimide and 0.25 g. of benzoyl peroxide. The succinimide formed was removed by filtration and the solution was fractionated through a 15 × 1.2 cm. helix-packed column. The recovery of 1,5-cycloöctadiene was 10.7 g. (determined by the weight of carbon tetrachloride–1,5-cycloöctadiene mixture recovered, and comparison of its refractive index with a linear plot of the refractive indices of known mixtures), and 5.4 g. (57% based on the N-bromosuccinimide) of bromocycloöctadiene (III) was obtained, b. p. 64° (1.9 mm.); $n^{25}D$ 1.5410; d^{25}_4 1.3420.

Anal. Calcd. for $C_8H_{11}Br$: C, 51.35; H, 5.93; Br, 42.72. Found: C, 51.27; H, 6.07; Br, 42.84.

Dibromocycloöctadiene was isolated in one instance from the reaction of 10.8 g. of 1,5-cycloöctadiene and 36 g. of N-bromosuccinimide in 100 ml. of dry carbon tetrachloride, which were heated under reflux with stirring in the presence of 0.5 g. of benzoyl peroxide for one hour. The succinimide formed was removed by filtration and the filtrate was washed with water, dried over Drierite and distilled under nitrogen. The dibromocycloöctadiene (14.2 g., b. p. 110–116° (2 mm.)) turned black after standing at room temperature for a few minutes, and in subsequent preparations was not isolated, but was treated directly with dimethylamine as outlined under the preparation of VII.

Dimethylaminocycloöctadiene (IV).—Bromocycloöctadiene (12.6 g.) and 250 ml. of a 20% solution of dimethylamine in benzene were allowed to stand for three days at room temperature. The mixture was extracted with 15% hydrochloric acid solution, which was then made basic with 20% sodium hydroxide and extracted with ether. The extracts were dried over magnesium sulfate, concentrated, and the residue was distilled under nitrogen through a 15 × 1.2 cm. helix-packed column. The yield of dimethylaminocycloöctadiene was 6.2 g. (61%); b. p. 58–60° (1.2 mm.); $n^{25}D$ 1.4972.

Anal. Calcd. for $C_{10}H_{17}N$: C, 79.40; H, 11.33; N, 9.26. Found: C, 79.39; H, 11.45; N, 9.17.

Dimethylaminocycloöctadiene was also prepared in about the same over-all yield from 1,5-cycloöctadiene in a similar preparation in which the intermediate bromo compound was not isolated, and was obtained as a by-product in the preparation of 1,6-bis-(dimethylamino)-2,4-cycloöctadiene (see below).

Dimethylaminocycloöctadiene methiodide (V) was prepared from 12.8 g. of dimethylaminocycloöctadiene and 30 g. of methyl iodide in 70 ml. of absolute alcohol. The solution was allowed to stand for thirty minutes and heated under reflux for one hour. The crystalline methiodide (V) separated on cooling in a yield of 22.6 g. (91%), m. p. 163–166° (dec.). An analytical sample which was recrystallized twice from absolute alcohol melted at 168–169° (dec.).

Anal. Calcd. for $C_{11}H_{10}NI$: C, 45.05; H, 6.88; N, 4.77; I, 43.28. Found: C, 44.76; H, 6.95; N, 4.66; I, 43.14.

Although this methiodide had a relatively sharp melting point (with decomposition) it is believed to be a mixture of isomers (Va and Vb), for further recrystallization raised the m. p. to 174–175°; moreover, a mixed m. p. of V with the isomeric α-des-dimethylgranatenine methiodide[4] was not depressed but intermediate between the two decomposition points (174–176° dec.), proving that

(12) We are indebted to Dr. Calvin L. Stevens for these data.

(13) Impure 1,5-cycloöctadiene containing about 20% of a bicycloöctene has been prepared by the Hofmann exhaustive methylation procedure from des-dimethylgranatanine; Willstätter and Veraguth, *Ber.*, **38**, 1979 (1905); *ibid.*, **40**, 960 (1907); Willstätter and Kametka, *ibid.*, **41**, 1482 (1908); Harries, *ibid.*, **41**, 672 (1908).

(14) Craig, *Ind. Eng. Chem., Anal. Ed.*, **9**, 441 (1937).

the decomposition points of mixtures of such isomeric methiodides can be sharp and not markedly lowered.[12]

A 2.24-g. sample of dimethylaminocycloöctadiene in 70 ml. of absolute alcohol was hydrogenated in the presence of 0.4 g. of prereduced platinum oxide catalyst. Hydrogen absorption was 99.5% of two molar equivalents. The dimethylaminocycloöctane produced was isolated by distillation in a Craig micro column; $n^{25}D$ 1.4717 (ref. 4, $n^{25}D$ 1.4707).

Anal. Calcd. for $C_{10}H_{21}N$: C, 77.34; H, 13.63; N, 9.02. Found: C, 77.36; H, 13.46; N, 9.15.

Dimethylaminocycloöctane methiodide was prepared as a derivative and recrystallized from absolute alcohol; m. p. 273–274° (dec.) (ref. 4, m. p. 274–275° dec.).

Anal. Calcd. for $C_{11}H_{24}NI$: C, 44.44; H, 8.13; N, 4.71; I, 42.70. Found: C, 44.16; H, 8.09; N, 4.63; I, 42.46.

Cycloöctatriene (VI).—Dimethylaminocycloöctadiene methiodide (21.4 g.) in 300 ml. of water and the silver hydroxide prepared from 37.5 g. of silver nitrate and 8.8 g. of sodium hydroxide were stirred at room temperature for one and one-half hours. The mixture was filtered and the filtrate was concentrated under reduced pressure. The quaternary base was decomposed by continuing the distillation at a pressure of 20 mm. and a bath temperature of 90°. The distillate, which was collected in a receiver cooled with Dry Ice, was extracted with ether, and the extracts (to which 1% of *t*-butylcatechol was added as a polymerization inhibitor) were dried over magnesium sulfate. Distillation through a 15 × 1.2 cm. helix-packed column under nitrogen yielded 6.1 g. (78%) of cyclooctatriene, b. p. 76° (90 mm.); $n^{25}D$ 1.5187; d^{25}_4 0.8971.

Anal. Calcd. for C_8H_{10}: C, 90.50; H, 9.50. Found: C, 90.28; H, 9.47.

1,6-bis-(Dimethylamino)-2,4-cycloöctadiene (VII).—1,5-Cycloöctadiene (21.6 g., 0.2 mole) in 300 ml. of dry carbon tetrachloride, 72.g. (0.4 mole) of N-bromosuccinimide and 1 g. of benzoyl peroxide were stirred vigorously and heated under reflux (80°) for one hour. Succinimide was separated by filtration and most of the carbon tetrachloride was removed from the filtrate by distillation under reduced pressure. To the residue was added 500 ml. of a 22.5% solution of dimethylamine in benzene, and the mixture was allowed to stand for ten days at room temperature. Fifteen per cent. hydrochloric acid was added until the mixture was acid (*p*H 2), and the amine salts were extracted with two portions of 0.01 *N* hydrochloric acid. The acid extracts were made basic with 20% sodium hydroxide and the amines were extracted three times with ether. The ether was distilled and the residue was heated at 60° for three minutes with 400 ml. of 2 *N* hydrochloric acid to hydrolyze substituted vinyl amine types. The solution was cooled, extracted with ether to remove any neutral material, and made basic with 20% sodium hydroxide. The product was extracted with ether and the extracts were dried over magnesium sulfate. The ether was distilled and the residue fractionated under nitrogen through a 15 × 1.2 cm. helix-packed column. Dimethylaminocycloöctadiene (IV) (5.1 g., 17%) was obtained as a low boiling fraction, followed by 13.3 g. (34%) of 1,6-bis-(dimethylamino)-1,4-cyclooctadiene (VII), b. p. 90° (1 mm.); $n^{25}D$ 1.4995; d^{25}_4 0.932 (ref. 4, $n^{25}D$ 1.4990; d^{25}_4 0.9317).

Anal. Calcd. for $C_{12}H_{22}N_2$: C, 74.16; H, 11.41. Found: C, 73.94; H, 11.06.

1,6-bis-(Dimethylamino)-2,4-cycloöctadiene dipicrate was prepared as a derivative and recrystallized from 95% alcohol; m. p. 194–195° (dec.) (ref. 4, m. p. 194.6–195.2°, dec.).

Anal. Calcd. for $C_{24}H_{28}N_8O_{14}$: C, 44.17; H, 4.33; N, 17.17. Found: C, 44.01; H, 4.52; N, 17.26.

1,6-bis-(Dimethylamino)-2,4-cycloöctadiene dimethiodide was prepared from 6.2 g. of 1,6-bis-(dimethylamino)-2,4-cycloöctadiene and 15 g. of methyl iodide in 50 ml. of absolute alcohol by refluxing for one hour. The salt which separated on cooling solidified on standing and was crystallized from a mixture of 90% alcohol and petroleum ether; yield 13.4 g. (87%), m. p. 172–173° (dec.); m. p. after recrystallization from absolute alcohol 172–173° (dec.)[12] (ref. 4, m. p. 173–174°, dec.).

Anal. Calcd. for $C_{14}H_{28}N_2I_2$: C, 35.16; H, 5.90; N, 5.86; I, 53.08. Found: C, 35.06; H, 5.91; N, 5.78; I, 53.28.

The above methiodide was separated from a much smaller amount (2–5%) of an isomeric dimethiodide which was relatively insoluble in alcohol. After two recrystallizations from alcohol and benzene the isomer (which may be a stereo or position isomer) darkened at 237–239° but did not liquefy or decompose with gas evolution below 285°.[12]

Anal. Calcd. for $C_{14}H_{28}N_2I_2$: C, 35.16; H, 5.90; N, 5.86; I, 53.08. Found: C, 35.25; H, 6.09; N, 6.01; I, 52.94.

A 2.30-g. sample of 1,6-bis-(dimethylamino)-2,4-cycloöctadiene in 30 ml. of absolute alcohol absorbed 110% of two molar equivalents of hydrogen slowly (during thirteen hours) in the presence of 0.5 g. of pre-reduced platinum oxide. The 1,4-bis-(dimethylamino)-cyclooctane formed was distilled through a Craig micro column: $n^{25}D$ 1.4820; d^{25}_4 0.9155 (ref. 4, $n^{25}D$ 1.4823, d^{25}_4 0.9166).

Anal. Calcd. for $C_{12}H_{26}N_2$: C, 72.66; H, 13.21; N, 14.13. Found: C, 72.62; H, 12.99; N, 14.07.

1,4-bis-(Dimethylamino)-cycloöctane dipicrate was prepared as a derivative and recrystallized from 95% alcohol; m. p. 173–174° (dec.) (ref. 4, m. p. 171.5–172.2°, dec.).

Anal. Calcd. for $C_{24}H_{32}N_8O_{14}$: C, 43.90; H, 4.90; N, 17.07. Found: C, 43.98; H, 5.04; N, 16.95.

1,4-bis-(Dimethylamino)-cycloöctane dimethiodide was prepared as a second derivative and recrystallized from 90% alcohol and petroleum ether; m. p. 255–256° (dec.) (ref. 4, m. p. 258–259°, dec.).

Anal. Calcd. for $C_{14}H_{32}N_2I_2$: C, 34.86; H, 6.69. Found: C, 34.81; H, 7.04.

Cycloöctatetraene.—1,6-bis-(Dimethylamino)-2,4-cycloöctadiene dimethiodide (22 g.), 100 ml. of water and the silver hydroxide prepared from 25.5 g. of silver nitrate and 6.0 g. of sodium hydroxide were stirred for one hour at room temperature and one hour at 50°. The mixture was filtered and the filtrate was concentrated under reduced pressure. The final stages of concentration and decomposition of the quaternary base were conducted at a pressure of 0.15–1 mm. and a bath temperature of 50° during four hours. The flask was heated at 100° for twenty minutes after the decomposition appeared to be complete. The distillate, which was collected in a receiver cooled with Dry Ice, was extracted with ether. The extracts were dried over magnesium sulfate, concentrated, and the residue distilled through a Craig micro column. The yield of cycloöctatetraene was 0.74 g. (15.5%); $n^{25}D$ 1.5342 (ref. 4, $n^{25}D$ 1.5342).

Anal. Calcd. for C_8H_8: C, 92.26; H, 7.74. Found: C, 91.92; H, 7.88.

The cycloöctatetraene obtained melted at −8.7 to −7.9°, and gave a mixed melting point with a sample of cycloöctatetraene prepared from acetylene (m. p. −5.9 to −5.3°) of −7.6 to −6.5°.

Ultraviolet Absorption Spectra.—Ultraviolet absorption spectra of compounds VI, VII and the cycloöctatetraene prepared in this way were determined in purified cyclohexane solution with a Beckmann quartz ultraviolet spectrophotometer. Absorption curves are shown in Figs. 1–3, in which curves for VII prepared from pseudopelletierine and cycloöctatetraene prepared from acetylene[4] are included for comparison.

Summary

Cycloöctatetraene has been prepared by a seven-step synthesis from chloroprene.

The Preparation and Properties of Some Substituted Benzyl Fluorides[1]

BY JACK BERNSTEIN,[2,3] JAY S. ROTH[4] AND WILLIAM T. MILLER, JR.

The substituted benzyl halides are of special importance because of their theoretical interest and because of their suitability for experimental investigation. Since a series of substituted benzyl fluorides had not been prepared previously, a general method for their preparation was sought in order to permit a study of their properties and relative reactivities. Benzyl fluoride and *p*-nitrobenzyl fluoride are the only compounds in this series which have been previously reported. They were prepared and characterized by the Ingolds[5]: benzyl fluoride itself by the thermal decomposition of benzyltrimethylammonium fluoride and *p*-nitrobenzyl fluoride by the nitration of benzyl fluoride. Swarts[6] had previously reported benzyl fluoride to be a liquid which decomposed very readily, but he did not describe his method of preparation or characterize the product. Ray and Ray[7] reported the preparation of benzyl fluoride by the action of thallous fluoride on benzyl bromide in absolute alcohol solution The product isolated by them was a yellow lachrymatory liquid which decomposed, and apparently was impure since benzyl fluoride is a colorless non-lachrymatory liquid. Attempts to prepare benzyl fluoride by the action of silver fluoride on benzyl chloride[8] and by the decomposition of phenyldiazomethane in 40% hydrofluoric acid[9] were unsuccessful.

In this research, benzyl fluoride was first prepared by thermally decomposing benzyl trimethylammonium fluoride according to Ingold's procedure. Poor yields were obtained, 22 to 29%, based on the starting benzyl chloride, due to polymerization which occurred during the decomposition of the quaternary salt. In addition, Ingold had shown that this method of preparation was not a general one, so that various other procedures had to be investigated. The reactions of benzyl halides with antimony fluoride, thallous fluoride,[7] silver fluoride and potassium fluoride were tried, but in no case could any benzyl fluoride be isolated from the reaction mixtures.

The method of synthesis finally found satisfactory as a general procedure consisted of treating mercuric fluoride[10] with benzyl bromides in chloroform solution. The replacement of the side-chain bromine by fluorine lowered the boiling point of the product sufficiently, about 40°, so that the benzyl fluorides could be easily separated from unreacted bromide by distillation. Absolutely anhydrous conditions were essential for satisfactory fluorinations since the presence of traces of water resulted in the formation of hydrogen fluoride which caused the polymerization of the benzyl fluoride. In general, the catalytic properties of hydrogen fluoride[11] greatly complicate the preparation and study of organic fluorine compounds as compared with the other halides and reactions leading to the formation of hydrogen fluoride are likely to be autocatalytic.

An attempt was made to prepare benzyl fluoride by the reaction of mercuric fluoride with benzyl chloride in benzene solution. From this reaction no benzyl fluoride was obtained, but a considerable quantity of diphenylmethane was isolated. The formation of this compound probably occurred through a Friedel–Crafts type reaction of either benzyl chloride or benzyl fluoride, catalyzed by the mercuric salts or by hydrogen fluoride. Calloway[12] has found that alkyl fluorides are the most reactive of the alkyl halides in Friedel–Crafts alkylation. The reaction of *p*-chlorobenzyl fluoride with benzene did not take place in the absence of a catalyst at moderate temperature. However, in the presence of boron trifluoride,[13] the benzyl fluorides reacted smoothly with aromatic hydrocarbons and diphenylmethane derivatives were isolated.

As indicated by Ingold, benzyl fluoride polymerizes very rapidly in the presence of catalysts. In this work the stability of the substituted benzyl fluorides was found to vary greatly with the substituent. No evidence was obtained for the polymerization of *p*-nitrobenzyl fluoride, and even *p*-bromobenzyl fluoride did not polymerize in the presence of a trace of sulfuric acid, which caused a very violent reaction when added to benzyl fluoride itself. In general, ring inactivating substituents made the benzyl fluoride more stable. This effect was consistent with a Friedel–Crafts type polymerization reaction as was the ready formation of diphenylmethane derivatives by reaction

with benzene.[14] The polymerization may be catalyzed by boron trifluoride or boron trifluoride etherate. Ingold had already reported that sulfuric acid, hydrogen fluoride and even soft glass catalyzed the decomposition of benzyl fluoride. When pure or in the presence of traces of bases, the benzyl fluorides were found to be stable in Pyrex glass at room temperature for long periods of time. Some samples of *p*-chlorobenzyl fluoride have remained undecomposed after seven years storage, although other samples decomposed violently after standing for several weeks. In general, the marked tendency to polymerize increased the difficulty of the preparation of the benzyl fluorides although the use of rigorously anhydrous conditions and reagents, and reasonable care to prevent thermal decomposition during distillation resulted in fairly satisfactory yields of products.

The benzyl fluorides are pleasant smelling compounds with odors similar to the parent hydrocarbons. They show typical halide reactivity in many reactions, and with the exception of the Friedel and Crafts reactions are in general considerably less reactive than the chlorides. Reaction in aqueous alcoholic sodium hydroxide led to the formation of the corresponding ether and alcohol. In dilute aqueous alcoholic hydrogen chloride, significantly, the corresponding ether was also formed. By refluxing the fluoride in a mixture of hydrochloric acid and dioxane, the fluorine could be replaced by chlorine, possibly through the alcohol. The reaction of a fluoride with sodium phenolate in excess phenol led to the formation of the phenyl ethers. These ethers are crystalline compounds, easily purified, and would be suitable as derivatives for the identification of the fluorides which are mostly liquids. The preparation of esters was attempted using the method of Reid.[15] Under conditions which give almost quantitative yields of esters from *p*-nitrobenzyl chloride in three hours, or from *p*-nitrobenzyl bromide in fifteen minutes, practically no reaction had occurred in forty-six hours with *p*-nitrobenzyl fluoride. A small yield of acetate was obtained by reaction with potassium acetate in acetic acid.

Several attempts were made to prepare a Grignard reagent from benzyl fluoride, since benzyl chloride forms a Grignard reagent with great ease. At reflux temperature with ethyl ether no reaction took place while under more vigorous conditions in di-*n*-butyl ether polymerization of the benzyl fluoride occurred. It was found possible to obtain dibenzyl by heating benzyl fluoride in ether solution with Gilman's[16] activated magnesium catalyst in a bomb tube at 100° for ten days, although using ordinary magnesium under similar conditions gave no reaction. Under these vigorous conditions, any Grignard reagent formed would be expected to enter into secondary reactions and consequently would not have been detected. A Wurtz–Fittig reaction was carried out in ether solution, using lithium metal, to form dibenzyl.

Experimental Part

Preparation of Benzyl Fluorides

Benzyl Bromides.—The substituted benzyl bromides were prepared from the corresponding toluenes by direct bromination, usually at the boiling point, in Pyrex all-glass apparatus, illuminated by a mercury vapor lamp. Their physical properties and the yields obtained, based on the starting toluenes, are summarized in Table I.

Mercuric Fluoride.—Mercuric fluoride was prepared by the fluorination of anhydrous mercuric chloride (powder) in a rotating brass reaction vessel according to the general method of Henne.[10] An improved reaction vessel was designed to permit more complete utilization of the fluorine. This consisted of a brass tube 52 cm. long and 5 cm. in diameter which was fitted with interchangeable screw caps. The tube was divided in the middle by a diaphragm with a center opening of 1.5 cm. Mercuric chloride, 0.3 mole and a nickel rod the length of the chamber, to prevent caking of the solid, were placed in each side. The tube was rotated at 30 r. p. m. and fluoride from a closed type nickel electrolysis cell[17] was passed in until the charge in the side into which the fluorine entered was completely converted to mercuric fluoride, as shown by a negative test for chloride ion. This chamber was then emptied and refilled with mercuric chloride. The reaction vessel was then reversed so that the fluorine passed first into the chamber containing partially converted mercuric chloride and the process repeated. The mercuric fluoride was either used directly or stored in a tightly closed copper container fitted with a metal cap and a lead gasket.

Benzyl Fluorides.—The fluorination reactions were carried out in 1-liter three-necked flasks which were fitted with a mercury-sealed stirrer, a reflux condenser and a section of 1.25″ rubber tubing which was closed just above the neck of the flask by a screw clamp. The reflux condenser was fitted with a drying tube and contained a thermometer suspended inside so that its bulb dipped into the chloroform solution. The apparatus was all carefully dried. Chloroform, usually 650 cc., and from 0.2

[a] First prepared by Ingold, who reported the b. p. as 55° at 30 mm. [b] See Gilman, "Organic Chemistry," Vol. II, 1938, p. 1737. The value of 1.09 used for the atomic refraction of fluorine was determined by Ingold. [c] Sodium peroxide decompositions were run on these samples to determine total fluorine. [d] Recrystallized from petroleum ether (b. p. 30–60°). [e] First prepared by Ingold, who reported the m. p. 38.5°. Sample was recrystallized from ether–petroleum ether mixture (1:1). [f] Treatment of *p*-nitrobenzyl fluoride with sodium ethoxide solution caused the formation of a dark brown solution. Upon steam distillation, a solid precipitated out, which was filtered off. The filtrate was treated with decolorizing carbon and then analyzed for F^-.

to 0.6 mole of the benzyl bromide were poured into the flask and about 50 cc. of chloroform distilled out, with the reflux condenser temporarily replaced by a condenser arranged for distillation, to assure removal of traces of water. The reflux condenser was then replaced. Freshly prepared mercuric fluoride, usually 0.3 mole, was placed in the rubber addition tube attached to the reaction flask and the open end stoppered. The solution was stirred vigorously and the mercuric fluoride added slowly by opening the screw clamp on the rubber tubing. The first portions of mercuric fluoride turned red-orange in color, but upon continued stirring the color changed to pale yellow and the temperature of the reaction mixture started to rise. When the temperature reached about 35°, the flask was cooled in water to prevent a more vigorous reaction. The addition of the mercuric fluoride was continued at 35° with occasional cooling of the reaction flask in a cold water-bath. About forty minutes were ordinarily required for the addition of the mercuric fluoride.

The reaction mixture was then stirred for from one-half to seventy hours. The longer times of reaction did not result in improved yields. The usual time of stirring was from two to four hours. The reaction mixture was then filtered and the residue washed with chloroform. The chloroform solutions were combined and washed once with saturated sodium carbonate solution, once with dilute nitric acid (1:10), again with saturated sodium carbonate solution, and finally with water. Two drops of pyridine or other tertiary amine were added to prevent polymerization of the fluoride and the chloroform solution dried over calcium chloride. After drying overnight, the chloroform was removed by distillation through an efficient column. The residue was then distilled under reduced pressure from a modified Claisen flask and then either redistilled or crystallized for further purification. In this redistillation, no pyridine was added.

A modified procedure was evolved for the preparation of benzyl and methyl-, fluoro- and *o*-chlorobenzyl fluorides which showed a great tendency to polymerize during the preparative reaction. One cc. of dry pyridine was added to the chloroform solution of the bromide before the addition of the mercuric fluoride. The addition of the mercuric fluoride then produced no immediate temperature rise and the solid in the reaction became red-orange in color. Continued stirring did not change this color, but upon gentle warming to about 40° the color changed to light yellow, and the reaction mixture had to be cooled in ice-water to prevent a rapid rise in temperature. When the temperature of the reaction mixture fell to 35°, the addition of the mercuric fluoride was continued. Stirring was continued for thirty minutes after all the mercuric fluoride had been added, 1 cc. of pyridine was added and the stirring continued for three hours. The remainder of the procedure was the same as indicated above.

The yields of benzyl fluorides isolated ranged from 40 to 60% but no attempt was made to secure maximum yields since higher still pot temperatures near the end of the distillations tended to cause thermal decomposition of the fluoride and result in polymerization of the distillate. The physical properties of the benzyl fluorides are given in Table II.

The purity of the benzyl fluorides was checked by analyses for fluorine and molecular refractivity determinations. The absence of any unreacted benzyl bromides in the products was shown by a completely negative test for bromide with boiling alcoholic silver nitrate solution.

Fluorine was determined by refluxing 1-g. samples of the fluorides with sodium ethoxide solution, prepared by dissolving 2.3 g. of sodium in 30 cc. of absolute alcohol, for forty-eight hours. Water, 100 cc., was added and the solution steam distilled to remove organic matter. Fluoride ion was then titrated in an aliquot with standard cerous nitrate solution using a divided titration vessel.[18] In the case of the fluorobenzyl fluorides sodium peroxide decompositions were run to determine total fluorine. A value of 17.5% F was found for *p*-fluorobenzyl fluoride using the sodium ethoxide decomposition indicating partial removal of ring as well as side chain fluorine.

Reactions of Benzyl Fluorides.—The observed reactions of the benzyl fluorides are listed below under reactants.

Aromatic Hydrocarbons.—*p*-Chlorobenzyl fluoride, 5.8 g., was refluxed for four hours in the absence of added catalyst with 40 cc. of dry benzene while a slow stream of

(18) Batchelder and Meloche, THIS JOURNAL, **53**, 2131 (1931); Hubbard and Henne, *ibid.*, **56**, 1078 (1934); Miller, unpublished work. This titration has recently been carefully investigated by Nichols and Olsen in this laboratory and an improved procedure described; *Ind. and Eng. Chem., Anal. Ed.*, **15**, 342 (1943).

nitrogen was passed through the reaction vessel. About 0.1% of the theoretical quantity of hydrogen fluoride was evolved. *m*-Bromobenzyl fluoride, 10.0 g., in 56.0 g. of *p*-xylene was refluxed for seven hours as above. About 1% of the theoretical amount of hydrogen fluoride was formed. The mixture was distilled. When about 75% of the *p*-xylene had been removed a vigorous reaction occurred with the copious evolution of hydrogen fluoride. Separation of the resulting mixture yielded 1.0 g. of starting fluoride, b. p. 82° at 10 mm., and 8.1 g. of viscous liquid, b. p. 185–186° at 10–12 mm. The latter material was indicated as 2,5-dimethyl-3-bromodiphenylmethane by analysis after redistillation at 0.5 mm. Calcd. for $C_{15}H_{15}Br$: Br, 29.1. Found: Br, 28.4.

p-Chlorobenzyl fluoride, 5.8 g., dissolved in 100 cc. of benzene was treated with gaseous boron trifluoride. Reaction was observed after two minutes and the boron trifluoride flow was stopped after four minutes. The solution was refluxed for an additional hour. Five grams of *p*-chlorobenzyl fluoride in 40 cc. of benzene was caused to react as above. The combined products yielded 11.4 g. of main fraction, b. p. 147–148° at 8 mm. This product, 4-chlorodiphenylmethane, on oxidation yielded *p*-chlorobenzophenone, m. p. 76–77°; reported m. p. 77–78°.[19]

m-Bromobenzyl fluoride, 11 g., dissolved in 100 g. of toluene was treated with gaseous boron trifluoride at Dry Ice temperature for six minutes. An immediate cloudiness was observed. On warming to room temperature without further addition of boron trifluoride the cloudiness disappeared and gas was evolved. The mixture was heated to reflux for thirty minutes. Distillation yielded a main fraction of 8.5 g., b. p. 170–173° at 7–8 mm. This product was characterized as 3-bromo-4′-methyldiphenylmethane by oxidation, with 10 g. of sodium dichromate in 15 cc. water and 10 cc. concentrated sulfuric acid at reflux temperature, to yield 3-bromo-4′-carboxybenzophenone. The purified acid had a neutral equivalent of 304.5; calcd. 305.

Sodium Hydroxide in Aqueous Alcohol.—Nine grams of *p*-chlorobenzyl fluoride dissolved in 200 cc. of 95% alcohol was mixed with 100 cc. of 0.99 *N* sodium hydroxide and heated at reflux on a steam-bath for one hundred hours. Extraction with petroleum ether and distillation yielded 7.5 g. of liquid, b. p. 104° at 15 mm., and 0.8 g. of solid residue. The residue after recrystallization from petroleum ether melted 69–70° and was shown to be *p*-chlorobenzyl alcohol. The redistilled liquid fraction, b. p. 220–223° at 746 mm., d^{14}_4 1.101, as compared with b. p. 225°, d^{14}_4 1.121 reported for ethyl *p*-chlorobenzyl ether, was cleaved with 48% hydrobromic acid to form ethyl bromide, converted to propionanilide m. p. 101–103°,[20] and *p*-chlorobenzyl bromide m. p. 48.5–49.5°, no depression in m. p. with authentic sample.

Hydrochloric Acid in Aqueous Alcohol.—Eleven grams of *m*-xylyl fluoride dissolved in 250 cc. of 95% alcohol was mixed with 125 cc. of 0.93 *N* hydrochloric acid and heated at reflux for seventy hours. Extraction with petroleum ether and distillation yielded 8.0 g. of liquid, b. p. 91–93° at 14 mm., without appreciable forerun or residue. The redistilled liquid had a b. p. 204–205° at 749 mm., d^{20}_4 0.939 as compared with b. p. 202° at 740 mm., d^{17}_4 0.930 reported for ethyl *m*-xylyl ether. Cleavage of the ether with 48% hydrobromic acid yielded ethyl bromide, b. p. 37–40°, which was converted into ethyl mercuric bromide,[21] m. p. 192–193°, and *m*-xylyl bromide, b. p. 215–217° at 747 mm., which was converted through the Grignard reagent into *m*-methylphenylacetic acid of m. p. 59.5–60.5°; reported m. p. 61°.

Hydrochloric Acid in Dioxane.—*p*-Nitrobenzyl fluoride, 2.0 g., dissolved in 20 cc. of dioxane was mixed with 5 cc. concentrated hydrochloric acid, and heated to reflux for sixteen hours. The mixture turned light brown and separated into two layers during this time. Distillation of the dioxane and extraction of the residue with hot 75% alcohol yielded 1.5 g. of crystals m. p. 64–67°. Two recrystallizations yielded m. p. 71–72° as compared with m. p. 71° reported for *p*-nitrobenzyl chloride.

m-Bromobenzyl fluoride was treated similarly to yield *m*-bromobenzyl chloride, m. p. 22°, as compared with reported m. p. 22.4°.

Sodium Phenolate.—Two grams of *p*-chlorobenzyl fluoride was heated for two hours in an oil-bath at 140° with a solution of sodium phenolate prepared by dissolving 0.5 g. of sodium in 5.0 g. of phenol. The reaction mixture was poured into 200 cc. of dilute sodium hydroxide and 3.0 g. of brown crystalline material separated. The solid was recrystallized from alcohol and melted at 86°; reported for *p*-chlorobenzylphenyl ether, m. p. 85.5–86.5°.

m-Bromobenzyl fluoride by a similar procedure yielded phenyl *m*-bromobenzyl ether, m. p. 37.5–38.0°, as compared with a reported m. p. of 36–37°. *p*-Chlorobenzyl fluoride yielded phenyl *p*-chlorobenzyl ether, m. p. 81°; reported m. p. 81°. *p*-Nitrobenzyl fluoride yielded phenyl *p*-nitrobenzyl ether, m. p. 91–92°; reported m. p. 91°.

Potassium Acetate.—Appreciable reaction did not occur when *p*-nitrobenzyl fluoride was refluxed in 67% aqueous alcohol solution with potassium or magnesium acetates for periods up to forty-six hours. Partial conversion to the acetate occurred when a solution of 2.0 g. of *p*-nitrobenzyl fluoride and 4 g. of potassium acetate in 30 cc. of glacial acetic acid was refluxed for twenty-four hours. Unreacted fluoride was slowly sublimed from the water insoluble product and a 0.3-g. residue obtained, m. p. 76°; m. p. with authentic *p*-nitrobenzyl acetate 77°.

Lithium and Magnesium Metals.—Lithium metal, 0.4 g. scraped and cut into small pieces under xylene, was added to 20 cc. of dry ether with nitrogen blanketing. Benzyl fluoride, 3.0 g., was added and the mixture warmed to reflux. A white deposit formed on the surface of the metal but after one and one-half hours the solution gave a negative test for benzyl lithium with Michler ketone.[22] After twelve hours, evaporation of the ether solution yielded 1.5 g. of dibenzyl, m. p. 51–52° after recrystallization from alcohol.

Thirteen grams of benzyl fluoride dissolved in 80 cc. of sodium dry ether was placed in the dropping funnel of a thoroughly dried Grignard set-up provided with nitrogen blanket. Freshly turned magnesium metal, 3.7 g., was introduced into the conical three-necked reaction flask and 20 cc. of the ether solution added. The mixture was stirred for several hours and warmed with no apparent reaction. Addition of iodine crystals or of Gilman activated magnesium catalyst[16] failed to produce any signs of reaction. Addition of phenylmagnesium bromide also failed to initiate reaction. Three cc. samples of the ethereal solution of benzyl fluoride were heated in glass bomb tubes with freshly turned magnesium and with the activated magnesium alloy at 100° for ten days. At the end of this period negative tests were obtained for the presence of Grignard reagent but the solution from the tube containing activated magnesium yielded crystals of dibenzyl, m. p. 51°. No dibenzyl could be obtained from the tube containing ordinary magnesium.

Summary

A general procedure for the preparation of benzyl fluorides by the reaction of mercuric fluoride with the corresponding benzyl bromide has been developed.

The benzyl fluorides underwent the typical Friedel–Crafts type reaction with aromatic hydrocarbons in many cases with great ease. They underwent typical halide replacement type reactions but at much slower rates than the corresponding chlorides.

The Grignard reagent could not be prepared

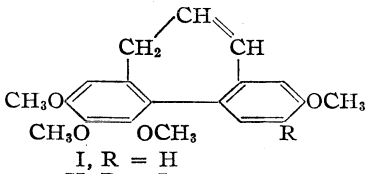
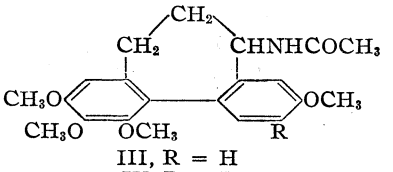
Studies on the Structure of Colchicine.[1] Syntheses in the Biphenyl Series

BY H. RICHARD FRANK,[2a] PAUL E. FANTA[2b] AND D. STANLEY TARBELL

Degradation studies on deaminocolchinol methyl ether[3] I and its iodine derivative[1] II have provided evidence for the presence of the central seven-membered ring. Assuming that no rearrangement of the carbon skeleton occurred during the formation of I or II from N-acetyl-(iodo)-colchinol methyl ether the latter compounds must have structures III and IV. It is obviously necessary, in order to establish the constitution of colchicine, to provide synthetic evidence for structures I–IV. Furthermore, the importance which colchicine and its derivatives have assumed in research on the cancer problem as a result of their antimitotic properties makes it highly desirable to explore possible methods of synthesizing compounds of this type.[4]

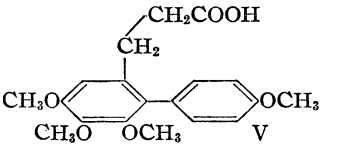


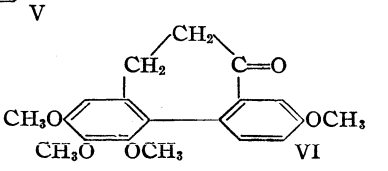
I, R = H
II, R = I



III, R = H
IV, R = I

Our work was designed to lead to structures I and III through the synthesis of the biphenylpropionic acid V and its ring closure to the ketone VI, which could be converted by obvious methods to compounds I and III.





The biphenyl aldehyde VIII seemed to offer a feasible approach to the acid V, since the propionic acid side chain could be readily built up from the aldehyde by condensation with malonic acid followed by decarboxylation and reduction.

The acid VII was therefore prepared in 25–35% yield by the crossed Ullmann[5] reaction from *p*-iodoanisole and methyl 2-bromo-3,4,5-trimethoxybenzoate. The Ullmann synthesis using the iodo ester, methyl 2-iodo-3,4,5-trimethoxybenzoate and iodoanisole, yielded the two symmetrical products to the exclusion of the desired unsymmetrical compound VII.

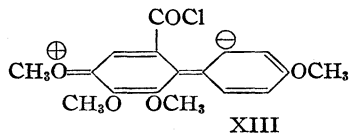
oxybenzoate were unsuccessful, the product being the azo compound XII. The same product was obtained by the action of N-nitroso-N-acetyl-*p*-anisidine on ethyl trimethoxybenzoate, followed by hydrolysis.[6]

When the acid VII was converted to the acid chloride IX even under mild conditions, the latter lost hydrogen chloride spontaneously to form the orange-red 2,3,4,7-tetramethoxyfluorenone XI.[7]



XIII

The ester of VII failed to form a hydrazide,[8] yielding instead what may have been the bis-hydrazide.

In a more successful approach to the synthesis of V, β-(3,4,5-trimethoxyphenyl)-propionic acid was prepared by the previously reported method,[9] with modifications, according to the scheme

$$\underset{\text{XIV}}{\text{ArCOCl}} \xrightarrow{H_2,\ Pd} \underset{\text{XV}}{\text{ArCHO}} + \underset{\text{XVI}}{\text{ArCOOCH}_2\text{Ar}}$$

(Ar = 3,4,5-Trimethoxyphenyl)

$$\text{ArCHO} + \text{CH}_2(\text{COOH})_2 \longrightarrow \underset{\text{XVII}}{\text{ArCH=CHCOOH}} \xrightarrow[\text{NaOH}]{H_2,\ Ni} \underset{\text{XVIII}}{\text{ArCH}_2\text{CH}_2\text{COOH}}$$

In agreement with previous reports,[10] it was found that the Rosenmund reduction of 3,4,5-trimethoxybenzoyl chloride gave variable yields; a by-product, which in some runs was the main product, was shown to be the ester XVI, by hydrolysis to the expected compounds. This product has been observed by previous workers[11] but was not identified. Reduction of the cinnamic acid XVII by sodium amalgam[9] gave a product which was difficult to purify, but the Raney nickel and hydrogen reduction of the sodium salt in aqueous solution[12] gave a practically quantitative yield of the pure hydrocinnamic acid XVIII.

The trimethoxyphenylpropionic acid XVIII was next iodinated, best with iodine monochloride, to yield β-(2-iodo-3,4,5-trimethoxyphenyl)-propionic acid XIX which was esterified with diazomethane to the ester XX. The iodo ester was then coupled with *p*-iodoanisole (in excess) at 250° with copper powder, and the unsymmetrical acid V was isolated in 55% yield.

In order to prevent ring-closure of V from forming the hydrindone XXVII, the free position in the trimethoxylated ring was blocked by bromination, yielding β-2-(3-bromo-4,5,6,4′-tetramethoxybiphenyl)-propionic acid XXI.

The structure of XXI was proved by brominating the trimethoxyphenylpropionic acid XVIII, to yield the monobromo derivative XXIII, which was iodinated by iodine monochloride to the bromoiodo compound XXIV. The ester XXV, on coupling with *p*-iodoanisole under the usual conditions, gave a small amount of the same bromo acid which had been obtained previously by direct bromination of the biphenyl acid V.

The problem of cyclizing the acid XXI to the desired ketone XXVI proved very troublesome. The acid was entirely unaffected by anhydrous hydrogen fluoride at room temperature,[13] and it seemed to be sulfonated to give water-soluble products when treated with sulfuric acid. Treatment of the acid chloride of XXI with phosphorus oxychloride in benzene or toluene gave a small amount of neutral material which proved to be the methyl ester XXII of the acid, apparently formed by intermolecular demethylation. The acid chloride of XXI when treated with stannic chloride in benzene gave no crystalline product.

Treatment of the acid chloride with aluminum chloride in tetrachloroethane gave variable results; in one case an impure carbonyl compound was obtained, which from the percentage composition of its oxime and semicarbazone, seemed to be nearly bromine free, and hence might be the desired ketone VI. Structure XXVII was considered as a possible one for this ketonic product, which could be formed from the bromo acid chloride by removal of the bromine[14] followed by ring-closure. The ketone XXVII was actually prepared by cyclization of the unbrominated acid V, and it had quite different properties from the product obtained by the cyclization of the bromo acid XXI

Although the product from the bromo acid thus appeared to have the desired structure, the poor

(6) These results were not entirely unexpected, since Grieve and Hey, *J. Chem. Soc.*, 108 (1938), found that diazotized aniline did not yield a biphenylcarboxylic acid with sodium benzoate. The diazonium compound has two possible modes of reaction, one as the ion ArN_2^+, to give an azo compound, and the other as the radical Ar· to form a biaryl. It is known (Grieve and Hey, *J. Chem. Soc.*, 1797 (1934)) that the radical reaction goes more slowly with toluene than with nitrobenzene, and hence seems to be retarded by electron-donating groups. The work of Fieser, Clapp and Daudt, THIS JOURNAL, **64**, 2052 (1942), shows that the methylation of aromatic systems by methyl radicals from lead tetraacetate goes more readily on polynitrated benzenes than on benzene or nitrobenzene. The three methoxyl groups in trimethoxybenzoic acid, being electron-donating groups, inhibit the attack on the ring by a free radical, and promote the attack by the electrophilic diazonium ion.

(7) This fact, while unfavorable for the immediate synthesis of the aldehyde, was nevertheless encouraging evidence for the feasibility of the general synthesis, since it implied that the *m*-methoxyl group in the acid V would not be an insuperable obstacle to cyclization in the desired manner. Recent observations of Johnson and Shelberg, THIS JOURNAL, **67**, 1853 (1945), indicate that cyclization *meta* to a methoxyl group is not as difficult as had previously been supposed. The extremely facile cyclization of IX is doubtless due to the high electron density in the 2′-position, caused by contributions from resonance forms such as XIII.

(8) This was desired in order to investigate the McFadyen-Stevens method of obtaining aldehydes (*J. Chem. Soc.*, 584 (1936)).

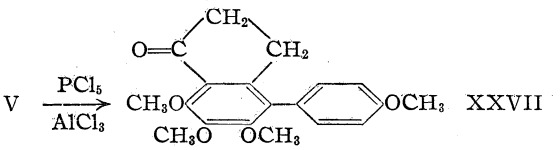
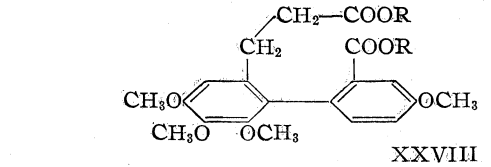
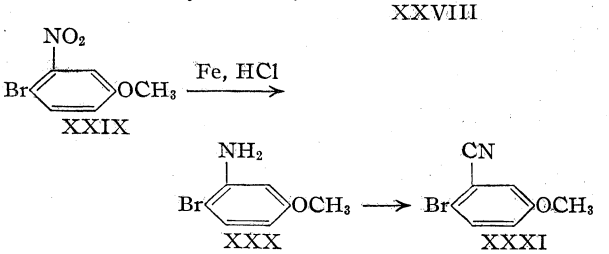
yield and erratic character of the reaction made it impractical for further synthetic operations. By



using nitrobenzene as solvent for the ring-closure' a small yield of crystalline product was obtained which had the percentage composition expected of the bromo ketone XXVI.[14a]

The difficulties mentioned above in the cyclization caused some effort to be spent on the synthesis of XXVIII, which could be converted to the desired ketone VI by a Dieckmann ring-closure.

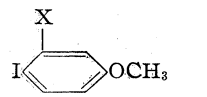




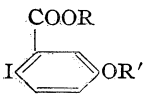
Some of the intermediates prepared for the synthesis of this compound will be described briefly.

3-Nitro-4-bromoanisole XXIX[1,15] was reduced with iron powder and acid and converted into the nitrile XXXI; the compound, however, was unchanged by refluxing with copper powder at 270°.

The preparation of the corresponding iodo compound was accordingly undertaken. 3-Nitro-4-iodoanisole[16] was prepared by a modified procedure, and the nitro group reduced with iron and acid. The crude amino compound XXXIII exploded violently during distillation, and attempts



XXXII, X = NO_2
XXXIII, X = NH_2
XXXIV, X = CN



XXXV, R = R' = H
XXXVI, R = CH_3, R' = H
XXXVII, R = H, R' = CH_3
XXXVIII, R = R' = CH_3

to prepare a number of derivatives from the crude product failed. The nitrile XXXIV was obtained from the crude amine by the Sandmeyer method, but in such small yield as to preclude further synthetic work.

The iodination of *m*-hydroxybenzoic acid, reported[17] to give 2-iodo-5-hydroxybenzoic acid XXXV, yielded in our hands 4-iodo-3-hydroxybenzoic acid[18]; the desired 2-iodo acid XXXV was obtained by a modification of the method of Brenans and Prost,[18] but methylation of the acid to the ether-ester XXXVIII proved extremely troublesome. The usual methods of methylation yielded only the carboxylic ester XXXVI. The desired product was finally obtained by treating the phenolic acid XXXV with a large excess of ethereal diazomethane over a period of several days.

The crossed Ullmann reaction between XXXVIII and the iodotrimethoxyphenylpropi-

(14a) Note added in proof: H. T. Huang in these laboratories recently has found that the bromo ketone obtained in this way possesses a five-membered ring. Work is being continued to determine the nature of the reaction.

Experimental[19]

3,4,5-Trimethoxybenzoic acid was prepared by methylating gallic acid.[20]

***p*-Iodoanisole.**[21]—A solution of 337 g. (3.12 moles) of anisole in 300 cc. of glacial acetic acid was stirred with cooling, while 508 g. (3.12 moles) of iodine monochloride was added during fifteen minutes. The reaction was completed by refluxing gently for two hours. The product was washed with an excess of sodium hydroxide solution containing a small amount of sodium sulfite. The colorless product was distilled through a Vigreux column, giving a forerun of 93 g. of material, and 459 g. of pale amber liquid, b. p. 70–78° (3 mm.). This partly solidified at room temperature, and, upon warming with 400 cc. of methanol, followed by cooling to 0°, yielded 337 g. (46%) of large white crystals of *p*-iodoanisole, m. p. 50–51°.

4,5,6,4′-Tetramethoxybiphenyl-2-carboxylic Acid (VII).—To 10 g. of methyl 2-bromo-3,4,5-trimethoxybenzoate[22] dissolved in 30–40 g. of *p*-iodoanisole in a large test-tube was added 25 g. of copper bronze. The mixture was immersed in a metal-bath held at 250–260° and stirred vigorously. After ten to fifteen minutes, when the mass had become too viscous for stirring, heating was continued at 260–265° for about twenty minutes. The hot reaction mixture was then transferred to a beaker, broken up, cooled and extracted repeatedly with acetone or benzene. The extracts were evaporated to dryness in a stream of air, taken up in methanol, and saponified by adding aqueous alkali to the refluxing solution. After two to three hours, when the saponification was complete, water was added and the alcohol removed by evaporation. After cooling the solution, 4,4′-dimethoxybiphenyl and unchanged iodoanisole were removed by filtration, and the filtrate shaken with Raney nickel and hydrogen at 3 atm. for three hours.[23] After removal of the catalyst by centrifugation, excess anisole present was removed by steam distillation and the residue carefully acidified. The combined oily acids were extracted with boiling water to remove trimethoxybenzoic acid. The residue was extracted with boiling benzene, which left undissolved the symmetrical 3,4,5,3′,4′,5′-hexamethoxybiphenyl-2,2′-dicarboxylic acid of m. p. 252–253°.[24] The benzene extract was evaporated to dryness, leaving a residue of the desired acid VII, which, recrystallized from alcohol, melted at 163.5–164.5°, solidifying and remelting at 173–174°. The yield was 25–37%. *Anal.* Calcd. for $C_{17}H_{18}O_6$: C, 64.14; H, 5.70. Found: C, 64.20; H, 5.66.

3,4,5-Trimethoxy-2-(4-methoxyphenylazo)-benzoic Acid (XII).—One mole of *p*-anisidine in a solution containing two moles of hydrochloric acid was diazotized at 0° with sodium nitrite. One mole of sodium acetate and one mole of the sodium salt of trimethoxybenzoic acid in the minimum volume of water were added to the diazonium solution and the mixture warmed up to room temperature. The acidic, orange azo-compound XII was obtained by acidifying the mixture, collecting the precipitate by filtration and washing the filter cake with methyl alcohol. The residue on the funnel, after recrystallization from ethanol or acetic acid, melted at 221°. *Anal.* Calcd. for $C_{17}H_{18}O_6N_2$: C, 58.95; H, 5.24. Found: C, 58.88; H, 5.31. From the methanol washings unchanged trimethoxybenzoic acid was isolated.

2,3,4,7-Tetramethoxyfluorenone (XI).—A solution of 1 g. of 4,5,6,4′-tetramethoxybiphenyl-2-carboxylic acid VII in 5 cc. of dry benzene was treated with the calculated amount of phosphorus pentachloride and refluxed for two hours. The reaction mixture was extracted with hot sodium bicarbonate solution and the benzene evaporated. The residue was crystallized from ethanol, giving orange-red needles of the fluorenone, m. p. 117–118°. *Anal.* Calcd. for $C_{17}H_{16}O_5$: C, 67.99; H, 5.37. Found: C, 67.97; H, 5.37. The fluorenone was also obtained when the evaporation of the phosphorus oxychloride present was attempted in high vacuum.

2-Carbomethoxy-4,5,6,4′-tetramethoxybiphenyl (X), obtained from the acid VII with ethereal diazomethane, crystallized from dilute alcohol as colorless plates, m. p. 63°. *Anal.* Calcd. for $C_{18}H_{20}O_6$: C, 65.05; H, 6.07. Found: C, 65.08; H, 6.08. Two grams of the ester in 20 cc. of alcohol were refluxed for two hours with 1 cc. of hydrazine hydrate: on cooling, crystals of m. p. 81° separated, which were insoluble in dilute acid. *Anal.* Calcd. for $C_{17}H_{20}N_2O_5$ (the hydrazide): C, 61.43; H, 6.07. Calcd. for $C_{34}H_{36}N_2O_{10}$ (the bis-hydrazide): C, 64.54; H, 5.74. Found: C, 64.66, 64.84; H, 6.66, 6.61.

3,4,5-Trimethoxybenzaldehyde (XV) was prepared in 30–50% yield by the Rosenmund reduction of 3,4,5-trimethoxybenzoyl chloride.[25]

3,4,5-Trimethoxybenzyl 3,4,5-Trimethoxybenzoate (XVI).—From some runs of the Rosenmund reduction, 3,4,5-trimethoxybenzoic anhydride, m. p. 160°,[26] and a product of m. p. 107° previously obtained by Späth and Mauthner[11] were isolated; the latter, insoluble in water and alkali, and unaffected by permanganate in boiling water, was saponified with alcoholic alkali. 3,4,5-Trimethoxybenzoic acid, m. p. 171°, and 3,4,5-trimethoxybenzyl alcohol (3,5-dinitrobenzoate, m. p. 147°[10]) were isolated from the saponification reaction. The compound of m. p. 107° is therefore the ester XVI. *Anal.* Calcd. for $C_{20}H_{24}O_8$: C, 61.22; H, 6.17. Found: C, 60.81; H, 6.03.

Isopropyl 3,4,5-Trimethoxythiolbenzoate.—This compound was prepared to see if the desulfuration procedure[27] could be used to obtain 3,4,5-trimethoxybenzaldehyde. A solution of 12.04 g. of trimethoxybenzoyl chloride and 7.4 g. (100% excess) of isopropylmercaptan in 30 cc. of pyridine was heated on the steam-bath for one hour. The product was obtained in 89% yield (crude), and, after recrystallization for analysis from aqueous methanol, melted at 47–48°. *Anal.* Calcd. for $C_{13}H_{18}O_4S$: C, 57.75; H, 6.70. Found: C, 57.96; H, 6.80.

A 4-g. portion of the thiol ester was refluxed with 25 g. of freshly prepared Raney nickel[28] in 100 cc. of 70% alcohol for twenty-four hours. The product was 1.97 g. of an oil which did not give an aldehyde test with dinitrophenylhydrazine reagent. The oil gave a poor yield of 3,4,5-trimethoxybenzyl 3,5-dinitrobenzoate, m. p. 143.5–

(28) Pavlic and Adkins, *ibid.*, **68**, 1471 (1946).

146.5° (reported,[10] 147–148°).[29] In other runs, using old Raney nickel in refluxing 70% alcohol, or shaking with fresh nickel at room temperature, unreacted ester was the only product obtained.[30]

3,4,5-Trimethoxycinnamic acid (XVII) was prepared by the procedure of Slotta and Heller,[9] by condensing the aldehyde with malonic acid in pyridine with 1% of piperidine as catalyst.

β-(3,4,5-Trimethoxyphenyl)-propionic Acid (XVIII).—A solution of 10 g. of 3,4,5-trimethoxycinnamic acid in 50 cc. of water and the calculated amount of sodium hydroxide was shaken for three hours with hydrogen at 4 atm. in the presence of Raney nickel. The catalyst was removed by filtration, the solution was cooled in ice and carefully acidified. The crystalline acid of m. p. 104° separated from the solution in practically quantitative yield. The previously reported m. p.'s are 98°[9] and 100–102°.[10]

β-(2-Iodo-3,4,5-trimethoxyphenyl)-propionic Acid (XIX).—To a solution of 50 g. of the trimethoxyphenylpropionic acid XVIII in 75 cc. of acetic acid and 300 cc. of water at 40° was added a 20% excess of iodine monochloride. After the exothermic reaction had subsided, the reaction mixture was allowed to stand for another hour, then decolorized with sodium bisulfite, and diluted with water to 800 cc. The iodo acid separated in 95% yield as granular crystals, which were purified by dissolving in sodium carbonate and reprecipitating from about 600 cc. of solution with hydrochloric acid. Crystallization from carbon tetrachloride or dilute methanol gave material of m. p. 124–125°. *Anal.* Calcd. for $C_{12}H_{15}IO_5$: C, 39.36; H, 4.13; neut. equiv., 366. Found: C, 39.00; H, 4.09; neut. equiv., 369. This method of iodination was far superior to that employing iodine and mercuric oxide, which was also used.

The methyl ester (XX) was obtained from the acid with ethereal diazomethane. After removal of the ether, the ester was used directly in the Ullmann reaction. An analytical sample, purified by vacuum distillation, had b. p. 175° (2.5 mm.), m. p. 36–37.5°. *Anal.* Calcd. for $C_{13}H_{17}IO_5$: C, 41.07; H, 4.51. Found: C, 41.00; H, 4.72.

β-2-(4,5,6,4′-Tetramethoxybiphenyl)-propionic Acid (V).—An Ullmann reaction between methyl β-(2-iodo-3,4,5-trimethoxyphenyl)-propionate (XX) and *p*-iodoanisole was carried out by a procedure similar to that described above for compound VII. The iodo ester (3.6 g.), *p*-iodoanisole (20 g.) and copper bronze (10 g.) were heated with stirring for one-half to one hour at 250–255°, and the products worked up as before. The aqueous solution of the saponified products was acidified, the oily acids taken up in benzene, and the fine needles, which formed almost immediately, were recrystallized from benzene; the product retained benzene of crystallization very tenaciously. The acid was very soluble in alcohol and acetone, slightly soluble in carbon tetrachloride, and melted, after crystallization from dilute ethanol, at 106.5–107°. *Anal.* Calcd. for $C_{19}H_{12}O_6$: C, 65.88; H, 6.40. Found: C, 65.58; H, 6.34.

β-2-(3-Bromo-4,5,6,4′-tetramethoxybiphenyl)-propionic Acid (XXI).—To 6 g. of the biphenylpropionic acid V in 10 cc. of acetic acid at 0–5° was added dropwise with stirring a solution of 3 g. of bromine in 10 cc. of acetic acid. The mixture was allowed to stand for several hours at room temperature, then an equal volume of water was added. The crystalline acid, which separated on cooling in ice, was collected and dissolved in hot saturated sodium bicarbonate solution. From this, the crystalline sodium salt precipitated on cooling. The salt was collected, dissolved in hot water and converted to the acid by adding mineral acid. The purified acid, after crystallization from ethanol, melted at 169–171°. *Anal.* Calcd. for $C_{19}H_{21}BrO_6$: C, 53.67; H, 4.98. Found: C, 53.67; H, 4.88.

The methyl ester (XXII) was prepared from the acid with ethereal diazomethane or by heating the dry sodium salt with dimethyl sulfate for thirty minutes on the steam-bath. Crystallization from methanol gave a product melting at 92–93°. *Anal.* Calcd. for $C_{20}H_{23}BrO_6$: C, 54.68; H, 5.28. Found: C, 54.85; H, 5.73. The methyl ester in methanol solution was heated with hydroxylamine and dilute sodium hydroxide on the steam-bath for ten minutes, cooled, filtered and saturated with carbon dioxide. The **hydroxamic acid** which precipitated melted at 172–173°, dec.; for analysis, see below.

β-(2-Bromo-3,4,5-trimethoxyphenyl)-propionic Acid XXIII.—A solution of 1.60 g. of bromine in 5 cc. of glacial acetic acid was added slowly to 2.4 g. of trimethoxyphenylpropionic acid XVIII in 5 cc. of acetic acid, cooled in an ice-bath. The solution was allowed to stand for two hours at room temperature, until the color of bromine had disappeared, and 10 cc. of water was then added. On cooling in the refrigerator, crystals separated; a second crop was obtained by diluting with more water. β-(2-Bromo-3,4,5-trimethoxyphenyl)-propionic acid, crystallized from carbon tetrachloride–petroleum ether, had the m. p. 92.5–93.5°. *Anal.* Calcd. for $C_{12}H_{15}BrO_5$: C, 45.16; H, 4.74; neut. equiv., 319. Found: C, 45.06; H, 4.65; neut. equiv., 322.

β-(2,6-Dibromo-3,4,5-trimethoxyphenyl)-propionic acid was prepared from XVIII for reference in the same manner as the monobromo acid XXIII, except that an excess of bromine in acetic acid was added. When the reaction was complete, the excess of bromine was reduced with sodium bisulfite solution. The dibromo acid may be purified through its sodium salt, which is only slightly soluble in cold water. The free acid, recrystallized from benzene-petroleum ether, melted at 119.5°, then solidified and remelted at 122°. *Anal.* Calcd. for $C_{12}H_{14}Br_2O_5$: C, 36.22; H, 3.54. Found: C, 36.46; H, 3.55.

β-(2-Bromo-6-iodo-3,4,5-trimethoxyphenyl)-propionic Acid XXIV.—A solution of 1.3 g. of the bromo acid XXIII in 3 cc. of acetic acid was treated with excess of iodine monochloride in acetic acid in the cold. The solution was slowly warmed on the water-bath, then cooled, and the excess halogen removed with bisulfite. On dilution with water, the iodobromo acid precipitated in fine plates. The acid was purified by crystallizing the slightly water-soluble sodium salt from benzene, then regenerating the acid. Final crystallization from dilute ethanol yielded an acid of m. p. 130–132°. The product was not analytically pure, but the presence of iodine and bromine is borne out by the analysis. *Anal.* Calcd. for $C_{12}H_{14}O_5BrI$: C, 32.38; H, 3.17. Found: C, 33.95; H, 3.27.

β-2-(3-Bromo-4,5,6,4′-tetramethoxybiphenyl)-propionic Acid XXI by the Ullmann Reaction.—The methyl ester of the above acid XXIV (0.4 g.) was heated with copper powder (2.5 g.) and *p*-iodoanisole (3 g.) for fifteen minutes at 250–260°. The mixture was extracted and saponified as in previous Ullmann reactions. The acids liberated consisted of a mixture of product and starting material, and were separated by the differential solubility of their dry sodium salts in benzene. The combined sodium salts were taken up in hot benzene. On cooling to room temperature the salt of the phenylpropionic acid XXIV precipitated out completely, leaving most of the biphenylpropionic acid XXI in solution. On evaporation of the solution and acidification, crystals were obtained (from ethanol) of m. p. 169–171°, giving no depression of mixed melting point with acid XXI prepared by the procedure described above.

Cyclization Experiments on the Acid XXI.—Only the following experiments are described in any detail; other methods tried are listed in the introduction.

With Phosphorus Oxychloride.—To 1 g. of the acid in 50 cc. of benzene (or toluene) was added the calculated weight of phosphorus pentachloride for conversion to the acid chloride The reaction mixture was refluxed for four hours, then cooled and extracted with cold concentrated

(29) Prelog and co-workers (*Helv. Chem. Acta*, **29**, 360, 684 (1946)) have observed reduction of thiol esters to primary alcohols by refluxing with Raney nickel.

(30) This work was carried out before the appearance of the paper by Spero, McIntosh and Levin, THIS JOURNAL, **70**, 1907 (1948), describing the use of partially deactivated Raney nickel for this reaction.

sodium bicarbonate solution. The residue from the organic layer was treated for an hour with hot concentrated sodium bicarbonate solution. A small amount of neutral oil, which remained undissolved, was crystallized from methanol, and melted at 91.5–92.5°; it gave no depression on mixed m. p. with the methyl ester XXII described above.

The hydroxamic acid, prepared as above, gave no depression on mixed m. p. with the authentic sample, and melted at 172–173°, dec. *Anal.* Calcd. for $C_{19}H_{22}BrNO_6$: N, 3.18. Found: N, 3.63. Both the ester and the hydroxamic acid yielded acid XXI on saponification.

With Aluminum Chloride.—A solution of the acid XXI (1 g.) in tetrachloroethane (50 cc.) was treated with the calculated weight of phosphorus pentachloride. The solution was heated to 80° for ten minutes to bring about complete conversion to the acid chloride and thereupon cooled to −10 to −5° in an ice–salt mixture. To the cold solution was added 0.33 g. of finely powdered aluminum chloride, some of which failed to go into solution despite vigorous agitation. The mixture, after being heated at 90° for ten minutes, was poured into 50 g. of ice and 10 cc. of concentrated hydrochloric acid to extract aluminum salts. The organic layer, after being washed with aqueous sodium bicarbonate, was evaporated at reduced pressure, and the residue extracted for one to two hours with hot concentrated sodium bicarbonate solution. The oily neutral residue (100–150 mg.) yielded in one case crystals of m. p. 141–144° from ethanol. The crude product yielded a semicarbazone, crystallized from ethanol, m. p. 210–212°, dec. *Anal.* Calcd. for $C_{20}H_{22}BrN_3O_5$: C, 51.85; H, 4.78; N, 9.05. Calcd. for $C_{20}H_{23}N_3O_5$: C, 62.32; H, 6.01; N, 10.90. Found: C, 59.62; H, 5.68; N, 11.24.

An oxime was also obtained which, crystallized from chloroform–ethanol, had m. p. 209–212°. Other fractions had m. p. 206–217°. *Anal.* Calcd. for $C_{18}H_{20}NBrO_5$: C, 54.04; H, 4.77. Calcd. for $C_{19}H_{21}NO_5$: C, 66.46; H, 6.17. Found: C, 65.46; H, 5.98.

In Nitrobenzene.—To 1 g. of the biphenylpropionic acid XXI in 25 cc. of nitrobenzene was added 0.5 g. of phosphorus pentachloride, the mixture being warmed to 80° to complete formation of the acid chloride. After cooling to 0°, 0.33 g. of aluminum chloride was added and the solution swirled vigorously. Heating for five minutes in a bath at 90° dissolved the aluminum chloride. The product was purified by extracting the nitrobenzene layer repeatedly with cold dilute hydrochloric acid and then with hot sodium bicarbonate solution. The dried organic layer was freed from solvent by vacuum distillation. The bromo ketone of m. p. 145° was obtained on crystallization from ethanol. *Anal.* Calcd. for $C_{19}H_{19}O_5Br$: C, 56.03; H, 4.70. Found: C, 55.88; H, 5.03.

An oxime, prepared from a less pure sample of ketone, gave a poor analysis for carbon.

4-(*p*-Methoxyphenyl)-5,6,7-trimethoxyhydrindone (XXVII).—A solution of 0.88 g. of β-(2-(4,5,6,4′-tetramethoxy)-biphenyl)-propionic acid in 25 cc. of tetrachloroethane was treated with the calculated weight of phosphorus pentachloride. After addition to the ice-cold solution of 0.33 g. of aluminum chloride, the mixture was swirled for ten minutes while immersed in an oil-bath at 90°. After decomposition of the reagents, removal of the solvent, and extraction with dilute alkali, there remained 0.24 g. of a compound, m. p. 86°, which when crystallized from ethanol, formed stout needles of m. p. 89°. The acid was not cyclized by anhydrous hydrofluoric acid. *Anal.* Calcd. for $C_{19}H_{20}O_5$: C, 69.50; H, 6.14. Found: C, 69.70; H, 5.94. The oxime crystallized in colorless prisms, m. p. 217°, dec., from a mixture of ethanol and chloroform. *Anal.* Calcd. for $C_{19}H_{21}NO_5$: C, 66.46; H, 6.17; N, 4.08. Found: C, 66.24; H, 6.01; N, 4.46.

3-Amino-4-bromoanisole XXX.—A 23.2-g. portion of 3-nitro-4-bromoanisole[16,31] (0.1 mole) in 100 cc. of 50% alcohol, and 17 g. (0.3 mole) of iron powder (J. T. Baker purified by hydrogen) were heated to refluxing on the steam-bath and stirred with a tantalum Hershberg stirrer, while 1.2 cc. of concentrated hydrochloric acid was added dropwise. The addition was very slow at first, and a vigorous reaction ensued. After all of the acid had been added, refluxing and stirring were continued for several hours. The solid material was removed from the hot product by centrifuging, the clear solution was brought to a slightly alkaline reaction with potassium hydroxide, and the flocculent precipitate was centrifuged down. The solution was boiled until a heavy oil separated and commended to steam distill. The oil was taken up in benzene, the solution clarified by centrifuging, the solvent removed by flash-distillation and the product distilled, giving 69% (13.9 g.) of pale yellow oil, b. p. 76–98° (2 mm.). The hydrochloride melted, after crystallization from water, at 183.5–184°, dec.[32] An attempted selective catalytic reduction of the nitrobromoanisole with hydrogen and platinum[33] was unsuccessful.

2-Bromo-5-methoxybenzonitrile XXXI.—The amine obtained above (13.9 g.) was diazotized and the clear dark red diazonium solution was poured into an ice-cold solution, which had been prepared by dissolving 9.3 g. of cuprous cyanide and 15.3 g. of sodium cyanide in 40 cc. of water. A thick brown mass was formed, and hydrogen cyanide was evolved; the mixture was heated on the steam-bath with stirring until a heavy oil settled out. This was taken up in 200 cc. of benzene, washed with dilute sodium hydroxide and hydrochloric acid, clarified by centrifuging, the solvent removed and the residue distilled at 2 mm., with precautions to prevent solidification in the side arm. A slightly yellow solid (8.2 g., 56%) was obtained, m. p. 84–97°. After crystallization from benzene an analytical sample was obtained as long, colorless needles, m. p. 98.5–99.5°. *Anal.* Calcd. for C_6H_6BrNO: C, 45.31; H, 2.85. Found: C, 45.41; H, 2.84. Hydrolysis of the nitrile with potassium hydroxide in diethylene glycol yielded 2-bromo-5-methoxybenzoic acid, m. p. 157–158°.[34] A portion of the nitrile was heated at the reflux temperature (about 270°) with copper bronze. The metal remained bright and no reaction seemed to occur.

3-Nitro-4-iodoanisole XXXII.—The published procedure[16] was modified as follows. A suspension of 44 g. of finely divided 3-nitro-4-aminoanisole in 250 cc. of ice and water was diazotized at −5°. The diazonium solution was poured into a cold solution of 65 g. (50% excess) of potassium iodide in 65 cc. of water. Heat and gases were evolved, and the mixture was heated on the steam-bath until a heavy oil separated, which solidified on cooling. It was taken up in benzene, washed with concentrated hydrochloric acid and with dilute sodium hydroxide solution containing a little sodium sulfite; after evaporation of the benzene, a 90% yield of crude material was obtained, which formed fine orange needles, m. p. 60.5–61.5° after crystallization from aqueous methanol.

3-Amino-4-iodoanisole (XXXIII).—Reduction of the nitro compound XXXII with iron and hydrochloric acid, by the method described above for the bromo compound, gave, in a small run, 52% yield of a red oil, b. p. 92–112° (0.2 mm.). Repetition of the reaction on a 1 mole scale was terminated by a violent explosion during the vacuum distillation.

The only crystalline compound that could be obtained from the crude aminoiodoanisole was the nitrile below. Reduction of the 3-nitro-4-iodanisole with stannous chloride, with ferrous hydroxide in ammonium hydroxide, or electrolytically, yielded either *m*-anisidine or intractable products.

2-Iodo-5-methoxybenzonitrile XXXIV.—The crude amine (5.7 g.) was diazotized and added to a solution of 4.03 g. of cuprous cyanide and 6.75 g. of sodium cyanide

(31) Samant, *Ber.*, **75**, 1008 (1942).

(32) The reported value[15] is 186°; the reduction was carried out previously,[15] but details were not given.

(33) *Cf.* Adams, Cohen and Rees, THIS JOURNAL, **49**, 1093 (1927).

(34) Pschorr, *Ann.*, **391**, 26 (1912), reports a m. p. of 161–162° for this compound.

n 20 cc. of water. The mixture was heated on the steam-bath, the heavy oil which separated was taken up in benzene, washed with acid and base, and the benzene was evaporated. The black tar remaining was subjected to vacuum sublimation, yielding a mushy yellow solid, which on resublimation and crystallization from benzene–petroleum ether, formed colorless plates, m. p. 98–100°. *Anal.* Calcd. for C_8H_6INO: C, 37.09; H, 2.34. Found: C, 37.46; H, 2.43.

3-Hydroxy-4-iodobenzoic Acid.—This reaction is described because this procedure is reported[17] to yield 2-iodo-5-hydroxy-benzoic acid XXXV. A solution of 13.8 g. of *m*-hydroxybenzoic acid in 200 cc. of concentrated ammonium hydroxide was stirred while a solution of 23.4 g. of iodine and 18.2 g. of potassium iodide in 100 cc. of water was added during five minutes. A precipitate of nitrogen triiodide was formed and reacted rapidly. The resulting green solution was stirred for an additional ten minutes and acidified to congo red by adding 180 cc. of concentrated hydrochloric acid. The thick precipitate was collected, and crystallized from a mixture of 100 cc. of water and 20 cc. of alcohol, giving a nearly quantitative yield of white needles, m. p. 225–227° dec; the acetyl derivative melted at 199.5–201.5°. The product was therefore the 3-hydroxy-4-iodobenzoic acid, which is reported[18a] to melt at 226° (acetyl derivative, 203°), and not the 2-iodo-5-hydroxy isomer.

2-Iodo-5-hydroxybenzoic Acid (XXXV).—The procedure of Brenans and Prost[18a] was modified as follows. An ice-cold solution of benzenediazonium chloride prepared from 37.2 g. of aniline was added with stirring to a solution of 55.2 g. of *m*-hydroxybenzoic acid and 48 g. of sodium hydroxide in 400 cc. of water. A sticky orange-red precipitate formed which dissolved on warming to 50°, the dark red solution was heated and stirred while a solution of 144 g. of sodium hydroxide in 150 cc. of water was added, followed by 210 g. of solid sodium hydrosulfite. With the solution at 80–90°, more sodium hydrosulfite was added in 5-g. portions at one-minute intervals until the dark red color was discharged. The solution was cooled to 30°, 500 g. of ice was added and the solution brought to a *p*H of 5.5 with concentrated hydrochloric acid. The pale yellow precipitate of 2-amino-5-hydroxybenzoic acid was collected, and diazotized at 0° with 67 cc. of concentrated sulfuric acid, 400 g. of ice and 26 g. of sodium nitrite. The diazonium solution was poured into a solution of 84 g. of potassium iodide in 150 cc. of water; the reaction which ensued was completed by heating on the steam-bath for an hour. Cooling to 0° gave 67.6 g. (64%) of dark purple crystalline product, which was purified by boiling with 15 g. of Nuchar in 700 cc. of water for an hour. Cooling to 0° yielded 52 g. (49% over-all from *m*-hydroxybenzoic acid) of nearly white needles which melted to a red liquid at 201–202.5°. The reported[18a] m. p. is 196–198°.

Methyl 2-iodo-5-hydroxybenzoate (XXXVI) was obtained from the acid with a slight excess of ethereal diazomethane solution. The product was isolated by vacuum sublimation followed by crystallization from benzene–petroleum ether; it formed white granular crystals, m. p. 102–103°. *Anal.* Calcd. for $C_8H_7IO_3$: C, 34.55; H, 2.54. Found: C, 34.90; H, 2.72.

Methyl 2-iodo-5-methoxybenzoate (XXXVIII) was obtained when 2.64 g. of 2-iodo-5-hydroxybenzoic acid was treated with a five-fold excess of ethereal diazomethane, and allowed to stand several days. The solution was washed with sodium hydroxide, dried, and the ether removed, leaving 1.81 g. (62%) of crude ester. This was distilled at 150° (0.8 mm.), giving a very pale yellow oil, $n^{22}D$ 1.6000. *Anal.* Calcd. for $C_9H_9IO_3$: C, 37.01; H, 3.11. Found: C, 37.34; H, 3.27. Hydrolysis of this compound yielded 2-iodo-5-methoxybenzoic acid (XXXVII), which could not be obtained analytically pure; apparently there was some loss of iodine during saponification.

4,4′-Dimethoxydiphenic Acid (XXXIX).—A 1.00-g. portion of methyl 2-iodo-5-methoxybenzoate was mixed with 1.00 g. of copper bronze, and heated at 280–300° for twenty minutes. The product was extracted with two 7 cc. portions of benzene, which, on evaporation, yielded a dark oil. This was saponified with Claisen alkali; acidification produced a brown precipitate which was refluxed with Nuchar in aqueous methanol until the color had been removed. Upon cooling, a white powder was obtained which was crystallized from nitrobenzene; the fine white crystals melted at 245–248° on the heated stage. *Anal.* Calcd. for $C_{16}H_{14}O_6$: C, 63.57; H, 4.67. Found: C, 63.78; H, 4.84.

2,2′,3,3′,4,4′-Hexamethoxy-6,6′-di-(β-carboxyethyl)-biphenyl (XL).—Methyl β-(3,4,5-trimethoxy-2-iodophenyl)-propionate (1.5 g.) and 1.5 g. of copper dust were heated in a test-tube in a Wood's metal bath at 265–270° for twenty minutes. The product was extracted with hot benzene, the extract was evaporated on the steam-bath and the residue was saponified by heating with Claisen alkali. Acidification gave an amber oil which was vacuum sublimed. A portion of the sublimate was crystallized from aqueous acetic acid, when it formed a white powder which sintered at 188–189° and melted to an amber liquid at 189–193°. *Anal.* Calcd. for $C_{24}H_{30}O_{10}$: C, 60.24; H, 6.32. Found: C, 59.98; H, 6.06.

Crossed Ullmann Reaction.—A mixture of equivalent quantities of methyl β-(3,4,5-trimethoxy-2-iodophenyl)-propionate and methyl 2-iodo-5-methoxybenzoate was heated with copper powder and the reaction product was converted to the free carboxylic acids in the usual way. The material thus obtained was subjected to an eight-plate multiple countercurrent extraction, using ether and 2 *M* phosphate buffer of *p*H 5.9 in 60-cc. separatory funnels.[35] The two symmetrical reaction products were separated in this way, but none of the desired unsymmetrical acid was obtained.

Summary

β-2-(3-Bromo-4,5,6,4′-tetramethoxybiphenyl)-propionic acid has been synthesized, its structure proved, and its ring-closure to the bromo ketone studied. 4,5,6,4′-Tetramethoxybiphenyl-2-carboxylic acid has been prepared, and found to cyclize spontaneously to the fluorenone, when converted to the acid chloride A number of new compounds have been prepared and characterized in connection with these syntheses.

Streptomyces Antibiotics. XVII. Heptabenzoylstreptidine from Streptomycin

BY ROBERT L. PECK, FREDERICK A. KUEHL, JR., CHARLES E. HOFFHINE, JR., ELIZABETH W. PEEL AND KARL FOLKERS

Streptomycin has been degraded to heptabenzoylstreptidine which served as a key product for the determination of the position of the linkage of streptobiosamine to streptidine.[1] The details of the formation and characterization of heptabenzoylstreptidine and certain of its reactions are described herein.

A suspension of crystalline streptomycin trihydrochloride-calcium chloride double salt[2] in benzoyl chloride and pyridine was heated for about twenty minutes. The crude reaction product was purified by chromatography on charcoal to give a low yield of benzoylated streptomycin as an amorphous white powder. The analytical data were in agreement with the formula for undecabenzoylstreptomycin.

The presence of some dodecabenzoylstreptomycin in the benzoylated streptomycin was possible, since the streptose moiety of streptomycin contains a tertiary hydroxyl group. Although this hydroxyl group is difficult to acylate,[3,4] a bis-*p*-nitrobenzoate of bis-desoxystreptose[3] was obtained. The presence of some of the dodecabenzoyl derivative in the undecabenzoylstreptomycin would be of no consequence in the present study; however, it is essential that the streptidine moiety in the product be completely (hepta) benzoylated.

The molecular weights of undeca- and dodecabenzoylstreptomycin are 1727 and 1831, respectively. Ebullioscopic molecular weight determinations of benzoylated streptomycin in benzene gave values of 1625–1650 ± 165 for two different preparations.

Alkaline hydrolysis of benzoylated streptomycin gave maltol by isolation, and substantiated the presence of the intact streptomycin carbon skeleton[4] in the benzoylated product. This hydrolysis also gave benzoic acid in a yield of 10.9 moles of benzoic acid per mole of undecabenzoylstreptomycin.

The treatment of benzoylated streptomycin with one to three equivalents of hydrogen bromide in chloroform–glacial acetic acid solution at room temperature cleaved the glycosidic linkage between the streptidine and streptobiosamine moieties. Crystalline heptabenzoylstreptidine was obtained from this reaction in 72% yield.

Heptabenzoylstreptidine melted at 256–258° when crystallized from benzene–methanol. When crystallized from benzene a molecule of solvent of crystallization was present which could be removed by drying at 110° *in vacuo*. Analyses and molecular weight measurements were in agreement with the formula, $C_8H_{11}N_6O_4(C_6H_5CO)_7$. Heptabenzoylstreptidine was found to be optically active, $[\alpha]^{25}D$ + 58° (in chloroform), $[\alpha]^{25}D$ −3° (in glacial acetic acid). Further characterization was provided by conversion of heptabenzoylstreptidine to acetylheptabenzoylstreptidine, m. p. 156–160°, $[\alpha]^{25}D$ + 3° (in chloroform), to anisoylheptabenzoylstreptidine, m. p. 213–216°, $[\alpha]^{25}D$ −12° (in chloroform), and to octabenzoylstreptidine, m. p. 263–264°, $[\alpha]D$ 0.

The significance of the optical activity of heptabenzoylstreptidine is detailed in conjunction with the results of the degradation of this compound to α,γ-dibenzamido-β-hydroxyadipaldehyde, which are described in an accompanying paper.[5]

Both heptabenzoylstreptidine and octabenzoylstreptidine yielded a crystalline monobenzoylstreptidine upon treatment with sodium methoxide in pyridine–methanol solution. The isolation of the monobenzoyl derivative may have been due to its insolubility in the reaction medium. Further treatment of this monobenzoyl derivative with acid readily yielded streptidine which was optically inactive, as were streptidine preparations produced by hydrolysis of streptomycin directly.[6,7] It has been observed that octaacetylstreptidine,[6,8] is deacetylated to streptidine at room temperature in methanol containing ammonia.

It was found that streptidine could be benzoylated, under conditions similar to those applied to streptomycin, to give optically inactive octabenzoylstreptidine. A hexabenzoylstreptidine has also been obtained. Octabenzoylstreptidine was distinguished from heptabenzoylstreptidine by melting point and by the fact that only the latter compound (obtained by cleavage of benzoylated streptomycin) is optically active.

Octabenzoylstreptidine was remarkably stable to hydrogen bromide, since it was recovered in nearly quantitative yield after a solution of the substance in glacial acetic acid containing excess hydrogen bromide was refluxed for one hour. Octaacetylstreptidine[6,8] formed a crystalline dihydrobromide when treated with hydrogen bromide in glacial acetic acid at room temperature. This salt hydrolyzed in aqueous solution, and the substance was partially deacetylated.

Thus, it is clear that heptabenzoylstreptidine could not have been derived from the presence and hydrolysis of octabenzoylstreptidine as a contaminant in benzoylated streptomycin. The cleavage reaction took place at room temperature, and the yield of heptabenzoylstreptidine was high. It is also clear from the data given above that the atom in the unbenzoylated functional group of heptabenzoylstreptidine is attached to the carbon atom of streptidine which is linked glycosidically to streptobiosamine.

Evidence for the presence of a free hydroxyl group in heptabenzoylstreptidine was provided by the action of chromic acid in 90% acetic acid on octa-, hepta- and hexabenzoylstreptidine at 45°. Only the heptabenzoylstreptidine was affected by this oxidizing reagent and gave crystalline dibenzoylguanidine, m. p. 165–166°.[9] The yield of dibenzoylguanidine was greater than one mole per mole of heptabenzoylstreptidine which showed that each guanido group in the streptidine moiety of benzoylated streptomycin possessed two benzoyl groups. This result provided evidence that streptobiosamine was linked to streptidine through an oxygen atom rather than through a nitrogen atom. Since hexabenzoylstreptidine was unaffected by chromic acid, there is presumably no free hydroxyl group present.

Previous indication that the linkage of streptobiosamine and streptidine was through an oxygen rather than a nitrogen atom was furnished by the ultraviolet absorption spectra of heptabenzoylstreptidine and octabenzoylstreptidine; their spectra were practically identical. Hexabenzoylstreptidine showed distinctly different absorption maxima. These spectra substantiate the interpretation that both guanido groups of heptabenzoylstreptidine contain two benzoyl groups each, as otherwise a change in position of the absorption maxima would be expected.

Dihydrostreptomycin has also been benzoylated under the conditions used for streptomycin. Analyses on benzoylated dihydrostreptomycin were in agreement with the formula for dodecabenzoyldihydrostreptomycin. Cleavage of dodecabenzoyldihydrostreptomycin also yielded heptabenzoylstreptidine.

Experimental

Benzoylation of Streptomycin.—Twenty-five grams of crystalline streptomycin trihydrochloride–calcium chloride double salt was suspended in a mixture of 150 cc. of pyridine and 55 cc. of benzoyl chloride, and the suspension was heated on a steam-bath for ten minutes and then heated at reflux temperature for ten minutes. At the end of the heating period, all of the suspended solid had dissolved. The solution was partially cooled and diluted with 300 cc. of chloroform. The chloroform solution was washed successively with water, dilute hydrochloric acid, sodium bicarbonate solution, and water. The chloroform solution was dried over magnesium sulfate, filtered, concentrated *in vacuo* to a volume of about 200 cc., and then poured with stirring into 2 l. of petroleum ether. The precipitated crude undecabenzoylstreptomycin was collected on a filter and dried; yield, 49 g. For purification, a solution of this material in about 150 cc. of benzene was allowed to flow into a dry chromatographic column containing a mixture of 500 g. of Darco G-60 and 150 g. of filter paper pulp. Fresh benzene was added to the column, and five eluates were collected. A 1:1 acetone–benzene mixture was used next and three more eluates were collected. Chloroform was used to produce the ninth eluate. The eluates were concentrated to *ca.* 25-cc. volume *in vacuo* and the concentrates were poured into about ten volumes of petroleum ether, which caused the precipitation of the benzoylated streptomycin. The details of this chromatographic experiment are summarized in Table I.

TABLE I

CHROMATOGRAPHY OF BENZOYLATED STREPTOMYCIN

Eluate no.	Volume of eluate, cc.	Weight of product, g.	$[\alpha]^{25}D$ (chloroform)
1	300	0.4	+60°
2	500	2.30	+34°
3	1000	2.50	+27.6°
4	1000	1.10	+19.7°
5	1800	0.98	+12.7°
6	1400	0.81	−18.6°
7	700	6.90	−43°
8	800	2.50	−64.5°
9	2100	1.23	−38°

The product from eluate 1 was reprecipitated by dissolving it in 3 cc. of chloroform and pouring the solution dropwise into 80 cc. of boiling petroleum ether. The precipitate was a white amorphous powder; 0.37 g., $[\alpha]^{25}D$ +59° (*c*, 1.0 in chloroform).

Anal. Calcd. for $C_{21}H_{27}N_7O_{12}(C_6H_5CO)_{12}$: C, 68.88; H, 4.79; N, 5.36; mol. wt., 1831: Calcd. for $C_{21}H_{28}N_7O_{12}(C_6H_5CO)_{11}$: C, 68.16; H, 4.85; N, 5.68; mol. wt., 1727. Found: C, 68.53; H, 4.84; N, 5.38; mol. wt. (ebullioscopic in benzene), 1625 ± 163.

A methanol solution of this product showed ultraviolet absorption maxima at 2325 Å. (*E*% 680) and at 2750 Å. (*E*% 285), and a shoulder at 2550 Å. (*E*% 350). A tetrachloroethane solution of this product showed infrared absorption bands at 5.77, 6.25, 6.37, 7.88, 8.50, 9.04, 9.14 and 9.36 μ.

The product from eluate 2 was analyzed without further reprecipitation.

Anal. Found: C, 68.72; H, 5.12; N, 5.38; mol. wt., 1651 ± 165.

The analytical data on the products from eluates 1 and 2 correspond closely to the composition of undecabenzoylstreptomycin and dodecabenzoylstreptomycin. The product obtained from eluate 1 in an analogous experiment had the composition: C, 69.05; H, 4.86; N, 5.46; $[\alpha]^{25}D$ +42° (*c*, 1.0 in chloroform).

The product from eluate 8 was reprecipitated by using chloroform and petroleum ether; 2.1 g.; $[\alpha]^{25}D$ −41° (*c*, 1.0 in chloroform).

Anal. Found: C, 63.17; H, 5.08; N, 6.20; mol. wt., 1100.

The product in eluate 8 was clearly less completely benzoylated.

Cleavage of Undecabenzoylstreptomycin to Maltol.—A sample of undecabenzoylstreptomycin (from eluate 2) weighing 431 mg. was suspended in 5 cc. of methanol and the solution was heated to the reflux temperature. Three cubic centimeters of aqueous 2.5 *N* sodium hydroxide was added to the methanol solution, and the mixture was heated at the reflux temperature for fifteen minutes. The yellow-brown solution was then concen-

(9) Korndörfer (*Arch. Pharm.*, **241**, 449 [1903]) reported dibenzoylguanidine, m. p. 215°, as the product of benzoylation of guanidine in aqueous solution. Walther and Wlodkowski (*J. prakt. Chem.*, **59**, 266 [1899]) and we have found that this reaction gives dibenzoylurea, m. p. 215°.

trated under reduced pressure until the methanol was removed. The residual solution was diluted with 10 cc. of water and extracted three times with chloroform. The chloroform extracts were discarded. The alkaline aqueous solution was then saturated with carbon dioxide, and extracted four times with chloroform. The chloroform extracts were dried and evaporated to dryness to give 28.5 mg. of a crystalline residue. The crystals gave a reddish-purple color with ferric chloride solution which was identical with that given by maltol. The residue was recrystallized from chloroform–ether to give crystals which melted at 159–160°. When this product was mixed with an authentic sample of maltol (m. p. 159–160°), the melting point of the mixture was 159–160°.

The chloroform-extracted aqueous solution was acidified with sulfuric acid to *p*H 2, and extracted three times with chloroform. The extract was dried and evaporated to dryness to yield 332 mg. of benzoic acid (neutral equivalent: calcd., 122; found, 125). This represents a yield of 10.9 moles of benzoic acid per mole of undecabenzoylstreptomycin.

Cleavage of Undecabenzoylstreptomycin to Heptabenzoylstreptidine.—One hundred thirty-five milligrams of undecabenzoylstreptomycin (from eluate 1) was dissolved in 3.0 cc. of chloroform, and to the solution was added 0.11 cc. of a 16% solution of hydrogen bromide in glacial acetic acid. The solution was allowed to stand at room temperature for twenty-four hours, diluted with 5 cc. of chloroform, and the mixture was extracted twice with saturated aqueous sodium bicarbonate solution. The chloroform solution was washed with water, dried and evaporated *in vacuo* to give 124.5 mg. of an amorphous glassy residue. The residue was dissolved in 1 cc. of warm benzene, and diluted with 2 cc. of methanol. A white granular crystalline precipitate quickly separated. The precipitate was collected on a filter and washed with methanol; yield, 55.7 mg. (yield, 72%); m. p. 245–252° (micro-block). Recrystallization of this product from benzene–methanol yielded heptabenzoylstreptidine of melting point 256–258° (micro-block); $[\alpha]^{25}D$ +58° (*c*, 1.24 in chloroform).

Anal. Calcd. for $C_{57}H_{46}N_6O_{11}$: C, 69.15; H, 4.68; N, 8.49; mol. wt., 991. Found: C, 69.10; H, 4.71; N, 8.72; mol. wt., (ebullioscopic in benzene), 1116 ± 112.

In the ultraviolet, an ethanol solution of heptabenzoylstreptidine showed maxima at 2350 Å. (E_M 59,000), 2530 Å. (E_M 53,000) and 2770 Å. (E_M 43,500).

Heptabenzoylstreptidine contained benzene of crystallization when it was recrystallized from benzene–acetone solution upon removal of acetone by evaporation.

Anal. Calcd. for $C_{57}H_{46}N_6O_{11}\cdot C_6H_6$: C, 70.77; H, 4.90; solvent of crystallization, 7.3. Found: C, 70.45; H, 4.89; weight loss on drying two hours at 110° *in vacuo*, 7.3.

Acetylheptabenzoylstreptidine.—A solution of 428 mg. of heptabenzoylstreptidine in 10 cc. of acetic anhydride was refluxed for forty-five minutes. The solution was evaporated *in vacuo* to a thick glassy residue. The residue was dissolved in hot benzene, and the solution was diluted with methanol, whereupon crystals separated quickly; yield, 400 mg.; m. p. 156–160° (micro-block); $[\alpha]^{25}D$ +3° (*c*, 2.98 in chloroform). This product contained benzene of crystallization.

Anal. Calcd. for $C_{59}H_{48}N_6O_{12}\cdot 2C_6H_6$: C, 71.71; H, 5.09. Found: C, 71.48; H, 4.54.

Anisoylheptabenzoylstreptidine.—A mixture of 507 mg. of heptabenzoylstreptidine, 1.0 cc. of anisoyl chloride and 10 cc. of pyridine was heated at the reflux temperature for thirty minutes, cooled, and diluted with chloroform. The chloroform solution was washed and evaporated to a volume of 5 cc., and poured into 50 cc. of petroleum ether. The precipitate of crude anisoylheptabenzoylstreptidine was dissolved in 10 cc. of benzene and the solution was chromatographed on Darco G-60 to yield anisoylheptabenzoylstreptidine in the first eluates. The first eluates on evaporation left a crystalline residue which was recrystallized from ether–methanol; yield, 251 mg.; m. p. 212–216° (micro-block). One further crystallization from acetone–methanol gave material which melted at 213–216° (micro-block), and which showed $[\alpha]^{25}D$ −12° (*c*, 2.29 in chloroform).

Anal. Calcd. for $C_{65}H_{52}N_6O_{13}$: C, 69.38; H, 4.66; N, 7.47; OCH_3, 2.76. Found: C, 69.22; H, 4.40; N, 7.49; OCH_3, 3.44.

A chromatographic fraction which was crystallized from acetone melted at 218–220° (micro-block), and contained acetone of crystallization.

Anal. Calcd. for $C_{74}H_{70}N_6O_{16}$: C, 68.40; H, 5.43; OCH_3, 2.39. Found: C, 68.32; H, 5.16; OCH_3, 2.08.

Octabenzoylstreptidine from Heptabenzoylstreptidine.—One hundred twenty milligrams of heptabenzoylstreptidine was dissolved in a mixture of 2 cc. of pyridine and 0.2 cc. of benzoyl chloride. The solution was refluxed for thirty minutes, diluted with chloroform, washed with dilute acid and aqueous sodium bicarbonate and then water. The chloroform solution was dried and evaporated *in vacuo*. The residue was crystallized from benzene–methanol to give 54 mg. of octabenzoylstreptidine which melted at 261–263° (micro-block). When this product was mixed with heptabenzoylstreptidine, the melting point of the mixture was depressed. When this product was mixed with octabenzoylstreptidine, which was prepared by benzoylation of streptidine, the melting point was unchanged.

Anal. Calcd. for $C_{64}H_{50}N_6O_{12}$: C, 70.19; H, 4.60. Found: C, 70.23; H, 4.79.

Octabenzoylstreptidine.—Four grams of streptidine dihydrochloride was mixed with 67 cc. of pyridine and 27 cc. of benzoyl chloride. The mixture was heated at the reflux temperature for twenty minutes, evaporated *in vacuo* to a thick sirup, and then the residue was dissolved in 50 cc. of chloroform. The chloroform solution was washed with dilute hydrochloric acid, saturated aqueous sodium bicarbonate, and water. It was then dried over magnesium sulfate and filtered through a layer of Darco G-60. The filtrate was poured into 900 cc. of petroleum ether to give a granular, tan precipitate. The crude product, which weighed 13.9 g., was dissolved in 30 cc. of benzene and the solution was allowed to flow through a column containing 135 g. of aluminum oxide. The first 200 cc. of eluate yielded 12 g. of solid on evaporation. This product was dissolved in 25 cc. of hot benzene and 60 cc. of methanol was added. On cooling, crystals separated; yield, 7 g. (three crops). This product melted and resolidified in the range of 120–140° and on continued heating melted at about 250–260° (micro-block). Rechromatography of this product and recrystallization of the major chromatographic fraction from benzene–methanol gave 4.65 g. of crystals which showed a transition of 125–140° and then melted at 261–264°. Further recrystallization of this product from benzene–methanol gave octabenzoylstreptidine which melted constantly at 263–264°; $[\alpha]_D$ 0.

Anal. Calcd. for $C_{64}H_{50}N_6O_{12}$: C, 70.19; H, 4.60; N, 7.68; mol. wt., 1095. Found: C, 70.74; H, 4.65; N, 7.69; mol. wt. (ebullioscopic in benzene), 1267 (±10%).

In the ultraviolet, an ethanol solution of octabenzoylstreptidine showed maxima at 2375 Å. (E_M 77,800), 2550 Å. (E_M 63,500) and 2750 Å. (E_M 50,400).

Hexabenzoylstreptidine (1,3-benzoylguanido-2,4,5,6-tetrabenzoyloxycyclohexane).—The chromatograph columns used for the purification of octabenzoylstreptidine were subsequently eluted with chloroform. Evaporation of the chloroform extracts to dryness, and crystallization of the residue from acetone and from acetone–benzene gave a white crystalline product. This material melted partially at 165–175° and then melted fully at 220–225° when heated on the micro-block; $[\alpha]_D$ 0 (*c*, 2.0 in acetone).

Anal. Calcd. for $C_8H_{12}N_6O_4(C_7H_5O)_6$: C, 67.71; H, 4.77; N, 9.47. Found: C, 67.20; H, 4.90; N, 9.88.

This substance showed no evidence of oxidation when treated with chromic acid in 90% acetic acid solution. An ethanol solution showed a single maximum in the ultraviolet at 2625 Å. with E_M 35,000.

This evidence is in agreement with a 1,3-benzoylguanido-2,4,5,6-tetrabenzoyloxycyclohexane for the structure of hexabenzoylstreptidine.

Treatment of Octabenzoylstreptidine with Hydrogen Bromide.—One and one-half grams of octabenzoylstreptidine was dissolved in 15 cc. of chloroform and 15 cc. of 2.8 *N* hydrogen bromide in glacial acetic acid was added. The solution was refluxed (76°) for one hour, cooled, diluted with 25 cc. of chloroform, washed with saturated aqueous sodium bicarbonate and with water. The dried chloroform solution was evaporated *in vacuo* to give 1.5 g. of residue. This residue was crystallized from a mixture of 3 cc. of benzene and 10 cc. of methanol to give 1.35 g. of crystals which showed a transition at 120–160° and melted at 255–263°. One further crystallization gave 1.2 g. of recovered octabenzoylstreptidine which showed the transition at 120–150° and melted at 261–263° (micro-block).

Anal. Calcd. for $C_{64}H_{50}N_6O_{12}$: C, 70.19; H, 4.60. Found: C, 70.20; H, 4.57.

Octaacetylstreptidine Dihydrobromide.—A solution of 178 mg. of octaacetylstreptidine[6,8] in 1 cc. of glacial acetic acid containing 15% of hydrogen bromide was allowed to stand at room temperature, and white crystals began to separate in about ten minutes. After twenty-four hours, the mixture was diluted with 6 cc. of chloroform, and evaporated *in vacuo*. The residue was recrystallized from methanol–ether solution to give 139 mg. of crystals which melted at 175–185° (micro-block). A second crop of crystals weighing 61 mg. was obtained from the mother liquors. After recrystallization from methanol–ether, the product weighed 100 mg. and melted over the range 183–190°. The substance appeared to be octaacetylstreptidine dihydrobromide.

Anal. Calcd. for $C_8H_{10}N_6O_4(C_2H_3O)_8 \cdot 2HBr$: C, 37.92; H, 4.77; N, 11.05; Br, 21.02; CH_3CO, 45.23. Found: C, 38.91; H, 4.97; N, 10.89; Br, 21.7; CH_3CO, 40.4.

The ultraviolet absorption spectrum of the product in ethanol showed maxima at 2150 Å. (E_M 22,200) and 2550 Å. (E_M 27,500).

A solution of 1 g. of octaacetylstreptidine in 6 cc. of glacial acetic acid containing 15% of hydrogen bromide deposited crystals. The product was collected on a filter, washed with ether, and dried; yield, 702 mg., m. p. 180–195° (micro-block).

Anal. Calcd. for $C_8H_{10}N_6O_4(C_2H_3O)_8 \cdot 2HBr$: C, 37.92; H, 4.77; Br, 21.02. Found: C, 37.34; H, 4.84; Br, 20.85.

A 545-mg. portion of octaacetylstreptidine dihydrobromide was treated with a little water. Some crystalline material remained which was collected on a filter and washed with water. These crystals weighed 4.4 mg., and melted at 250–257° (micro-block) corresponding to octaacetylstreptidine. The aqueous filtrate was neutralized with sodium bicarbonate, and the precipitate was extracted with chloroform. The chloroform extract was evaporated to give 245 mg. of crystalline residue which melted at 170–230°. This material appeared to be partially deacetylated.

Hydrolysis of Octaacetylstreptidine to Streptidine Carbonate.—A solution of 229 mg. of octaacetylstreptidine in 100 cc. of absolute methanol was saturated at 0° with gaseous ammonia. After three hours, the solution was evaporated *in vacuo*, and the residue was extracted with chloroform to remove acetamide. The chloroform-insoluble residue weighed 110 mg. and appeared to be a mixture of streptidine and streptidine carbonate. A portion of this residue was converted to the picrate, which melted at 281–283° (micro-block). The melting point of this product on admixture with authentic streptidine picrate was not depressed. Twenty-eight milligrams of the residue was dissolved in 1.5 cc. of water; the solution was strongly alkaline. The addition of 2 cc. of methanol caused the separation of a crystalline product, which weighed 14 mg. and decomposed gradually above 240° (micro-block).

Anal. Calcd. for $C_8H_{18}N_6O_4 \cdot H_2CO_3 \cdot H_2O$: C, 31.58; H, 6.48; N, 24.55. Found: C, 31.25; H, 6.31; N, 24.54; acetyl, nil.

Stepwise Hydrolysis of Octabenzoylstreptidine to Monobenzoylstreptidine and Streptidine Dihydrochloride.—A solution of 504 mg. of octabenzoylstreptidine in 10 cc. of dry pyridine was mixed with 10 cc. of absolute methanol containing approximately 3 mg. of sodium methoxide. The solution was heated at the reflux temperature for three hours, during which time a crystalline solid separated. The crystals were removed, washed with methanol, and dried; weight 158 mg.; m. p. 232–235° (dec.) (micro-block). An aqueous solution of the product was alkaline and showed an ultraviolet absorption maximum at 2575 Å. (E_M 15,700).

Anal. Calcd. for $C_8H_{17}N_6O_4(C_6H_5CO)$: C, 49.17; H, 6.05; N, 22.94. Found: C, 48.50; H, 6.16; N, 22.09.

Nineteen milligrams of monobenzoylstreptidine was converted to a crystalline sulfate by treatment with a dilute sulfuric acid–acetone solution; yield, 24 mg. The crystals decomposed gradually when heated above 245° (micro-block).

Anal. Calcd. for $C_8H_{17}N_6O_4(C_6H_5CO) \cdot H_2SO_4 \cdot 2H_2O$: C, 36.00; H, 5.64; N, 16.79; S, 6.41. Found: C, 36.03; H, 6.62; N, 16.02; S, 5.63.

Another sample of the monobenzoylstreptidine was heated for two hours at the reflux temperature with 6 *N* hydrochloric acid. The hydrolysis mixture yielded benzoic acid and streptidine dihydrochloride. The latter was identified by conversion, in good yield, to octaacetylstreptidine.

Hydrolysis of Heptabenzoylstreptidine to Monobenzoylstreptidine.—Using the procedure described for the hydrolysis of octabenzoylstreptidine, a sample of heptabenzoylstreptidine weighing 2.004 g. was debenzoylated with methanol and sodium methoxide. The monobenzoyl derivative, which separated, was converted to the crystalline sulfate; yield, 379 mg. The crystalline salt decomposed gradually above 240° (micro-block).

Anal. Calcd. for $C_8H_{17}N_6O_4(C_6H_5CO) \cdot H_2SO_4 \cdot 2H_2O$: C, 36.00; H, 5.64; N, 16.79. Found: C, 36.17; H, 5.13; N, 17.41.

This product showed an ultraviolet absorption maximum which shifted with a change in the *p*H of the solution. In *N* hydrochloric acid, the maximum appeared at 2400 Å. (E_M 15,500). At *p*H 7, the maximum was at 2550 Å. (E_M 12,000). In 0.2 *N* sodium hydroxide, the maximum was at 2600 Å. (E_M 12,500). An aqueous solution of the compound showed a maximum at 2575 Å. (E_M 18,700).

Chromic Acid Oxidation of Heptabenzoylstreptidine; Isolation of Dibenzoylguanidine.—One and two-tenths grams of heptabenzoylstreptidine was dissolved in 20 cc. of acetic acid and the solution was mixed with 90 cc. of a 10% solution of chromic acid in 90% acetic acid. The solution was allowed to stand at 45° for five hours, and at room temperature for sixteen hours, and was then frozen and dried from the frozen state. The residue was dissolved in water, and the solution was neutralized to *p*H 7.0 with sodium bicarbonate and extracted four times with chloroform. The chloroform extract was washed with water, dried over magnesium sulfate, and evaporated *in vacuo* to give a crystalline residue weighing 357 mg. The residue was dissolved in hot benzene, and the solution was filtered through a small pad of Darco G-60. The filtrate deposited white needles which weighed 100 mg., m. p. 163–164° (micro-block).

Anal. Calcd. for $CH_3N_3(C_7H_5O)_2$: C, 67.40; H, 4.90; N, 15.72; mol. wt., 267.3. Found: C, 67.25; H, 4.86; N, 15.44; mol. wt. (ebullioscopic in benzene), 264 ± 3.

Further recrystallizations from benzene and from

benzene–petroleum ether gave material which melted constantly at 165–166° (micro-block).

Anal. Calcd. for $CH_3N_3(C_7H_5O)_2$: C, 67.40; H, 4.90; N, 15.72. Found: C, 67.58; H, 5.15; N, 15.63.

This substance exhibited two maxima in the ultraviolet at 2450 Å. with E_M 32,000 and 2750 Å. with E_M 32,000 in methanol solution.

The data obtained on this oxidation product were in agreement with a dibenzoylquinidine, but the melting point was lower than that reported in the literature (m. p. 215°; Korndörfer, *Arch Pharm.*, **241**, 449 [1903]). Accordingly, a 28.7-mg. sample was dissolved in 3.0 cc. of concentrated hydrochloric acid and the solution was refluxed for ninety minutes. The hydrolysis solution was diluted with water and extracted with ether. Evaporation of the ether extracts left a crystalline residue of practically pure benzoic acid; yield, 23.7 mg. The residual acid aqueous solution was evaporated to dryness to give a crystalline residue which was dissolved in 3.0 cc. of water. Addition of 2.0 cc. of saturated aqueous picric acid caused a crystalline precipitate to separate. The picrate was recrystallized once from hot water; yield, 25.9 mg., m. p. 335–336° (micro-block). Admixture with authentic guanidine picrate (m. p. 335–336°) did not alter the melting point of the product.

Anal. Calcd. for $CH_5N_3 \cdot C_6H_3N_3O_7$: C, 29.17; H, 2.80; N, 29.17. Found: C, 29.33; H, 3.10; N, 29.39.

The oxidation product is thus established to be dibenzoylguanidine. The yield of dibenzoylguanidine from heptabenzoylstreptidine would be 28% if one dibenzoylguanido moiety were present in the latter molecule, or 56% if both guanido groups were di-benzoylated. The yields of dibenzoylguanidine obtained in three oxidation experiments were 48, 30 and 43%, respectively.

Dodecabenzoyldihydrostreptomycin.—Benzoylation of 2.80 g. of dihydrostreptomycin trihydrochloride, using the conditions described above for streptomycin, gave 5.82 g. of buff-colored benzoylated dihydrostreptomycin. Chromatographic purification of 5.5 g. gave a first-eluate fraction in the form of a white amorphous powder weighing 0.5 g., $[\alpha]^{25}D$ +51° (*c*, 1.78 in chloroform).

Anal. Calcd. for $C_{21}H_{29}N_7O_{12}(C_7H_5O)_{12}$: C, 68.81; H, 4.90; N, 5.35. Found: C, 68.40; H, 5.25; N, 5.66.

Heptabenzoylstreptidine from Dodecabenzoyldihydrostreptomycin.—A 347-mg. sample of dodecabenzoyldihydrostreptomycin was dissolved in 6.62 cc. of chloroform and 0.16 cc. of 30% hydrogen bromide in glacial acetic acid was added. The solution was allowed to stand overnight, then diluted with chloroform and extracted with water and aqueous sodium bicarbonate. The chloroform solution was dried, evaporated to dryness, and the residue was dissolved in 0.5 cc. of benzene and 2.5 cc. of methanol. On standing, there was deposited 101 mg. of crystalline precipitate. Recrystallization of the precipitate from benzene–acetone and from benzene–methanol gave 22 mg. of white crystals of heptabenzoylstreptidine which melted at 256–258°, and showed $[\alpha]^{32}D$ +54° (*c*, 0.98 in chloroform). There was no change in the melting point of this material when mixed with heptabenzoylstreptidine (m. p. 256–258°) obtained from undecabenzoylstreptomycin.

Acknowledgment.—The authors wish to express their thanks to Dr. N. R. Trenner and his associates for carrying out ultraviolet and infrared absorption measurements, to Dr. J. B. Conn and his associates for molecular weight determinations, and to Mr. R. Boos and his associates for the microanalyses.

Summary

Streptomycin was benzoylated to give undecabenzoylstreptomycin, which was degraded by alkali to maltol and by hydrogen bromide to heptabenzoylstreptidine.

Dihydrostreptomycin was also benzoylated to give dodecabenzoyldihydrostreptomycin, which was likewise cleaved by hydrogen bromide to give heptabenzoylstreptidine.

Heptabenzoylstreptidine was further characterized by acetyl and anisoyl derivatives and by conversion to octabenzoylstreptidine. A hexabenzoylstreptidine and a monobenzoylstreptidine were also characterized. Hydrolysis of octabenzoyl-, heptabenzoyl- and octaacetylstreptidine yielded streptidine, showing that acylation and hydrolysis reactions involved no change in the structure of streptidine.

Heptabenzoylstreptidine gave more than one equivalent of dibenzoylguanidine upon chromic acid oxidation showing that streptobiosamine is linked to streptidine through an oxygen atom.

Streptomyces Antibiotics. XVIII. Structure of Streptomycin

BY FREDERICK A. KUEHL, JR., ROBERT L. PECK, CHARLES E. HOFFHINE, JR., AND KARL FOLKERS

The degradation of streptomycin to N,N′-dibenzoyldesoxystreptamine, and the oxidation of this degradation product to show that streptobiosamine is linked glycosidically at position 4 of streptidine, have been reported.[1]

The unbenzoylated functional group of heptabenzoylstreptidine[2] is attached to the carbon atom of streptidine which is linked glycosidically to streptobiosamine. This unbenzoylated functional group was considered to be a hydroxyl group because of the facile methanolysis[3] of streptomycin, and because of the formation of more than one mole of dibenzoylguanidine[2] per mole of heptabenzoylstreptidine upon chromic acid oxidation. Conclusive evidence excluding a nitrogen-atom linkage was obtained in the present study.

Streptidine and octabenzoylstreptidine[2] are optically inactive, showing that they are *meso* forms and have *cis* guanido groups; however, heptabenzoylstreptidine is optically active.[2] This optical activity proves that the unbenzoylated hy-

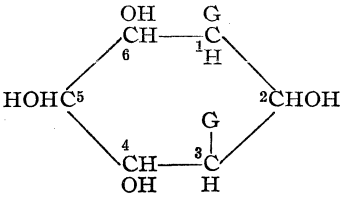
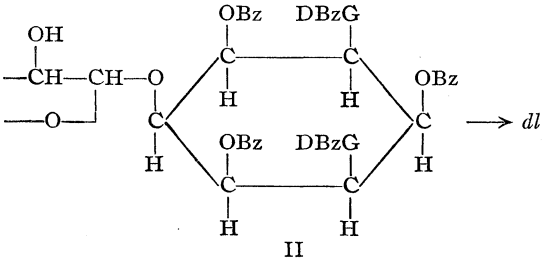
droxyl group in heptabenzoylstreptidine cannot be either at positions 2 or 5 of streptidine (I),



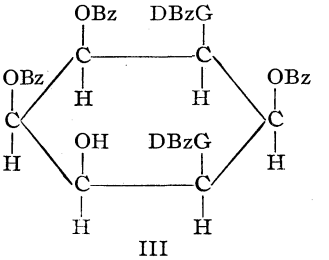
I, G = guanido

since these positions are in the plane of symmetry, and a heptabenzoylstreptidine with a free hydroxyl group at either position 2 or 5 would be optically inactive. The configuration of the groups about carbon atoms 4 and 6 is identical in streptidine and in the heptabenzoylstreptidine since there is no evidence of a Walden inversion in the formation of the latter compound. On the basis of these considerations of optical activity, the unbenzoylated hydroxyl group in heptabenzoylstreptidine is at position 4 (position 6 is equivalent).

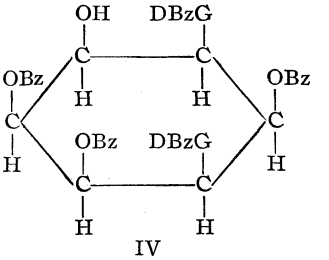
If streptobiosamine were linked glycosidically to position 5 of *meso*-streptidine, and if in the cleavage reaction an acyl group migrated from position 4 to position 5, such a migration might also be expected to occur from position 6 to result in a *dl*-heptabenzoylstreptidine. This hypothetical reaction is illustrated by the structures II, III, and IV, using one of the eight *meso* forms arbitrarily. The optical activity of the isolated heptabenzoylstreptidine eliminates such a rearrangement, unless an asymmetric rearrangement is considered possible.



II



III



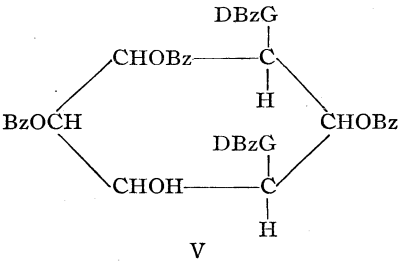
IV

DBzG = dibenzoylguanido
Bz = benzoyl-

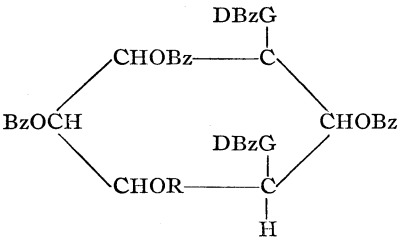
The determination of the position of the free hydroxyl group in heptabenzoylstreptidine by a series of degradative reactions led to a conclusion which is in agreement with that based on stereochemical considerations.

The most promising degradative method for locating the free hydroxy group appeared to be that of converting the >CHOH group to a $>CH_2$ group, because it seemed that the desoxy derivative would withstand the anticipated hydrolytic reactions.

Heptabenzoylstreptidine (V) reacted with methanesulfonyl chloride and toluenesulfonyl chloride to give mesylheptabenzoylstreptidine



V

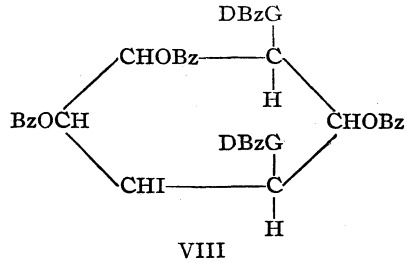


VI. R = CH_3SO_2—
VII. R = *p*-$CH_3C_6H_4SO_2$—

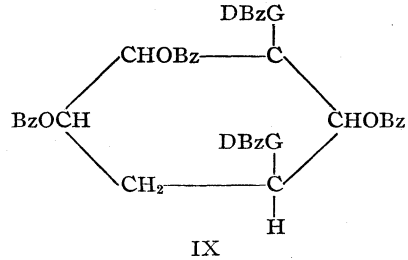
(VI) and tosylheptabenzoylstreptidine (VII), respectively. Mesyl derivatives of secondary alcohols in contrast to the corresponding tosyl derivatives have been reported[4] to react readily with sodium iodide to give the iodides. The mesyl derivative (VI) reacted with sodium iodide in acetone at 100° to give the iodoheptabenzoylstreptidine (VIII), and this mesyl derivative was used preparatively for this reaction. It was found later that the tosyl derivative (VII) also reacted readily with sodium iodide to give the iodo derivative (VIII). The formation of iodoheptabenzoylstreptidine constitutes conclusive evidence for an oxygen atom rather than a nitrogen atom linking streptidine to streptobiosamine.

Although iodoheptabenzoylstreptidine did not undergo hydrogenolysis over a palladium catalyst,

(4) Helferich and Gnuchtel, *Ber.*, **71B**, 712 (1938).



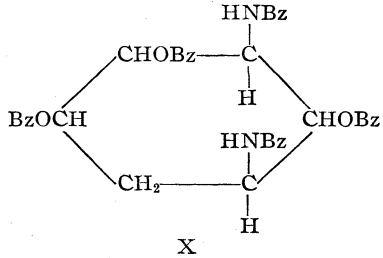
VIII



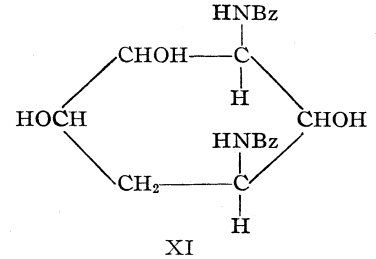
IX

the desired reduction product, heptabenzoyldesoxystreptidine (IX), was obtained when Raney nickel catalyst was used.

Heptabenzoyldesoxystreptidine (IX) was debenzoylated in methanol solution with barium methoxide. The resulting desoxystreptidine was then hydrolyzed to desoxystreptamine by baryta in the manner described for the conversion[5] of streptidine to streptamine. Desoxystreptamine was benzoylated to give pentabenzoyldesoxystreptamine (X), which was selectively debenzoylated in methanol solution with barium methoxide to N,N′-dibenzoyldesoxystreptamine (XI).

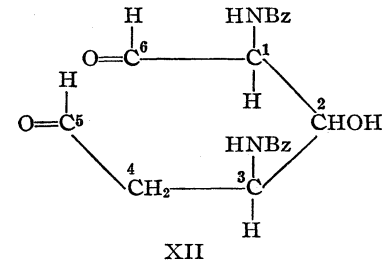


X

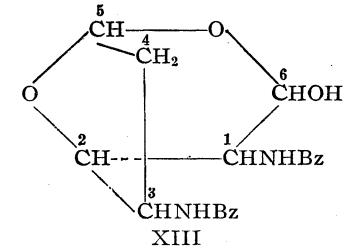


XI

Titration of N,N′-dibenzoyldesoxystreptamine with sodium periodate showed the consumption of one mole of periodate in seventeen hours and no further reaction in forty hours. The oxidation product was readily isolable as a crystalline compound which had a composition in agreement with that for α,γ-dibenzamido-β-hydroxyadipaldehyde (XII). The sharply defined consumption of one

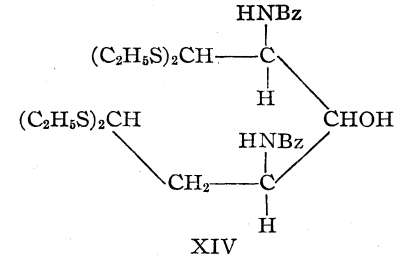


XII



XIII

mole of periodate was shown by treating the N,N′-dibenzoyldesoxystreptamine with excess periodate in aqueous solution, whereupon the same oxidation product crystallized directly from the solution after several days. In connection with the possibility that the aldehyde oxidation product actually has the cyclized structure XIII, the infrared absorption spectrum of the oxidation product was examined and a band for the aldehydic carbonyl group was not found. Only bands at 2.82, 6.38, 6.20 and 6.53 μ were observed Furthermore, the product exhibited a stability which is more compatible with structure XIII than the free aldehyde structure XII. The potential dialdehydic nature of the oxidation product was demonstrated, however, by the reaction of the compound with ethyl mercaptan and hydrogen chloride to give a crystalline derivative of the composition $C_{28}H_{40}N_2O_3S_4$; this derivative corresponds to structure XIV.

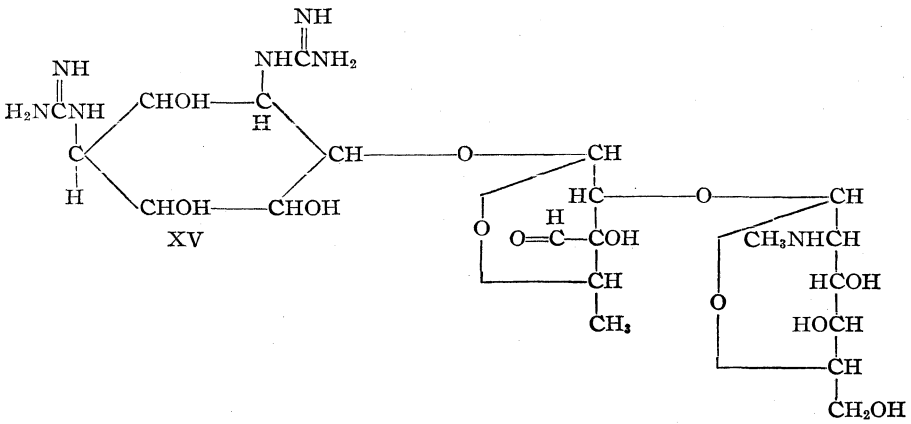


XIV

If the methylene group were positions 2 or 5 in desoxystreptamine, an aldehyde corresponding to structure XII or XIII could not have been formed. Thus, desoxystreptamine has the methylene group in position 4, and on the basis of the partial structure of streptomycin previously proposed,[6] the linkage of streptobiosamine to streptidine may be represented by structure XV. Structure XV for

(5) Peck, Hoffhine, Peel, Graber, Holly, Mozingo and Folkers, THIS JOURNAL, **68**, 776 (1946).

(6) Kuehl, Flynn, Brink and Folkers, *ibid.*, **68**, 2679 (1946).



XV

streptomycin possesses a free formyl group. This group might also exist in hemiacetal form as a result of intramolecular cyclization.

Other workers[7] have treated streptomycin in aqueous solution with excess periodate, and obtained an oxidation product which yielded streptidine, glyoxal and an unidentified acid upon mild hydrolysis. They interpreted this result as strongly indicating that streptobiosamine is attached at carbon atom 5, although attachment at carbon atom 4 could not be entirely disregarded. On the basis of structure XV for streptomycin, perhaps the periodate oxidation data might be explained by intermediary formation of a product of structure XVI as the combined result of oxidation and hydrolytic reactions. Our experience has shown that streptose derivatives oxidize rapidly and streptidine oxidizes very slowly. Cyclization o the aldehydic product (XVI) might give the six-membered hemiacetal (XVII) which could be sufficiently stable to block oxidation of the streptidine nucleus.

Experimental

Mesylheptabenzoylstreptidine.—A solution of 1.543 g. of heptabenzoylstreptidine in 20 ml. of pyridine was cooled to 5° and treated with 1.5 ml. of methanesulfonyl chloride. After remaining at 5° for fourteen hours, the reaction mixture was treated dropwise with 1 ml. of water at 5° to decompose the excess reagent. This mixture was poured into water, and the resulting oily suspension was extracted three times with chloroform. The combined chloroform extract was washed successively with dilute hydrochloric acid, sodium bicarbonate solution and water. The residue obtained from the dried chloroform solution was dissolved in 3 ml. of chloroform and at the boiling point of the solution was treated dropwise with methanol. Crystallization began quickly and after the mixture was cooled in ice-water for several hours, 1.520 g. of mesylheptabenzoylstreptidine was obtained, m. p. 241–242°. This product melted at 241.5–242° after a second recrystallization from the same solvent mixture; $(\alpha)^{25}D$ +18° (*c*, 0.8 in chloroform).

Anal. Calcd. for $C_{58}H_{48}N_6O_{13}S$: C, 65.16; H, 4.53; N, 7.85; S, 2.99. Found: C, 65.40; H, 4.29; N, 8.15 S, 2.46.

Iodoheptabenzoylstreptidine from Mesylheptabenzoylstreptidine.—A solution of 2.831 g. of mesylheptabenzoylstreptidine and 7 g. of dry sodium iodide in 50 ml. of anhydrous acetone was heated in a sealed tube for two hours at 100°. The acetone was removed *in vacuo*, and the yellow residue was shaken with a mixture of 50 ml. of water and 50 ml. of chloroform. The water layer was extracted three times with chloroform. The combined chloroform extract was washed successively with dilute sodium bicarbonate solution, sodium thiosulfate, water, and then dried over anhydrous magnesium sulfate. The colorless chloroform residue, 2.932 g., was dissolved in 5 ml. of chloroform and treated with 25 ml. of methanol. This solution yielded 2.542 g. of iodoheptabenzoylstreptidine, m. p. 153–154°, $(\alpha)^{25}D$ +23° (*c*, 0.08 in chloroform). Further recrystallization from the same solvent mixture did not alter the melting point.

Anal. Calcd. for $C_{57}H_{45}N_6O_{10}I$: C, 62.18; H, 4.12; I, 11.54. Found: C, 61.88; H, 4.05; I, 11.83.

Tosylheptabenzoylstreptidine.—A mixture of 275 mg. of heptabenzoylstreptidine, 115 mg. of tosyl chloride and 1.5 ml. of pyridine was allowed to stand in the cold room overnight. The clear solution was mixed with 10 ml. of cold water and allowed to stand for thirty minutes. The precipitated material was extracted with chloroform, and the chloroform solution was washed, dried over magnesium sulfate, and evaporated to dryness. The residue was crystallized from benzene–methanol; yield, 190 mg.; m. p. 200–203° (micro-block); $(\alpha)^{25}D$ +33° (*c*, 3.43 in chloroform).

Anal. Calcd. for $C_{64}H_{52}N_6O_{13}S$: C, 67.12; H, 4.58; N, 7.34; S, 2.80. Found: C, 67.40; H, 4.76; N, 7.47; S, 2.92.

Iodoheptabenzoylstreptidine from Tosylheptabenzoylstreptidine.—A mixture of 378 mg. of tosylheptabenzoylstreptidine, 3.4 g. of sodium iodide and 15 ml. of acetone was sealed in a bomb tube and heated at 100° for two hours. The contents of the tube were evaporated and water was added to the residue. The mixture was extracted with chloroform, and the chloroform extracts were washed with water and a little aqueous sodium thio-

sulfate. The colorless chloroform solution was evaporated to a volume of 2 ml. and diluted with 10 ml. of methanol. The first crop of iodoheptabenzoylstreptidine weighed 148 mg. and melted at 149–152° (micro-block). The second crop weighed 120 mg. and melted at 149–152°. Recrystallization of the combined material gave iodoheptabenzoylstreptidine, m. p. 151–153°.

Anal. Calcd. for $C_{57}H_{45}N_6O_{10}I$: C, 62.18; H, 4.12; I, 11.54. Found: C, 61.91; H, 4.40; I, 10.77.

Heptabenzoyldesoxystreptidine.—A solution of 5.58 g. of iodoheptabenzoylstreptidine in 330 ml. of aqueous 80% dioxane was reduced catalytically for one hour at 40 lb. pressure in the presence of about 25 g. of Raney nickel catalyst. After removal of the catalyst the solution was concentrated *in vacuo* to *ca.* 10-ml. volume. This solution was extracted several times with chloroform and distillation of the chloroform gave a colorless glassy residue. The residue was dissolved in a small amount of chloroform and crystallization was aided by adding methanol. The yield of crystalline product was 4.437 g., m. p. 187–191°. A number of recrystallizations alternately from chloroform–methanol and ethyl acetate–methanol was required to obtain pure heptabenzoyldesoxystreptidine, m. p. 198–199°.

Anal. Calcd. for $C_{57}H_{46}N_6O_{10}$: C, 70.21; H, 4.76; N, 8.62. Found: C, 70.25; H, 4.76; N, 8.49.

Pentabenzoyldesoxystreptamine.—A suspension of 321 mg. of heptabenzoyldesoxystreptidine in 150 ml. of absolute methanol containing 5 ml. of 0.4 *N* methanolic barium methoxide was stirred overnight at room temperature. The resulting clear solution was treated with carbon dioxide and concentrated *in vacuo* to a residue. This residue was leached with 20 ml. of 50% methanol, and after removal of the solvent from the extract, 119 mg. of desoxystreptidine carbonate was obtained as a white powder. A solution of desoxystreptidine in 20 ml. of saturated baryta was boiled for twenty-three hours, and then concentrated to *ca.* 10-ml. volume. Excess hydrochloric acid was added, and the solution was concentrated to dryness. This residue of desoxystreptamine hydrochloride and barium chloride was leached with 30 ml. of boiling methanol. The methanol-soluble material was again leached with 10 ml. of hot methanol. Removal of the methanol gave crude desoxystreptamine hydrochloride which was benzoylated at 5° with 20 ml. of pyridine and 3 ml. of benzoyl chloride. After standing overnight, the reaction mixture yielded pentabenzoyldesoxystreptamine which was crystallized from chloroform–ether; yield, 67 mg., m. p. 293–294°. After two recrystallizations from the same solvent mixture, the pentabenzoyldesoxystreptamine melted at 298–299°.

Anal. Calcd. for $C_{41}H_{34}N_2O_8$: C, 72.12; H, 5.02; N, 4.10. Found: C, 72.37; H, 5.10; N, 4.19.

N,N′-Dibenzoyldesoxystreptamine.—A suspension of 43 mg. of pentabenzoyldesoxystreptamine in 25 ml. of absolute methanol containing 2 ml. of 0.4 *N* methanolic barium methoxide was shaken at room temperature for ten minutes. The resulting clear solution was maintained at a temperature of 5° for fourteen hours and then treated with carbon dioxide. The solvent was removed *in vacuo*, and the residue was leached with 5 ml. of hot 50% methanol. This methanol-soluble portion, after removal of the solvent, was again leached with 5 ml. of hot methanol, and 18 mg. of methanol-soluble material was obtained which was redissolved in 1 ml. of methanol. Ten milligrams of N,N′-dibenzoyldesoxystreptamine was obtained; m. p. 287–289°; $(\alpha)^{25}D$ −4° (*c*, 1.1 in 50% acetic acid). The melting point remained unchanged after a second recrystallization from acetone–water.

Anal. Calcd. for $C_{20}H_{22}N_2O_5$: C, 64.85; H, 5.99; N, 7.50. Found: C, 64.72; H, 6.21; N, 7.80.

Titration of N,N′-Dibenzoyldesoxystreptamine with Sodium Periodate.—A 10.4-mg. sample was dissolved in 5 ml. of water and treated with 3.0 ml. of sodium periodate solution (1 ml. ≅ 6.355 ml. of 0.01 *N* arsenite solution); the total volume was adjusted to 10.0 ml. One-milliliter aliquots were removed and titrated periodically with 0.01 *N* standard arsenite solution. The data on the titration are given in Table I.

TABLE I

TITRATION OF N,N′-DIBENZOYLDESOXYSTREPTAMINE

Time in hours	0.01 *N* arsenite utilized	Moles of $NaIO_4$ consumed
17	0.580	1.03
21	.585	1.04
24	.580	1.03
41	.570	1.02

Oxidation of N,N′-Dibenzoyldesoxystreptamine to α,γ-Dibenzamido-β-hydroxyadipaldehyde.—A solution of 106.5 mg. of N,N′-dibenzoyldesoxystreptamine in 100 ml. of hot water was treated with 10.8 ml. of sodium periodate solution (1 ml. ≅ 5.67 mg. of $NaIO_4$). After forty hours, when titration indicated the consumption of 0.8 mole of oxidizing agent, the solution was concentrated *in vacuo* to a residue. Trituration of the residue with acetone gave 102 mg. of acetone-soluble material which was dissolved in 15 ml. of hot water. α,γ-Dibenzamido-β-hydroxyadipaldehyde crystallized from the aqueous solution; yield, 32 mg.; m. p. 148–149°; $(\alpha)^{25}D$ +12° (*c*, 1.0 in methanol) (initial). The melting point did not change upon recrystallization from acetone–water.

Anal. Calcd. for $C_{20}H_{20}N_2O_5$: C, 65.18; H, 5.48; N, 7.60. Found: (sample dried at 100°) C, 65.37; H, 5.57; N, 7.57.

α,γ-Dibenzamido-β-hydroxyadipaldehyde Tetraethyl Mercaptal.—A suspension of 38 mg. of α,γ-dibenzamido-β-hydroxyadipaldehyde in 15 ml. of ethyl mercaptan was saturated with anhydrous hydrogen chloride. After shaking for fifteen minutes, the crystals dissolved and the clear solution was allowed to stand overnight at room temperature. The ethyl mercaptan was removed *in vacuo*, and the 64-mg. residue was dissolved in 5 ml. of ether. The ethereal solution was allowed to flow into a column containing 5 g. of acid-washed alumina. Elution of the alumina with 15 ml. of ether gave a residue which crystallized from benzene–petroleum ether; yield, 15 mg.; m. p. 143–144°. Further elution with 10 ml. of chloroform resulted in the isolation of 14 mg. of material, m. p. 146–146.5°. The melting point of α,γ-dibenzamido-β-hydroxyadipaldehyde tetraethyl mercaptal remained at 146–146.5° after repeated recrystallizations.

Anal. Calcd. for $C_{28}H_{40}N_2O_3S_4$: C, 57.79; H, 6.94; N, 4.81; S, 22.03. Found: C, 57.90; H, 6.82; N, 5.17; S, 22.40.

Acknowledgment.—The authors wish to thank Miss Mary Neale Bishop for technical assistance, Dr. N. R. Trenner for the infrared analysis, and Mr. R. N. Boos and his associates for microanalyses.

Summary

Heptabenzoylstreptidine reacted with methane sulfonyl chloride and tosyl chloride to give mesylheptabenzoylstreptidine and tosylheptabenzoylstreptidine, respectively. Treatment of both the mesyl or tosyl derivatives with sodium iodide gave iodoheptabenzoylstreptidine. Hydrogenolysis of the iodo derivative gave heptabenzoyldesoxystreptidine, which was converted stepwise into pentabenzoyldesoxystreptamine and N,N′-dibenzoyldesoxystreptamine.

Oxidation of N,N′-dibenzoyldesoxystreptamine with sodium periodate gave α,γ-dibenzamido-β-

hydroxyadipaldehyde. The adipaldehyde derivative was also characterized as the tetraethyl mercaptal.

These results show that streptobiosamine is linked glycosidically at position 4 of streptidine.

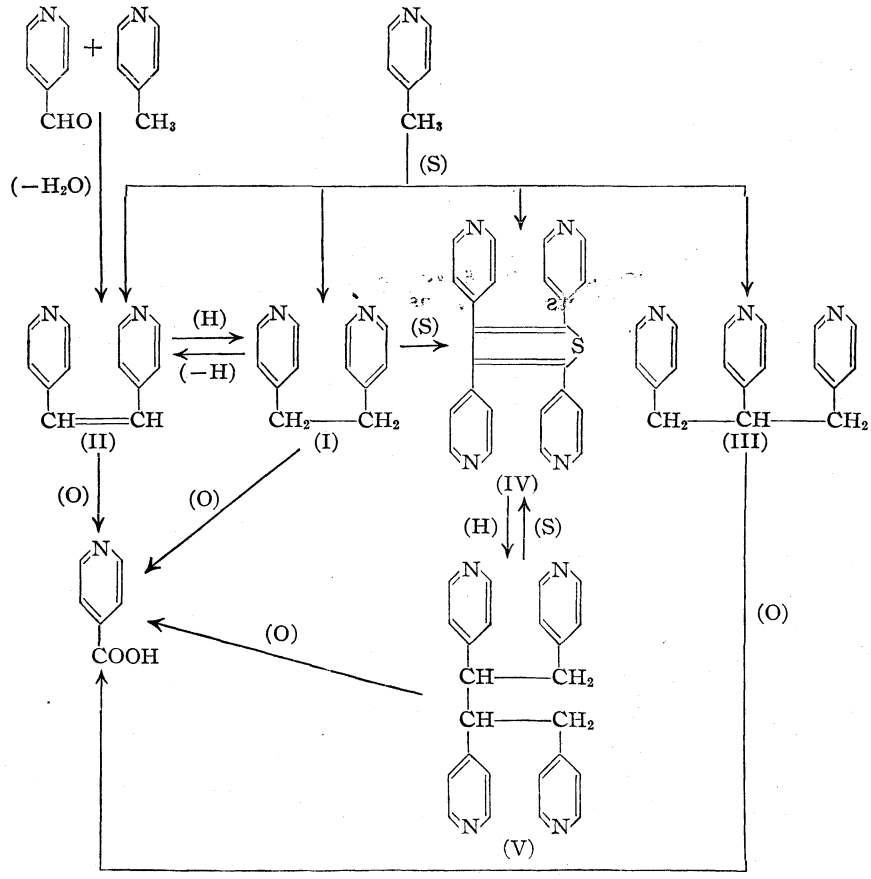
Action of Sulfur on Certain Pyridine and Quinoline Derivatives. I. Action of Sulfur on 4-Picoline

BY HELEN I. THAYER AND B. B. CORSON

The dehydropolymerizing action of sulfur on the picolines has not been previously noted, but certain examples of this action have been recorded in the methylbenzene series. For example, it is known that sulfur converts toluene to stilbene and tetraphenylthiophene, and xylenes to dimethylstilbenes and dimethylbenzyls.[1]

This paper describes the synthesis of several higher molecular weight bases from 4-picoline by the action of sulfur. Five products were obtained: hydrogen sulfide, 1,2-di-(4-pyridyl)-ethane (I), 1,2-di-(4-pyridyl)-ethylene (II), 1,2,3-tri-(4-pyridyl)-propane (III) and 2,3,4,5-tetra-(4-pyridyl)-thiophene (IV). In the absence of sodium hydroxide the yield of tetrapyridylthiophene (IV) was negligible, but it was the main product (85–90% yield) when the reaction mixture contained a catalytic amount of sodium hydroxide and the final reaction temperature was in the vicinity of 300°. In general, the presence of sodium hydroxide favored the production of the unsaturated compounds of dipyridylethylene (II) and tetrapyridylthiophene (IV) at the expense of the saturated compounds of dipyridylethane (I) and tripyridylpropane (III). The product-distribution was also affected by temperature, length of reaction time, and sulfur–picoline ratio.



At the lower temperatures, sulfur-free compounds (I, II, and III) resulted, whereas at the higher temperatures the main product was the sulfur-containing tetrapyridylthiophene (IV). These results are similar to those of Aronstein and von Nierop,[1] who treated toluene with sulfur at 200° and 250–300° to obtain stilbene and tetraphenylthiophene, respectively. Likewise, Oddo and Raffa[2] obtained the sulfur-free compound 3,3′-biindole by treating indole with sulfur at 115–125° and sulfur-containing products at higher reaction temperatures.

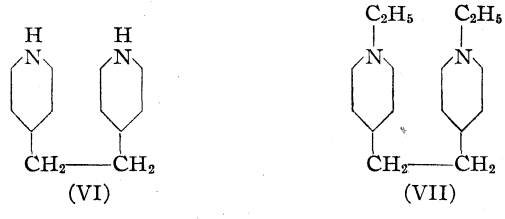
The structures of I and II were established as follows: (1) oxidation of these compounds to isonicotinic acid; (2) hydrogenation of II to I; (3) dehydrogenation of I to II; and (4) the synthesis of 1,2-di-(4-pyridyl)-ethylene (II) by the condensation of 4-pyridylaldehyde with 4-pico-

(1) Aronstein and von Nierop, *Rec. trav. chim.*, **21**, 448 (1902).

(2) Oddo and Raffa, *Gazz. chim. ital.*, **69**, 562 (1939).

line. The structure of 1,2,3-tri-(4-pyridyl)-propane (III) was based on its oxidation to isonicotinic acid. Evidence for the structure of 2,3,4,5-tetra-(4-pyridyl)-thiophene (IV) was threefold: (1) its synthesis from 1,2-di-(4-pyridyl)-ethane (I); (2) its conversion to the sulfur-free compound (V); (3) the similarity of its spectrum in the region 280–370 mμ (Fig. 1) to that of 2,3,4,5-tetraphenylthiophene. The synthesis of IV from 1,2-di-(4-pyridyl)-ethane (I) was accomplished by heating the latter with sulfur as in the synthesis of tetraphenylthiophene from dibenzyl and sulfur,[3] and tetrapyridylthiophene (IV) was degraded to tetrapyridylbutane (V) with zinc and hydrochloric acid as in the reductive fission of tetraphenylthiophene to tetraphenylbutane.[4] The structure of 1,2,3,4-tetra-(4-pyridyl)-butane (V) was based on its oxidation to isonicotinic acid, and the conversion of V to IV by reaction with sulfur.

Catalytic hydrogenation of 1,2-di-(4-pyridyl)-ethane (I) in cyclohexane solution gave 1,2-di-(4-piperidyl)-ethane (VI), whereas hydrogenation in ethanol gave the di-N-ethyl derivative (VII).[5]



The various reaction mixtures were scrutinized for intermediate produc to serve as clues to the reaction mechanism. In the benzene series, polymeric thiobenzaldehyde, benzyl mercaptan and dibenzyl sulfide have been hypothesized as intermediates in the reaction of toluene with sulfur because they pyrolyze to certain of the end-products of this reaction, *viz.*, stilbene and tetraphenylthiophene.[1] However, in the present case, no analogous intermediates were isolated to justify the postulation of a reaction mechanism.

Experimental

4-Picoline.—The 4-picoline (95+% pure, b. p. 144.2–144.4° (743 mm.), $n^{20}D$ 1.5050, d^{20}_4 0.953) was a product of the Koppers Company, Inc.

Reaction of 4-Picoline with Sulfur (below 200°).—Yield data on several experiments are listed in Table I. The general procedure was to heat a mixture of 4-picoline with flowers of sulfur (with or without sodium hydroxide) in a 3-neck flask equipped with condenser, stirrer and thermometer. The mixture darkened and hydrogen sulfide was evolved. The final temperature of the reaction mixture depended upon the length of the heating period. After cooling, unreacted picoline was removed through a short column at about 45 mm. pressure, distillation being discontinued when the pot temperature reached 180°. Redistillation of the overhead showed it to be at least 90% 4-picoline; no higher boiling material was present. The reaction product residue was stirred into a mixture of ice and 50% sulfuric acid; unreacted sulfur was removed by filtration, and the filtrate was made alkaline with 30% sodium hydroxide solution. The oil layer was separated while warm. The water layer was extracted with benzene and the extract was added to the oil. The crude product, dark brown and semi-solid after removal of water and benzene, was distilled at about 3 mm. into several fractions. These distillates crystallized in the receiver and were purified by crystallization; the pot residue was a black, charred solid.

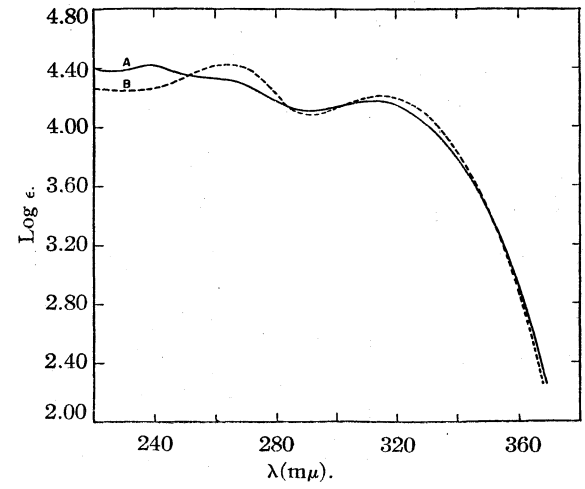


Fig. 1.—Absorption curves of tetraphenylthiophene (A) and tetra-(4-pyridyl)-thiophene (B) in 95% ethanol.

Effect of Reaction Variables (Table I).—In the absence of sodium hydroxide the main product was dipyridylethane; there was considerable tripyridylpropane, but little dipyridylethylene. Doubling the relative amount of sulfur (*e. g.*, increasing the sulfur–picoline ratio from 1:2 to 1:1) did not change the product-distribution, but it increased the picoline conversion somewhat. The effect of lengthening the reaction time was to increase the picoline conversion, partly due to the resulting higher final reaction temperature. As remarked above, the effect of sodium hydroxide was to favor the formation of dipyridylethylene and tetrapyridylthiophene at the expense of dipyridylethane and tripyridylpropane.

1,2-Di-(4-pyridyl)-ethane (I).—Repeated crystallization of the fraction melting at 107–110° (b. p. 167–174° at 3 mm.) from cyclohexane–benzene (3:1) gave compact, colorless crystals, m. p. (capillary) 110–111°, f. p. (cooling curve) 110.9–110.2°.[6]

Anal. Calcd. for $C_{12}H_{12}N_2$: C, 78.2; H, 6.6; N, 15.2; mol. wt., 184. Found: C, 77.8; H, 6.9; N, 15.0; mol. wt., 189.[7]

The hydrochloride was precipitated from an alcohol solution of the base by hydrogen chloride; white crystalline powder, 95% yield, m. p. 329–330° (dec.).

Anal. Calcd. for $C_{12}H_{12}N_2 \cdot 2HCl$: Cl, 27.6. Found: Cl, 27.5.

1,2-Di-(4-pyridyl)-ethylene (II).—Three fractions boiling at 175–189° (2.5 mm.), 175–205° (2 mm.) and 193–220° (2 mm.), respectively, were combined and fractionally crystallized from benzene to yield impure I and II, the latter being long, white needles, m. p. 151–152°, f. p. 151.5–151.2°.

Anal. Calcd. for $C_{12}H_{10}N_2$: C, 79.1; H, 5.5; N, 15.4; mol. wt., 182. Found: C, 78.8; H, 5.3; N, 15.6; mol. wt., 180.

Its hydrochloride, precipitated from alcohol in 99% yield, was a white crystalline solid, m. p. 347° (sealed tube, dec.).

Anal. Calcd. for $C_{12}H_{10}N_2 \cdot 2HCl$: Cl, 27.8. Found: Cl, 27.8.

1,2,3-Tri-(4-pyridyl)-propane (III).—The fraction boiling at 230–242° (2 mm.) was repeatedly crystallized from ethyl acetate to yield pale yellow crystals, m. p. 110–111°, f. p. 109.9–109.3°. Its melting point was depressed 10–12° by admixture with an equal amount of di-(4-pyridyl)-ethane (I) which also melted at 110–111°.

Anal. Calcd. for $C_{18}H_{17}N_3$: C, 78.5; H, 6.2; N, 15.3; mol. wt., 275. Found: C, 78.8; H, 6.3; N, 15.2; mol. wt., 282.

Its hydrochloride, precipitated from alcohol in 85% yield, was a white hygroscopic powder, m. p. 230–232° (dec.).

Anal. Calcd. $C_{18}H_{17}N_3 \cdot 3HCl$: Cl, 27.7. Found: Cl, 27.4.

Reaction of 4-Picoline with Sulfur (above 200°).—At temperatures above 200° in the presence of catalytic amounts of sodium hydroxide, the main products were 2,3,4,5-tetra-(4-pyridyl)-thiophene (IV) and hydrogen sulfide. The data listed in Table II were obtained from small experiments in which hydrogen sulfide was swept out of the reaction mixture by nitrogen and collected in Ascarite preceded by pumice–sulfuric acid. Approximately the theoretical amount of hydrogen sulfide was recovered; the maximum utilization of sulfur was at the picoline–sulfur ratios of 4:6 and 4:7. The decreased yield of tetrapyridylthiophene obtained at the smallest picoline:sulfur ratio of 4:10 (as compared with the theoretical ratio of 4:7) was probably due to inclusion of product in the recovered excess sulfur. In typical larger scale reactions, a mixture of 4 moles of picoline, 8 moles of sulfur, and 0.025 mole of sodium hydroxide was heated for fourteen hours (final temperature *ca.* 245°). The reaction mixture was poured into acid and unreacted sulfur was removed by filtration; the acid filtrate was made alkaline and the precipitated tetrapyridylthiophene isolated (85–90% yield).

2,3,4,5-Tetra-(4-pyridyl)-thiophene (IV).—The crude product gave about 80% yield of compound IV, m. p. 251.8–252.6°, pale yellow crystals from methanol or pyridine.

Anal. Calcd. for $C_{24}H_{16}N_4S$: C, 73.4; H, 4.1; N, 14.3; S, 8.2; mol. wt., 393. Found: C, 73.6; H, 4.0; N, 14.2; S, 8.4; mol. wt., 401.

The hydrochloride, precipitated from ethanol in 95% yield, was a pale yellow hygroscopic solid, m. p. 283–285° (dec.).

Anal. Calcd. for $C_{24}H_{16}N_4S \cdot 4HCl$: Cl, 26.3. Found: Cl, 26.0.

Proof of Structure

Oxidation of Compounds I, II, III and V.—1,2-Di-(4-pyridyl)-ethane (1.84 g.) in 100 cc. of water was oxidized at about 60° with 6 g. of potassium permanganate added in several portions during one and one-half hours. From the filtrate (at *p*H 3.6) two crops of isonicotinic acid were obtained, 1.81 g. (m. p. 317–319° (dec.)) and 0.36 g. (m. p. 314–316° (dec.)). The neutral equivalents were 124.3 and 125.6, respectively, compared with the theoretical of 123.1. The yield of isonicotinic acid was therefore 87%. In similar manner, 1,2-di-(4-pyridyl)-ethylene, 1,2,3-tri-(4-pyridyl)-propane, and 1,2,3,4-tetra-(4-pyridyl)-butane were oxidized to isonicotinic acid in 76, 84 and 74% yields, respectively.

Synthesis of 1,2-Di-(4-pyridyl)-ethylene (II) from 4-Pyridylaldehyde and 4-Picoline.—Selenium dioxide oxidation of 4-picoline in wet dioxane at 90° under nitrogen produced a small yield of 4-pyridylaldehyde, b. p. 68–74° (11 mm.), $n^{25}D$ 1.5382, m. p. of phenylhydrazone 177.5–178.5°.[8] 4-Pyridylaldehyde (1.79 g.) was heated with 1.56 g. of 4-picoline and 2.28 g. of zinc chloride for sixteen hours at 200–215°. The reaction mixture was cooled, dissolved in 20 cc. of 3 *N* sulfuric acid and two 5-g. portions of sodium hydroxide pellets were added. The cooled alkaline solution was repeatedly extracted with ether followed by chloroform. Removal of the solvent left a semi-solid product which was filtered; the filtrate was distilled (b. p. 182–189° (4 mm.)) to yield a distillate which partially solidified. The weight of the combined solids was 0.41 g. (13% yield). Three crystallizations from benzene with boneblacking gave colorless needles

(8) Wibaut, Kooyman and Boer, *Rec. trav. chim.*, **64**, 30 (1945).

which melted at 151–152° and showed no depression in melting point when admixed with di-(4-pyridyl)-ethylene (II).

Anal. Calcd. for $C_{12}H_{10}N_2$: C, 79.1; H, 5.5; N, 15.4. Found: C, 78.9; H, 5.3; N, 15.7.

Hydrogenation of 1,2-Di-(4-pyridyl)-ethylene (II) to 1,2-Di-(4-pyridyl)-ethane (I).—Hydrogenation of dipyridylethylene in methanol with platinum gave a 76% yield of product which melted at 111–112° and did not depress the melting point of 1,2-di-(4-pyridyl)-ethane (I).

Anal. Calcd. for $C_{12}H_{12}N_2$: C, 78.2; H, 6.6; N, 15.2. Found: C, 78.2; H, 6.7; N, 15.3.

Dehydrogenation of 1,2-Di-(4-pyridyl)-ethane (I) to 1,2-Di-(4-pyridyl)-ethylene (II).—Dipyridylethane (117 g.) was passed over 60 g. of a ferruginous dehydrogenation catalyst[9] at 600°, atmospheric pressure, and one second contact time, with 15 volumes of diluent steam. The catalyst carbonized to the extent of 10.9 weight per cent. The catalyzate was a mixture of solid, oil and water (ammoniacal odor), from which were separated 30 g. of unchanged dipyridylethane, 20 g. of dipyridylethylene, and 14 g. of 4-picoline (identified as methiodide, m. p. and mixed m. p. 152–153.5°).

Sulfuration of 1,2-Di-(4-pyridyl)-ethane to 2,3,4,5-Tetra-(4-pyridyl)-thiophene.—A mixture of 3.68 g. of 1,2-di-(4-pyridyl)-ethane (I) and 1.60 g. of sulfur was heated for eight and one-half hours at 170–240°; 0.85 g. of hydrogen sulfide was evolved, 0.75 g. of sulfur was recovered, and 2.5 g. of a reddish-brown solid was obtained. Crystallization from methanol gave 1.69 g. of solid melting at 246–250°, and recrystallization gave yellow crystals melting at 251.5–252.5° whose melting point was not depressed by admixture with 2,3,4,5-tetra-(4-pyridyl)-thiophene (IV).

Anal. Calcd. for $C_{24}H_{16}N_4S$: C, 73.4; H, 4.1; N, 14.3. Found: C, 73.6; H, 4.2; N, 14.2.

Reductive Desulfurization of 2,3,4,5-Tetra-(4-pyridyl)-thiophene (IV) to 1,2,3,4-Tetra-(4-pyridyl)-butane (V).—A mixture of 7.84 g. of tetrapyridylthiophene, 20 g. of zinc dust, and 100 cc. of 25% hydrochloric acid was refluxed for two hours; 25 cc. of 25% hydrochloric acid was added and the refluxing was continued for another hour. The grayish solid was filtered, boiled for a short time with 25% caustic to decompose the zinc chloride complex, and the mixture was filtered. The solid was extracted with dilute hydrochloric acid, and the nitrogen base (4.21 g., 57% yield) was precipitated from the extract by caustic (m. p. 262–265° after recrystallization from 96% ethanol).

Anal. Calcd. for $C_{24}H_{22}N_4$: C, 78.6; H, 6.1; N, 15.3; mol. wt., 366. Found: C, 78.5; H, 6.1; N, 15.4; mol. wt. (Rast), 347.

Sulfuration of 1,2,3,4-Tetra-(4-pyridyl)-butane (V) to 2,3,4,5-Tetra-(4-pyridyl)-thiophene (IV).—A mixture of 1.44 g. of tetrapyridylbutane and 0.75 g. of sulfur was heated for two and one-half hours at 140–245° in a slow stream of nitrogen; 0.38 g. of hydrogen sulfide was collected in Ascarite and 0.31 g. of sulfur was recovered. The filtrate was made alkaline and 1.36 g. (89% yield) of tan-colored precipitate was filtered. Recrystallization from methanol gave pale-yellow crystals (m. p. 251.5–252.5°) whose melting point was not depressed by admixture with 2,3,4,5-tetra-(4-pyridyl)-thiophene (IV).

Anal. Calcd. for $C_{24}H_{16}N_4S$: C, 73.4; H, 4.1; N, 14.3; S, 8.2. Found: C, 73.7; H, 4.3; N, 14.6; S, 7.8.

Hydrogenation of 1,2-Di-(4-pyridyl)-ethane (I) to 1,2-Di-(4-piperidyl)-ethane (VI).—Dipyridylethane (114 g.) was hydrogenated in 300 cc. of cyclohexane at 135 atm. and 175–190° with nickel.[10] Distillation yielded 86 g. of material boiling at 125–130° (2 mm.) which solidified in the receiver. Crystallization from Skellysolve B–benzene (6:1) gave 68 g. of colorless crystals (m. p. 110–113.5°) which rapidly formed a carbonate on exposure to air. A recrystallized sample of carbonate-free material melted at 113–114°.

Anal. Calcd. for $C_{12}H_{24}N_2$: C, 73.4; H, 12.3; N, 14.3. Found: C, 73.4; H, 12.1; N, 14.3.

The hydrochloride (colorless powder, 96% yield) melted at 366–368° (dec.).

Anal. Calcd. for $C_{12}H_{24}N_2 \cdot 2HCl$: Cl, 26.3. Found: Cl, 26.0.

Hydrogenation of 1,2-Di-(4-pyridyl)-ethane (I) to Di-(N-ethyl-4-piperidyl)-ethane (VII).—Dipyridylethane (18 g.) was hydrogenated in ethanol at 90 atm. and 200–220° with nickel. The crude product (21 g.) boiled at 139–143° (1.5 mm.); redistilled product ($n^{20}D$ 1.4836, d^{20}_4 0.9005) boiled at 153–156° (3.5 mm.). The colorless liquid base formed a solid hydrate which dehydrated over phosphorus pentoxide. The hydrochloride was obtained in 91% yield, a white, hygroscopic powder.

Anal. Calcd. for $C_{16}H_{32}N_2 \cdot 2HCl$: Cl, 21.8. Found: Cl, 21.8.

The picrate, yellow needles from benzene, melted at 178.5–180°.

Anal. Calcd. for $C_{16}H_{32}N_2 \cdot 2C_6H_3N_3O_7$: C, 47.3; H, 5.4. Found: C, 47.7; H, 5.4.

Ethylation of 1,2-Di-(4-piperidyl)-ethane (VI).—An ethanol solution (25 cc.) of 5.9 g. of dipiperidylethane and 9.8 g. of ethyl iodide was refluxed for two and one-half hours. The solid (9.8 g.), which separated on standing overnight, was filtered and treated with 65 cc. of 4% potassium hydroxide. The mixture was ether extracted, and the solid recovered from the ether was shaken with benzenesulfonyl chloride in 10% caustic. The solid sulfonamide of the non-ethylated dipiperidylethane was filtered and the filtrate was ether extracted. Double distillation of the ether-soluble oil gave a heart-cut (b. p. 149–150° (2.5 mm.) $n^{20}D$ 1.4839) which formed a picrate (m. p. 178.5–180°) which showed no depression with the picrate of compound VII.

Anal. Calcd. for $C_{16}H_{32}N_2 \cdot 2C_6H_3N_3O_7$: C, 47.3; H, 5.4. Found: C, 47.0; H, 5.3.

Acknowledgment.—Thanks are expressed to J. E. Nickels, B. F. Tatterson, and J. J. McGovern for assistance in dehydrogenation, hydrogenation and spectroscopy, respectively, and to J. L. Keller for initiation of the early phases of the work.

Summary

1,2-Di-(4-pyridyl)-ethane, 1,2-di-(4-pyridyl)-ethylene, 1,2,3-tri-(4-pyridyl)-propane and 2,3,4,5-tetra-(4-pyridyl)-thiophene were obtained from the reaction of 4-picoline with sulfur, the product-distribution depending upon the conditions.

2,3,4,5-Tetra-(4-pyridyl)-thiophene was converted to 1,2,3,4-tetra-(4-pyridyl)-butane by reductive desulfurization.

1,2-Di-(4-pyridyl)-ethane and 1,2,3,4-tetra-(4-pyridyl)-butane reacted with sulfur to form 2,3,4,5-tetra-(4-pyridyl)-thiophene.

1,2-Di-(4-pyridyl)-ethane was hydrogenated in cyclohexane solution to 1,2-di-(4-piperidyl)-ethane, and in ethanol solution to 1,2-di-(N-ethyl-4-piperidyl)-ethane.

Preparation of Some Polymerizable Esters of Long-Chain Saturated Aliphatic Acids with Unsaturated Alcohols

BY DANIEL SWERN AND E. F. JORDAN, JR.

If long-chain aliphatic compounds could be copolymerized with olefinic monomers of low molecular weight, the long chain would be chemically bound in the polymer molecule and the problems of exudation, evaporation and leaching of the modifying agent would be eliminated. The intramolecularly modified polymer would retain its original properties for a long time and perhaps for its entire period of use. By the proper selection of monomers and the relative proportions of low molecular weight olefinic monomer to fatty compound, a wide range of modified polymers could be obtained. The major obstacle, perhaps, to the preparation of such intramolecularly modified copolymers in the past has been the unavailability of pure long-chain compounds containing the necessary functional groups.

In a previous publication we described a series of polymerizable esters of oleic acid, and discussed briefly polymers obtained from some of them, as well as their copolymers with vinyl acetate.[2] The copolymers or intramolecularly modified polymers displayed a wide range of properties (hard, glass-like products to tough or soft rubber-like materials or viscous liquids), depending on the content of oleate ester. When only 1% of the more reactive and also the more promising oleate esters (vinyl, 2-chloroallyl, methallyl and allyl) were employed, insoluble hard, glass-like copolymers, which differed only slightly from unmodified polyvinyl acetate, were obtained. Since soluble, thermoplastic copolymers with a wide range of physical properties are of great industrial importance and their production is steadily increasing, we undertook the preparation of reactive monofunctional esters from long-chain, saturated aliphatic acids for use as intramolecular modifiers for low molecular weight olefinic monomers.

The purpose of the present paper is to describe the preparation and some of the physical properties of the vinyl, 2-chloroallyl, methallyl, allyl, 3-buten-2-yl, crotyl and furfuryl esters of caproic, caprylic, pelargonic, capric, lauric, myristic, palmitic and stearic acids, as well as to report briefly on the polymerization and copolymerization of some of the more reactive esters.

Examination of the literature revealed that some of the esters we wished to prepare had been described by earlier workers, primarily in patents and usually with little or no experimental details, and, in general, the products were incompletely characterized. Furthermore, in these publications no information regarding the purity of the starting materials or final products was given. Inasmuch as commercially available long-chain saturated fatty acids, which the earlier workers apparently employed, are not pure compounds and are almost invariably contaminated with unsaturated acids, it is highly probable that the products reported in the literature were impure and, more important, were not monofunctional. In preparing soluble, thermoplastic, intramolecularly modified copolymers of the type described earlier in this paper, the purity of the monomers, especially with respect to their functionality, is of the utmost importance. In fact, the difficulty experienced by earlier investigators in preparing soluble copolymers of high molecular weight in which one of the monomers is a long-chain compound, was undoubtedly due to the presence of polyfunctional impurities in the long-chain compound.

Vinyl esters of long-chain saturated aliphatic acids have been described in patents[3,4] and in a recent publication.[5] 2-Chloroallyl laurate[6] and stearate,[6] and the methallyl esters of long-chain acids from caprylic to stearic have also been reported in recent patents.[7] Allyl caproate,[8,9] pelargonate,[10] laurate,[11] palmitate[8,12] and stearate[12] have been described in several papers and patents. Furfuryl palmitate has been described in two publications.[13,14] No reference to the preparation or properties of crotyl and 3-buten-2-yl esters of long-chain fatty acids could be found.

The vinyl esters were prepared by the procedure of Toussaint and MacDowell.[4] The results are summarized in Table I. The vinyl esters were colorless, mobile liquids, with the exception of the palmitate and stearate, which were crystalline solids melting at 27 and 35°, respectively. They were insoluble in water and soluble in organic solvents. The short-chain esters had fruit-like odors and the long-chain esters were odorless.

When the purified vinyl esters were analyzed, low iodine and high saponification numbers were

[a] Pure products after two to three distillations, with the exception of the stearate, which was purified by recrystallization of the once-distilled product from acetone. [b] One-hour Wijs method and a 200% excess of iodine chloride solution. [c] Δn per degree = −0.0004. [d] M. p. 26.7–27.1°. [e] d^{35}_4 0.8571. [f] M. p. 35–36°. [g] At 40°.

obtained.[2] The failure to obtain correct iodine numbers was attributed to the reduction in the rate of addition of iodine chloride to the double bond because of the effect of the electron-attracting acyloxy group in reducing the nucleophilic properties of the double bond.[15] Reasonably

$$R—CO_2 \leftarrow CH=CH_2$$

satisfactory iodine numbers (97 to 99%) (Table I) were obtained by allowing the iodine number determination to proceed for twenty-four hours or, preferably, by employing a 200% excess of Wijs solution and a one-hour reaction period. Since it was noticed that the saponification number increased as the reflux time was lengthened, the anomalous saponification number was attributed to the consumption of alkali by acetaldehyde, the tautomer of vinyl alcohol. The procedure finally employed consisted in a five-minute reflux period followed by rapid chilling of the sample in ice water and immediate titration. Fairly satisfactory results were obtained in this way (saponification numbers ranging from 95 to 105% of theoretical values), but difficulty was experienced in duplicating the analyses. For this reason saponification numbers are not listed in Table I.

Polymerization of the vinyl esters in the presence of 0.5% benzoyl peroxide as catalyst[16] yielded soft, elastic polymers, with the exception of polymerized vinyl palmitate and stearate, which were white wax-like solids.[3,17] The iodine numbers of the polymers were usually less than five, thus indicating fairly complete polymerization, although occasionally somewhat higher iodine numbers were obtained. The polymerized vinyl esters were thermoplastic. They were readily soluble in benzene and hot amyl acetate and, with the exception of polymerized vinyl caproate, insoluble or slightly soluble in acetone and glacial acetic acid, and insoluble in water.

Copolymerization of the vinyl esters with vinyl acetate or styrene[16] yielded products which ranged in physical appearance from hard and glass-like (low content of long-chain ester) to very soft and elastic (high content of long-chain ester), with the exception of the copolymers of vinyl stearate with vinyl acetate, which were hard wax-like solids at room temperature. The products containing styrene showed indications of incompatibility, particularly at high contents of long-chain esters. All the copolymers were thermoplastic and colorless, or slightly straw-yellow when styrene was a monomer. They were readily soluble in benzene and amyl acetate, and either slightly soluble or insoluble in acetone and acetic acid, particularly at high contents of long-chain esters. The copolymers were insoluble in water.

The wide range of physical properties attainable in copolymers containing vinyl esters of long-chain fatty acids suggests numerous potential uses for the products.[5,17,18] Furthermore, the polyvinyl esters themselves may be useful as modifying agents for other polymers, particularly where intramolecular modification is either not feasible or is undesirable.

The 2-chloroallyl esters were prepared by direct esterification of the alcohol with the appropriate acid, naphthalene-2-sulfonic acid being employed as catalyst and the water formed during the reaction being azeotropically removed.[2] The results are summarized in Table II. The esters, with the exception of 2-chloroallyl stearate, which decomposed extensively on heating to its boiling point, were isolated in 85 to 95% yields by vacuum distillation of the reaction mixture, and they were substantially pure without further treatment. On redistillation, 60 to 85% yields of pure esters were obtained. The stearate was purified by recrystallization to constant melting point from acetone. The 2-chloroallyl esters were colorless, mobile liquids, with the exception of the stearate, which was a crystalline solid. They were soluble in organic solvents and insoluble in water. The 2-chloroallyl esters were unstable, liberating hydrogen chloride rapidly at elevated temperatures and slowly at room temperature. Products stored for some time gradually became discolored and contained free hydrogen chloride.

[a] Pure products after two distillations. [b] One hour Wijs method. [c] Δn per degree = −0.0004. [d] This compound solidified only after standing for several months at about 25°. M. p. 30.5–31°.

2-Chloroallyl caprate, myristate and stearate were converted to dark-yellow or brown viscous oils when polymerized in the presence of benzoyl peroxide as catalyst.[16] Copolymers of these esters with vinyl acetate were tough, elastic, colorless products when not more than 10% of long-chain ester was employed. As the proportions of 2-chloroallyl ester were increased, the products became darker and softer, and at the maximum content of long-chain ester (60%) they were yellow to brown viscous oils. The copolymers containing 40% of 2-chloroallyl caprate were readily soluble in hot acetone, acetic acid, amyl acetate and benzene. Those containing 40% of 2-chloroallyl myristate were slightly soluble in hot acetone and glacial acetic acid and readily soluble in the other solvents, and the copolymers containing 40% of 2-chloroallyl stearate were slightly soluble in amyl acetate, acetic acid and acetone but readily soluble in benzene.

Although it has been reported in the literature that methallyl esters of long-chain acids can be prepared by a direct esterification technique in which toluenesulfonic acid is employed as catalyst,[7] we observed that considerable isobutyraldehyde was obtained[19] and that the esters were difficult to purify. For these reasons, we employed the alcoholysis method previously described,[2] and had no difficulty in obtaining the pure esters in fair yields (35 to 55%) from the methyl esters of the acids and methallyl alcohol containing dissolved sodium. The results are summarized in Table III. The methallyl esters were colorless, mobile, stable liquids, insoluble in water and soluble in organic solvents.

Under the conditions employed in the polymerization of the vinyl and 2-chloroallyl esters, the methallyl esters of the long-chain acids showed little tendency to polymerize. This was demonstrated by the fact that the iodine numbers of the products after polymerization were only about 10% lower than those of the pure monomers In this respect they were similar to the methallyl esters of short-chain acids.[20] Copolymers containing methallyl esters were not prepared.

The allyl, 3-buten-2-yl and crotyl esters were prepared in 80 to 90%, 55 to 85% and 50 to 85% yields, respectively, by direct esterification of the acids with the alcohols, with naphthalene-2-sulfonic acid as catalyst, the water formed during the reaction being azeotropically removed.[2] We also prepared several of the crotyl esters by alcoholysis[2] of the methyl esters, but the yields were considerably lower than by the direct method. The results are summarized in Tables IV, V and VI. The physical properties of a given crotyl ester prepared by either esterification technique were identical, indicating that the acid catalyst did not cause isomerization of the crotyl portion of the molecule. The allyl, 3-buten-2-yl and crotyl esters were colorless, stable, mobile liquids with the exception of allyl stearate, which was a solid melting at 37°. They were insoluble in water and

[a] Pure products after two distillations. [b] One hour Wijs method. [c] Δn per degree = −0.0004. [d] Yield by direct esterification of crotyl alcohol with the fatty acid. All other yields in this table are for the alcoholysis reaction. [e] d^{35}_4 0.8581. [f] M. p. 30.5–31°. [g] At 35°.

soluble in organic solvents. The short-chain allyl esters had fruit-like odors, whereas the long-chain compounds were odorless.

The allyl esters also showed little tendency to polymerize when heated with 0.5% benzoyl peroxide as catalyst,[16] the iodine numbers of the products being only 10 to 20% lower than those of the corresponding monomers. Copolymers of the allyl esters with diallyl phthalate ranged from tough to soft colorless gels as the content of allyl ester was increased from 1 to 20%. These copolymers were insoluble in acetone, amyl acetate, benzene and acetic acid.

Because of the known lack of polymerizability of the 3-buten-2-yl and crotyl esters,[2] their polymers or copolymers were not prepared.

The furfuryl esters were obtained in only 30 to 50% yields by alcoholysis of the methyl esters of the long-chain acids with furfuryl alcohol containing dissolved sodium.[2] The results are summarized in Table VII. They were pale-yellow, mobile liquids, with the exception of the stearate, which was a solid melting at 41°. The furfuryl esters were insoluble in water and soluble in organic solvents. The stearate, isolated by distillation, was pale-yellow when molten. When recrystallized from acetone, it was a beautiful crystalline solid which was colorless when molten and had physical properties identical with those of the product purified by distillation alone, indicating that the discoloration of the products was caused by impurities present only in traces.

Experimental

All the reactions and distillations described were conducted in an atmosphere of nitrogen.

Starting Materials.—Pure caproic, caprylic, pelargonic and capric acids were prepared from the 90% commercial grades of these acids by repeated distillation under vacuum

through efficient fractionating columns. Pure lauric acid was prepared from the purest commercial grade by two recrystallizations from acetone (10 ml. of solvent per gram of solute) at −40°, followed by fractional distillation under vacuum. Pure myristic acid was similarly prepared, except that two crystallizations at −20° were employed. Pure palmitic acid was prepared by repeated crystallization of the purest commercial grade from acetone (10 ml. of solvent per gram of solute) at 0° until a constant melting point was obtained. Pure stearic acid was prepared by two recrystallizations from acetone at 0° of the fatty acids obtained from completely hydrogenated soybean oil. The methyl esters were prepared from the acids by refluxing them for six hours with a large molar excess (500%) of anhydrous methyl alcohol containing a small quantity (2% by weight of the acid) of 95% sulfuric acid as catalyst. The reaction mixture was poured with thorough mixing into a large quantity of warm water (40–50°) in a separatory funnel, and the lower aqueous layer was separated and discarded. The esters were washed with warm water until free of sulfuric acid and dried by heating to 100° under moderate vacuum in a stream of inert gas. They were then distilled under vacuum through an efficient fractionating column. The products employed in the reactions described had the theoretical neutralization or saponification equivalents, and their physical properties (m. p., b. p., and n_D [Abbe]) agreed with the best values reported in the literature.[21,22,23]

The unsaturated alcohols were distilled through efficient fractionating columns before use.

Vinyl acetate, styrene and diallyl phthalate, were obtained from the commercial grades by fractional distillation. These substances were used immediately after isolation.

Vinyl Esters.—The procedure of Toussaint and MacDowell[4] was employed. The yield of once-distilled ester was 50 to 70%, and upon redistillation in the presence of sufficient sodium bicarbonate to neutralize the small quantities of free acid which these esters usually contained, 30 to 60% yields of pure vinyl esters were obtained. Negligible residues were obtained on redistillation, with the exception of the distillations of vinyl palmitate and stearate, the two highest boiling vinyl esters prepared. Vinyl stearate was most conveniently purified by recrystallization of the once-distilled product from acetone (3 ml. of solvent per gram of solute) at 0°. It was a crystalline solid, and its physical properties and those of the product purified by redistillation were identical. The results are summarized in Table I.

2-Chloroallyl, Allyl, 3-Buten-2-yl and Crotyl Esters.—The azeotropic method previously described[2] was employed, and refluxing was continued until the theoretical quantity of water was evolved. In the preparation of the 3-buten-2-yl esters, eighteen to twenty-four hours of reflux time was usually required, whereas only three to six hours was required when the primary alcohols were employed. The esters were isolated from the reaction mixture by vacuum distillation, with the exception of allyl and 2-chloroallyl stearate and allyl palmitate, which were recrystallized to constant melting point from acetone (3 to 4 ml. of solvent per gram of solute) after recovery of the unreacted alcohol. Some of the crotyl esters were also prepared by the alcoholysis method,[2] but the yields were much lower than by the direct method. The results are summarized in Tables II, IV, V and VI.

Methallyl and Furfuryl Esters.—The alcoholysis method previously described was employed.[2] The results are summarized in Tables III and VII.

Polymerization of Vinyl, 2-Chloroallyl, Methallyl and Allyl Esters.—Approximately 5-ml. portions of the freshly distilled esters were weighed into test-tubes, 0.5% by weight of benzoyl peroxide was added and the polymerizations were conducted in a thermostatically controlled oven.[15] Solubilities were determined in benzene, acetone, glacial acetic acid and amyl acetate at room temperature, and in the case of those solvents in which the polymers were insoluble, also at 100° or at the boiling point, whichever was reached first. The results obtained have been discussed earlier in the manuscript.

Copolymerization of Vinyl, 2-Chloroallyl and Allyl Esters.—The vinyl esters were copolymerized[16] with vinyl acetate and also with styrene, the 2-chloroallyl esters with vinyl acetate only, and the allyl esters with diallyl phthalate. Benzoyl peroxide (0.5% on a total monomer basis) was employed as catalyst. When vinyl acetate was employed as a monomer, copolymers were prepared containing from 1 to 60% of long-chain ester, on a total monomer basis. When styrene and diallyl phthalate were employed as monomers, copolymers were prepared containing a maximum content of long-chain ester of 40 and 20%, respectively.

Acknowledgment.—We are indebted to C. L. Ogg and associates for the carbon and hydrogen analyses, to Geraldine N. Billen for some of the density and refractive index determinations, and to R. E. Koos for most of the iodine number and saponification equivalent determinations.

Summary

Vinyl, 2-chloroallyl, methallyl, allyl, 3-buten-2-yl, crotyl and furfuryl esters of caproic, caprylic, pelargonic, capric, lauric, myristic, palmitic and stearic acids have been prepared, and some of their properties have been determined. Modified procedures for the determination of the iodine and saponification numbers of the vinyl esters are described.

The polymerization of the vinyl, 2-chloroallyl, methallyl and allyl esters, with benzoyl peroxide as catalyst, has been studied briefly. The polymerized vinyl esters are soft, colorless, elastic masses, with the exception of polymerized vinyl palmitate and vinyl stearate, which are white, wax-like solids. The polymerized 2-chloroallyl es-

ters are dark-yellow or brown viscous oils. The methallyl and allyl esters display little tendency to polymerize.

The vinyl esters have been copolymerized with vinyl acetate and also with styrene, the 2-chloroallyl esters with vinyl acetate only and the allyl esters with diallyl phthalate. The wide range of properties attainable in the copolymers suggests numerous potential uses for the products.

Equilibrium Equations for a Model of Antibody–Antigen Combination

BY MANUEL F. MORALES, JEAN BOTTS AND TERRELL L. HILL

Application of statistical procedures to models of antibody–antigen combination yields expressions involving certain thermodynamic constants of the equilibrium; such expressions enable the calculation of these constants from conventional measurements, and may therefore be of interest. We wish to present here certain relations of this sort based on a useful model proposed recently by Teorell.[1,2,3]

In Teorell's model, antibody (A) is assumed univalent,[4] and antigen (G) is assumed n-valent; the aggregate compounds have therefore the formulas, A_iG, and the equilibrium is formally similar to that of ampholyte dissociation[5]

$$\left.\begin{aligned} A + A_{i-1}G &\rightleftarrows A_iG \\ K_i &= [A_iG]/[A][A_{i-1}G] \end{aligned}\right\} \quad i = 1, 2, \ldots, n \qquad (1)$$

We shall assume in what follows that the total concentrations of antibody and antigen, A_0 and G_0, respectively, are known experimentally. Deferring until later a discussion of the matter, we shall also suppose that the concentration ratio of total bound antibody to total bound antigen in the initial solution

$$R = \sum_{i=1}^{i=n} i[A_iG] / \sum_{i=1}^{i=n} [A_iG]$$

is measurable (actually this ratio is measurable only in the precipitate which subsequently forms). Clearly, $\lim_{A_0 \to \infty} R = n$, the antigen valence. In certain cases it will be further required to know the amounts of bound A and G. Various assumptions regarding the aggregation will now be considered separately.

I. The reactivity of a vacant reactive site on the surface of an A–G aggregate is assumed to be completely independent of the remainder of the structure on which it exists. In this case it may be shown that

$$R = \frac{K_1[A](1 + K_1[A]/n)^{n-1}}{(1 + K_1[A]/n)^n - 1} \qquad (2)$$

If A_0 and G_0 be given special values, A_0' and G_0' such that [A] becomes equal to n/K_1, then R takes on a special value, $R' = (n/2)/(1 - 1/2^n)$, which is very nearly $n/2$ for $n \geqq 4$. Conversely, one may vary A_0 and G_0 experimentally until R becomes, say, $n/2$; at that point [A] equals n/K_1, and one may also show that on this account

$$K_1 = n/(A_0' - R'G_0') \qquad (3)$$

K_1 is thus obtainable from the usual concentration measurements. All other equilibrium constants are derivable from K_1 by means of the formula

$$K_i = (K_1/n)(n - i + 1)/i \qquad (4)$$

II. The antibody molecules on the surface of the same antigen are assumed to attract or repel one another. It is assumed (rather reasonably) that these interactions can be represented as an A–A bond energy, E_{AA}, and that they operate only between nearest neighbor molecules. To treat this case one must make specific assumptions about the surface lattice formed by the reactive sites on the antigen. We shall here consider three such lattices, corresponding to the contact points on any sphere[6] in the (a) hexagonal closest packing of spheres, (b) cubic closest packing of spheres, and (c) simple cubic packing of spheres. In this case we have

$$R = \frac{\sum_{i=1}^{i=n} \sum_{p} i(K_1[A]/n)^i W_i^{(p)} \exp(-pE_{AA}/kT)}{\sum_{i=1}^{i=n} \sum_{p} (K_1[A]/n)^i W_i^{(p)} \exp(-pE_{AA}/kT)} \qquad (5)$$

where, for a given lattice, $W_i^{(p)}$ is the number of microscopically different ways in which i antibody molecules may be placed on an antigen molecule in such a manner that among the antibody molecules there will be p nearest neighbor pairs. The calculation of the $W_i^{(p)}$ is considered elsewhere.[7]

(2) Teorell, *J. Hyg.*, **44**, 227 (1946).

(3) Teorell, *ibid.*, **44**, 237 (1946).

(4) The unsettled rivalry between this model, which goes back to the concepts of Bordet, and the framework model proposed independently by Marrack and Heidelberger and later greatly elaborated by Pauling (THIS JOURNAL, **62**, 2643 (1940)) is acknowledged. The same methods here used, however, appear applicable to the latter case, although with more difficulty.

(5) Analogs to our cases I and II below have been given for ampholyte dissociation by Kirkwood in Cohn and Edsall, "Proteins, Amino Acids and Peptides," Reinhold Publ. Corp., New York, N. Y., 1943, pp. 290–294. The specific model treated, however, is quite different.

(6) Pauling, "Nature of the Chemical Bond," Cornell University Press, Ithaca, N. Y., 1940.

(7) Morales and Botts, *J. Chem. Phys.*, **16**, 587 (1948).

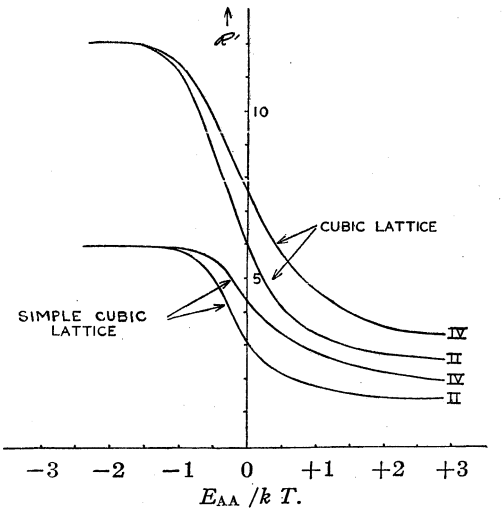

Fig. 1.—Critical value of R as a function of E_{AA}/kT, for two different lattices and for two degrees of approximation (cases II and IV of the text).

Suffice to say here that the value of R, *viz.*, R', at which $K_1 = n/(A_0' - R'G_0')$ is now no longer $n/2$, but depends also upon E_{AA}. Once E_{AA} is known, as from colligative property measurements on concentrated solutions of pure antibody, then R' is calculable (see, for example, Fig. 1, curves II). The relation between the K_i and K_1 is given by

$$K_i = \frac{K_1 \sum_p W_i^{(p)} \exp(-pE_{AA}/kT)}{n \sum_p W_{i-1}^{(p)} \exp(-pE_{AA}/kT)} \quad (6)$$

III. A and G are assumed to be spherical molecules of approximately the same mass and radius, and the moment of inertia of A_iG is assumed to be the same as that of an equivalent sphere having the aggregate mass and volume of $i + 1$ molecules. The inclusion now demanded of the translational and rotational effects upon the equilibrium can only be done very approximately, employing gas-type partition functions, but the results have some comparative value over those derived in section I. One finds that

$$R = \frac{Q(Q+1)^4(1 + K_1[A]/16n)^n}{(Q+1)^4(1 + K_1[A]/16n)^n - 1} \quad (7)$$

where Q^k stands for the operation, $\partial/\partial \log[A]$. In this case $K_1 = 16n/[A]$ when R takes on a definite value $R'(n)$ readily calculable from (7). However, it will in general be required to measure [A] at this point (as distinct from simply knowing A_0). The formula for K_i is

$$K_i = (K_1/16n)[(i+1)/i]^4(n - i + 1)/i \quad (8)$$

IV. The conditions in II and III above are to be combined. For this case

$$R' = \frac{\sum_{i=1}^{i=n} i(i+1)^4 \sum_p W_i^{(p)} \exp(-pE_{AA}/kT)}{\sum_{i=1}^{i=n} (i+1)^4 \sum_p W_i^{(p)} \exp(-pE_{AA}/kT)} \quad (9)$$

the value of R when $K_1 = 16n/[A]$, can be plotted for a given lattice (Fig. 1, curves IV) as a function of E_{AA}. It is, as in Case III, required to know [A] experimentally. For K_i we have

$$K_i = (K_1/16n)[(i+1)/i]^4 \frac{\sum_p W_i^{(p)} \exp(-pE_{AA}/kT)}{\sum_p W_{i-1}^{(p)} \exp(-pE_{AA}/kT)} \quad (10)$$

In the foregoing cases, I–IV, we have considered varying degrees of approximation to the description of the equilibrium (1) presumably in the *solution* phase; however, we have already indicated that total amounts, ratios, etc., are actually measured in the precipitate which appears upon completion of the "secondary reaction" or flocculation, this secondary reaction customarily being aided by the application of a centrifugal field. It is now necessary to discuss the relation between the solution composition (as described by the equations above) and the precipitate composition. The simplest hypothesis of all, and the one with which we will content ourselves for the present, is to assume (as have Teorell and others) that $[A_iG]_{sol'n.} = [A_iG]_{ppt.}$ Rash as this may sound, it is nevertheless possible to imagine situations in which it may be approximately true. On the basis of a monovalent antibody the qualitative reason for the insolubility of the A-G aggregates (compared to A and G) is ascribed to the occlusion[8] by A-G bond formation of sites which ordinarily would interact strongly with the solvent, and confer an appreciable solubility on the molecule. If we suppose that the "primary" reaction (1) reaches equilibrium and then a precipitating condition (*e. g.*, centrifugation or flocculation by quite a different mechanism) is *suddenly* applied, one would obtain

$$R_{ppt} = \frac{\sum_i i\{[A_iG]_{sol'n.} - [A_iG]_{sat.}\}}{\sum_i \{[A_iG]_{sol'n.} - [A_iG]_{sat.}\}} \quad (11)$$

where $[A_iG]_{sat.}$ is the molar solubility of the A_iG aggregate in the presence of the suddenly applied condition. If, in particular, all $[A_iG]_{sat.}$ are near zero,[9] then we are left with the R dealt with in cases I–IV. Quite a different justification for the assumption $[A_iG]_{sol'n.} = [A_iG]_{ppt.}$ has been suggested by Teorell,[2] namely, that molecules of the size and nature (number of reactive sites) involved here may, as it were, be "precipitated in part" or, more specifically, that sites on the structure which have not reacted may participate in the solution equilibrium; the fact that certain enzymes (*e. g.*, beef catalase) when acting as antigens can catalyze their specific reaction even after having been pre-

(8) Boyd, "Fundamentals of Immunology," Interscience Publishers, New York, N. Y., 1947.

(9) This restriction may be lightened by developing approximate expressions for $[A_iG]_{sat.}$ based on Meyer's solubility equation (see Mark, "The Physical Chemistry of High Polymeric Systems," Interscience Publishers, New York, N. Y., 1940, p. 249).

cipitated in A-G form is cited by him as indicating the plausibility of the phenomenon. It is certainly true that neither of the two foregoing arguments is thoroughly convincing, and the assumption must be regarded as provisional, even though the experimental comparison of equations based upon it is quite encouraging.[8] Probably the most satisfactory treatment would be to introduce definite solubilities for the aggregate molecules and treat the solution–precipitate equilibrium in the standard way. This has been done for the restricted case of bivalent antibody and bivalent antigen (corresponding, so far as mechanical considerations are concerned, to our case I) by Pauling, *et al.*[10] It can also be done, although with considerable awkwardness, for the present cases.

So long as the numerical values are not taken too literally but viewed, rather, in a comparative sense, it may be of some interest in closing to examine numerically the effect on the equilibrium constants of including the perturbations of cases II, III, and IV. Previous treatments (corresponding to case I) do not appear to have included them, or, when allowing for perturbations of any sort, have not specified how they can be calculated. Let us consider, for example, a system where A and G are spherical molecules of molecular weight, 100,000 g., and radius, 75 Å., the temperature is 37°, and the surface lattice of reactive sites on G is the hexavalent lattice, (c). To estimate the effect of translation and rotation we may compare the results of case I with those of case III. By the method of case I the K_1 are determined only up to a multiplicative constant (involving the translational and rotational factors) which is supposed to be independent of i. This is also clearly the case in ordinary thermodynamic formulations and in so-called "kinetic" derivations, wherein no method is provided for calculating the proportionality constant on the basis of mechanical information about the reactant molecules. Actually, as a result of translation and rotation and A-A interactions (cases II–IV), the "constant" does depend on i. Since we cannot compute the absolute value of $K_i^{(I)}$, we cannot examine the effect (say, translation and rotation) of this dependence upon the ratio, $K_i^{(I)}/K_i^{(III)}$; however, we may consider instead the function $(K_1^{(III)}/K_6^{(III)})/(K_1^{(I)}/K_6^{(I)})$, in which the proportionality "constant" does not appear, and which, if translational–rotational effects are negligible, should be unity. Actually, it turns out to be about 8.7 in this example. The effect of even very slight A-A interactions can be estimated by a comparison of case I and case II.[7] Assuming a repulsion, $E_{AA} = +kT$, one finds $K_1^{(I)}/K_1^{(II)} = 1$, $K_3^{(I)}/K_3^{(II)} = 4.9$, and $K_6^{(I)}/K_6^{(II)} = 328$, again emphasizing that such interactions are not to be disregarded. Still a third instructive computation is an estimate of the absolute value of the equilibrium constants and therefore of the standard free energy change per reaction site. (This is admittedly quite rough, because the system for which a good value of ΔH has been measured does not conform too well with our particular numerical example.) Using a hemocyanin as an antigen and horse antibody, Boyd, *et al.*,[11] found the ΔH (or what we shall here assume as equivalent, ΔE) per site to be about $-40{,}000$ cal. This leads[12] to a $K_1^{(III)}$ value of 1.18×10^8 li. mole^{-1}, and a ΔF_1° of $-11{,}400$ cal. Assuming that an A–G bond is really the composite of several "weak" bonds of bond energy *ca.* 5,000 cal.,[6] one finds for our example a free energy change per individual weak bond of about -1400 cal., which is not an unreasonable value.

The authors are indebted to Professors Linus Pauling and William C. Boyd for criticisms helpful in the preparation of this manuscript.

Summary

Assuming a polyvalent antigen and a monovalent antibody, there are derived by conventional statistical methods certain relations between measurable concentrations of the reactants and the dissociation constants characterizing the equilibrium. From these relations it is possible to calculate the constants, given the appropriate concentration data. This is done for various assumptions regarding the nature of the reaction. Rough estimates made on the basis of existing information suggest that certain perturbations of the equilibrium, such as the interaction between nearest neighbor antibody molecules on the same antigen molecule or the effects of translation and rotation, may not be negligible as usually has been assumed in the past.

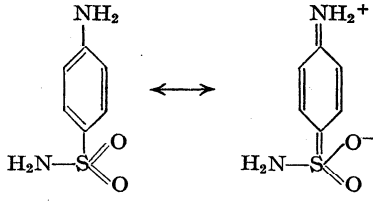
The Fine Structure of Sulfanilamide

BY A. WEIZMANN

The physical properties of sulfanilamide (its solubility, low in non-polar, and high in polar solvents, its absorption spectrum,[1] its high electric moment[2]) may be explained by the assumption of a charged structure contributing to the actual state of the molecule. The possibility that S=O double bonds participate in such resonating systems as



has, however, been doubted occasionally on the strength of the hypothesis that S=O is not a real double bond, but a "semipolar" bond system.[3]

A decision appeared possible by the application of a method first used by Birtles and Hampson[4] in the case of 4-nitroaniline. If the high dipole moment of sulfanilamide is due to a contributing charged structure, ortho-substituents bulky enough to prevent the necessary monoplanar arrangement of the substituents of the double bond, should make the charged form incapable of existence and should, therefore, reduce the electric moment.

2,3,5,6-Tetramethylsulfanilamide has, indeed, a lower moment (5.3 ± 0.8) than the parent substance (6.63). According to Kumler and Halverstadt[2] the theoretical value for the moment of sulfanilamide (and, of course, its tetramethyl derivative), should be 5.82, if the classical formula is correct.

For the sake of comparison, it is interesting to note that in contradistinction with the behavior of sulfanilamide, the moments of methyl 2,3,5,6-tetramethylbenzoate (2.6 ± 0.4) and 2,3,5,6-tetramethylphenylurethan (3.1 ± 0.8 in benzene; 3.2 ± 0.4 in dioxane) are somewhat higher than those of the parent substances, methyl benzoate (1.9 ± 0.5)[5] and phenylurethan (2.56 ± 0.03), respectively. The reason for this phenomenon is obscure; in neither case a significant contribution of a charged form is to be expected; in the latter, the acylation of the amino-group prevents its participation in such a formula.[6]

Some preliminary observations on the biological activity of tetramethyl-sulfanilamide may be of interest.[7] The substance showed no bactericidal or bacteriostatic action *in vitro*, perhaps due to its low solubility in water. *In vivo*, however, it showed approximately the same activity as sulfaguanidine, especially against gram-negative bacteria.

Experimental

Durene was prepared according to v. Braun and Nelles[8] and aminodurene according to Willstätter and Kubli,[9] who also described briefly the **N-acetyl derivative** (m. p. 207°). If in its preparation (5 g. of aminodurene, 15 cc. of acetic anhydride on the water-bath for thirty minutes; cooling; filtration; recrystallization from glacial acetic acid) the reaction mixture is heated to the boiling point, the **N,N-diacetyl derivative**, m. p. 137°, is formed.

Anal. Calcd. for $C_{14}H_{19}O_2N$: C, 72.1; H, 8.2. Found: C, 72.0; H, 8.3.

By treatment with the theoretical amount of 15% methanolic potassium hydroxide solution (two hours), one acetyl group is split off.

The N-Acetyl-2,3,5,6-tetramethylaminobenzenesulfonamide.—N-Acetylaminodurene (0.9 g.) was added slowly to chlorosulfonic acid (10 g.) at 10–15°. The reaction was completed at 55–60° (ninety minutes) and the product poured on ice, filtered, washed with water and boiled for ten minutes with 15% aqueous ammonia; from glacial acetic acid, m. p. 262°.

Anal. Calcd. for $C_{12}H_{18}O_3N_2S$: C, 53.3; H, 6.7. Found: C, 53.6; H, 6.7.

Boiling 15% aqueous potassium hydroxide, 10% alcoholic potassium hydroxide solution or 10% alcoholic hydrochloric acid left the substance unattacked; the last-mentioned reagent at 180° gave aminodurene, m. p. 75°.

For the synthesis of tetramethylsulfanilamide, the following route proved more successful:

N-Carbethoxyaminodurene (2,3,5,6-tetramethylphenylurethan).—To a well-agitated mixture of aminodurene (1 g.), sodium carbonate (0.53 g.) and benzene (15 cc.), ethyl chlorocarbonate (2 g.) was added at room temperature. The reaction was completed at 80° (ten minutes) and the reaction product recrystallized successively from dilute acetic acid and benzene or petroleum ether. It formed needles of m. p. 154–155°.

Anal. Calcd. for $C_{13}H_{19}O_2N$: C, 70.6; H, 8.6. Found: C, 70.8; H, 8.8.

N-Carbethoxy-2,3,5,6-tetramethylaminobenzenesulfonamide.—The preceding substance (0.5 g.) was added slowly with agitation and cooling (0°) to chlorosulfonic acid (10 cc.). After thirty minutes at room temperature, the product was poured on ice, and the waxy solid filtered, washed with ice water and boiled for five minutes with 15% aqueous ammonia. It crystallized from 50% acetic acid in platelets, m. p. 225° (dec. 230°); yield, 61%.

Anal. Calcd. for $C_{13}H_{20}O_4N_2S$: C, 52.0; H, 6.7. Found: C, 52.0; H, 6.6.

2,3,5,6-Tetramethyl-aminobenzenesulfonamide.—The N-carbethoxy- compound was hydrolyzed with boiling

A Study of the Exchange of Nickel in Certain Complex Compounds Using Radioactive Nickel[1]

BY J. ENOCH JOHNSON[2] AND NORRIS F. HALL

In general, it has been found that exchange of the central atom in a complex ion or compound proceeds rapidly only when the bonds present approach ionic rather than covalent character. This has been assumed by many investigators (*e. g.*, Steigman[3]) to be the basis of the success of the Szilard–Chalmers method of concentrating radioactive isotopes. Certain exceptional cases have been discussed by Seaborg[4] and others[5] but in the majority of cases a satisfactory correlation has been demonstrated between exchange data and other types of evidence for covalent bonds. Magnetic susceptibility, interpreted in the light of quantum theory by Pauling,[6] gives evidence of bond type for complexes whose central atom can undergo a redistribution of electrons in changing from ionic or weak covalent bonds to strong covalent bonds. In certain 4-coördinated complexes,[7] X-ray data have definitely indicated covalent bonding by demonstrating a square planar arrangement of the coördinated groups.

Nickel forms a number of complex compounds and ions of the coördination type. Pauling pointed out that it is possible by pairing up all the electrons in the 3d shell of the nickel ion to obtain strong covalent (sp^2d) bonds resulting in a square planar structure, in contrast to the tetrahedral structure of weak covalent (sp^3) bonds. In the planar structure the nickel atom should be diamagnetic rather than paramagnetic as in the weak covalent tetrahedral structure and the simple nickel ion. A number of 4-coördinated nickel compounds have been found to be diamagnetic and X-ray examination has shown such diamagnetic nickel compounds to have a planar structure. Sugden[8] has prepared two diamagnetic geometrical isomers of nickel derivatives of several unsymmetrical glyoximes, which can be explained by assuming a planar structure.

Nickel also forms 6-coördinated complex ions such as $(Ni\ dipyridyl_3)^{++}$, some of which have been separated into optical isomers. Where optical resolution of coördination complexes has been demonstrated, strong covalent bonding is generally assumed.[9] According to the Pauling theory, the magnetic susceptibility of the nickel atom in 6-coördinated nickel complexes can give no evidence of covalency, because in either case there would be two unpaired electrons.

Due to these considerations, it was expected that exchange studies would show no exchange of simple nickel ions with 4-coördinated nickel compounds for which strong covalent bonds are indicated by magnetic susceptibility, X-ray examination and demonstration of geometrical isomers. Also 6-coördinated complex nickel ions for which strong covalent bonds are indicated by resolution of optical isomers should not show exchange with simple nickel ions. Nickel complexes having predominantly ionic or weak covalent bonds were expected to exhibit interchange of the nickel atoms.

Experimental

Preparation of Compounds.—The nickel complex compounds were prepared by procedures described in the literature references cited in footnotes to Table I. These compounds were analyzed for nickel by the gravimetric dimethylglyoxime method. The analytical results are given in Table I.

Radioactive Nickel.—The radioactive nickel (Ni^{65}, 2.6 hour half-life) used in this investigation was obtained by neutron bombardment of metallic zinc, nickel or an aqueous suspension of nickel dimethylglyoxime containing a little nickel chloride. The neutrons were produced by the bombardment of lithium or beryllium by deuterons accelerated by the voltage gradient supplied by an electrostatic generator in the University of Wisconsin physics department. Best results were obtained by bombarding metallic zinc with (Li + D) neutrons.

The irradiated metallic zinc was dissolved in hydrochloric acid and filtered. The residue was dissolved in perchloric acid and a little cupric chloride and nickel chloride added to the combined solutions. The nickel was precipitated by the addition of dimethylglyoxime and sodium acetate. The precipitate was dissolved in nitric acid–hydrochloric acid mixture (1:4) and evaporated to dryness to obtain the nickel chloride. This was taken up in water, neutralized with aqueous ammonia and diluted to give the desired concentration of nickel chloride. Alternatively, the metallic zinc was dissolved in nitric acid and the nitric acid removed by evaporating with hydrochloric acid before precipitating the nickel with dimethyl glyoxime.

Acetone, methyl cellosolve and ethyl cellosolve solutions of radioactive nickel perchlorate were prepared similarly except that the last precipitate of dimethylglyoxime was dissolved in dilute (30%) perchloric acid solution and evaporated nearly to dryness to decompose the organic part of the molecule. The residue was taken up in water, neutralized with aqueous ammonia, nickel perchlorate added to approximate the desired amount and the solution evaporated nearly to dryness. The residue was taken up in the appropriate solvent and diluted to give the concentration desired for the experiment.

The irradiated metallic nickel was dissolved in boiling hydrochloric acid solution, precipitated by dimethyl glyoxime and treated as above. The irradiated nickel dimethylglyoxime was filtered from the suspension and the active nickel chloride solution was treated as above. It was found that the specific activity of the nickel ions was ten to fifteen times the specific activity of the nickel

[k] In these experiments, concentrated aqueous ammonia was added immediately before precipitation of the complex by dilution with water.

in the nickel dimethylglyoxime, demonstrating the application of the Szilard–Chalmers principle, and giving strong indication that there is no exchange between the two forms of nickel involved.

Exchange Procedure.—The general method of determining the exchange of nickel between the 4-coördinated nickel compounds and simple nickel ions was to mix at room temperature (about 25°) a solution (in acetone, methyl cellosolve or ethyl cellosolve) of the complex compound with a solution of radioactive nickel perchlorate in the same solvent. After an appropriate time interval, the complex compound was separated from the solution by dilution with several volumes of water. In the case of bis-methylbenzylglyoxime nickel and bis-salicylaldimine nickel, sodium chloride was added to salt out the complex compound.

The activity of the complex compound was measured on the solid precipitate or on a solution of the compound in dilute hydrochloric acid or, in the case of the dithiocarbamate compounds, in acetone. The activity of the

nickel ions in the filtrate was determined by precipitation by the usual method with dimethylglyoxime, dissolving this precipitate in dilute hydrochloric acid solution and diluting to the desired volume. The activity measurements were made on the solution or on the dimethyl glyoxime precipitate.

The determination of exchange of nickel between 6-coördinated complex nickel ions and radioactive nickel chloride was made by mixing the aqueous solutions. The tris-ethylenediamine nickel ion was separated by precipitation with chloroplatinic acid or sodium thiosulfate solution. The precipitate was redissolved in 60% perchloric acid to determine its activity. In the case of the tris-dipyridyl nickel ion, the nickel ion was separated from the solution by precipitating with dimethylglyoxime, leaving the dipyridyl nickel ion in solution. The filtrate was evaporated to a small volume, filtered again and diluted with water to the desired volume.

Analysis for Nickel.—All the analyses for nickel were made by the gravimetric method using dimethylglyoxime. The weight of nickel was obtained by using the value of 20.3% as the percentage of nickel in the dimethylglyoxime precipitate. In case the solution to be analyzed contained nickel combined with an organic substance besides dimethylglyoxime, the solution was evaporated with 60% perchloric acid until it fumed strongly. The solution was cooled, diluted with water and handled in the usual manner. If the solution contained an organic solvent such as acetone, this was evaporated off before treatment with perchloric acid. It was found necessary to fume strongly with sulfuric acid in analysis of solutions containing dipyridyl to decompose it prior to nickel analysis.

Measurements and Calculations.—The activity of the nickel samples was determined by the use of a Geiger–Mueller counter. For counting dry samples the counter tube was contained in a felt-padded brass jacket fitted into a lead box built in two parts. The sample contained on a small watch glass was placed on a brass holder and slipped into a slot below the counter tube. Solution samples were run into an annular glass jacket which was slipped over the counter tube. Solutions whose activity was to be measured were usually made up to 25 ml. in a volumetric flask. Since the volume of the annular jacket was approximately 15 ml., it was completely filled each time so that all measurements were made under the same conditions.

The observed activity (counts/min.) was corrected for background count (12–15 counts/min.), for counting losses and for the decay of the radioactive nickel. The specific activity (counts per minute per milligram of nickel) was calculated by dividing the corrected counts per minute by the number of milligrams in the sample. The samples contained approximately 10–20 mg. of nickel. The corrected activity for active samples was usually 100–400 counts per minute.

The results of the exchange experiments are given in Table I. The values given under the heading "Ratio of Specific Activities" is the ratio of the specific activity of the nickel in the complex compound to the specific activity of the simple nickel ion. The value of this ratio should be 1.00 when complete exchange has occurred.

Behavior with Dimethylglyoxime.—In preliminary experiments to find satisfactory means of separating the complex nickel compounds from the nickel perchlorate and nickel chloride, the behavior of these compounds of nickel in the presence of dimethylglyoxime was studied. These observations seemed noteworthy because of the striking correlation with the exchange data for these compounds. Nickel tris-dipyridyl chloride in aqueous solution gave no precipitate with dimethylglyoxime whereas the nickel tris-ethylenediamine ion gave an immediate precipitate of nickel dimethylglyoxime. The addition of 1% alcoholic dimethylglyoxime to the acetone solutions of the nickel complexes with the two glyoximes, the two dithiocarbamates and disalicylaldehyde-ethylenediamine did not give a precipitate even after an hour. An immediate precipitate of nickel dimethylglyoxime was formed when the dimethylglyoxime solution was added to the methyl cellosolve solution of bis-salicylaldoxime nickel and bis-salicylaldehyde nickel. bis-Salicylaldimine nickel in acetone solution did not give an immediate precipitate, but after dilution with water a precipitate of nickel dimethylglyoxime formed after a short time.

Results and Discussion

bis-Methylbenzylglyoxime Nickel.—Sugden[8] found this compound to be diamagnetic and he succeeded in separating two geometrical isomers which he called the α-form, m. p. 168°, and the β-form, m. p. 75–77°. Sugden concluded that this isomerism is made possible by the planar configuration of the four Ni–N bonds. The α-isomeride (m. p. 167–168°) was used in these exchange experiments. As was expected, the data in Table I show that no exchange occurred between the nickel atoms in bis-methylbenzylglyoxime nickel and nickel perchlorate within sixty minutes under the conditions of the experiment.

bis-Methyl-*n*-butylglyoxime Nickel.—Cavell and Sugden[10] reported that this compound is diamagnetic and that it occurs in two steroisomeric forms. Because of this proof of a planar configuration of the bonds, no exchange was expected to occur between the nickel atoms of the compound and nickel ions in homogeneous solution. The results of the activity measurements are interpreted to mean that no exchange had occurred. The slight activity of the nickel complex is attributed to the fact that the precipitate of the nickel glyoxime was not wet appreciably by the wash water, which could allow radioactive nickel ions to remain adsorbed on the precipitate.

***bis*-N,N-Di-*n*-propyldithiocarbamate Nickel.**—Malatesta[11] and Cavell and Sugden[10] found this compound to be diamagnetic. Malatesta stated further that the dithiocarbamates of nickel in general maintain the diamagnetic state in solution as well as in the fused condition. Cavell and Sugden were unable to isolate stereoisomers of this compound and concluded that this was probably due to a symmetrical structure of the molecule. Peyronel,[12] on the basis of X-ray measurements, found this compound to be planar. The sum of this information made it seem likely that no exchange of nickel atoms would be found with this compound. The exchange data show that no exchange had occurred when separation of the complex compound from the nickel perchlorate was made by simply diluting with water. In the experiments where concentrated aqueous ammonia was added to facilitate the precipitation of the complex, complete exchange was obtained within five minutes. Because this did not agree with the results obtained when the ammonia treatment was omitted, this phenomenon was further investigated with the di-isoamyl dithiocarbamate complex of nickel.

bis-N,N-Di-iso-amyldithiocarbamate Nickel.—Although no structural data were available

(12) Peyronel, *Z. Krist.*, **103**, 157 (1941).

for this compound, there was no reason to believe that it should behave differently from the di-*n*-propyl derivative. The exchange experiments were performed in essentially the same way as with the propyl compound. The data show that no appreciable exchange had occurred when the separation of the complex from the nickel perchlorate was made by merely diluting with water. However, when concentrated aqueous ammonia was added to the acetone solution before dilution with water, complete exchange occurred. The time elapsing between the addition of ammonia and the complete separation of the precipitated complex compound by filtration was less than two minutes. It was concluded that the presence of ammonia has a profound effect upon the stability of the nickel dithiocarbamate structures. Ammonia apparently weakens the bonds of the complex units to the nickel so much that thermal exchange may occur in a short time at room temperature.

bis-Salicylaldoxime Nickel.—Cox[13] and coworkers found that the nickel and palladium compounds of salicylaldoxime are isomorphous, which is significant since all quadricovalent palladium compounds are planar in structure. The nickel compound was found by them to be diamagnetic. However, Malatesta[14] reported that bis-salicylaldoxime nickel is paramagnetic to the extent of 2.70 magnetons. The results of the exchange experiments given in Table I show complete interchange of the nickel atoms within five minutes in methyl cellosolve solution. This might seem to substantiate Malatesta in regard to the magnetic susceptibility of this compound. However, Willis and Mellor[15] recently reported this compound to be diamagnetic in the solid state and in benzene solution, but to be paramagnetic to the extent of 1.1 and 3.1 Bohr magnetons in chloroform and pyridine, respectively. They postulated, in the case of pyridine, the formation of an octahedral complex containing pyridine in equilibrium with the planar molecules. But they felt that chloroform would be unlikely to form such a complex. They agreed that the difference of stability of square and tetrahedral complexes may in some cases be so small that the solvent may cause partial conversion to the tetrahedral structures as was earlier suggested by French, Magee and Sheffield[16] in the case of bis-formylcamphor–ethylenediamine nickel in methanol solution. The present authors feel that the exchange observed with bis-salicylaldoxime nickel in methyl cellosolve solution does indicate a change of bond type.

bis-Salicylaldehyde Nickel.—This compound is paramagnetic in the solid state and in pyridine solution and is therefore believed to have predominantly ionic or weak covalent bonds. As was expected from this information, complete exchange occurred with nickel ions in methyl cellosolve solution within five minutes.

bis-Salicylaldimine Nickel.—Tyson and Adams[17] found this compound to be diamagnetic in the solid state as did Willis and Mellor,[15] although the latter found it to be paramagnetic to the extent of 2.3 Bohr magnetons in pyridine solution. The results of the exchange experiments show complete exchange within five minutes in acetone solution. The addition of sodium chloride in the separation of the complex compound is not believed to have caused the exchange of nickel atoms because the addition of sodium chloride was used in the separation of bis-methylbenzylglyoxime nickel which showed no exchange. It is more probable that the covalent bonds of the diamagnetic solid compound are modified sufficiently by the solvent to allow thermal exchange.

bis-Salicylaldehyde-ethylenediamine Nickel.—Willis and Mellor[15] recently reported this compound to be diamagnetic both in the solid state and in pyridine solution. The exchange study of this compound was made in ethyl cellosolve solution and the results show definitely that there was no exchange of nickel atoms within an hour. The presence of another five-membered ring in this complex molecule apparently stabilizes the molecule which is otherwise similar in structure to bis-salicylaldimine nickel and bis-salicylaldoxime nickel.

tris-Ethylenediamine Nickelous Chloride Dihydrate.—Rosenbohm[18] and Cambi, Cagnasso and Tremolada[19] found this compound to have a magnetic susceptibility sufficient to show two unpaired electrons just as in the simple nickel ion. However, Pauling's explanation of the stability of 6-coördinated nickel complexes does not require pairing of all the valence electrons. Consequently, magnetic susceptibility measurements are of no value in predicting stability. Bucknall and Wardlaw[20] were able to resolve the tartrates and *d*-camphor sulfonates of this complex ion, but the optical activity was lost on conversion of these salts to the chloride. The results in Table I show that the nickel atoms in the ethylenediamine complex ion exchanged completely with nickel ion in water within five minutes. This was not unexpected due to the failure to resolve this complex ion into stable optical isomers.

tris-α,α'-Dipyridyl Nickelous Chloride Heptahydrate.—Morgan and Burstall[21] were able to resolve this complex nickel chloride into its optical isomers. This has been substantiated by others. These optically active salts racemize in aqueous solution. For example, it was reported that racemization is complete after 115 minutes at

17°, or in about sixty minutes at 20°. The fact that this salt is resolvable indicates that its complex ion is quite stable. The results in Table I show that the nickel atom in the complex ion exchanges at a measurable rate with the simple nickel ion in water solution. No attempt was made to establish the rate of this exchange under varying conditions. The observed interchange indicates that racemization of the optical isomers may be due to partial dissociation of the complex ion. This exchange of the nickel atom in the dipyridyl complex is interesting because Ruben, *et al.*,[5] found a slow exchange of iron atoms between ferrous ion and ferrous α,α'-dipyridyl ion, although the latter is diamagnetic so that no exchange was predicted.

Acknowledgments.—The authors wish to thank Dr. Truman P. Kohman who made helpful suggestions, Dr. J. L. McKibben who built the counting apparatus and operated the electrostatic generator for the preparation of the radionickel and Mr. Dave Frisch who also operated the generator. This work was supported in part by the Research Committee of the Graduate School from funds supplied by the Wisconsin Alumni Research Foundation.

Summary

1. The nickel exchange of ten nickel coördination compounds was studied using Ni^{63} as the tracer. In the main the results, which are discussed in detail, show a satisfactory correlation with predictions of bond type based on other criteria.

2. bis-Methylbenzylglyoxime nickel, bis-methyl-*n*-butylglyoxime nickel, bis-N,N-di-*n*-propyldithiocarbamate nickel, bis-N,N-di-iso-amyldithiocarbamate nickel and bis-salicylaldehyde-ethylenediamine nickel was found not to exchange under the experimental conditions used in accordance with expectation based on the magnetic and other structural evidence for strong covalent bonds. The two dithiocarbamate compounds of nickel did, however, show exchange with nickel perchlorate in the presence of ammonia.

3. bis-Salicylaldehyde nickel and tris-ethylenediamine nickel chloride were found to exchange as predicted.

4. bis-Salicylaldoxime nickel and bis-salicylaldimine nickel, although diamagnetic in the solid state, were found to exchange. This is believed to be evidence that these compounds exhibit a change of bond type when dissolved in methyl cellosolve.

5. Although tris-α,α'-dipyridyl nickel chloride heptahydrate has been resolved into its optical isomers and was not therefore expected to exchange, it did exchange at a measurable rate. This may be connected with the racemization observed for this compound.

Reaction of Ferrous and Ferric Iron with 1,10-Phenanthroline. I. Dissociation Constants of Ferrous and Ferric Phenanthroline

BY T. S. LEE, I. M. KOLTHOFF AND D. L. LEUSSING

The intensely red colored complex of divalent iron and phenanthroline is used extensively for the colorimetric determination of iron and as an oxidation–reduction indicator. The dissociation constants of ferrous and ferric phenanthroline have hitherto not been determined, nor has a systematic study been made of the effect of acid on the dissociation of these complexes. Moreover, no study has been made of the kinetics of the formation and the dissociation of either complex. Such information is of general and especially of analytical interest.

The present paper is divided into three parts: (1) the basic strength of phenanthroline, (2) dissociation of "ferroin" (the ferrous phenanthroline complex) and (3) the dissociation of "ferriin" (the ferric phenanthroline complex).

In a subsequent paper the kinetics of formation and dissociation of ferroin and ferriin will be discussed.

Experimental

Materials Used.—1,10-Phenanthroline ("ortho-phenanthroline") monohydrate was obtained from the G. Frederick Smith Chemical Co. The phenanthroline content of several different samples of this compound was found by conductometric titration with acid to be 100 ± 1% of theoretical. Standard solutions of phenanthroline and phenanthrolium chloride were prepared by dissolving the calculated amount of phenanthroline in water or in standard hydrochloric acid.

Standard solutions of the following compounds were prepared from analytical reagent chemicals and standardized by accepted procedures: ferrous sulfate, sulfuric acid, hydrochloric acid, ceric sulfate and potassium chloride.

Potentiometric Titration of Phenanthroline with Hydrochloric Acid.—One-hundredth *M* phenanthroline solution in water was titrated at room temperature with 0.2 *N* hydrochloric acid. The *p*H was measured with a glass electrode (Leeds and Northrup *p*H Meter, Model No. 7661).

Determination of *p*H of Mixture of Phenanthrolium Chloride and Phenanthroline.—Solutions were prepared which were 0.0200 *M* in phenanthroline, 0.0100 *M* in hydrochloric acid, and 0.001, 0.010, 0.100, 0.500 or 1.00 *M* in potassium chloride. The *p*H of these solutions was measured at 25 ± 0.1° with the apparatus described above.

Conductometric Titration of Phenanthroline with Hydrochloric Acid.—One hundredth *M* phenanthroline solution in water was titrated with 0.2 *N* hydrochloric acid. The titration was carried out at room temperature in a titration conductance cell with freshly platinized elec-

trodes. The conductance bridge used was model RC-1B, Industrial Instruments, Inc.

Conductometric Determination of the Acid Dissociation Constant of Phenanthrolium Ion.—The equivalent conductances of the following solutions were determined: (1) 0.00100 *M* in phenanthroline and 0.00100 *M* in hydrochloric acid, (2) 0.0060 *M* in phenanthroline and 0.00100 *M* in hydrochloric acid and (3) 0.00100 *M* hydrochloric acid. The temperature of the solutions was maintained at 25 ± 0.1°. The cell constant was determined with 0.01 *M* hydrochloric acid using the value 412.0 for the equivalent conductance of this solution.[1]

Determination of Ferroin in Equilibrium Mixtures of Phenanthroline, Ferrous Sulfate and Sulfuric Acid.—Equilibrium mixtures were prepared by pipetting the appropriate quantities of reagent solutions into volumetric flasks and diluting to the mark. The reaction mixtures were allowed to stand in a thermostat at 25 ± 0.1° for one or two days, after which time equilibrium had been established. A portion of the solution was removed and the extinction of the solution was measured at 500 mμ with a Beckman Model DU Spectrophotometer. The concentration of ferroin was found by comparing the extinction with that on a calibration curve determined with known concentrations of ferroin. The extinction of ferroin was found to be unaffected by ionic strength, at least up to a value of 1 *M* (sodium sulfate used as the electrolyte).

Measurement of E. m. f. of the Cell Au|Fe^{++}, Fe^{+++}, H_2SO_4|$FePh_3^{++}$, $FePh_3^{+++}$, H_2SO_4|Au (Ph denotes phenanthroline).—One of the half cells consisted of a gold electrode immersed in a solution $2.5\cdot10^{-3}$ *M* in ferrous sulfate, $2.5\cdot10^{-3}$ *M* in ferric sulfate and *a M* in sulfuric acid. The other half cell consisted of a gold electrode and a solution $2.5\cdot10^{-3}$ *M* in ferrous phenanthroline sulfate, $2.5\cdot10^{-3}$ *M* in ferric phenanthroline sulfate and *a M* in sulfuric acid. This solution was prepared by adding ferrous phenanthroline sulfate to the calculated quantity of ceric sulfate (of known sulfuric acid content) and sulfuric acid solution. The two half cells were connected by a bridge containing *a M* sulfuric acid. The concentrations, *a*, of sulfuric acid used in different experiments were 0.05, 0.5, 1, 2 and 8 *M*. The temperature of the cell was maintained at 25 ± 0.1° by means of a thermostat. The Leeds and Northrup instrument mentioned above was used to measure the E. m. f. The E. m. f. of the cell was found to vary with time due to the slow dissociation of ferroin and ferriin in the acid solution. The E. m. f. of the cell at zero time (time of addition of ferroin to sulfuric acid and ceric sulfate) was found by plotting E. m. f. against time and extrapolating to zero time.

Acid Strength of Phenanthrolium Ion.—Although the phenanthroline molecule possesses two basic nitrogen atoms it was found to combine with only one proton in acid solution The reason for this is that the nitrogen atoms are separated by a distance of only about 2.5 Å. and occupy such positions in the molecule that electrostatic or steric forces or both prevent two protons from combining with the phenanthroline (see Fig. 1).

The experimental points obtained in a potentiometric titration of phenanthroline with hydrochloric acid are plotted in Fig. 2. A relatively large change in *p*H occurs in the region corresponding to approximately one mole of acid per mole of phenanthroline. Little change in *p*H occurs in the region corresponding to approximately two moles of acid per mole of phenanthroline. The drawn curve in Fig. 2 is the theoretical curve calculated for the titration of phenanthroline with acid assuming that phenanthroline is a mono-acid base

(1) T. Shedlovsky, THIS JOURNAL, **54**, 1411 (1932).

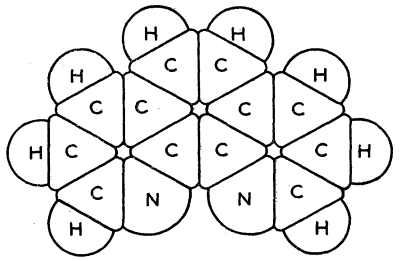

Fig. 1.—Fisher–Hirshfelder–Taylor steric model of 1,10-phenanthroline. All atoms of the phenanthroline molecule lie in the same plane.

and that the dissociation constant of the phenanthrolium ion is 1.1×10^{-5} (see below). It is seen that the calculated curve agrees with the experimental data.

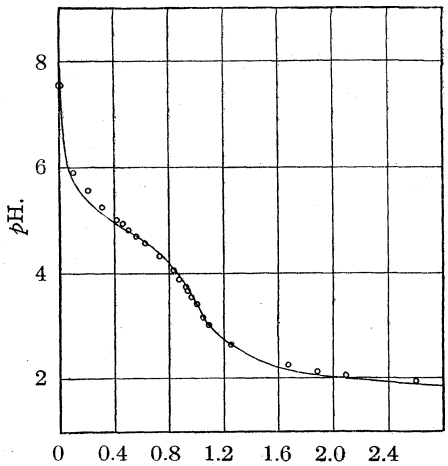

Fig. 2.—Potentiometric titration of phenanthroline with hydrochloric acid (curve is calculated, dots are experimental points).

The acid constant of the phenanthrolium ion K_A was determined potentiometrically by measuring the *p*aH (hydrogen ion activity) of solutions which were 0.01 *M* in phenanthroline and 0.01 *M* in phenanthrolium chloride, and which contained potassium chloride at various concentrations. The results are given in Table I.

TABLE I

DEPENDENCE OF HYDROGEN ION ACTIVITY OF 0.01 *M* PHENANTHROLINE–0.01 *M* PHENANTHROLIUM CHLORIDE BUFFER ON IONIC STRENGTH

Concentration of KCl, *M*	Observed *p*aH	Total ionic strength, μ	γ_{PhH^+}
0.001	4.81	0.011	0.91
.010	4.83	.020	.87
.100	4.91	.11	.73
.500	5.03	.51	.55
1.00	5.12	1.01	.45

In Figure 3 the observed values of *p*aH are plotted against the square root of the ionic

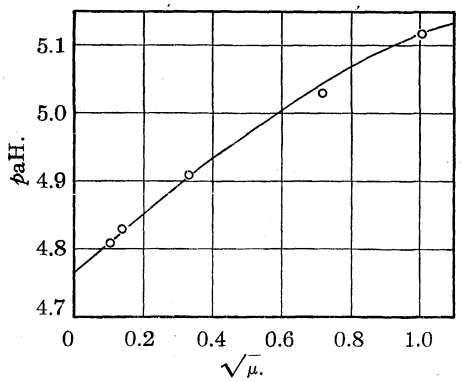

Fig. 3.—Dependence of hydrogen ion activity of phenanthrolium chloride–phenanthroline solution on ionic strength.

strength. It is seen that the curve is nearly linear at low ionic strengths and extrapolates to a value of *pa*H of 4.77 at zero ionic strength. This value corresponds to a hydrogen ion activity of 1.7×10^{-5}, hence the acid dissociation constant K_A of the phenanthrolium ion is about 1.7×10^{-5} at 25°. The data of Table I involve a small error due to the liquid junction potential between the saturated potassium chloride solution in the salt bridge and the potassium chloride, phenanthrolium chloride solution under investigation.

For use in calculations described below approximate activity coefficients of the phenanthrolium ion were calculated. The equation employed was

$$\gamma_{PhH^+} = \frac{a_{H^+}\gamma_{Ph}(Ph)}{K_A(PhH^+)} \qquad (1)$$

where γ represents activity coefficient, a represents activity, and parentheses indicate molar concentrations. The values of γ_{PhH^+} given in Table I are subject to an error due to liquid junction potential.

Figure 4 shows the results of the conductometric titration of 0.01 *M* phenanthroline with 0.2 *N* hydrochloric acid. (The conductivity of the solution was corrected for the small change in volume which occurred during the titration.) It is seen that phenanthroline behaves as a mono-acid base. Only one mole of hydrogen ion combines with one mole of phenanthroline.

The degree of hydrolysis, *h*, of the phenanthrolium ion in 0.001 *M* phenanthrolium chloride solution was determined by means of the relation

$$h = (\Lambda_1 - \Lambda_2)/(\Lambda_3 - \Lambda_2) \qquad (2)$$

where Λ_1 is the equivalent conductance of 0.001 *M* phenanthrolium chloride, Λ_2 is the equivalent conductance of 0.001 *M* phenanthrolium chloride in the presence of an excess of phenanthroline (to repress hydrolysis), and Λ_3 is the equivalent conductance of 0.001 *M* hydrochloric acid. The value of Λ_1 was found to be 136.0 at 25°, and the value of Λ_2 104.5. Taking the value of Shedlovsky[1] of 421.4 for the equivalent conductance of 0.001 *M* hydrochloric acid at 25°, we find that *h*

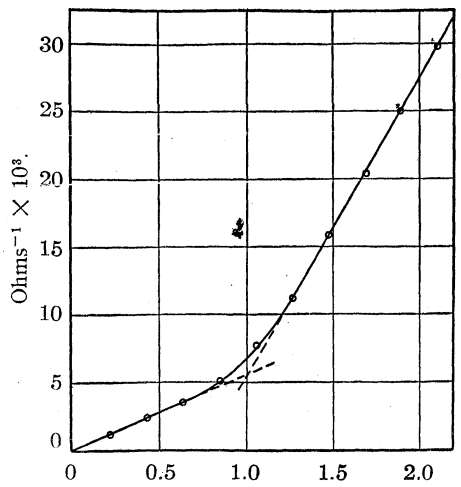

Fig. 4.—Conductometric titration of phenanthroline with hydrochloric acid.

for 0.001 *M* phenanthrolium chloride is 1.0×10^{-1}. From this value the acid dissociation constant of the phenanthrolium ion is calculated to be 1.1×10^{-5}. The computation involves the assumption that the activity coefficient of phenanthrolium ion is equal to that of the hydrogen ion in a solution of an ionic strength of 0.001 *M*. From the value of the acid constant, 1.1×10^{-5} at 25°, it is found that the ionization constant of the base phenanthroline in water is about 9×10^{-10} at 25°.

Dissociation of Ferroin.—It is known that in ferroin the iron is joined to three phenanthroline molecules.[2,3] The formula may be represented by $FePh_3^{++}$. Gould and Vosburgh[4] found that complexes with one and with two phenanthroline molecules per iron atom do not exist in spectrophotometrically detectible amounts in neutral aqueous mixtures of ferrous iron and ferroin. As will be described in a subsequent paper we found evidence that the complexes $FePh^{++}$ and $FePh_2^{++}$ exist in acid solutions at appreciable concentrations if the iron concentration is very high. However, for the present purposes only $FePh_3^{++}$ need be considered.

In acid solutions with a *p*H of 3 or less phenanthroline is present chiefly as the phenanthrolium ion rather than as free phenanthroline, and the equilibrium between ferroin and a strong acid may be represented by

$$FePh_3^{++} + 3H^+ \rightleftharpoons Fe^{++} + 3PhH^+ \qquad (3)$$

The value of the equilibrium constant, K_c', of reaction (3) was found by determining the concentration of ferroin in equilibrium with known concentrations of ferrous sulfate and sulfuric acid. The results are given in Table II.

7	.502	496	200	7.70	487	164	.584	14	1.8

[a] In calculating the activity equilibrium constant from the concentration equilibrium constant the values 0.87, 0.71 and 0.47 were used for the activity coefficients of phenanthrolium ion in mixtures 1, 2, and 3–7, respectively. The values 0.92, 0.85 and 0.92 were used for the activity coefficients of hydrogen ion in reaction mixtures 1, 2, and 3–7, respectively.

The concentration equilibrium constant

$$K_c' = \frac{(Fe^{++})(PhH^+)^3}{(FePh_3^{++})(H^+)^3} \qquad (4)$$

where parentheses represent concentrations, was calculated for each of the reaction mixtures. The concentration of phenanthrolium ion was calculated from the expression

$$(PhH^+) = (Ph)_t - 3 \times (FePh_3^{++}) \qquad (5)$$

where $(Ph)_t$ represents the total initial concentration of phenanthroline. The concentration of ferrous iron was calculated from the relation

$$(Fe^{++}) = (Fe^{++})_t - (FePh_3^{++}) \qquad (6)$$

where $(Fe^{++})_t$ represents the total initial concentration of iron. The concentration of hydrogen ion was estimated by assuming that the first hydrogen ion of sulfuric acid is completely dissociated and that the second dissociation constant is 0.012.[5] The calculated value of the hydrogen ion concentration depends on the values used for the activity coefficients of hydrogen ion, hydrogen sulfate ion, and sulfate ion. These activity coefficients were estimated by the individual ion activity coefficient method.[6] This method involves the assumption that the activity coefficients of potassium ion and chloride ion are equal in any given solution, and that the activity coefficient of an individual ion depends on the nature of the ion and on the total ionic strength of the solution but does not depend on the nature of electrolyte.

In evaluating the activity constant

$$K' = a_{Fe^{++}} a^3_{PhH^+} / a_{FePh_3^{++}} a^3_{H^+} \qquad (7)$$

it was assumed that $\gamma_{Fe^{++}} = \gamma_{FePh_3^{++}}$ where γ denotes activity coefficient. The values for γ_{PhH^+} were taken from Table I.

In experiments 1–3 of Table II the total concentration of iron was held constant and the acid and phenanthroline concentrations were varied. The values of K' were nearly the same in the three experiments. In experiments 4 and 5 the acid and iron concentrations were held constant and the phenanthroline concentration was varied. In experiments 6 and 7 the acid and phenanthroline concentrations were held constant and the iron concentration was varied. The total variation in K' was from 1.8 to 8.4 $\times 10^{-7}$. Considering the uncertainty in activity coefficients, especially in 0.5 M sulfuric acid, the reported values of K' may be considered as reasonably constant. The average value of K' at 25° is 4×10^{-7}. In view of the fact that the hydrogen ion concentration was varied by a factor of 100 in these experiments and that the hydrogen ion activity occurs in equation (7) as a cube power it may be stated that the experimental data confirm the validity of equation (7) over the range of concentrations studied.

Equilibrium "constants" for the hypothetical reaction

$$FePh_3^{++} + 6H^+ = Fe^{++} + 3PhH_2^{++} \qquad (8)$$

were also calculated from the data of Table II. The "constant" calculated for reaction (8) changes by a factor of about one million when the sulfuric acid concentration is changed from 0.005 to 0.5 M. This result substantiates the conclusion given in the previous section that phenanthroline is a mono-acid base.

The constant for the dissociation of ferroin, represented by the equations

$$FePh_3^{++} = Fe^{++} + 3Ph \qquad (9)$$

$$K_{diss.\ ferroin} = a_{Fe^{++}} a^3_{Ph} / a_{FePh_3^{++}} \qquad (10)$$

can be calculated from the equilibrium constant K' of reaction (7) and the acid constant of the phenanthrolium ion. The relation is $K_{diss.\ ferroin} = K'K_A^3$. The values 4×10^{-7} and 1.1×10^{-5} for K' and K_A, respectively, give a value of 5×10^{-22} for $K_{diss.\ ferroin}$ at 25°. In a subsequent paper it will be shown that this value is in agreement with a value determined by an entirely independent method.

Knowledge of the nature of the dissociation of ferroin in acid solution (equation 3) and of the value of K' can be applied to the colorimetric determination of iron. The quantitative conversion of ferrous iron to ferroin is dependent on the ratio of phenanthroline to acid. If the colorimetric determination of iron is carried out at relatively high acidity, the concentration of excess

(5) W. Hamer, THIS JOURNAL, **56**, 860 (1934).

(6) Lewis and Randall, "Thermodynamics," McGraw-Hill Book Co., Inc., New York, N. Y., 1923, p. 381.

phenanthroline must be correspondingly high. In order that the reaction be 99% complete, the ratio of excess phenanthrolium ion to hydrogen ion should be 0.035 or greater. Thus if the hydrogen ion concentration is 10^{-3} M, the concentration of excess phenanthrolium ion must be 3.5×10^{-5} M or greater.

Dissociation Constant of Ferriin.—The constant for the dissociation of ferriin (a reaction analogous to reaction 9) was calculated from the dissociation constant of ferroin and the equilibrium constant for the reaction of ferrous iron with ferriin

$$Fe^{++} + FePh_3^{+++} = Fe^{+++} + FePh_3^{++} \quad (11)$$

The equation expressing this relation is

$$K_{\text{diss. ferriin}} = \frac{a_{Fe^{+++}} a^3_{Ph}}{a_{FePh_3^{+++}}} = \frac{a_{Fe^{+++}} a_{FePh_3^{++}}}{a_{Fe^{++}} a_{FePh_3^{+++}}} K_{\text{diss. ferriin}} \quad (12)$$

The equilibrium constant K'' for the reaction of ferrous iron with ferriin was calculated by two different methods: (1) from the e. m. f. of the cell $Au|Fe^{++}, Fe^{+++}, H_2SO_4|FePh_3^{++}, FePh_3^{+++}, H_2SO_4|Au$, and (2) from the formal potentials of the ferroin-ferriin couple and of the ferrous–ferric couple. The former method is somewhat more direct and is thought to be more reliable. The experimental data for method (1) are given in Table III. The data for use in method (2) were taken from the literature.[7,8,9,10]

The values of the dissociation constant of ferriin calculated from the experimental data using equation (12) were found to be 8.0×10^{-15} in 0.05 M sulfuric acid, 2.5×10^{-15} in 0.5 M, 1.0×10^{-15} in 1 M, 2.9×10^{-16} in 2 M, and 7.5×10^{-21} in 8 M. In the calculations it is assumed that the activity coefficients of ferric and ferriin ions are approximately equal.

(10) E. H. Swift, "System of Chemical Analysis," Prentice-Hall, New York, N. Y., 1939, p. 540.

TABLE III

EQUILIBRIUM CONSTANT FOR THE REACTION OF FERRIC IRON WITH FERROIN

Concn. of H_2SO_4, M	E. m. f. of cell, volts	K'' From e. m. f.	K'' From formal potentials
0.05	0.425	$1.6\ 10^7$	....
0.5	.395	$5.0\ 10^6$	....
1	.373	$2.1\ 10^6$	$4.4\ 10^6$
2	.340	$5.8\ 10^5$	$9.1\ 10^5$
8	.110	$1.5\ 10$	$2.3\ 10$

The dissociation constant of ferriin appears to decrease with increasing sulfuric acid concentrations. This variation is opposite to that which would be expected if the effect were due merely to complexing of the ferric ion with sulfate. The variation is also opposite to that which would be expected if the activity coefficient of ferriin were greater than the activity coefficient of ferric ion. (The ferriin ion is larger and might be expected to have the larger activity coefficient.) The variation may be explained if it is assumed that the ferriin ion possesses a proton in solutions of high acidity, $FeHPh_3^{++++}$. This will be discussed in a subsequent paper.

Acknowledgment is made to the Graduate School of the University of Minnesota for a grant which enabled us to carry out this investigation. The authors also wish to thank Professor R. T. Arnold for helpful suggestions.

Summary

1,10-Phenanthroline has been found to behave as a typical mono-acid base in aqueous solutions. The acid dissociation constant of the phenanthrolium ion is 1.1×10^{-5} at 25°.

The dissociation constants of ferrous and ferric phenanthroline have been evaluated. The constant of ferrous phenanthroline in various concentrations of sulfuric acid is 5×10^{-22} at 25° and that of ferric phenanthroline in 0.05 M sulfuric acid is 8×10^{-15} at 25°.

Differential Heats of Adsorption of Nitrogen on Carbon Blacks

BY L. G. JOYNER AND P. H. EMMETT

It has long been realized that measurements of the heat evolved during the physical adsorption of gases upon solids might yield considerable information concerning the nature of the solid surface. Of particular interest would be the variations of the differential heat with the amount of gas adsorbed.

Unfortunately, very little accurate work has been done by either the calorimetric or the isosteric method for measuring heats of adsorption and few attempts have been made to compare the two methods. Such attempts as have been made have been well summarized and discussed by Brunauer.[1]

In recent years calorimetric technique has been so improved, especially by Beebe[2] and his coworkers, that it is possible to detect variations in the differential heat of adsorption which are smaller than the experimental error involved in much of the early work in the field. More precise methods for measuring the adsorption of gases on solids have also been developed. In view of the fact that calorimetric measurements such as Beebe's are rather complicated and time consuming, it seemed worthwhile to ascertain whether the simpler isosteric method for measuring the heat of adsorption was capable of detecting the same details of the heat curve as the calorimetric method. To this end, we have carried out and are here reporting detailed adsorption studies of nitrogen on portions of the same samples of carbon black for which Beebe, Biscoe, Smith and Wendell[2a] have recently reported the most complete calorimetric measurements of the heat of adsorption of nitrogen that have so far been published. The samples were kindly given to us by Dr. Beebe.

Experimental

Materials.—Two carbon blacks were selected for the present investigation. These were the same samples used by Beebe, Biscoe, Smith and Wendell[2a] and have been described in detail in their paper. The two carbon blacks were Spheron Grade 6 and Graphon. The Spheron Grade 6 is a medium processing channel black (MPC). Graphon is a partially "graphitized" carbon black formed by heating MPC black to 3200°.

The nitrogen adsorbate was Airco Prepurified nitrogen. It was merely dried in a liquid nitrogen trap prior to being used.

Apparatus.—The adsorption apparatus was a modified version of the type described by Emmett.[3] Pressures above 1 cm. were determined to 0.1 mm. on a 10-mm. bore manometer with a vernier reader. Lower pressure determinations were made on a special manometer read by means of a microscope cathetometer. This was similar to the system described by Harkins and Jura.[4] The precision of these low-pressure readings was about 0.01 mm. The normal vapor pressure of nitrogen (P_0) was determined continuously and directly by means of a separate manometer and bulb partially filled with liquid nitrogen and placed in the low-temperature bath in close proximity to the adsorption bulb.

The adsorption isotherms at −183 and −195° were made using a liquid oxygen and a liquid nitrogen bath, respectively. The isotherms at −205° were made in a specially designed, low temperature system, details of which will be published in the near future. Briefly, the lower temperature was obtained by decreasing the pressure over liquid nitrogen. By means of a vapor pressure controller, relay and pump, the pressure was kept constant to within a few tenths of a mm. The total temperature variation over an entire run was less than 0.1°.

All surface area values were obtained by a linear plot of the adsorption data according to the Brunauer, Emmet and Teller (B.E.T.) equation[5,6]

$$\frac{x}{V(1-x)} = \frac{1}{V_m C} + \frac{(C-1)x}{V_m C} \qquad (1)$$

where x is the relative pressure at which the volume V of gas (S.T.P.) is adsorbed, V_m is the volume of gas required to form a monolayer and C is a constant proportional to exp. $(E_1 - E_L)/RT$. E_1 is defined[5] as the "average heat of adsorption for the first layer" and E_L the heat of liquefaction of the adsorbate.[7]

Results

Figure 1 shows the nitrogen adsorption isotherms for Grade 6 Spheron at −183.1° and −194.6°. Similar isotherms for Graphon at −182.8°, −194.8° and −204.7° are shown in Fig. 2. In Fig. 3 the low pressure regions of the Graphon isotherms are given in more detail. All of the isotherms are actually composites of several separate runs. Many more points were taken

(7) It must be kept in mind that E_1 does not and should not necessarily agree with direct experimental values for the heat of adsorption in the first layer.[2a] To begin with, E_1 is evaluted from plotting adsorption data by equation 1 for relative pressures ranging from 0.05 to about 0.3. Accordingly, the E_1 as deduced from the constant C in equation 1 is more nearly the average heat of adsorption for the less active part[5] of the surface since most of the first layer would have been completed already at a relative pressure of 0.05 for many adsorbates. Furthermore, since C is defined as

$$\frac{a_1 b_2}{a_2 b_1} \text{ exp. } (E_1 - E_L)/RT$$

it is possible to obtain E_1 from C only by evaluating the term a_1b_2/a_2b_1. Actually this term is frequently assumed equal to unity though recent calculations[6,8] suggest that it may differ from unity by a factor of 10 to 100. Accordingly, equation 1 can be expected to yield only an approximate value for E_1 and at best gives an E_1 characteristic of the less active parts of the surface.

than are shown.[9] Those given in the figures, however, are representative and serve to illustrate the precision of the measurements. Separate runs are indicated by the different symbols in Fig. 3. The −183° isotherms could not be carried above a a relative pressure of about 0.4 because of the limitations of the apparatus. That the carbon blacks are probably non-porous is indicated by the superposition of the desorption points on the adsorption curve in the region above 0.4 relative pressure, this being the region in which hysteresis usually occurs for porous substances. The desorption points were taken after the maximum volume of gas shown by the curves in Fig. 2 had been adsorbed.

Calculations and Discussion

Calculation of the Heat of Adsorption.—The differential heat of adsorption was calculated from the Clausius–Clapeyron equation in the form[10]

(9) For additional data order Document 2530 from American Documentation Institute, 1719 N St., N. W., Washington 7, D. C., remitting 50¢ for microfilm or 50¢ for photoprints.

(10) Wilkins, *Proc. Roy. Soc.* (*London*), **A164**, 496 (1938), has suggested that the correct method of applying the Clausius–Clapeyron equation to adsorption data entails the use of a constant fraction of the surface covered rather than a constant volume of adsorbed gas at the several temperatures being used. If such calculations are made for the data in the present paper for constant values of V/V_m (V_m varying with temperature as indicated in column 3 Table I) the resulting ΔH value is smaller in absolute value than the curves

$$\Delta H = 2.303R\left(\frac{T_1T_2}{T_2 - T_1}\right)(\log P_2 - \log P_1)_{\text{const. } V} \quad (2)$$

For each isotherm log P was plotted against the volume of gas adsorbed, V. Figure 4 show this plot for the three isotherms on Graphon. The vertical distance between the lines was measured at a given value of V and inserted into Equation 2; ΔH for various given values of V was then calculated.

In Figure 5 are plotted as a function of V/V_m the differential heat of adsorption for nitrogen on Spheron measured isosterically as above (solid line) and the calorimetric results for the same system (symbols) as measured by Beebe and his co-workers.[2a] Figure 6 shows a similar comparison for the nitrogen–Graphon system.

Since Equation 2 is very sensitive to small variations in the pressure, especially in the low pressure region, vertical lines are used in Figs. 5 and 6 to indicate the maximum variation observed. The extent of this variation in terms of pressure is indicated by the envelope lines for the −194.8° curve in Fig. 4. Variations of only 0.01 to 0.02 mm. in the low pressure region have a considerable effect upon the calculated heat value, whereas at higher pressures even larger variations have negligible effect.

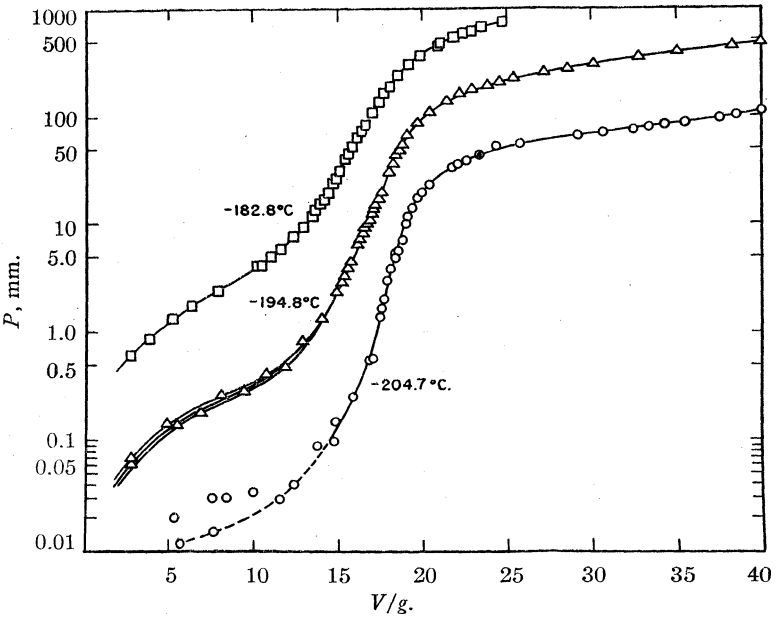

Fig. 4.—Logarithmic plot of the Graphon isotherms for purposes of calculating the differential heat of adsorption, showing the experimental deviations at extreme low pressures.

Changes in ΔH, ΔF and ΔS during the Adsorption of Nitrogen on Carbon Blacks.—It is apparent from Figs. 5 and 6 that the agreement between the differential heats of adsorption as calculated from the isotherms by Equation 2 and those determined calorimetrically by Beebe[2a] is remarkably good. The isosteric heats of adsorption of nitrogen on the Graphon sample are of better precision than those on Grade 6 Spheron, due to an improvement of the apparatus. It is doubtful, however, that this lower precision for the Spheron data can account for the rather large discrepancy observed for Spheron in the region of the monolayer between the isosteric heats and the portion of the calorimetric heats represented by the closed circles. It may be noted that the calorimetric data represented by the open circles and triangles are much closer to the isosteric line in this region than are points shown as closed circles.

For the adsorption of nitrogen on Graphon the agreement between the isosteric and calorimetric heats is especially good. The isosteric data reproduce faithfully the rather unusual calorimetric curve. Since for this system the isotherm was determined at three temperatures, there are three possible ways of calculating the differential heats by Equation 2. The various results are indicated in the figure by separate symbols. Above 0.7 monolayer the heats calculated from all three pairs of isotherms agree very well. Below 0.7 monolayer the −204.7° isotherm involves a larger possible error because of the low absolute pressure and cannot be used to calculate an isosteric heat with accuracy. It is not surprising, therefore, that the heat values calculated from the −204.7° and the −182.8° isotherms and shown by open triangles are in poor agreement with the other isosteric and with the calorimetric values.

The isotherms of the Graphon system shown in Fig. 2 all have an unusual hump starting at a relative pressure of about 0.2. This hump was also obtained but not discussed by Beebe[2a] and is not directly associated with the large rise in the differential heat curve since the latter occurs at 0.75 monolayer while the isotherm hump is much higher. There is, however, a much smaller rise in the heat curve at 1.75 monolayers which is associated with the isotherm hump. It is remarkable that the second and smaller rise in the differential

shown in Figs. 5 and 6 by 100 to 400 calories. However, the justification of this proposed method of applying the Clausius–Clapeyron equation is not clear at the present writing. Certainly the two papers of Wilkins (also Wilkins, *Proc. Roy. Soc.* (London), **A164**, 510 (1938)) dealing with the subject appear to be so full of misprints as to be unsuitable as a theoretical guide to the problem. Our own data show definitely that any heat of adsorption values calculated on the basis of constant fraction of the surface covered will be smaller than those calculated by equation 2 with volume of adsorbed gas constant. Wilkins' theoretical treatment led to what seems to be an erroneous conclusion that the heat of adsorption is larger if calculated by constant fraction of the surface covered than by constant volume.

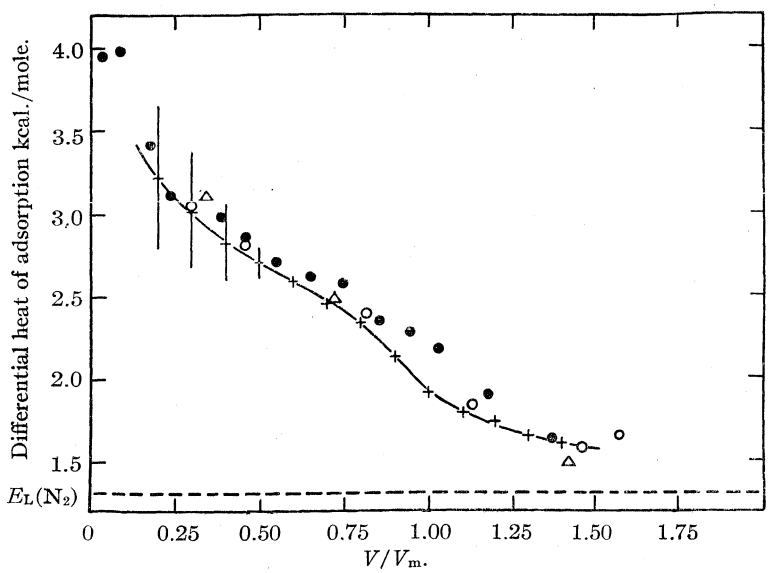

Fig. 5.—Differential heats of adsorption for nitrogen on Grade 6 Spheron as determined calorimetrically by Beebe, Biscoe, Smith and Wendell,[2a] (O, ●, △), and isosterically by the authors (+). The length of the vertical lines represents the total spread of the values calculated from the isosteric data.

heat curve is almost exactly one monolayer separated from the larger rise. It would almost seem that whatever forces cause the first rise are carried through and repeated in the second layer.

If one considers the process

$$N_2 \text{ (liquid)} \longrightarrow N_2 \text{ (adsorbed)}$$

it is a simple matter to calculate from the foregoing data the change in heat content, (ΔH); the free energy change, (ΔF); and the entropy change, (ΔS). ΔH is simply the difference between the differential heat of adsorption and the heat of liquefaction. ΔF is given by

$$\Delta F = RT \ln P/P_0 \qquad (5)$$

The free energy change so calculated was found to be independent of the temperature at least over the range of temperature studied. The entropy change is then obtained from the relation $T\Delta S = \Delta H - \Delta F$.

Figures 7 and 8 show how these properties vary with V/V_m for the two carbon blacks studied. Although the portion of the ΔS curve for Spheron below a V/V_m value of 0.5 is quantitatively questionable, ΔS undoubtedly remains negative down to at least a value of V/V_m equal to 0.2. For Graphon, the value of ΔS is positive up to a V/V_m value of 0.3 and again for a V/V_m value between 1.0 and 1.5.

Beebe and his co-workers[2a] have pointed out that on the basis of calculations by Barrer[11] the observed decrease in the heats for the Spheron with the amount of surface coverage cannot be accounted for by interaction between adsorbed molecules. However, as they point out, it is possible that such interaction forces may account for the increase in heats over the V/V_m range between 0.5 and 1.0 in the case of Graphon.

If one accepts Beebe's[2a] suggestion that the heat treatment to which Spheron is subjected when it is converted to Graphon eliminates most of the highly active centers found on the Spheron a possible explanation of the entropy curves is suggested. In the case of the Spheron where active points are present, the adsorbed phase is more or less ordered with a resulting negative entropy change over the entire course of the adsorption. In the Graphon system the first molecules are adsorbed in a very random or disordered manner giving rise to the positive portion of the entropy curve. Once the surface is partially covered, interaction forces, such as those discussed by Barrer[11] may cause a more orderly adsorption of the remainder of the monolayer, hence giving rise to the negative entropy change. It must be admitted, however, that it stretches

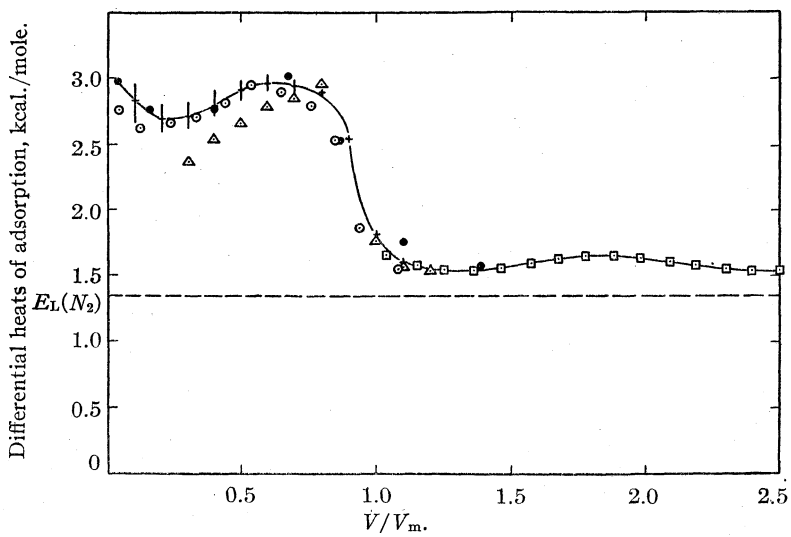

Fig. 6.—Differential heats of adsorption for nitrogen on Graphon as determined calorimetrically by Beebe, Biscoe, Smith and Wendell,[2a] (O,●), and isosterically by the authors (+, −194.8 to −182.8°; △, −204.7 to −182.8°; □, −204.7 to −194.8°). The length of the vertical lines represents the total spread of the values calculated from the isosteric data.

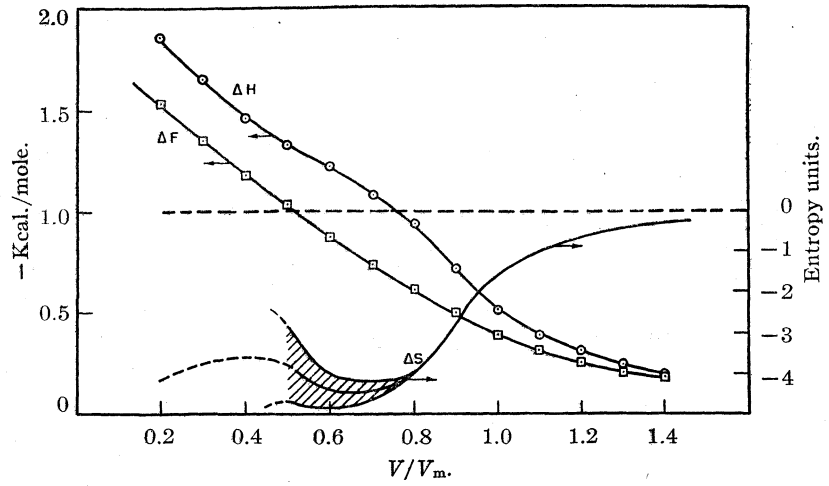

Fig. 7.—Variation in free energy change, change in heat content and entropy change for the transfer of nitrogen from the liquid state to the adsorbed state on Grade 6 Spheron with the system at −194.6°.

this picture rather far to imagine this process being repeated to explain the positive entropy which appears in the second layer.

Surface Area Measurements on the Carbon Blacks.—In Figure 9, the data for the adsorption of nitrogen on Graphon are plotted according to the usual B.E.T. linear equation. At all three temperatures excellent straight lines are obtained up to 0.2 relative pressure. Above this pressure the experimental points fall below the B.E.T. plot. This behavior has been noted twice before in the literature, once with butane on silica gel[5] and once with nitrogen on activated magnesia.[12] There has been little basis for judging the course of this behavior in the first two instances. The points could fall below the B.E.T. curves either because E_2, the heat of adsorption in the second layer was higher than E_L, or as suggested by Walker and Zettlemoyer[13] because of the presence of a considerable amount of surface characterized by a low C value (2 to 10) in addition to the surface having the usual C value (50 to 150). In the B.E.T. plots of the nitrogen adsorption on Graphon shown in Fig. 9, it seems reasonable to attribute the behavior to the same cause that is responsible for a rise in the heat of adsorption in the range between adsorption volumes equivalent to 0.5 and 0.9 fraction of a monolayer and 1.6 and 1.8 monolayers. It seems extremely unlikely that the explanation suggested by Walker and Zettlemoyer[13] can explain the results in Fig. 9 because on no carbon black so far studied has C ever been lower than about 100 and because such low C values as would be necessary have never been observed for nitrogen adsorption on any solid except hide.[14]

V_m for Graphon was calculated by the usual B.E.T. method from the linear portion below 0.2 relative pressure. The cross-sectional area of the nitrogen molecule was calculated for the various temperatures from the equation given by Emmett and Brunauer[15] using the data of Yost and Russell,[16] for the density of liquid nitrogen. V_m and the cross-sectional area factor F (in sq. m./cc.) are given in Table I.

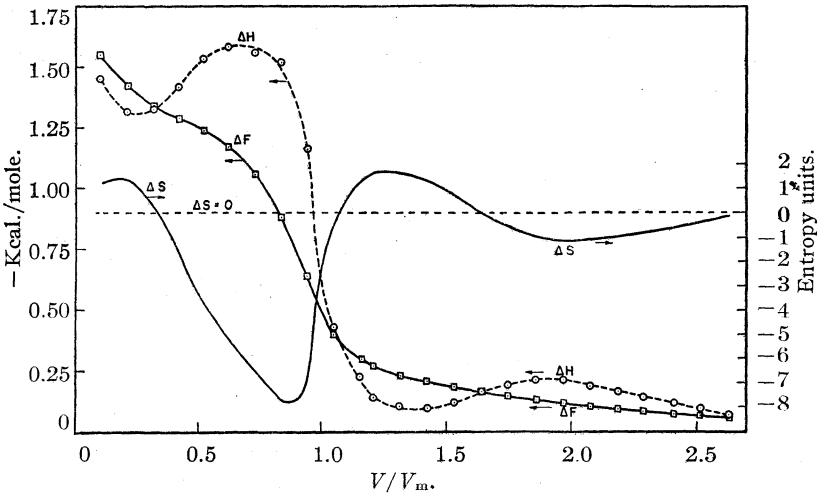

Fig. 8.—Variation in the free energy change, change in heat content and entropy change for the transfer of nitrogen from the liquid state to the adsorbed state on Graphon with the system at −194.8°.

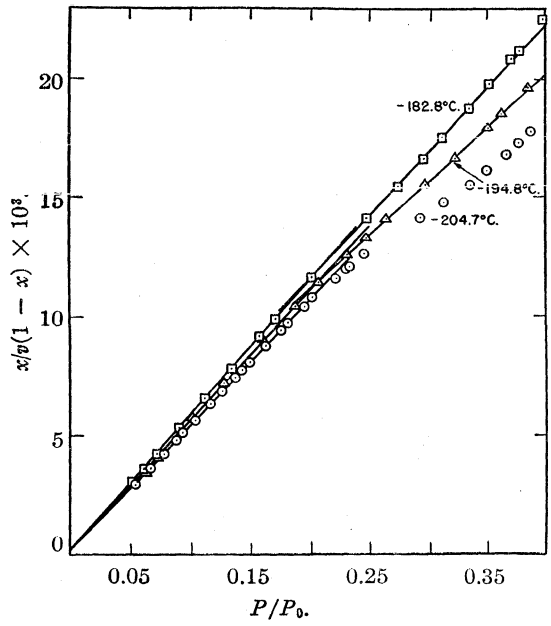

Fig. 9.—B. E. T.[5] plots of the three isotherms of nitrogen on Graphon.

The areas calculated by multiplying these two agree for all three temperatures within one per cent. This is an excellent confirmation of the variation with temperature of the cross-sectional area of the adsorbed nitrogen molecule as calculated by the equation of Emmett and Brunauer.[15] It also justifies the selection of the lower linear portion of Fig. 9 for the determination of V_m since no such agreement occurs if the upper, apparently linear, portion is used.

This break in the B.E.T. plot for the Graphon data accounts for the discrepancy between the value of V_m of Beebe, Biscoe, Smith and Wendell[2a] and that reported here. In determining V_m they used an average straight line and hence their value of 19.17 cc. is 5.5% above that obtained from the lower linear portion of the −194.8° curve in Fig. 9. In Fig. 6, Beebe's value of V_m was used to calculate the fraction of the surface covered in order to keep both heat values on the same basis.

Figure 10 shows the Graphon data plotted according to the method of Harkins and Jura.[4] Again two linear portions occur with the break occurring at 0.2 relative pressure. This pressure is almost exactly where the hump in the isotherm begins. Indicated in Fig. 10 is the slope which the −194.8° line should have if it is to give the same area by the Harkins and Jura[4] method as was obtained by the B.E.T. method. The slope of the linear portion occurring at low pressure is closer to this slope than that of the higher pressure data. A $\pi-\sigma$ plot of the Graphon data showed no evidence of a phase change occurring in this system.

Both the B.E.T. and the Harkins and Jura plot of the Spheron isotherms are quite normal.

Table II gives the area of the two carbon blacks as determined by the B.E.T. method at the various temperatures and also the area obtained from the −194.8° isotherm by the Harkins and Jura[4] method using 4.06 for the proportionality constant k. Isotherms at temperatures other than −194.8° could not be used for Harkins and Jura determinations since k is not known for nitrogen except at that temperature. The B.E.T. results for both blacks are surprisingly self-consistent, the maximum variation among the areas for a given adsorbent being less than 1%. The agreement between the B.E.T. values and the Harkins and Jura value is also remarkably good, being within about 10%. As a matter of fact, it is interesting to note that the cross-sectional areas that have to be assigned to the nitrogen molecule to obtain surface areas by the B.E.T. method in agreement with those obtained by Harkins and Jura plots exhibit the same relationship to the constant C shown by one of the authors[8] to exist for numerous adsorptions being 17.93 Å.^{2} and 17.04 Å.^{2} for C values of 273 and 166, respectively.

Utilizing the slope of the Harkins and Jura plot of the isotherms at temperatures other than −194.8° and the area, calculated from the −194.8° data by their method, it is possible to calculate a value of the Harkins and Jura[4] proportionality constant k at the other temperatures. The results of such calculations are shown in the last two columns of Table II. The agreement between calculated k values for the two non-porous carbon blacks at −182.8° is remarkable and is an excellent confirmation of the self-consistency of the Harkins and Jura[4] method when applied to non-porous substances. Incidentally, the varia-

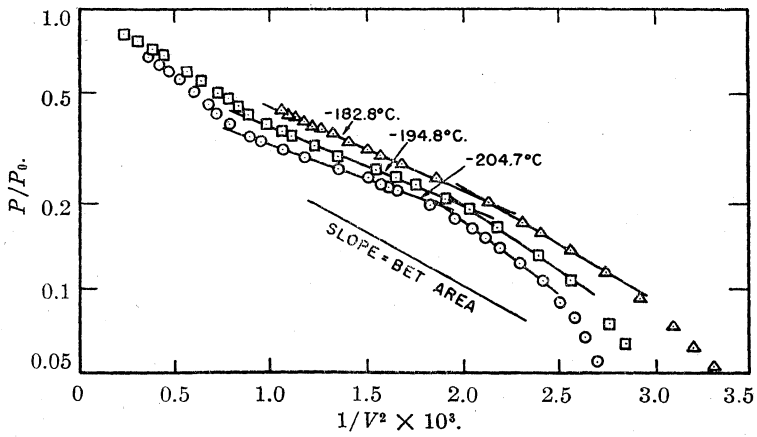

Fig. 10.—Harkins and Jura[4] plots of the three isotherms of nitrogen on Graphon. For comparison is shown the slope required to equal the B. E. T.[5] area for the −194.8° isotherm.

tion of k with temperature in Table II is in approximate agreement with the prediction of Davis and DeWitt[17] that the Harkins and Jura k value for a given adsorbate should be proportional to $1/T^{1/2}$.

TABLE II

Comparison of areas of Graphon and Grade 6 Spheron as determined by the B. E. T. method[5] at three temperatures and by the Harkins and Jura method[4] at −195°.

	Area, sq. m./g.					k calculated from H & J area at −195°C.
	B.E.T.			H & J k = 4.06		
Temp., °C.	−195	−183	−205	−195	−183	−205

Spheron	120.4	120.7		126.3	4.47	

Summary

1. Adsorption isotherms for nitrogen on two samples of carbon black were determined at −205, −195 and −183°.

2. The differential heats of adsorption of nitrogen on the two samples of carbon black were measured isosterically.

3. Excellent agreement with the calorimetric data of Beebe and his co-workers[2a] for the same samples of carbon black was obtained. ΔF and ΔS values for the process liquid nitrogen going to adsorbed nitrogen were determined as a function of the surface covered and a possible interpretation of the results is suggested.

4. The areas of the various samples as calculated by the B.E.T.[5] theory were compared to the areas calculated by the method of Harkins and Jura.[4]

Differential Heats of Adsorption and Desorption of Nitrogen on Porous Glass

BY L. G. JOYNER AND P. H. EMMETT

Gleysteen and Deitz[1] recently calculated by the Clausius-Clapeyron equation from the data of Lambert and Clark[2] the differential heat of adsorption and the differential heat of desorption of benzene on ferric oxide gel. They found the heat of desorption to be about 760 calories larger in the region where hysteresis occurs and suggested that this value could be used in conjunction with the Brunauer, Deming, Deming and Teller[3] adsorption equation to account approximately for the hysteresis observed in this benzene–iron oxide gel system.

It was felt that these observations of Gleysteen and Deitz[1] were of sufficient importance to warrant their being checked by another set of data. To this end we have determined the adsorption and desorption isotherms for nitrogen at −204.8° and −194.6° on a sample of porous glass.

Experimental

Materials.—The porous glass sample was one of a number furnished by the Corning Glass Company (Hood and Nordberg, U. S. Patent 2,106,774). It was one of the samples used by Emmett and Cines[4] for adsorption work at −195°.

The nitrogen adsorbate was Airco prepurified nitrogen. It was merely dried in a liquid nitrogen trap prior to being used.

Apparatus.—The adsorption and temperature controlling apparatus and the procedure were the same as for the preceding paper.[5] All surface area values were calculated by the standard B. E. T. equation.[6]

Results

The adsorption and desorption data for nitrogen on the porous glass have been plotted in Fig. 1. For each temperature, adsorption and desorption points for two separate runs are shown. The agreement between the separate runs was excellent. The isotherms are what have been called "Type IV" and resemble somewhat the isotherms obtained by Lambert and Clark[2] for benzene on iron oxide gel.

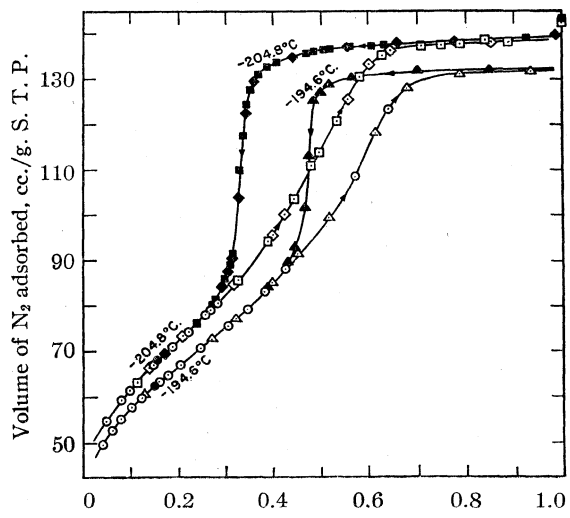

Fig. 1.—Adsorption of nitrogen on porous glass at −204.8 and −194.6°. Solid symbols are desorption points.

Calculations and Discussion

Comparison of the Heat of Adsorption of Nitrogen with the Heat of Desorption.—Brunauer, Deming, Deming and Teller[3] de-

veloped a general adsorption theory by which five types of adsorption isotherms may be deduced from the single equation

$$V = V_m \left[\frac{x}{1-x} + A\right] \quad (1)$$

where A is a complicated function of C, x, $\bar{n}$ and h. V_m is the volume of gas required to form a monolayer on the surface and x is the relative pressure. In the function A of equation 1, $\bar{n}$ is the maximum number of layers that can fit into a capillary; C is related to the heat of adsorption of the first layer in the same way as in the regular B.E.T. equation[6]; and $h = (\bar{n}C^2 - C^2 + 2C)\exp. Q/RT$ where Q is an additional energy term associated with the last layer to enter the capillary.

Brunauer, Deming, Deming and Teller[3] applied the above equation to the data of Lambert and Clark[2] for the adsorption of benzene on ferric oxide gel and obtained reasonably good agreement. Gleysteen and Deitz[1] showed that if all the constants of Equation 1, as calculated from the adsorption data, are held fixed except for the value of Q and, if this is increased by the 760 calories that they had calculated as the amount by which the heat of desorption of benzene on ferric oxide gel exceeded the heat of adsorption, a reasonable facsimile of the experimental desorption curve is obtained.

In applying the suggestion of Gleysteen and Deitz[1] to our data we have elected to assign such excess heat to the Q for desorption as is needed to make the desorption isotherm for $-194.6°$ as calculated from equation 1 agree with that shown in Fig. 1. The curve for this calculated excess Q (labeled calcd. B.D.D.T.) is shown in Fig. 2. It is apparent that no single value for the amount by which the Q for the desorption curve exceeds that for the adsorption curve would suffice to give agreement between the experimental and calculated isotherms. Furthermore, it is evident that at low relative pressures and at high relative pressures the heats of adsorption and desorption will be equal.

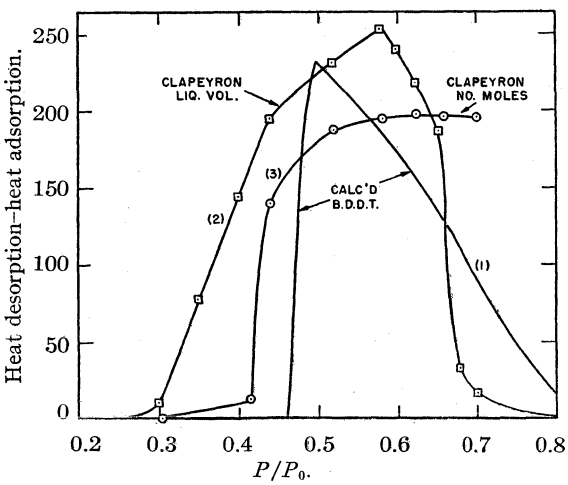

Fig. 2.—Excess of the heat of desorption over the heat of adsorption for nitrogen (in calories per mole) on porous glass over the hysteresis region, as calculated by three different methods.

Some explanation of how the calculated curve (marked B.D.D.T. calcd. in Fig. 2) for the heat of desorption minus the heat of adsorption was obtained may be in order. The values for V_m and C for the $-194.6°$ isotherm were obtained in the usual manner from the simple B.E.T. plot (see equation 1 of the preceding[5] paper). The values of the parameters $\bar{n}$ and Q which gave the best fit of Equation 1 to the adsorption isotherm were then determined by a trial and error method. The Q so determined may be designated as $Q_{ads.}$ Agreement between experiment and theory was obtained to about the same degree as was obtained by Brunauer, Deming, Deming and Teller[3] for the benzene–ferric oxide system. Using the values of V_m, C and $\bar{n}$ from the adsorption part of the curve, values of V and x from the desorption isotherm were inserted into Equation 1 and $Q_{des.}$ calculated. The calculated curve of Fig. 2 is simply $Q_{des.} - Q_{ads.}$ plotted as a function of the relative pressure at $-194.6°$.

The conventional isosteric calculation of heats of adsorption and desorption by the Clausius–Clapeyron equation is fraught with considerable uncertainty when applied to data such as shown in Fig. 1. As pointed out by McBain[7] it is impossible to construct isosteres for the higher relative pressure regions for those cases in which the volume of gas adsorbed (S.T.P.) at saturation varies with temperature. The difficulty can apparently be avoided if one applies the Clausius–Clapeyron equation at constant liquid volume (and hence constant volume of pore space filled with adsorbate) rather than to constant volume of gas adsorbed. The amount by which the heat of desorption exceeds the heat of adsorption per mole is shown in Fig. 2 as a function of the relative pressure (for the $-194.6°$ isotherm) when calculated both on the basis of constant liquid volume of adsorbate and also when calculated for constant number of moles of adsorbate on the porous glass.

From what has already been said, it follows that curve 3 cannot be extended above about 0.7 relative pressure because at this point the isotherm for $-194.6°$ levels off and becomes independent of pressure.

The three curves shown in Fig. 2 are in remarkably good agreement considering the assumptions involved in the Brunauer, Deming, Deming and Teller[3] theory and the methods used in calculating curve 2. They all combine to indicate that the quantity of heat involved in desorbing adsorbate from capillaries is greater than the heat evolved during adsorption. This excess heat is probably of fundamental importance in determining the cause of the hysteresis loop, though the exact relationships involved may remain obscure until

(7) McBain, "The Sorption of Gases and Vapors by Solids," G. Routledge and Sons Ltd., London, 1932, p. 141.

more is learned concerning the phenomenon of hysteresis.

Variation of the Inception of Desorption Hysteresis with Temperature.—One other observation relative to the isotherms in Fig. 1 is of interest. A few years ago, Cohan,[8] on the basis of an "open pore" theory of adsorption, predicted that the lower relative pressure at which the desorption branch of an isotherm rejoins the adsorption branch should decrease as the temperature decreases. Qualitatively our data shown by the plots in Fig. 1 and similar data by Lambert and Clark[2] for benzene adsorption on ferric oxide agree with Cohan's hypothesis.[8] However, the agreement with his prediction is not quantitative. Thus, the value of the relative pressure corresponding to the beginning of hysteresis at −204.8° should be 0.305 according to Cohan[8] if, as in Fig. 1, the corresponding relative pressure in the −194.6° isotherm is 0.420. Actually, the hysteresis at −204.8° begins at about 0.265 relative pressure.

Surface Area Measurements on Porous Glass.—The adsorption data at both temperatures yield excellent linear portions when plotted according to either the B.E.T.[6] or the Harkins and Jura[9] method. The B.E.T. areas and C values for porous glass as calculated from both the −194.6° and the −204.8° isotherms are given in Table I. The Harkins and Jura area was calculated from the −194.6° isotherm by the use of 4.06 for the proportionality constant k. The agreement between the B.E.T. areas, although not as good as for the carbon blacks of the preceding paper, is still within 2%. Again the Harkins and Jura area is somewhat higher than but nevertheless is in reasonable agreement with that obtained by the B.E.T. method. We find as in the preceding paper[5] that the cross-sectional area (16.9 Å.²) that has to be assigned to the nitrogen molecule to obtain a surface area by the B.E.T. method in agreement with that obtained by the Harkins and Jura[9] plot exhibits the same relationship to the constant C (123) which has been shown to exist by one of the authors.[10]

TABLE I

k calculated from H. & J. area at −194.6°C.		3.35
B.E.T. C	123	147

[a] The cross-sectional molecular areas for nitrogen for −194.6° and −204.8° were taken as 16.26Å.² and 15.67 Å.², respectively, for these area calculations.

(8) Cohan, THIS JOURNAL, **66**, 98 (1944).

(9) Harkins and Jura, THIS JOURNAL, **66**, 1366 (1944).

If we utilize the slope of the Harkins and Jura[9] plot for the −204.8° isotherm and calculate a value of the Harkins and Jura proportionality constant k required to yield the same value of the surface area as was obtained by their method from the data at −194.6°, we obtain a value for k of 3.35 for the porous glass. A similar calculation in the preceding paper[5] for the non-porous solid Graphon at the same temperature yielded a k value of 3.86. This difference of about 17% in the value of k found between the porous and non-porous substances at −204.8° is to be compared to the perfect agreement between k values found for the two non-porous carbon blacks at −183° in the preceding paper.[5] These two examples are insufficient to warrent final conclusions but they do suggest that the temperature coefficient of k may be different for porous and non-porous substances.

Summary

1. Adsorption isotherms for nitrogen on a sample of porous glass were determined at −204.8° and −194.6°.

2. The differential heat of adsorption and the differential heat of desorption of nitrogen on the porous glass were measured isosterically.

3. For the porous glass the differential heat of desorption was shown to be in excess of the differential heat of adsorption over the hysteresis region by as much as 250 calories. The excess heat of desorption over the heat of adsorption was correlated with the hysteresis loop by means of the Brunauer, Deming, Deming and Teller[3] theory of multilayer adsorption in a way similar to that suggested by Gleysteen and Deitz.[1]

4. The area of the porous glass as calculated by the B.E.T.[6] theory from the adsorption data at −194.6° was compared to and found to agree with the area calculated by the method of Harkins and Jura.[9]

Chemical and Physical Adsorption of Gases on Carbon Dust

BY ROBERT H. SAVAGE AND CALLAWAY BROWN

The clean-up of hydrogen by fresh carbon or graphite wear-dust,[1] at room temperature, has been interpreted as a chemical adsorption resulting from the opening of the graphite lattice during the process of frictional seizure. The amount of hydrogen adsorbed by the dust was found to be 10^5 times greater than that adsorbed by a typical activated charcoal at the same temperature and pressure, and represented a chemically-active surface of the order of one square meter per gram. The supposition was made that the *total* surface of the dust was considerably greater than this, as roughly indicated by the color of the material; and this possibility was strengthened by a subsequent study with an electron microscope which revealed[2] that the carbon particles occurred in a wide distribution of size and showed a fineness extending beyond the resolving power of the instrument. The suggestion was then made that a determination of the total surface of this carbon by nitrogen adsorption at low temperature[3] would complete the data relating the chemically active surface to the total (physical) surface.

For carbon we have not found published information relating the two types of adsorption. According to the work of Lowry and Hulett,[4] after a charcoal has been outgassed thoroughly at 900–1000° and has been allowed to cool in vacuum to room temperature, such gases as hydrogen, nitrogen, carbon monoxide, can be admitted and subsequently recovered quantitatively at room temperature. The adsorption of these gases is clearly no more than physical. Yet surface films held by primary valences evidently occur since there are recovered large quantities of hydrogen as well as oxides of carbon during the degassing of charcoal[5] at 600 to 1200°. Nitrogen, also, has been recovered in the degassing of graphite[6] at temperatures up to 2200°, and is the predominant gas evolved in the range 1700 to 2200°.

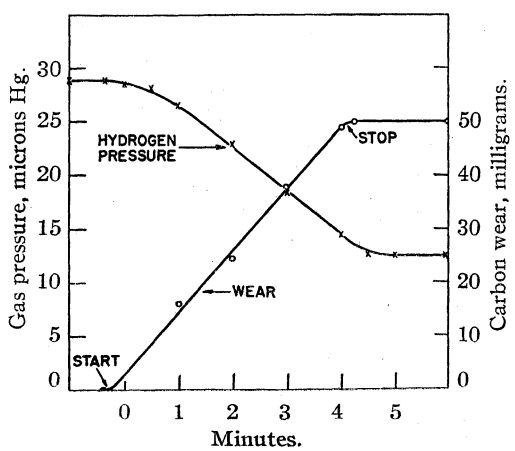

Fig. 1.—Clean-up of hydrogen by graphite wear-dust.

The lack of a detailed knowledge of the surface films on carbon seems to result from the fact that previous work has been concerned almost exclusively with the determination of adsorption characteristics of carbons which are already saturated chemically and which are not cleaned by the usual activation methods involving bake-outs at relatively low temperatures. Since an important part of the surface film may not be removed by such heating alone, the carbon wear-dust as a research material offers the novel advantage of providing *clean* carbon surfaces of exceptional extent by a simple mechanical process, so that the *formation* of the primary films may be measured. Employing the carbon dust we have observed an irreversible (chemical) clean-up at room temperature of hydrogen, nitrogen, oxygen, carbon dioxide, carbon monoxide and methane. This report is concerned particularly with (A) the hydrogen clean-up in relation to (B) a low temperature nitrogen adsorption performed after the clean-up to determine the total surface area.

Experimental

Part A.—Carbon wear-dust was made by operating graphite rods (brushes) against a rotating copper disk in a friction apparatus[1] containing hydrogen at a low pressure. (In the absence of certain vapors required for graphite lubrication, the graphite seizes to the moving base and rapidly disintegrates into a black dust which immediately cleans up the hydrogen. The clean-up is substantially the same whether the dust is formed in hydrogen directly or whether it is formed in vacuum and the hydrogen admitted after wear has stopped. Further, it occurs independently of the presence of copper in the moving base; *i. e.*, it is observed also with graphite rods sliding on a graphite disk.)

The observed wear (brush-volume) and the hydrogen clean-up were measured, as shown by Fig. 1. From the observed pressure drop in the system of 5.3-liter volume

we have calculated the adsorption, and also the specific area, of the *chemically active surface*, Table I. For reasons to be discussed, the area saturated per hydrogen molecule was assumed to be 9.6×10^{-16} sq. cm. (the area of two C atoms in the plane perpendicular to the graphite hexagonal plane). Several additional runs were then made to increase the amount of dust, and to check these results, after which the bell-jar was removed and a sample of the dust transferred to a small Pyrex tube for determination of surface area.

Part B.—The tube was next sealed into an adsorption apparatus[7] by means of a spherical ground-glass joint. The carbon sample was degassed in vacuum at room temperature and again for one hour at 500°, and the adsorption of nitrogen at −195° was determined after each pumping in the usual manner with helium as the reference gas. (Only the results following the 500° bake-out will be included because these are indicated to be more representative; the other data agreed however within 20%.) The dust was then removed and was replaced, first, with a sample of the original graphite "stock-powder" from which (with the addition of about 2% coked-binder) the brush had been made by pressing and firing to 1350°; and second, with samples of finished graphite rods of apparent density 1.9 g. per cc. Nitrogen adsorption at −195° was determined for each of these and the results are summarized, for comparison with the wear-dust, in Table II. The surface areas were calculated from these adsorption data, shown in Fig. 2, using the Brunauer, Emmett, Teller adsorption equation[8] and the value 16.2×10^{-16} sq. cm. for the area covered by a nitrogen molecule.

TABLE II

PHYSICAL ADSORPTION

Sample	g.	V_m (from BET plot) cc. N_2	Specific V_m cc. N_2/g.	Sp. surface (total) m^2/g.
Wear dust	0.0786	7.86	100.0	435
Stock powder	2.579	4.53	1.76	7.65
Rod	0.281	0.084	0.30	1.30

Finally the work was extended to include graphite rods of contrasting physical properties, with the results shown in Table III. The electrographitized carbon shown under (2) had been fired to about 2800° in contrast to the natural graphite rod 1, fired at 1350°. The powder under (2) was formed by grinding one of the rods in a high-speed impact grinder to produce a surface area of 4.62 sq. m./g., in striking contrast to the 435 and 390 sq. m./g. areas shown for the two wear-dust samples. The three samples of rod 1 of different cross-section and history show the reproducibility of the results.

Discussion

Tables I and II show the changes in surface which accompany the processes of rod manufacture (pressing and bonding of graphite particles) and of rod wear. The stock powder is a relatively coarse graphite showing an area 7.65 sq. m./g., and this is decreased to 1.3 sq. m./g. as a result of the rod formation. The process of wear results in a fine subdivision of the individual graphite particles, increasing the surface by 335-fold, within the range of the fine colloidal carbon blacks (color blacks). Of the total surface, 99.7% is apparently fresh surface developed in the wearing process. Only a portion of this fresh surface can be chemically active toward hydrogen since the 1.98 cc./g. hydrogen adsorption, although many times larger

(7) E. O. Kraemer, "Advances in Colloid Science," (by P. H. Emmett), Interscience Publishers, New York, 1942, pp. 1–36.

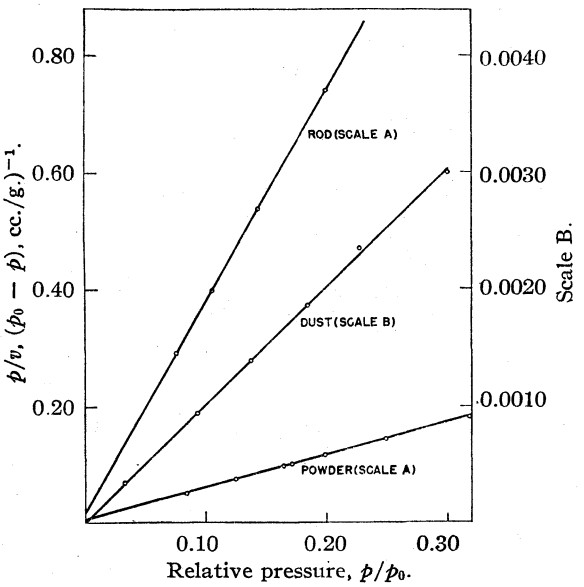

Fig. 2.—Adsorption of nitrogen at −195° on graphite (BET plots).

than that reported for any previous carbon, is only 2% of the monolayer nitrogen adsorption of 100 cc./g. The hydrogen adsorption would seem to represent the proportion of carbon atoms which have been exposed so as to show one or more strong valences of unsaturation, such as those of free radicals. This exposure would not occur if the graphite crystal is simply delaminated or scaled away, but would occur if the crystal is opened both along the main cleavage plane *and* at right angles to this plane (so as to uncover both face atoms and edge atoms).

The laminar structure of graphite, together with the indication that the chemically active surface represents only a small proportion of the total surface, suggests that the wear-dust particles are composed of thin plates, and that only edge atoms combine with hydrogen while face atoms in the main cleavage plane of graphite make up most of the total surface area. In this case the area of the chemically active surface and the fraction of the surface atoms which are chemically active may be readily calculated from the lattice dimensions. The main cleavage plane of graphite consists of carbon hexagons with the smallest interatomic distance 1.42 Å. and the separation between planes 3.39 Å. The area per carbon atom along an edge perpendicular to the main plane is therefore $1.42 \times 3.39 = 4.81$ sq. Å. If the hydrogen adsorption is due to one-to-one combination of hydrogen atom with edge carbon atoms, the chemically active surface covered by 1.98 cc. per gram is 5.12 sq. m./g. as listed in Table I. Any other lattice points reacting with hydrogen would lead to an even smaller value for the area of the chemically active surface. The remaining total surface, 430 sq. m./g., is considered to represent facial area. Each surface hexagon (equivalent to 2 carbon

atoms) occupies 5.24 sq. Å., so the total number of face atoms per g., $n_f = 430 \times 10^4/2.62 \times 10^{-16}$. The proportion of surface atoms which combine with the 1.98 cc. of hydrogen, presumably as edge atoms, is therefore $^1/_{155}$ or 0.65%. Although the "chemical" surface represents only a small fraction of the total surface, its absolute magnitude, 5.12 sq. m./g., is large compared with the *total surface* of the rod from which the dust was worn and is comparable with the *total surface* of natural graphite powders.

Size and Shape of Graphite Fragments.—The values of equivalent particle size in Table III

TABLE III

Sample	Specific surface, sq. m./g.	Equiv. part.-size, microns

represent the diameter of hypothetical spheres (or the edge of cubes), calculated from the equation $d_3 = 6/\rho S$ where d_3 is in microns when S is in sq. m./g. and the density ρ is in g./cc. (2.25 for graphite). It is convenient to use the spherical model for comparison with the more usual forms of black carbon but a laminar model with a large ratio of area to thickness appears much more likely from the evidence discussed above. For a plate-like particle of area A and thickness t, the surface area may be considered as $2A$ with only a small error if the ratio of edge surface to total surface is small. The mass of the particle is $At\rho$, and the surface area per unit mass $S = 2/t\rho$. As long as the thickness t remains small compared with the area A, the specific surface area of the graphite is *independent of the size and shape* of the plates and is determined by the thickness. For wear-dust 1 with $S = 435 \times 10^4$ sq. cm./g., therefore, the indicated thickness $t = 20.4 \times 10^{-8}$ cm.

From the specific surface area alone there is no limitation on the size and shape of plate-like particles; only the thickness is determined. A probable limitation on the face to edge surface ratio appears in the ratio of total surface, from nitrogen adsorption at −195°, to "chemical" surface, from hydrogen clean-up at room temperature. The ratio of total surface atoms to hydrogen atoms adsorbed has been calculated to be 155. If this is assumed to represent the ratio of face atoms to edge atoms, the average size of the plates may be calculated. For a plate of area A, perimeter p, and thickness t, the total number of facial atoms $n_f = 10^{16} \times 2A/2.62$; the number of edge atoms in each basal plane $10^8\ p/1.42$, and the number of basal planes $10^8\ t/3.39$ approximately. The total number of edge atoms, therefore, $n_e = 10^{16}\ pt/4.81$ and the ratio of face to edge atoms, $n_f/n_e = 3.67\ (A/pt)$. When the thickness $t = 20.4$ Å. and the ratio $n_f/n_e = 155$, the ratio of area to perimeter, $A/p = 862 \times 10^{-8}$ cm.

In the limiting case of a circle of radius r, $A/p = r/2$; then $r = 1720$ Å. Circular plates of average radius 1720 Å. and thickness 20.4 Å. thus satisfy the requirements for both "total" and "chemical" surface, assuming combination of hydrogen with edge atoms. Plates of shape other than circular still satisfy the total surface requirement if the thickness is 20.4 Å. but must be of larger area than $\pi(1720 \times 10^{-8})$ sq. cm. in order for the ratio of face to edge atoms to remain at 155.

Evidence from Electron Microscope and X-Ray Diffraction.[8]—A typical electron micrograph of the wear-dust appears in Fig. 3. The electron microscope studies are discussed more fully elsewhere[2] but it is clear that a large range of sizes is present extending from 10000 Å. down to 100 Å. or less in diameter. A number of particles semi-transparent to the electron beam are present and these are certainly of a thickness considerably less than 100 Å. Furthermore the thin plates are

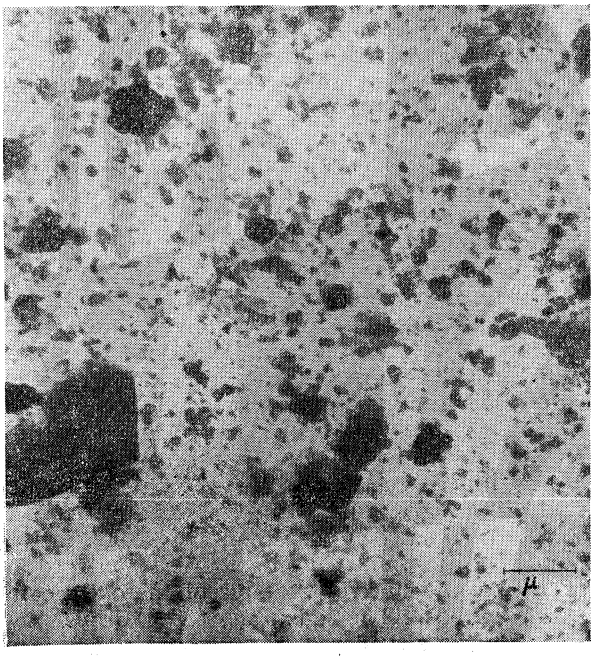

Fig. 3.—Electron micrograph of graphite wear-dust.

(8) The authors wish to thank Ernest F. Fullam for the electron micrograph, and David Harker for the X-ray data and its interpretation.

seen to vary in respect to thickness from opacity to invisibility; and since the gradation is continuous we cannot determine the concentration of particles too thin to be visible. Quantitative treatment is thus complicated by the large range of sizes present and by the transparency to the electron beam of very thin platelets.

X-Ray diffraction results provide interesting independent evidence for the structure of the wear-dust particles. Diffraction of copper Kα radiation from a thin layer of the wear-dust powder was carried out in a Geiger counter X-ray spectrometer. The output of the recorder, which plots intensity of the diffracted radiation against the diffraction angle, is shown in Fig. 4.

The sharp peak at 27° corresponds to the 00.2 reflection of massive graphite. (This reflection is from the cleavage planes.) The graphite crystals responsible for this reflection must be thicker than about 1000 Å. The sharp peak just mentioned is superimposed on a very broad maximum of about 10° width at half height. Such a diffraction effect is consistent with the assumption of either (a) distortion of the crystal lattice, (b) extremely small particle size or (c) both. The electron microscope evidence points toward alternative (b). If the line broadening is due entirely to particle size, the particles must be of the order of five times the interplanar distance or 20 Å. in thickness. This reflection provides no information on particle size in directions other than normal to the cleavage plane of graphite.

Thus the electron micrographs and X-ray diffraction show that the particles are predominantly very thin perpendicular to the hexagonal plane and of comparatively large diameter. Although a portion of the powder appears to consist of relatively thick fragments the results on the whole are in excellent agreement with the thin plate model. This supports the assumption that hydrogen reacts quantitatively with edge atoms. It should be noted that the estimate of 20 Å. thickness from the surface area is independent of the location of the chemisorbed hydrogen. Only the estimate of the face dimension depends on the ratio of edge to face atoms.

Clean-up of Other Gases.—Preliminary studies of nitrogen clean-up by the carbon wear-dust have indicated this is considerably less than for hydrogen. On two carbons it has been indicated to be 180 cu. mm. (STP)/g. or higher. The fact that it is appreciable seems to us to be rather remarkable since molecular nitrogen does not react with charcoal.[9] Preliminary data for methane showed an adsorption of roughly one-half that obtained with hydrogen; that is, roughly the same number of hydrogen atoms were involved per gram of carbon dust. The carbon monoxide adsorption was indicated to be somewhat higher than that of hydrogen.

(9) R. B. Anderson and P. H. Emmett, *J. Phys. Colloid. Chem.*, **51**, 1327 (1947).

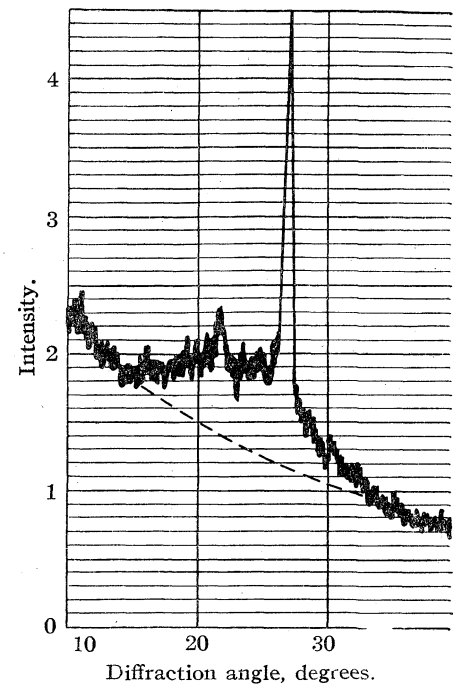

Fig. 4—X-Ray diffraction record for graphite wear-dust.

In measuring the chemical clean-up of these gases during the initial stages of the work, the bell-jar trap was chilled with liquid nitrogen to condense traces of water vapor. The trap was observed to collect a much larger proportion of the wear-dust when chilled than when held at room temperature, and because of the large carbon surface involved, there resulted considerable physical adsorption of such gases as nitrogen and methane at the low temperature. This complicated the chemical measurements, and to correct this difficulty in a later series of experiments the trap was retained at room temperature during the clean-up. Another complication was found to occur when the trap was warm, *viz.*, a slow evolution of water vapor which tended to compete in the clean-up and to modify the pressure reading. Further work is under way to bring the data on the other gases up to the degree of reproducibility found for hydrogen.

Summary

1. Carbon dust, formed by the high wear of graphite rods rubbing against a rotating base in vacuum, has been found to adsorb hydrogen, nitrogen, oxygen, carbon monoxide, carbon dioxide and methane irreversibly at room temperature. The hydrogen clean-up, 2 cc./g. of dust, is 10^5 times the adsorption shown by representative activated charcoals at room temperature and low pressures of the order of 10 microns.

2. In a typical case the *chemically active* specific surface of the dust is indicated by the hydrogen clean-up to be 5.12 sq. m./g. The total (physical) specific surface is found by nitrogen adsorption at −195° to be 435 sq. m./g., as calculated from the

measured adsorption of 100 cc. of N_2/g. for the monolayer. This total surface of the *graphite* dust is comparable with those of the best commercial activated carbons, and in addition 1.2% of this total surface showed a powerful chemical activity.

3. Nitrogen adsorption isotherms on graphite powder (raw material), finished graphite rods (brushes), and powder formed by pulverizing the rods in a high-speed impact grinder indicated surface areas of 7.7, 1.3 and 4.6 sq. m./g., respectively, compared with 435 sq. m./g. for the wear-dust.

4. It is shown that for a laminar model of graphite fragments in which the ratio of edge area to face area is small, the surface area per unit weight is independent of size and shape and depends only on the thickness of the fragments. A thickness of 20.4 Å. is indicated for the carbon wear-dust. A minimum average diameter of 3500 Å. is indicated for the face dimension on the assumption that hydrogen reacts quantitatively with edge atoms.

5. It is suggested that the chemically active portion of the dust represents unsaturated carbon valences at points of cleavage at right angles to the main cleavage plane. The wear dust appears to differ from previous carbon samples studied in that these strong valence bonds have been freshly opened, mechanically, and occur in large numbers; whereas the corresponding bonds in other carbons are ordinarily saturated by chemisorbed gas and are not opened by ordinary outgassing procedures.

Thermodynamics of Aqueous Solutions of Potassium Hydroxide[1]

BY G. C. AKERLOF[2] AND PAUL BENDER[3]

Introduction

The results presented in this paper represent a continuation of a program of studies of the thermodynamic properties of concentrated aqueous electrolytic solutions in which measurements on hydrochloric acid[4] and sodium hydroxide[5] solutions have already been reported. A detailed description of the experimental procedure and the method of calculation employed here has been given previously.[5] In the following all symbols agree with common usage or with those in earlier papers.

Preliminary Treatment of the Data.—The cell measured has the composition

$$Pt,H_2/KOH(m)/KxHg/KOH(m_r)/H_2,\ Pt$$

The cell reaction and the resulting electromotive force expression are given, respectively, by

$$KOH(m) + H_2O(m_r) + {}^1/_2H_2(m) \rightarrow KOH(m_r) + H_2O(m) + {}^1/_2H_2(m_r) \quad (1)$$

$$E = -\frac{RT}{F} \ln \frac{a_{KOH(m_r)} a_{H_2O(m)} a_{H_2(m_r)}^{1/2}}{a_{KOH(m)} a_{H_2O(m_r)} a_{H_2(m)}^{1/2}} \quad (2)$$

The reference concentration m_r was held constant at 0.09154 molal for twenty concentrations m of potassium hydroxide ranging from 0.2240 to 17.544 molal. The method employed to eliminate carbonate from the solutions has been described previously.[6] Measurements were made at ten-degree intervals from 0 to 70°; a small linear correction was applied to the observed electromotive force values to correct them to round temperatures.

A critical survey of the vapor pressure measurements of Smits,[7] Tammann,[8] Paranjpe[9] and Kobayashi[10] provided the information necessary for the correction of the observed electromotive forces to unit activity of hydrogen gas in each half-cell. Since all the measurements available were made by the static method, which tends to give too high values because of difficulty in the complete elimination of air from the solutions, somewhat greater weight was assigned to the lower vapor pressure values reported at a given concentration. The resulting correction reached a maximum value of 4.5 millivolts at 70° and 17.54 molal. The corrected electromotive force values are summarized in Table I; the average deviation of the observed points from smoothed values obtained by the method of least squares, assuming a quadratic dependence on the temperature, is less than 0.4 millivolt.

The water transfer potentials

$$\Delta E_{H_2O} = -\frac{RT}{F} \ln \frac{a_{H_2O(m)}}{a_{H_2O(m_r)}}$$

were evaluated by the method suggested by Akerlof and Kegeles[5] and more recently generalized by Stokes.[11] Their validity was checked by comparison with those calculated from the final log a_1 values; the agreement was well within the experimental error of the electromotive force measure-

ments. The conclusion of Harned and Cook[12] that below four molal the water transfer potential is practically constant in the temperature range from 0 to 35° was confirmed.

Thermodynamic Properties of Solutions of Potassium Hydroxide.—The logarithm of the mean ionic activity coefficient of the solute was calculated using the equation

$$\log \gamma = \frac{-u\sqrt{m}}{1+\sqrt{2m}} + Bm + Cm^2 + Dm^3 + Em^4 \quad (3)$$

where u is the universal constant of the limiting law, and B, C, D, and E are empirical coefficients evaluated as functions of the temperature by the method of least squares. A summary of the results of this process is given in Table II. The extension of the calculation to the other thermodynamic properties of solute and solvent in terms of the constants of equation (3) has been given explicitly by Akerlof and Kegeles.[5] Figures 1 and 2 show the dependence on the concentration of log γ and of $(\log a_1)/m$ at the various temperatures at which measurements were made.

Discussion

The first amalgam cell measurements on potassium hydroxide solutions were made at 25° by Ming Chow,[13] who used flowing potassium amalgam and mercury–mercuric oxide electrodes. His results were considered unreliable by Knobel,[14] who repeated the work using hydrogen electrodes instead of the mercury–mercuric oxide type. Knobel's experimental results were subsequently recalculated, taking into account the water transfer potential, by Harned,[15] Scatchard,[16] and Harned and Akerlof.[17] In the latter calculations, in which the extrapolations were based on the Debye–Huckel theory, log γ values were obtained which are in fair agreement with those here reported. More recently amalgam cell measurements covering a concentration range up to four molal at temperatures from 0 to 35° were reported by Harned and Cook.[12] Our results are on the whole in good agreement with theirs over their entire measuring range.

The electromotive force measurements at 25° of Shibata and co-workers[18] are in excellent agreement with ours at hydroxide concentrations up to seven molal with an average deviation of 0.3 mv. between the two sets of results. This comparison suggests that contrary to previous opinion the mercury–mercuric oxide electrode might function reversibly without undesirable side reactions, at least in dilute alkali solutions. At higher concentrations investigated in the two researches greater deviations are observed. In this connection the

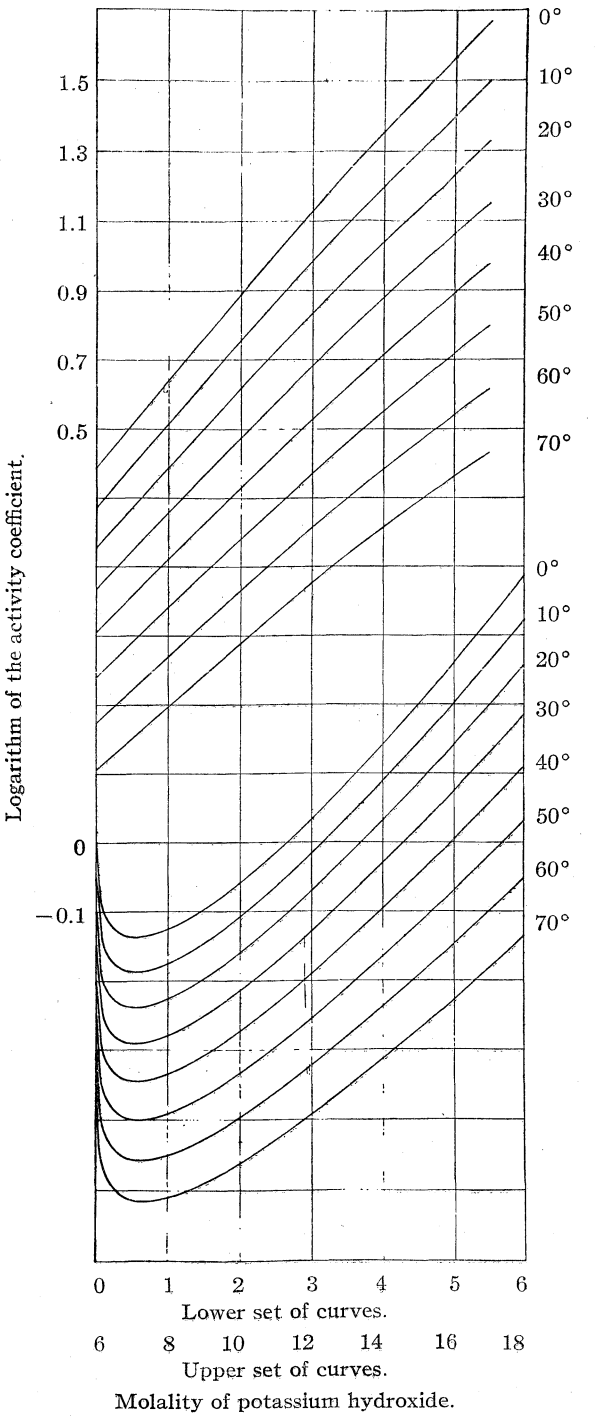

Fig. 1.—Isotherms for the logarithm of the activity coefficient of potassium hydroxide. The curves for the concentration range 6 to 17.5 molal are plotted on half the scale of those for the range 0 to 6 molal. The figures on the ordinates are for 0°; for each 10° rise in temperature the ordinate is shifted by 0.05 for the lower set of curves, and by 0.1 for the upper set.

possibility of specific effects arising in very concentrated hydroxide solutions cannot be ignored.

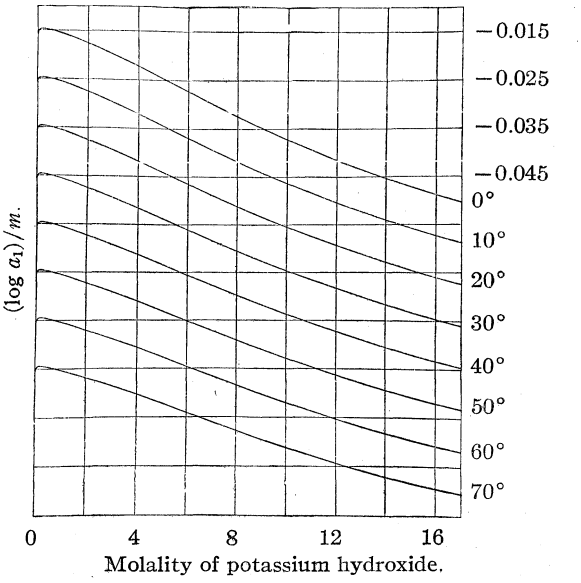

Fig. 2.—Isotherms for the function (log a_1)/m for aqueous solutions of potassium hydroxide. The figures on the ordinates are for 0°; for each 10° rise in temperature the ordinate is shifted by 0.010.

In a comparison of the curves for log γ for sodium and potassium hydroxides and hydrochloric acid we find that with increasing temperature and concentration they approach each other rapidly, the large individual differences observed at lower temperatures and moderate concentrations tending to disappear. A study of the behavior of these curves at concentrations or temperatures considerably above those previously employed would be of great interest.

A direct determination of log a_1 from electromotive force measurements on the cell $Pt,H_2/KOH_{(m)}/HgO\text{-}Hg$ has been attempted by Shibata, Kobayashi and Furukawa,[19] but the values reported by them differ appreciably from ours, which are in good agreement with the available experimental vapor pressure data.

An attempt to determine the relative partial molal heat contents and heat capacities subjects the original data to a very severe test, since the evaluation of these quantities involves the first and second differential coefficients of the original results with respect to the temperature. Values have been calculated for the relative partial molal heat content of the solute and compared with those of Harned and Cook[12] and Rossini,[20] whose computation was based on the calorimetric determinations of Richards and Rowe[21] and Pratt.[22] The calculation gives in both cases what might seem to be only fair agreement. This is due partly to the very high accuracy required in the basic experimental work, and partly to the method of compu-

(22) Pratt, *J. Franklin Inst.*, **185**, 663 (1918).

tation employed. The use of quadratic equations instead of cubic equations for the coefficients of equation 3 changes the value of $\bar{L}_2$ by over 70 calories per mole at a concentration of 2 molal and 18°, although the changes so produced in the values of the coefficients themselves amount to a few tenths of a per cent. at most. Actually the agreement between our results and those obtained by Rossini is quite respectable, as is shown by the following comparison for a temperature of 18°

m	0.09	0.16	0.25	0.36	0.64	1.00	1.44	1.96
$\bar{L}_2$, cal./mole, this study	145	168	186	198	218	242	292	374
$\bar{L}_2$, cal./mole, Rossini	131	145	148	147	147	137	164	207

No direct comparison with the work of Shibata and associates[18] is possible, but from their measurements can be derived values of E and dE/dT for the cell

$$Hg-HgO/KOH(m)/K_xHg/KOH(m_r)/HgO-Hg$$

for which there holds the relation

$$FE - FT\,(dE/dT) = \bar{L}_2(m) - \bar{L}_2(m_r) + {}^1/_2\bar{L}_1(m_r) - {}^1/_2\bar{L}_1(m) \quad (4)$$

Values of the right-hand side of the equation calculated from their data differ by an average of 100 calories from those calculated for the left-hand side from our data, over a concentration range from one to twenty molal at 25°.

In the case of the relative partial molal heat capacity of the solute, our values differ from those of Harned and Cook[12] by an average of only one calorie per degree per mole for concentrations up to four molal in the temperature range from 0 to 25°. The average difference between our results and the direct calorimetric measurements of Gucker and Schminke[23] at 25° is less than three calories per degree per mole.

In the calculation of the relative partial molal entropy of the solute and solvent an interesting result was obtained. At high solute concentrations on each isotherm the values obtained for these quantities were constant within the experimental error, the entropy level for both solute and solvent changing almost linearly with the temperature. This behavior is illustrated for the solute in Fig. 3. The deviations of the entropy changes of the solvent in concentrated solutions from the requirements of the limiting law should be connected with definite structural changes, and they will be of the greatest interest when a more adequate theory is available. The practically constant values obtained for the relative partial molal entropies at high concentrations of potassium hydroxide would seem to suggest evidence for a structural constancy of the solutions over a large concentration range.

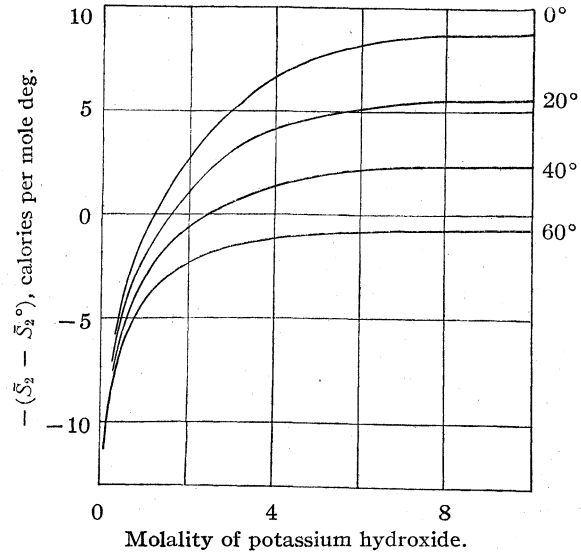

Fig. 3.—Isotherms for the relative partial molal entropy of the solute in aqueous solutions of potassium hydroxide.

Summary

The electromotive force of the cell $Pt,H_2/KOH(m)/K_xHg/KOH(m_r)/H_2,Pt$ has been measured at a number of hydroxide concentrations up to 17 molal over the temperature range from 0 to 70°. Various thermodynamic properties of both solute and solvent were computed and compared with earlier, pertinent data in the literature.

Characterization of Ion Exchange Resins. I. Acidity and Number of Constituent Cation Exchange Groups[1,2]

BY HARRY P. GREGOR AND J. I. BREGMAN[3]

Investigations of the resinous ion exchange process are possible only on an empirical level without a knowledge of the physio-chemical properties of the resins themselves. In order to determine the numbers and kinds of exchange groups making up a resin, two techniques were developed, the first being a direct titration of the resin with base in the presence of neutral electrolyte; the second procedure involved adding to the resin the salt of a weak acid and determining the extent of reaction by back-titration of the buffer. Resins made from known starting materials have been characterized.

Cation exchange resins are high molecular weight polyacids which are virtually insoluble in aqueous and non-aqueous media. The acid or acids which constitute the exchange groups are usually of the sulfonic, carboxylic or phenolic type, and are substituents in the resin structure (usually of the phenol-aldehyde type).[4] Their exchange properties can be ascribed as being entirely due to the exchange of various cations for the dissociable hydrogen ion. Resins of the phenol-sulfonic–phenol–formaldehyde type have been prepared and are commercially available which contain 10% sulfur, and a corresponding exchange capacity of 3.1 mmoles. per gram. Therefore, the $-SO_3H$ group itself must comprise at least 25% of the mass of the resin in the dry state. When the resin is placed in water it swells strongly, usually doubling its weight. Thus approximately 60% of the hydrated mass of the resin is the exchange group itself and the water associated with it. Therefore, a true picture of a cation exchanger is that of a structure containing large polar exchange groups held together by a three-dimensional hydrocarbon network.

If the direct titration of a cation exchange resin in the hydrogen state is attempted, there will be no *p*H change in the external solution until the end-point of the titration is reached if the exchanger contains only strong acid groups. The reaction can be written

$$R—SO_3H + NaOH = R—SO_3Na + H_2O$$

Here the actual titration is taking place within the pores of the resin, and the *p*H changes cannot be measured directly. An exact empirical expression[5] describing the exchange reaction is

$$\frac{(Na^+)_R}{(H^+)_R}\left[\frac{(H^+)_S}{(Na^+)_S}\right]^n = K$$

where the subscripts refer to the resin and external solution phases. Since the ratio of the activity coefficients of univalent cations is nearly equal to unity, concentrations are used in place of activities. If a large excess of a neutral sodium salt is added, the ratio $(Na^+)_R/(Na^+)_S$ becomes small because n is 0.8–1.0 and K is 0.5–2.0 for most resins. The ratio $(H^+)_S/(H^+)_R$ must become very large and virtually all of the hydrogen ions are in the solution phase. Thus the addition of neutral salt displaces an ion into solution upon dissociation, and yields results comparable to those which would be obtained if the resin were soluble. This is also the case for the weak acid resins.

For the buffer titration an acid resin is added to the salt of a weak acid. An excess of neutral salt is also required, and the reaction is

$$R—H + Na^+ + A^- = R—Na + H^+ + A^-$$

where R—H represents the acid resin and HA the weak acid. The number of exchangeable hydrogen ions of the resin equals the moles of hydrogen ions which are displaced at the equilibrium *p*H. The resin is filtered and the solution back-titrated with sodium hydroxide to the initial *p*H of the buffer salt solution; the number of displaced hydrogen ions in the resin is the equivalent of base required at the equilibrium *p*H. A plot of these capacity values as a function of *p*H is the equivalent of the titration curve of the resin acid.

The terms "number of exchangeable" hydrogen ions and the conventional term "exchange capacity" do not necessarily mean the same thing, for the number of cations taken up by a hydrogen exchanger may be greater[6] than the number of hydrogen ions displaced. This may be due to complex ions, and is usually found when polyvalent ions are exchanged.

Experimental

Selection and Treatment of Resins.—The resins were either ones prepared from the patent literature or commercial resins where the procedures for the synthesis were known. Since the chemicals were usually of technical grade, the resins themselves were, as a rule, not of high purity. In addition, the curing treatment which includes heating for prolonged periods at elevated temperatures may partially decompose the resins and introduce new exchange groups. The resins used included: (A) phenol–formaldehyde, alkaline condensed[7]; (B)

phenolsulfonic acid–phenol–formaldehyde, acid condensed[8]; (C) phenolsulfonic acid–phenol–formaldehyde, alkaline condensed[8]; (D) phenol–formaldehyde, alkaline condensed in the presence of sodium sulfite[9]; (E) phenol–formaldehyde, alkaline condensed, cured and dried, then treated with sodium sulfite[9]; (F) salicylic acid–phenol–formaldehyde, alkaline condensed[8]; (G) coal treated with 2 *M* sodium hydroxide at elevated temperatures in a bomb; (H) coal treated with hot concentrated sulfuric acid[10]; (J) polystyrene directly sulfonated with chlorosulfonic acid.[11]

The resins were wet screened to −20 + 30 mesh, and "conditioned," *i. e.*, treated alternately with large excesses of 1 *M* hydrochloric acid and 1 *M* sodium chloride to remove soluble components of the resin and displace any heavy metal cations present. The resins were regenerated, *i. e.*, converted to the hydrogen or acid state by passing a large excess of 1 *M* hydrochloric acid through a bed of the resin very slowly and then rinsed with carbon dioxide free distilled water to an effluent *p*H of 4. Due to resin solubility, *p*H values above 4 are usually not obtained at slow flow rates. The material was then air dried until the particles no longer adhered to one another, and its moisture content determined by drying over phosphorus pentoxide. Air dried resin was used for experiments because the desiccated form is very hygroscopic and frequently decrepitates in water. Resin ground to give particles of a smaller size was regenerated again to remove added impurities and to convert to the acid state any newly available exchange groups.

Direct Titration.—In order to obtain a resin containing different acidic groups, resin K was prepared by sulfonating phenol with an excess of fuming sulfuric acid, adding phenol and a slight excess of formaldehyde and condensing in the acid state. This resin showed an increased exchange capacity with increasing alkalinity, indicating the presence of "weak-acid" capacity.

A number of 0.5-g. portions of resin K were weighed into flasks containing 100 ml. of varying concentrations of sodium chloride made up in doubly distilled water. Different amounts of standard (0.5 *N*) sodium hydroxide were added to each flask, which was then shaken for twenty-four hours and which was sufficient for the establishment of equilibrium, as shown by tests to be described later. The equilibrium *p*H of the solution was measured with a Beckman "high *p*H" glass electrode. All values given hereafter are for 1 g. of moisture-free hydrogen resin.

Experimental values for the direct titration are shown in Fig. 1. These experimental curves, showing a displacement to lower values of *p*H as the neutral salt concentration is increased, are in qualitative agreement with curves calculated using the empirical expression given above.[5] Sodium chloride solutions more concentrated than 0.5 *N* gave the same results as the 0.5 *N* solution.

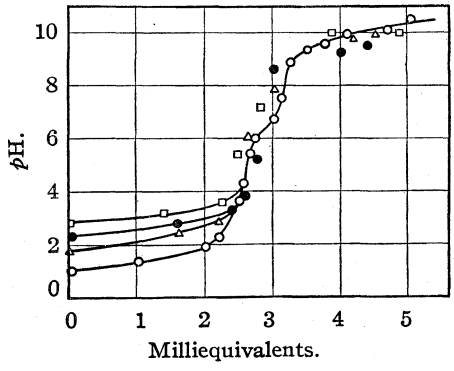

Fig. 1.—Direct titration of resin K with sodium hydroxide in sodium chloride solutions: □, 0.000 *N*; ●, 0.002 *N*; △, 0.028 *N*; ○, 0.500 *N*.

Resin K was also titrated rapidly in 0.5 *N* sodium chloride in the customary manner, and curves for −20 + 30 and −100 mesh material is shown in Fig. 2. The curve for 0.02 *N* hydrochloric acid is included for comparison.

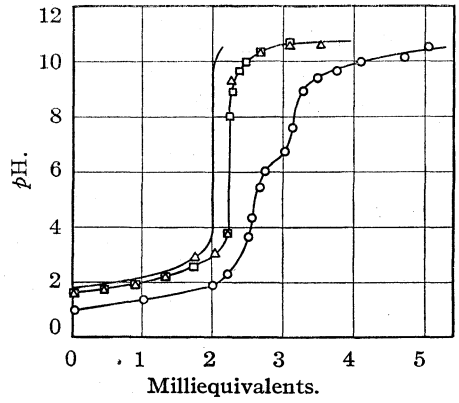

Fig. 2.—Rapid direct titration in 0.5 *N* sodium chloride of resin K: △, −20 + 30 mesh; □, −100 mesh; ○, −20 + 30 equilibrium value; —, 0.02 *N* hydrochloric acid.

Buffer Titrations.—These determinations were carried out by adding 0.5-g. samples of resin K to 100 ml. of 0.02 *M* solutions of sodium salts of weak acids in 0.5 *N* sodium chloride, shaking for twenty-four hours, filtering off resin and back titrating to the original *p*H of the solution with sodium hydroxide. Buffer salts were selected which covered the *p*H range from 3 to 10, and which gave a sharp back titration end-point. These included sodium tartrate, acetate, citrate, monohydrogen phosphate, carbonate and phosphate. The buffer titration curve for resin K is shown in Fig. 3, together with the direct titration curve for the same resin.

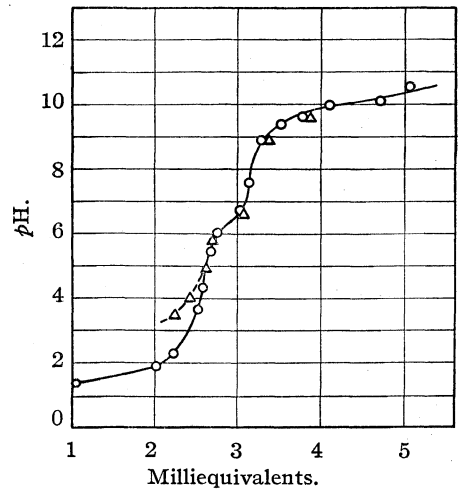

Fig. 3.—Direct (○) and buffer (△) titration curves for resin K.

Several variations of the above procedure were investigated. When sodium salts were replaced with those of lithium and potassium, identical titration curves were found. When the concentration of the buffer salt was varied from 0.01 to 0.1 *M*, the curves were unchanged when corrected to an ionic strength of 0.5. When the

(11) G. F. D'Alelio, U. S. Patent 2,366,007, Dec. 26, 1944.

sodium chloride concentration was made lower than 0.2 *N* the titration curves became altered, presumably because insufficient neutral salt was present to displace all of the dissociated hydrogen ions.

When the −20 + 30 mesh resin was ground to −100 mesh, regenerated and titrated, the titration curve was found to be unchanged. However, when a lot of commercial resin was screened and each fraction tested, wide variations in the results frequently appeared.

The rate of exchange was determined by treating hydrogen resin with 0.5 *N* sodium chloride with rapid stirring, using a glass electrode to measure the rate. After a constant *p*H was reached, the resin was filtered and placed in a 0.02 *M* solution of disodium hydrogen phosphate in 0.5 *M* sodium chloride, and the rate measured as before. At equilibrium the process was repeated with trisodium phosphate. The milliequivalents of hydrogen ion displaced were calculated from the experimental *p*H values, using as a calibration curve the titration of that same buffer salt solution with hydrochloric acid.

While the rate was measured at a variable *p*H value, well defined results were obtained, as shown in Fig. 4 with resin C.

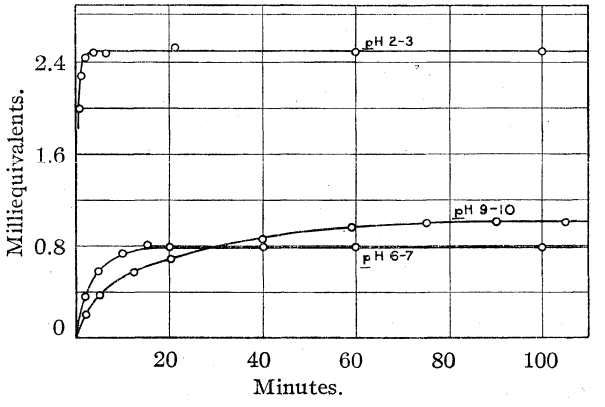

Fig. 4.—Rate of exchange at different *p*H levels for resin C.

Buffer titration curves for a number of different resins are shown in Figs. 5 and 6, the letters adjacent to each curve referring to the resins described earlier.

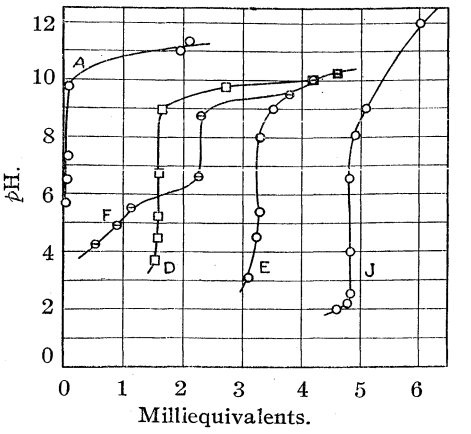

Fig. 5.

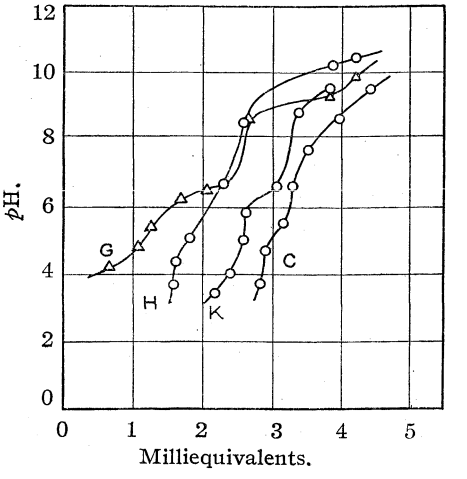

Fig. 6.

Discussion

The direct or buffer titration of a resin, when carried out in an excess of neutral salt, gives results comparable to those that would be obtained if the resin were in true solution. Since the process is one of displacement of the hydrogen ion, the nature of the cation used does not appreciably affect the results when only alkali metal cations are used.

The apparent anomalies in the rate studies can be explained by considering that the strong acid groups, by virtue of their high degree of hydration and large hydrated volume, are surrounded by a more open resin matrix than the smaller, weakly dissociated groups. Therefore the rate of diffusion of the exchanging ion to a strong acid group is greater than for a weak acid group. This is shown by the rate studies in Fig. 4. When the particle is reduced in size by grinding, the fractures probably occur at the wider pores, and the time for reaction of a weak acid group is reduced only by the time required for diffusion into the wider pores. Thus a rapid titration of even a resin of small particle size does not show the presence of weak acid groups. Further studies are in progress to test the validity of this postulate.

The electro-chemical nature of the acidic groups does not seem to be strongly affected by their being a part of the resin structure. The phenolic group has a *pKa* value of approximately 10, and the carboxyl group has a *pKa* value of 5.5. Resins prepared using sodium sulfite do not show the diverse groups which appear in the sulfonated resins, presumably as a result of the oxidizing sulfonating procedure. The two cation exchangers not of resinous nature show titration curves compatible with their preparative procedures. The gradual slopes of their curves indicate the complex nature of these natural products.

A true cation exchange resin can now be defined as a solid phase containing dissociable cations which will exchange for any other cation independently of the nature of the anion of the exchanging cation in solution. A base absorbent is a solid phase containing dissociable cations which will exchange for any other cation only when weak acid anions or hydroxyl ions are the anions of the exchanging cation in solution. A comparable

definition would restrict true cation exchange resins to those which contain only completely dissociated acidic groups, *i. e.*, strong acid resins.

Chain Transfer in the Polymerization of Styrene. II. The Reaction of Styrene with Carbon Tetrachloride[1]

BY R. A. GREGG AND FRANK R. MAYO

Using literature data on the uncatalyzed polymerization of styrene, a previous paper[2] from this Laboratory showed that the effects of solvents in reducing the molecular weight of polymerizing styrene could be correlated on the basis that the growing polymer radical captures an atom from the solvent molecule, resulting in a radical which starts a new chain[3] and in the incorporation of solvent in the polymer. Since these relations promised to be useful in making quantitative comparisons of the reactivities of solvents toward free radicals, a thorough test of the equations and concepts on the styrene–carbon tetrachloride system was begun. The present paper considers both the uncatalyzed and peroxide-catalyzed polymerization of styrene at 60–132° to give products averaging more than thirty styrene units per polymer molecule, or per incorporated carbon tetrachloride molecule. A succeeding paper[4] will consider formation of products averaging as low as two styrene units per carbon tetrachloride residue.

Experimental

Purification of Materials.—Dow styrene was freed from inhibitor by vacuum distillation and the middle fractions were partially crystallized by stirring in a Dry Ice-bath. The process was repeated from six to eight times until the freezing point became constant. The recrystallized material was distilled under nitrogen: b. p. 44.9–50° at 18 mm.; $n^{20}D$ 1.5465; f. p. −30.7° ± 0.1°. The styrene was stored in sealed, evacuated tubes in Dry Ice.

Reagent grade carbon tetrachloride was stirred with concentrated sulfuric acid and then with potassium hydroxide solution, washed with water, and dried over calcium chloride. It was distilled from paraffin wax[5] through a 1-meter helices-packed column: b. p. 76.8° at 760 mm.; $n^{20}D$ 1.4605.

Benzoyl peroxide was twice dissolved in cold chloroform and precipitated by pouring into cold methanol, collected on a sintered glass filter, and dried under vacuum at room temperature. It liberated 100.0–100.4% of the theoretical quantity of iodine from potassium iodide in glacial acetic acid.[6]

Preparation of Polystyrene Samples.—Weighed amounts of carbon tetrachloride and styrene (and benzoyl peroxide, when used) were placed in a flamed Pyrex tube equipped with a standard taper joint. The tube was attached to the vacuum line and the sample was frozen in liquid nitrogen. The tube was then evacuated and the sample was degassed twice by thawing and refreezing. The tube was then sealed at a pressure of 10^{-5} mm. Check experiments in which both the solvent and the styrene were distilled under high vacuum into the reaction tube showed no difference, even with large volumes of other solvents. The polymerizations were carried out in thermostats at 60 ± 0.05°, 100 ± 0.1°, and 132 ± 1°, and held to about ten per cent. conversion.

The polymer was precipitated with methanol and redissolved in twenty-five to fifty times its weight of benzene. This solution was then treated with three to five times its volume of methanol. An additional solution and precipitation was used for many of the samples whose molecular weights were determined osmometrically. The decanted precipitating medium was usually centrifuged to obtain any suspended polymer. The polymer was dissolved in benzene; the solution was frozen in Dry Ice, and the benzene was removed by sublimation.[7]

The above procedure results in loss of some of the very low molecular weight polystyrene; where the average molecular weight of the polymer was low, some of the precipitating solutions were rapidly concentrated by distillation *in vacuo* and the residue was dissolved in benzene and added to the main portion of the polymer. This procedure permits distillation of monomer from a *small* amount of *low* molecular weight polymer instead of from the whole polymer and gave products, marked in Table I, with appreciably lower average degrees of polymerization.

Determination of Number Average Molecular Weights from Osmotic Pressure.—These determinations were made by Drs. R. H. Ewart, H. C. Tingey and M. Wales.[8] The osmotic pressures were measured either in glass[9] or metal osmometers[10] with cellophane membranes and at three or more concentrations. Either butanone or benzene was used as the solvent, with identical end results.

Viscosity Determinations.—Solution viscosities were determined in benzene at 30°, using Fenske viscometers with 80–120 second flow times and neglecting kinetic energy corrections. Such corrections would give an increase of about 5% in intrinsic viscosities but would not affect the present molecular weight estimates from viscosity data. Where the molecular weight was determined independently, the intrinsic viscosity,[11] $[\eta]$, was obtained from specific viscosities at three or more polymer concentrations. Otherwise, the intrinsic viscosity was obtained from the specific viscosity of a single solution, measured in two

different viscometers, and the equation

$$[\eta] = \frac{\sqrt{1 + 1.5\eta_{sp}} - 1}{0.75C_v} \qquad (1)$$

where C_v is the grams of polymer per 100 cc. of solution at the temperature of the viscosity measurement.

Chlorine Determinations (by Dr. O. W. Lundstedt and Mr. G. S. Mills).—For the determination of very small proportions of chlorine, the method of Shriner[12] was modified. A 20 mm. i. d., 80-cm. Vycor tube was heated in a furnace to about 800°. The tube had a 15 cm. section of crushed platinum foil in the hottest portion of the furnace and the remainder of the tube was packed with crushed Vycor interspersed with 50-mesh platinum disks. Oxygen, at a rate of 20 cc. per minute, was used to burn the sample which was heated by a mechanically-advanced auxiliary furnace. The products were absorbed in 5 ml. of 3% hydrogen peroxide and 1 ml. (20 mg.) of sodium acetate solution contained in a six bulb Will-Varrentrapp type absorber. The sample size was such that 2–10 ml. of silver nitrate were required. The halogen was titrated with 0.01 *N* silver nitrate in 50% acetone solution with dichlorofluorescein indicator according to the recommendations of Bullock and Kirk.[13] Blanks were negligible and analysis of a known sample agreed with the theoretical within two parts per thousand.

Results and Discussion

The Relation between Intrinsic Viscosity and Number Average Molecular Weight for Unfractionated Polystyrene.—In order to permit molecular weight determinations on unfractionated polystyrenes from viscosity measurements, the relation between number average molecular weight, $\overline{M}_n$, and intrinsic viscosity, $[\eta]$, was determined. Molecular weights of polystyrenes by osmotic pressure determinations in the molecular weight range 50,000–600,000 and by chlorine analyses in the range 10,000–200,000 are compared with intrinsic viscosities in Table I and Fig. 1. The figure shows that, within experimental error, over the range 10,000–600,000

$$\overline{M}_n = 184{,}000\ [\eta]^{1.40} \qquad (2)$$

and this relation was used to calculate number average molecular weights in all experiments where viscosities were determined.[14] Equation (2) is applicable only to polystyrenes prepared at low conversions where the molecular weight distribution is uncomplicated by changing solvent–monomer ratio or branching reactions.[15] The relation is apparently independent of the chain transfer solvent[8,14] and temperature.[16]

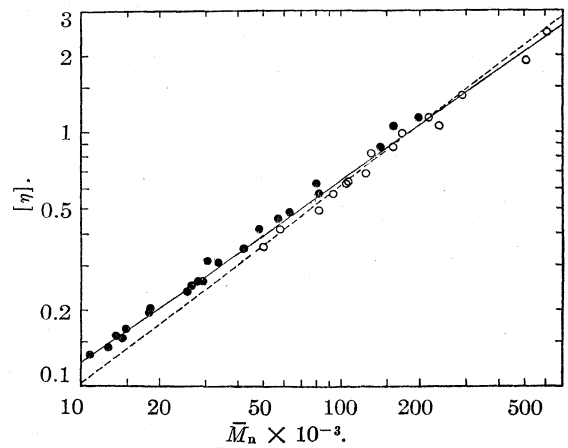

Fig. 1.—Relation between intrinsic viscosity, $[\eta]$, and number average molecular weight, $\overline{M}_n$, for unfractionated polystyrenes prepared at 60°, 100°, and 132° in presence of carbon tetrachloride: $\overline{M}_n$ by osmotic pressure, O, by chlorine analysis, ●. Solid line corresponds to Equation (2), broken line to older equation.[14]

Transfer Constant of Carbon Tetrachloride in the Thermal Polymerization of Styrene.—Table I summarizes results on the uncatalyzed polymerization of styrene in carbon tetrachloride. The reactions involved were discussed previously[2] and it was shown that

$$1/\overline{P} = C[S]/[M] + 1/\overline{P}_0 \qquad (3)$$

(13) Bullock and Kirk, *Ind. Eng. Chem., Anal. Ed.*, **7**, 178 (1935).

(14) A large number of osmotic determinations on polystyrenes of molecular weight 50,000–600,000, prepared in various other solvents, without catalysts at three temperatures and with benzoyl peroxide at 60°, had indicated the relation[5]

$$\overline{M}_n = 184{,}000\ [\eta]^{1.277}$$

used previously by Gregg and Mayo, *Trans. Faraday Soc.*, **43B**, in press (1947). For molecular weights above 50,000, the two equations give substantially the same results.

(15) Equation 2 is based upon polystyrenes with a distribution function (assumed to be) governed by termination through chain transfer and disproportionation and with the termination steps independent of chain length. If polystyrene chains in the absence of solvent terminate by combination of radicals, then $\overline{P}_0$ values calculated from intrinsic viscosities and Equation 2 should be too low by about 20%. However, osmotic determinations on polymers from pure styrene at 100 and 132° give $\overline{P}_0$ values agreeing with those calculated from Equation (2). For 60° polymers, osmotic determination of $\overline{P}_0$ is impractical, but plots of $1/\overline{P}$ (from osmotic determinations) against solvent:monomer ratio extrapolate to the $1/\overline{P}_0$ value calculated from intrinsic viscosity. The data thus reveal no different distribution of molecular weights in the absence of solvent.

(16) Similar equations have been proposed for polystyrene fractions and an effect of temperature of preparation of the polymer has been reported, Alfrey, Bartovics and Mark, THIS JOURNAL, **65**, 2319 (1943).

where $\overline{P}$ and $\overline{P}_0$ are the degrees of polymerization of styrene, in the presence and absence of solvent, respectively, at solvent and monomer concentrations [S] and [M], and where C, the transfer constant, is the ratio of the rate constants for chain transfer and chain growth for all polystyrene radicals. An effort was made to hold reaction of the styrene to 10% or less. The small variation in over-all second order rate constant with solvent:monomer ratio shows that the thermal reaction is not seriously complicated by traces of catalysts and justifies the assumption in deriving Equation (3) that the rate constants for chain initiation, growth, and termination do not change significantly with solvent or chain length.

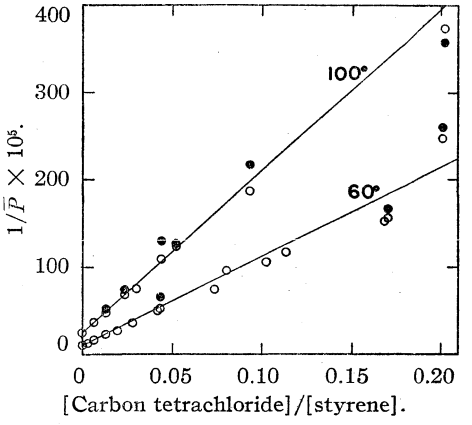

Fig. 2.—Thermal polymerization of styrene in carbon tetrachloride: $1/\overline{P}$ from intrinsic viscosity, O; from chlorine analysis, ●.

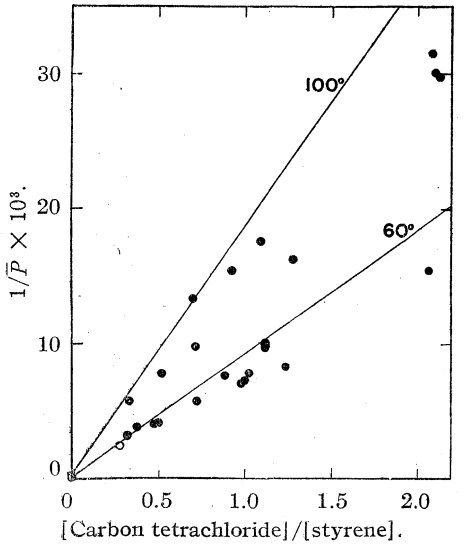

Fig. 3.—Thermal polymerization of styrene in carbon tetrachloride: $1/\overline{P}$ from intrinsic viscosity, O; from chlorine analysis, ●.

Except for low degrees of polymerization, where the proportion of monomer consumed in starting polymer chains cannot be neglected[4]

$$C[\mathrm{S}]/[\mathrm{M}] = \mathrm{d}[\mathrm{S}]/\mathrm{d}[\mathrm{M}] \quad (4)$$

where d[S]/d[M] is the molar ratio of solvent to monomer in the polymer being formed. The average degree of polymerization and number average molecular weight, $\overline{M}_n$, in Table I are calculated from chlorine analyses by the relations

$$\mathrm{d}[\mathrm{S}]/\mathrm{d}[\mathrm{M}] = 104.14/[(14183/\%\ \mathrm{Cl\ in\ polymer}) - 153.84] \quad (5)$$

$$1/\overline{P} = \mathrm{d}[\mathrm{S}]/\mathrm{d}[\mathrm{M}] + 1/\overline{P}_0 \quad (6)$$

$$\overline{M}_n = 104.14\,\overline{P}(1 + 153.84\,\mathrm{d}[\mathrm{S}]/104.14\,\mathrm{d}[\mathrm{M}]) = 104.14\,\overline{P}/(1 - 0.01085\%\ \mathrm{Cl}) \quad (7)$$

$\overline{M}_n$ is also determined from intrinsic viscosity by Equation (2); then

$$1/\overline{P} = (104.14\text{–}153.84/\overline{P}_0)/(\overline{M}_n - 153.84) \backsimeq 104/(\overline{M}_n - 154) \quad (8)$$

The transfer constant, C, is calculated from Equations (3) or (4).

Since, in each experiment, the styrene concentration decreases appreciably while the carbon tetrachloride concentration does not, *average* solvent:monomer ratios have been used in all calculations and plots. Calculations of transfer constants in Table I are based on all chlorine analyses and on intrinsic viscosities above 0.35 (where they have been standardized against osmotic molecular weights) and in Figs. 2 and 3 the same data for 60 and 120° runs have been plotted for graphical determination of transfer constants. The lines in Figs. 2 and 3 are based on experiments with solvent:monomer ratios below 0.4 and other experiments where low molecular weight material was recovered after polymer precipitation. The slopes of the lines are the transfer constants for carbon tetrachloride with styrene at 60° and 100°, 0.0092 (±0.0010) and 0.0185 (±0.0022), respectively, the experimental error being taken as the standard deviation of the transfer constants in Table I for those experiments on which the lines were based. The two 1:1 experiments at 60° where low molecular weight material was recovered fall slightly below the line only because of the failure of Equation (3) to apply to low degrees of polymerization and the failure of the shortest radicals to transfer normally,[4] but only part of the deviation of the best 100° experiments can be ascribed to these causes. Almost all other experiments at 60° and 100° at solvent:monomer ratios above 0.4 show the effects of loss of low molecular weight material in precipitating polymer. The linear relation between solvent:monomer ratio and $1/\overline{P}$ is taken as proof that the transfer constant, the ratio of the rate constants for chain transfer and chain growth, is substantially constant for radicals averaging 100–10000 styrene units.

The transfer constant at 132° is taken as the average of the six values in Table I, 0.0304 (±0.0023). From the values of the transfer con-

stant at 60, 100, and 132°, the activation energy for chain transfer is found to be about 4.5 kcal./mole higher than for chain growth and the frequency factor for transfer is then about eight times as large as for growth.

The reaction mixture in the last listed experiment at 100° was diluted with five volumes of benzene, which, in comparison with carbon tetrachloride, is substantially inert in chain transfer.[2,14] Since the rate of reaction and the molecular weight of the product were entirely consistent with the other experiments, the use of an inert diluent is justified in the experiments in Table II.

Transfer Constants from Peroxide Initiated Polymerizations.—In order to extend quantitative work on chain transfer to other monomers and to very low styrene concentrations, where uncatalyzed rates are very small or difficultly reproducible, the benzoyl peroxide–catalyzed polymerization of styrene was investigated. The relation between monomer and peroxide concentration and rate and degree of polymerization seems well established[17,18] and has recently been interpreted by Matheson[19] in this Laboratory. Matheson's equations and previous methods[2] have been used to derive Equation (9)

$$1/\bar{P} = C\frac{[S]}{[M]} + \frac{2(k_a k_3\,[\text{peroxide}])^{1/2}}{k_2[M]}\left(\frac{k_c[M]}{k_b + k_c[M]}\right)^{1/2} \quad (9)$$

Here k_a, k_b and k_c are, respectively, the rate constants for the primary dissociation of peroxide into radicals, the first order recombination of radicals from the peroxide, and the reaction of these radicals with styrene; k_2 and k_3 are the rate constants for chain growth and termination. Uncatalyzed initiation is neglected and the final factor is the fraction of peroxide radicals which initiate chains. This development assumes that the rate constants concerned are independent of the composition of the polymerizing system, a condition which is met in Table II, as shown by the over-all rates. The condition may not be met when the decomposition of the peroxide is affected by the solvent.[20] This equation may be applied for low conversions under either of two sets of conditions. If solvent and monomer concentration are kept constant while the peroxide concentration is varied, C is obtained from the intercept of the line formed by plotting $1/\bar{P}$ *vs.* $[\text{peroxide}]^{1/2}$. This method has thus far given poor results partly because of the extrapolation involved and the necessity for keeping conversions low and equal.

If the concentrations of both monomer and peroxide are held constant, C is the slope of the line formed by plotting $1/\bar{P}$ *vs.* [S]/[M]. Table II and Fig. 4 illustrate this method, benzene being used as an inert diluent. The slope of the line (determined by the least squares method, assuming no error in [S]/[M]) and the transfer constant are 0.0093, in excellent agreement with the value obtained in thermal polymerization. This method may be applied to monomers or solvents which cannot be freed of peroxides and to monomers which themselves undergo chain transfer.

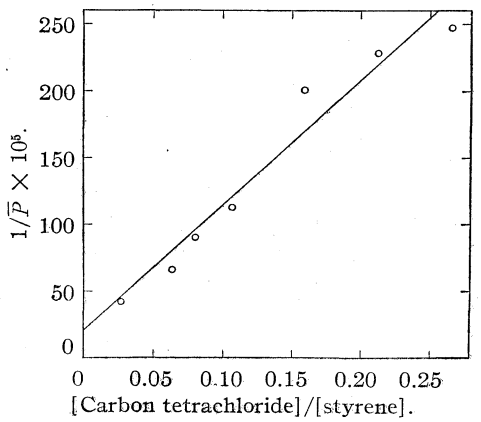

Fig. 4.—Benzoyl peroxide catalyzed polymerization of styrene in presence of carbon tetrachloride at 60°.

Summary

The polymerization of styrene in carbon tetrachloride has been studied over the temperature range 60–132°, over a range of solvent:monomer ratios from 0.003 to 3, and in the presence and absence of benzoyl peroxide as catalyst. Equations are presented which account for the average molecular weights (2500 to 1,000,000) of the products obtained. At 60°, the rate constant for the reaction of a growing polymer radical with carbon tetrachloride is 0.0092 times as large as the rate constant for addition of the radical to styrene. The temperature coefficient of this ratio shows that the chain transfer reaction has both a higher activation energy and a higher frequency factor. The constancy of this ratio and of the over-all rate con-

stant for polymerization indicate that the reactions of the growing polymer radical are independent of average chain length over the range 100 to 10,000 styrene units. The results establish the validity of a simple and accurate method for comparing the reactivities of solvents in general with the free radicals which occur in polymerizing systems.

Number average molecular weights of the products of thermal polymerizations of styrene at low conversions have been determined by osmotic pressure measurements and by chlorine analyses; they bear a simple relation to the intrinsic viscosities of the unfractionated polymers.

Monomers and Polymers. IV. Vinylthiophenes[1,2]

BY G. BRYANT BACHMAN AND LOWELL V. HEISEY

The desirable polymerization and copolymerization characteristics of the chlorinated styrenes[3] and alpha-methylstyrenes[2b] have suggested studying their analogs in the thiophene series. We have synthesized a representative group of compounds with one, two or three chlorine or bromine atoms and an alpha- or beta-vinyl or isopropenyl group substituted on the thiophene nucleus. These compounds have been found to polymerize and copolymerize similarly to the corresponding benzene compounds, the rates increasing with the number of chlorine atoms present on each thiophene nucleus. The polymers were all somewhat colored, however, in spite of careful purification of the monomers. This seems to be inherent in the alpha-halothiophenes themselves. Even 2-chlorothiophene, which is color stable in stoppered tubes at 70° for days, colors within a few hours at this temperature in the presence of peroxides.

The preparation of vinylthiophenes is a problem very similar in nature to that of preparing vinylbenzenes except that the thiophene nucleus is more reactive, less stable, and subject to different rules of orientation than the benzene nucleus. We have been especially interested in observing the results of exchange metallation in the thiophene series. Either an alpha-hydrogen or an alpha-halogen may be replaced by lithium when treated with alkyllithium compounds. Thus 2-chloro-, 2,5-dichloro- and 2,3,4,5-tetrachlorothiophenes gave the corresponding metallo-derivatives with lithium in the 2-position and chlorine in the 5-, 5- and 3,4,5-positions, respectively. Magnesium reacted with 2,5-dibromothiophene normally, but with 2-bromo-5-chloro- and with 2,3,4,5-tetrachlorothiophenes it reacted well only in the presence of a co-halide (ethyl bromide). These lithium reagents and the corresponding Grignard reagents gave alcohols (Table I) with acetaldehyde, propionaldehyde, or acetone which were readily dehydrated to the desired vinylthiophenes (Table II). Some of the tertiary alcohols dehydrated spontaneously during isolation. Other vinylthiophenes were prepared from the corresponding methyl thienyl ketones by reduction or by reaction with methylmagnesium halide followed by dehydration of the resulting alcohols.

α-Methylstyrenes with ortho halogen atoms have been shown[2b] not to polymerize or copolymerize freely, a fact which is attributed to the steric hindrance to free rotation of the isopropenyl group provided by the ortho substituent. This hindrance is not as extreme in the thiophene series. The angles between adjacent positions amount to about 72° for five-membered rings and only about 60° for six-membered rings. Models show that the isopropenyl group in 2,5-dichloro-3-isopropenylthiophene is free to rotate about a full circle, and in agreement with the model and the theory this vinyl compound copolymerizes satisfactorily with butadiene in an emulsion system. That it is a borderline case is indicated by the fact that its bulk polymer with maleic anhydride and its emulsion polymer with styrene were obtained in only small yields (about 5%).

Acknowledgment.—We wish to express our appreciation to the Purdue Research Foundation and to the General Tire and Rubber Company for financial support in the form of a fellowship.

Experimental

Unsubstituted Vinylthiophenes.—2-Vinylthiophene has been previously reported.[4] 2-Isopropenylthiophene was prepared by adding 2-acetylthiophene to an ether solution of methylmagnesium bromide (a different method from that used by Thomas[5]), and steam distilling the unstable hydrolyzed product with 2% sulfuric acid.

Anal. Calcd. for C_6H_6S: C, 67.7; H, 6.5. Found: C, 67.7; H, 6.5.

5-Bromo-2-vinylthiophenes.—2,5-Dibromothiophene,[6] 182 g. (0.75 mole), in 250 ml. of dry ether was converted to the mono-Grignard reagent with 18.3 g. (0.75 mole) of magnesium. Benzene, 200 ml., caused the ether-insoluble red oil to dissolve. Addition of acetaldehyde 34 g. (0.77 mole) or acetone 43.5 g. (0.75 mole) and hydrolysis with dilute acetic acid gave the corresponding alcohols mixed

[a] T stands for thienyl. Parenthetical numbers give positions of vinyl groups. [b] Methods of preparation: A, spontaneous dehydration of the alcohol prepared from 5-bromo-2-thienylmagnesium bromide and RCOR′; B, dehydration of the corresponding alcohol over activated Al_2O_3 at 300°; C, dehydration of the corresponding alcohol by heating with $KHSO_4$; D, dehydration of the alcohol from 2-acetylthiophene and CH_3MgX. [c] Reported by Thomas,[5] b. p. (727 mm.) 166–167°.

with their dehydration products. The mixtures were steam distilled with 2% sulfuric acid and the vinyl derivatives rectified and isolated with 34% and 53% yields, respectively. Their properties are listed in Table II.

2-Bromo-5-chlorothiophene.—2-Chlorothiophene, 118.6 g. (1.0 mole), in carbon disulfide, 200 ml., was brominated with 160 g. (1.0 mole) of bromine at 0°. After twenty-four hours the mixture was decolorized with 5% sodium sulfite solution, the solvent removed, and the residue heated on a steam cone with 5% sodium hydroxide solution for four hours. Rectification of the product through a short column gave 147 g. (74.6% yield) of a colorless liquid, b. p. (18 mm.) 69.5–70.0°; m. p. −22° to −20°; $n^{25}D$ 1.5924; d^{25}_{25} 1.803.

Anal. Calcd. for C_4H_2SClBr: C, 24.33; H, 1.00. Found: C, 24.31, 24.42; H, 1.19, 1.30.

5-Chloro-2-vinylthiophenes:—**(A) From 2-Chlorothiophene.**—A solution of 11.9 g. (0.1 mole) of 2-chlorothiophene in 25 ml. of dry ether was added at 0° to a solution of butyllithium prepared from 1.80 g. (0.26 mole) of lithium and 11.1 g. (0.12 mole) of *n*-butyl chloride in 45 ml. of dry ether. The resulting light yellow suspension was refluxed for six hours and then carbonated with Dry Ice to determine the structure of the lithium compound. A 10.4-g. yield (65%) of 5-chloro-2-thiophenecarboxylic acid,[7] m. p. 150–152°, was obtained. Similar solutions prepared with five to ten times as much of each reactant were treated with one and a half molar quantities of acetaldehyde, propionaldehyde and acetone, respectively, at 0°. The resulting mixtures were stirred for two hours at room temperature, hydrolyzed by dropwise addition of 10% aqueous sodium carbonate, and the organic materials separated, ether-extracted and fractionated under reduced pressure. The alcohols were colorless oily liquids.

Attempts to convert 2-chlorothiophene to 5-chloro-2-thienylmagnesium bromide by exchange metallation with ethylmagnesium bromide in boiling ether or benzene were unsuccessful. No ethane was evolved within two hours and carbonation with Dry Ice gave only propionic acid and recovered dichlorothiophene.

(B) From 2-Acetyl-5-chlorothiophene.—Reduction of 2-acetyl-5-chlorothiophene with aluminum isopropoxide and fractional distillation of the product gave a 71% yield of 5-chloro-2-(1′-hydroxyethyl)-thiophene.

(7) "Thiophene Chemicals," Socony-Vacuum Oil Co., Inc., New York, N. Y., 1946.

Treatment of 2-acetyl-5-chlorothiophene with methylmagnesium halide gave 5-chloro-2-isopropenylthiophene but none of the corresponding alcohol.

(C) From 2-Bromo-5-chlorothiophene.—The Grignard reagent from 29.0 g. (0.4 mole) of 2-bromo-5-chlorothiophene in 150 ml. of ether was treated with 26 g. (0.6 mole) of acetaldehyde in 100 ml. of ether and 150 ml. of benzene. The mixture was refluxed half an hour, worked up and distilled to obtain 6 g. (0.04 mole) of 5-chloro-2-vinylthiophene, 15 g. (0.11 mole) of 5-chloro-2-(1′-hydroxyethyl)-thiophene and 1.0 g. (0.02 mole) of 5,5′-dichloro-2,2′-dithienyl, m. p. 107–109.[8] Later attempts to prepare this Grignard reagent directly were unsuccessful, and it was found better to use a cohalide (ethyl bromide).

(D) From 2,5-Dichlorothiophene.—Carbonation of 5-chloro-2-thienyllithium prepared from about 0.3 mole of butyllithium and 30.6 g. (0.2 mole) of 2,5-dichlorothiophene gave a 63% yield of 5-chloro-2-thiophenecarboxylic acid, indicating the feasibility of preparing 5-chloro-2-vinylthiophenes by this approach. The method was not applied, however, because satisfactory results were obtained by the simpler syntheses already indicated.

The alcohols prepared by these syntheses were dehydrated as indicated in Table II. Dehydrations over alumina were accomplished in a furnace which consisted of a vertical, electrically heated, 25 mm. × 50 cm. Pyrex reaction tube packed with 4–8 mesh alumina. The top of the tube had two dropping funnels, one for the alcohol and the other for solvent to flush the system. The bottom of the reaction tube was connected to a water aspirator through a water-cooled condenser and a trap immersed in a Dry Ice–trichloroethylene bath. The alumina was activated before use by drawing a slow stream of air through it at 500° overnight.

The dehydrations were conducted by dissolving the alcohols in an equal volume of dry benzene and passing the solution through the furnace at 300° and 30–100 mm. at the rate of 100 ml. per hour. A similar amount of benzene was passed through the furnace after the main fraction to flush the system, and one hour was allowed for drainage before the product was removed.

Dehydrations with potassium hydrogen sulfate catalyst were done at a pressure which permitted dehydration but not distillation of the alcohol. The yields by this method were good only for the tertiary alcohols.

Trinitrobenzene was regularly used as an inhibitor to polymerization in distilling the vinyl compounds.

The 2,5-Dichloro-3-vinylthiophenes.—3-Acetyl-2,5-dichlorothiophene was prepared by the method of Steinkopf and Köhler[6] but their yield (16%) was greatly improved (to 84%) by using carbon disulfide as solvent instead of petroleum ether. The Perrier technique[4] gave only 57% yields in carbon disulfide. Hypochlorite oxidation of the above ketone gave 2,5-dichloro-3-thiophenecarboxylic acid.[8a]

Aluminum isopropoxide reduction of 3-acetyl-2,5-dichlorothiophene gave on distillation 2,5-dichloro-3-(1′-hydroxyethyl)-thiophene (90%). Treatment of the ketone with methylmagnesium halide gave 2,5-dichloro-3-(2′-hydroxyisopropyl)-thiophene (93%).

The above alcohols were dehydrated satisfactorily to the corresponding vinyl compounds in the vapor phase over alumina at 300°.

The 3,4,5-Trichlorovinylthiophenes.—2,3,4,5-Tetrachlorothiophene, 5.56 g. (0.025 mole), was added to a filtered solution of butyllithium (0.03 mole) in 50 ml. of ether. Refluxing for four hours, carbonation with Dry Ice, and isolation of the product gave 3.2 g. (55.4% yield) of 3,4,5-trichloro-2-thiophenecarboxylic acid, m. p. 223–224° (reported,[9] m. p. 224°).

Conversion of 2,3,4,5-tetrachlorothiophene to a Grignard reagent using a cohalide (C_2H_5Br) proceeded less satisfactorily. Reaction of either metallo derivative with acetaldehyde or with acetone instead of Dry Ice gave the desired alcohols. These were dehydrated at 300° over alumina. Other methods were unsuccessful.

Polymerization Studies.—Small samples of the vinyl compounds described were polymerized alone and with styrene, methyl methacrylate, vinyl acetate and maleic anhydride by heating at 70° in 3-inch test-tubes with 0.5% of benzoyl peroxide. The propenyl compound did not polymerize or copolymerize. The isopropenyl compounds did not polymerize alone but did copolymerize. However those compounds with the isopropenyl group in the 2-position and with a halogen in the 5-position polymerized on long exposure to sunlight. It is believed that this is the result of a partial photochemical decomposition yielding hydrogen halides which are known to catalyze the polymerization of isopropenylbenzene. The vinylthiophenes polymerized and copolymerized normally.

Rubbery copolymers with butadiene were prepared in a typical GR-S type emulsion system containing: butadiene 7.5 g., olefin 2.5 g., water 17.5 g., potassium persulfate 0.03 g., lauryl mercaptan 0.06 g. and soap 0.5 g. These copolymerizations were run in sealed tubes rotating in a water-bath at 40° until no further change occurred as evidenced by cessation of fall of the liquid meniscus in the tube. Evidence of copolymerization was determined by the amount and character of the precipitated and acetone-extracted copolymer. Satisfactory rubbers were obtained from all of the vinyl compounds except the 5-chloro-2-propenylthiophene, which did not copolymerize, and the 3,4,5-trichloro-2-isopropenylthiophene, which was not studied.

The copolymers of 2,5-dichloro-3-isopropenylthiophene were of especial theoretical interest and were therefore purified and analyzed. The product with styrene, obtained through an emulsion polymerization at 40–60° for three weeks, was precipitated with aqueous sodium chloride, washed with methanol, and extracted continuously with acetone for eight hours. The residue (5%) was a white powder.

Anal. Calcd. for $(C_8H_8 \cdot C_7H_6SCl_2)_x$: Cl, 23.9. Found: Cl, 21.47, 21.24.

The product with maleic anhydride, obtained through a bulk polymerization of the reactants at 70° for one month, was extracted continuously with benzene for six hours. The residue (5%) was a white powder.

Anal. Calcd. for $(C_4H_2O_3 \cdot C_7H_6SCl_2)_x$: Cl, 25.4. Found: Cl, 19.08, 18.84.

The product with butadiene, obtained in 90% yield in sixty-six hours as described above, was a brown rubbery solid.

Anal. Calcd. for $(3C_4H_6 \cdot C_7H_6SCl_2)_x$: Cl, 9.01. Found: Cl, 9.27, 9.14.

These data indicate that copolymerization occurred.

Summary

A number of halogenated thiophene alcohols have been prepared and dehydrated to the corresponding vinyl halogenated thiophenes in order to study the polymerization and copolymerization characteristics of these olefins.

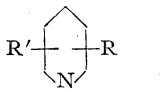
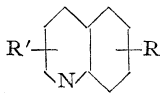
Monomers and Polymers. V. Vinylpyridines and Vinylquinolines[1,2]

BY G. BRYANT BACHMAN AND D. DONALD MICUCCI

The examination of synthetic rubbers prepared by the copolymerization of butadiene with various olefins has shown that the nature of the olefin exerts a considerable influence on the properties of the rubbers obtained. Relative to butadiene–styrene rubbers the butadiene–dichlorostyrene rubbers are more easily milled and processed and show better hot tensile strength. The butadiene–vinylpyridine rubbers are outstanding in tensile strength but are nervy and tough and mill poorly. It was hoped that, by combining the effects of halogen atoms and heterocyclic nuclei in the same molecule, monomers might be obtained which would give rubbers of outstanding value. The present paper reports the preparation of vinylpyridines and vinylquinolines, some of which contain nuclearly substituted halogen atoms, and describes preliminary experiments to determine the polymerizing and copolymerizing characteristics of each. The following compounds were studied.



I, R = 2-C(CH$_3$)=CH$_2$, R′ = H
II, R = 3-C(CH$_3$)=CH$_2$, R′ = H
III, R = 3-C(CH$_3$)=CH$_2$, R′ = 5-Br
IV, R = 3-CH=CH$_2$, R′ = 5-Br
V, R = 3-C(CH$_3$)=CH$_2$, R′ = 5-Cl



VI, R = 2-CH=CH$_2$, R′ = H
VII, R = 2-CH=CH$_2$, R′ = 6-Cl
VIII, R = 2-C(CH$_3$)=CH$_2$, R′ = H
IX, R = 2-C(CH$_3$)=CH$_2$, R′ = 6-Cl

Of these I,[3,4] II[5] and VI[6,7] have been prepared previously by others, but their polymerization characteristics are not reported. Compound VII was not obtained as a monomer since it polymerized very readily and attempts to prepare it by methods analogous to those used successfully for VI gave only a polymer.

In accord with our previous observations[2] the vinyl compounds of this series polymerized and copolymerized satisfactorily, while the alpha-methylvinyl compounds did not polymerize alone but did copolymerize with butadiene and other polymerizable vinyl compounds. The 2-alpha-methylvinyl derivatives of both pyridine and quinoline were however exceptional in that they did not copolymerize satisfactorily with butadiene, although they did form hard, black, brittle solids with maleic anhydride.
